In the recent past, multiple NLP tasks and papers have explored Offense identification which include (bullying, aggression, hate-speech, obscenity, insults and identity threat). (Fortuna and Nunes, 2018) has elaborately surveyed several approaches employed for automatic detection of hate speech.
(Yin et al., 2009) was one of the first to address recognition of offensive language by employing supervised classification technique along with manually developed n-gram regex matches and, contextual attributes that considered the intensity of abuse in preceding sentences. (Sood et al., 2012) indicated that certain banned words when used in appropriate manner and context, does not warrant to be categorized as abusive/offensive. Further, they showed a considerably improved scheme of profanity detection, by incorporating lists and distance metric, which enabled identification and categorization of un-normalized terms like ”@$$” or ”m0r0n”. (Chen et al., 2012) used lexical and parser features, for detecting comments from YouTube that are offensive. Without any preset semantics of toxic content, they came up with the tool that could be manipulated through a modifiable threshold. This threshold was to be treated as a measure of toxicity, filtering the online toxic content, prior to display of contents in the client's browser. Their work incorporated Support Vector Machines (SVMs) classifiers, which included regex (manually developed), n-gram, black-lists and dependency parse features, which achieved higher precision and recall values.
(Dadvar et al., 2013) affirmed that user context was crucial in the bonafide detection of cyberbullying. (Djuric et al., 2015) highlighted the effectiveness of comment embeddings in detection of hate speech, by joint modelling comments and words using Continuous-Bag of Words (C-BOW) to generate a low dimensional embedding. The embedding is passed to binary classifier for hate speech detection. (Mehdad and Tetreault, 2016) explored the significance of features to the extent of character to word and weighed the importance of each attribute. Since the style of comments, in online forums, vary from person to person, and often includes sub-standard profane English (i.e. ”f u c k e r”), learning how adjacent characters communicate with each other reveal more about the abusiveness of a comment as a whole.
(Vijayan et al., 2017) surveyed the pros and cons of several techniques of machine learning and deep learning in their comprehensive study of text classification algorithms. (Malmasi and Zampieri, 2017) employed n-gram and skip gram based SVM classifier, to detect and classify hate-speech, into three categories: Hate, Offensive and Ok. (Gambäck and Sikdar, 2017) employed multiple CNN models totaling four for Hate-Speech Classification of Twitter posts into one of the following:sexism, racism, either(sexism and racism) and not hate speech. The first model, trained on character based n-grams (4-grams), the next model trained on word vectors built using word2vec. The third model was trained on word vectors which were produced in random. The fourth model was trained on word vectors in addition to char n-gram for the classification task. The fourth model performed comparatively better in the classification task. (Waseem et al., 2017)

proposed a typology, to capture the similarity and difference between sub-tasks, and discuss their role, involved in annotating data and emulating feature construction. Their work was instrumental in identifying if the offense was targeted towards an individual or an entity, and whether the offensive language was explicit or implicit. (Zhang et al., 2018) introduced a new method, combining Convolutional Neural Network (CNN) and Gated Recurrent Unit (GRU) to perform a compartive evaluation on public datasets, and set new benchmarks, in Hate Speech Detection on Twitter.

3 Methodology and Data

Besides being fast and parallel, the important aspect of TCN is causal convolution, its capability to take any arbitrary length sequence and generate an output sequence of the same arbitrary input length.

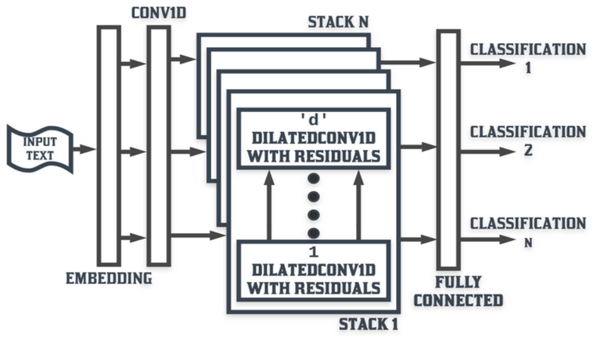

Figure 1: Temporal Convolutional Neural Network

Ever since (Bahdanau et al., 2014) introduced attention mechanism in NLP, for machine translation there have been multiple advances in memory related tasks. Further (Yin et al., 2016) established that attention based CNN performed better than attention based LSTM (Long Short Term Memory) for the answer selection task.

Here in Sub-Task A:Offense Identification, TCN was extended for sub-task A, with attention mechanism. Instead of the conventional dropout layer, a simple attention mechanism is applied at the output of embedding layer and at the output of TCN before classification layer, as illustrated in Figure 2 and Figure 3. The intention is to avoid random dropout of constituent data, which might be crucial, and introduce a mechanism with the ability, to selectively focus on input and capitalize on the crucial contributing parameters with

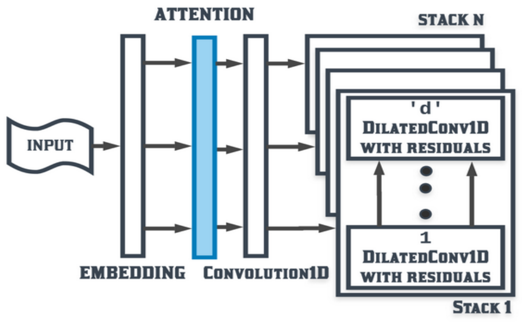

Figure 2: Temporal Convolutional Neural Network with Attention layer at the output of Embedding layer

varying attention weights and contextual vectors. ReLu (Nair and Hinton, 2010) activation is used for DilatedConvolution1D (Yu and Koltun, 2015) and softmax (Bridle, 1990) is used at the final classification layer.

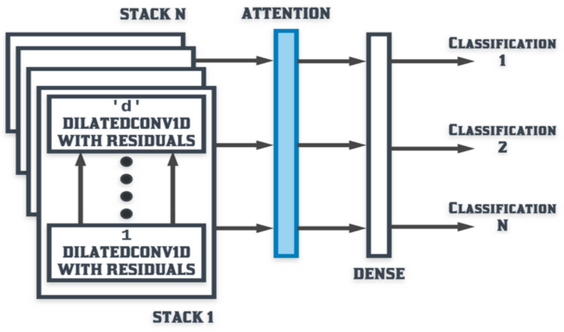

Figure 3: Temporal Convolutional Neural Network with Attention layer at the output of TCN before final Classification

Parameters	A	B	C
# Features	100*	250*	250*
# Filters	3*	5*	5*
Kernel Size	4	5	5
Dilation Range	11	11	11
Stack Count	1	1	1
Dropout Rate	0.05	0.01	0.01
Batch Size	32	32	32

Table 1: Hyper-parameters for each Sub-Task A, B and C respectively. Parameters are in numbers. *x10^2

For Sub-Task B:Automatic Categorization of Offense Type, a slight modification is introduced, to the model used for the previous sub-task, by incorporating Self Attention at the output of Embedding layer.

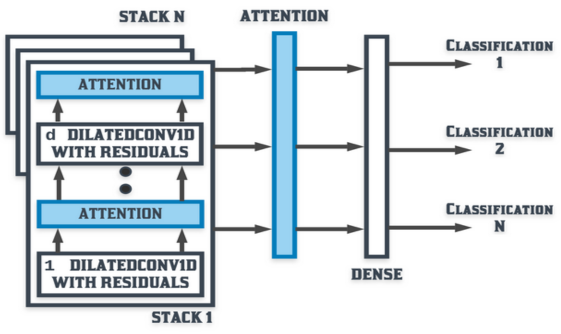

Figure 4: Temporal Convolutional Neural Network with Attention layer at the output of each Dilated-Conv1D and

Self-Attention is introduced for characterization of multiple location of the tokens, a sentence has, in addition to extraction of semantic features. Additionally, Attention layer is stacked at the output of every 'd' dilated convolution blocks, to augment the contextual vectors, as illustrated in Figure 4. For Sub-Task C:Offense Target Identification, the model used in the sub-task B was employed to identify and categorize the target of the posts into Individual (IND), Group (GRP) and Other (OTH) classes. For all the variants, binary cross-entropy loss function is employed with the focus on categorical accuracy.

The methods employed for gathering the data, preparation and compilation of dataset, used in OffensEval shared task is described in Zampieri et al. (2019a). Two additional datasets, Kaggle Toxic Comment Classification dataset and TRAC-1 Aggression Identification in Social Media Shared Task dataset were used for sub-task A and sub-task B respectively.

In 2018, Kaggle hosted a Toxic Comment Classification competition in association with Jigsaw, which focused on classifying Wikipedia comments into one of six categories: insult, obscene, severe toxic, threat & identity hate and toxic. The instances which do not fall into one of the six categories are clean. All the six toxic categories are mapped to Offensive (OFF) class and the clean instances are mapped to Not Offensive (NOT) class.

The mapped instances were combined with the training dataset, provided for sub-task A, which produced a total of 172811 instances, of which 20625 instances were Offensive and 152186 in-

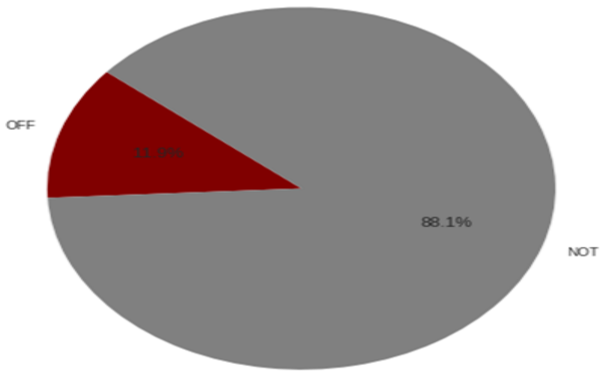

Figure 5: Shared Sub-Task A, training data instance share (OFF and NOT)

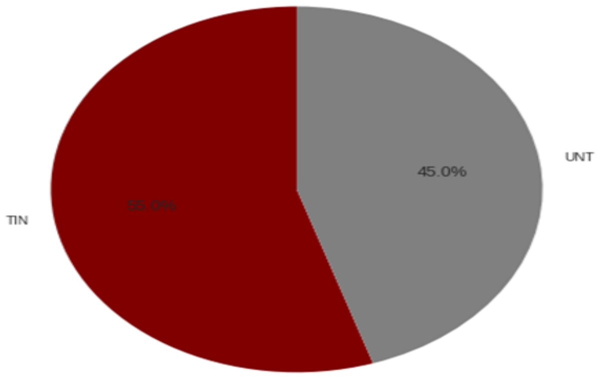

Figure 6: Shared Sub-Task B, training data instance share (TIN and UNT)

stances were clean, as depicted in Figure 5. For the training data of Sub-Task B, TRAC-1 data (Kumar et al., 2018) was used, in addition to the provided training data, producing a total of 14174 instances containing 7799 Targeted Insults and Threats (TIN), and 6375 Untargeted (UNT) instances. No other additional training dataset was used, apart from the provided dataset for Sub-Task C. It comprised of 3876 Offensive instances, of which 1074 Offensive instances belong to Individual (IND) category, 2407 Offensive instances belong to Group (GRP) category and 395 Offensive instances target belong to (OTH) category.

4 Results

The macro averaged F1 was employed as the official metric for all the sub-tasks involved in this task accounting for the high class imbalance ratio. Our first model (ATT-TCN), employed for the shared Sub-Task A, produced an overall accuracy of 65.81% (best of 3 for evaluation test data @CodaLab). The second variant (SAE-ATT-TCN), employed for the shared Sub-Task

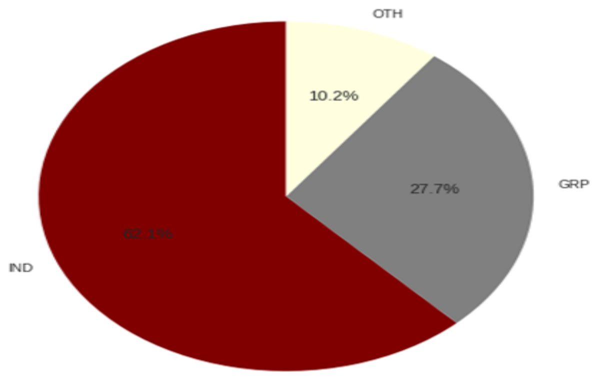

Figure 7: Shared Sub-Task C, training data instance share (IND, GRP and OTH)

B and Sub-Task C produced an overall accuracy of 75.83% and 61.5% (best of 3 for Evaluation Test data @CodaLab), respectively. The neural network model generation, fine-tuning and the evaluation test data prediction, all the activities have been executed in Google Colaboratory environment, utilizing the on hand GPU hardware accelerator. The cross validation results, and the detailed evaluation test data results have been listed in the tables accordingly.

System	Accuracy
Base ATT-TCN	0.9477
SAE-ATT-TCN[1]	0.7144
SAE-ATT-TCN[2]	0.7215

Table 2: Cross-Validation Results for Sub-Tasks A,[1]B and [2]C respectively.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
Base ATT-TCN	**0.4682**	**0.6581**

Table 3: CodaLab Test Results for Sub-Task A.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
SAE-ATT-TCN	**0.6164**	**0.7583**

Table 4: CodaLab Test Results for Sub-Task B.

The confusion matrices for the best performing variant of each Sub-Task have been depicted in Table 6, Table 7 & Table 8. In Table 6, for Sub-Task A, it is evident that the number of NOT Offensive instances (540) have been predicted correctly attributing to the higher count of training data instances for that class, and count of correct Offensive (OFF) instances prediction is less attributing to the less training instances for that category. The higher number of false positives for the Sub-Task A clearly indicate not so good classification performance of the variant ATT-TCN. The higher number of true positives for Targeted Insult and Threat (164 TIN instances), and the lesser true negatives (18 UNT instances), in Table 7, indicate the model has better generalization ability, and performed significantly better, compared to the previous model.

In Table 8, it is clear that the Group (GRP) offense target classification is predicted correctly compared to Other (OTH), and Individual (IND) categories respectively.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
SAE-ATT-TCN	**0.5132**	**0.615**

Table 5: CodaLab Test Results for Sub-Task C.

	NOT	OFF
NOT	540	80
OFF	214	26

Table 6: Sub-Task A, Confusion Matrix for Base ATT-TCN at threshold 0.45

	TIN	UNT
TIN	164	49
UNT	9	18

Table 7: Sub-Task B, Confusion Matrix for SAE-ATT-TCN at threshold 0.70

	GRP	IND	OTH
GRP	44	27	7
IND	10	81	9
OTH	14	15	6

Table 8: Sub-Task C, Confusion Matrix for SAE-ATT-TCN at threshold 0.55

5 Conclusion

Based on the results, it is evident that SAE-ATT-TCN has performed significantly better than the base model ATT-TCN. From Sub-Task A, we learned that rather than going ahead with random sampling for train and test split, proceeding with a categorical split, to the best possible even ratio, would increase the generalization ability. When the dataset has class imbalance ratio, retaining even number of instances for each class as much as possible, would ensure normal distribution of the instances for each class. Such data distribution would not be skewed for a particular class which ensure better generalization capability leading to improved classification accuracy. We note that processing the sequence in both the directions (forward and backward) would further improve the classification performance attributing to better context and semantic representation learning capabilities. We are working on Bi-Directional Attention based Temporal Convolutional Network model. Our participation in the SemEval 2019: Task 6 competition has been a very good learning experience for our team, and we are eager to learn from other best performing entries.

Acknowledgement

Our team would like thank and appreciate the SemEval 2019 organizing team for affording an opportunity to participate in such classification task. We look forward to additional NLP classification tasks.

Abstract

This paper describes the work that our team bhanodaig did at Indian Institute of Technology (ISM) towards OffensEval i.e. identifying and categorizing offensive language in social media. Out of three sub-tasks, we have participated in sub-task B: automatic categorization of offensive types. We perform the task of categorizing offensive language, whether the tweet is targeted insult or untargeted. We use Linear Support Vector Machine for classification. The official ranking metric is macro-averaged F1. Our system gets the score 0.5282 with accuracy 0.8792. However, as new entrant to the field, our scores are encouraging enough to work for better results in future.

1 Introduction

Social media has become most popular among users in these days. Based on survey (Johnson et al., 2011), it has been observed that 70% of teenagers use social media sites on daily basis. Users share their views with help of social media like twitter, facebook, instagram, youtube. Ritesh et al. (Kumar et al., 2018a) tried to identify hate speech. On the one hand Users get benefited from social media by learning or interacting with other users on the other hand they face offensive online contents. With exponential growth of social media it has become quite significant to identify and categorize offensive language in social media.

A key challenge among researchers is to automatically categorization of offense type languages in social media. few research have been performed but it is still a hot topic among researchers. keeping it in mind, we develop a system that could categorize offensive language in social media. The relevant shared task description, data and results are described in the paper (Zampieri et al., 2019b).

In this paper, we use Linear Support Vector Machine (LSVM) for classifying and identifying offensive language in social media. We use snowball stemmer to find out root words. Also, we have used unigram and bigram language models without stopwords.

The rest of the paper is organized as follow. Section 2 describes related work. The proposed methodology and used data is described in section 3. Section 4 describes results obtained after experiment. Finally, we conclude and future work in section 5.

2 Related Work

The interest in identifying and categorizing aggression, cyber-bullying and hate speech, particularly on social media, has been growing in recent years. This topic has attracted attention from researchers interested in linguistic and sociological features of aggression, and from engineers interested in developing tools to deal with aggression on social media platforms. In this section, we review a number of studies and briefly discuss their findings. For a recent and more comprehensive survey on hate speech detection we recommend (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018).

Davidson et al. (Davidson et al., 2017) used crowd source to label a sample of tweets into three categories: hate speech, only offensive and those with neither. The Hate Speech Detection dataset used in (Malmasi and Zampieri, 2017) and a few other recent papers such as (ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018).

A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). For studies on languages other than English has been described in (Su et al., 2017) on Chinese and (Fišer et al., 2017) on Slovene. Finally, for recent discussion on identifying profanity vs. hate speech is discussed in (Malmasi and Zampieri, 2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
LSVM	**0.5282**	**0.8792**

Table 1: Results for Sub-task B using model LSVM and best result is highlighted with boldface.

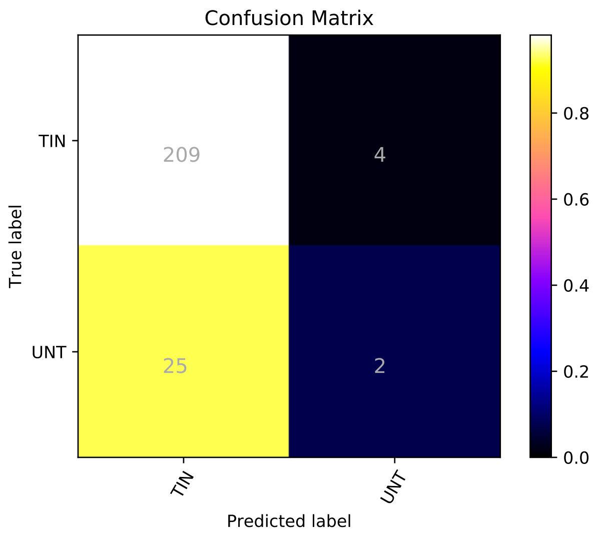

Figure 1: Sub-task B, LSVM

language.

Additionally, the related work has been performed in the related workshops such as TA-COS[1], Abusive Language Online[2], and TRAC[3] and related shared tasks such as GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018b).

3 Methodology and Data

The description of our system and different runs has been described in this section. We have been provided training dataset with 13,240 tweets, a trial set with 320, and a test set with 860 (Zampieri et al., 2019a). Each instance is composed of a tweet and its respective labels for tasks A, B and C. The three levels/subtasks are as follows:
Task A : Whether the tweet is offensive (OFF) or non-offensive (NOT).
Task B : Whether the tweet is targeted (TIN) or untargeted (UNT).
Task C : If the target is an individual(IND), group (GRP) or other (OTH; e.g., an issue or an organisation).

We have focused on subtask B. In our methodology, tweets are preprocessed by replacing following words with corresponding words shown below:

what's	$\rightarrow$ what is
've	$\rightarrow$ have
can't	$\rightarrow$ can not
n't	$\rightarrow$ not
i'm	$\rightarrow$ i am
're	$\rightarrow$ are
'd	$\rightarrow$ would
'll	$\rightarrow$ will
'scuse	$\rightarrow$ excuse

followed by stemming words with snowball stemmer. LSVM is used for classification. We perform the task for only categorizing offensive language in social media, whether tweet is targeted insult or untargeted. SVM is categorizing offensive language in social media. For this, tf-idf of words unigrams and bigrams (without stopwords) that are occured at least 3 times are considered as features with 12 normalization.

[1]http://ta-cos.org/
[2]https://sites.google.com/site/abusivelanguageworkshop2017/
[3]https://sites.google.com/view/trac1/home

4 Results

In this section, we describe our experimental results. The official ranking metric is macro-averaged F1. We have included accuracy here as well for comparison. In table 1 , we see that we get the best result **0.5282** with accuracy **0.8792** using LSVM model. All TIN (targeted insult) baseline has got the score 0.4702 with accuracy 0.8875 and All untargeted baseline has got the score 0.1011 with accuracy 0.1125. The confusion matrix has been shown in figure 1.

5 Conclusion and future work

This year we participated in OffensEval sub-task B i.e. automatic categorizing offensive language in social media. We use LSVM model for classification. While there can be no denial of the fact that our overall performance is average, initial results are suggestive as to what should be done next. As we have taken ngrams for training set, our model unable to handle OOV (out of vocabulary) words. Pretrained word embeddings would have handled this problem. LSTM with these word embeddings might give better results. We explore these models in coming future.

Abstract

In this study we deal with the problem of identifying and categorizing offensive language in social media. Our group, BNU-HKBU UIC NLP Team2, use supervised classification along with multiple version of data generated by different ways of pre-processing the data. We then use the state-of-the-art model Bidirectional Encoder Representations from Transformers, or BERT (Devlin et al. (2018)), to capture linguistic, syntactic and semantic features. Long range dependencies between each part of a sentence can be captured by BERT's bidirectional encoder representations. Our results show 85.12% accuracy and 80.57% F1 scores in Subtask A (offensive language identification), 87.92% accuracy and 50% F1 scores in Subtask B (categorization of offense types), and 69.95% accuracy and 50.47% F1 score in Subtask C (offense target identification). Analysis of the results shows that distinguishing between targeted and untargeted offensive language is not a simple task. More work needs to be done on the unbalance data problem in Subtasks B and C. Some future work is also discussed.

1 Introduction

Social media is an essential part of human communication today. People can share their opinions in this platform with anonymity. Some people use offensive language and hate speech casually and frequently without taking any responsibility for their behavior. For this reason, SemEval 2019 (Zampieri et al. (2019b)) set up the task OffensEval: identifying and categorizing offensive language in social media. This task is divided into three subtasks: offensive language identification, automatic categorization of offensive types, and offence target identification.

Our group uses the Natural Language Processing (NLP) latest model, Bidirectional Encoder Representations from Transformers (BERT). It is a general-purpose "language understanding" model trained on a large text corpus such as Wikipedia (Devlin et al. (2018)). After fine-tuning, the model can be used for downstream NLP tasks. Because BERT is very complex and is the state-of-art model, it is prudent for us not to change its internal structure. Hence, we focus on preprocessing the data and error analysis. After much experimentation with the data, such as translating emoji into words, putting more weight on some metaphorical words, removing the hashtag and so on, we find that using the original data will give the best performance. The reason for this is perhaps if we remove some information from the sentence, some features that affect the prediction result will be lost. So we end up using the original data to train our model.

2 Related Work

Much research has been done in detecting offensive language, aggression, and hate speech in user-generated content. In recent years, researches tend to follow several approaches: use a simple model with logistic regression to perform detection, use a neural network model, or use some other methods.

For the simple model, Davidson and Warmsley (Davidson et al. (2017)) used a sentiment lexicon designed for social media to assign sentiment scores to each tweet. This is an effective way to identify potentially offensive terms. Then they use logistic regression with $L2$ regularization to detect hate speech in social network.

Neural network models use n-gram, skip-gram or some other methods to extract features from the data. These features are used to train different models. The results produced by these models will be used as the input for training the meta-classifier (e.g. Malmasi and Zampieri (2018))

For other methods, using bag-of-words is an effective way to detect hate speech, but it is difficult to distinguish hate speech from text with offensive words that are not hate speech (Kwok and Wang (2013)). For identifying the targets and intensity of hate speech, syntactic features method is a good method (Burnap and Williams (2015)).

3 Methodology and Data

Only the training data provided by the organizer (Zampieri et al. (2019a)) are used in training our model. The data contain 13,240 pieces of tweet that had been desensitized (replacing the user names and website URLs). There are three labels that are labeled with crowdsourcing for each of the three subtasks. Gold labels obtained through crowdsourcing are confirmed by three annotators. We segmented the training set by 90% for the training set, 5% for the cross-validation set, and 5% for the test set.

Because some offensive language is subtle, less ham-fisted, and sometimes cross sentence boundary, the model trained for this task must make full use of the whole sentence content in order to extract useful linguistic, syntactic and semantic features which may help to make a deeper understanding of the sentences, while at the same time less subjected by the noisiness of speech. So, we use BERT in all three subtasks. Unlike most of the other methods, BERT uses bidirectional representation to make use of the left and right context to gain a deeper understanding of a sentence by capturing long range dependencies between each part of the sentence.

The uncased base version of the pre-trained model files [1] is used during the entire training. The training data are processed in many ways to fine-tune the model. Processing methods include removing all username tags, URL tags and symbols, converting all text to lowercase, and translating emoji into text[2]. One or more of the above methods is selected to process the training data, and then use the processed data to train the model.

In Subtask A, the accuracy after the various operations is shown in the following table.

Preprocessing	**Accuracy**
Original Data	0.8184
Remove tag & symbols	0.8126
Emoji translation v1	0.8081
Emoji translation v2	0.7960

Table 1: Training results for Sub-task A.

After all attempts, the best performing model for Subtask A is the model trained by the original data. Therefore, the original data are also used in the training of the Subtasks B and C models.

4 Results

For Subtask A, The BERT-Base, Uncased, original training data model get macro F1 score of 0.8057 and total accuracy of 0.8512.

For Subtask B, The BERT-Base, Uncased, original training data model get macro F1 score of 0.50 and total accuracy of 0.8792.

For Subtask C, The BERT-Base, Uncased, original training data model get macro F1 score of 0.5047 and total accuracy of 0.6995.

Results table and confusion matrices for Subtasks A, B and C are shown below.

5 Conclusions

Our model for Subtask A ranked 6 out of the 103 groups. This shows that BERT can identify offensive language. However, the results for Subtasks B and C are not as good. We will try to explain the possible reasons using error analysis.

First, some speech may be miss-labeled by annotators. In our test set, some predictions were judged as wrong, but our manual examination shows the predictions seem correct. For example, *"@USER B***hhhhh I'm jell"* and *"@USER Crazy Russian dude owns all your data"* are both labeled **NOT** (not offensive). The model, as well as our manual examination, deem these as offensive.

Second, we also notice a problem is that it is hard for our model to understanding some specific noun such as people name when our training data is not enough. For example, our model predict sentence *"Hitler will be so proud of David Hogg"* as not offensive. The word "Hitler" has a very special meaning that can makes an otherwise innocent sentence to be offensive. Our model presently can't detect this.

Another problem is emoji characters in offensive languages, which usually contains strong emotions. And may be used to express irony. So emoji characters are translated by two methods[2] to help BERT model understand the meaning of tweet posts. But the results show that both translation methods lead to a drop in accuracy. The main reason should be that some emoji characters contain different meanings in different contexts. For example, 🙂 (Slightly Smiling Face) can contain emotion of happy but also banter as well. Thus, it is difficult to understand the meaning of emoji characters in context.

Moreover, unbalanced data is a big problem. In Subtask B, few sentences are predicted as untargeted, and in Subtask C, no sentence is predicted as in the Others category. This leads to a low F1 score in these subtasks. Over-sampling in less numerous categories would not work not well in our task, and threshold moving only slightly raises the F1 score. To deal with this problem as future work, we may have to remove the labels and use unsupervised learning.

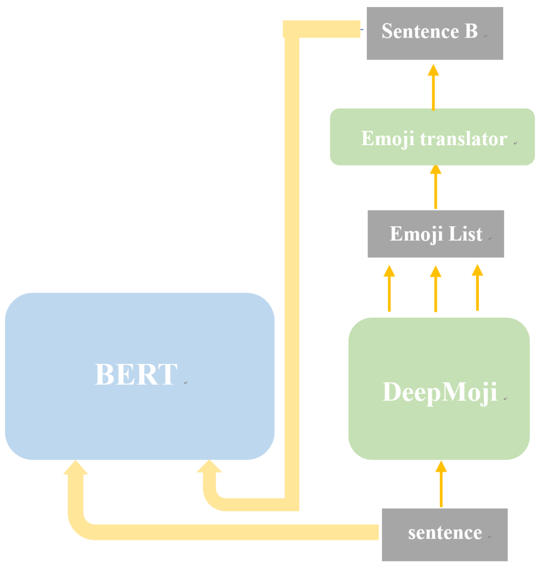

Figure 4

For future work, we notice that offensive languages often contain strong emotions such as angry, banter or taunt. This emotion and other useful contents may be improved by using DeepMoji (Felbo et al. (2017)), which translates a sentence into an emoji list to express a sentence's hidden information, such as sentiment and sarcasm. A list of emoji related to the meaning of a sentence produced by DeepMoji can be used to help BERT to better classify the sentence categories, as show in the Figure 4. The last step is to put the original sentence and the encoded new sentence as input for BERT's sentence-pair classification task.

Abstract

We describe the CAMsterdam team entry to the SemEval-2019 Shared Task 6 on offensive language identification in Twitter data. Our proposed model learns to extract textual features using a multi-layer recurrent network, and then performs text classification using gradient-boosted decision trees (GBDT). A self-attention architecture enables the model to focus on the most relevant areas in the text. We additionally learn globally optimised embeddings for hashtags using node2vec, which are given as additional tweet features to the GBDT classifier. Our best model obtains 78.79% macro F1-score on detecting offensive language (subtask A), 66.32% on categorising offence types (targeted/untargeted; subtask B), and 55.36% on identifying the target of offence (subtask C).

1 Introduction

The SemEval-2019 shared task 6 ('OffensEval') involved three sub-parts: the classification of tweets as offensive or not (subtask A), classifying whether they are targeted insults or not (subtask B), and finally whether the targeted insults are aimed at an individual, group or otherwise (subtask C). Further details may be found in the shared task report (Zampieri et al., 2019b). Here we describe CAMsterdam's competition entry.

In recent years, there has been a growing interest in the automatic detection of offensive opinions expressed in online texts, including those posted in discussion forums, news article comment sections, and social networks. Such detection is not straightforwardly a matter of identifying texts containing obscene words (Malmasi and Zampieri, 2018); offensiveness often arises from the context, current affairs, world knowledge, the use of acronyms and slang, and the identity of the authors and audience. Therefore the task is a challenging one, but one with real world impact: if measures can be taken to identify and curtail trolling, the toxicity of the internet can to some extent be reduced. There is evidence that online harassment is connected with oppression, violence and suicide (Dinakar et al., 2011; Sood et al., 2012; Wulczyn et al., 2017), and there may moreover be reasons for concern about the perpetrator's wellbeing along with that of the victims (Cheng et al., 2017).

Our approach to the task extends the work of Mishra et al. (2018b), who extract features from tweets using an RNN for subsequent use in a gradient-boosted decision tree (GBDT) (Ke et al., 2017). Firstly, we experiment with changes to the RNN, including the use of self-attention (Rei and Søgaard, 2019) and ELMo embeddings (Peters et al., 2018). Secondly, we add additional features to the GBDT, including globally-optimised hashtag embeddings learned from a graph of tweet contents using node2vec (Grover and Leskovec, 2016). We show that this method of learning distributional information about hashtags improves performance over just learning their embeddings within a RNN.

2 Related Work

There has been much work characterising offensive online discourse including hate speech and cyberbullying (Warner and Hirschberg, 2012; Kwok and Wang, 2013; Xu et al., 2013; Waseem et al., 2017; Ribeiro et al., 2018). This work also includes creating datasets for training and evaluating detection models, for example the Hate Speech Twitter Annotations and Wikipedia Comments Corpora (Waseem and Hovy, 2016; Davidson et al., 2017; Wulczyn et al., 2017). Most work has been conducted on English data – tweets in particular – with some extensions to other domains (e.g. hacking forums (Caines et al., 2018)) and other languages (e.g. Arabic (Mubarak et al., 2017), Chinese (Su et al., 2017), Slovene (Fišer et al., 2017)).

Automated detection approaches have drawn on traditional document classification methods for spam detection and sentiment analysis, and tend to use lexical and syntactic features (Nobata et al., 2016; Li et al., 2017; Bourgonje et al., 2018). Machine learning techniques range from logistic regression (Cheng et al., 2015) to support vector machines (Yin et al., 2009) to neural networks (Gambäck and Sikdar, 2017).

We draw on the work by Mishra and colleagues, who used a character-based recurrent neural network to form contextual word representations of out-of-vocabulary words (Mishra et al., 2018b), and moreover employed graph-based author embeddings to represent group behaviour within social networks, significantly improving abuse detection (Mishra et al., 2018a). In this shared task, we do not have access to author information, but instead adapt the approach by building a graph of the tokens which occur in the training data, a method described in further detail in Section 4.4.

3 Data

The OffensEval shared task uses the Offensive Language Identification Dataset (OLID) (Zampieri et al., 2019a), which hierarchically labels tweets according to whether or not they are offensive, whether any offence is targeted, and if so targeted at whom: an individual, a group or otherwise. The three subtasks in this shared task correspond to predicting labels at each level of granularity. The data is structured to allow this: all tweets presented in subtask B are guaranteed to be offensive, and all of those in subtask C are targeted.

Tweets were collected by using the Twitter API to search for terms that are frequently associated with offensive behaviour. These included political keywords, as political content may attract a disproportionate amount of offensive comments. The dataset is evenly split between tweets sourced from these keywords and non-political ones. The authors additionally found that an effective strategy for gathering offensive tweets was to search for those flagged by Twitter's safe search feature. All tweets were anonymised by replacing usernames and URLs with placeholder tokens.

Each of the $14,100$ collected tweets were manually annotated by at least two annotators; where the original two annotators disagreed on a tweet, it was further annotated until agreement reached 66%. Table 1 presents the number of tweets in each category.

A	**B**	**C**	**Train**	**Test**	**Total**
OFF	TIN	IND	2,407	100	2,507
OFF	TIN	OTH	395	35	430
OFF	TIN	GRP	1,074	78	1,152
OFF	UNT	—	524	27	551
NOT	—	—	8,840	620	9,460
All			13,240	860	14,100

Table 1: Count of tweets in each category of OLID (Zampieri et al., 2019a).

4 Methodology

In this section, we extend the model proposed by Mishra et al. (2018b) for offensive language classification. The architecture uses a 2-layer RNN, optimised using Adam (Kingma and Ba, 2015), to predict the class of a given tweet. The pre-softmax activation values from the output layer are given as input to a GBDT for final classification. Using the GBDT for classification was found to give better results compared with predicting from the RNN directly, and allows us to include additional features into the model. The RNN is initialised with pre-trained word embeddings which are fine-tuned during training. For previously unseen words, we follow Mishra et al. (2018b) in using a neural character-based compositional model to generate plausible embeddings of unseen words. This component is optimised to compose context-aware character embeddings into word-level embeddings that are similar to the pre-trained representations, trained on words for which the embeddings are available. This methodology is effective in generating reasonable quality embeddings in instances where words were deliberately obscured to evade detection.

Following common practice in named entity recognition (Sang and De Meulder, 2003), where fine-grained labels are used to improve performance on the sequence labeling task, we take advantage of the hierarchical labels available for each tweet. For subtasks A and B we train a model to predict all cascading labels, and sum the probabilities of labels under the relevant class to make a final prediction. For example, for subtask A the model is trained to predict between 5 classes: not-offensive (NOT), offensive but not targeted (UNT), targeted towards an individual (IND), towards a group (GRP), and towards any other target (OTH). We classify a tweet as offensive if the cumulative probability mass for UNT, IND, GRP, and OTH is greater than NOT.

We also introduce several architectural extensions to the Mishra et al. (2018b) model. Firstly, we augment the core RNN with ELMo embeddings and a self-attention mechanism. Secondly, we add both the post-softmax output from the RNN as well as graph-based representations of tweets as input features to the GBDT classifier. We provide details of each extension in the following sections.

For each subtask, we experiment with combinations of the above and additionally tune the RNN type (between LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014)), dimension, and batch size, whether to use character n-grams ($n \in [1, 4]$), and, when used, the size of self-attention layers. We also run experiments using the unmodified model to find which pre-trained embeddings give the best performance. We compare publicly available embeddings trained using Word2Vec (Mikolov et al., 2013), FastText (Mikolov et al., 2018), and GLoVe (Pennington et al., 2014).

4.1 ELMo

We use embeddings generated from ELMo concatenated with pre-trained word embeddings as input to the RNN. ELMo generates embeddings on a character level, so does not share the same out-of-vocabulary issue as pre-trained embeddings and is always able to generate a word representation. We used the largest pre-trained model available online[1], and learn a weighted linear combination of its three layers.

4.2 Self-attention

The model proposed by Mishra et al. (2018b) uses the last hidden state of the RNN as the feature representation for each tweet; instead, we propose the use of a self-attention mechanism to learn a weighted combination of all intermediate hidden states (Rei and Søgaard, 2019). The weights $\hat{a}_i$ for each hidden state h_i are learned by passing h_i through two dense layers with $\tanh$ activation, and a further 1-dimensional dense layer. The final dense layer has either sigmoid or exponential activation, corresponding to soft or sharp attention respectively. The weights are normalised to sum to 1, yielding final attention values $\widetilde{a_i}$, which are used to obtain the final sentential representation $s = \sum_i \widetilde{a_i} h_i$. The RNN is then trained using categorical cross-entropy on s passed through a final $\tanh$ layer.

4.3 RNN Prediction

This modification includes the post-softmax output of the RNN as an additional input feature to the decision tree.

4.4 node2vec

We make use of node2vec to learn low-dimensional continuous representations of hashtags used in tweets on the basis of whole-tweet contexts. We first represent every token (including all hashtags) and each tweet as nodes in a graph, with edges formed between tweets and the tokens they contain. node2vec first follows a tunable sampling strategy to perform random walks from each node, generating directed acyclic graphs with a maximum out degree of 1 (i.e. a sequence of nodes). It then applies the SkipGram model (Mikolov et al., 2013) to learn a representation of each node based on its neighbours in the sampled sequences. Specifically, given a graph with nodes V, node2vec maximises the log probability: $\sum_{v \in V} log(P(N_s(v)|v))$, where $N_s(v)$ is the set of neighboring nodes for node v generated from a sampling strategy s.

We train these node2vec representations on two data sets: the OLID training data, and our own scrape of Twitter using `rtweet` (Kearney, 2018). We collect this additional data by searching for each of the 24 hashtags which appear at least 10 times in the training set, with at least 1 in 4 occurrences in tweets labelled offensive. Intuitively, these common and frequently offensive hashtags are a more reliable signal of offensiveness than less frequent hashtags. It remains to be seen whether collecting more tweets with all hashtags in OLID would help, but the strict rate limits on the Twitter API meant that we ran out of time to explore this.

We trained 200-dimensional embeddings on a random sample of $10,000$ of the resulting tweets. To represent each tweet we sum the embeddings of each hashtag present, and normalised the re-

sulting vector to unit length. These vectors, or a 200-dimensional 0-vector for tweets containing no hashtags with trained embeddings, were then concatenated with the RNN features (either from self-attention where it was used, or the last hidden state if not) prior to being input into the GBDT.

5 Results

In this section, we present a sample of results obtained during model selection, and results on each of the official subtask test sets. Model selection is carried out by evaluating each model on a consistent 90% training and 10% validation split of the provided training data. Before carrying out model selection, we ran an unmodified version of Mishra et al. (2018b)'s model on subtask A and found that 300-dimensional FastText embeddings trained on Common Crawl gave the best performance[2].

We submitted three models for each of the three subtasks. We submit models that differ in two ways. The first is the amount of data they are trained on. Models labelled ALL-DATA are trained on all of the provided data, while models tagged TRAIN-SPLIT are trained on just the 90% training split, but have a known performance via their results on the development set. It is beneficial to know this as there is a large amount of variance in model results due to stochasticity in the training process. The second way in which the models differ is designed to handle this variance by ensembling three models via majority vote. Such submissions are labelled with ENSEMBLE, while those only using a single model are labelled BEST.

In all three subtasks we find that the best performing system is that which ensembles three identical models trained on the entire training set.

5.1 Subtask A

Subtask A concerns classifying a tweet as OFF (offensive) or NOT (see Section 3). We experiment with adaptations of the model from Mishra et al. (2018b) to perform a 5-WAY classification between all categories, and select the most effective feature combination for each subtask. We experiment with features mentioned in Section 4: ELMo, self-attention, character n-grams, and node2vec. Results from ablation studies are presented in Table 2.

We found that the best performing model used features extracted from a RNN that used ELMo embeddings in addition to FastText and compositional character-based word embeddings, with sharp self-attention over a GRU with 256 hidden units trained using a batch size of 64. These features were used in a GBDT alongside the 10,000 most frequently occurring character n-grams, and node2vec representations of the tweets.

Table 3 shows our results for subtask A on the test data. All three submissions use the model architecture and hyperparameters described above.

System	F1	Accuracy
All NOT baseline	0.419	0.721
All OFF baseline	0.218	0.279
TRAIN-SPLIT-BEST	0.776	0.835
ALL-DATA-ENSEMBLE	**0.788**	**0.847**
ALL-DATA-BEST	0.769	0.835

Table 3: Accuracy and macro F1 results on the official subtask A test set. All three models have the same hyperparameters.

5.2 Subtask B

Subtask B involves a binary classification of whether a tweet is untargeted (UNT) or targeted (TIN). Following Subtask A, we maintain a finer grained classifier using a 4-WAY classification (TIN, IND, GRP, OTH), where we classify a tweet as targeted if the probability for TIN is less than the sum of probabilities for the 3 other labels.

We re-ran feature selection experiments to op-

[2]https://fasttext.cc/docs/en/english-vectors.html

System	F1	Accuracy

ALL-DATA-ENSEMBLE	**0.663**	**0.904**
TRAIN-SPLIT-ENSEMBLE	0.657	0.900

Table 4: Accuracy and macro F1 results on the official subtask B test set.

timise for this task. Development experiments showed that the use of character n-grams does not improve performance on this subtask, LSTM performs better than a GRU, and that reducing the RNN dimension to 64 and training batch size to 32 is beneficial. These smaller hyperparameter values are likely more suitable due to the smaller amount of available training data. We found that training node2vec using the provided training data, rather than the scraped dataset, gave better representations, with F1 scores on our held-out development set of 0.635 for OLID data and 0.618 for the extra tweets we obtained from Twitter's API (section 4.4).

Results on the test set are presented in Table 4, where we once again find that the ensemble of classifiers trained on all of the data performs best.

5.3 Subtask C

Subtask C involves classifying the target of an offensive tweet as either an individual, group, or other. As this is the last subtask, only classification between these three labels is possible: there are no finer-grained labels that can be trained on. We find that the best performing model is the same as that in subtask B, except that a GRU is used and the softmax from the RNN is included in the GBDT. Results on the test data are presented in Table 5.

System	F1	Accuracy
All GRP baseline	0.179	0.366
All IND baseline	0.213	0.470
All OTH baseline	0.094	0.164

6 Discussion

In all subtasks, our best performing submission was an ensemble of three identical models, independently trained on all of the training data. Ensembling helps to account for the high variance observed during model training, which occurred despite fixing random seeds.

Across all subtasks we find the inclusion of node2vec features to be helpful. These features offer contextualised representations of hashtags in terms of the tokens they appear with across the corpus, suggesting that features that share information between tweets are useful in addition to those derived from each individually.

We observe that performance drops from subtask A to C. This could be due to the decreasing amounts of training data, from 13,240 instances in Subtask A, to 4,400 in subtask B and 3,876 in subtask C. Very small amounts of data are available for two classes in particular – untargeted offence (UNT) with only 524 training instances, and offence targeted at those other than individuals and groups (OTH) with 395.

As seen in Figures 1 and 2, our model achieves high recall for the NOT class (0.952) in subtask A and for TIN (0.986) in subtask B, but low recall for the other classes OFF (0.575) and UNT (0.259). Figure 3 shows that in subtask C we perform worst on the OTH label, with a low recall of 0.086. In all cases, the model shows weakest performance on the classes for which we have least training data. Therefore, we expect that model performance would improve given more training instances of the minority classes.

Furthermore, in subtask C, the definition of the 'other' class is less clear-cut than the other two cat-

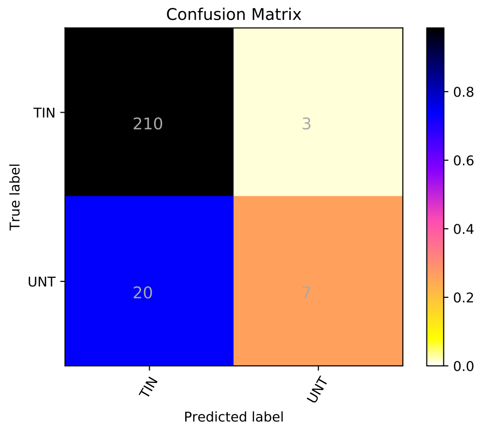

Figure 2: Subtask B, ALL-DATA-ENSEMBLE model.

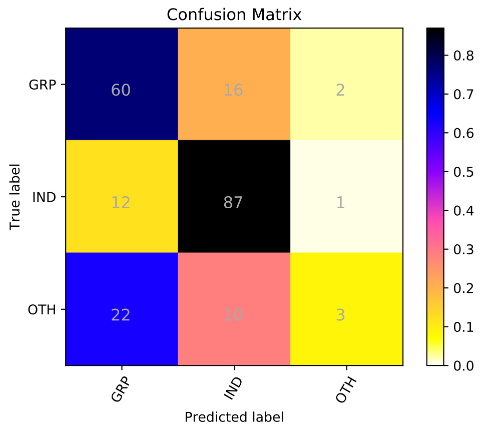

Figure 3: Subtask C, ALL-DATA-ENSEMBLE model.

egories GRP and IND, including abstract concepts such as events or issues, and serving as a catch-all for targeted insults against anything other than specific people or groups of people with a common characteristic. A manual inspection of the data suggests that a large amount of the OTH data includes politically-motivated insults, though similar language also appears in the two other categories, which may make classification harder.

7 Conclusion

The CAMsterdam team attempted the OffensEval tasks taking inspiration from the approach of Mishra and colleagues (2018b), feeding the pre-softmax activation layer of an RNN into a GBDT to classify tweets into one of the applicable fine-grained classes for each subtask. The probabilities of the fine-grained classes were summed to obtain a probability for the desired class: for instance, in subtask A, we summed the probabilities of UNT, IND, GRP and OTH, and compared this sum with the probability of NOT to classify a tweet as offensive or not.

We extended the work of Mishra et al. by using ELMo embeddings as additional input to the RNN, and incorporating a self-attention mechanism following Rei and Søgaard (2019). We also used node2vec to train graph-based representations of hashtags, using both tweets from the OLID training set and new data obtained from the Twitter API featuring hashtags frequently found in the offensive subset. We focus on hashtags on the intuition that they are employed by users to reach those interested in similar topics, and are thus indicative of tweet content. Their use encodes this useful information directly, which we show to be useful for classification. We take into account the fact that hashtags are used in many positions in a tweet by constructing the graph based on co-occurrence across the whole tweet, rather than only within a small window as other embedding methods do.

During development, we found that our best performing models were those formed from an ensemble of three models trained in an identical fashion, thereby smoothing random variation in the training process. The results of the test phase show that our model performed in line with expectations set during development, with F1-scores which decrease from subtask A to C, and lowest precision and recall on the minority classes.

In the future, we will seek to address the imbalance in the training data, inspect the tweets further to analyse the linguistic differences between targeted and untargeted insults, group- and individual-targeted insults and so on. Further architectural changes include collecting more instances of hashtags frequently found in offensive tweets as extra unsupervised data, and we can seek to include author embeddings, a technique found to greatly improve the performance of Mishra et al's system (Mishra et al., 2018a). Finally, we would aim to evaluate our model on other offensive text classification datasets, to discover how well the design generalizes beyond OLID.

Abstract

Offensive language has become pervasive in social media. In Offensive Language Identification tasks, it may be difficult to predict accurately only according to the surface words. So we try to dig deeper semantic information of text. This paper presents use an attention-based two layers bidirectional long-short memory neural network (BiLSTM) for semantic feature extraction. Additionally, a residual connection mechanism is used to synthesize two different deep features, and an emoji attention mechanism is used to extract semantic information of emojis in text. We participated in three sub-tasks of SemEval 2019 Task 6 as CN-HIT-MI.T team. Our macro-averaged F1-score in sub-task A is 0.768, ranking 28/103. We got 0.638 in sub-task B, ranking 30/75. In sub-task C, we got 0.549, ranking 22/65. We also tried some other methods of not submitting results.

1 Introduction

Recognition of Offensive information has research and application value in many aspects. With the popularity of social media, people's comments on social media has become an important part of public opinion. Although freedom of speech is advocated, there are still some unacceptable words. The study of offensive language has only recently arisen. With the deepening of the research, we need to consider the different sub-tasks of its decomposition.

In OffensEval tasks (Zampieri et al., 2019b), offensive content was divided into three sub-tasks taking the type and target of offenses into account. Sub-task A is offensive language identification. We should identify a short text sentence as offensive or non-offensive. Sub-task B is automatic categorization of offense types. We need to classify a sentence as having an attack target or not, if this is an offensive sentence. Sub-task C is offense target identification. Its purpose is to identify the target of an attack sentence with an attack target. The target is individual, group or other.

User's comments on Twitter are usually cluttered. In order to clean up the data, a series of preprocessing for the data is necessary. Then, pre-trained word vectors are helpful to extract semantic features from deep learning model. For classification model, bidirectional long-short memory neural network can catch the contextual information in text, in order to get offensive semantics from text. A residual connection cascade the first layer's output and the second layer's output can get features of text at different levels. Attention mechanism is used for the final output. Besides, referring to ZHANG et al. (2018), emojis in a sentence have a significant impact on sentiment. We assume them may affect the offensive semantics of text too, and double attention mechanism can deal with this semantic relationship.

The rest of this paper is organized as follows. Section 2 introduces some research advances in Aggression Identification and Hate Speech. Section 3 describes the data we use and the detailed introduction of our system. Section 4 shows the performance of our system and comparison with other models. Section 5 describes some of our summaries and future work directions.

2 Related Work

Due to the universality of offensive language in social media, in order to cope with offensive language and prevent abuse in social media, research on related aspects has gradually emerged in recent years.

There have been several seminars on offensive language research, such as TRAC[1] which shared task on Aggression Identification summarized in Kumar et al. (2018), need to distinguish open, secret and non-aggressive texts. And ALW[2] which is work for Abusive Language. Fišer et al. (2017) did some work on the legal framework, dataset and annotation schema of socially unacceptable discourse practices on social networking platforms in Slovenia. Gambäck and Sikdar (2017) introduced a deep learning based Twitter Hate Speech text include racism, sexism, both and non-hate-speech classification system. Waseem et al. (2017) put forward a series of subtasks of hate speech, cyberbullying, and online abuse. Su et al. (2017) described a system for detecting and modifying Chinese dirty sentences. And GermEval is also shared related tasks (Wiegand et al., 2018) which initiate and foster research on the identification of offensive content in German language microposts. Additionally, the main work of Malmasi and Zampieri (2017) and Malmasi and Zampieri (2018) is to approach the problem of distinguishing general profanity from hate speech. Zhang et al. (2018) tried to use a Convolution-GRU for detecting hate speech on Twitter.

3 Methodology and Data

3.1 Method

Our method is composed of 6 stages: Preprocessing, Embedding, Bidirectional LSTM, Attention, Double attention and Softmax. The whole architecture of the single model is shown in Figure 1.

3.1.1 Preprocessing

We have done some processing on the original training data and test data. The main purpose is to make the data cleaner, reduce the number of unknown words in the dictionary, and do some processing of error words. The first step is to convert all words into lowercase. Our preliminary view is that uppercase or lowercase has no direct impact on offensive language recognition tasks. The second step is to deal with punctuation symbols. We use space as separator to divide sentences into words. But in many cases in data sets, punctuation symbols and words, as well as punctuation symbols and punctuation symbols are closely linked without space. In this way, the system will not be able to recognize them. Just like ”sloth.” or ”!!!”, and we turned them into ”sloth .” and ”! ! !”. The third step is abbreviation processing. We converted ”don't”, ”you're” and so on into ”do n't” and ”you 're”, because there is no ”don't” or ”you're” in the dictionary. We haven't expanded the abbreviations like ”do not” or ”you are”, because the results may not be unique just like ”I'd” can represent ”I would” or ”I had”. Forth, we also need to separate the emojis refer to the dictionary of emojis. (We will introduce the word dictionary and emoji dictionary in detail in embedding section). In addition, we regard all numbers as one word.

After completing the above preprocessing, if a word is still detected as an unknown word, we use ekphrasis[3] tool (Baziotis et al., 2017) for further processing. The first step is word segmentation. We separate some words together may be a customary expression by spaces. For example, ”Googlearecorrupt” is turned into ”Google are corrupt”. Second, if the word still does not exist in the dictionary, we do an error correction operation. After all operations, words that do not exist in the dictionary are marked as unknown words.

Step-by-step processing instead of direct batch processing without intermediate detection improves reliability and avoids modifying correct expressions to errors.

3.1.2 Embedding Layer

We used a word embedding layer to represent words as vectors. The 200 dimension word vectors[4] is pre-trained by GloVe based on a large corpus of Twitter provided by Jeffrey et al. (2014). It includes 1,193,514 words and their vector representations.

A sentence sequence $S(w_1, w_2, ..., w_l)$ is represented as $C(c_1, c_2, ..., c_l)$, where $w_i (i \in [1, l])$ represents a word, c_i represents the vector corresponding to the word. C is the matrix representation of the sequence S.

We also use emoji vectors provided by Eisner et al. (2016) to represent the emoji that appears in a sequence. It includes 1,661 emojis used in

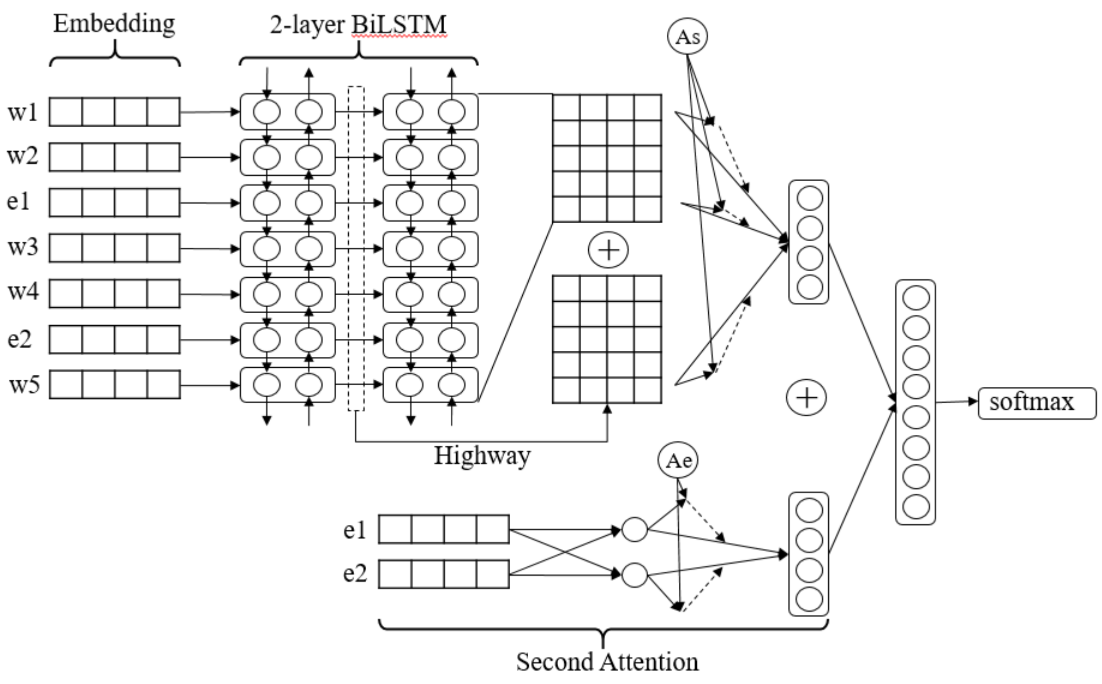

Figure 1: The whole architecture of 2-layer BiLSTM with Double Attention Based Offensive Language Identification. Where w is word, and e is emoji

Twitter and their 300 dimension vector representations. We have made a PCA dimension reduction on emoji vectors, making 300 dimensions into 200 dimensions to suit word vectors. In addition, all bottom feature representation vector are normalized.

3.1.3 Bidirectional LSTM Layer

The structure of one cell in LSTM is shown in Figure 2. Three gated mechanisms of LSTM allows LSTM memory unit to store and access information for a long time. i_t express input gate, f_t express forget gate and o_t express output gate. c_t express memory cell, s_t express memory state and h_t express hidden state. Where t denotes at time t. The forward pass of LSTM is shown in (1)-(6).

$$i_t = f(W_i x_t + U_i h_{t-1} + V_i c_{t-1}) \tag{1}$$

$$f_t = f(W_f x_t + U_f h_{t-1} + V_f c_{t-1}) \tag{2}$$

$$o_t = f(W_o x_t + U_o h_{t-1} + V_o c_t) \tag{3}$$

$$c_t = g(W_c x_t + U_C h_{t-1}) \tag{4}$$

$$s_t = f_t \odot c_{t-1} + i_t \odot c_t \tag{5}$$

$$h_t = o_t \odot g(c_t) \tag{6}$$

Where x_t is the input at time t, $f(.)$ is the sigmoid function, $g(.)$ is the hyperbolic function. W, U and V are trainable weight parameters. In order to extract the semantic relationship features of

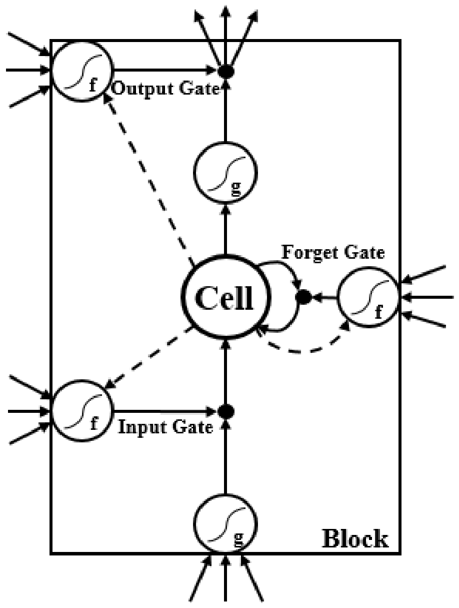

Figure 2: The structure of one cell in LSTM

sentences before and after, we use Bidirectional LSTM to process a sentence. Forward and backward LSTM obtains hidden states $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$:

$$\overrightarrow{h_t} = \overrightarrow{LSTM}\ (w_t, \overrightarrow{h_{t-1}}) \tag{7}$$

$$\overleftarrow{h_t} = \overleftarrow{LSTM}\ (w_t, \overleftarrow{h_{t-1}}) \tag{8}$$

Cascade the results of bidirectional hidden state as the result of BiLSTM:

$$H_t = \overrightarrow{h_t} \oplus \overleftarrow{h_t} \tag{9}$$

We stack two layers of BiLSTMs. The output of the first layer BiLSTM is used as the input of the second layer. Meanwhile, we consider that the first layer can collect low-level semantic information such as lexical or grammatical information, while the second layer can collect high-level semantic information such as sentiment or offensiveness information. So we added a residual connection between the two layers:

$$H_t^{final} = H_t^{layer_1} \oplus H_t^{layer_2} \tag{10}$$

3.1.4 Attention Layer

We input the representation of hidden state obtained by Bidirectional LSTM layer into attention layer to get sentence coding:

$$s_i = \sum_t \alpha_{it} H_{it}^{final} \tag{11}$$

Where a is the weight value:

$$\alpha_{it} = \frac{exp(u_{it}^{\mathsf{T}} u_w)}{\sum_t exp(u_{it}^{\mathsf{T}} u_w)} \tag{12}$$

$$u_{it} = tanh(W_w H_{it}^{final} + b_w) \tag{13}$$

3.1.5 Double Attention Mechanism

We use another attention mechanism similar to that of encoding sentences to encode emojis in sentences, referring to (ZHANG et al., 2018). If there are emojis in a sentence, we get the corresponding vector representation from the emojis dictionary mentioned in Section 3.2.2. Then the coding is obtained through the attention mechanism:

$$s_i^e = \sum_t \alpha_{it}^e E_i \tag{14}$$

Where E is the vector representation of emojis in a sentence.

3.1.6 Softmax Layer

Finally, we concatenate sentence coding and emojis coding through the full connection layer. We use the softmax classifier to construct scoring vectors for each category and convert them into probabilities:

$$r = s \oplus s_e \tag{15}$$

$$\hat{y} = \frac{exp(Wr + b)}{\sum_{i \in [1,l]} exp(W_i r + b_i)} \tag{16}$$

Where W and b is the layer's weights and biases. We use cross-entropy loss function with L2 regularization term:

$$L(\hat{y}, y) = -\sum_{i=1}^{N} \sum_{j=1}^{C} y_i^j log(\hat{y_i^j}) + \lambda(\sum_{\theta \in \Theta} \theta^2) \tag{17}$$

3.2 Data

We only use the training dataset which contains 13,240 tweets provided by SemEval 2019 Task 6 (Zampieri et al., 2019a). Table 1 shows three different levels of tasks and their corresponding amount of data.

A	B	C	Train	Test	Total
OFF	TIN	IND	2,407	100	2,507
OFF	TIN	OTH	395	35	430
OFF	TIN	GRP	1,074	78	1,152
OFF	UNT	-	524	27	551
NOT	-	-	8,840	620	9,460
All			13,240	860	14,100

Table 1: Distribution of label combinations in the data provided by OLID

We have 13,240 tweets to train subtask A. Of these, 4,400 are offensive and 8,840 are non-offensive. There are 4,400 tweets for subtask B. Of these, 3,876 are targeted insult and threats and 524 are untargeted. In 3,876 targeted tweets, 2,407 of them are individual, 1,074 of them are group, and 395 of them are other.

4 Results

In this part, some experimental settings are briefly described. Additionally, we list the experimental results we submitted and compared them with baseline. We use 5-fold cross validation to get 5 same models. Using the probability predicted by these 5 models to do a soft-vote to get the final probability distribution. The highest probability is the predictive class of our system. What's more, we compare performance on offensive identification detection of different models by 5-fold cross validation.

The number of hidden units in 2-layer of BiLSTM is 150 each layer for sub-task A, where it is 100 for sub-task B and 80 for sub-task C. The size of randomly initialized attention query vector is 256 dimensions. We chose the adam optimizer, and the learning rate starts at $7e-4$, decreases to 0.9 times per 20 epoch, always greater than $1e-4$. The λ of L2 regularization is $1e-5$

Tables 2, 3 and 4 show the performance of our system on test dataset in subtasks A, B and C, respectively. The first 2 or 3 rows of the table show the baseline of the officially provided subtasks.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
Submitted System	**0.7684**	**0.8244**

Table 2: The results of Sub-task A we submitted. The system is a 2-layer BiLSTM with Double Attention which is described in Section 3.2

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	**0.8875**
All UNT baseline	0.1011	0.1125
Submitted System	**0.6381**	0.8417

Table 3: The results of Sub-task B we submitted. The system is a 2-layer BiLSTM with Double Attention which is described in Section 3.2. It has different hyperparameter settings from Sub-task A

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
Submitted System	**0.5488**	**0.6338**

Table 4: The results of Sub-task C we submitted. The system is a 2-layer BiLSTM with Double Attention which is described in Section 3.2. It has different hyperparameter settings from Sub-task A and Sub-task B

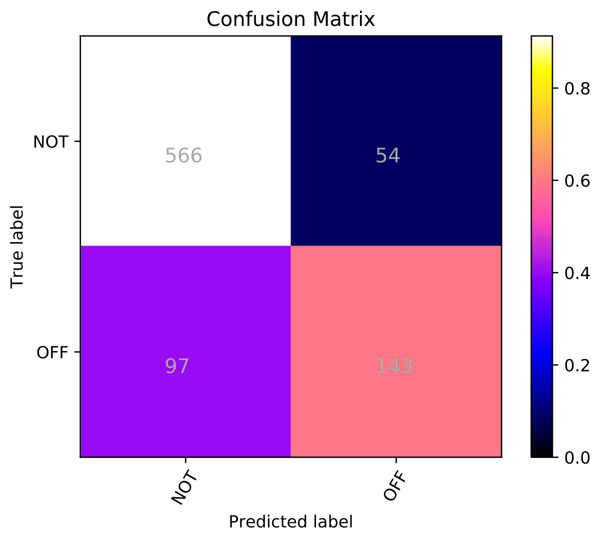

Figure 3: The confusion matrix of the classification results in Sub-task A

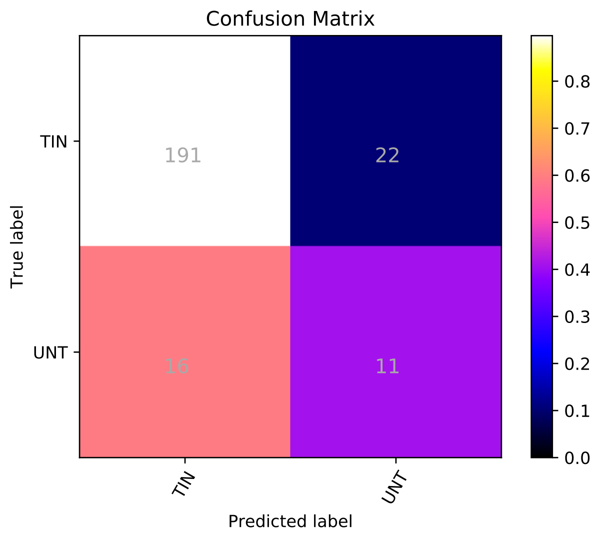

Figure 4: The confusion matrix of the classification results in Sub-task B

Figures 3, 4 and 5 show the confusion matrix of the classification results of our system on the test dataset in subtasks A, B and C, respectively.

We can clearly see from figures that our system performs better in category has more training data. This may be because more data in this category makes the system more inclined to classify these samples correctly in training, not because some categories are easier to identify and others are harder. We used the over-sampling method, but the effect is not obvious. Categories with fewer data quickly reach the state of over-fitting, while those with more data are still under-fitting.

Table 5 shows some comparative experiments on closed validation sets. We use 5-fold cross validation, and each data has the same category ratio.

We can see that if we only use the second layer's features, the performance is worse than using the first layer's. When using two layers features at the same time, the effect is the best. In addition, Word Attention can significantly improve system performance, but Emoji Attention only improve system performance a little. This may be because emojis have little impact on text offensive semantics. It is worth mentioning that the system performance is improved obviously after data preprocessing, and the F1 score has increased by 3.12%.

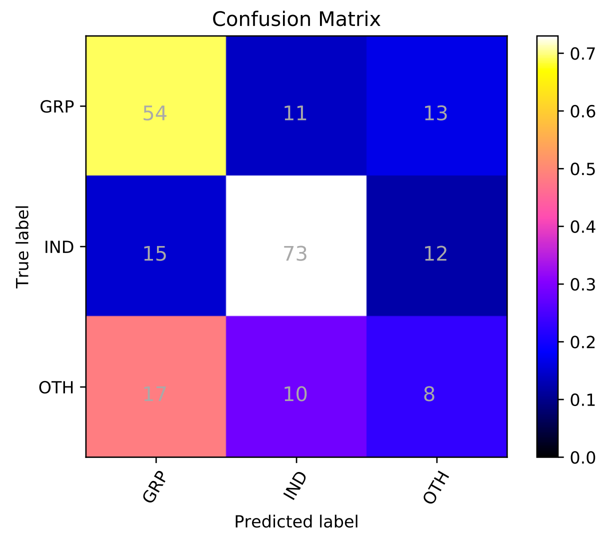

Figure 5: The confusion matrix of the classification results in Sub-task C

Model	A	B	C
1-layer BiLSTM	0.749	0.610	0.527
1-layer BiLSTM with Attention	0.757	0.632	0.544

2-layer BiLSTM (residual connected) with Attention	0.764	0.643	0.549
2-layer BiLSTM (residual connected) with Double Attention (Emojis)	**0.766**	**0.643**	**0.550**

Table 5: Some comparative experiments on closed validation sets

5 Conclusion

This paper introduces a deep learning method Attention-based residual connected BiLSTM with Emojis Attention for SemEval 2019 Task 6: Identifying and Categorizing Offensive Language in Social Media. Our system didn't get the leading score in the competition. Maybe there are the following reasons. Except for the corpus used for pre-training word vectors, we do not use other data for training. Some machine learning models may achieve better results with fewer data. Additionally, we think that hyperparameter adjustment in our system is not perfect. Most importantly, we do not associate the characteristics of offensive language recognition tasks with our model.

The next step of this paper is to associate tasks with models. We will try to constructing a dictionary of offensive words for tasks. We will also try other ways of using external dictionaries except double attention mechanism such as Position Embedding. In addition, we will try some language models that are currently leading the NLP task such as BERT proposed by Devlin et al. (2018).

Abstract

This paper presents the application of two strong baseline systems for toxicity detection and evaluates their performance in identifying and categorizing offensive language in social media. **Perspective** is an API, that serves multiple machine learning models for the improvement of conversations online, as well as a toxicity detection system, trained on a wide variety of comments from platforms across the Internet. **BERT** is a recently popular language representation model, fine tuned per task and achieving state of the art performance in multiple NLP tasks. **Perspective** performed better than **BERT** in detecting toxicity, but **BERT** was much better in categorizing the offensive type. Both baselines were ranked surprisingly high in the SEMEVAL-2019 OFFENSEVAL competition, **Perspective** in detecting an offensive post (12th) and **BERT** in categorizing it (11th). The main contribution of this paper is the assessment of two strong baselines for the identification (**Perspective**) and the categorization (**BERT**) of offensive language with little or no additional training data.

1 Introduction

Offensive language detection refers to computational approaches for detecting abusive language, such as threats, insults, calumniation, discrimination, swearing (Pavlopoulos et al., 2017b), which could be targeted (at an individual or group) or not (Waseem et al., 2017). These computational approaches are often used by moderators who face an increasing volume of abusive content and would like assistance in managing it efficiently.[1]

Although offensive language detection is not a new task (Dinakar et al., 2011; Dadvar et al., 2013; Kwok and Wang, 2013; Burnap and Williams, 2015; Tulkens et al., 2016), the creation of large corpora (Wulczyn et al., 2017), along with recent advances in pre-training text representations (Devlin et al., 2018) allow for much more efficient approaches. Furthermore, while new competitions and corpora are being introduced (Zampieri et al., 2019a),[2] there is a need for strong baselines to assess the performance of more complex systems. This paper assesses two systems for the detection and categorization of offensive language, which require few or no task-specific annotated training instances.

The first baseline is a Convolutional Neural Network (CNN) for toxicity detection, trained on millions of user comments from different online publishers, which is made publicly available through the **Perspective** API.[3] This model requires no extra training or fine tuning and can be directly applied to score unseen posts. The second strong baseline is the recently popular Bidirectional Encoder Representations from Transformers (**BERT**), a pre-trained model that has been reported to achieve state of the art performance in multiple NLP tasks with limited fine-tuning on task-specific training data (Devlin et al., 2018).

Section 2 below summarizes related work and Section 3 discusses the SEMEVAL-2019 OFFENSEVAL dataset we used. In Section 4 we describe the two proposed baselines and we report experimental results in Section 5. Section 6 concludes our work and suggests future directions.

2 Related Work

Various forms of offensive language detection have recently attracted a lot of attention (Nobata et al., 2016; Pavlopoulos et al., 2017b; Park and Fung, 2017; Wulczyn et al., 2017). Apart from the growing volume of popular press concerning

[1]See, for example, `https://goo.gl/VQNDNX`.

[2]See also `https://goo.gl/v7kA1K`.

[3]`https://www.perspectiveapi.com/`

toxicity online, the increased interest in research into offensive language is partly due to the recent Workshops on Abusive Language Online,[4] as well as other fora, such as GermEval for German texts,[5] or TA-COS[6] and TRAC (Kumar et al., 2018),[7]. The literature contains many terms for different kinds of offensive language: toxic, abusive, hateful, attacking, etc. Largely, these are defined by different survey methods. In (Waseem et al., 2017), abusive language is divided into explicit vs. implicit, and directed vs. generalized. However, other researchers have created different taxonomies based on sub-kinds of toxic language (Table 2).

Although some previous research has considered several types of abuse and their relations (Malmasi and Zampieri, 2018), detecting varieties of hate has attracted more attention (Djuric et al., 2015; Malmasi and Zampieri, 2017; ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018). The first publicly available dataset for hate speech detection was that of Waseem and Hovy (2016). It contained 1607 English tweets annotated for sexism and racism. A larger dataset was published by Davidson et al. (2017), containing approx. 25K tweets collected by using a hate lexicon. Despite the popularity of hate speech detection in literature, no larger publicly available hate speech datasets seem to exist. For recent overviews of hate speech detection, consult Schmidt and Wiegand (2017) and Fortuna and Nunes (2018).

Research into the various kinds of offensive language detection is mainly focused on English, but some work in other languages also exists. Work on a large dataset of Greek moderated news portal comments is presented by Pavlopoulos et al. (2017a). A dataset of obscene and offensive user comments and words in Arabic social media was presented by Mubarak et al. (2017). Previous work includes a system to detect and rephrase profanity in Chinese (Su et al., 2017), and an annotation schema for unacceptable social media content in Slovene (Fišer et al., 2017).

3 Data

The SemEval-2019 OffensEval dataset that is available to participants contains 13240 tweets; the counts of the labels are shown in Table 1. The OffensEval task consists of three subtasks, described in detail by Zampieri et al. (2019b). Subtask A aims at the detection of offensive language (OFF or NOT in Table 3). Subtask B aims at categorizing offensive language as targeting a specific entity (TIN) or not (UNT). Subtask C aims to identify whether the target of an offensive post is an individual (IND), a group (GRP), or unknown (OTH). Table 1 also shows the size of the vocabulary per class (label), which, unsurprisingly, is proportional to the class size. It is worth noting that offensive tweets targeting a group are the lengthier texts, with 28 tokens on average (see Table 1, column C, GRP column).

4 Baselines

We now describe the two baselines (**Perspective**, **Bert**) that we implemented and evaluated.

4.1 Perspective

We employed the **Perspective** API, which was created by Jigsaw and Google's Counter Abuse Technology team in Conversation-AI,[8] to facilitate better conversations online and protect voices in conversations (Hosseini et al., 2017). Although open-source code is available,[9] we chose to use pre-trained models, accessible through the API. For offensive language detection in Subtask A, we used the *Toxicity* model, which is a CNN based on GloVe word embeddings,[10] trained over millions of user comments from publishers such as the New York Times and Wikipedia. This is a robust model, which we expect to be somewhat adaptable to different datasets (and their labels for closely related forms of offensive language), such as the offensive tweets of OffensEval. For offensive language categorization in Subtask B, we employed other experimental models, also available via the **Perspective** API, which detect various abuse types including those of Table 2.

4.2 BERT

Bert (Devlin et al., 2018) is a deep bidirectional network built using Transformers (Vaswani et al.,

[9]https://goo.gl/yN196H
[10]https://goo.gl/rHYMqt

Subtask	A		B		C		
Label	NOT	OFF	UNT	TIN	IND	GRP	OTH
Number of Tweets	8840	4400	524	3876	2407	1074	395
Class specific vocabulary size	29.2K	18.6K	3.5K	17.3K	11.5K	7.8K	3.5K
Average number of tokens / Tweet	22	24	19	24	22	28	25

Table 1: Number of tweets, size of vocabulary, and average number of tokens per tweet, for each label (class). In Subtask A, the labels are 'not offensive' (NOT) or 'offensive' (OFF). In Subtask B, the labels are 'not targeted threat' (UNT) and 'targeted insult or threat' (TIN). In Subtask C, they are 'targeted insult or threat towards an individual' (IND), 'towards a group' (GRP), or 'towards another target' (OTH).

TOXICITY	@user Fuck you, you fat piece of shit

2017). It is pre-trained to detect (a) a masked word from its left and right context, and (b) the next sentence. We used the publicly available **BERT**-BASE version,[11] with 12 Transformer layers, 768 hidden states size, which is pre-trained on a monolingual corpus of 3.3B words. For a particular NLP task, a task-specific layer is added on top of **BERT**. In our case, the extra layer comprises dropout, a linear transformation, and softmax.[12] During the task-specific 'fine-tuning', the extra layer is trained jointly with **BERT** (refining the pre-trained **BERT** model) on task-specific data. Previous research demonstrated that fine-tuning **BERT** leads to state of the art performance in several NLP tasks (Devlin et al., 2018).

System	**F1 (macro)**	**Accuracy**

BERT	**0.6817**	0.8708
BEST 2019	0.7550	—

Table 4: Results for Subtask B.

5 Results

5.1 Offensive Language Detection

For Subtask A, we used the *toxicity* score from **Perspective** and returned the offensive label (OFF) when the returned score was above 0.5. No fine tuning was performed for **Perspective**. For **BERT**, we split the dataset to training (10K tweets) and development (3240) subsets, and fine-tuned **BERT** for 3 epochs.[13]

In this subtask, **Perspective** outperformed **BERT** and was ranked 12th out of 103 submissions. The difference from the top-ranked model was 3.5 F1 points. The performance of **Perspective** in this subtask is particularly interesting, considering that the training data for these models were not labeled for offensiveness, but rather for other attributes such as toxicity, threats, and insults.[14] Ignoring **Perspective**, **BERT** was ranked

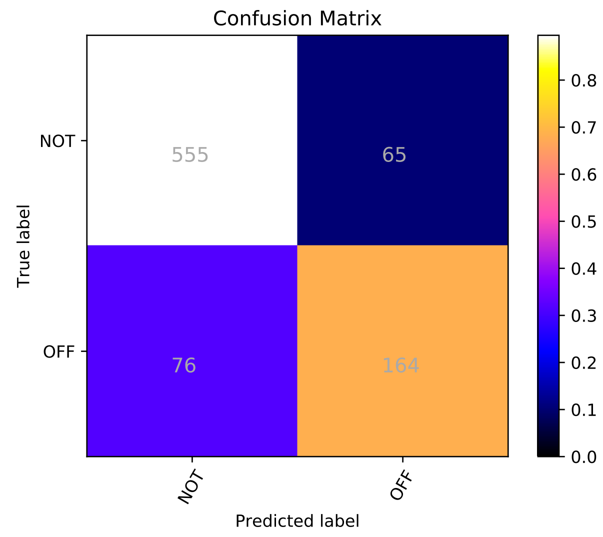

Figure 1: Confusion matrix for **Perspective** in Subtask A (Offensive Language Detection).

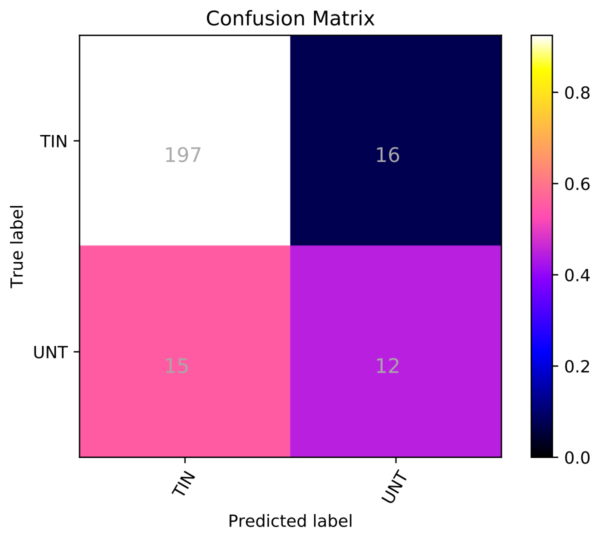

Figure 2: Confusion matrix for **BERT** in Subtask B (Offense Type Detection).

27th. As shown in Table 3, both of our strong baselines outperform the naive majority baselines for this subtask.

The confusion matrix of **Perspective** is shown in Fig. 1. Both recall and precision are high for the NOT label (87.96% and 89.81%), but lower for OFF (68.33% and 71.62%). This is explained by the fact that NOT is two times the size of OFF (Table 1). We also used **Perspective** to score the training data, since no fine-tuning was performed on the training data for **Perspective**. Macro F1 was 78.01% (85.02% for NOT, 71% for OFF) and accuracy was 80.24%, which are lower but close to the respective values on the test data (Table 3).

5.2 Offense Type Detection

For Subtask B, we used the experimental *insult*, *threat* and *attack on commenter* models from Perspective. We averaged *insult* and *attack on commenter* and used this average to compare with the *threat* score. The **Perspective** baseline returned a targeted insult/threat (TIN) when the average was greater, and untargeted (UNT) otherwise. The **BERT** baseline was fine-tuned on the entire dataset that was available to participants, because we considered that dataset too small for a training/development split.[15] **BERT** clearly outperformed the **Perspective** baseline (Table 4) and ranked 11th in this subtask among 73 participants, whereas the best system achieved 7.8 points higher in F1. The confusion matrix of **BERT** for this subtask is shown in Fig. 2. The large class imbalance (TIN tweets are approx. 7 times than UNT, see Table 1) significantly reduces both the recall (44.44%) and precision (42.86%) of **BERT** for the UNT class, compared to TIN (92.49% and 92.92%, respectively).

5.3 Offense Target Detection

For Subtask C, Perspective has no suitable model to respond yet and the **BERT**-based systems submitted were in an experimental phase, due to time constraints.[16] We consider the results we obtained for this subtask as not relevant and leave the development and evaluation of baselines for this subtask as future work.

6 Conclusion

This paper proposed and evaluated two strong baselines, based on the **Perspective** API and **BERT**, for identifying and categorizing offensive language in social media. Both baselines require few (**BERT**) or no additional task-specific training data (**Perspective**) and this is the first work, to our knowledge, to assess their performance in the tasks we considered. The **Perspective**-based baseline was ranked 12th among 103 submissions for the task of classifying a post as offensive or not. The **BERT** baseline was ranked 11th among

[15]We used the cased system with batch size 16, based on preliminary experiments.

[16]**BERT** base and **BERT** large (trained on CPU) were examined for this subtask, but preliminary experiments showed that the majority class was always returned.

73 submissions for the task of recognizing whether an offensive post is targeted or not. Both baselines were ranked surprisingly high in the corresponding tasks, considering that they were given no or few, respectively, additional task-specific training instances. Furthermore, the Perspective baseline, which required no fine tuning outperformed **BERT** by a large margin in the task of detecting offensive language. In future work, we intend to examine stronger, yet easy to apply baselines, and release source to make it easier to use them.

Abstract

This paper presents the participation of team DA-LD-Hildesheim of Information Retrieval and Language Processing lab at DA-IICT, India in Semeval-19 OffenEval track. The aim of this shared task is to identify offensive content at fined-grained level granularity. The task is divided into three sub-tasks. The system is required to check whether social media posts contain any offensive or profane content or not, targeted or untargeted towards any entity and classifying targeted posts into the individual, group or other categories. Social media posts suffer from data sparsity problem, Therefore, the distributed word representation technique is chosen over the Bag-of-Words for the text representation. Since limited labeled data was available for the training, pre-trained word vectors are used and fine-tuned on this classification task. Various deep learning models based on LSTM, Bidirectional LSTM, CNN, and Stacked CNN are used for the classification. It has been observed that labeled data was highly affected with class imbalance and our technique to handle the class-balance was not effective, in fact performance was degraded in some of the runs. Macro F1 score is used as a primary evaluation metric for the performance. Our System achieves Macro F1 score = 0.7833 in sub-task A, 0.6456 in the sub-task B and 0.5533 in the sub-task C.

1 Introduction

NLP researchers are developing innovative systems based on the input of the text data. The power of predictions has moved from simple sentiment classification task to much more advanced labeling of the content. The task related to hate, aggression, abusive or offensive speech currently attracts research more to algorithms making decisions which can also be ambiguous for humans. Due to the availability of standard datasets, such data collections are created based on social media data and are offered at forum like TRAC [1] (Kumar et al., 2018), GermEval [2], and SemEval OffenEval 2019 (Zampieri et al., 2019a)[3].

The exponential rise in social media user-base backed by the cutting edge mobile data technologies leads to the inorganic growth in the posts related to hate speech or offensive speech. Researchers working in the area of domain-specific sentiment analysis move to the problem of domain specific or open domain hate or offensive speech detection. They are reshaping the hate speech problem into the new notion like abusive, aggressive, or offensive speech. Such categorization of social media posts, help law-enforcement agencies with the surveillance of the social media.

The shared task in SemEval-OffenEval 2019 was introduced as a 3-level classification task (Zampieri et al., 2019b). In the first level, sub-task A, systems are required to classify tweets into two class, namely: Offensive (OFF) and Non-offensive (NOT). In the second level, sub-task B, offensive tweets are further required to be categorized into two labels, namely :targeted (TIN)-post which contain threat/insult to the targeted entity and untargeted (UNT), respectively. In the sub-task C, target of insults and threats are further classified to Individual (IND), Group (GRP), or Other (OTH) classes. Table 1 presents the statistic about the dataset. One can observe that classes in dataset, particularly for the sub-task B and sub-task C, is highly imbalanced.

Our approach for this shared task is based on distributed word representation and deep learning. fastText pre-trained word embedding (Mikolov et al., 2018) is used to initialize embedding layer or first layer of the model and fine tuned for classification task. The rest of the model is still needed

to be trained from scratch.(Howard and Ruder, 2018) termed this techniques as shallow representation against the hierarchical representation.

The rest of this paper is organized as follows. In section 2 we briefly discuss the related work in this area. In section 3, we present our method and model. In section 4, we present results and give the brief analysis. In section 5, we will give our final conclusion along with future works.

2 Related Work

Hate Speech Detection research attracts researchers from diverse background like computational Linguistic, computer science, and social science. The actual term hate speech was coined by (Warner and Hirschberg, 2012). Various Authors used different notion like offensive language (Razavi et al., 2010), cyberbullying (Xu et al., 2012), aggression (Kumar et al., 2018). (Davidson et al., 2017) studied tweet classification of hate speech and offensive language and defined hate speech as following: language that is used to express hatred towards a targeted group or is intended to be derogatory, to humiliate, or to insult the members of the group. Authors observed that offensive language is often miss-classified as hate speech. They have trained a multi-class classifier on N-gram features weighted by its TF-IDF weights and PoS tags. In addition to these, features like sentiment score of each tweet, number of hashtags, and URLS, mentions are considered. Authors concluded that Logistic Regression and Linear SVM are better than NB, Decision Tree, and Random Forests. (Schmidt and Wiegand, 2017) perform comprehensive survey on hate speech. They have identified features like surface features, sentiment, word generalization, lexical, linguistics etc. can be used by classifier.

(Malmasi and Zampieri, 2018) tried to address the problem of discriminating profanity from hate speech in the social media posts. N-grams, skip-gram and clustering based word representation features are considered for the 3-class classification. The author uses SVM and advance ensemble based classifier for this task and achieved 80% accuracy. (Gambäck and Sikdar, 2017) performed 4-class classification on Twitter messages using CNN with word embedding generated through Word2vec and character n-grams. Authors claim that word embedding generated through Word2vec outperformed random vector and n-gram characters. (Zhang et al., 2018) proposed a new method based on CNN and LSTM with drop out and pooling for hate speech detection. Authors concluded that their method achieved improvement on F1 score of most of the hate speech datasets.

3 Methodology and Data

Since the social media data suffers from the data sparsity problem, classifier based on the BoW features might not be appropriate as compared to distributed word representation. Our previous work (Majumder et al., 2018) also supported this intuition. Empirical evidence (Majumder et al., 2018) suggest that pre-trained vector trained on huge corpus provides better word embedding than embedding generated from a limited training corpus. Some authors (Howard and Ruder, 2018) termed it as a shallow-transfer learning approach. In this method, first layer or embedding layer of deep neural network is initialized with pre-trained vectors and the rest of the network is trained from scratch. Since fastText generates word embedding for a word which is unseen during the training by using the subword or n-gram of the word, it is the better choice than Word2vec and Glove. As discussed in the previous section, there is substantial class imbalance particularly in sub-task B and C. To address this issue, class weights are incorporated into the cost function of the classifier which gives higher weight to minority class and lower weights to the majority class. Four deep learning based models: Bidirectional LSTM, Single LSTM, CNN and stacked CNN are designed for the classification.

Pre-processing : Track organizers have partially pre-processed tweets in the dataset. User mention, URL are replaced with standard tags. We did not perform any sort of further pre-processing or stemming on the texts.

Word embedding : fastText pre-trained word vectors with dimension 300 are used to initialize the embedding layer. This model is trained on 600B tokens of commonly crawled corpus.

3.1 Model Architecture and Hyperparameters

In this sub-section, we briefly describe our models used for the classification. The first model is based on Bidirectional LSTM model includes the embedding layer with 300 dimensions, Bidirectional LSTM layer with 50 memory units followed by one-dimensional global max pooling and dense layer with softmax/sigmoid activations. Hyperparameters are as follows: Sequence length is fixed at 30. Number of features is equal to the half of total vocabulary size in each task. Models are trained for 10 epoch. Adam optimization algorithm is used to update network weights.

The second model is based on LSTM. The model includes embedding layer with 300 dimensions, LSTM layer with 64 memory units, followed by two dense layers with softmax/sigmoid activations. A dropout layer is added to the hidden layer to counter the overfitting. Hyperparameters of the model is the same as the first model.

Rest of the two models are based on Convolution Neural Network, includes embedding layer with embed size of 300, followed by a one-dimensional convolution layer with 100 filters of height 2 and stride 1 to target biagrams. In addition to this, Global Max Pooling layer is added. Pooling layer fetches the maximum value from the filters which are feeded to the dense layer. There are 256 nodes in the hidden layer without any dropout. The last model is same as previous CNN model except three one-dimensional convolution layer are stacked together. Different

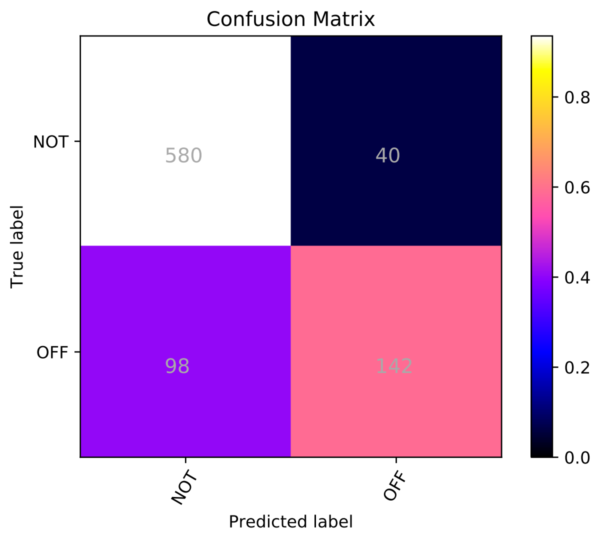

Figure 1: Sub-task A, Confusion Matrix:BLSTM classifier

one-dimensional filters with height 2,3,4 to target bigrams, trigrams, and four-grams features. After convolution layers and max pool layer, model concatenate max pooled results from each of one-dimensional convolution layers, then build one output layer on top of them. (Majumder et al., 2018). Hyperparameters of the model is the same as the first model.

4 Results

In this section, we report the results obtained by the model discussed in the previous section. Table 2, 3, 4 display results of sub-task A, B, and C, respectively. We have randomly splitted the dataset into 80% training and 20% validation. By and large, results on test dataset are better than cross-validation. F1-macro score is the primary metric for the evaluation. Results are comparable with the top team and substantially outperforms all the random baselines. Figure 1, 2, and 3, show the confusion matrices for all the sub-tasks.

5 Conclusion

In this paper, we have presented our deep learning based approach for multi-level offensive text classification. The system reports reasonable performance. Macro f1 and accuracy score around 78.3% and 84% in sub-task A. In sub-task B, our system performs the worst in UNT class(offensive post without target). The reason behind this underperformance is few number of training examples for the UNT class. Similar case happened in the

DeepAnalyzer at SemEval-2019 Task 6: A deep learning-based ensemble method for identifying offensive tweets

Gretel Liz De la Peña Sarracén and **Paolo Rosso**
PRHLT Research Center, Universitat Politècnica de València, Spain

Abstract

This paper describes the system we developed for SemEval 2019 on Identifying and Categorizing Offensive Language in Social Media (OffensEval - Task 6). The task focuses on offensive language in tweets. It is organized into three sub-tasks for offensive language identification; automatic categorization of offense types and offense target identification. The approach for the first subtask is a deep learning-based ensemble method which uses a Bidirectional LSTM Recurrent Neural Network and a Convolutional Neural Network. Additionally we use the information from part-of-speech tagging of tweets for target identification and combine previous results for categorization of offense types.

1 Introduction

The use of Internet has become an important media of personal and commercial communication. In this scenario, some users take advantage of the anonymity of this kind of communication, using this to engage in behaviour that many of them would not consider in real life. Therefore, much of the offensive language is widespread in social networks. Then, studying offensive language in texts from the social media is an essential task for security, the prevention of cyber-bullying, among other abusive behavior.

To increase the research in this areas, several workshops have been organized, such as ALW[1] and TRAC[2]. Recently, OffensEval[3] (Zampieri et al., 2019b), which is a shared task at the SemEval-2019[4] workshop has been launched on the research community. The aim of OffensEval is to deal with offensive language detection in the English language focusing on messages from Twitter.

In OffensEval, the treatment of offensive content is divided into three subtasks taking the type and target of offenses into account:

- A: Offensive language identification.
- B: Automatic categorization of offense types.
- C: Offense target identification.

In this work, we present the methodology proposed to each of these sub-tasks, which includes an ensemble of a LSTM Recurrent Neural Network and a Convolutional Neural Network, and additionally linguistic features for the last two subtasks. The architecture of the system will be more detailed in the following sections.

The paper is organized as follows. Next section briefly describes other works in this area. Then, Section 3 describes the proposed metodology and the dataset. Results are discussed in Section 4. Finally, we draw our conclusions together with a summary of our findings in Section 5.

2 Related Work

Some approaches have been proposed to tackle the problem of offensive language detection. It is the case of recent works (Waseem et al., 2017; ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018) and surveys (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018). There are even studies on languages other than English such as (Su et al., 2017) on Chinese and (Fišer et al., 2017) on Slovene.

Many of the last approaches rely on neural network models. For instance, the work of (Ganesan et al., 2018) presents a Multi-Layer Feedforward Neural Networks. Moreover, (Park and Fung, 2017) proposes to implement three models based

on Convolutional Neural Networks (CNN) to classify sexist and racist abusive language: Char-CNN, WordCNN, and HybridCNN. It work reports that can boost the performance of simpler models. Also, (Pitsilis et al., 2018) proposes a detection scheme that is an ensemble of Recurrent Neural Network classifiers. It incorporates various features associated with user-related information. They report that the scheme can successfully distinguish racism and sexism messages from normal text.

3 Methodology and Data

The corpus provided by the organizers consists of 14,100 tweets in English. The data collection methods used to compile the dataset used in OffensEval is described in Zampieri et al. (2019a).

The first step is the preprocessing of the tweets, where texts are cleaned. All emoticons, hashtag and urls are removed. Then, the texts are represented as vectors with word embedding vectors. We used the pre-trained word vectors of Glove (Pennington et al., 2014), trained on 2 billion words from Twitter.

The method proposed in this work is based on an architecture that sequentially obtains the output for each of the subtasks. In the first level we use a model whose input is the word embeddings of a tweet and the output is a vector (*r_vector*) that is taken as a compact representation of the input and is used in the following steps. For the model, two types of networks have been used. In a first approach a Recurrent Neural Network (RNN) is used, and as a second approximation a Convolutional Neuronal Network (CNN). These two models are described below.

3.1 Convolutional Neural Network

The model is a version of the convolutional neural networks presented in (Kim, 2014) for sentence-level classification tasks. Here, the input of the model is a matrix where each row corresponds to the embedding vector of each word in the tweet. Three different filters of sizes 3, 4 and 5 are applied in a 1D convolution step to capture information from 3-grams, 4-grams and 5-grams. The feature maps produced by the convolution layer are forwarded to a Maxpooling layer. We used 2x2 filters for this pooling function on a feature map to reduce it to the single most dominant features.

Finally, the r_vector is generated by the concatenation of the results for each of the filters.

3.2 Recurent Neural Network

In NLP problems, standard LSTM Recurrent Neural Networks receive sequentially (left to right order) at each time step a word embedding w_t and produces a hidden state h_t.

On the other hand, the bidirectional LSTM makes the same operations as standard LSTM but, processes the incoming text in a left-to-right and a right-to-left order in parallel. Thus, the output is a two hidden state at each time step $\overrightarrow{h_t}$ and $\overleftarrow{h_t}$. The proposed method uses a Bidirectional LSTM network which considers each new hidden state as the concatenation of these two $\hat{h_t} = [\overrightarrow{h_t}, \overleftarrow{h_t}]$. The idea of this Bi-LSTM is to capture long-range and backwards dependencies.

3.3 Sub-task A

For the first sub-task, which consists in the identification of offensive language in tweets, *r_vector* is used as input of a Fully Connected Neural Networks (FCNN) of two layers with activation function relu. The class (offensive or not) is obtained in a third layer of two units, that refer to the number of classes, with a softmax activation function.

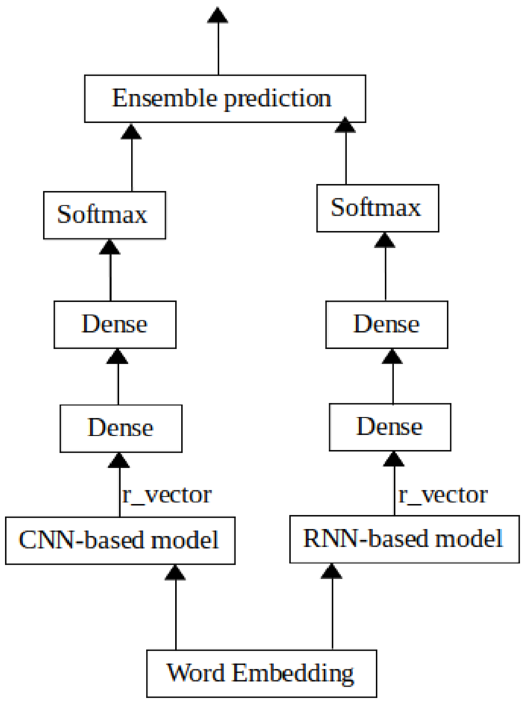

Figure 1: Architecture. Sub-task A

The Figure 1 shows the general scheme commented. Given this architecture, three weights of both CNN and RNN models were made. In the first weighting all the weight is for RNN (RNN_run). In contrast, in the second one, all the weight is for CNN (CNN_run). Finally, the third one is the actual ensemble model where both models are assigned equal weight (Ensemble_run). For combining the results of both models, the system gets the mean of the predictions of each one.

3.4 Sub-tasks B and C

In the sub-task of detecting the target of offensive language, the information of the part-of-speech tagging process of the tweets is used. This allows us to make more fine-grained distinctions on the words in texts which can identify to the target of aggressiveness. For instance, this information allows to discriminate between a proper noun and other kind of noun, and if a noun is plural or singular. In this way the model can learn sequences of tags which represent each type of target. The POS labels are obtained with Standford CoreNLP and they are represented as a one hot vectors. The sequence of labels is analyzed with a LSTM RNN, and a representation *p_vector* is obtained. Then, the concatenation of vectors *r_vector* and *p_vector* is used as input to another FCNN of one hidden layer with the activation function relu, and an output layer with two neurons with a softmax activation function. In this way, the prediction corresponding to the offensive target in the tweets is obtained. The Figure 2 shows this processing.

Finally, for the sub-task of classifying the types of offensive tweet, the prediction is obtained in a similar way to the previous sub-task. Here, a one hot vector corresponding to the POS tags present in the tweet is added to *r_vector*. Then, the prediction is calculated using another FCNN.

Finally, cross entropy is used as the loss function, which is defined as:

$$L = -\sum_{i} y_i * log(\hat{y}) \quad (1)$$

Where y_i is the ground true classification of the tweet and $\hat{y}$ the predicted one.

4 Results

In the evaluation, the official ranking metric is macro-averaged F1. The results obtained in each subtask are shown in the next tables and confusion matrices. For each case, each of the three approaches discussed above (CNN_run, RNN_run

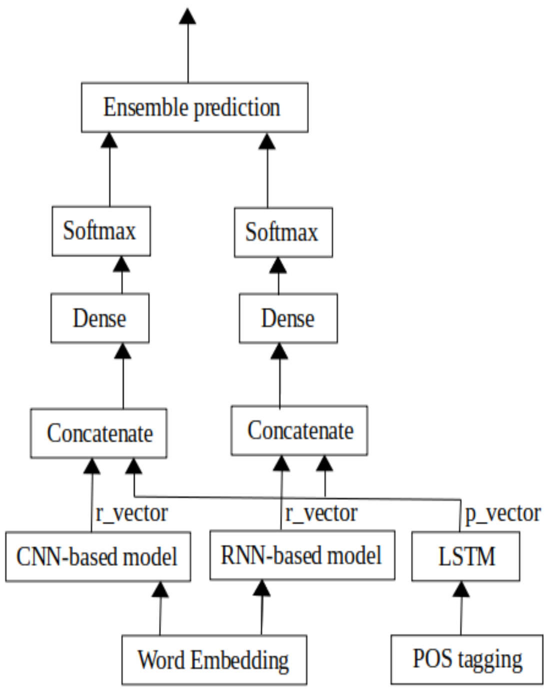

Figure 2: Architecture. Sub-task B

and Ensemble_run) was evaluated and the results are shown in the tables with the name that was indicated. Also, random baseline generated by assigning the same labels for all instances are included. For example, ”All OFF” in sub-task A represents the performance of a system that labels everything as offensive. It was used for comparison.

System	macro F1
All NOT baseline	0.4189
All OFF baseline	0.2182
Best	0.829
RNN_run	0.5984
CNN_run	**0.6600**
Ensemble_run	0.5925

Table 1: Results for Sub-task A

These results reveal a behavior not as good as expected, since although the baselines were exceeded in each case, the results were relatively far from the best results of the competition. Perhaps this is due to the fact that the different linguistic characteristics that could be extracted from tweets, such as information related to emoticons, hashtags and urls, were not analyzed in detail.

Another aspect to note is that for the three tasks

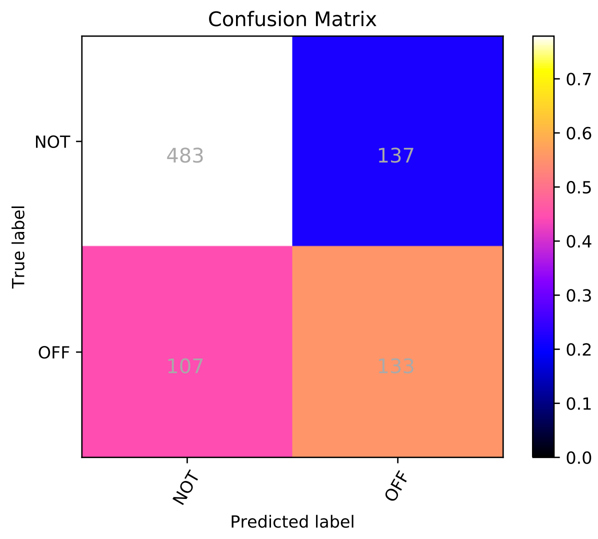

Figure 3: Sub-task A: CNN_run

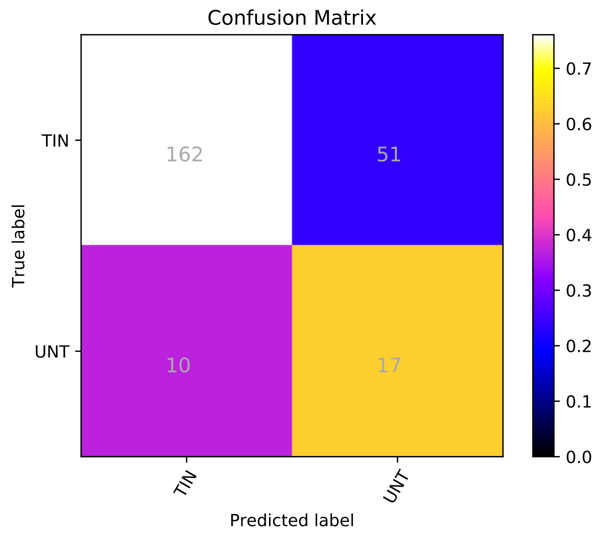

Figure 4: Sub-task B: RNN_run

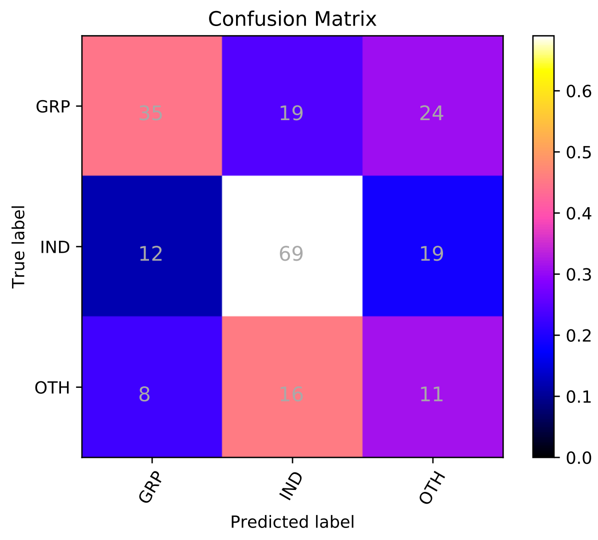

Figure 5: Sub-task C: CNN_run

System	macro F1
All TIN baseline	0.4702
All UNT baseline	0.1011
Best	0.755
RNN_run	**0.5997**
CNN_run	0.5704
Ensemble_run	0.5587

Table 2: Results for Sub-task B.

System	macro F1
All GRP baseline	0.1787
All IND baseline	0.2130
All OTH baseline	0.0941
Best	0.660
RNN_run	0.3848
CNN_run	**0.4833**
Ensemble_run	0.4174

Table 3: Results for Sub-task C.

the best approach is based on simple models instead of a combination of models that in our case was obtained with an ensemble of models based on neural networks. So that, for two of the tasks the best results were obtained only with the use of CNN and for the other one with the RNN.

5 Conclusion

In this paper our solution for the OffensEval challenge in SemEval 2019 was presented. We used an ensemble of models based on deep learning, and compared the results obtained to those ob- tained with each of the models independently. As a conclusion, it can be said that it may be more important for this kind of tasks to search for properly linguistic characteristics instead of designing complex models with a lot of parameters.

Abstract

In this paper we built several deep learning architectures to participate in shared task *OffensEval: Identifying and categorizing Offensive language in Social media by semEval-2019* (Zampieri et al., 2019b). The dataset was annotated with three level annotation schemes and task was to detect between offensive and not offensive, categorization and target identification in offensive contents. Deep learning models with POS information as feature were also leveraged for classification. The three best models that performed best on individual sub tasks are stacking of CNN-Bi-LSTM with Attention, BiLSTM with POS information added with word features and Bi-LSTM for third task. Our models achieved a Macro F1 score of 0.7594, 0.5378 and 0.4588 in Task(A,B,C) respectively with rank of 33rd, 54th and 52nd out of 103, 75 and 65 submissions.

1 Introduction

Due to the exponential rise in the usage of internet user generated content in the form of blogs, posts, comments etc. have been increased manifold. Some users also using this platform to target any individual or any particular group on social media on the basis of certain attributes, sharing different views. Many studies have been conducted on offensive language, hate speech, cyberbullying, profanity, aggression detection. These contents are major concern for governments, so robust computational systems need to be developed to tackle these posts to maintain social harmony. This paper is organized as follows. Related work have been discussed in section 2, Methodology have been described in Section 3 followed by data sets and other settings used to solve the tasks in Section 4. Results and analysis of the models is described in Section 5 with the limitation of the models in Error Analysis in section 6. Section 7 contains the conclusion and Future scope.

1.1 Problem Definition

The organizers proposed a hierarchical three level annotation model and divided into three sub tasks.
Task A: This task consist of classifying between *offensive* and *not offensive* comments
Task B: The Offensive language was further needs to be classified into *Targeted(TIN)* and *UnTargeted(UNT)*.
Task C: The targeted offensive needs to be further classified into *Individual(IND)*, *Group(GRP)* and *Other(OTH)*.

2 Related Work

(Nockleby, 2000) defined hate speech as any communication that demean any person or any group on the basis of race, color, gender, ethnicity, sexual orientation, and nationality. (Kowalski et al., 2014) defined cyber aggression as using digital media to intentionally harm another person. (Schmidt and Wiegand, 2017) presents a survey on the existing research in this field and different set of features used in machine learning and Deep learning were discussed. (Silva et al., 2016) proposed and validated sentence structure to detect hate speech and also used this to construct hate speech datasets. They also provided the characteristics study to identify the main targets of hate speech in Twitter and Whisper. They designed two rules i.e *I*<intensity><user intent><hate Target> and <one word> people ex:"black people","maxican" people. (Waseem, 2016) examined the performance of classification based on training performed on amateur and expert annotations. (Ross et al., 2017) concluded that hate speech requires significantly better definitions and guidelines. (Sood et al., 2012) detected profanity by identifying offensive words using list based methods and incorporated edit distance to find similar obscene words. (Davidson et al., 2017) observed that seperating offensive and hate speech is very challenging task. *nigga*, *hoe* , *bitch*, *fag* are very offensive in nature but can be used in different manner. They reported Logistic Regression as their best classifier in detecting approx. 25K Tweets by using N-grams weighted by TF-IDF, POS n-grams and using sentiment score as their features.(Samghabadi et al., 2017) used surface level features like word n-grams and char n-grams, LIWC and SentiWordNet to get the sentiment score as well as some domain related features. (Malmasi and Zampieri, 2017) used char n-grams, word n-grams and word skip grams to get accuracy of 78% on Data set of 14509 tweets classified into 3 classes. (Waseem et al., 2017) tried to capture similarities between different sub tasks. They proposed a typology to differentiate language on the basis of individual or group attack or if the content is explicit or implicit. (Gambäck and Sikdar, 2017) used random vector, word vectors and also concatenated word based CNN and character based CNN to classify 6909 tweets into 4 classes. (Xu et al., 2012) used LDA to find out relevant and useful sentiment in bullying texts. (Zhang et al., 2018) proposed a CNN-GRU based structure which outperformed 6 out of 7 datasets by at most 13 F1 points. They have used surface level features, linguistic features, sentiment features as well as number of misspellings , percentage of capitalisation for SVM. (Aroyehun and Gelbukh, 2018) implemented several neural networks and also found that char n-grams is more superior than word n-grams in NBSVM. They also used data augmentation, pseudo labeling and sentiment score as feature. (Kumar et al., 2018) discuss the task of developing a classifier to discriminate *Overtly*,*Covertly* and *Non Aggressive* text using 15000 annotated social media data in both English and Hindi(in Roman and Devanagri script) as part of TRAC-1. (Badjatiya et al., 2017) experimented with several deep neural architecture and found that it outperformed state of the art word/char n-grams.(Djuric et al., 2015) proposed paragraph to vector for modelling of comments. (Gao and Huang, 2017) discusses the Bi-LSTM with attention mechanism with learning components context improved the classifier performance.

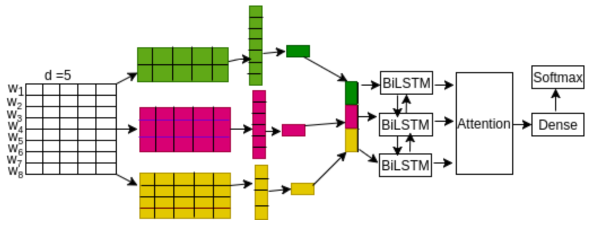

Figure 1: **Sub Task A:CNN-BiLSTM-Attention**

(Founta et al., 2018) studied different forms of abusive behaviour and made public annotated corpus of 80K Tweets categorized into 8 labels like Hate, aggressive, cyber bullying, normal , Spam.

3 Methodology

3.1 Task A:CNN-BiLSTM-Attention

In this model first we converted all the words to their unique index. Then all the unique index in the sentences were mapped to their real valued vectors of Dimensions 100 using Glove by (Pennington et al., 2014) from Embedding Matrix. Convolution layers is used to extract useful information by convolving i words at a time using learnable kernel of size i*h where i = [2,3,4] and h is of size equal to the dimensions. The element wise dot product is performed to get the feature map f_1. N numbers of filters are used to get feature map = [f_1,f_2...f_n]. Pooling reduces the size of representation by selecting max value from each feature map which is then passed to the BiLSTM layer with 100 hidden units. The sentence level representation is then passed to activation layers to capture the important keywords informations. This vector representation is then passed to softmax classification to get the probability values of each class.

Attention It tries to make RNN better by letting the network to know the weight of important keywords. It produces state of the art results on several NLP tasks. We used the approach followed by (Ding et al., 2018) for sentence level attention which follows the following equation.

$$e_t = tanh(Wh_t + b) \quad (1)$$

$$\alpha_t = softmax(e_t) \quad (2)$$

$$output = \sum_{t=1}^{t=n} \alpha_t h_t \quad (3)$$

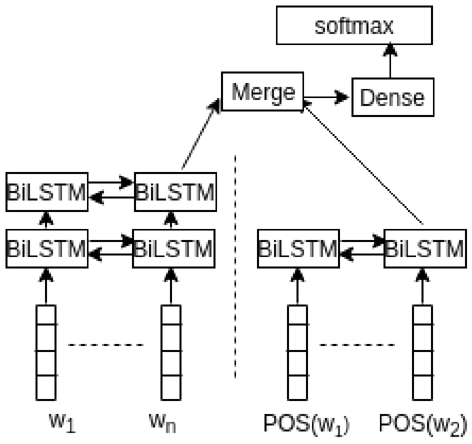

Figure 2: **Sub Task B:BiLSTM(Word+POS)**

3.2 Task B:BiLSTM(Word+POS)

In this model two layers of BiLSTM were used with hidden nodes of 100 where the sentences were being represented by Glove embedding. BiLSTM uses 2 LSTM that is useful for keeping both the past and future information. The input sequence $(i_1,i_2,...i_n)$ is converted to $(h^1_i,h^2_i...h^n_i)$ taking into account each words. Each word was tagged with its POS Tag and embedding for each Tag was calculated. Each sequence was then converted to their POS Tag real valued vector of Dimensions of 20 using embedding matrix. The input sequence is then passed to BiLSTM layer with hidden nodes of 100. The outputs of both the channels were concatenated and passed to the Fully connected layer followed by softmax Classification.

3.3 Task C: BiLSTM

We used BiLSTM using 100 dimensions to represent sequences by fixing the maximum length to 40 . Post padding with 0 was used for shorter sequences as it helps in preserving the information at the borders. After getting desired hidden representation from 2 layers it is passed to the Fully Connected layers followed by softmax Classifier for getting probability distribution among classes.

4 Data Sets

The Datasets provided by organisers (Zampieri et al., 2019a) were three level annotated social media text. The task was divided into three parts,description of their data sets is in Table**1**, Table **2** and Table **3** .

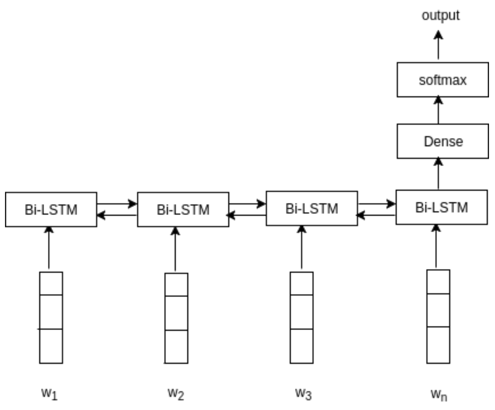

Figure 3: **Sub Task C:BiLSTM**

Class	#Training	#Test
Offensive	4400	240
Not Offensive	8840	820

Off_Tar_OTH	395	35

Table 3: **Data set:Task C**

4.1 Parameter Tuning,Word embedding and evaluation Metrics

We use Keras with Tensorflow as backend,Scikit-learn library for implementation. For every dataset we use 80:20 for 80% to use in Training and using grid search to learn batch size and epochs. Experiments were performed using stratified 5-fold cross validation to train all the classes according to their proportion and 20% of remaining data were used as testing the model. We are reporting our results on Training data provided by orgainsers by standard Precision, Recall and F-score by averaging all the cross fold results. Categorical cross entropy loss function and Adam optimiser were used for training . In the experiment we use publicly available Glove embedding by (Pennington et al., 2014). We used batch size of(16,32,64) and drop out of (0.1,0.2,0.3).

4.2 Preprocessing

As the datasets are collected from social media it contains lots of noise and inconsistencies in the form of urls, typos and abbreviations. So we start by applying light preprocessing by expanding all appostrophes containing words and then removing characters like : , & ! ? and also all the tokens were tranformed to lower case to avoid capitalized versions of same word being treated as different words. We also used dictionary to expand the misspelled words to its original form. The POS tags were obtained from NLTK.

Class	OFF	NOT	F1	Acc.

Table 8: **Test Set: Task B**

5 Results and Analysis

We have reported the cross validation split accuracy and F-score in Table 4, Table 5 and Table 6 for all the three subtasks. The results for test set is also included in Table 7 .Table 8 and Table 9. For our systems we got almost comparable results for both training and test datasets. We got F-score of 75.94%, 53.78% and 45.88% in sub task A, B, C respectively. Table 10 shows the performance of our system compared with best systems.

Class	GRP	IND	OTH	F1	Acc.
GRP	48	30	0	45.88	64.32
IND	11	89	0		
OTH	15	20	0		

Table 9: **Test Set: Task C**

Task	Ours	Best
A	75.94%	82.9%
B	53.78%	75.5%
C	45.88%	66%

Table 10: **System Performance**

6 Error analysis

Error analysis was carried out to analyze the errors that we encountered in our system by quantitative analysis using Confusion matrix of our best models for each task.

6.1 Quantitative Analysis

From Table 7 it can be seen that false negative rate of offensive class is 45% where as for Not Offensive True Positive rate is 93.22% in Task 1. 42 instances of Not Offensive also got misclassified as Offensive showing evidence of challenges in classification. For Task2 Table 8 shows that TIN True positive rate is almost 100% but system fails to classify UNT class with only 0.08% true positive rate. For Task3 Table 9 shows that system completely fails to detect OTH class with false negative rate of 100%. However GRP and IND class obtained True positive rate of 61.5% and 89% respectively . The misconversion instances of GRP and IND to each other is 30 and 11.

7 Conclusion and Future Scope

In this paper we have explored the effectiveness of deep neural network for Offensive speech detection. We can conclude that fine grained analysis of offensive language detection needs careful attention. Linguistic features can also be leveraged for improvement in classifier.

Duluth at SemEval-2019 Task 6: Lexical Approaches to Identify and Categorize Offensive Tweets

Ted Pedersen
Department of Computer Science
University of Minnesota
Duluth, MN 55812 USA
tpederse@d.umn.edu

Abstract

This paper describes the Duluth systems that participated in SemEval–2019 Task 6, Identifying and Categorizing Offensive Language in Social Media (OffensEval). For the most part these systems took traditional Machine Learning approaches that built classifiers from lexical features found in manually labeled training data. However, our most successful system for classifying a tweet as offensive (or not) was a rule-based black–list approach, and we also experimented with combining the training data from two different but related SemEval tasks. Our best systems in each of the three OffensEval tasks placed in the middle of the comparative evaluation, ranking 57th of 103 in task A, 39th of 75 in task B, and 44th of 65 in task C.

1 Introduction

Social media is notorious for providing a platform for offensive, toxic, and hateful speech. There is a pressing need for NLP tools that can identify and moderate this type of content.

The OffensEval task (Zampieri et al., 2019b) focuses on identifying offensive language in tweets, and determining if specific individuals or groups are being targeted. Our approach was to rely on traditional Machine Learning methods as implemented by Scikit (Pedregosa et al., 2011) to build classifiers from manually labeled examples of offensive tweets. Our models relied on lexical features, including character ngrams, words, and word ngrams. We also included a dictionary based black–list approach, and experimented with combining training data from two related yet different SemEval-2019 tasks.

Offensive language is an umbrella term that covers hate speech, cyber-bullying, abusive language, profanity, and so on. Recognizing offensive language is an important first step in dealing with different kinds of problematic text. Language that is offensive may simply violate community standards regarding the use of profanity, but in other cases may cross over to become abusive, threatening, or dangerous. Detecting such language has proven to be a challenging problem, at least in part because it remains difficult to make distinctions between the casual and even friendly use of profanity versus more serious forms of offensive language (Fortuna and Nunes, 2018; Schmidt and Wiegand, 2017).

2 Experimental Data

OffensEval is made up of three tasks that were carried out in stages during January 2019. Task A is to classify a tweet as being offensive (OFF) or not (NOT). Task B takes the offensive tweets from task A and decides if they are targeted insults (TIN) or not (UNT). Task C looks at the targeted insults from task B and classifies them as being directed against an individual (IND), group (GRP) or other entity (OTH).

Task A provides 13,240 training tweets, of which 8,840 (66.7%) were not offensive (NOT). Task B is made up of the 4,400 training tweets that were offensive (OFF), where 3,876 (88.1%) of these are targeted insults (TIN). Task C includes the targeted insults from task B, of which 2,407 (62.1%) were targeted against individuals (IND) and 1,074 (27.7%) were against groups (GRP). Additional details about the task data can be found in (Zampieri et al., 2019a)

The distribution of classes in the evaluation data was similar. Task A has 860 evaluation tweets of which 620 (72%) were not offensive. Task B includes 240 offensive evaluation tweets, where 213 (89%) were targeted insults. These made up the evaluation data for task C, where 100 (47%) were against individuals, and 78 (37%) were against groups.

The amount of training data is modest, particularly for tasks B and C. In addition, the classes in Task B are quite skewed. Given these factors we decided to rely on traditional Machine Learning techniques, since these have the potential to perform well even with limited training data.

3 System Descriptions

We created three systems for each of the three tasks. Preprocessing was very simple : tweets were converted to lower case and then tokenized into character ngrams, words, or word ngrams.

In task A we relied on unigram models. However, for tasks B and C we focused on character ngrams in order to try and find regularities in the smaller amounts of training data available for these tasks.

3.1 Task A

The goal of Task A was to classify a tweet as offensive (OFF) or not (NOT). We relied on the default settings for vectorization and Machine Learning as provided in Scikit, except as noted below. This results in tokenization based on space separated strings where punctuation and other non-alphanumeric characters are discarded.

A-Sub1 is a Logistic Regression classifier that weighs unigram features using tf-idf.

A-Sub2 is the same as A-Sub1 except that the training data is augmented with the training data from Semeval-2019 Task 5 HatEval (Basile et al., 2019), a task that identifies hate speech. It provides 22,240 training examples where 14,057 (65.2%) are not hate speech. We made the obviously incorrect assumption that tweets that aren't hate speech would also not be offensive. We had hoped that doubling the amount of training data would improve our performance despite our flawed assumption (although it did not).

A-Sub3 is a very simple rule based on a black–list created by merging the following sources:

- words or terms used in offensive tweets five or more times in the OffensEval training data,
- words or terms used in hateful tweets five or more times in the HatEval training data, and
- black–lists found via web search said to be used by WordPress, Google, Facebook, and Youtube[1].

[1]https://www.freewebheaders.com/

Any word or term that appears in two or more of these lists is selected, leading to a master black–list of 563 words. Any tweet that includes any of these words is labeled as offensive (OFF).

3.2 Task B

Task B seeks to identify if an offensive tweet is a targeted insult (TIN) or not (UNT). All three systems relied on character-based ngrams and the default Scikit settings for vectorization and the specific learning method.

B-Sub1 learns a random forest classifier, and B-Sub2 learns a decision tree. Both represent features as 3 alphanumeric character sequences.

B-Sub3 learns a linear Support Vector Machine from the training data. Features are represented as 3 non-space character sequences. We used non-space characters in this case in order to capture special characters that would be discarded by B-Sub1 and B-Sub2. We were particularly interested in retaining # (hashtags) and @ (user ids).

3.3 Task C

All tweets in task C are targeted insults (TIN). The goal is to identify if the target is an individual (IND), group (GRP), or some other entity (OTH).

All of these systems used the default settings from Scikit for vectorization and Machine Learning, except as noted below.

C-Sub1 learns a multinomial Naive Bayesian classifier from the training data. Features are simple unigrams made up of alpa-numeric characters. During development we noticed that Naive Bayes tended to find more balanced distributions of classes than our other approaches.

C-Sub2 learns a decision tree classifier from the training data. Features are 3 character sequences. During development we observed that this was the only method that assigned tweets to the other (OTH) category.

C-Sub3 learns a logistic regression classifier from the training data. Features are word ngrams made up of sequences of 1, 2 and 3 words that occur in more than 10 tweets in the training data.

4 Experimental Results

The official rankings in OffensEval were based on macro–averaged F1, and accuracy was also reported. The performance of individual classes was measured by Precision, Recall, and the $F1$ score.

System	F1-Macro	Accuracy
A-TOP	.83	
A-Sub3	.73	.80
A-Sub2	.69	.80
A-Sub1	.68	.80
A-Baseline	.42	.72
B-TOP	.76	
B-Sub1	.60	.88
B-Sub2	.57	.82
B-Sub3	.52	.77
B-Baseline	.47	.89
C-TOP	.66	
C-Sub1	.48	.67
C-Sub3	.45	.62
C-Sub2	.42	.53
C-Baseline	.21	.47

	670	190	860	.79	.80	.79

A-Sub3 : Rule Based, black–list

Table 2: Task A Confusion Matrices

The results of the Duluth Systems are summarized in Table 1. X-TOP is the 1st ranked system in each task. X-Baseline assigns each test tweet to the most frequent class in the training data.

Next, we'll examine the results from each task in more detail. In the confusion matrices provided, the distribution of gold answers (ground truth) is shown on the rows, and the system predictions are on the columns.

4.1 Task A

Task A asks whether a tweet is offensive (or not). It had the largest amount of training data (13,240 examples), of which 33% were considered offensive (OFF) and 67% were not (NOT). In Table 2 and the discussion that follows a true positive is a tweet that is known by ground truth to be not offensive (NOT) and that is predicted to be not offensive (NOT). A true negative is a tweet that is known to be offensive (OFF) and is predicted to be offensive (OFF).

4.2 Confusion Matrix Analysis

A-Sub3 had a modest advantage over the other two systems. A-Sub3 was a simple rule-based black–list approach, while A-Sub1 and A-Sub2 used Machine Learning. All three systems scored identical accuracy (80%), but in looking at their confusion matrices some interesting differences emerge.

Table 2 shows that the rule based method A-Sub3 has a much smaller number of false negatives (112 versus 160 and 152). It also has a larger number of true negatives (128 versus 80 and 88). Overall the rule based system finds more tweets offensive (190) than the Machine Learning methods (91 and 106). This happens because our rule based system only needs to find a single occurrence of one of our 563 black–listed terms to consider a tweet offensive, no doubt leading to many non-offensive tweets being considered offensive (62 versus 11 and 18).

The only difference between A-Sub1 and A-Sub2 was that A-Sub2 had approximately double the number of training tweets. The extra tweets were from the SemEval-2019 hate speech task (HatEval). We hypothesized that more training data might help improve the results of a logistic regression classifier (which was used for both A-Sub1 and A-Sub2). After increasing the training data, A-Sub2 is able to classify exactly one more tweet correctly (690 versus 689). We were somewhat surprised at this very limited effect, although the HateEval corpus is focused on a particular domain of hate speech where the targets are women and immigrants. This does not appear to have matched well with the OffensEval training data.

Table 4: Task A Feature Analysis - A-Sub2

4.2.1 Feature Analysis

Table 3 shows the top 30 most heavily weighted features according to the A-Sub1 logistic regression classifier (which was trained on 13,240 instances). We will have the convention of upper casing features indicative of an offensive tweet and lower casing not offensive features. There are some stark differences between these feature sets, where the offensive ones are for the most part profanity and insults.

In Table 4 we show the top 30 weighted features in A-Sub2, a logistic regression classifier trained on the combination of OffensEval and HatEval data. Terms relating to hatred of women and immigrants abound, and include numerous hash tags (recall that our tokenization only used alphanumerics so # are omitted).

In Tables 3 and 4 we bold face the 18 features that were shared between A-Sub1 and A-Sub2. This gives us some insight into the impact of merging the OffensEval and HatEval training data. Some generic offensive features remain in Table 4 but are strongly augmented by HatEval features that are oriented against women and immigrants.

The 13 shared terms that were indicative of the not offensive class are shown in italics. Some features are what we'd expect for non-offensive tweets : *love, beautiful, thanks, thank, justice* and *best*. Others are more artifacts of the data, *user* is an anonymized twitter id and *url* is an anonymized web site. Others are less clearly not offensive, and seem related to political conversation : *antifa, conservatives,* and *brexit*.

Ratio	Feature	OFF	NOT
61.0	BITCH	61	0
17.5	IDIOT	35	2

2.9	BULLSHIT	23	8
2.6	SUCK	21	8
2.5	KILL	32	13

Table 5: Task A Feature Analysis - A-Sub3

However, there are some inconsistencies to note. In Table 3 NIGGA is not necessarily an offensive term and points to the need for annotators to have subtle understandings of culture (Waseem et al., 2018). In Table 4 *kunt* is a deliberate misspelling meant to disguise intent (c.f. (Gröndahl et al., 2018)).

Table 5 shows the top 30 terms from our black–list system A-Sub3 that proved to be most discriminating in identifying an offensive tweet. Recall that A-Sub3 had the highest F1-Macro score of our task A systems. The first column shows a simple ratio of the number of times a feature is used in an offensive tweet (OFF in 3rd column) versus a not offensive one (NOT in 4th column). The most discriminating feature BITCH occurred in 61 offensive tweets and in 0 that were not offensive.

Table 6: Task B Duluth Systems

4.3 Task B

Task B includes 4,400 training tweets, all of which are judged by ground truth to be offensive. This is a fairly modest amount of training data, particularly given how noisy tweets tend to be. As a result we shifted from using unigrams as features (as in Task A) and moved to the use of character ngrams, in the hopes of identifying patterns that may not exist at the unigram level.

The data in Task B is also the most skewed of all the tasks. Nearly 90% of the tweets belonged to the class of targeted insult (TIN). Our three Task B systems used different Machine Learning classifiers, and all tended to produce very skewed results, where most tweets were judged to be targeted insults (TIN). This is clearly illustrated in Table 6, which shows that the random forest classifier (B-Sub1) was better in terms of Precision and Recall for TIN, whereas all three classifiers struggled with the UNT class.

4.4 Task C

Task C had an even smaller amount of training data (3,876 instances). Given a targeted insult, systems were asked to decide if the target an individual (IND), group (GRP) or other (OTHER). These appear as I, G, and O in Table 7. The Other

	G	I	O		P	R	F1
G	53	25	0	78	.70	.68	.68
I	9	90	1	100	.66	.90	.76
O	14	21	0	35	.00	.00	.00
	76	136	1	213	.57	.67	.61

C-Sub1 : Multinomial Naive Bayes

	G	I	O		P	R	F1
G	39	27	12	78	.51	.50	.50
I	21	70	9	100	.63	.70	.66
O	17	15	3	35	.13	.09	.10
	77	112	24	213	.50	.53	.51

C-Sub2 : Decision Tree

	G	I	O		P	R	F1
G	48	25	5	78	.61	.62	.61
I	13	85	2	100	.67	.85	.75
O	18	17	0	35	.00	.00	.00
	79	127	7	213	.54	.62	.58

C-Sub3 : Logistic Regression

Table 7: Task C Duluth Systems

class is very sparse, and C-Sub1 and C-Sub3 did very poorly on it. However, C-Sub2 (a decision tree) had slightly more success. C-Sub1 and C-Sub2 rely on character ngrams, while C-Sub3 uses word unigrams, bigrams, and trigrams as features.

5 Qualitative Review of Training Data

Finally, we qualitatively studied some of the training data for task A and saw that there is potential for some noise in the gold standard labeling. We found various tweets labeled as offensive that seemed innocuous:

- She should ask a few native Americans what their take on this is.
- gun control! That is all these kids are asking for!
- Tbh these days i just don't like people in general i just don't connect with people these days just a annoyance..
- Dont believe the hype.
- Ouch!
- Then your gonna get bitten
- there is no need to be like That

We also found tweets labeled as not offensive despite the presence of insults and profanity.

- Ppl who say I'm not racist are racist. You Are A Racist. Repeat after me
- I'M SO FUCKING READY
- Great news! Old moonbeam Just went into a coma!
- No fucking way he said this!
- Yep Antifa are literally Hitler.
- Any updates re ending your blatant #racism as #Windrush #Grenfell proves you are

The annotation guidelines from the OffensEval organizers seem relatively clear in stating that all profanity should be considered offensive, although an annotator may intuitively wish to make a more nuanced distinction. Resolving these kinds of inconsistencies seems important since the data from task A is also used for task B and C, and so there is a danger of unintended downstream impacts.

6 Conclusion

Offensive language can take many forms, and some words are offensive in one context but not another. As we observed, profanity was often very indicative of offensive language, but of course can be used in much more casual and friendly contexts. This quickly exposes the limits of black–listing, since once a word is on a black–list it use will most likely always be considered offensive. Identifying targeted targeted individuals or organizations using lexical features and Machine Learning was extremely difficult, particularly given the small amounts of training data. Incorporating the use of syntactic analysis and named entity recognition seem necessary to make progress.

We also encountered the challenging impact of domain differences in identifying offensive language. Our attempt to (naively) increase the amount of available training data by combining the OffensEval and HatEval data had no impact on our results, and our feature analysis made it clear that the two corpora were different to the point of not really providing much shared information that could be leveraged. That said, we intend to explore more sophisticated approaches to transfer learning (e.g., (Karan and Šnajder, 2018; Park and Fung, 2017; Waseem et al., 2018)) since there are quite a few distinct corpora where various forms of hate speech have been annotated.

Abstract

In this paper, the used methods and the results obtained by our team, entitled Emad, on the OffensEval 2019 shared task organized at SemEval 2019 are presented. The OffensEval shared task includes three sub-tasks namely Offensive language identification, Automatic categorization of offense types and Offense target identification. We participated in sub-task A and tried various methods including traditional machine learning methods, deep learning methods and also a combination of the first two sets of methods. We also proposed a data augmentation method using word embedding to improve the performance of our methods. The results show that the augmentation approach outperforms other methods in terms of macro-f1.

1 Introduction

With the growth of social networking platforms, the need for automatic methods that manages the emerging issues or facilitate using them is rising. One of the rising trends in social networks such as Twitter is offensive behavior that can cause the offended users leave their social network. Therefore, the need for effective automatic methods for identifying offensive language in textual data is important.

The OffensEval shared task has been organized in order to give a boost to computational methods for identifying and categorizing offensive content on social media. Three sub-tasks defined in the offensEval shared task are identification of offensive language(sub-task A), categorization of offense types(sub-task B) and identification of the offense target(sub-task C) (Zampieri et al., 2019b).

The main goal in sub-task A is to identify offensive tweets from non-offensive ones. By definition, a post is labeled as offensive if it contains any form of non-acceptable language (profanity) or a targeted offense, which can be veiled or direct.

This year, we participated in sub-task A. Our methods for this sub-task include two approaches. In the first approach, traditional machine learning methods, deep learning methods and also a combination method are employed for the task. In the second approach, a data augmentation method is proposed to improve the performance of the methods of the first approach.

2 Related Work

Offenseive language identification which is also known as aggression, cyberbullying, hate speech and abusive language has been widely studied in previous works(Davidson et al., 2017; Malmasi and Zampieri, 2017, 2018).

Based on a survey conducted by Fortuna and Nunes (2018), the majority of previous works are on English and the researchers mainly use machine learning for this task and most proposed methods on abusive content detection have modeled the problem as a binary classification task. Based on another survey (Schmidt and Wiegand, 2017), different types of features have been employed by previous works including surface features, word generalization features such as word embeddings, sentiment-based features, lexical features, linguistic features, knowledge-based features and multimodal information features. The methods utilized for offensive language identification are mainly supervised learning methods including SVM, Random Forest, Naive Bayes and also deep learning approaches (Gambäck and Sikdar, 2017) As an example, (Gambäck and Sikdar, 2017) proposed a model based on convolutional neural networks which takes word embedding vectors of a document as input and decides whether the document contains hate-speech content or not.

3 Methodology and Data

3.1 Datasets

The dataset used in this competition is available as part of the OffensEval 2019 Shared Task Zampieri et al. (2019a). The training set contains 13240 tweets and the test set contains 860 tweets. We have also employed two external datasets including TRAC-1 data (Kumar et al., 2018) and 50K tweets collected by (Founta et al., 2018) in our experiments.

3.2 Features

In our methods, we make use of the following features:

Content-based Features Tweet text contains words which are the most prominent features to convey feelings. Therefore, based on the content of each tweet, we extract the following features as content-based features: the number of mentions, the number of links, the number of hashtags, the average word length, the number of punctuation marks, the average sentence length(based on the number of words in a each sentence), the total number of words, the number of uppercase and the number of emoticons in each tweet.

Sentiment-based Features Usually hate speech has negative sentiment. Thus, using the sentiment information of tweets may improve the performance of our methods. We use three types of sentiment-based features including polarity, subjectivity and emotion. In order to find the emotion label, we trained a random forest classifier on an external dataset annotated for emotions and polarity which contains 40K tweets and 13 classes of emotion (such as happiness, sadness, and anger)[1].

TF-IDF Features TF-IDF is one of the most popular term-weighting approaches which shows the importance of a term in a document or a collection. We use this feature in combination with other features.

Hate-based Feature Hate-based dictionary is a lexicon that can be used to identify hate speech and offensive language (Davidson et al., 2017). We considered the number of hate words and the number of hate n-grams of length 1 to 4 as hate-based features. Hate-base lexicon is available at `www.hatebase.org`.

3.3 Methods

In this section, the methods employed by our team for sub-task A are explained. We used several methods including traditional machine learning methods such as SVM, Random Forest and Naive Bayes in additions to a deep learning method and a combination method. In addition to the methods mentioned above, we proposed an augmentation method in order to improve the performance of our methods.

3.3.1 Traditional Machine Learning Methods

Traditional machine learning methods, in particular, supervised classification methods is known as the most effective approach for offensive language identification. Therefore, in our experiments we applied three classifiers including SVM, Naive-Bayes and Random Forest. Among the most recent methods in the literature, deep learning methods has shown to be an effective approach for offensive language detection. Hence, we employed CNN, as our deep learning solution.

3.3.2 Combination Method

In this method, we employed majority voting rule to combine the results of our best performing systems on the training set. Precisely speaking, for each tweet we find the majority label of three systems which are SVM, CNN trained on over 50k + 13k tweets and another CNN which trained on 50k + 13k + 10k tweets. The results are shown in Table 1.

CNN Architecture: The word-level CNN model has 1D convolution layer with 150 filters and kernel size 6, dropout 0.2, cross entropy loss funtion and four dense layers with ReLU, tanh, sigmoid and softmax activation respectively.

3.3.3 Data Augmentation Method

A common technique to enhance model generalization is data augmentation. In this method, we employed an external dataset containing 50K tweets labeled as hateful, aggressive, normal and spam, in two different ways as follows. In direct augmentation, we added all tweets to the training set such that the tweets labeled as hateful or aggressive are added as offensive and normal or spam labeled tweets as non-offensive.

In indirect augmentation, first of all, the average word embedding of each tweet in the training set is calculated. Then, the average of the embedding vectors in each class is calculated to be used as the representative (or center) of offensive and non-offensive class. Finally, the average word embedding vector of each tweet in the external dataset is calculated and compared with the offensive and non-offensive representative vectors through cosine similarity computation between each tweet and two centers. We defined a threshold for labeling new tweets. If the absolute difference of the distances between tweet's vector and each of the class center is higher than the threshold, we assign tweet to the nearest class. Thus, the tweets of the external dataset are labeled as their most similar class and added to the training set. During the indirect augmentation process, we used word2vec pre-trained Google News model (GoogleNews-vectors-negative300) to calculate embedding vectors of tweets. The threshold is determined 0.03 by experiments.

4 Results

4.1 Models' Performance Evaluation

In this section, the performance of all methods explained in section 3.3 on the training set using 5-fold cross validation is reported. The results of all of the used models on the training set are shown in Table 1. According to table 1, SVM outperforms other two methods in terms of macro-F1. Comparing the results of SVM and CNN shows that these two methods have close performance on the training set.

System	F1 (macro)	Accuracy
Naive Bayes	0.54 (+/- 0.02)	0.70 (+/- 0.02)
Random Forest	0.64 (+/- 0.02)	0.74 (+/- 0.01)
SVM	0.68 (+/- 0.01)	0.73 (+/- 0.01)
CNN	0.67	0.74

Table 1: Results for all methods on the training set using 5-fold cross validation (the variance of the scores for each fold are shown in parentheses)

4.2 Features' Evaluation

In this section, the impact of using the features explained in section 3.2 on the performance of the SVM method is studied. The results are noted in Table 2.

We perform 5-fold cross-validation on the training set and report the results for SVM using different combinations of the feature sets. The first observation is that TF-IDF features outperform other three sets of features in the first section of table 2 which corresponds to using only one feature set. The combination of TFIDF and sentiment-based features, TFIDF and hate-based features and TFIDF, content-based and hate-based features equally show the best performance among all combinations.

4.3 Augmentation Method Evaluation

In this section, the impact of the augmentation method on the performance of our classifier is evaluated. Table 3 shows the results of SVM on the training set using 5-fold cross validation in three different settings; when no augmentation is done, when the external dataset is used directly and when the augmentation method (i.e. using the external data indirectly) is employed. As table 3 shows, the augmentation method produces the best results.

4.4 Results on the Test Set

In this section, the results of three systems that we submitted to OffensEval 2019 is reported. Table 4 shows the results of SVM using augmentation method with two external datasets (SVM-50k+13k), CNN using augmentation method with three external datasets (CNN-50k+13k+10k) and the majority voting method using the outputs of two mentioned methods on the test set. Furthermore, the results of two random baseline generated by assigning the same labels for all instances (all offensive and all non-offensive) are reported for comparison. According to the table, the combination of first two method using majority voting has the best performance.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
SVM-50k+13k	0.7076	0.7884
CNN-50k+13k+10k	0.7155	0.7814
Majority Vote	0.7325	0.8186

Table 4: Results for Sub-task A.

5 Conclusion

In this paper, we address the challenge of automatically detecting offensive and non-offensive language in textual content spread in twitter. We conducted experiments with SVM with varying feature sets and CNN model. We also proposed an augmentation method to improve the performance our classifiers.

System	**F1 (macro)**	**Accuracy**
TF-IDF features	0.68 (+/- 0.02)	0.74 (+/- 0.01)
Content features	0.42 (+/- 0.01)	0.73 (+/- 0.02)
Sentiment features	0.50 (+/- 0.01)	0.69 (+/- 0.01)
Hatebased features	0.49 (+/- 0.01)	0.69 (+/- 0.01)
TF-IDF + Content	0.67 (+/- 0.03)	0.73 (+/- 0.02)
TF-IDF + Sentiment	0.71 (+/- 0.02)	0.76 (+/- 0.01)
TF-IDF + Hatebased	0.71 (+/- 0.02)	0.76 (+/- 0.01)
Content + Sentiment	0.54 (+/- 0.02)	0.68 (+/- 0.01)
Content + Hatebased	0.49 (+/- 0.01)	0.68 (+/- 0.01)
Sentiment + Hatebased	0.51 (+/- 0.04)	0.70 (+/- 0.02)
TF-IDF + Content + Sentiment	0.68 (+/- 0.02)	0.73 (+/- 0.01)
TF-IDF + Content + Hatebased	0.68 (+/- 0.03)	0.74 (+/- 0.02)
TF-IDF + Content + Hatebased	0.71 (+/- 0.02)	0.76 (+/- 0.01)
Content + Sentiment + Hatebased	0.56 (+/- 0.02)	0.70 (+/- 0.01)
TF-IDF + Content + Sentiment + Hatebased	0.68 (+/- 0.01)	0.73 (+/- 0.01)

Table 2: Results for SVM method using different sets of features on the training set using 5-fold cross validation (the variance of the scores for each fold are shown in parentheses)

System	**F1 (macro)**	**Accuracy**
Without using the external dataset	0.68	0.73
With using the external dataset directly	0.73	0.89
With using the external dataset indirectly (augmentation method)	0.76	0.88

Table 3: Results for SVM method on the training set without using the external dataset, with using the external dataset directly and with using the external dataset indirectly(the augmentation method)

Abstract

SemEval-2019 Task 6 was OffensEval: Identifying and Categorizing Offensive Language in Social Media. The task was further divided into three sub-tasks: offensive language identification, automatic categorization of offense types, and offense target identification. In this paper, we present the approaches used by the Embeddia team, who qualified as fourth, eighteenth and fifth on the three sub-tasks. A different model was trained for each sub-task. For the first sub-task, we used a BERT model fine-tuned on the provided dataset, while for the second and third tasks we developed a custom neural network architecture which combines bag-of-words features and automatically generated sequence-based features. Our results show that combining automatically and manually crafted features fed into a neural architecture outperform transfer learning approach on more unbalanced datasets.

1 Introduction

Over the years, computer-mediated communication, like the one on social media, has become one of the key ways people communicate and share opinions. Computer-mediated communication differs in many ways, both technically and culturally, from more traditional communication technologies (Kiesler et al., 1984). However, the ability to fully or partially hide our identity behind an internet persona leads people to type things they would never say to someone's face (Shaw, 2011). Not only is hate speech more likely to happen on the Internet, where anonymity is easily obtained and speakers are psychologically distant from their audience, but its online nature also gives it a far-reaching and determinative impact (Shaw, 2011). Although most forms of intolerance are not criminal, hate speech and other speech acts designed to harass and intimidate (rather than merely express criticism or dissent), deteriorate public discourse and opinions, which can lead to a more radicalized society.

Online communities, social media platforms, and technology companies have been investing heavily in ways to cope with offensive language to prevent abusive behavior in social media. Social media companies Facebook, Twitter and Google's YouTube have greatly accelerated their removal of online hate speech, and report reviewing over two-thirds of complaints within 24 hours. It has been proven in practice that naive word filtering systems do not manage to scale well to different forms of hate and aggression (Schmidt and Wiegand, 2017). The most promising strategy for detecting abusive language is to use advanced computational methods. This topic has attracted significant attention in recent years as evidenced in recent publications (Waseem et al., 2017; Davidson et al., 2017; Malmasi and Zampieri, 2018).

The SemEval-2019 Task 6 — OffensEval: Identifying and Categorizing Offensive Language in Social Media (Zampieri et al., 2019b) is to use machine learning text classification methods to identify offensive content and hate speech. The task organizers have provided a new dataset (Zampieri et al., 2019a) comprised of Twitter posts which employs a three-level hierarchical labeling scheme, according to the three hierarchically posed sub-tasks, where each sub-task serves as a stepping stone for the next sub-task. Sub-task A aims to identify offensive content, Sub-task B aims to classify offensive content as a targeted or untargeted offense, while Sub-task C aims to identify the target of the offense.

In this paper, we present the approaches used by the Embeddia team to tackle the three sub-tasks of SemEval-2019 Task 6: OffensEval. The Embeddia team qualified as fourth, eighteenth and fifth on Sub-tasks A, B and C, respectively. The Embeddia team used different neural architectures and transfer learning techniques (Devlin et al., 2018). We also explore if combining automatically generated sequence-based features with more traditional manual feature engineering techniques improves the classification performance and how different classifiers perform on unbalanced datasets. Our results show that a combination of automatically and manually crafted features fed into a neural architecture outperforms the transfer learning approach on the more unbalanced datasets of Subtasks B and C.

This paper is organized as follows. In Section 2, we present related work in the area of offensive and hate speech detection. Section 3 describes in more detail the provided dataset and the methodology used for the task. Section 4 reviews the results we obtained on the three sub-tasks with our models. Section 5 concludes the paper and presents some ideas for future work.

2 Related Work

A number of workshops that dealt with offensive content, hate speech and aggression were organized in the past several years, which points to the increasing interest in the field. Due to important contributions of publications from TA-COS[1], Abusive Language Online[2], and TRAC[3], hate speech detection became better understood and established as a hard problem. The report on shared task from the TRAC workshop (Kumar et al., 2018) shows that of 45 systems trying to identify hateful content in English and Hindi Facebook posts, the best-performing ones achieved weighted macro-averaged F-scores of just over 0.6.

Schmidt and Wiegand (2017) note in their survey that supervised learning approaches are predominantly used for hate speech detection. Among those, the most widespread are support vector machines (SVM) and recurrent neural networks, which are emerging in recent times (Pavlopoulos et al., 2017). Zhang et al. (2018) devised a neural network architecture combining convolutional and gated recurrent layers for detecting hate speech, achieving state-of-the-art performance on several Twitter datasets. Malmasi and Zampieri (2018) used SVMs with different surface-level features, such as surface n-grams, word skip-grams and word representation n-grams induced with Brown clustering. They concluded that surface n-grams perform well for hate speech detection but also noted that these features might not be enough to discriminate between profanity and hate speech with high accuracy and that deeper linguistic features might be required for this scenario.

A common difficulty that arises with supervised approaches for hate speech and aggression detection is a skewed class distribution in datasets. Davidson et al. (2017) note that in the dataset used in the study only 5% of tweets were labeled as hate speech. To counteract this, datasets are often resampled with different techniques to improve on the predictive power of the systems over all classes. Aroyehun and Gelbukh (2018) increased the size of the used dataset by translating examples to four different languages, namely French, Spanish, German, and Hindi, and translating them back to English. Their system placed first in the Aggression Detection in Social Media Shared Task of the aforementioned TRAC workshop.

A recently emerging technique in the field of natural language processing (NLP) is the employment of transfer learning (Howard and Ruder, 2018; Devlin et al., 2018). The main idea of these approaches is to pretrain a neural language model on large general corpora and then fine-tune this model for a task at hand by adding an additional task-specific layer on top of the language model and train it for a couple of additional epochs. A recent model called Bidirectional encoder representations from transformers (BERT) (Devlin et al., 2018) was pretrained on the concatenation of BooksCorpus (800M words) (Zhu et al., 2015) and English Wikipedia (2,500M words) and then successfully applied to a number of NLP tasks without changing its core architecture and with relatively inexpensive fine-tuning for each specific task. According to our knowledge, it has not been applied on a hate speech detection task yet, however it reached state-of-the-art results in the question answering task on the SQuAD dataset (Rajpurkar et al., 2016) as well as beat the baseline models in several language inference tasks.

3 Methodology and Data

This section describes the tasks, the dataset, the methodology used and the experiments.

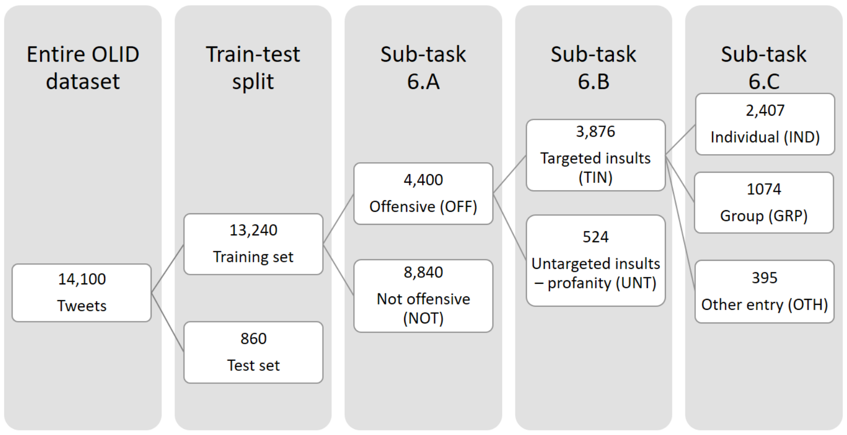

Figure 1: Schema of SemEval-Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media. The hierarchy of the sub-tasks and respective dataset sizes.

3.1 Dataset

The SemEval-2019 Shared Task 6: Identifying and Categorizing Offensive Language in Social Media was divided into three sub-tasks, namely offensive language identification (Sub-task A), automatic categorization of offense types (Sub-task B) and offense target identification (Sub-task C). The organizers provided a new dataset called OLID (Zampieri et al., 2019a) which includes tweets labeled according to the three-level hierarchical model. On the very first level, each tweet is labeled as offensive (OFF) or not offensive (NOT). All the offensive tweets are then labeled as targeted insults (TIN) or as untargeted insults (UNT), which simply contain profanity. On the last level, all targeted insults are categorized as targeting an individual (IND), a group (GRP) or other entity (OTH). The dataset contains 14,100 tweets split into training and test sets. The training set containing 13,240 tweets and the test set without labels were made available to the participants for the task. The inspection of the dataset reveals that the classes at first level are slightly imbalanced with the imbalances between classes getting more prominent with each subsequent level. A more detailed breakdown of the dataset is presented in Figure 1. We didn't use any additional datasets in any of the three sub-tasks.

3.2 Methodology

According to the findings from the related work, we decided to test two different types of architectures. First was a pretrained BERT model, which was fine-tuned on the provided dataset for distinguishing offensive and not offensive posts in the Sub-task A. For the sub-tasks B and C, a neural network architecture was developed, which tried to achieve synergy between two types of features that both proved successful in the past approaches to the task at hand, by basing its predictions on a combination of classical bag-of-words features and automatically generated sequence-based features. The three models, as well as their source code, are available for download in a public repository[4].

Three models were trained using the provided dataset, one for each sub-task. In the Sub-task A, the large pretrained BERT transformer with 24 layers of size 1024 and 16 self-attention heads was used for generating predictions on the official test set. A linear sequence classification head responsible for producing final predictions was added on top of the pretrained language model and the whole classification model was fine-tuned on the SemEval input data for 3 epochs. For training, a batch size of 8 and a learning rate of 2e-5 were used. The training dataset for the Sub-task A was randomly split into a training set containing 80% of the tweets and a validation set containing 20% of the tweets. Only a small amount of text preprocessing was needed on the data for the Sub-task A since the dataset already had all Twitter user mentions replaced by @USER tokens and all URLs by URL tokens. Additionally, we lowercased and tokenized the tweets using BERT's built-in tokenizer.

For Sub-task B, the non-offensive tweets were first filtered out of the original dataset. The re-

[4]https://gitlab.com/Andrazp/embeddia-semeval2019

duced dataset had 4400 tweets. To offset the lower quantity of data, we decided to split the dataset into a training set containing 90% of the data and a validation set containing 10% of the data. The second issue with the data was a severe class imbalance as only 12% of tweets in the filtered dataset were labeled as untargeted insults. We decided to resample the dataset in order to minimize the impact of the imbalance on our training. The approach that yielded the best results based on the validation set performance was to randomly remove the instances of the majority class until the classes were balanced. The remaining instances were lowercased and tokenized with the tweet tokenizer from the NLTK package (Bird et al., 2009). Stopwords were also removed from every tweet using an English stopwords list provided in the NLTK package.

As the BERT model was showing worse performance on the resampled data according to the validation set results, a new neural network architecture was devised for this sub-task (Figure 2). The neural architecture takes two inputs. The first input is a term frequency-inverse document frequency (tf-idf) weighted bag-of-words matrix calculated on 1- to 5-grams and character 1- to 7- grams using sublinear term frequency scaling. N-grams with document frequencies less than 5 were removed from the final matrix. Furthermore, the following additional features are generated for each tweet in the training set and added to the tf-idf matrix:

- The number of insults: using a list of English insults,[5] the insults in each tweet are counted and their number is added to the matrix as a feature.

- The length of the longest punctuation sequence: for every punctuation mark that appears in the Python built-in list of punctuations, its longest sequence is found in each tweet. The length of the sequence is then added as a feature.

- Sentiment of the tweets: the sentiment of each tweet is predicted by an SVM model (Mozetič et al., 2016) pretrained on English tweets. The model classifies each tweet as positive, neutral or negative. The predictions are then encoded and added as features.

The second input is word sequences, which are fed into an embedding layer with pretrained 100-dimensional GloVe (Pennington et al., 2014) embedding weights trained on a corpus of English tweets. The pretrained embeddings are additionally fine-tuned during the training process on the dataset for the task. The resulting embeddings are fed to an LSTM layer with 120 units, on the output of which we perform global max pooling. We perform a dropout operation on the max pooling output and the resulting vectors are concatenated with the tf-idf vectors. The resulting concatenation is sent to a fully-connected hidden layer with 150 units, the output of which is fed to a rectified linear unit (RELU) activation function. After performing dropout, final predictions are produced by a fully-connected hidden layer with a sigmoid activation function. For training, we use a batch size of 16 and Adam optimizer with a learning rate of 0.001. We trained the model for a maximum of 10 epochs and validated its performance on the validation set after every epoch. The best performing model was later used for generating predictions on the official test set.

For Sub-task C, the dataset was additionally filtered by removing the tweets that were labeled as non-targeted insults. The class imbalance for this task was even more prominent with only 28% of tweets being labeled as insults targeted towards groups and 10% as targeted insults that do not target an individual or a specific group of people. In light of such class imbalance, the dataset was again undersampled by removing 75% of tweets from the majority class and 50% percent of tweets from the middle class. Due to the dataset being even more aggressively filtered, the 90-10% split from the previous sub-task was kept. A modified version of the neural architecture from Sub-task B was used for prediction. We tried to capture the relationship between insults and their targets using sentence structure information. To this end, we added a third input to the neural architecture that accepts sequences of part-of-speech (POS) tags. First, all the tweets were POS-tagged using the POS tagger from the NLTK package and the resulting POS tag sequences were then fed to a randomly initialized embedding layer. Output embeddings are then fed to an LSTM layer with 120 units, on the output of which we performed global

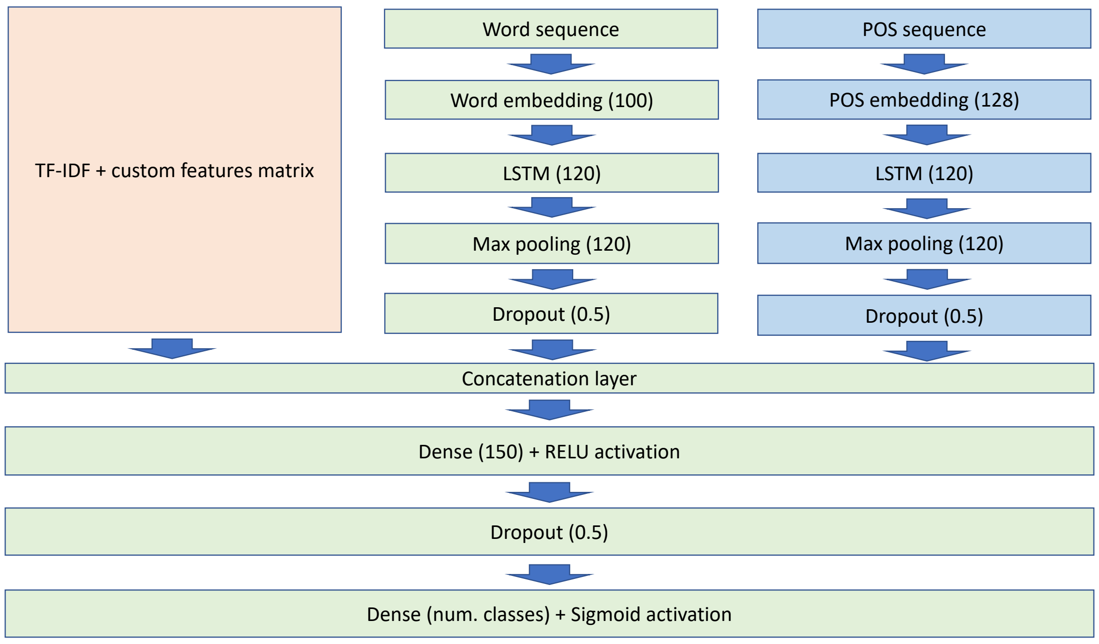

Figure 2: System architecture used in Sub-tasks B and C. Parts of the infrastructure depicted in blue were only used in Sub-task C.

max pooling. Next, dropout was applied, and the resulting vector matrix was then concatenated with the matrices from other inputs and sent to the fully-connected layer (see Figure 2).

4 Results

The results on the official test sets for all three tasks are presented in Table 1. In the Sub-task A, our BERT model, fine-tuned on the provided dataset, achieved a macro-averaged F1 score of 0.808. When we compare this result to other teams participating in the SemEval-2019 OffensEval Sub-task A, we rank fourth.

As the dataset was filtered and the class imbalances became more prominent in the subsequent tasks, the performance of our models started to deteriorate. Even though the undersampling of the dataset to offset class imbalances further reduced the available data, it proved to be the best way to ensure somewhat reliable predictions. The models for Sub-task B and C had macro-averaged F1 scores of 0.663 and 0.613 respectively and placed eighteenth and fifth overall in the SemEval-2019 OffensEval official ranking.

A closer look at the confusion matrices further confirms our claim about the impact of class imbalances on our systems' performance. While the predictions for both classes were fairly accurate in the Sub-task A (Figure 3a), we can see a dwindling performance on the untargeted insults (UNT) class in Sub-task B (Figure 3b) where approximately two thirds of the instances were misclassified as targeted insults (TIN) class on the test set.

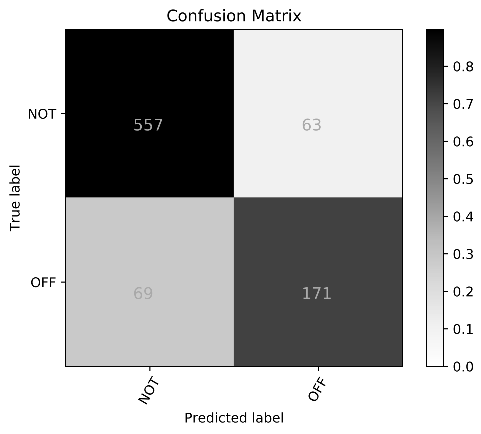
The confusion matrix for Sub-task C (Figure 3c) paints a very similar picture. Even though the majority individual (IND) and middle group (GRP) classes were heavily imbalanced in the original dataset, our model was still able to successfully discriminate between them. However, it again performed subpar on the minority other entity (OTH) class, which was heavily underrepresented compared to the other two. Of the 35 instances in the test set, three out of four were misclassified.

5 Conclusion

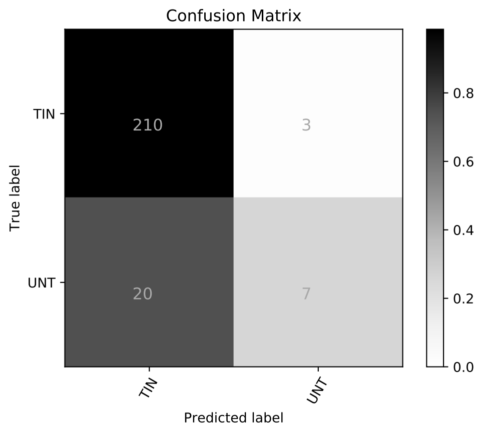
In this paper, we presented the results of the Embeddia team on the SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media using the dataset provided by the organizers of the task. The task was further divided into three sub-tasks, namely offensive language identification (Sub-task A), automatic categorization of offense types (Sub-task B) and offense target identification (Sub-task C). We trained three models, one for each sub-task. For Sub-task A, we used a BERT model fine-tuned on the OLID dataset, while for the second and third tasks we developed a neural network architecture

Sub-task	System	F1 (macro)	Accuracy
A	BERT	0.8078	0.8465
B	BOW+GloVeLSTM	0.6632	0.9042
C	BOW+GloVeLSTM+POS_LSTM	0.6133	0.7042

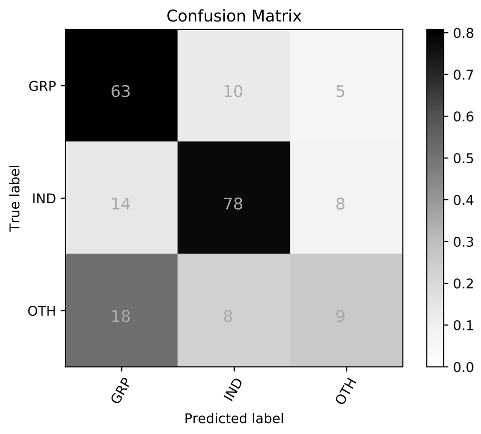
Table 1: Results of the submitted systems for each sub-task.



(a) Confusion matrix for the BERT system, fine-tuned on the provided dataset for Sub-task A.



(b) Confuaion matrix of the two-input neural network with a LSTM based on word sequences and a bag-of-words matrix for Sub-task B.



(c) Confusion matrix of the three-input neural network with an LSTM based on word sequences, LSTM based on part-of-speech tags sequences and a bag-of-words matrix for Sub-task C.

which combines bag-of-words features and automatically generated sequence-based features. Our models ranked fourth, eighteenth and fifth in Subtasks A, B and C, respectively.

We noticed that the class imbalances in the datasets had a significant impact on the performance of our systems and were especially deteriorating for the performance of the BERT system. To counteract the impact of class imbalances we used various techniques to resample the original datasets. While randomly removing instances from the majority classes proved to be the most consistent approach to improve the predictive power of our systems, the effect of the class imbalance persisted.

Our aim for the future is to make the systems more robust to imbalanced data to better generalize over all the classes. Since we already have several models that perform adequately, a good next step would be to implement an ensemble model using a plurality voting or a gradient boosting scheme. We will also conduct an ablation study to identify which features work particularly well for offensive content and hate speech detection.

Abstract

This paper describes our system (Fermi) for Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media of SemEval-2019. We participated in all the three sub-tasks within Task 6. We evaluate multiple sentence embeddings in conjunction with various supervised machine learning algorithms and evaluate the performance of simple yet effective embedding-ML combination algorithms. Our team (**Fermi**)'s model achieved an F1-score of 64.40%, 62.00% and 62.60% for sub-task A, B and C respectively on the official leaderboard. Our model for sub-task C which uses pretrained ELMo embeddings for transforming the input and uses SVM (RBF kernel) for training, scored third position on the official leaderboard.

Through the paper we provide a detailed description of the approach, as well as the results obtained for the task.

1 Introduction

Social media provides anonymity which can be misused to target offensive comments to targeted parties. Users may engage in generating offensive content on social media which may show aggressive behaviour and may also include hate speech. As a result, it is imperative for social media platforms to invest heavily in creating solutions which can identify offensive language and to prevent such behaviour on social media.

Using computational methods to identify offense, aggression and hate speech in user generated content has been gaining attention in the recent years as evidenced in (Waseem et al., 2017; Davidson et al., 2017; Malmasi and Zampieri, 2017; Kumar et al., 2018) and workshops such as Abusive Language Workshop (ALW) [1] and Workshop on Trolling, Aggression and Cyberbullying (TRAC) [2].

2 Related Work

In this section we briefly describe other work in this area.

Papers published in the last two years include the surveys by (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018), the paper by (Davidson et al., 2017) which presented the Hate Speech Detection dataset used in (Malmasi and Zampieri, 2017) and a few other recent papers such as (ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018; Badjatiya et al., 2017).

A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). For studies on languages other than English see (Su et al., 2017) on Chinese and (Fišer et al., 2017) on Slovene. Finally, for recent discussion on identifying profanity vs. hate speech see (Malmasi and Zampieri, 2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

Some of the similar and related previous workshops are Text Analytics for Cybersecurity and Online Safety (TA-COS) [3], Abusive Language Workshop [4], and TRAC [5]. Related shared tasks include GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018).

3 Methodology

3.1 Word Embeddings

Word embeddings have been widely used in modern Natural Language Processing applications as

[2]https://sites.google.com/view/trac1
[3]http://ta-cos.org/
[4]https://sites.google.com/site/alw2018
[5]https://sites.google.com/view/trac1

they provide vector representation of words. They capture the semantic properties of words and the linguistic relationship between them. These word embeddings have improved the performance of many downstream tasks across many domains like text classification, machine comprehension etc. (Camacho-Collados and Pilehvar, 2018). Multiple ways of generating word embeddings exist, such as Neural Probabilistic Language Model (Bengio et al., 2003), Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and more recently ELMo (Peters et al., 2018).

These word embeddings rely on the distributional linguistic hypothesis. They differ in the way they capture the meaning of the words or the way they are trained. Each word embedding captures a different set of semantic attributes which may or may not be captured by other word embeddings. In general, it is difficult to predict the relative performance of these word embeddings on downstream tasks. The choice of which word embeddings should be used for a given downstream task depends on experimentation and evaluation.

3.2 Sentence Embeddings

While word embeddings can produce representations for words which can capture the linguistic properties and the semantics of the words, the idea of representing sentences as vectors is an important and open research problem (Conneau et al., 2017).

Finding a universal representation of a sentence which works with a variety of downstream tasks is the major goal of many sentence embedding techniques. A common approach of obtaining a sentence representation using word embeddings is by the simple and naïve way of using the simple arithmetic mean of all the embeddings of the words present in the sentence. Smooth inverse frequency, which uses weighted averages and modifies it using Singular Value Decomposition (SVD), has been a strong contender as a baseline over traditional averaging technique (Arora et al., 2016). Other sentence embedding techniques include p-means (Rücklé et al., 2018), InferSent (Conneau et al., 2017), SkipThought (Kiros et al., 2015), Universal Encoder (Cer et al., 2018).

We formulate each of the sub-tasks of OffensEval as a text classification task. In this paper, we evaluate various pre-trained sentence embeddings for identifying the offense, hate and aggression. We train multiple models using different machine learning algorithms to evaluate the efficacy of each of the pre-trained sentence embeddings for the downstream sub-tasks as defined in this task. In the following, we discuss various popular sentence embedding methods in brief.

- InferSent (Conneau et al., 2017) is a set of embeddings proposed by Facebook. InferSent embeddings have been trained using the popular language inference corpus. Given two sentences the model is trained to infer whether they are a contradiction, a neutral pairing, or an entailment. The output is an embedding of 4096 dimensions.

- Concatenated Power Mean Word Embedding (Rücklé et al., 2018) generalizes the concept of average word embeddings to power mean word embeddings. The concatenation of different types of power mean word embeddings considerably closes the gap to state-of-the-art methods mono-lingually and substantially outperforms many complex techniques cross-lingually.

- Lexical Vectors (Salle and Villavicencio, 2018) is another word embedding similar to fastText with slightly modified objective. FastText (Bojanowski et al., 2016) is another word embedding model which incorporates character n-grams into the skipgram model of Word2Vec and considers the sub-word information.

- The Universal Sentence Encoder (Cer et al., 2018) encodes text into high dimensional vectors. The model is trained and optimized for greater-than-word length text, such as sentences, phrases or short paragraphs. It is trained on a variety of data sources and a variety of tasks with the aim of dynamically accommodating a wide variety of natural language understanding tasks. The input is variable length English text and the output is a 512 dimensional vector.

- Deep Contextualized Word Representations (ELMo) (Peters et al., 2018) use language models to get the embeddings for individual words. The entire sentence or paragraph is taken into consideration while calculating these embedding representations. ELMo uses

a pre-trained bi-directional LSTM language model. For the input supplied, the ELMo architecture extracts the hidden state of each layer. A weighted sum is computed of the hidden states to obtain an embedding for each sentence.

Using each of the sentence embeddings we have mentioned above, we seek to evaluate how each of them performs when the vector representations are supplied for classification with various off-the-shelf machine learning algorithms. For each of the evaluation tasks, we perform experiments using each of the sentence embeddings mentioned above and show our classification performance on the *dev* set given by the task organizers.

4 Dataset

The data collection methods used to compile the dataset used in OffensEval is described in (Zampieri et al., 2019). Sub-task A (Offensive language Detection) deals with classifying posts as offensive (OFF) vs not (NOT). Sub-task B (Categorization of Offensive Language) deals with categorization of offense as: targeted (TIN) and untargeted (INT). Sub-task C (Offensive Language Target Identification) categorizes the targets of insults and threats as individual (IND), group (GRP), and other (OTH). The overall dataset across the three sub-tasks consists of 14100 posts. Fig. 1 (reproduced from (Zampieri et al., 2019)) shows dataset size details.

A	**B**	**C**	**Training**	**Test**	**Total**
OFF	TIN	IND	2,407	100	2,507

5 Results and Analysis

Note that we have not used any external datasets to augment the data for training our models.

In Tables 1, 2, and 3, we provide the dev set macro-averaged F-1 and accuracy for each of the three sub-tasks A, B and C respectively.

We notice the best performance across tasks with ELMo embeddings with SVM (using the RBF kernel).

The confusion matrices for our test set classifications are also given in Tables 4, 5, 6 respectively for each of the sub-tasks A, B and C.

Similar trends are observed for the final classification results on the test set (scored on CodaLab) for the sub-tasks A, B and C in Tables 7, 8, 9 respectively. Our system performed the third best in sub-task C of the 2019 SemEval task.

Overall, this work shows how different set of pre-trained embeddings trained using different state-of-the-art architectures and methods when used with simple machine learning classifiers perform very well for the classification task of categorizing text as offensive or not.

6 Conclusions and Future Work

It is also important to note that the experiments are performed using the default parameters, so there is further scope for improvement with a lot of fine-tuning, which we plan on considering for future research purposes. Further, we observe that the class distribution is highly imbalanced due to which there might be a bias introduced by the training algorithms. We plan to explore SMOTE (Chawla et al., 2002) for making the class labels balanced and then train the classification which will prevent the bias towards the unbalanced classes.

Abstract

This paper presents the models submitted by Ghmerti team for subtasks A and B of the OffensEval shared task at SemEval 2019. OffensEval addresses the problem of identifying and categorizing offensive language in social media in three subtasks; whether or not a content is offensive (subtask A), whether it is targeted (subtask B) towards an individual, a group, or other entities (subtask C). The proposed approach includes character-level Convolutional Neural Network, word-level Recurrent Neural Network, and some preprocessing. The performance achieved by the proposed model for subtask A is 77.93% macro-averaged F_1-score.

1 Introduction

The massive rise in user-generated web content, alongside with the freedom of speech in social media and anonymity of the users has brought about an increase in online offensive content and anti-social behavior. The consequences of such behavior on genuine users of the social media have become a serious concern for researchers in Natural Language Processing and related fields in recent years.

The shared task number 6 at SemEval 2019, OffensEval (Zampieri et al., 2019b), proposes to model the task of offensive language identification hierarchically, which means identifying the offensive content, whether it is targeted, and if so, the target of the offense. In OffensEval, offensive language is defined as “any form of non-acceptable language (profanity) or a targeted offense, which can be veiled or direct” which includes “insults, threats, and posts containing profane language or swear words” (Zampieri et al., 2019b).

We have participated in the first two subtasks (A and B) of OffensEval with the proposed approach of a deep model consisting of a Recurrent Neural Network (RNN) for word-level and Convolutional Neural Network (CNN) for character-level processing[1]. Character-level processing is beneficial, as offensive comments are likely to follow unorthodox writing styles, contain obfuscated words, or have irregular word separation which leads to tokenization issues (Mehdad and Tetreault, 2016; Nobata et al., 2016). We also experimented with two other methods, a Support Vector Machine (SVM) with TFIDF and count features and another SVM with BERT (Devlin et al., 2018) -encoded sentences as input, both with lower performances comparing with the deep model.

After overviewing the related work in section 2, we discuss the methodology and the data in details in section 3, and the results in section 4. In section 5, we analyze the results and conclude the paper in section 6.

2 Related Work

Offensive language identification has been of interest for researchers in recent years. Early work in the related fields include detection of online trolling (Cambria et al., 2010), racism (Greevy and Smeaton, 2004), and cyberbullying (Dinakar et al., 2012).

Papers published in recent years include (Davidson et al., 2017), which introduces the Hate Speech Detection dataset and experiments with different machine learning models, such as logistic regression, naïve Bayes, random forests, and linear SVMs to investigate hate speech and offensive language, (Malmasi and Zampieri, 2017) which experiments further on the same dataset using SVMs with n-grams and skip-grams features, and (Gambäck and Sikdar, 2017) and (Zhang et al., 2018), both exploring the performance of neural networks and comparing them with other machine

[1]You can find the code of the deep model on this project’s repository on github: github.com/edoost/offenseval

learning approaches. Also, there has been published a couple of surveys covering various work addressing the identification of abusive, toxic, and offensive language, hate speech, etc., and their methodology including (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018).

Additionally, there were several workshops and shared tasks on offensive language identification and related problems, including TA-COS[2], Abusive Language Online[3], and TRAC[4](Kumar et al., 2018), and GermEval (Wiegand et al., 2018), which shows the significance of the problem.

3 Methodology and Data

The methodology used for both subtask A, offensive language identification, and subtask B, automatic categorization of offense types, consists of a preprocessing phase and a deep classification phase. We first introduce the preprocessing phase, then elaborate on the classification phase.

3.1 Preprocessing

The preprocessing phase consists of (1) replacing obfuscated offensive words with their correct form and (2) tweet tokenization using NLTK tweet tokenizer (Bird et al., 2009). In social media, some words are distorted in a way to escape the offense detection systems or to reduce the impertinence. For instance, 'asshole' may be written as 'a$$hole', 'a$sh0le', 'a**hole', etc. Having a list of English offensive words, we can create a list containing most of the possible permutations. Using such a list will ease the job for the classifier and searching in it is computationally cheap. Furthermore, replacing contractions, e.g. 'I'm' with 'I am', and replacing common social media abbreviations, e.g. 'w/' with 'with', were not helpful and were not used to train the final model.

3.2 Deep Classifier

Given a tweet, we want to know if its offensive or not (subtask A), and if the offense is targeted (subtask B). Regarding that both subtasks are problems of binary classification, we used one architecture to tackle both. To define the problem, if we have a tweet x, we want to predict the label y, `OFF` or `NOT` in subtask A, and `TIN` or `UNT` in subtask B. Two representations are therefore created for each input x:

1. x_c which is the indexed representation of the tweet based on its characters padded to the length of the longest word in the corpus. The indices include 256 of the most common characters, plus 0 for padding and 1 for unknown characters.

2. x_w which is the embeddings of the words in the input tweet based on FastText's 600B-token common crawl model (Mikolov et al., 2018).

Then, x_c is fed into an embedding layer with output size of 32 and a CNN layer after that. x_c is then concatenated with x_w and both are fed to a unidirectional RNN with LSTM cell of size 256, the output of which is the input to two consecutive fully-connected layers that map their input to an $\mathbb{R}^{128}$ and an $\mathbb{R}^2$ space, respectively. We also applied dropout of keeping rate 0.5 on CNN's output, x_w, RNN's output, and the first fully-connected layer's output.

The CNN layer consists of four consecutive sub-layers:

1. CNN consisting of 64 filters with kernel size of 2, stride of 1, same padding and RELU activation;

2. max-pooling layer with pool size and stride of 2;

3. another CNN, same as the first one, but with 128 filters;

4. the same max-pooling again.

Finally, we used an AdamOptimizer (Kingma and Ba, 2014) with learning rate of $1\mathrm{e}{-3}$ and batch size of 32 to train the model.

3.3 Baseline Methods

We used two baseline methods for subtask A:

- an SVM with 1- to 3-gram word TFIDF and 1- to 5-gram character count feutrue vectors as input;

- an SVM with BERT representations of the tweets (using average pooling (Xiao, 2018)) as input using `BERT-Large, Uncased` model.

[2] http://ta-cos.org/
[3] https://sites.google.com/site/abusivelanguageworkshop2017/
[4] https://sites.google.com/view/trac1/home

The SVMs were trained for 15 epochs with stochastic gradient descent, hinge loss, alpha of 1e−6, `elasticnet` penalty, and `random_state` of 5. The SVMs were implemented using Scikit-learn (Pedregosa et al., 2011).

3.4 Data

The main dataset used to train the model is Offensive Language Identification Dataset (OLID) Zampieri et al. (2019a). The dataset is annotated hierarchically to identify offensive language (OFFensive or NOT), whether it is targeted (Targeted INsult or UNTargeted), and if so, its target (INDividual, GRouP, or OTHer). We divided the 13,240 samples in the training set into 12,000 samples for training and 1,240 samples for validation.

As neural networks require huge amount of training data, we tried adding more data from the dataset of the First Workshop on Trolling, Aggression, and Cyberbullying (TRAC-1) (Kumar et al., 2018) which was not helpful. However, adding the training data from Toxic Comment Classification Challenge on Kaggle (Conversation AI, 2017) increased the macro-averaged F_1-score on the validation set by $\sim 2\%$. This data comprises tweets with positive and negative tags in six categories: `toxic`, `severe_toxic`, `obscene`, `threat`, `insult`, `identity_hate`. We only used `toxic` and `severe_toxic` positive samples as `OFF` and the ones with no positive label in any category as `NOT`. None of the data from other categories, either positive or negative, were included in the additional training data. After that, we were left with 109,236 samples, most of which were labeled as `NOT`. To balance `OFF` and `NOT` samples, 84,626 of `NOT` samples were randomly removed. In the end, 12,305 `OFF` and 12,305 `NOT` samples were added to the training data.

4 Results

Finally, we trained the baseline models in 3.3 and the model described in 3.2 using the combination of the OLID training data and the data from Toxic Comment Classification Challenge (which is described in 3.4).

You can see the macro-averaged F_1-score and accuracy on the test set for the baseline scores provided by task organizers, baseline methods we used (on both training and validation data), and the deep classifier model (DeepModel) in table 1. DeepModel is trained on the training data (not including the validation data) and DeepModel+val on the combination of the training and validation data. The best performance is in bold.

System	Macro F_1	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
SVM	0.7452	0.8011
BERT-SVM	0.7507	0.8011
DeepModel	0.7788	0.8326
DeepModel+val	**0.7793**	**0.8337**

Table 1: Results for subtask A

The best performance belongs to DeepModel+val by a margin of more than 2.8 percent, with the best baseline performance, BERT-SVM. However, it should be mentioned that the results in the first two rows belong to a model trained only on OLID. You can see the confusion matrix for the best performance in figure 1.

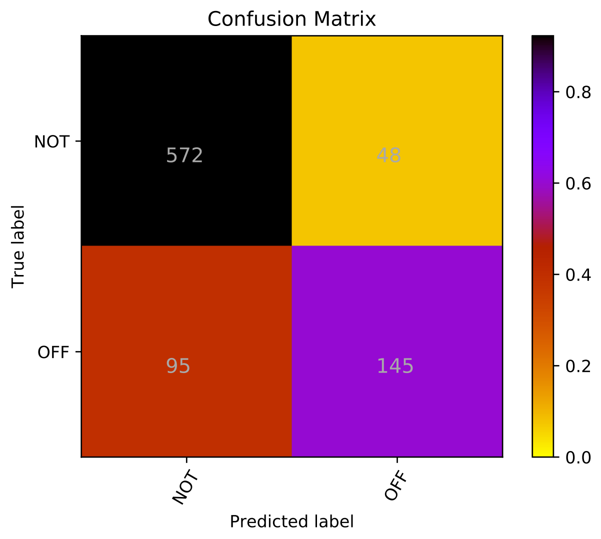

Figure 1: The confusion matrix for DeepModel+val in subtask A

From the confusion matrix we can see that the performance of DeepModel+val on `NOT` is quite good, but not on `OFF`. You can see the detailed results of DeepModel+val in table 2.

	Precision	Recall	F_1-score
`NOT`	0.8576	0.9226	0.8889
`OFF`	0.7513	0.6042	0.6697

Table 2: Detailed DeepModel+val results in subtask A

In subtask B, DeepModel+val outperformed the baseline results by a large margin, like subtask A. The results for subtask B are presented in table 3.

System	Macro F_1	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
DeepModel	0.6065	0.8583
DeepModel+val	**0.6400**	**0.8875**

Table 3: Results for subtask B

This time, adding the validation data made a considerable difference, as the training data for subtask B is fewer. You can see the confusion matrix for DeepModel+val in figure 2.

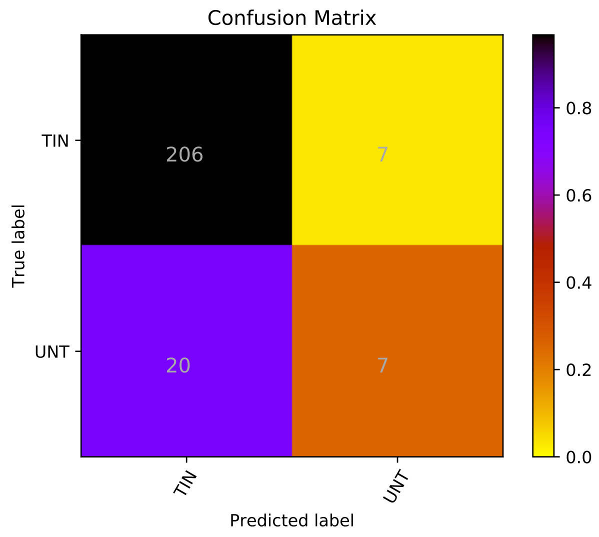

Figure 2: The confusion matrix for the DeepModel+val in subtask B

The confusion matrix shows that the performance of the model is good for `TIN`, but poor for `UNT`. Table 4 shows the detailed results for DeepModel+val in subtask B, which indicates that the imbalance is worse than subtask A and the poor performance on `UNT` is mainly due to low recall.

	Precision	Recall	F_1-score
`TIN`	0.9115	0.9671	0.9385
`UNT`	0.5000	0.2593	0.3415

Table 4: Detailed DeepModel+val results in subtask B

5 Analysis

In subtask A, DeepModel+val outperformed the second best method, BERT-SVM, by 2.86% Macro F_1-score. BERT-SVM results, however, were not much better than the SVM with TFIDF and count features, probably due the fact that the BERT model requires fine-tuning for more task-specific representations.

The majority of DeepModel+val's errors are in `OFF` class and can be categorized into (1) sarcasm: the model is unable to detect sarcastic language which is even difficult for humans to detect; (2) emotion: discerning emotions, such as anger, seems to be a challenge for the model; (3) ethnic and racial slurs, etc. Solving these problems require a more comprehensive knowledge of the context and the language, which was examined in works such as (Poria et al., 2016) and improved the results. However, experimenting with emotion embeddings in the current work was not helpful and did not appear in the final results. Being aware of the emotion of the text, personality of the author, and sentiment of the sentences is helpful to detect offensive language, as many offensive contents have an angry tone (ElSherief et al., 2018) or do not contain profane language (Malmasi and Zampieri, 2018). One can also make use of the benefits of BERT's context and sentence sequence awareness by fine-tuning it on the training data, which is computationally expensive and was not feasible for the authors of this paper.

6 Conclusion

In this paper, we introduced Ghmerti team's approach to the problems of 'offensive language identification' and 'automatic categorization of offense type' in shared task 6 of SemEval 2019, OffensEval. In subtask A, the neural network-based model outperformed the other methods, including an SVM with word TFIDF and character count features and another SVM with BERT-encoded tweets as input. Furthermore, analysis of the results indicates that sarcastic language, inability to discern the emotions such as anger, and ethnic and racial slurs constitute a considerable portion of the errors. Such deficiencies demand larger training corpora and variety of other features, such as information on sarcasm, emotion, personality, etc.

Abstract

This paper describes the submissions of our team, HAD-Tübingen, for the SemEval 2019 - Task 6: "OffensEval: Identifying and Categorizing Offensive Language in Social Media". We participated in all the three sub-tasks: Sub-task A - "Offensive language identification", sub-task B - "Automatic categorization of offense types" and sub-task C - "Offense target identification". As a baseline model we used a Long short-term memory recurrent neural network (LSTM) to identify and categorize offensive tweets. For all the tasks we experimented with external databases in a postprocessing step to enhance the results made by our model. The best macro-average F_1 scores obtained for the sub-tasks A, B and C are 0.73, 0.52, and 0.37, respectively.

1 Introduction

The use of offensive language is an ubiquitous problem one faces when using social networking services like Twitter. Users of such services often take advantage of the anonymity of the individual platforms for using the computer-mediated communication to engage in offensive behaviour against individuals, groups and/or organizations. Due to increasing problems with offensive language and a raising demand for offensive language detection on platforms like Twitter, tasks, similar to the current one have already become popular for several different languages: English (Waseem et al., 2017), German (Wiegand et al., 2018) and Spanish (Rosso et al., 2018). With increasing popularity of Twitter, over 1.48 billion users (June 2013) and still new accounts signing up every day, the need for improvement on tackling the well known problem of insults inside the platform has become more and more necessary.

The Twitter platform[1] describes itself as a connection to "what's happening in the world and what people are talking about right now". For this reason alone, its data attracts more and more NLP researchers all over the world. "Tweets", the messages one can send over this platform can be described as micro-texts, limited to 280 characters, over which users can interact with each other or simply post statements. Since the input is up to the user, one could include misspellings, emoticons, hashtags but also slang and abusive words, what makes those messages a valuable source for different analyses.

As was mentioned in the beginning, the goal of this paper is to consider our approach for the SemEval 2019 - Task 6: "OffensEval: Identifying and Categorizing Offensive Language in Social Media", for task information (see Zampieri et al. 2019b) and for dataset description (see Zampieri et al. 2019a). We took part in all of the three subtasks, using an LSTM based classifier. In the remainder of the paper, we describe our methods and discuss both our results and suggestions for further work.

2 System description

Neural network models have recently gained more and more popularity for text classification tasks, since they perform quite efficiently in modeling of sequences and offer advantages for computation. For this competition, we used unidirectional LSTM, where the recurrent component took a sequence of words as an input. We set the basic parameters in the model as follows: 30 as the number of epochs, a batch size of 43 for sub-task A, since it was the smallest batch size that the 860 tweets could be divided by, where our model

[1]https://twitter.com/

still performed well. For the other sub-tasks we went with 30 and 71 as batch sizes for the test sets of 240 and 213 tweets, accordingly. We used 4 hidden layers with 50 neurons per each, since our overall score declined by decreasing and increasing their number. Our dropout ratio was set to 0.95, the embedding size to 100, learning rates varied between submissions from 0.003 to 0.005.

The model was implemented in Python and makes use of Tensorflow (Abadi et al., 2015) and Scikit-learn (Pedregosa et al., 2011) libraries for training the classifier. We optimized our architecture parameters by predictions of support vector machine (SVM) model, described in (Rama and Çöltekin, 2017) and (Çöltekin and Rama, 2018). It used 'bag of n-grams' as features, and took not only word n-grams, as in our LSTM based model, but combined character and word n-grams, weighted by sublinear TF-IDF scaling. We picked the epoch with the best F_1-score for each parameter setting according to these SVM predictions. Our repository can be found on github https://github.com/cicl2018/semeval-2019-task-6-HAD.

2.1 Preprocessing

For neural network classification, data preprocessing has a great impact on the system's performance. Thus, at least one step from the following procedure was applied for all the submissions:

- lowercasing, since uppercased words can be both offensive and not
- hashtag parsing (e.g. #retrogaming → # retro gaming) (see, Baziotis et al. 2017)
  This tool is trained on 2 big corpora:
  - English Wikipedia
  - a collection of 330 million English Twitter messages
- removing tokens, containing "@USER"
  The user names are not given, thus this information is irrelevant for the classification task.
- character normalization
  We removed all the following charachters " : . , — ˜ ", digits and single quotation marks except for abbreviations and possessors (e.g. *u're* → *u're*, but *about'* → *about*)
- using '=', '!', '?' and '/' as token splitters (e.g. *something!important* → *something important*)

2.2 Sub-task A - Offensive language identification

Sub-task A was a binary classification task. The goal was to identify whether the post is offensive (OFF) or not (NOT). The provided tweets were labeled as OFF if they contained any form of non-acceptable language or a targeted offense, and labeled as NOT in any other case.

2.2.1 System pipeline for sub-task A

Figure 1 describes the system architecture for sub-task A. For each of the three submissions we tried different approaches.

1. All the preprocessing steps (Section 2.1) + LSTM classifier with the use of SVM predictions, (see Section 2.2.2 and green arrows in Figure 1).
2. All the preprocessing steps + LSTM classifier with SVM predictions + additional manually created offensive word list, (see Section 2.2.3 and black arrows in Figure 1).
3. Hashtag parsing as a single preprocessing step + LSTM classifier with SVM predictions, (see Section 2.2.4 and red arrows in Figure 1).

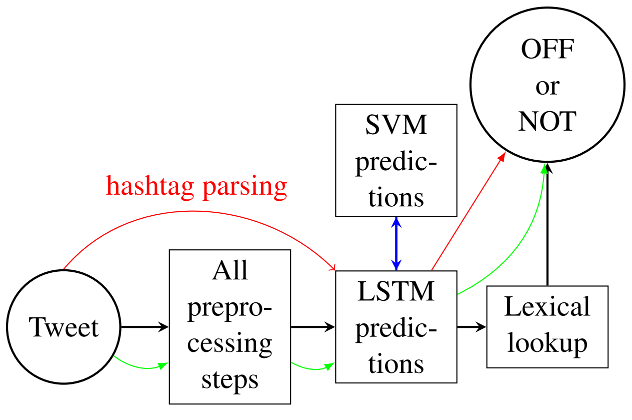

Figure 1: Pipeline of sub-task A

2.2.2 Submission 1, Sub-task A

In our first submission, we fed the preprocessed data into our LSTM model, setting the configurations (e.g. a learning rate of 0.003), according to the outcome of SVM predictions (Figure 1: green arrows).

2.2.3 Submission 2, Sub-task A

For the second submission we used a manually created additional offensive word list. After all the preprocessing steps, we ran the model with the same configurations as in the first submission except for the learning rate of 0.005, picking the epoch with the best F_1-score regarding SVM predictions. Then we postprocessed the results by using external manually collected offensive vocabulary, reannotating the tweets as offensive, if they contained abusive words from this list, but were labeled as not offensive by our model (Figure 1: black arrows).

2.2.4 Submission 3, Sub-task A

As a third submission, we preprocessed raw tweets only by hashtag parsing and let an LSTM model with a learning rate of 0.005 classify the data, choosing the epoch with the best F_1-score, according to the SVM predictions (Figure 1: red arrows).

2.3 Sub-task B - Automatic categorization of offense types

Sub-task B was a classification task of targeted (TIN) vs. untargeted (UNT) tweets. The test set contained only offensive (OFF) posts from the first sub-task. Tweets were considered as targeted, if they were insults/ threats to an individual or group, untargeted in any other case. For this sub-task we reduced the initial training set of 13.240 tweets to 4300, removing the tweets labelled with NOT, since non-offensive tweets would not add any improvement to the learning model and might even distort the learning process.

2.3.1 System pipeline for sub-task B

The system architecture for this sub-task is illustrated in Figure 2. Since the number of the representative tweets in the training data differed between categories a lot (i.e. 524 and 3876 for UNT and TIN, respectively), we used a weighted cross entropy to balance the data. Like in sub-task A, our approaches varied between submissions but this time we handed in 2 submissions.

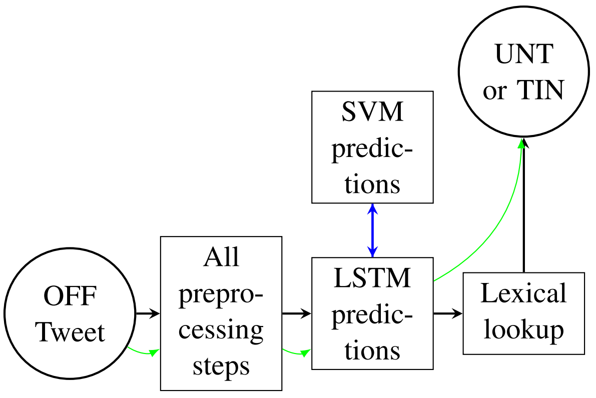

Figure 2: Pipeline of sub-task B

2.3.2 Submission 1, Sub-task B

The architecture of the first submission in this sub-task is very much similar to the first submission in sub-task A with the only difference being that a learning rate was changed to 0.005 (Figure 2: green arrows).

2.3.3 Submission 2, Sub-task B

For the second submission we added a postprocessing step, where we reannotated the tweets that comprised particular word forms from a manually created list of potential insult victims as targets (Figure 2: black arrows). This database included following four parts:

- Names of representatives of top twitter profiles from the USA, the UK, Saudi Arabia, Brazil, India and Spain, since these countries have the most Twitter users[2] and Iran, Iraq, Turkey, Russia and Germany, because we predicted a possible aggression towards the users from these countries. The data was obtained from `https://www.socialbakers.com/statistics/twitter/profiles/`.
- A list of ethnic slurs, mostly extracted from `https://en.wikipedia.org/wiki/List_of_ethnic_slurs`
- A list of name-callings, primarily collected from `https://www.urbandictionary.com/`
- A list of 2nd and 3rd personal pronouns and abbreviations with them (e.g. *you*, *they've* etc.)

[2]This statistic can be found on `https://www.statista.com/statistics/242606/number-of-active-twitter-users-in-sele\protect\discretionary{\char\hyphenchar\font}{}{}cted-countries/`

2.4 Sub-task C - Offense target identification

The third sub-task addressed offense target identification. This time we had three categories to choose from: Individual (IND), group (GRP), or other (OTH). The tweets were labeled as individually targeted, if a potential victim was a famous person, a named IND or an unnamed person interacting in the conversation. It was labeled as GRP, if the tweet was offensive with respect to a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or similar, and was labelled as OTH, if the tweet intended to abuse an organization, a situation, an event, or an issue. The test data contained 213 offensive targeted tweets from sub-task B. The training set of 4300 offensive tweets was reduced to 3909 targeted ones for this sub-task.

2.4.1 System pipeline for sub-task C

The system architecture for this sub-task is illustrated in Figure 3.

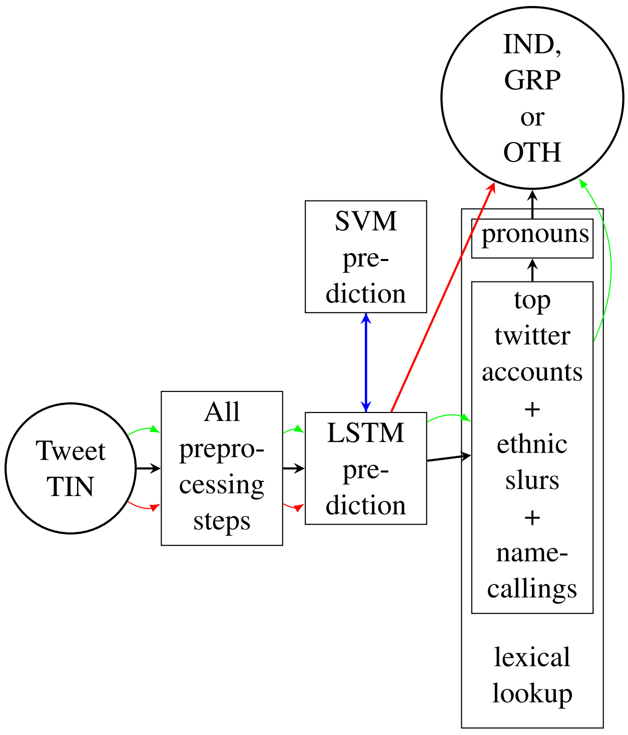

Figure 3: Pipeline of sub-task C

2.4.2 Submission 1, Sub-task C

This submission is reminiscent of the two previous first submissions, but the batch size was set to 71 and the learning rate to 0.003 (Figure 3: red arrows).

2.4.3 Submission 2, Sub-task C

In the second submission, we postprocessed the classified data, using the following datasets:

- Names of representatives of top twitter profiles from the USA, the UK, Saudi Arabia, Brazil, India, Spain, Iran, Iraq, Turkey, Russia and Germany. The data was obtained from `https://www.socialbakers.com/statistics/twitter/profiles/`:
  - celebrities and society/politics industries for identifying individual targets
  - community/political and community/religion industries for recognizing group targets
  - places, brands and entertainment/event industry for other targets
- A list of ethnic slurs, (see Section 2.3.3), for identifying group targets
- A dataset of name-callings, (see Section 2.3.3), for recognizing individual victims

These datasets helped to classify the categories IND, GRP or OTH by looking them up in our lists. (Figure 3: green arrow).

2.4.4 Submission 3, Sub-task C

The third submission differed from the previous one only in adding a list of 2nd and 3rd personal pronouns including their contractions to the existing database for the postprocessing step. We decided to try an approach with personal pronouns despite the fact, that they can both target individuals (e.g. "Take it out, you fucking wanker, or I'll take you out".) and groups (e.g. "All you democrats suck, and your momma's fat!").

3 Results

The results presented below were obtained using the macro-averaged F_1-score, provided by the organisers of OffensEval 2019. They included accuracy as well for comparison. Random baseline generated results by assigning the same labels for all instances were also added to the result Table 1. For example, "All OFF" in sub-task A represented the performance of a system that labels everything as offensive.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
LSTM + Prepr.	0.6652	0.7337
LSTM + Prepr. + Lex. lookup	0.6487	0.7349
LSTM + Hashtag parsing	**0.7327**	**0.7977**

Table 1: Results for Sub-task A.

The best results for the first sub-task were produced by the simplest approach, which included only hashtag parsing as a preprocessing step and an LSTM based classifier with configurations, set according to SVM predictions. A plausible explanation to the bad performance of the second submission with a lexical lookup is that a task-specific lexicon should better be used as an input feature, which can only influence data classification, rather than as a decisive postprocessing step.

For sub-task B one can see the scores of our two submissions in Table 2. As before, the organizers have also included random baseline generated results by assigning the same labels for all instances.

System (Sumbission)	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
LSTM + Prepr.	**0.5246**	**0.8417**
LSTM + Prepr. + Lex. lookup	0.5022	0.8833

Table 2: Results for Sub-task B.

The best results for this sub-task were also achieved only by applying preprocessing steps to an LSTM model. Most likely, the problem was that our external dataset largely aimed to recognize names of top twitter accounts, which most frequently occur as usernames in tweets. However, in our case they were anonymized in both training and test sets (@USER). Last table shows the scores of our submissions for sub-task C:

System (Submission)	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
LSTM + Prepr.	0.2027	0.3099
LSTM + Prepr. + Lex. lookup without Pronouns	0.3582	0.3709
LSTM + Prepr. + Lex. lookup with Pronouns	**0.3769**	**0.4883**

Table 3: Results for Sub-task C.

For the last sub-task, which was devoted to categorizing targets of offense, a considerable increase in F_1-score can be observed by using the external datasets for postprocessing. Hence, the results showed that using a lexical lookup could be much more efficient in categorizing the possible victims than in identifying the presence of aggression per se. Below one can also find the confusion matrices of our best runs:

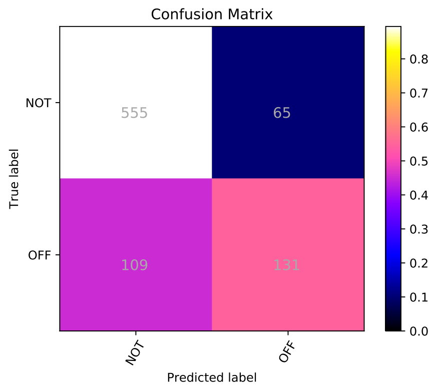

Figure 4: Sub-task A, HAD-Tübingen LSTM + Hashtag parsing.

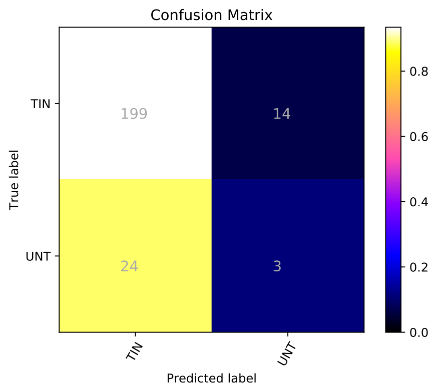

Figure 5: Sub-task B, HAD-Tübingen LSTM + Preprocessing.

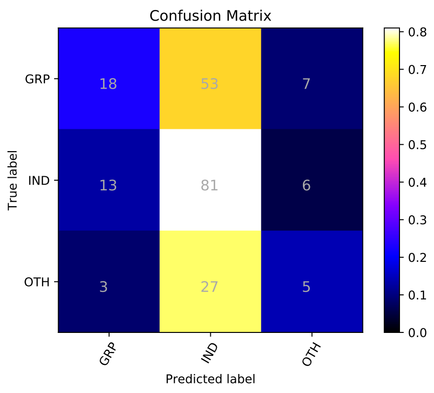

Figure 6: Sub-task C, HAD-Tübingen LSTM + Preprocessing + Lexical lookup with Pronouns.

It is also worth mentioning that a model choice and its settings should be made according to the training set size. In our case, the volume differed significantly for all the sub-tasks. However, a significantly lower performance of all the submissions can be observed on the last sub-task with the smallest training set.

4 Conclusion and future work

In our paper we presented the contribution of HAD-Tübingen to the OffensEval 2019 (SemEval 2019 - Task 6). Our approach combines sentence simplification as a preprocessing step and a lexical lookup as a postprocessing step with an unidirectional LSTM with 4 hidden layers. We picked the epochs according to the best F_1-score for our model configurations, according to SVM predictions. We found out that simple LSTM models are not likely to outperform SVM in such classification tasks. However, as a next possible step in working with an LSTM based classifier, could be using an external task-specific lexicon as an input feature to our model, but not as a postprocessing step. We would also like to make use of the pretrained vectors from Fastext library that are based on sub-word character n-grams for improving our model.

Abstract

We present our results for OffensEval: Identifying and Categorizing Offensive Language in Social Media (SemEval 2019 - Task 6). Our results show that context embeddings are important features for the three different subtasks in connection with classical machine and with deep learning. Our best model reached place 3 of 75 in sub-task B with a macro F_1 of 0.719. Our approaches for sub-task A and C perform less well but could also deliver promising results.

1 Introduction

User generated content in social media platforms such as Twitter often includes high levels of rude, offensive, or sometimes even hateful language. The increasing vulgarity in online discussions and user comment sections have recently been discussed as relevant issues in society as well as in science.

The identification of offensiveness, aggression, and hate speech in user-generated content has been addressed in recent research (Waseem et al., 2017; Davidson et al., 2017a; Malmasi and Zampieri, 2018) and previous shared tasks (Wiegand et al., 2018; Kumar et al., 2018). However, detecting such content automatically is still challenging. We developed classification models to identify *offensive language*, different *categories of offense types*, and *targets of offensive language* throughout the SemEval-2019 challenge on Identifying and Categorizing Offensive Language in Social Media (Zampieri et al., 2019b).

2 Methodology and Data

In this section, we introduce the datasets, the features and classifiers we use.

2.1 Datasets

The training dataset provided for this task is further described in Zampieri et al. (2019a). For sub-task A: Offensive Language Detection 4.400 offensive (*OFF*) and 8.840 not offensive (*NOT*) tweets are given for the training and 240 offensive plus 620 not offensive tweets are given as test data. Sub-task B: Categorization of Offensive Language is provided with a training set of 3876 targeted insult (*TIN*) and 524 untargeted (*UNT*) tweets and a test set of 213 targeted insult plus 27 untargeted tweets. The train data distribution for sub-task C: Offensive Language Target Identification are 2407 tweets targeting an individual (*IND*), 1074 targeting a group (*GRP*) and 395 targeting any other category (*OTH*). The test data given counts 100, 78 and 35, respectively.

We use Davidson et al. (2017b)'s dataset for hate speech detection as an additional source of knowledge and to address the problem of overfitting in our deep learning models. Tweets were collected and filtered using a lexicon of common hate speech terms. The remaining tweets were then each classified by at least 3 CrowdFlower users into the three categories *hate speech*, *offensive language* or *none*. Each tweet was assigned a label, which was chosen based on a majority vote. In order to match the labels to this task, we merged the categories: *hate speech* and *offensive language* into a single offensive label *OFF* and renamed the label *none* to *NOT*. This resulted in 20620 *OFF* and 4163 *NOT* labeled additional tweets. It should be noted that our assumption to equate hate speech and offensive language does not apply in general.

2.2 Features

Word and Char-Level Features We transformed the tweet texts into tf-idf weighted bag of words and bag of chars representations using scikit-learn

(Pedregosa et al., 2011). The feature *CHARS* is built from bigrams to 6-grams on character level. For the feature *WORDS* we use unigrams and bigrams on word level, excluding stop words. In order to reduce variance in the text data, we also built the feature *STEMS* with unigrams and bigrams. For this, we applied the TweetTokenizer from NLTK (Bird et al., 2009) that removes user name handles from a tweet and replaces repeated characters with a sequence of only 3. Afterwards, the word tokens are reduced to their stems using the Snowball Stemming algorithm (Porter et al., 2002).

Named Entities Named entities in a tweet can indicate whether this tweet is person-related or relates to e.g. religious or political groups or organizations. This information might help with the target identification. The feature *NE* is implemented using the named entity recognition of spacy[1], building a bag of named entities for every tweet preserving all OntoNotes5 (Weischedel et al., 2013) named enity types, which results in an 18-dimensional feature vector per tweet.

Grammatical Number of Nouns and Pronouns The grammatical number of a noun might also indicate if a tweet insults a specifiable target. We use spacy's part-of-speech tagger, which uses the OntoNotes5 tagging scheme. The feature *ND* models the noun distribution of singular and plural nouns and is implemented building a bag of tags for the tags NNS, NN, NNP and NNPS, normalized by the tweets' token count. Contrarily, feature *SPNR* describes the ratio of singular noun tags (NN and NNP) and plural noun tags (NNPS and NNS) per tweet. The first value is divided by the latter one, smoothing both by adding 1. Another feature to separate single person targets from groups is the absolute count of single pronoun words (he, she, him, her, his, hers, himself, herself) per tweet, hereinafter referred to as *SPC*. It should be noted that the corresponding procedure for plural pronouns could not bring any benefit in our evaluations and is therefore not further described.

Dependencies Another consideration was whether syntactic dependency relations could provide information for one of the three sub-tasks. For the feature *DEP*, every tweet is transformed into the corresponding list of dependency labels. These representations are subsequently used to build n-grams in the range (2,4) which are then vectorized using tf-idf.

Global Vectors for Word Representation (GloVe) Feeding words into machine learning models often requires a meaningful vector representation that captures syntactic and semantic information. We use GloVe word embeddings (Pennington et al., 2014), an unsupervised learning algorithm for obtaining vector representations of words. A set of pre-trained word vectors, trained on over 2 billion tweets, containing vector representations for over 1.2 million words in various dimensions (25, 50, 100, 200) is publicly available on the author's website[2]. In this work, we use 200 dimensions.

Embeddings from Language Models (ELMo) Traditional pre-trained word representations merely contain meaning based on statistical information and therefore struggle with word-sense disambiguation. Since offensive words change their meaning greatly depending on their context, a contextualizing method would help to tackle this task. ELMo (Peters et al., 2018) is a novel approach on creating word representations and shows a significant improvement of state of the art systems on many benchmarks. It models a function using character-based word representations and bidirectional long-short term memories of not only each single word, but also the entire input sentence. Thus, it can be useful for solving the problem of processing ambiguous words that are not offensive by themselves but could point to offensive language depending on the context they are used in. For these reasons, we expect ELMo to increase the results of this task. The pre-trained model can be downloaded from TensorFlow Hub[3].

χ^2 Feature Selection To quantify the contribution of a feature, we choose the χ^2 test statistic, that excludes features that are most likely to be independent from a class, and keep the k features with the highest values for χ^2.

2.3 Classifier

We use logistic regression (Nelder and Wedderburn, 1972), support vector machines (Cortes and Vapnik, 1995) and neural networks with long short-term memory units (Hochreiter and Schmidhuber, 1997) for the different classification prob-

[1] `https://spacy.io/`

[2] `https://nlp.stanford.edu/projects/glove/`

[3] `https://tfhub.dev/google/elmo/2`

lems. The classifiers are implemented with scikit-learn and TensorFlow (Abadi et al., 2015).

Logistic regression has been used by several teams of the GermEval shared task on offensive language identification (Wiegand et al., 2018) with promising results. We therefore decided to use it as a baseline approach. In the multiclass case the one-vs-rest scheme is used.

Support vector machines (SVM) are also known to perform well on a variety of classification tasks and have been used in the context of hate and offensive speech and abusive language detection in recent years (Malmasi and Zampieri, 2017; Wiegand et al., 2018). We use the rbf kernel. In the multiclass case the one-vs-one scheme is used.

To overcome class imbalances, class weights are adjusted inversely proportional to the train data class frequencies for both classifiers.

As seen in recent challenges focused on offensive language detection in social media like TRAC (Kumar et al., 2018), long-short term memories (LSTM) play an important role and are often used among the best classifiers. Their ability of sequential data iteration and of memorizing recent content across time provides them with a good opportunity not only to analyze individual words, but also to find problem-specific dependencies between them.

3 Models

This chapter describes the development of the models for the submissions and how they perform on the training data.

3.1 Sub-task A

The training data was split into a training set containing 3400 OFF and 7840 NOT labels and a validation set, which consists of the remaining 1000 OFF and 1000 NOT labels. To establish a baseline for this sub-task, we used the features *CHARS*, *WORDS* and *STEMS*, which were the features that were mainly used by the most powerful systems in the TRAC challenge that did not use deep learning. We opted for logistic regression, because it performed better than the SVM. C was set to the default value 1. Table 1 gives an overview of all model results for sub-task A. The baseline approach, denoted as *Baseline A*, reaches a macro F_1 of 0.712 on the validation set.

Our first deep learning model architecture *LSTM A1* uses ELMo context embeddings as inputs into a bidirectional LSTM layer with a size of 64 cells. For classification, we used the hidden states of the LSTM cells generated when passing the last token from each tweet to the LSTM. A fully connected layer was used to compute the two class scores that were normalized using softmax. Its highest macro F_1 value of 0.742 on the validation set was reached after only two epochs, which means that the network tends to overfit very quickly. To overcome this problem, we placed an additional fully connected layer with a dimensionality of 64 and L2 loss between the high-dimensional ELMo output (1000 dimensions) and the LSTM layer to insert a relatively strong regularization loss to the system. We expected this to force the system to look for more universal patterns in the embeddings before passing them to the LSTM layer. While improving the F_1 score by 1%, this architecture, named *LSTM A2*, still started overfitting after two epochs. As a further adjustment against overfitting we used an extra heavy dropout layer with a 70% dropout between the ELMo embeddings and the fully connected layer. We also tried other dropout rates (30%, 40%, 50%, 60%, 80%, 90%), but 70% worked best. A higher percentage did not yield meaningful results. Through this modification of the architecture, *LSTM A3*, the overfitting was delayed until the 16th epoch. The F_1 score also showed a slight improvement.

System	F_1 (macro)	Accuracy
Baseline A	0.712	0.718
LSTM A1	0.742	0.745
LSTM A2	0.753	0.753
LSTM A3	0.759	0.759
LSTM A4	0.729	0.731
LSTM A5	0.764	0.764
LSTM A6	**0.767**	**0.768**
Feature Union A	0.760	0.760

Table 1: Overview of the performance by different models for sub-task A

Comparing non-contextualized to contextualized word embeddings, the developed architecture was also evaluated with GloVe (*LSTM A4*) as well as with a vector concatenation of GloVe and ELMo Embeddings *LSTM A5*. It turned out that ELMo embedding inputs alone exceed the GloVe embedding inputs in this model and that they work together even better than each one on its own.

Due to the remaining problem of overfitting, we used the additional data described in Section 3.1. Pre-training the network with this additional data and then training it with our training set, a small but no significant improvement was achieved. With a macro F_1 of 0.767, this model (*LSTM A6*) shows the best performance on the validation set and was therefore used for our first submission. We used a learning rate of 0.001 and a batch size of 64 for all models. The number of epochs was chosen dependent on the stagnating progress on the validation set.

We used logistic regression with the default $C = 1$ for the second submission system. As feature representation for each tweet, we combined *CHARS*, *WORDS* and *STEMS* with the output of the already trained LSTM of *LSTM A6* as 128-dimensional fixed features. This system *Feature Union A* could not surpass *LSTM A6*, but achieves nevertheless a F_1 of 0.760. It should also be noted, that the χ^2 feature selection could reduce the features used in this feature union to only four of them without affecting the accuracy of the classification. All of them derived from the LSTM output features. The full architecture of this model, including all the models described earlier in this section, is illustrated in Figure 1.

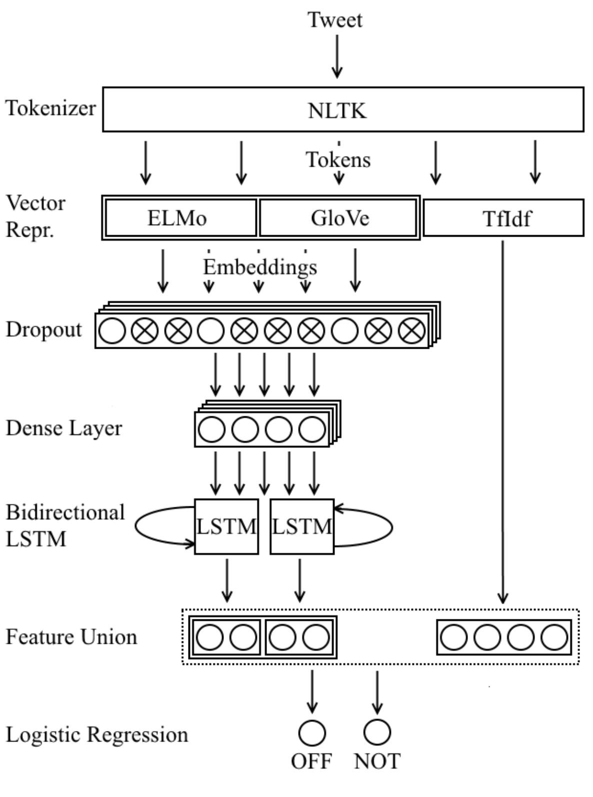

Figure 1: Model architecture for the *Feature Union A* system

3.2 Sub-task B

System	F_1 (macro)	Accuracy
Baseline B	0.615	**0.869**
LSTM B1	0.602	0.745
LSTM B2	0.628	0.809
Feature Union B	**0.653**	0.825

Table 2: Overview of the performance by different models for sub-task B

In sub-task B we split the data into 80% training and 20% validation set. We trained the same baseline model as in sub-task A, which reached a macro F_1 of 0.615 on the validation set and forms the baseline for the list of all models build for this sub-task shown in Table 2.

For our first deep learning approach on this sub-task, we used the same structure as in *LSTM A6*, but with smaller layer sizes as another way to reduce overfitting, because the training data given for this sub-task was even smaller than for sub-task A. The dense layer between the dropout layer and the bidirectional LSTM consists of 8 and the LSTM of 32 cells. This system named *LSTM B1* achieves 0.623 on the validation set.

Pseudo Labeling was used on the additional data described in Section 3.1 to generate the missing labels for this task. For this, we first labeled the additional data using *LSTM B1*, which had already been trained on the training data. Then the resulting labels are used to extend the training data. In addition, we have focused only on the labels which softmax class score was higher than 0.7 for the predicted label to reduce noisy labels. This results in about 2000 UNT and 17500 TIN labeled tweets. The resulting system named *LSTM B2* reaches a macro F_1 of 0.628 on the validation set.

As first classifier *Feature Union B*, we used the same structure as in sub-task A and combined *CHARS*, *WORDS* and *STEMS* and the output of *LSTM B2* as feature input. The value for C in the logistic regression was selected using grid search and was set to 0.51. Together these features improved the macro F_1 even further and reached our best result 0.653 for sub-task B on the validation set.

For the second submission, we trained additional four models of *LSTM B2* and we used the *Feature Union B* from the first submission as a fifth classifier. We then performed a majority vote on all five resulting labels.

All deep learning models in sub-task B are trained with a learning rate of 0.001 and a batch size of 32 for all models. The number of epochs was defined in the same way as in sub-task A.

3.3 Sub-task C

The evaluation for sub-task C is done on a 80%-20% train-validation split making sure that the test data set contains a 20% proportion of each class. Additionally, the train data was enriched with the trial data, where all occurrences of class ORG were replaced by class OTH. Deep learning was not used for the implementation of this sub-task due to the small amount of training data. To select the best feature sets for the used classifiers, logistic regression and SVM all combinations were tested including grid search to find the best parameter values for C and γ, respectively.

Class	Features	Prec.	Recall	F_1
GRP	ELMo	0.566	**0.679**	0.617
	ELMo+NE	0.573	0.674	0.62
	ELMo+ND	0.567	0.61	0.614
	ELMo+NE+ND	0.58	0.674	0.623
	all	**0.582**	0.674	**0.625**
IND	ELMo	0.820	0.789	0.804
	ELMo+NE	0.821	0.795	0.808
	ELMo+ND	0.567	0.67	0.614
	ELMo+NE+ND	0.823	0.795	0.809
	all	**0.825**	**0.798**	**0.811**
OTH	ELMo	0.360	0.237	0.286
	ELMo+NE	0.365	0.250	0.297
	ELMo+ND	0.370	0.263	0.308
	ELMo+NE+ND	0.375	0.276	0.318
	all	**0.386**	**0.29**	**0.331**
macro	ELMo	0.582	0.568	0.57
	ELMo+NE	0.587	0.573	0.575
	ELMo+ND	0.586	0.574	0.575
	ELMo+NE+ND	0.593	0.582	0.584
	all	**0.598**	**0.587**	**0.589**

Table 3: Overview of feature impact on the logistic regression system with $C = 0.011$

Logistic regression classifies best on the validation set using $C = 0.011$ and the combination of the features *WORDS*, *NE*, *SPC*, *DEP*, *SPNR*, *ND* and the ELMo embeddings trained for sub-task B achieving a macro F_1 of 0.589. Table 3 gives an overview of the model performance for the three classes. The features are broken down by influence, where *all* denotes the entire feature set used. ELMo is the most important feature here and gives a macro F_1 of 0.57. The further two percent are largely due to the use of named entities and the noun distribution. The additional features (*WORDS*, *SPC*, *DEP*, *SPNR*) have only little influence of the classification. A closer look reveals that the class performances differ widely depending on class size. Underrepresented classes benefit the most from adding other features to the embeddings, OTH in particular: Precision and recall increase by two and five percent, which leads to a rise in F_1 of about four percent.

Class	Features	Prec.	Recall	F_1
GRP	ELMo	0.537	**0.729**	0.618
	ELMo + SPNR	0.554	0.715	0.625
	all	**0.554**	0.715	**0.625**
IND	ELMo	0.871	0.706	0.78
	ELMo + SPNR	0.873	0.706	0.781
	all	**0.874**	**0.708**	**0.782**
OTH	ELMo	0.296	0.342	0.317
	ELMo + SPNR	0.317	0.434	0.367
	all	**0.32**	**0.434**	**0.369**
macro	ELMo	0.568	0.592	0.572
	ELMo+SPNR	0.582	0.618	0.591
	all	**0.583**	**0.619**	**0.592**

Table 4: Overview of feature impact on the SVM system with $C = 6$, $\gamma = 0.0001$

Table 4 depicts the results for the best SVM model, using a feature set of *WORDS*, *DEP*, *SPNR*, *ND* and the ELMo embeddings trained for sub-task B. The best parameter values we found are $C = 6$ and $\gamma = 0.0001$ and lead to a macro F_1 of 0.592 on the validation set. As in the previous setting, ELMo is the key feature and achieves 0.572 macro F_1. The union with feature *SPNR* leads to 0.591 macro F_1. As with logistic regression, the addition has a positive effect on the less common classes.

In addition, we use a majority vote as third submission. For this, we build a voting classifier out of the previously developed logistic regression and SVM classifiers and a further logistic regression classifier which uses *CHARS*, *WORDS* and *STEMS* and the output of *LSTM B2* as feature input. It should be noted, that the LSTM has not been re-trained on the sub-task C data. Subsequently, a majority decision is taken and in case of doubt, the label prediction of the latter logistic regression classifier is given preference.

4 Results

After the previous description of the submission models, an overview of the test results follows in this section.

4.1 Sub-task A

In order to prepare the *LSTM A6* system for submission, we re-trained it with the complete available training data. This classifier reached a macro F_1 of 0.768, as shown in Table 5 on the test set, which is comparable to the result reached on the validation set in Table 1.

As a second submission we chose the *Feature Union A* classifier, but took the output of the LSTM from the first submission for the LSTM output features in the feature union instead. With 0.742, it reached a somewhat lower macro F_1 on the test set than on our validation set as shown in comparison of Table 1 and Table 5.

System	F1 (macro)	Accuracy
All NOT baseline	0.419	0.721
All OFF baseline	0.218	0.279
LSTM A6	**0.768**	**0.807**
Feature Union A	0.742	0.788

Table 5: Test results for sub-task A

4.2 Sub-task B

The *Feature Union B* system reached a macro F_1 score of 0.671. Comparing the results from Table 2 and Table 6, the classifier works equally well on the train and on the test data.

The majority vote classifier achieved our best result with a macro F_1 score of 0.719 (Table 6). This result is remarkably good which we think is caused by a high robustness resulting from the different strengths of the incorporated classifiers.

System	F1 (macro)	Accuracy
All TIN baseline	0.470	0.888
All UNT baseline	0.101	0.113
Feature Union B	0.671	**0.871**
Majority Vote B	**0.719**	0.850

Table 6: Test results for sub-task B

4.3 Sub-task C

On the test data, all systems perform inferior than on the validation set. The best macro F_1 is obtained by the SVM having 0.571, followed by the logistic regression with 0.551 and then the voting classifier with 0.539. Overall, the performance is fairly stable compared to the validation set and the fact that no cross validation was used in the model selection process.

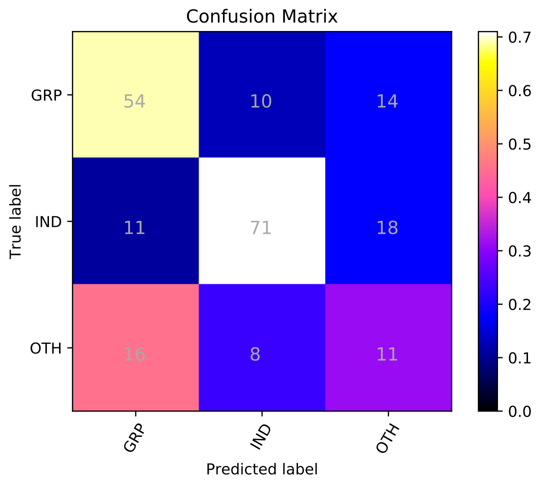

Figure 2: Confusion matrix for sub-task C and the best performing model SVM

Figure 2 shows the confusion matrix for the best performing system. As can be seen, most tweets of GRP and IND are classified correctly, whereas almost half of the OTH tweets are incorrectly recognized as GRP. On the one hand, the rare class occurence in the training seems to obstruct the classifier in learning. On the other hand, it was challenging for us as humans to differentiate between the classes GRP and OTH in the data set: For instance "Liberals are mentally ill!" is labeled as GRP, whereas "@USER republicans/conservatives are the most disgusting people" has label OTH.

5 Conclusion

We showed that contextualized embeddings work well in the context of offensive language identification and the two different categorization tasks. Other language and linguistic features could deliver only small improvements.

The main problems in using deep learning are the model size and the dimensionality and number of parameters resulting in fast overfitting. We plan to address this problem through strategies to reduce model size (primarily in reducing the high-dimensional ELMo output without loosing relevant information before connecting it to the less high-dimensional LSTMs using a fully connected layer), or to include more data when available. Another consideration for sub-task A would be the use of the majority vote model from sub-task B, which showed good results. For sub-task C, the development of deep learning models would be interesting.

Abstract

User's content share through social media has reached huge proportions nowadays. However, along with the free expression of thoughts on social media, people risk getting exposed to various aggressive statements. In this paper, we present a system able to identify and classify offensive user-generated content.

1 Introduction

With the constant spread of social media, users are spending increasing amounts of time on various social networking sites aiming to connect with peers, to share information or common interests. While users benefit from their use of social media by interacting with and learning from others, they are also at the risk of being exposed to large amounts of offensive contents.

Considering that people are negatively affected by harmful contents, detecting online offensive language to protect users online safety becomes an urgent task. To address concerns on people's access to offensive content over the internet, social media administrators often need to manually review online texts to detect and delete offensive materials. However, manually reviewing and identifying offensive messages is a highly human and time consuming task. Some automatic content filtering software packages have been developed to detect and filter offensive WebPages or paragraphs, mostly word-based approaches.

The "OffensEval: Identifying and Categorizing Offensive Language in Social Media" task at the SemEval 2019 competition (Zampieri *et al.*, 2019a) focuses on detecting and classifying offenses, pervasive in social media.

In this paper, we present a system able to identify whether a tweet is abusive language or not, and if abusive, if it is offensive or not. We trained a model to differentiate between these categories and then analyzed the results to better understand how we can improve the system.

The rest of the paper is organized as follows: section 2 presents other projects related to offensive language identification, section 3 presents the project's data set and methods, section 4 presents the results we have obtained and a short analysis, followed by our last point represented by section 5 with the conclusions.

2 Related Work

This topic has attracted significant attention in recent years, evidenced by increasing number of recent publications and a several scientific events such as ALW and TRAC workshops.

Offensive language is often subdivided into various intercalated categories, since different subtasks have been grouped under this label. One of the most analyzed such language is "hate speech", i.e. discriminative remarks, such as the racist or sexist ones (Norbata *et al.*, 2016).

Based on work on hate speech, cyberbullying and online abuse, Waseem *et al.*, 2017 proposses a typology that captures central similarities and differences between subtasks and discuss its implications for data annotation and feature construction. Additionally, Waseem *et al.* (2017) emphasize the practical actions that can be taken by researchers to best approach their abusive language detection subtask of interest.

Lexical detection methods for the offensive language tend to have low precision because they fail to classify messages not containing listed offensive terms. On the other hand, various machine learning methods are used in the literature, from Logistic regression, Naïve Bayes, Decision Trees, Random forests, SMVs to neural networks. Previous analysis of hate speech modeling (Schmidt and Wiegand, 2017) shows that there is a too wide range of features used, and a more advanced feature relevance analysis was needed (Waseem *et al.*, 2017).

A first shared task on aggression identification aiming to classify aggressive speech into overt, covert or no aggression was held at the TRAC Workshop collocated with COLING 2018 (Kumar *et al.*, 2018). 130 teams registered to participate in the task, 30 teams submitted their test runs and 20 teams sent their system description paper, which are included in the TRAC workshop proceedings.

The problem of distinguishing general profanity from hate speech is not a trivial task (Malmasi and Zampieri, 2018) and requires features that capture a deeper understanding of the text not always possible with surface grams.

3 Data set and Methods

The data set for SemEval 2019 task 6 was formed from 14100 tweets, 13240 training instances, retrieved from social media and distributed in tab-separated format and 860 tweets for testing (Zampieri *et al.*, 2019b). Using this data set, we were able to identify offense, aggression and hate speech in user generated content.

This section presents our approach for the different subtask, for each submission we uploaded.

Sub-task A: Offensive language identification

Submission 1. We analyzed the training data to identify specific words or expressions for offensive, respectively non-offensive tweets. Based on these expressions, we crafted a set of rules consisting in exact or partial matches of these expressions in the test corpus. Tweets that have complied with these rules have been annotated as offensive. Tweets containing such expression only in a negated form were annotatd as non-offensive. The rest of the tweets were randomly classified in offensive or non-offensive. The application code was written in the Java programming language and the results are presented in Table 1.1.

Submission 2. We created a lexicon based on two lists of words of offensive lexicons[1], freely available online, along with the list resulted from the analysis of the set of training tweets, as described above. Using these offensive words or expressions, we developed patterns and we classified the tweets in offensive tweets and non-offensive tweets. If the tweet was containing at least one word from the lists, it means that the tweet is offensive, otherwise the tweet would be considered not offensive. The results are presented in Table 1.2.

Submission 3: For this submission, we used the same lists of offensive words obtained from external sources, along with the list of offensive words found in the training data, but we put a restriction on the size of the words (more than 4 letters). This constraint was considered due to the fact that we noticed that they introduced noise in the non-offensive tweets. Additionally, we used WordNet to obtain the synonyms of the words we had in our lists. The results are presented in Table 1.3.

Sub-task B: Automatic categorization of offense types

Submission 1: We tokenized the tweets annotated with targeted offensive words and collected different lists of cue words. Additionally, we noticed that if the tweet contained a proper name towards the middle of the sentence, the tweet was marked as a targeted tweet; otherwise it was marked as an untargeted tweet. We used this restriction and made the first submission, with the results presented in Table 2.1.

Submission 2: For the second submission, we tokenized the test tweets and checked if those words were found in the list of pronouns[2]. If a tweet was containing a pronoun from that list, then that tweet was marked as a targeted offensive one, otherwise it was marked as an untargeted offensive tweet. The results are presented in Table 2.2.

[1] One available at the GitHub repository for the paper (Davidson *et al.*, 2017) and one from Luis von Ahn (2018), consisting on English terms that could be found offensive on websites.

[2] https://www.really-learn-english.com/list-of-pronouns.html

Submission 3: We separated the tweets in words and counted how many words begin with a capital letter. We didn't take into consideration the "#" (hashtags) and @(@USER) because the vast majority were written with a capital letter. If a tweet was containing at least 2 words with capital letter, then the tweet was marked as being a targeted offensive tweet, otherwise was marked as an untargeted offensive tweet. The results are presented in Table 2.3.

Sub-task C: Offense target identification

We created two lists with pronouns. One list was used for the personal pronouns in singular for and the second one for the personal pronouns in plural. Therefore, we obtained 3 scenarios:

- If the tweet contains a personal pronoun from the singular pronoun list, then the tweet is marked IND.
- If the tweet contains a personal pronoun from the plural pronoun list, the tweet is marked GRP.
- If the tweet does not contain any pronouns from the above lists then the tweet is marked as OTH. The results are presented in Table 3.

4 Results

Below are the results for each individual level using the test set. We report Precision (P), Recall (R), and F-measure (F) for each baseline on all classes along with weighted averages and Macro-F1. The result for sub-task A are presented in table 1, the results for sub-task B are presented in table 2 and the results for sub-task C are presented in Table 3.

5 Conclusions

The offensive language in social media commonly comes from an unpleasant condition or something that is disgusting or forbidden. We discussed the challenges in detecting offensive language including the abusive words writing patterns in social media.

This paper presents our system participating at SemEval Task 6. We present simple baseline scores on all classes in all of the three sub-tasks.

In the future, we would like to make a comparison between our system and datasets annotation for similar tasks such as aggression or abusive identification and hate speech detection.

As further work, we have already started to study how to use the datasets for applying deep learning techniques to improve our results, based on word embedding, similar to the work presented in (Badjatiya *et al.*, 2017).

Abstract

This paper describes our participation in HatEval and OffensEval challenges for English and Spanish languages. We used several approaches, B4MSA, FastText, and EvoMSA. Best results were achieved with EvoMSA, which is a multilingual and domain-independent architecture that combines the prediction from different knowledge sources to solve text classification problems.

1 Introduction

Social media platforms, like Twitter and Facebook, are spaces where people interact with others and express themselves; while these platforms encourage free speech, other issues could emerge such as the usage of offensive language that could mock or insult individuals or groups of people. Thus, detecting offenses and misbehavior expressed in text form is interesting to measure the people's feelings and warn them about possible attacks on others such as abusive language, hate speech, cyberbullying, trolling, among others (Waseem et al., 2017).

In order to tackle these text classifications problems, SemEval-2019 proposed two tasks: multilingual detection of hate speech against immigrants and women in Twitter HatEval, task 5 (Basile et al., 2019), and identification and categorization of offensive language in social media OffensEval, task 6 (Zampieri et al., 2019b). In this paper, we present the results from our participating in these two tasks.

The HatEval challenge consists in detecting hate speech for two targets, immigrants and women, in Twitter for Spanish and English languages. There are two subtasks, subtask A is a binary classification where systems have to predict whether a tweet with a given target (immigrants or women) is hateful or not hateful; subtask B is about aggressive behavior and target classification, systems are asked to classify hateful tweets as aggressive or not aggressive, and identify the target harassed (individual or group).

On the other hand, OffensEval challenge consists in determining if a given message has offensive content. It is divided into three subtasks. Subtask A is dedicated to identifying the offensive language, i.e., determine if a message is offensive or not offensive. Subtask B is about categorizing offense types; that is, a tweet containing an insult or threat to someone, or a tweet containing non-targeted profanity and swearing. Finally, subtask C focus on identifying the target, i.e., whether the offensive post is about an individual, a group, or others.

Both HatEval and OffensEval are related tasks to abusive language, Waseem et al. (Waseem et al., 2017) describe tasks on this theme; authors focus their analysis on two primary factors that could guide the modeling of systems: i) language is directed towards a specific individual, entity, or generalized group; ii) the abusive content may be explicit or implicit.

For instance, Schmidt and Wiegand (Schmidt and Wiegand, 2017) present a collection of works on hate speech detection highlighting the features commonly used such as surface-level features. For instance, authors use bag of words (n-grams) and character-level n-grams to attenuate the spelling variation issue on informal text, frequency of URL mentions, punctuation, token lengths, capitalization, among others; word generalization such as topic identification (LDA) and word embeddings (Mikolov et al., 2013); outcomes from sentiment analysis classifiers (for example, samples predicted as negative polarity) as auxiliary evidence of hate for multi-step approaches; usage of lexical resources containing specific negative words (slurs, insults, etc.); linguistic aspects such as parts of speech and syntactic information; knowledge information such as ontologies and taxonomies (ConcepNet, WordNet, etc.).

For both tasks, we use the same approach for final runs. Our approach takes into account several features mentioned above. For example, the effects of character-level n-grams are broadly studied for related tasks in (Tellez et al., 2017b). In particular, text modeling is a crucial factor in our approach; therefore we used the approach presented in (Tellez et al., 2018) that selects the best configuration on the datasets concerned. We also use external knowledge to the given training set to support the classification task; in this sense, our approach named EvoMSA (§2.1) is a stacking system based on genetic programming, and particularly on the use of semantic genetic operators, that focus on sentiment analysis, and, in general, on text classification.

2 System Description

We used our framework based on genetic programming named EvoMSA to evaluate HatEval and OffensEval tasks. EvoMSA is composed of a stack of B4MSA classifiers to produce predictions, and EvoDAG combines the predictions into the final one.

2.1 EvoMSA

EvoMSA[1] (Graff et al., 2018a,b) is a Generic Sentiment Analysis System based on B4MSA and EvoDAG. It is an architecture of two phases to solve classification tasks, see Figure 1. EvoMSA improves the performance of a global classifier combining the predictions of a set of classifiers with different models on the same text to be classified. Roughly speaking, in the first stage, a set of B4MSA classifiers (see Sec. 2.1.1) are trained from several views of the same datasets; datasets provided by SemEval. It creates a decision functions space with mixtures of values coming from different views of knowledge, one coming from B4MSA trained with the training set of the competition (it is used as generic classifier), a lexicon-based model (it only counts affective words: positive and negative, based on several lexicons (Liu, 2017; Albornoz et al., 2012; Sidorov et al., 2013; Perez-Rosas et al., 2012)), an emoji-based space (the sixty-four most probable emoticons for the message) (Graff et al., 2018b), and the output of FastText (Grave et al., 2018) (word embeddings of dimension of 100) trained with the training set. Finally, EvoDAG's inputs are the concatenation of all the decision functions predicted, and EvoDAG produces a final value or prediction. The following subsections describe the internal parts of EvoMSA. The precise configuration of our benchmarked system is described in Sec. 4.

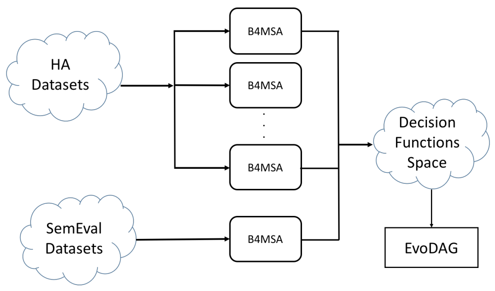

Figure 1: EvoMSA Architecture

2.1.1 B4MSA

B4MSA[2] focus on multilingual sentiment analysis. For complete details of the model see (Tellez et al., 2017a,b). The core idea behind B4MSA is to tackle the sentiment analysis problem as a model selection problem, using a different view of the underlying combinatorial problem, i.e., B4MSA combines a bunch of different text tokenization, text transformations, weighting methods, and internally uses an SVM with a linear kernel to classify. Also, B4MSA takes advantage of several domain-specific particularities like emojis and emoticons and makes explicit handling of negation statements expressed in texts. Nonetheless, EvoMSA avoids the sophisticated use of B4MSA fixing the model for each language in favor of performing an optimization process at the level of the decision functions of several models (Miranda-Jiménez et al., 2017). Table 1 shows text transformation parameters used in our system for English and Spanish languages.

2.1.2 EvoDAG

EvoDAG[3] (Graff et al., 2016, 2017) is a Genetic Programming system specifically tailored to tackle classification and regression problems on very high dimensional vector spaces and large datasets. In particular, EvoDAG uses the principles of Darwinian evolution to create models represented as a directed acyclic graph (DAG). An EvoDAG model

[1]https://github.com/INGEOTEC/EvoMSA

[2]https://github.com/INGEOTEC/b4msa

[3]https://github.com/mgraffg/EvoDAG

has three distinct node's types; the inputs nodes, that as expected received the independent variables, the output node that corresponds to the label, and the inner nodes are the different numerical functions such as sum, product, sin, cos, max, and min, among others. Due to lack of space, we refer the reader to (Graff et al., 2016) where EvoDAG is broadly described.

3 Experimental Settings

As we mentioned, to determine the best configuration of parameters for text modeling, B4MSA integrates a hyper-parameter optimization phase that ensures the performance of the classifier based on the training data. The text modeling parameters for B4MSA were set for all process as we show in Table 1 for English and Spanish languages. A text transformation feature could be binary (yes/no) or ternary (group/delete/none) option. Tokenizers denote how texts must be split after applying the process of each text transformation to texts. Tokenizers generate text chunks in a range of lengths, all tokens generated are part of the text representation. B4MSA allows selecting tokenizers based on n-words, $q-$grams, and skip-grams, in any combination. We call n-words to the popular word n-grams; in particular, we allow to use any combination of unigrams, bigrams, and trigrams. Also, the configuration space allows selecting any combination of character, q-grams, for $q = 1$ to 9. Finally, we allow skip-grams such as $(3, 1)$ and $(2, 2)$, three words separated by one word (gap), and two words separated by two gaps.

We use two baselines B4MSA and the FastText's classifier (Bojanowski et al., 2016) for both contests. FastText represents sentences with a weighted bag of words, and each word is represented as a bag of character n-gram to create text vectors based on word embeddings. Our custom FastText searches automatically the best parameters, e.g., for OffensEval with parameters such as window $size = 9$, learning $rate = 0.01$, $epochs = 10$, size of word $vectors = 10$, minimum and maximum length of character n-grams, 2 and 5, respectively; and some other preprocessing steps such as group numbers and reduce duplicated characters.

3.1 Datasets

SemEval contests provide datasets to train systems for each task. Table 2 presents the data distribution of the HatEval dataset. *Hate* class (HATE) defines tweets that convey hate against immigrants or women; its complement correspond to these messages not having hate content (NO-H), aggressive (AGGR) and no aggressive (NO-A), and target harassed (TARG) as individual and group.

Text transformation	**English (HE)**	**Spanish (HE)**	**English (OE)**
remove diacritics	yes	yes	yes
remove duplicates	yes	yes	yes
remove punctuation	yes	yes	yes
emoticons	group	group	group
lowercase	yes	yes	false
numbers	group	delete	delete
urls	group	none	group
users	group	group	none
hashtags	none	none	none
entities	none	none	none
stemming	yes	yes	yes
Term weighting			
TF-IDF	yes	yes	yes
Entropy	no	no	no
Tokenizers			
n-words	$\{1, 3\}$	$\{1, 2\}$	$\{1, 2, 3\}$
q-grams	$\{3, 5, 9\}$	$\{2, 5, 7, 9\}$	$\{3, 4, 5, 9\}$
skip-grams	$\{(3, 1)\}$	$\{(3, 1)\}$	$\{(3, 1), (2, 2)\}$

Table 1: Example of set of configurations for text modeling, HatEval (HE), and OffensEval (OE)

Table 3 shows the OffensEval data distribution. In Task A, class OFF defines tweets that have offenses or insults; while class NOT describes tweets with no offensive content. Messages with labeled as TIN contain an insult or threat to an entity; UNT defines the opposite. Group (GRP), individual (IND), and others (OTH) classes contain the target of the offensive messages. The OffensEval collection is described in detail in Zampieri et al. (2019a).

DataSet	**NO-H**	**HATE**	**NO-A**	**AGGR**	**NO-T**	**TARG**
training (English)	5,217	3,783	7,441	1,559	7,659	1,341

development	243	77	34	39	4	30	2

Table 3: Statistics of OffensEval datasets for English language.

4 Results

We present the results of our approaches for HatEval contest in Table 4 and Table 5. We performed our experimentation on the development dataset provided by HateEval. Table 4 shows the results of task A, given a tweet is hateful or not hateful for English and Spanish languages. In the case of task A, the macro-F1 score is used to measure the performance. Table 5 shows the results of task B, classify tweets as aggressive or not aggressive and the target harassed.

In the case of OffenseEval, Table 6 shows the results for the three task proposed offensive language identification (Task A), categorization of offense types (Task B), and offense target identification (Task C).

We present three system configurations for both tasks. B4MSA uses only the training data provided by the contest as the knowledge base to classify texts, i.e., B4MSA is our baseline, but it is also its outcome is an additional input for our more sophisticated classifier (EvoMSA). FastText generates word embeddings from the provided dataset. We do not use pre-training vectors, using pre-trained vectors did not provide any significant improvement in this case, but increased the complexity of the models and the processing pipeline. EvoMSA (Graff et al., 2018a) combines, using EvoDAG, the output of different text models such as B4MSA, a lexicon-based model, an emoji-space model, and FastText.

As we can see the performance in all results Tables, EvoMSA is systematically better than our other systems; under these circumstances, we decided to use EvoMSA firstly in the evaluation phase. Following the rules of HatEval, only the last run would be valid; therefore we used EvoMSA for this chance. In the case of OffensEval, up to three predictions were allowed on the test dataset, but only the best one was compared with other systems. As we can see, Table 6 shows the performance of our three systems on gold standards; EvoMSA stays ahead in all tasks including the baselines from the contest. The table also shows the performance of two baselines, "All NOT" and "ALL OFF", that correspond to labeling all tweets as NOT or OFF, respectively; similarly, the rest of the tasks have baselines for "All TIN", "All UNT", "All GRP", "ALL IND", and "ALL OTH" labeling strategies.

System	F1	Accuracy

FastText	0.822	0.801
Performance on gold standard		
EvoMSA	0.710	0.710

Table 4: Results of HateEval: Task A

5 Conclusions

In this paper was presented our solution for HatEval and OffensEval, two campaigns of SemEval 2019. We show the competitiveness of our approach in both training and test phases. EvoMSA and B4MSA are designed to be multilingual and language and domain independent as much as possible. For the training step, we used extra knowledge from datasets out of any specific emotion of the contests, but categories or emotions related to sentiment-analysis information. Our solution performs well in Spanish and some task for English languages; however, there is room for further improvements in performance for tasks in English language using another sort of knowledge for specific domains.

Abstract

In this paper, we describe our submissions to SemEval-2019 task 6 contest. We tackled all three sub-tasks in this task "OffensEval - Identifying and Categorizing Offensive Language in Social Media". In our system called JCTICOL (Jerusalem College of Technology Identifies and Categorizes Offensive Language), we applied various supervised ML methods. We applied various combinations of word/character n-gram features using the TF-IDF scheme. In addition, we applied various combinations of seven basic preprocessing methods. Our best submission, an RNN model was ranked at the 25th position out of 65 submissions for the most complex sub-task (C).

1 Introduction

Offensive language is frequent in social media. For instance, ScanSafe's monthly "Global Threat Report" reported that up to 80% of blogs contained offensive contents and 74% included porn in the format of the image, video, or offensive language (Cheng, 2007). There are people that take advantage of the perceived anonymity of computer-mediated communication, using this to write in behavior that many of them would not consider in real life.

Online news and social networking services, online communities, social media platforms, and various computer companies have been investing a lot of effort, time and money to cope with offensive language in order to prevent abusive behavior.

Computational methods are among the most effective strategies to identify various types of aggression, offense, and hate speech in user-generated content (e.g., comments, microblogs, posts, and tweets). Detection of offensive language has been investigated in recent years in various studies (Waseem et al. 2017; Davidson et al., 2017, Malmasi and Zampieri, 2018, Kumar et al. 2018) and various workshops such as ALW (Abusive Language Online) and TRAC (Trolling, Aggression, and Cyberbullying).

In this paper, we describe our submissions to SemEval-2019 task 6 contest. In Task-6, OffensEval, there are three different sub-tasks. Sub-task A deals with offensive language identification. Sub-task B deals with the automatic categorization of offense types. Sub-task C deals with offense target identification.

The report of the OffensEval task is described in Zampieri et al. (2019A) and the description of the OLID dataset that was used for the competition is in Zampieri et al. (2019B).

The structure of the rest of the paper is as follows. Section 2 discusses work related to offensive language in social media, tweet classification, and data preprocessing. Section 3 presents, in general, the task description. In Section 4, we describe the submitted models and their experimental results. Section 6 summarizes and suggests ideas for future research.

2 Background

2.1 Offensive Language in Social Media

In recent years, there has been an increase in the number of studies dealing with Offensive language in social media. Nobata et al. (2016) developed a machine learning based method to detect hate speech on online user comments from two domains. They also built a corpus of user comments annotated accordingly to three subcategories (hate speech, derogatory, profanity). Waseem and Hovy (2016) introduced a list of criteria founded in critical race theory and used them to label a publicly available corpus of more than 16k tweets with tags about both racial and sexist offenses.

A survey on hate speech detection is presented by Schmidt and Wiegand (2017). The authors introduced various NLP methods that were developed in order to detect hate speech. Davidson et al. (2017) presented a multi-class classifier to distinguish between three categories: hate speech, offensive language, and none of these two. The analysis of the predictions and the errors show when we can reliably separate hate speech from other offensive language and when this differentiation is more difficult. Anzovino et al. (2018) built a labelled corpus containing 2,227 misogynous (hate speech against women) tweets and no-misogynous tweets and explored various NLP features and ML models for detecting and classifying misogynistic language.

2.2 Tweet Classification

Sriram et al. (2010) presented a new classification model that uses a small set of domain-specific features extracted from the author"s profile and text. Experimental results showed that the classification accuracy of their model is better than the classification accuracy of the traditional Bag-Of-Words model. Batool et al. (2013) introduced a system that extracts knowledge from tweets and then classifies the tweets based on the semantics of knowledge contained in them. For avoiding information loss, knowledge enhancer is applied that enhances the knowledge extraction process from the collected tweets.

Stance classification of tweets was investigated by HaCohen-Kerner et al. (2017). Given test datasets of tweets from five various topics, they classified the stance of the tweet authors as either in FAVOR of the target, AGAINST it, or NONE. Their algorithm used a few tens of features mainly character-based features where most of them are skip char ngram features. The experimental results showed that this algorithm significantly outperforms the traditional 'bag-of-words' model.

2.3 Data preprocessing

Data preprocessing is an important step in data mining (DM) and ML processes. In tweets, it is common to find typos, emojis, slang, HTML tags, spelling mistakes, irrelevant and redundant information. Analyzing data that has not been carefully cleaned or pre-processed might lead to misleading results.

Not all of the preprocessing types are considered effective in the text classification community. For instance, Forman (2003), in his study on feature selection metrics for text classification, claimed that stop words occurring frequently and are ambiguous and therefore should be removed, However, HaCohen-Kerner et al. (2008) demonstrated that the use of word unigrams including stop words lead to improved text classification results compared to the results obtained using word unigrams excluding stop words in the domain of Hebrew-Aramaic Jewish law documents.

In our system, we applied various combinations of seven basic preprocessing types: C - spelling Correction[1] using a dictionary of containing 479k English words[2], L – converting to Lowercase letters, P – Punctuation removal, S – Stopwords Removal, R – Repeated characters removal, T – sTemming, and M - leMmatizion) in order to employ the best combination.

3 The Competition of Task 6

SemEval-2019 Task 6 consists of three subtasks:

1. Subtask A: Given a tweet, predict whether it contains offensive language or a targeted (veiled or direct) offense or it does not contain offense or profanity.
2. Subtask B: Given a tweet containing offensive language, predict whether it contains an insult or threat to an individual, a group, or others, or contains non targeted profanity and swearing.
3. Subtask C: Given a tweet containing an insult or threat, predict whether the target is an individual or a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or something else, or does not belong to any of the previous two categories (e.g., an organization).

The dataset of Task 6 contains tweets that were annotated using crowdsourcing. The dataset of sub-task A contains 13,240 tweets: 4,404 OFF (Offensive language) tweets (about 33%) and 8,836 NOT (Not Offensive) tweets (about 67%).

[1] https://github.com/phatpiglet/autocorrec.

[2] https://github.com/dwyl/english-words.

The dataset of sub-task B contains 4,400 offensive tweets: 3,876 TIN (Targeted Insult) tweets (about 88%) and 524 UNT (Untargeted) tweets. The dataset of sub-task C contains 3,876 tweets: 2,407 IND (Individual) tweets (about 62%), 1,074 GRP (Group) tweets (about 28%), and 395 OTH (Other) (about 10%). The test data of sub-tasks A, B, and C contain 860, 240, and 213 unlabeled tweets, respectively.

4 The Submitted Models and Experimental Results

We have submitted 17 models: 6 models to task 6-A, 6 models to task 6-B, and 5 models to task 6-C. We applied the Python module called Scikit-learn (Pedregosa et al., 2011) using the TF-IDF scheme called TfidfTransformer[3] and we applied various supervised ML methods with various numbers of n-gram features, skip word/char n-grams (HaCohen-Kerner et al., 2017) and combinations of pre-processing types.

While all teams' submissions in all three sub-tasks of task 6 were ranked according to their F-Measure scores, we were wrong in all these sub-tasks in the sense that we submitted models according to their accuracy scores.

Most of our submitted models were RNN models. Each RNN model was a bidirectional RNN with 4 hidden layers, with different numbers of LSTMs, values of Dropout, and number of vectors of GloVe (Pennington et al., 2014). Additional explanations to our RNN models, which are given in the next paragraphs are mainly based on the explanations given by Nikolai Janakiev in "Practical Text Classification with Python and Keras"[4].

We used the Tokenizer utility class, which converts a text corpus into a list of integers. Each integer maps to a value in a dictionary that encodes the entire corpus, with the dictionary's keys being the vocabulary terms themselves.

We chose to use the Twitter-aware tokenizer, designed to be flexible and easy to adapt to new domains and tasks (e.g., for tweet processing).

We used the word embeddings method. This method represents words as dense word vectors, which are trained, unlike the one-hot encoding which is hardcoded. The word embeddings map the statistical structure of the language used in the corpus. Their aim is to map semantic meaning into a geometric space. This geometric space is then called the embedding space. This method would map semantically similar words close on the embedding space.

There are two options to get such a word embedding. One way is to train the word embeddings during the training of our neural network. The other way is to use a precomputed embedding space that utilizes a larger corpus. Among the most popular methods are GloVe (Global Vectors for Word Representation) developed by the Stanford NLP Group (Pennington et al., 2014) and Word2Vec developed by Mikolov et al. (2013).

GloVe applies a co-occurrence matrix and by using matrix factorization while Word2Vec applies neural networks. Word2Vec is more accurate and GloVe is faster to compute. We used the GloVe method for our model.

4.1 Results of Task 6-A

Table 1 presents the main characteristics and results of our six submitted models to task 6-A. The models are presented in descending order according to their F-measure score on the test set.

Table 1: Results of our 6 models in task-A.

The main results and conclusions that can be derived from Table 1 are as follows:

- The best submitted model is an RNN model with F-measure of 0.74 and accuracy of 0.81 obtaining the 43rd position out of 103 submissions.
- The best combination of N-gram features for this model contains 5000 word unigrams and 100 word bigrams (without any word trigrams).
- In addition, this model used 512 LSTMs and in its FC layer, it used seven different ML methods.
- This model did not use any combination of pre-processing types.
- Simpler RNN models and non RNN models e.g. the SVM-linear model (last row in Table 1) as well as other models that were tested but not submitted, were less successful.

4.2 Results of Task 6-B

Table 2 presents the main characteristics and results of our six submitted models to task 6-B. The models are presented in descending order according to their F-measure score on the test set. It should be noted that the train set for sub-task b contains imbalanced sets of tweets. The number of tweets classified as UNT is 524 (about 12%) while the number of tweets classified as TIN is 3,876 (about 88%). The main results and conclusions that can be derived from Table 2 are as follows:

- Our best submitted model is a SVC - support vector classifier with F-measure of 0.49 and accuracy of 0.85 obtaining the 62nd position

[5] DFS – Decision Function Shape.

out of 75 submissions. This model used a combination of the MPR pre-processing types.

- This model used 10,000 char trigrams where for each character trigram we allow up to a maximum of 7 skipped characters in-between the chosen ones.
- As mentioned before, while the submitted models were ranked according to their F-Measure results, we were wrong and submit models according to their accuracy results.

5 Conclusions and Future Research

In this paper, we describe our submissions to three sub-tasks of Task 6 of SemEval-2019 contest. Our system JCTICOL (Jerusalem College of Technology Identifies and Categorizes Offensive Language) includes 17 formal submissions: 6 for sub-task A, 6 for sub-task B, and 5 for sub-task C. We used the TF-IDF scheme and we applied various supervised ML methods with various numbers of n-gram features and combinations of pre-processing types. Our best submission was ranked at the 25th position out of 65 submissions for the most complex sub-task (C).

Future research proposals that may contribute to better classification are as follows. (1) Using additional feature sets such as stylistic feature sets (HaCohen-Kerner et al., 2010B) and keyphrases that can be extracted from the text corpora (HaCohen-Kerner et al., 2007); (2) Using acronym disambiguation (e.g., HaCohen-Kerner et al., 2010A), i.e., selecting the correct long form of the acronym depending on its context will enrich the tweet's text; and (3) Using other deep learning models.

Acknowledgments

This research was partially funded by the Jerusalem College of Technology, Lev Academic Center.

Abstract

In this paper, the team jhan014 presents two methods to identify and categorize the offensive language in Twitter. In the first method, we develop a deep neural network consisting of bidirectional recurrent layers with Gated Recurrent Unit (GRU) cells and fully connected layers. In the second method, we establish a probabilistic model, modified sentence offensiveness calculation (MSOC) to evaluate the sentence offensiveness level and target level according to different sub-tasks. Based on task results, We evaluate the performance of each method based on F1 score and analyze the advantages and disadvantages of these two methods with the type I error and type II error. In conclusion, deep neural network behaves well in all subtasks but has more type I error and fails to categorize subclasses with minor data or less character, while MSOC model does better in target categorizing but has more type II error in offensive identifying.

1 Introduction

With the popularity of social media like Twitter, offensive language has become a serious problem(Zampieri et al., 2019b) on these media platforms. People have to face with abusive behavior from others in social media from time to time. To solve this problem, finding a method to identify and categorize offensive languages is an urgent need.

In this paper, two different methods, deep learning method and modified sentence offensiveness calculation method, are used to categorize the type and target of offensive language and the difference of results are revealed and analyzed.

2 Related Work

Deep learning method: Deep learning methods are widely used in natural language processing (Liu et al., 2016). Models like Recursive neural network are commonly used to identify if a sentence contain certain emotion. In our work, a deep neural network with GRU layers and all connection layers is built.

Offensiveness Content Filtering: Offensive language targets can be understood through the sentence structure (Silva et al., 2016) or lexical analysis (ElSherief et al., 2018). We take both sentence structure and the offensiveness level of words into consideration. Furthermore, we also concentrate on the special punctuation (like @ and #) in online social media.

3 Methodology and Data

3.1 Deep Neural Network

In the offensive language detection task, we developed a deep neural network based system with binary cross-entropy output.

System Design The system consists of bidirectional recurrent layers with Gated Recurrent Unit(GRU) cells and fully connected layers (Chung et al., 2014). Because the output of the last time-step is used as the embedding of a sentence, we conduct zero padding in the beginning of each sequence to construct the feature matrix. The system architecture is shown in Table 1.

Optimization Steps Parameters in both RNN layers and Dense layers are initialized by Xiaver initialization method (Glorot and Bengio, 2010). The model is optimized by Adam optimization method with 0.01 learning rate. While training the

Layer Name	Output Dimension	Parameter #
Embedding	100	1000000
GRU	128	63360
GRU	128	74112
GRU	128	74112
GRU	128	74112
Dense	256	33024
Dense	128	32896
Dense	64	8256
Dense	32	2080
Dense	2	66

Table 1: System Architecture

neural network, an early stopping method with 2-iteration tolerance is applied to monitor the process. Once the early stopping method is triggered, we manually lower the learning rate by $1/10$ to overcome the vibration and search for a smaller minimum loss.

3.2 Modified Sentence Offensiveness Calculation

Based on the sentence offensiveness calculation method in this paper(Chen et al., 2012), we develop a model to evaluate the sentence offensiveness.

Offensiveness Dictionary Construction We can always find pejoratives, profanities, or obscenities in offensive twitters. Strongly profanities are always undoubtedly offensive when at users or related to some topics (like #) directly; but there are many other weakly pejoratives and obscenities that may also be offensive.
Word offensiveness is defined(Chen et al., 2012) as: for each offensive word, w, its offensiveness

$$O_w = \begin{cases} a_1 & \text{if w is a strongly offensive word} \\ a_2 & \text{if w is a weakly offensive word} \\ 0 & \text{otherwise} \end{cases}$$

where $0 < a_1 < a_2 < 1$, for the offensiveness of strongly offensive words is higher than weakly offensive words.

Syntactic Intensifier Detection We also built the syntactic features by an intensifier(Zhang et al., 2009). In a sentence, words syntactically related to offensive word, w, are categorized in an intensifier set, $i_w = \{c_1, \ldots, c_k\}$, for each word c_j, its intensify value, d_j, is defined as

$$d_j = \begin{cases} b_1 & \text{if } \mathrm{c_j} \text{ is @ or \#} \\ b_2 & \text{if } \mathrm{c_j} \text{ is an offensive word} \\ 1 & \text{otherwise} \end{cases}$$

where $0 < b_1 < b_2 < 1$, for offensive words used to describe users are more offensive than the words used to describe other offensive words. Thus, the value of intensifier, I_w, for offensive word, w, can be calculated as $\sum_{j=1}^{k} d_j$.

Sentence Level Offensiveness Value Consequently, the offensiveness value of sentence, s, becomes a determined linear combination of words' offensiveness

$$O_s = \sum O_w I_w$$

From the training data, we learn two thresholds θ_1, θ_2. For each sentence, s, we apply these two values

$$P(s = OFF) = \begin{cases} 1 & \text{if } \mathrm{O_s} > \theta_2 \\ \frac{O_s - \theta_1}{\theta_2 - \theta_1} & \text{if } \theta_1 \le \mathrm{O_s} \le \theta_2 \\ 0 & \text{if } \mathrm{O_s} < \theta_1 \end{cases}$$

If the offensiveness value is greater than θ_1, the language will be seen as offensive, while if it is smaller than θ_2 then the language will be not offensive. Otherwise, the result will follow a probabilistic distribution.

When solving other sub-tasks, this method can also be used with changing the dictionary and redefine the target words list.

3.3 Data

We use the datasets in Zampieri et al. (2019a) and apply following methods to preprocess or transform the data.

3.3.1 Preprocessing

The raw twitter data is preprocessed by a data pipeline. All the information which has nothing to do with word vectors such as stop words and emojis are stripped and the output of the pipeline are lower-case stemmed word sequencies.

3.3.2 Word Embedding

A word embedding step is applied to transform the text into numerics for deep neural networks. 100-dimensional Global Vectors(GloVe) word embeddings trained with twitter data are applied in this study considering the trade-off between performance and efficiency of the training process (Pennington et al., 2014). We also explore embedding layers in this study and the pretrained embedding out-performs the embedding layer because of the immense amount of information brought by GloVe's training set with 27-billion tweets.

4 Results

4.1 Sub-task A - Offensive language identification

When identifying whether a sentence is offensive or not, two methods show great difference while the accuracy and F1-score are close (see Table 2). In RNN method, there is more type I error (see Figure 1) which means the model classifies some non-offensive sentences as offensive ones. Since origin dataset is unbalanced, the neural network may not have enough non-offensive training examples to learn. Consequently, it cannot catch the feature and structure of the non-offensive sentences.
In MSOC method, this problem is improved. Due to fixed human defined offensiveness dictionary, the non-offensive sentence is not easily misclassified as offensive one. However, since there are still some offensive words appeared in dataset that are not defined in the dictionary, there is still much type II error (see Figure 2).

System	F1 (macro)	Accuracy
All NOT	0.4189	0.7209
All OFF	0.2182	0.2790
RNN	0.6899	0.7395
MSOC	0.6761	0.7895

Table 2: Results for Sub-task A.

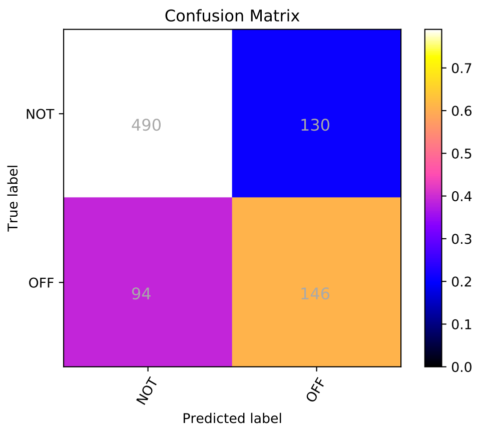

Figure 1: Sub-task A,RNN method

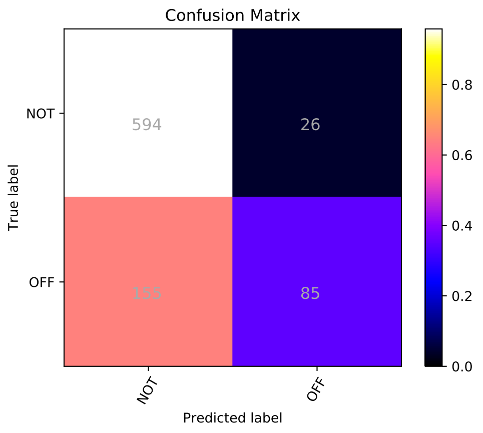

Figure 2: Sub-task A,MSOC method

4.2 Sub-task B - Automatic categorization of offense types

The behavior of MSOC method defeats RNN method from all aspects (see Table 3 and Figure 3, 4) when categorizing the types of offense. This is because usually targeted offensive language have different sentence structure with untargetted ones, this make it a really high accuracy approach to categorize offensive type. In details, a target sentence always contains third-person pronouns like him her it them. And in most target tweets, the sentence has some special punctuation like @ and also related to some hot topics #.

System	F1 (macro)	Accuracy
All TIN	0.4702	0.8875
All UNT	0.1011	0.1125
RNN	0.6153	0.8667
MSOC	0.7545	0.925

Table 3: Results for Sub-task B.

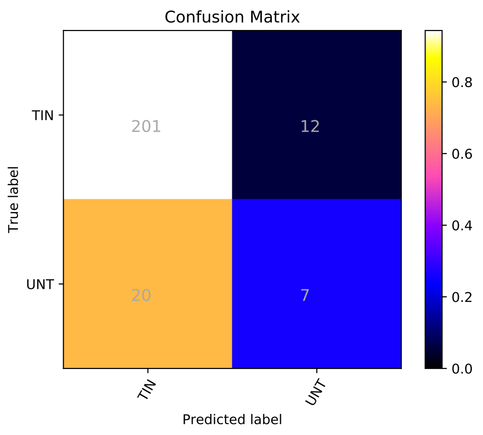

Figure 3: Sub-task B,RNN method

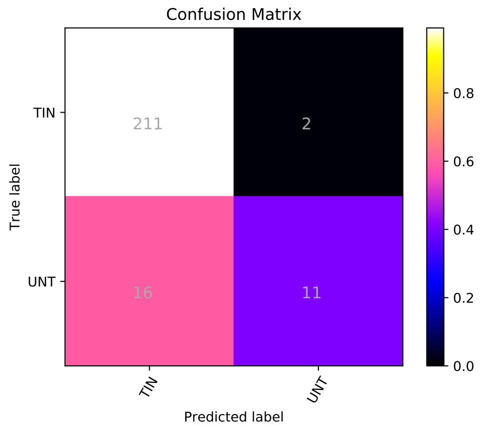

Figure 4: Sub-task B,MSOC method

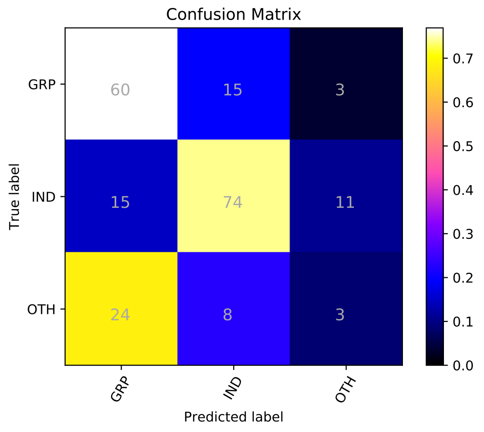

Figure 6: Sub-task C,MSOC method

4.3 Sub-task C - Offense target identification

In offense target identification, RNN method, although has the similar accuracy and F1 score with MSOC method (see Table 4), fails to classify any of the test sentences into 'OTH' class.(see Figure 5) The main reason of this result is 'OTH' class is not as characteristic as other two classes and the partition of this class is the smallest as well. On contrast, MSOC method can successfully classify some test sentences in 'OTH' class. (see Figure 6) This may contribute to the predefined dictionary and sentence structure.

System	F1 (macro)	Accuracy
All GRP	0.1787	0.3662
All IND	0.2130	0.4695
All OTH	0.0941	0.1643
MSOC	0.5149	0.6432
RNN	0.4630	0.6432

Table 4: Results for Sub-task C.

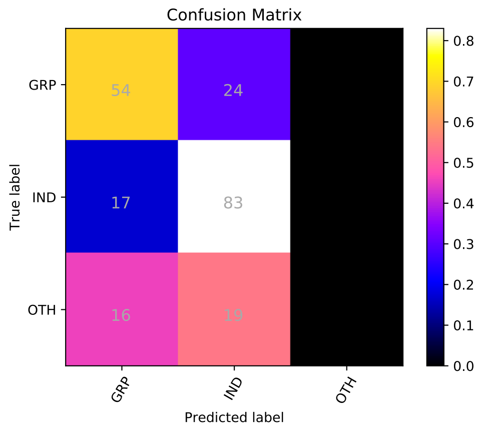

Figure 5: Sub-task C,RNN method

5 Conclusion

RNN is an easy-implemented and high-efficiency method to solve classification problem in natural language processing. In this case, RNN shows an acceptable result but it has many obvious drawbacks. Such as high recall rate when handling unbalanced data, fail to classify certain class if the class is lack of obvious character. The MSOC mehod, on the contrary, can give classification result of same quality. Even though MSOC cannot improve the accuracy or the F1 score of classification to a great extend, we believe we can combine this method with deep learning method to get a better result in similar problems in the future.

cvaca@fiec.espol.edu.ec

Abstract

In this paper, we propose the use of a Convolutional Neural Network (CNN) to identify offensive tweets. We use an end-to-end model (i.e., no preprocessing) and fine-tune pre-trained embeddings (FastText) during training for learning words' representation. We compare the proposed CNN model to a baseline model, such as Linear Regression, and several neural models. The results show that CNN outperforms other models, and stands as a simple but strong baseline in comparison to other systems submitted to the Shared Task.

1 Introduction

The fast growth of online social networks (OSNs) has provided a medium for users to express their ideas and opinions about any topic. However, some users post offensive content which may deter other users from engaging in online discussions. Despite the tools provided by some OSNs to *block* other users and *report* offensive content, the manual verification of these events are limited in scale and costs due to a large number of malicious events performed by users or bots. Therefore, it is critical to developing automated tools to moderate the content that are robust to ambiguity, sarcasm, and adversarial attacks (Fortuna and Nunes, 2018).

Offensive language detection is an active research area, and several research efforts aim to contribute datasets, propose taxonomies, and improve current models to identify offensive content. In this direction, Zampieri et al. (2019b) proposed a shared task for Identifying and Categorizing Offensive Language in Social Media. The shared task is composed of the following subtasks: **a)** Offensive language identification, **b)** Automatic categorization of offense types, and **c)** Offense target identification.

tweet	Subtask		
	A	B	C
If the tournament of shit ain't on here...	OFF	UNT	-
He is so full of BS!	OFF	TIN	IND
swear niggas make me wanna turn this phone off	OFF	TIN	GRP
Kick the absolute shite out of the car.	OFF	TIN	OTH

Table 1: Examples of Offensive Tweets in the dataset.

Table 1 shows some examples in the dataset of the shared task, and the labels in each of the subtasks. The labels indicate if the tweet is Offensive (OFF) and if it is an untargeted (UNT) or targeted (TIN) offense. The targets of the offensive tweets are individual (IND), group (GRP), other (OTH). This paper contributes specifically to the subtask A in the shared task.

The unstructured and noisy nature of user-generated content on OSNs poses a challenge for classification models. Traditional approaches use a sparse representation for text data, such as the bag of words (BOW) or TF-IDF (Manning et al., 2008).

We propose a model based on Convolutional Neural Networks (CNN) to identify and categorize offensive language on tweets. The learning representation relies on FastText pre-trained word embeddings (Mikolov et al., 2018). Although, this paper focus only on the first subtask, it can be extended to learn the other subtasks.

The rest of the paper describes related work in section 2. Then, we explain in detail our proposed model in section 3, and section 4 shows the results. Finally, we outline the conclusions and future work in section 5.

2 Related Work

Previous work has studied several types of online misbehavior such as aggression (Cheng et al., 2015), cyberbullying (Pieschl et al., 2015), hate speech (Saleem et al., 2017), offensive, and abusive language identification (Waseem et al., 2017).

The major challenge in studying online misbehavior is the several forms it can take and the lack of a standard definition (Saleem et al., 2017). (Waseem et al., 2017) proposed a typology of abusive language sub-tasks. Similarly, a taxonomy proposed to detect toxic messages on Wikipedia discussion pages demonstrated the impact on community health both on and offline (Wulczyn et al., 2017). Wikimedia Foundation found that 54% of contributors decreased participation in the activities when they suffer harassment [1]. The same impact could happen on social media when aggression and offensive language deter other users from engaging in online discussions.

Previous works introduced several datasets like the Internet Argument Corpus (Walker et al., 2012) and the "Hate Speech Twitter Annotations" corpus (Waseem and Hovy, 2016). Most datasets are small in comparison to the Wikipedia dataset (Wulczyn et al., 2017), which enables to train neural models on a large-scale dataset.

In the multilingual aspect, several studies tackle languages other than English like Chinese (Su et al., 2017), Slovene (Fišer et al., 2017), and related shared tasks such as GermEval (Wiegand et al., 2018). However, the studies tackle each language individually due to the difficulty for automated systems to handle multiple languages as idiomatic expressions are dependent on the location and culture. Recent research on identifying profanity vs. hate speech highlighted the challenges of distinguishing between profanity and threatening language which may not contain profane language (Malmasi and Zampieri, 2018).

Recent surveys by (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018) summarizes the taxonomies and methods proposed for detecting abusive language. Also, recent work by (Davidson et al., 2017) introduces the Hate Speech Detection dataset used in several studies (Malmasi and Zampieri, 2017; ElSherief et al., 2018; Zhang et al., 2018).

3 Methodology

The model architecture, shown in Figure 1, is a slight variant of the CNN architecture proposed by Kim (2014). We define $\mathbf{x}_i \in \mathbb{R}^k$ as the k-dimensional word vector (i.e., word embeddings) corresponding to the i-th word in the tweets. We padded the tweets to make all equal length, and represent a tweet of length n as

$$\mathbf{x}_{1:n} = \mathbf{x}_1 \oplus \mathbf{x}_2 \oplus \ldots \oplus \mathbf{x}_n, \tag{1}$$

where $\oplus$ is the concatenation operator. In general, we refer $\mathbf{x}_{i:i+j}$ to the concatenation of words $\mathbf{x}_i, \mathbf{x}_{i+1}, \ldots, \mathbf{x}_{i+j}$. Then, we apply a convolution operation that uses a *filter* $\mathbf{w} \in \mathbb{R}^{hk}$, over a window of h words to produce a new feature. For example, we generate feature c_i from a window of words $\mathbf{x}_{i:i+h-1}$ by

$$c_i = f(\mathbf{w} \cdot \mathbf{x}_{i:i+h-1} + b). \tag{2}$$

We denote $b \in \mathbb{R}$ as the bias term and f as a RELU activation function defined as $f(x) = x^+ = \max(0, x)$, where x in the input to the neuron (Glorot et al., 2011) . The convolution layer applies the filter to each possible window of words in the sentence $\{\mathbf{x}_{1:h}, \mathbf{x}_{2:h+1}, \ldots, \mathbf{x}_{n-h+1:n}\}$ to produce a *feature map*

$$\mathbf{c} = [c_1, c_2, \ldots, c_{n-h+1}], \tag{3}$$

with $\mathbf{c} \in \mathbb{R}^{n-h+1}$. Then, we apply a max-over-time pooling operation over the feature map and take the maximum value $\hat{c} = \max\{\mathbf{c}\}$ as the feature corresponding to this particular filter. The goal is to capture the essential feature (the highest feature value) for the feature maps. The pooling scheme allows us to deal with variable sentence lengths.

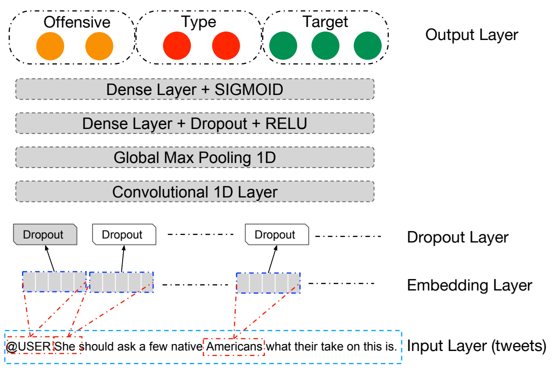

Figure 1: The CNN architecture used to identify offensive tweets using binary output layer.

We have described the process by which we extract *one* feature from *one* filter. The model uses multiple filters to obtain multiple features. These features feed a fully connected layer with a RELU activation function, and finally a sigmoid layer that outputs the probability distribution over labels.

For regularization, we employ a dropout layer with rate $r = 0.2$, constrained on l_2-norms of the weight vectors. We apply the dropout after the embeddings and the penultimate layer. Dropout prevents co-adaptation of hidden units by randomly dropping out (i.e., set to zero) a proportion of p of the hidden units during forward-backpropagation. That is, given the penultimate layer $\mathbf{z} = [\hat{c}_1, \ldots, \hat{c}_m]$ (note that here we have m filters), instead of using

$$y = \mathbf{w} \cdot \mathbf{z} + b \tag{4}$$

for output unit y in forward propagation, dropout uses

$$y = \mathbf{w} \cdot (\mathbf{z} \circ \mathbf{r}) + b, \tag{5}$$

where $\circ$ is the element-wise multiplication operator and $\mathbf{r} \in \mathbb{R}^m$ is a *masking* vector of Bernoulli random variables with probability p of being 1. Gradients are backpropagated only through the unmasked units. At test time, the learned weight vectors are scaled by p such that $\hat{\mathbf{w}} = p\mathbf{w}$, and $\hat{\mathbf{w}}$ is used (without dropout) to score unseen sentences. We additionally constrain l_2-norms of the weight vectors by rescaling $\mathbf{w}$ to have $||\mathbf{w}||_2 = s$ whenever $||\mathbf{w}||_2 > s$ after a gradient descent step.

4 Experiments

In this section, we describe the experimental settings and the results for the subtask A: identifying offensive tweets. We use the data provided in the shared task OffensEval described in Zampieri et al. (2019a). Table 2 describe the label distribution for each of the subtasks. We use the F_1 score as an evaluation metric for the models, and it is the official ranking metric for the shared task is macro-averaged F1.

Subtask A	tweets
NOT	8840
OFF	4400

Table 2: Distribution of the labels in the training dataset.

4.1 Embeddings

We evaluate the CNN model with several word embeddings such as: **a)** Random Uniform initialized, **b)** Word2Vec (Mikolov et al., 2013), and **c)** FastText (Mikolov et al., 2018).

During training, we fine-tune the embedding layer for each type of embeddings. Table 3 shows that FastText embeddings provide the best results, and we use it in further experiments.

Embedding	**Precision**	**Recall**	F_1
Random	71.69	69.47	70.23
Word2Vec	70.67	70.15	70.38
FastText	**71.76**	**71.97**	**71.86**

Table 3: Evaluation of different embeddings.

4.2 Models

We compare the CNN model against baseline models such.

Logistic Regression (LR) with *liblinear* solver and *class weight* to account for the imbalance of the labels.

FastText as a simple and efficient baseline for text classification, and often on par with deep learning classifiers regarding the accuracy but orders of magnitude faster for training and evaluation (Joulin et al., 2016).

LSTM in its vanilla implementation (Tang et al., 2015), with one LSTM layer after the Embeddings Layer.

Bi-LSTM implements a bi-directional LSTM architecture (Zhou et al., 2016).

Table 4 shows the performance of cross-validation data for the proposed CNN model and the baseline models. For evaluation purposes, we split the training dataset in 80% for training subset and 20% testing subset. We use k fold cross validation ($k = 10$) on the training subset. The CNN model outperforms other models in detecting Offensive Tweets and the overall Macro F_1 but detecting Not Offensive tweets works better with Bi-LSTM. We found that the non-neural LR model outperforms neural models such as FastText and LSTM. Bi-LSTM and CNN performance

	Not Offensive			Offensive			Macro		
Model	Precision	Recall	F_1	Precision	Recall	F_1	Precision	Recall	F_1
LR	81.80	75.90	78.74	58.27	66.59	62.15	70.03	71.24	70.45
CNN	81.33	80.50	80.91	62.18	63.44	**62.81**	71.76	71.97	**71.86**
LSTM	77.73	78.97	78.34	57.03	55.23	56.11	67.38	67.10	67.23
Bi-LSTM	80.68	81.92	**81.30**	63.11	61.19	62.14	71.90	71.56	71.72
FastText	77.87	79.02	78.44	57.24	55.57	56.39	67.56	67.30	67.42

Table 4: Benchmark of supervised learning models. CNN yields the best performance based on the metric F_1.

are on pair, and further evaluation of the hyper-parameters (e.g., number of layers/neurons, activation functions) is required to determine which of them performs better.

Table 5 show the results in the shared task evaluated on the testing dataset for subtask A. We include a random baseline generated by assigning the same labels for all instances. For example, ”All OFF” in sub-task A represents the performance of a system that labels everything as offensive. The CNN model outperforms by a large margin the random baseline.

System	F_1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
CNN	**0.7591**	**0.8105**

Table 5: Results for Sub-task A using CNN model compared to simple baseline.

Figure 2 shows the confusion matrix for the results with our CNN model. Due to the imbalance in the labels, the False Negatives in the results affects by a large margin the F_1 macro score.

5 Conclusion

In this paper, we proposed a neural model based on Convolutional Neural Networks to identify and categorize offensive tweets on social media. The model outperforms baseline models and other Sequential Models such as LSTM and Bi-LSTM. The reason CNN perform better than sequential models could be due to the noisy and unstructured form of the tweets.

In future work, we plan to use several variations of CNN such as multi-channel and multi-view architectures. Also, we will use recent advances in learning representations based on deep contextualized embeddings such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018).

Abstract

This paper describes our system submissions as part of our participation (team name: JU_ETCE_17_21) in the SemEval 2019 shared task 6: "OffensEval: Identifying and Categorizing Offensive Language in Social Media". We participated in all the three sub-tasks: i) Sub-task A: offensive language identification, ii) Sub-task B: automatic categorization of offense types, and iii) Sub-task C: offense target identification. We employed machine learning as well as deep learning approaches for the sub-tasks. We employed Convolutional Neural Network (CNN) and Recursive Neural Network (RNN) Long Short-Term Memory (LSTM) with pre-trained word embeddings. We used both word2vec and Glove pre-trained word embeddings. We obtained the best F1-score using CNN based model for sub-task A, LSTM based model for sub-task B and Logistic Regression based model for sub-task C. Our best submissions achieved 0.7844, 0.5459 and 0.48 F1-scores for sub-task A, sub-task B and sub-task C respectively.

1 Introduction

Today, very large amounts of information are available in online documents. As part of the effort to better organize this information for users, researchers have been actively investigating the problem of automatic text categorization. Tweets are short length pieces of text, usually written in informal style that contain abbreviations, misspellings and creative syntax (like emoticons, hashtags etc). In this paper we show that our multi-view ensemble approach that leverages simple representations of texts may achieve good results in the task of message polarity classification. We used different machine learning algorithm and neural network approaches for all the tasks which are explained in the subsequent sections. The paper is organized as follows: Section 2 lists down the related work and Section 3 describes our approach. Section 4 presents the experiments, results on the development set and discussion about the confusion matrix and Section 5 details about the observation. Section 6 concludes the paper with possible future work.

OffensEval@SemEval-2019 shared task description, data and results are described in the overview paper (Zampieri et al., 2019b).

[*]These two authors have contributed equally

2 Related Work

Papers published in the last two years include the surveys by (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018), the paper by (Davidson et al., 2017) presenting the Hate Speech Detection dataset used in (Malmasi and Zampieri, 2017) and a few other recent papers such as (ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018).

A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). For studies on languages other than English see (Su et al., 2017) on Chinese and (Fišer et al., 2017) on Slovene. Finally, for recent discussion on identifying profanity vs. hate speech see (Malmasi and Zampieri, 2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

In addition, we would also like to mention the previous editions of related workshops such as TA-COS[1], Abusive Language Online[2], and TRAC[3] and related shared tasks such as GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018).

3 Methodology and Data

3.1 Data Description

The organizers provided a dataset of 13,240 tweets which were annotated with the following task-specific categories.

- **Sub-task A:** Offensive language identification.
  1. Not Offensive (*NOT*): These posts do not contain offense or profanity.
  2. Offensive (*OFF*): These posts contain offensive language or a targeted (veiled or direct) offense.
- **Sub-task B:** Automatic categorization of offense types.
  1. Targeted Insult and Threats (*TIN*): A post containing an insult or threat to an individual, a group, or others (see categories in sub-task C).
  2. Untargeted (*UNT*): A post containing non-targeted profanity and swearing.
- **Sub-task C:** Offense target identification.
  1. Individual (*IND*): The target of the offensive post is an individual: a famous person, a named individual or an unnamed person interacting in the conversation.
  2. Group (*GRP*): The target of the offensive post is a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or something else.
  3. Other (*OTH*): The target of the offensive post does not belong to any of the previous two categories (e.g., an organization, a situation, an event, or an issue).

[3] https://sites.google.com/view/trac1/home

Table 1: Statistics of the training dataset

NOT				8040
OFF	UNT			524
	TIN	IND	2407	3876
		GRP	1074	
		OTH	395	
TOTAL				12440

The data collection methods used to compile the dataset used in OffensEval is described in Zampieri et al. (2019a). Table 1 provides statistics of the training dataset.

3.2 Preprocessing

Raw tweets scraped from twitter generally result in a noisy dataset. This is due to the casual nature of people's usage of social media. Tweets have certain special characteristics such as re-tweets, emoticons, user mention, etc. which have to be suitably extracted. Therefore, raw twitter data has to be normalized to create a dataset which can be easily learned by various classifiers. We applied an extensive number of pre-processing steps to standardize the dataset and reduce its size. Initially, we performed basic pre-processing operations on tweets which are as follows:

1. Convert the tweets to lower case.
2. Selective removal of special twitter features like URL, User mention, Hash-tags etc. (Cf. Table 2)
3. Converting abbreviated negative english words to common negative verbs.
4. Removing special characters and numbers.
5. Tokenization.

Table 2: Regex used for pre-processing

Twitter Feature	Regex pattern
URL	https?://[^]+ | www.[^]+
Mention	@[A-Za-z0-9]+
Hashtags	#[A-Za-z0-9]+

3.3 Machine Learning

Most of the machine learning (ML) algorithms are heavily reliant on hand crafted features designed by experts. This makes ML algorithms less generalizable. So we did not use any language specific features. We used various Machine Learning techniques to classify the tweets. When comparing various machine learning algorithms, baseline provides a point of reference to compare. While developing the models, we employed TextBlob[4] as baseline. We compared the validation result with TextBlob. Textblob is a python library for processing textual data. Apart from useful tools such as POS tagging, n-gram,etc. it has a built-in sentiment classification tool. We also tried a variation for the fine-grained classification task where the predicted output from task A was also added as a feature to the TF-IDF and list specific features. We validated our models using 15% of the training data. We built an ensemble (voting) classifier with top 5 models for different types of vectorizers, number of features, n-grams, etc.

3.4 Convolutional Neural Network

Word embedding: We used Glove[5] as the vector representation of the words in tweets. The dimension of the embedding is 300. We fine-tuned the word embedding during the network training.

Network Architecture: As shown in the Figure 1 embedding layer is used to provide word embedding. We used 300 dimensional word vectors for each words. We used 1D CNN on text data represented in word vectors. Filter column width is same as the data column width. It will ensure that matrix will stride vertically only. The padded data of the input text is of size 65x300 for each sentences. Therefore, filter's column width will be 300. Height is similar to the concept of n-gram. If the filter height is 2, the filter will stride through the document computing the calculations with all the bigrams; if the filter height is 3, it will go through all the trigrams in the document, and so on. The output height is measured by the following mathematical expression :

$$Output\ height = ((H - hf)/s) + 1$$

where, H: Input data height hf: Filter height s: Stride size

[4]https://textblob.readthedocs.io/en/dev/
[5]https://nlp.stanford.edu/projects/glove/

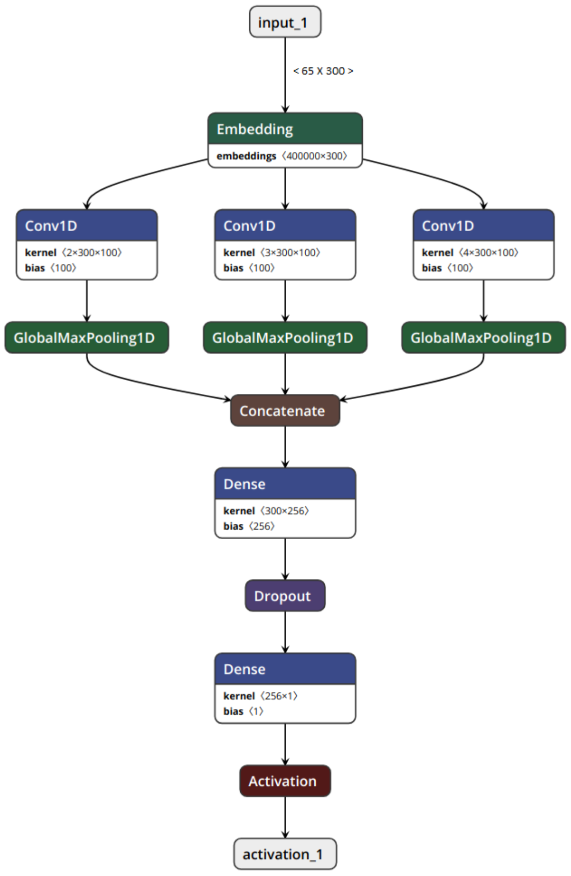

Figure 1: Convolutional Neural Network

Global Max Pooling layer extracts the maximum value from each filter, and the output dimension is 1-dimensional vector with length as same as the number of filters we applied. This can be directly passed on to a dense layer without flattening.

We implemented the above with bi-gram, tri-gram and four-gram filters. However, this is not linearly stacked layers, but parallel layers. And after convolutional layer and max-pooling layer, it simply concatenated max pooled result from each of bi-gram, tri-gram, and four-gram, then build one output layer on top of them. We added one fully connected hidden layer with dropout just before the output layer. Output layer has just one output node with Sigmoid activation.

3.5 Recurrent Neural Networks

Long Short-Term Memory networks are an extension for RNN. We employed LSTM as RNN architecture.

Word embedding: Here, we also used Glove as the vector representation of the words in tweets. The dimension of the embedding is 200. We fine-tuned the word embedding during the network training.

Network Architecture: The matrix contains 400,000 word vectors, each with a dimensionality mentioned above. We imported two different data structures, one was a Python list with the 400,000 words, and another was a $400,000 \times 200$ dimensional embedding matrix that holds all of the word vector values. We defined the necessary hyper-parameters and specified the two placeholders, one for the inputs into the network, and one for the labels. The most important part about defining these placeholders was understanding each of their dimensionality. For both tasks, the output layer contained nodes equal to the number of class labels(2 for task A and B, 3 for task C).

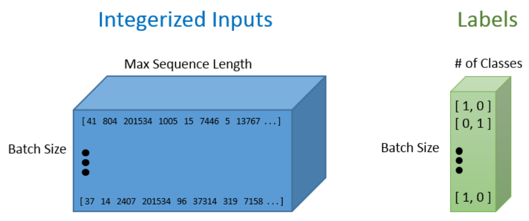

Figure 2: Vectorized tweets and corresponding labels

Each row in the integerized input placeholder represents the integerized representation of each training example that we included in our batch. Hidden state vector can be represented as :

$$h_t = \sigma(w^H h_{t-1} + w^X x_t)$$

where, w^H and w^X are weight metrics, x_t is a vector that encapsulates all the information of a specific word.

We also used LSTM network as a module in RNN for better understanding of a sentence. All the vectors are given as a sequence of vectors for a bidirectional LSTM. The representation of a tweet is the representation learned after passing the whole sequence of tokens through the biLSTM. We defined a standard cross entropy loss with a softmax layer put on top of the final prediction values. For the optimizer, we used Adam and the default learning rate of 0.001.

4 Results

This section presents the obtained results for the three sub-tasks.

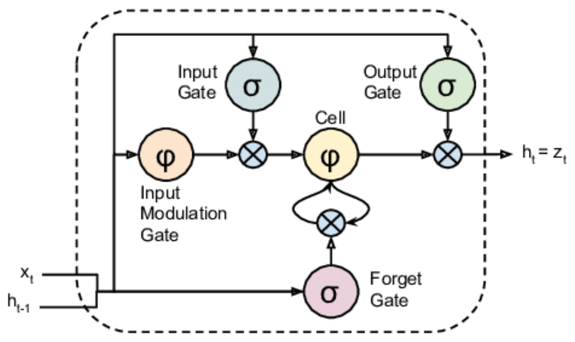

Figure 3: LSTM unit

4.1 Sub-task A:

We implemented all the three systems for this sub-task. For Machine learning, we obtained best results for Count-vectorizer with tri-gram and 90,000 features and with Logistic Regression Classifier. We achieved best results for CNN-Glove with Macro-F1 0.7844 and overall Accuracy 0.8419. However, due to paucity of time, we were unable to extract the output from our RNN model in the stipulated time frame.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
ML model	0.7231	0.8105
CNN-glove	**0.7844**	**0.8419**

Table 3: Results for Sub-task A.

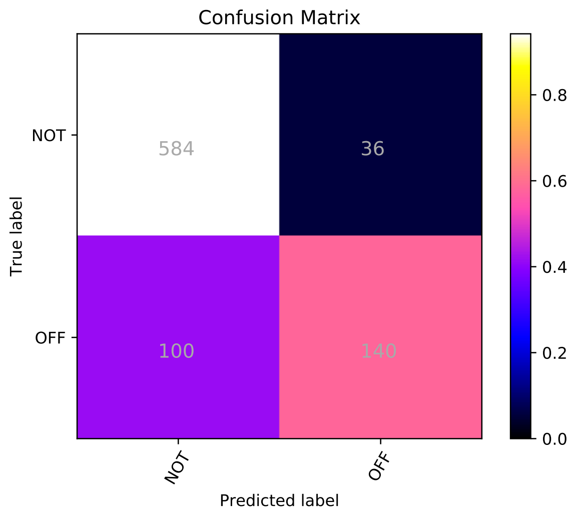

Figure 4: Confusion matrix of CNN-glove model for Sub-task A

4.2 Sub-task B:

Our approach was similar to that in the previous Sub-task. We changed the training set and labels of the same appropriately, and got our results. We used 2 class layers for training.We observed that the model gives better validation accuracy while fitted with cleaned data parsing with @*user*. While training the RNN network, we used alternative targeted and non-targeted tweets from annotated data. We obtained best results for RNN with Macro-F1 0.54587543782 and overall Accuracy 0.804166666667. The Hyper-parameters of this model are: Batchsize:24, LSTM Units:64, Epochs Number:1,00,000, Glove embeddings:200D, Optimizer:Adam. In Machine Learning, we used several traditional techniques. Best validation accuracy was found for Logistic Regression as classifier, countvectorizer - trigram - 50k feature.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
ML model	0.5378	**0.8917**
RNN-LSTM	**0.5459**	0.8042

Table 4: Results for Sub-task B.

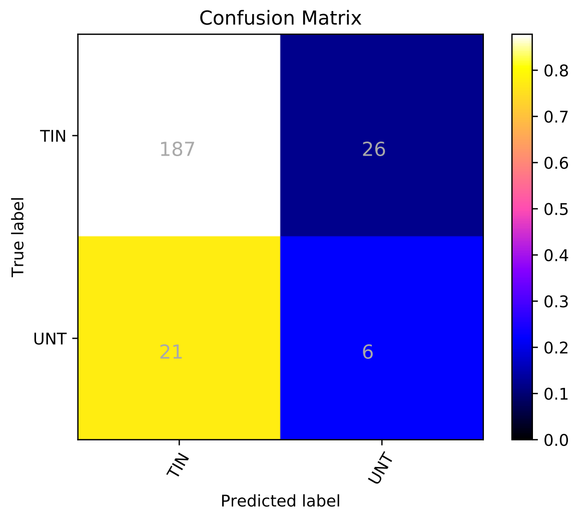

Figure 5: Confusion matrix of RNN-LSTM model for Sub-task B

4.3 Sub-task C:

This task was the most challenging among the three tasks because of the small training data. The training data contains only 3876 tweets and the 3 sub-classes are unevenly distributed. First of all, since this was a ternary classification task, we could only pursue a handful of machine learning algorithms and secondly for neural network architectures, there is a paucity of huge dataset to train the model properly. We used 10% of training dataset for testing and validation purposes, while the rest used for training. We converted our text documents to a matrix of token counts (CountVectorizer), then transformed a count matrix to a normalized tf-idf representation (tf-idf transformer). After that, we trained several classifiers from Scikit-Learn[6] library. Now among the various classifiers, we built an ensemble (voting) classifier with top 5 models and found the best accuracy result for Logistic Regression. To make the vectorizer transformer-classifier easier to work with, we used Pipeline class in Scikit-Learn that behaves like a compound classifier. For RNN, the same previous system was used but with some alterations as change in labels and change in iterative conditions for output prediction as this was a ternary classification task. We obtained best results for Machine Learning with Logistic Regression Classifier with 0.480057590252,0.577464788732 in terms of Macro-F1 and overall Accuracy respectively.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
RNN-LSTM	0.4580	0.5681
CNN-glove	0.4352	**0.6056**
ML Model	**0.4801**	0.5775

Table 5: Results for Sub-task C.

5 Observations

We noticed that both the F1(macro) and accuracy are high, in Sub-task A. This is probably due to relatively large size of training data. In sub-task B, we have found that, though the accuracy is optimum, F1(macro) is surprisingly low. This is due to imbalanced dataset. Many classes have fewer samples to create robust models. This goes same for the sub-task C .

[6]https://scikit-learn.org/stable/

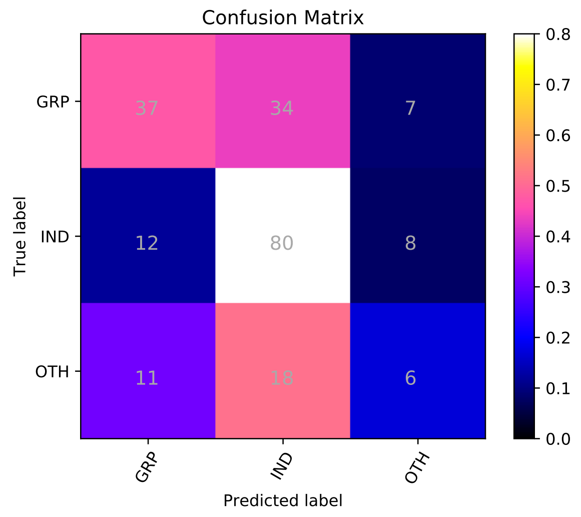

Figure 6: Confusion matrix of ML model for Sub-task C

6 Conclusions

In this paper, we have briefly described our submissions to SemEval2019 Task 6 on Identification and Categorization of Offensive Language on Twitter data. Our systems ranked 21st out of 103 participants for Sub-task A, 50th out of 75 participants for Sub-task B and 47th out of 66 participants for Sub-task C.Although our validation accuracy was high, the F1-score primarily dropped due to unequal distribution of opposite polarity data.

We could have made the system work better by training our model with additional tweets which we could have annotated manually. We could have also used Siamese Network to train our model, which has been generally used for image data.

Abstract

In this paper, we present the system description of offensive language detection tool which is developed by the KMI−Coling Group under the OffensEval Shared task. The OffensEval Shared Task was conducted in SemEval 2019 workshop. To develop the system, we have explored n-grams up to 8-gram and trained three different systems namely A, B and C system for three different sub tasks within the OffensEval task which achieves the accuracy of 79.76%, 87.91% and 44.37% respectively. The task was completed using the data set provided to us by OffensEval organisers, which was the part of OLID data set. It consists of 13,240 tweets extracted from twitter and were annotated at three levels using crowd sourcing.

1 Introduction

The very first question which arises in one's mind when one starts working in the area of computational sociolinguistics research related to the language usage in social media and networking sites is what is offensive language and its related terms such as hate speech, aggression and all? The second question arises is related to the definition of this terminology. We would suggest that offensive language is still not a very well-defined phenomenon. As we know that the natural language is productive in nature. These aspect of the language use has always existed as part of the speech repertoire of the speaker. In the area of scientific study, we need to move forward with a definition. Therefore we will go by the definition given by Jay and Janschwetiz which states that Offensive language is vulgar, pornography and hateful language (Chen et al., 2012). But even this definition does not incorporate the many more structure which is neither vulgar nor pornography nor hateful but are definitely offensive. Such type of structure is what leads to challenges in the detection of offensive language in the discourse. With the increase in the culture of social media and social networking sites, the use of offensive language has increased rapidly. Moreover, it has also given a very good platform to conduct different research in the given area.

2 Literature review

This section gives a brief outline of the existing literature and approaches that are available for offensive language detection. Lots of research works are being done to detect offensive language and there has been significant progress over time. Lexical Syntactic based framework was used for sentence offensive detection and user offensive detection by Chen et al. (2012). Another study by Xiang et al. (2012) which uses keyword matching technique that performed very well in literature domain. Razavi et al. (2010) uses auxiliary weighted repository by matching the text to its graded entries with the help of both rule-based and statistical pattern to detect flames from the text. Maisto et al. (2017) uses a lexicon-based method for the automatic identification and classification.

3 System Overview

We built three different systems for three sub tasks in the shared task. The system was built using a supervised machine learning approach trained on different classifiers using n-gram model.

3.1 System A

The very first was developed to detect whether the tweets are offensive or not. The system uses unigram and bigram in the feature set and was trained on Linear SVM classifier.

3.2 System B

The second system was developed to detect whether the tweets are targeted or non-targeted only if the tweets are offensive in nature. This system has also been trained on linear SVM with n-gram language model which consisted of unigram, bigram, trigram and 4-gram.

3.3 System C

The third system was one step ahead to detect whether the tweets are targeted to an individual, group or other. In which the third category 'other' includes a wide range of categories such as entity, organisation, place, country and many more. The system is trained on decision tree with n-gram feature starting from uni-grams to 8-grams.

4 Experiments

In this section, we briefly describe the experimental settings which are used to develop offensive language detection tool.

4.1 Data set

The data we used to train and test the system was provided by SemEval shared task 2019 under task 6 called OffensEval (Zampieri et al., 2019a). The data set consists of 13,240 annotated tweets which were extracted from OLID, Offensive Language Identification Dataset (Zampieri et al., 2019a). The data set was further divided into training and testing set in the ratio 80:20. We have used the same data set to train and test all the three systems developed to participate in the sub task of Task 6 in SemEval 2019.

4.2 Annotation

The data was hierarchically annotated using crowd sourcing. The gold labels were assigned by taking inter-annotator agreement into consideration. No correction has been carried out on the crowd sourcing annotations. The tweets were annotated at three levels. Level A differentiates the tweets between offensive and non-offensive. Level B category the offensive tweets in another level that whether the offensive tweets are targeted or non-targeted insults or threat. Level C category further categorise the targets of the insult into three different categories as an individual, group or other (Zampieri et al., 2019a).

4.3 Development of systems for sub tasks

In the next step, we developed three offensive detection systems to detect offensive tweets, targeted insults and to categorise the targeted insults using n-gram language model.

Training and development of system for sub task A
The systems were trained independently on SVM. To explore the role of n-gram feature in the detection of offensive language we have used the scikit-learn toolkit to experiment with unigram, bigram, trigram and 4-gram. We used the tweets and only Label A to train the system for development of system A.

Training and development of system for sub task B
Like system A, system B is trained on SVM with the scikit-learn toolkit to experiment with unigram, bigram, trigram and 4-gram. The system was trained and tested using tweets, Label A and Label B.

Training and development of system for sub task C
The third system was trained on two different classifier SVM and Decision tree with the same scikit-learn toolkit. The feature set for the system consists of n-gram ranging from unigrams to 8-gram.s In order to train the system, we have used the tweets, Label B, and Label C.

5 Detailed Error Reports of the KMI−Coling System

This section presents a detailed study of the result that is achieved by the developed systems.
System A performs well with the only unigram when trained with SVM. We also weighted the feature set with TF-IDF but that turned out to give very disappointing results and thus was discarded from the final feature set. Similarly, bigram, trigram and 4-gram decrease the accuracy of the system. The final trained system gave the precision of 78.72%, recall of 79.77% with an F1 score of 78.58%. The confusion matrix of the system providing the detail error is given in figure 1, which shows that 122 offensive tweets were called as non-offensive. Whereas 568 tweets were recognised correct by the system. On the other hand, 52 non-offensive tweets were labelled as offensive tweets and 118 offensive tweets were marked correctly by the system (Zampieri et al., 2019b).

System B, unlike system A, performed well in terms of accuracy, but the recall of non-targeted offensive tweets is lowered when trigram and 4-gram are implemented. Weighting the feature set using TF-IDF also did not work well as it de-

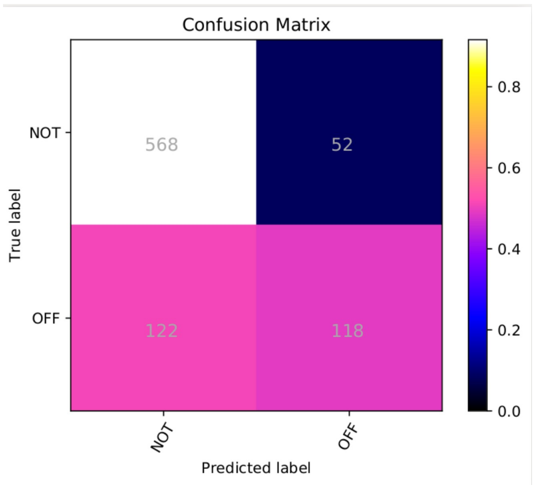

Figure 1: Confusion matrix of sub task A

creases the accuracy of the system. Finally, the system was trained only with unigram and bigram. The overall precision of the system is 84.38%, recall is 87.92% and F1 score is 85.37%. Figure 2 shows the confusion matrix of the system. The matrix gives the error report such that 23 non-targeted tweets were label targeted by the system whereas only 6 targeted tweets were marked as non-targeted.

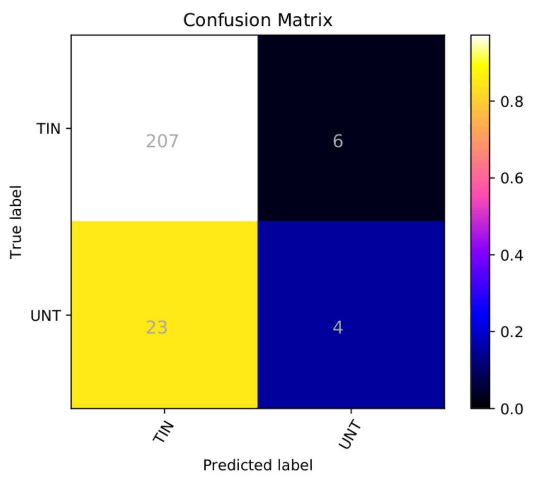

Figure 2: Confusion matrix of sub task B

As we have mentioned above system c was trained on two classifiers SVM and Decision Tree. We will be only reporting the final confusion matrix of the system C which was trained on Decision Tree. The precision of the system is 52.84%, recall is 59.15% and F1 score is 55.31%. We can easily detect and study the error from the confusion matrix given in Figure 3. Twenty tweets which originally belong to other group categorised in GROUP, 14 tweets in INDIVIDUAL. Secondly, 13 tweets which belong to INDIVIDUAL were put into GROUP and 6 of them in OTHER. Thirdly, 30 tweets which were targeted towards a group were labelled in INDIVIDUAL and 4 tweets in OTHER.

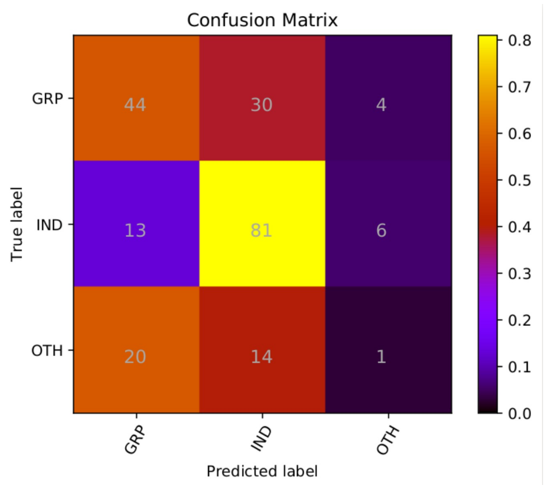

Figure 3: Confusion matrix of sub task C

6 Conclusion

In this paper, we propose an offensive detection tool which is only based on the n-gram model. We have experimented with n-gram model where n = 1,2,3,4,5,6,7,8 via statistical model. The n-gram model has been shown to perform well in very less amount of time in comparison to other models. The accuracy of system A is 79.76%, system B is 87.91% and of system C is 44.37% in our experiment. In addition to this, it is very easy to implement n-gram and consume very less amount of time. Our system can be further improved with the help of neural network. As we can see that the n-gram model also accommodate the phrase level structure from the given text. Therefore, implementing simple sentence feature would not help in increasing the accuracy. The sentence level feature would work only when there is a language specific feature.

Acknowledgments

We are grateful to the organizers of Offsemeval-2019 for providing us with the tweet Corpus and evaluation scores.

Abstract

This paper describes a bidirectional Long-Short Term Memory network for identifying offensive language in Twitter. Our system has been developed in the context of the SemEval 2019 Task 6 which comprises three different sub-tasks, namely A: Offensive Language Detection, B: Categorization of Offensive Language, C: Offensive Language Target Identification. We used a pre-trained Word Embeddings in tweet data, including information about emojis and hashtags. Our approach achieves good performance in the three sub-tasks.

1 Introduction

As the amount of user generated content in social media is increasing at an exponential pace, detecting offensive language and harmful content automatically in an efficient way is a very important issue for the society. Recent work has shown that offensive language in various forms such as hate speech, cyberbullying, profanity and harassment has negative effects especially in adolescents (Hamm et al., 2015).

The shared task, Categorizing Offensive Language in Social Media (SemEval 2019 - Task 6), focuses on improving identification of offensive language by considering type and target of the offense into account (Zampieri et al., 2019b). The task is composed of three sub-tasks. Sub-task A aims to identify if a given tweet is **offensive** or **not** (annotated as **OFF** or **NOT**). Sub-task B aims to categorize the offense type in offensive tweets into two categories: **targeted** (**TIN**) or **untargeted** (**UNT**) meaning that if a tweet contains an insult or threat to an individual, a group or something else or if a tweet contains non-targeted offense such as general profanity or non-acceptable language. Lastly, Sub-task C aims to identify the **target type** of targeted offensive posts. The target type is supposed to be classified as individual, group or other for the rest (annotated as **IND**, **GRP** or **OTH**). We submitted three different runs for each sub-task.

The training dataset released by the shared task organizers, consists of 14,100 English tweets with one annotation layer per task with a hierarchical annotation scheme where each annotation level is related to an independent sub-task. The methods used to collect this dataset is described in (Zampieri et al. (2019a)). Examples from the dataset with annotations at the end are given below:

> *"@USER That shit weird! Lol OFF (offensive) - -"*
>
> *"@USER @USER You are an embarrassing citizen!! OFF TIN -"*
>
> *"@USER @USER Liberals ruin everything! OFF TIN GRP"*

This paper describes a bidirectional Long Short Term Memory network (biLSTM) model with an Attention layer to identify offensive language in Twitter. The rest of the paper is organized as follows: In section 2, we introduce an overview of the work related to identification of offensive language. In Section 3 we describe our model structure and differences between the different runs submitted for each sub-task. In Section 4 we provide the results and discuss the performance of the system. Finally, in Section 5 we conclude giving an outline for the future work.

2 Related Work

Identification of offensive language in user-generated content can essentially be considered as a classification task. Previous research on the

issue has been carried out with approaches from different perspectives such as abusive language (Waseem et al., 2017) (Chu et al., 2017), hate speech (Davidson et al., 2017) (Schmidt and Wiegand, 2017) (Fortuna and Nunes, 2018) and cyberbullying (Hee et al., 2018).
It has been referred by (Kumar et al., 2018) that for identification of aggression in a more general manner, classifiers such as SVM and logistic regression can equalize the results of neural networks-based systems if the right features are selected. On the other hand, (Zhang et al., 2018) pointed out that a deep neural network model combining convolutional neural network and long short term memory network, performed better than state of the art, including SVM. Furthermore, indicated that automatically selected features performed better than manual features.

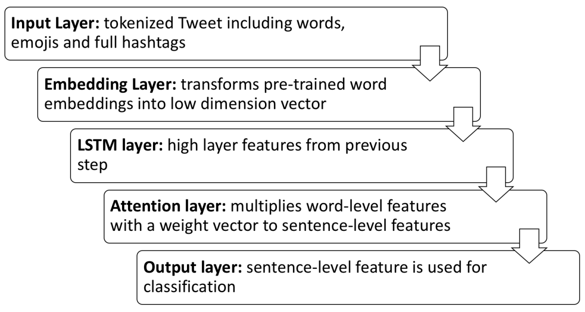
Recent research also includes the work of (ElSherief et al., 2018) focusing on the target of the hate speech found that in terms of word characteristics, such as frequency of specific words, differences can be observed between hate to individuals or to groups.

(Gambäck and Sikdar, 2017) investigated classification of different sub-categories of hate speech with different Convolutional Neural Network models founding that word2vec embeddings performed best. Davidson et al. worked on distinguishing hate speech and offensive language by training a multi-class classifier showing that using lexicons is useful in agreement with the previous research (Davidson et al., 2017).

Both for English and other languages similar shared tasks have been organized. At GermEval that aims to identify offensive language in German tweets; popular features were lexicons of offensive words, word embeddings and character n-grams. Between deep learning approaches and traditional supervised classifiers there was not a clear superior system in terms of the scores (Wiegand et al., 2018). EVALITA 2018 Hate Speech Detection Shared Task focused on Italian text on Facebook and Twitter. Best performed system in this shared task utilized polarity and subjectivity lexicon with word embeddings (Caselli et al., 2018).

3 Methodology and Data

This paper describes a neural network based on the model proposed by Zhou et al. (2016) for relation extraction. The model consist of a bidirectional Long Short-Term Memory Networks (biLSTM) model with an Attention layer on top. The model capture the most important semantic information in a tweet, including emojis and hashtags, to face the three sub-tasks. In Figure 1 a simplified schema of our model can be seen. In the following we explain how the model works.



Input Layer: tokenized Tweet including words, emojis and full hashtags
Embedding Layer: transforms pre-trained word embeddings into low dimension vector
LSTM layer: high layer features from previous step
Attention layer: multiplies word-level features with a weight vector to sentence-level features
Output layer: sentence-level feature is used for classification

Figure 1: Simplified schema of the model

First, the tweets were tokenized removing punctuation marks and keeping emojis and full hashtags because can contribute to define the meaning of a tweet.

Second, the embedding layer transforms each element in the tokenized tweet (such as words, emojis and hashtags) into a low-dimension vector. The embedding layer, composed of the vocabulary of the task, was randomly initialized from a uniform distribution (between -0.8 and 0.8 values and with 300 dimensions). Recent studies have reported that pre-trained word embeddings are far more satisfactory than the randomly initialized embeddings (Erhan et al., 2010; Kim, 2014). For that reason, the initialized embedding layer was updated with the word vectors included in a pre-trained model based on all the tokens, emojis and hashtags from 20M English tweets (Barbieri et al., 2016), which were updated during the training.

Then, a biLSTM layer gets high-level features from previous embeddings. The LSTM were introduced by Hochreiter and Schmidhuber (1997) and were explicitly designed to avoid the long-term dependency problem. LSTM systems keep relevant information of inputs by incorporating a loop enabling data to flow from one step to the following. LSTM gets a word embedding sequentially, left to right, at each time step, produces a hidden step and keeps its hidden state through time. Whereas, biLSTM, does the same process as standard LSTM, but processes the text in a left-to-right as well as right-to-left order in parallel. Therefore, gives two hidden state as output at each step and is able to capture backwards and long-range dependencies.

A critical and apparent disadvantage of seq2seq models (such as LSTM) is that they compress all information into a fixed-length vector, causing the incapability of remembering long tweets. Attention mechanism aims to overcome the limitation of fixed-length vector keeping relevant information from long tweet sequences. In addition, attention techniques have been recently demonstrated success in multiple areas of the Natural Language Processing such as question answering, machine translations, speech recognition and relation extraction (Bahdanau et al., 2014; Hermann et al., 2015; Chorowski et al., 2015; Zhou et al., 2016). For that reason, we added an attention layer, which produces a weight vector and merge word-level features from each time step into a tweet-level feature vector, by multiplying the weight vector. Finally, the tweet-level feature vector produced by the previous layers is used for classification task by a fully-connected layer.

Furthermore, we applied dropout regularization in order to alleviate overfitting. Dropout operation sets randomly to zero a proportion of the hidden units during forward propagation, creating more generalizable representations of data. As in Zhou et al. (2016), we employ dropout on the embedding layer, biLSTM layer and before the output layer. The dropout rate was set to 0.5 in all cases.

We used an additional annotated dataset for the sub-task A. This additional dataset was released with Shared Task on Aggression Identification organized as part of the First Workshop on Trolling, Aggression and Cyberbullying (TRAC - 1) (Kumar et al., 2018). This dataset is composed of 15,000 aggression-annotated Facebook Posts that were annotated as Overtly Aggressive, Covertly Aggressive, and Non-aggressive texts. For this sub-task A, posts with aggressive annotations were considered as offensive (OFF) and Non-aggressive annotation as not (NOT).

For every sub-task, three different runs were submitted following the same scheme of the neural network. Specifically, for sub-task A, we submitted 2 runs taking into account the additional dataset (using Adam in the Run1A and RMSProp optimizer in the Run3A). The third run (Run2A) was obtained using only the dataset provided by the organizers and using Adam as optimizer.

For sub-tasks B and C, we did not use additional data for training. Instead, we weighted the classes in the training giving major relevance to unbalanced classes. For the rest of the runs, some parameters were changed in order to obtain different results. Specifically, the Run1B and Run1C the Adam optimizer was used with 50 units in the LSTM. The RMSProp optimizer was used in the Run2B and RUN2C with the previous number of LSTM units. Finally, in the Run3B and Run3C was also applied the RMSProp optimizer but with 100 units in the LSTM. Additionally, to improve the model performance and reducing the overfitting for sub-task C, which contains the smallest number of instances for training, the LSTM layer included a weight regularization (L1 and L2).

4 Results

F1 scores and accuracies of our three different submissions for sub-task A are shown in Table 1. For this sub-task we have achieved the highest score with the system we did not train with an additional dataset. F1 scores and accuracies of all submissions for the subsequent tasks are seen in Table 2 and 3 respectively.

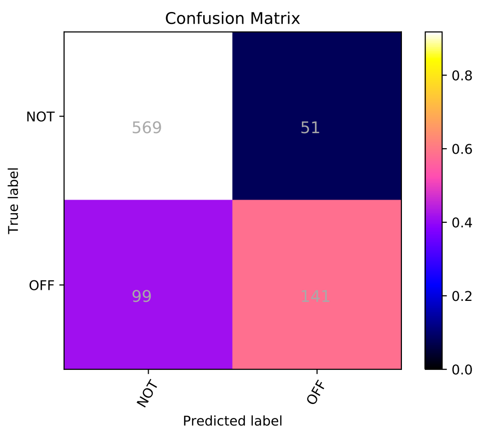


Figure 2: Confusion matrix of our best performed model for Sub-task A (biLSTM with specific configuration - Run2A)

The confusion matrix of our best performed model for the first task (see Figure 2) illustrates that between the two classes, NOT (not offensive) class achieves the best result where the majority of the data being correctly classified.

For sub-task B, classification of TIN (targeted

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
LaSTUS/TALN - Run1A	0.7406	0.7860
LaSTUS/TALN - Run2A	**0.7682**	**0.8256**
LaSTUS/TALN - Run3A	0.7411	0.7872

Table 1: Results of different submissions for **Sub-task A**.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
LaSTUS/TALN - Run1B	0.6425	0.8458
LaSTUS/TALN - Run2B	0.6150	0.8292
LaSTUS/TALN - Run3B	**0.6618**	**0.8542**

Table 2: Results of different submissions for **Sub-task B**.

insult and threads) and UNT (untargeted) content from a sub-set of offensive tweets, the confusion matrix demonstrates that our best performed model has the highest precision for class TIN as shown in Figure 3.

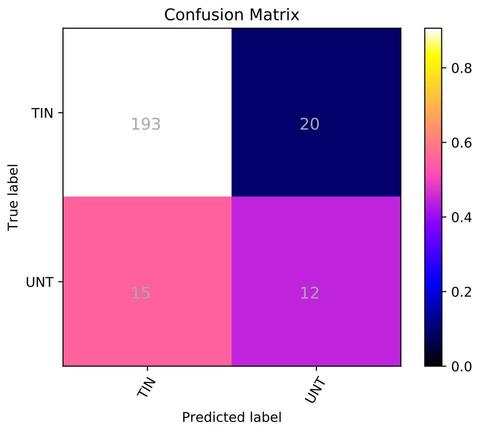

Figure 3: Confusion matrix of our best performed model for Sub-task B (biLSTM with specific configuration - Run3B)

The confusion matrix of our best performed model for sub-task C can be seen in Figure 4. It includes three classes as GRP (group), IND (individual) and OTH (other) for a sub-set of tweets containing targeted offense. The system achieves the highest precision for IND. The color range also shows the level of precision from darker to lighter.

Overall, we have achieved competitive results and rankings for each sub-task. Out of all our submissions, best performed ones for each sub-task and their comparison with the winner system of the shared task are given in Table 4.

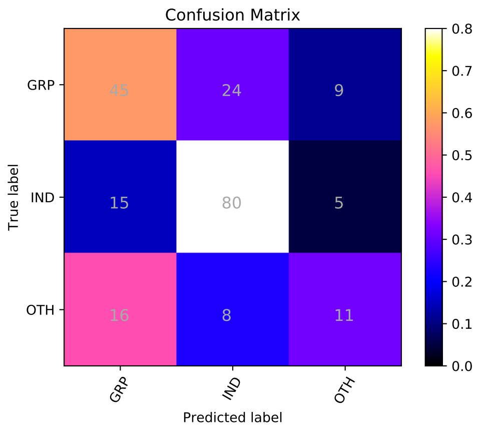

Figure 4: Confusion matrix of our best performed model for Sub-task C (biLSTM with specific configuration - Run3C)

5 Conclusion

In this paper, participation of LaSTUS/TALN to OffensEval: Identifying and Categorizing Offensive Language in Social Media (SemEval 2019 - Task 6) has been presented. We described and evaluated our system which is a bidirectional LSTM (biLSTM) model with an Attention layer on top, to classify if a tweet contains offensive language and the type and target of the offense for the offensive content.

For the future work, more detailed analyses on integration of linguistic annotations into neural network can be considered. In addition, a larger amount of data and also meta-data such as whether a tweet is a response to another tweet can represent contextual information and used to improve

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662

Abstract

This paper describes LTL-UDE's systems for the *SemEval 2019 Shared Task 6*. We present results for Subtask A and C. In Subtask A, we experiment with an embedding representation of postings and use a Multi-Layer Perceptron and BERT to categorize postings. Our best result reaches the 10th place (out of 103) using BERT. In Subtask C, we applied a two-vote classification approach with minority fallback, which is placed on the 19th rank (out of 65).

1 Introduction

The Internet is frequently used for online debates and discussions, where individuals or groups are increasingly often verbally attacked. Online platform providers aim to remove such attacking posts or ideally, prevent them from being published. Manual verification of each posting by a human moderator is infeasible due to the high amount of postings created every day. Consequently, automated detection of such attacking postings is the only feasible way to counter this kind of hostility.

In this work, we present our results for the *SemEval 2019 Shared Task 6: Identifying and Categorizing Offensive Language in Social Media* (Zampieri et al., 2019b) on the OLID dataset (Zampieri et al., 2019a). Subtask A focuses on the binary distinction if a post is offensive or not, while Subtask C determines if the target is an individual, group, or other entity. Our submission for Subtask A ranks 10th, for Subtask C ranks 19th.

For Subtask A, we experiment with word list-based classification, using classifiers such as SVM or logistic regression based on sentence embeddings, and neural network-based models such as a Multi-layer Perceptron (MLP) and Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018). We find that the SVM performs best on our development set, but BERT reaches the best result on the test dataset. Moreover, a learning curve experiment suggests that more training data will lead only to minor improvements. In Subtask C, we choose a two-vote classification approach, where we let two systems compete with a fallback to the minority class in case the systems disagree. This fallback approach has a high robustness between our development and the official test dataset.

2 Related Work

Detection of offensive or potentially hurtful online postings is investigated under a variety of names. Waseem et al. (2017) focuses on *abusive language*, Kumar et al. (2018) tackles the problem as *aggression* while Macbeth et al. (2013) approaches this problem as *cyberbullying* to mention just a few. Furthermore, the field of hate speech detection is strongly related, which aims at detecting a similar kind of online statements (Waseem and Hovy, 2016; Wojatzki et al., 2018).

Common approaches to detecting such socially unacceptable statements utilize rich feature sets consisting of word ngrams, surface forms and syntactical features (Warner and Hirschberg, 2012; Nobata et al., 2016). Human-knowledge is provided by word lists containing offenses as key words or phrases (Bassignana et al., 2018; Wiegand et al., 2018b). Xiang et al. (2012) approaches the task as topic modelling problem using Latent Dirichlet Allocation (Blei et al., 2003).

These tasks are tackled with feature engineering-based approaches such as SVM or regression models but also with convolutional neural networks (Wiegand et al., 2018b).

3 Subtask A: Offensiveness

Subtask A is a binary classification task. A posting is either offensive or not offensive. For this task, we experiment with the following approaches:

Preprocessing We lowercase all postings and use the Ark Tokenizer (Gimpel et al., 2011) for word splitting. These preprocessing steps are used in all experiments.

Lexical Matching We use the following hand-crafted word lists of abusive words: (i) Profane Word List[1] containing more than 1,300 English tokens, (ii) UdS Lexicon of Abusive Words[2] having 1,651 entries (Wiegand et al., 2018a), and (iii) *Multilingual Lexicon of Words to Hurt* from HurtLex (Bassignana et al., 2018) with 9,313 terms.[3] A posting is classified as offensive if it contains any words in the before mentioned lists.

Posting Embeddings We represent each posting by a dense embedding, which we create from word embeddings by summing up the vector values of the word representations. The resulting posting vector is re-scaled into the range zero to one. We use the pre-trained embeddings provided by Mikolov et al. (2018), which are trained on the common crawl corpus.

Classifiers We apply the following classifiers: SVM (Chang and Lin, 2011), Logistic Regression (Fan et al., 2008), Random Forest (Breiman, 2001) and a Decision Tree (Breiman et al., 1984). We use the implementation provided by scikit-learn (Pedregosa et al., 2011) using default parameters.

Multi-Layer-Perceptron (MLP) With the same pre-processing and feature extraction steps used as for shallow models described above, we train a MLP with 100 hidden units in Scikit-Learn with ReLu as activation function and Adam optimizer (Kingma and Ba, 2014). We initialize the neural network with the *fasttext* word embeddings provided by Mikolov et al. (2018).

BERT We use the provided pre-trained BERT-base model (Devlin et al., 2018) to create a vector representation of a posting. We fine-tune the model on the training data set using a sequence-length of 128 and batches of 32. We also investigate the impact of enriching the training dataset with additional data by using machine translation. We back and forth translate the training data to obtain paraphrases of the original training data, which we expect to improve model performance. We translated the data into Russian, Chinese, and Arabic and back to English using Google's translation service. We repeated the fine-tuning with this enriched dataset.

Ensemble We combine the best three approaches (BERT, SVM, and Logistic Regression) in an ensemble, which was reported to often account for improvements in a similar shared task for German (Wiegand et al., 2018c). We use the majority vote of these classifiers as the prediction.

Set	Approach	F_1	Acc

Table 1: Subtask A: Results in term of macro F_1 on a held-back development dataset containing 1,048 offensive postings and 2,192 not offensive (NOT) ones.

3.1 Results

Table 1 shows the results for Subtask A. We report results on a self-created development dataset (25% of the original training data, 3,240 postings of which 1,048 postings are labeled as offensive and 2,192 as not offensive). We use the majority class as a baseline. On our dev dataset, we find that a SVM with the posting vector-representation achieves the best F-Score, followed by BERT. Contrary to our expectation, BERT's performance decreased by adding the machine-translated data. On the test dataset, we find BERT to perform best followed by the ensemble, which seems to add some additional robustness to the classification.

Learning curve A central question for shared tasks such as this one is if the amount of provided training data is sufficient to train a reliable clas-

Table 2: Subtask C results

sifier. Figure 1 shows a learning curve computed over the provided training data with testing against the hold-out development set. We split the training data into equal-sized data blocks which are randomly distributed over labels and add an increasing number of data blocks to see the performance improvement by adding more data. The results shows that improving the machine learning model is a more promising strategy than providing even more data as the slope indicates only minor improvements if more data is added.

4 Subtask C: Offense Targets

The goal in this subtask is to identify the kind of target at which a tweet is directed at (i.e. at this point it is already known that the tweet is a targeted offense, just the target itself is not yet determined). A target is either an individual (IND), a group (GRP), or other (OTH), if none of the previously mentioned two categories apply. We apply the same approaches as already used in Subtask A.

Two-Vote Classification with Minority Fallback Furthermore, an analysis of the class distribution showed that the class for *other* has comparatively few instances. This makes it challenging for a classifier to reliably detect such an under-represented class. Therefore, we attempt to redefine the problem as a binary classification problem using two classifiers. If the two classifiers agree in their prediction, we take the predicted class (either *individual* or *group*). In case of an disagreement, we select the minority class, *other*, as prediction. Thus, we also alter the training data to contain only two classes. The labels of the under-represented *other* class are mapped for one classifier to *individual* and for the other one to *group*, which creates a kind of minority-class noise. Our intuition is, if both classifier overcome the uncertainty added by the (small) amount of noise, the prediction is considered reliable. Consequently, we consider a disagreement as evidence for assigning the minority class.

Results Table 2 shows the results. We find that our two vote classification approach, using two MLPs, reaches the highest F-Score on the development and test set. On the development set, we reach the best accuracy result with an SVM but the considerably lower F-Score shows a strong bias towards a single class. Moreover, MLP+MLP shows a high robustness when comparing the F-Score performance between development and test set.

5 Conclusion

In this paper, we presented our approach on identifying and categorizing offensive language in social media. We mostly rely on lexical and semantic features for all subtasks. Results shows that semantic features have a significant impact on system performance. In general, our system leaves much room for improvement. Detection of offensiveness could probably benefit from more semantically oriented features that go beyond the surface form of words. We make the source code of our experiments publicly available[4].

Abstract

In this paper, we present our approach and the system description for Sub-task A and Sub Task B of SemEval 2019 Task 6: Identifying and Categorizing Offensive Language in Social Media. Sub-task A involves identifying if a given tweet is offensive or not, and Sub Task B involves detecting if an offensive tweet is targeted towards someone (group or an individual). Our models for Sub-task A is based on an ensemble of Convolutional Neural Network, Bidirectional LSTM with attention, and Bidirectional LSTM + Bidirectional GRU, whereas for Sub-task B, we rely on a set of heuristics derived from the training data and manual observation. We provide a detailed analysis of the results obtained using the trained models. Our team ranked 5th out of 103 participants in Sub-task A, achieving a macro F1 score of 0.807, and ranked 8th out of 75 participants in Sub Task B achieving a macro F1 of 0.695.

1 Introduction

The unrestricted use of offensive language in social media is disgraceful for a progressive society as it promotes the spread of abuse, violence, hatred, and leads to other activities like trolling. Offensive text can be broadly classified as abusive and hate speech on the basis of the context and target of the offense. Hate speech is an act of offending, insulting or threatening a person or a group of similar people on the basis of religion, race, caste, sexual orientation, gender or belongingness to a specific stereotyped community (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018). Abusive speech categorically differs from hate speech because of its casual motive to hurt using general slurs composed of demeaning words. Both of them are the popular categories of offensive content, widespread in different social media channels.

With the democratization of the web, the usage of offensive language in online platforms is a clear indication of misuse of our right to 'Freedom of Speech'. While censorship of free moving online content curtails the freedom of speech, but unregulated opprobrious tweets discourage free discussions in the virtual world making the problem of identifying and filtering out offensive content from social media an important problem to be solved for creating a better society, both in and out of the Internet.

Detecting offensive content from social media is a hard research problem due to variations in the way people express themselves in a linguistically diverse social setting of the web. A major challenge in monitoring online content produced on social media websites like Twitter, Facebook and Reddit is the humongous volume of data being generated at a fast pace from varying demographic, cultural, linguistic and religious communities. Apart from the problem of information overload, social media websites pose challenges for automated information mining tools and techniques due to their brevity, noisiness, idiosyncratic language, unusual structure and ambiguous representation of discourse. Information extraction tasks using state-of-the-art natural language processing techniques, often give poor results when applied in such settings (Ritter et al., 2011). Abundance of link farms, unwanted promotional posts, and nepotistic relationships between content creates additional challenges. Due to the lack of explicit links between content shared in these platforms it is also difficult to implement and get useful results from ranking algorithms popularly used for web pages (Mahata et al., 2015).

Interests from both academia and industry has led to the organization of related workshops such as TA-COS[1], Abusive Language Online[2], and TRAC[3], along with shared tasks such as GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018). The task 6 of SemEval 2019 (Zampieri et al., 2019b) is one such recent effort containing short posts from tweets collected from the Twitter platform and annotated by human annotators with the objective of *identifying expressions of offensive language*, *categorization of offensive language* and *identifying the target against whom the offensive language is being used*, leading to three sub tasks (A, B and C). We only participate in two of them for which we define the problems.

Problem Definition Sub-task A - *Given a labeled dataset D of tweets, the objective of the task is to learn a classification/prediction function that can predict a label l for a given tweet t, where $l \in \{OFF, NOT\}$, OFF - denoting a tweet being offensive, and NOT - denoting a tweet being not offensive.*

Problem Definition Sub Task B - *Given a labeled dataset D of tweets, the objective of the task is to learn a classification/prediction function that can predict a label l for a given tweet t, where $l \in \{TIN, UNT\}$, TIN - denoting an offensive tweet targeted towards a group or an individual, and UNT - denoting a tweet that does not contain a targeted offense although it might use offensive language.*

Towards this objective we make the following contributions in this work:

- Train deep learning models of different architectures - Convolutional Neural Networks, Bidirectional LSTM with attention and Bidirectional LSTM + Bidirectional GRU, and report their results on the provided dataset. Our best model which ranked 5th in Sub-task A, is an ensemble of all the three deep learning architectures.

- We perform an analysis of the dataset, point out certain discrepancies in annotation and show how undersampling directed by error analysis could be sometimes useful for increasing the performance of the trained models.

[2] `https://sites.google.com/site/abusivelanguageworkshop2017/`

[3] `https://sites.google.com/view/trac1/home`

Next, we present previous works related to the task.

2 Related Work

Most of the previous works in this domain deals with the identification and analysis of the use of hate speech (Davidson et al., 2017), and abusive languages in online platforms (Nobata et al., 2016). Abusive speech categorically differs from hate speech because of its casual motive to hurt using general slurs composed of demeaning words. A proposal of typology of abusive language subtasks is presented in (Waseem et al., 2017). Both abusive as well as hate speech are sub-categories of offensive language. Detailed surveys of the works related to hate speech could be found in (Schmidt and Wiegand, 2017) and (Fortuna and Nunes, 2018).

One of the earliest efforts in hate speech detection can be attributed to (Spertus, 1997) who had presented a decision tree based text classifier for web pages with a 88.2 % accuracy. Contemporary works on Yahoo news pages were done (Sood et al., 2012), and later taken up by (Yin et al., 2016). (Xiang et al., 2012) detected offensive tweets using logistic regression over a tweet dataset with the help of a dictionary of 339 offensive words. Offensive text classification in online textual content have been tried previously for languages other than English, like German (Ross et al., 2017), Chinese (Su et al., 2017), Slovene (Fišer et al., 2017), Arabic (Mubarak et al., 2017), and in challenging cases of code-switched languages such as Hinglish (Mathur et al., 2018). However, despite the various endeavors by language experts and online moderators, users continue to disguise their abuse through creative modifications that contribute to multidimensional linguistic variations (Clarke and Grieve, 2017).

(Badjatiya et al., 2017) used CNN based classifiers to classify hateful tweets as racist and sexist. (Park and Fung, 2017) introduced a combination of CharCNN and WordCNN architectures for abusive text classification. (Gambäck and Sikdar, 2017) explored four CNN models trained on character n-grams, word vectors based on semantic information built using word2vec, randomly generated word vectors, and word vectors combined with character n-grams to develop a hate-speech text classification system. (Pitsilis et al., 2018) used an ensemble of RNNs in order to identify hateful content in social media.

Some of the recent works in this domain has been on identifying profanity vs. hate speech (Malmasi and Zampieri, 2018), which highlights the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language. On a similar direction there has been work on understanding the main intentions behind vulgar expressions in social media (Holgate et al., 2018). Various approaches have been taken to tackle both textual as well as multimodal data from Twitter and social media in general, in order to build deep learning classifiers for similar tasks (Baghel et al., 2018; Kapoor et al., 2018; Mahata et al., 2018a,b; Jangid et al., 2018; Meghawat et al., 2018; Shah and Zimmermann, 2017).

3 Dataset

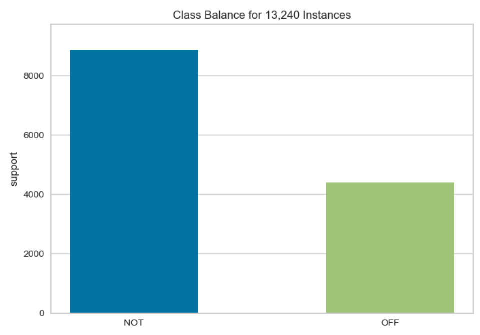

Figure 1: Distribution of classes (OFF - Offensive and NOT - Not Offensive) for Sub-task A.)

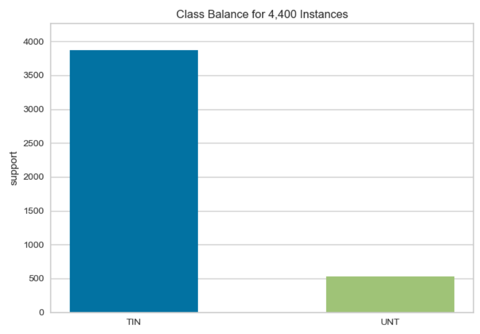

Figure 2: Distribution of classes (TIN - Targeted Offense and UNT - Untargeted Offense) for Sub Task B.)

The dataset provided for the tasks was collected through Twitter API by searching for tweets containing certain selected keyword patterns popular in offensive posts. Around 50% of the keyword patterns were political in nature such as 'MAGA', 'antifa', 'conservative' and 'liberal'. The other half were based on keyword patterns such as 'he is', 'she is', in combination with metadata provided by the Twitter API that marks a tweet to be 'unsafe'. The annotation of the collected data was done using figure eight, which is a popular crowdsourcing platform. 14,100 tweets were selected in the final dataset with 13,240 provided as the training data and 860 as the test data. The details of the dataset, its collection process and annotation agreements could be found in (Zampieri et al., 2019a).

Figures 1 and 2, shows the distribution of the classes in the subsets of the data provided for Subtask A and Sub Task B, respectively. The distributions show the imbalance in class labels. We also took a detailed look at the dataset and found discrepancies between the definition of the classes as provided by the organizers and the actual annotations. The mislabeling was more prominent as an offensive post being labeled as not offensive. We observed such wrong annotations when performing manual error analysis on the predictions provided by an initially trained classifier, which was a simple Convolutional Neural Network. About 4 % of the posts seemed to have been mislabeled, which we found through manual inspection and removed them from the training data. Here are few such examples.

- @user @user @user @user @user @user @user what a stupid incompetent devious and toxic pm ! may haven't you forgotten 17.4 million voters ? betray us at your peril ! you are eroding faith in democracy + destroying tory party ! you should go url. (**Original Label: NOT**)

- angelina is so funny at rhe wrong times imngonna shoot this bitch uppdoals. (**Original Label: NOT**)

- @user @user so and accusation by a libtarded trump hating liberal activist against a trump appointee doesnt make u wonder if the accusation was politically motivated in the slightest ? no ? this is why conservatives think u are all stupid . because u are . (**Original Label: NOT**)

This increased the performances of our trained models and could be considered as a heuristic based undersampling of the provided dataset.

4 Experiments and Results

We train different deep learning models for the Sub-task A and rely on heuristics learnt from the training data for Sub-task B. In this section we explain the steps taken for pre-processing data and training the predictive models and give a short description of the heuristics that we came up with after analyzing the data.

4.1 Data Preprocessing

Before feeding the dataset to any machine learning model we took some steps to process the data. For all our experiments we used Keras[4] as the machine learning coding library. Some of the preprocessing steps that we took are:

Tokenization - Tokenization is a fundamental preprocessing step and could be one of the important factors influencing the performance of a machine learning model that deals with text. As tweets include wide variation in vocabulary and expressions such as user mentions and hashtags, the tokenization process could become a challenging task. We used the nltk's[5] tweet tokenizer in order to tokenize the tweets provided in the dataset by overriding the default tokenizer provided in keras.

Cleaning and Normalization - Normalization of tokens were also done using some hand-crafted rules. The # symbol was removed from the tweets along with mapping few popular offensive words to a standard form. For example, 'bi*ch', 'b**ch', 'bi**h', 'biatch' were all mapped to 'bitch', and 'sob', 'sobi*ch', were mapped to 'son of bitch'. The @user tokens were removed. The hashtags that contained two or more words were segmented into their component words. For example #fatbastard was converted to fat bastard.

4.2 Training Deep Learning Models

In order to train deep learning models we need to provide the input as a matrix and the input words need to be mapped to their embeddings which provides richer semantic representation of words in comparison to the one-hot vectors. Each tweet is treated as a sequence of words and may vary in their lengths. We fix 200 as the max length and pad the input sequences in order to make their lengths fixed to 200. For, our experiments we used the 200 dimensional Glove embeddings[6] trained on tweets and 400 dimensional Godin embeddings[7]. There was no significant difference in the results while training our initial models by using one over the other. Therefore for all our models as presented in this work we selected the Glove embeddings as the pre-trained word embedding of our choice due to its lower dimensions resulting in lesser training of weights in the neural network.

We train the following architectures for Sub-task A having the parameters as explained next.

Convolutional Neural Network - Convolutional neural networks are effective in text classification tasks primarily because they are able to pick out salient features (e.g., tokens or sequences of tokens) in a way that is invariant to their position within the input sequence of words. In our model, we use three different filters with sizes 2, 3 and 4. For each filter size, 256 filters are used. A max pooling layer is then applied for each filter size. The resultant vectors are concatenated to form the vector that represents the whole tweet. A drop out layer with drop out rate 0.3 is applied before the input to the Multi Layer Perceptron with 256 neurons for classification. We also use a dropout layer after the embedding with dropout rate 0.3 to randomly drop words, which we find helpful to resolve overfitting issue. Sigmoid activation function is applied to the final layer.

Bidirectional LSTM with Attention - Bidirectional LSTM (BLSTM) is an extension of LSTM in which two LSTM models are trained on the input sequence. The first on the input sequence as-is and the second on its reversed copy. This can provide additional context to the network and result in faster and sometimes better learning. They have shown very good results in sequence classification tasks. We use 64 LSTM units with 0.2 drop out, one attention layer is added on the sequence of result vectors from BLSTM. 128 neurons are used in the final Multi Layer Perceptron layer for classification. Sigmoid activation function is applied to the final layer.

Bidirectional LSTM followed by Bidirectional GRU - We use 64 LSTM units wrapped by a Bidirectional layer, 0.3 was the dropout rate, followed by a Bidirectional GRU with 64 GRU units also with 0.3 dropout. Then a max pooling and average pooling are used and concatenated before input to the final Multi Layer Perceptron layer with 128 neurons for classification. Sigmoid activation

function is applied to the final layer.

For all three models we add a drop out layer after the embedding to randomly drop words, which we find helpful to address overfitting issue, and early stop is used with restoring the best model weights. Grid search is used to find the best parameters for each model. Table 1 presents the performance of each of these networks on the modified dataset as already explained in Section 3.

Often, one solution to a complex problem does not fit to all scenarios. Thus, researchers use ensemble techniques to address such problems. Historically, ensemble learning has proved to be very effective in most of the machine learning tasks including the famous winning solution of the Netflix Prize. Ensemble models can offer diversity over model architectures, training data splits or random initialization of the same model or model architectures. Multiple average or low performing learners are combined to produce a robust and high performing learning model. We do the same in our experiments. We combine the trained deep learning models having different architectures as an ensemble by averaging their final predictions. We had also tried the stacked ensemble approach as explained in (Mahata et al., 2018b). But it didn't give promising results in first few iterations. Moreover, it was computationally expensive and due to lack of sufficient time we, did not go further in that route.

Our ensemble model performed better than the individual models and was also submitted to the competition, which was finally ranked 5th amongst 103 participants. Figure 3 presents the confusion matrix of our submission for Sub-task A. Some of the samples from the training dataset,

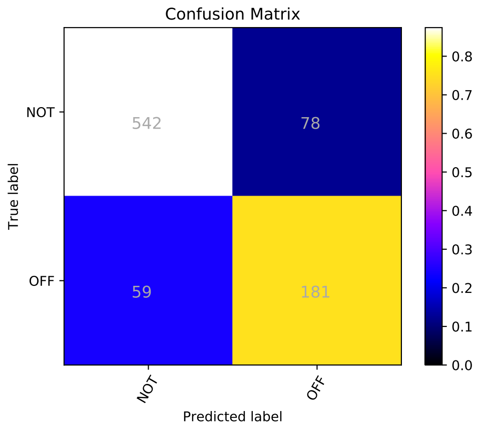

Figure 3: Confusion Matrix for MIDAS submission 2 for Sub-task A.

which were very hard for our final model to predict are:

- More like #Putin every day. #MAGA URL (OFF)
- @USER Hitler would be so proud of David Hogg trying to disarm American citizen so when Democrats come to power-we are helpless And cannot defend ourselves-; that's why we have they AR15's (NOT)
- @USER good job (sarcasm). Also great they have gun control laws its saving lives! (More sarcasm). (OFF)

4.3 Heuristics for Sub-task B

Due to lack of time from our part, we were not able to train good machine learning models for Sub-task B. The preliminary models that we trained showed performances that was similar to that of a random model biased by the class distribution of the training data. The training dataset for Sub-task B was highly imbalanced which was a major challenge. We would like to have an in depth look at Sub-task B in the near future.

For the sake of submission to the competition we came up with certain heuristics in order to decide whether an offensive post is targeted or not.

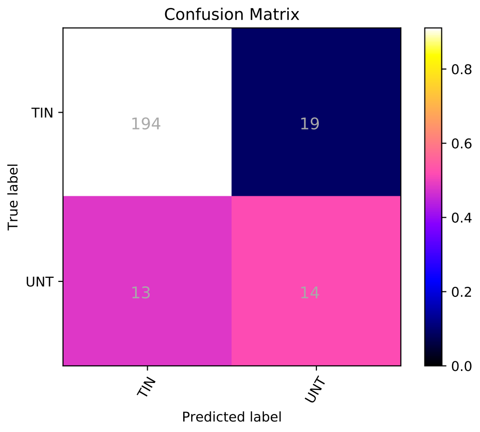

Figure 4: Confusion Matrix for MIDAS submission 1 for Sub-task B.

We skipped the pre-processing part of the tweets that we did before training the machine learning models as described in Section 4.1. We looked at the frequency distribution of words and hashtags in the training dataset as well as observed the patterns of the posts. After doing that we did find that some of the hashtags like '#maga', '#liberals', '#kavanaugh', '#qanon', etc were frequently occurring. and so are some of the tokens like 'antifa', 'president', 'trump', 'potus', 'liberals', 'conservatives', 'democrat', 'nigga', 'gay', 'jew'. Top 100 such tokens and hashtags were compiled after eliminating some of them manually if they didn't make any sense, for example some unwanted stop words. We also extracted POS tags of the tweets using TweeboParser[8] and extracted named entities (only PERSON, ORG, LOCATION, FACILITY) using SpaCy[9]. We framed our final heuristic based on the following rules:

- If the post includes any of the 100 hashtags then it is considered as targeted offense (TIN).
- else if the post includes any of the 100 tokens then it is considered as targeted offense (TIN).
- else if no named entity in the post and no Personal Pronoun and Proper Nouns are present in the post then it is a untargeted offense (UNT).
- else if the post has he/she is, you are, he she then it is considered as targeted offense (TIN).
- else if the post has pattern ' Starts with hashtag followed by verbs and named entity' then it is considered as targeted offense (TIN).
- else If there is a named entity then it is considered as targeted offense (TIN).
- all other cases are considered as untargeted offense (UNT).

We do not think this to be a robust model and it was only possible to come up with the heuristics because there were certain patterns in the dataset that was very obvious to bare human eye. Given that the dataset is very small, these heuristics can never scale well. One of the reasons behind discovering such patterns could also be because of the way the dataset was collected. Now that we know how it was collected as explained in Section 3, these patterns make more sense and it does explain why we could perform reasonably well even though we came up with such naive patterns in haste. Figure 4 presents the confusion matrix of our submission for Sub-task B and Table 2 presents the performance on the test dataset.

5 Conclusion and Future Work

In this work, we report our models and their respective performances in Sub-task A and B of SemEval-2019 Task 6 OffensEval: Identifying and Categorizing Offensive Language in Social Media. We showed how an ensemble of deep learning models performed well in the provided dataset and was ranked 5th in the competition in Sub-task A. Due to the inherent biases in collecting the dataset we believe that we were able to come up with naive heuristics for Sub-task B and was able to rank 8th in the competition.

In the future we would like to solve Sub-task B using a machine learning approach. We would also like to look at other machine learning architectures and ensemble methods for the different sub tasks in the competition. Out of three sub tasks, we were able to attempt only two of them. In the near future we would like to tackle the problem posed in Sub-task C. Some of the other areas that could be explored are cleaning the dataset by correcting the annotations and studying the problem of inherent biases that can occur in samples collected based on keyword patterns.

Abstract

This paper examines different approaches and models towards offensive tweet classification which were used as a part of the OffensEval 2019 competition. It reviews Tweet preprocessing, techniques for overcoming unbalanced class distribution in the provided test data, and comparison of multiple attempted machine learning models.

1 Introduction

The purpose of this paper is to explore different approaches towards classifying tweets based on whether they are offensive or not, whether offensive tweets are targeted, and identifying the target group of offensive tweets either an individual, a group, or other. Those are the terms of the OffensEval 2019 competition in which we participated. Each of the described activities constituted a separate subtask from the competition. A maximum of three submissions were allowed per subtask which required careful preliminary analysis of the model results during the training phase. A training set of over 13,000 tweets, containing labels for all three subtasks. Each of the subtasks was scored using macro F1 score.

2 Related Work

One of the most effective strategies for tackling this problem is to use computational methods to identify offense, aggression, and hate speech in user-generated content (e.g. posts, comments, microblogs, etc.). This topic has attracted significant attention recently as evidenced in publications from the last two years.

Survey papers describing key areas that have been explored for this task include (Schmidt and Wiegand, 2017), (Fortuna and Nunes, 2018) and (Malmasi and Zampieri, 2017). The dataset for this competition is explained in (Zampieri et al., 2019a) and different approaches to the same problem are reported in (Zampieri et al., 2019b).

In order to classify correctly abusive language it is important to analyze its types. A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017) and (ElSherief et al., 2018) examines the target of the speech: either directed towards a specific person or entity, or generalized towards a group of people sharing a common protected characteristic. (Fišer et al., 2017) proposes a legal framework, dataset and annotation schema of socially unacceptable discourse practices on social networking platforms in Slovenia. Finally, a recent discussion on identifying profanity vs. hate speech is presented in (Malmasi and Zampieri, 2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

Approaches to detecting hate speech on Twitter using convolutional neural networks and convolution-GRU based deep neural network are discussed in (Gambäck and Sikdar, 2017) and (Zhang et al., 2018) respectively.

Additional related work is presented in workshops such as TA-COS[1], Abusive Language Online[2], and TRAC[3] and related shared tasks such as GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018).

3 Methodology and Data

The data was split into a training and validation set in a ratio of 10:1. All tasks had similar preprocessing and multiple models were trained on the training set. Depending on their performance on the validation set each time the best 3 were submitted.

3.1 Preprocessing

We started our tweet preprocessing by removing most punctuation marks which do not include any useful information for text classification. The symbols '@' and '#' were excluded from the list due to their specific semantics in tweets. Afterwards the tweets were subjected to tokenization and lowercasing.

All occurrences of tokens beginning with a hashtag were split into the separate words comprising the token, provided that each separate word is uppercased. For example, the token #HelloThere is split into two tokens hello and there.

Afterwards we proceeded with removing a variety of different stop words. When training models for the second and third subtask, we excluded personal and possessive pronouns from the list of stop words, as they can contain valuable information for classifying a tweet as targeted or not, or identifying the target group of a targeted tweet. We also attempted lemmatization and spell correction but the results were slightly worse or on par with the ones achieved without using these two techniques.

Pre-trained word vectors on Twitter from project GloVe (Pennington et al., 2014) were used for encoding words to a vector space. Four different vector dimensions were available for use 25, 50, 100, and 200. Although results were slightly better when using higher dimensional vectors, using 200-dimensional vectors proved to have no significant advantage in achieved results over 100-dimensional ones, and proved to be more computationally expensive, which lead us to use 100-dimensional vectors for each subtask.

3.2 Models

We trained a large variety of different models and combined the best of them in ensembles. For all models the embedding layer was freezed, becaused that proved less prone to overfitting.

- Standard Nave Bayes and Support Vector Machine (SVM) from scikit-learn library in python.
- Convolutional Neural Network (CNN) with GlobalMaxPooling and hidden dense layer on top.
- Multilayer Perceptron Network (MLP) with two hidden layers.
- FastText models with n-grams of size 2.
- Recurrent Neural Network (RNN) with GRU units and attention layer and hidden dense layer on top.
- Deep Pyramid Convolutional Neural Network (DPCNN) (Johnson and Zhang, 2017).
- Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018).
- Soft Voting Classifier (SVC) - averages the predictions of the single models.
- Logistic Regression - meta model trained on half of the validation set with predictions from the single classifiers as features.

3.3 Class imbalance

One of the challenges of the competition was the imbalance of classes for the second and third subtask. We experimented with different techniques for overcoming this challenge:

- Oversampling duplicating some of the examples from the poorly represented classes.
- Class weights assigning lower weights to examples from classes which are better represented and higher weights to examples from classes with a lower overall count.
- Modification of the thresholds used for classifying an example. For example, for a standard binary classification a threshold of 0.5 is applied to the predicted probability in order

to distinguish between the two classes. We attempted to lower this threshold to different levels.

For all model apart from BERT the class weight option was chosen. Only for BERT on subtask C the thresholds were changed instead. For classes OTH and GRP we used thresholds of 0.2 and 0.3 respectively and if any of them was exceeded we would directly assign that class. If both were exceeded we would assign OTH as the class. The coefficients were derived via cross-validation.

4 Results

The results from the test sets for each subtask are displayed below. We have also provided the results from our validation sets, those were the basis upon which we decided which models predictions to submit.

The individual model with the best performance on subtask A was BERT-Large, Uncased with a macro F1 score of 0.781 on the validation set and was selected as one of the models for submission. The other two submitted models were the soft voting classifier with score of 0.788 and the logistic regression model 0.800. The scores of the other trained models are displayed below.

System	F1 (macro)
Logistic Regression	**0.800**
SVC	0.788
BERT-Large	0.781
RNN	0.773
DPCNN	0.768
CNN	0.765
FastText	0.759
Nave Bayes	0.744
MLP	0.742
SVM	0.705

Table 1: Results on the validation set for Sub-task A.

The ensemble models proved to have overfit on the training data and out of the models we have submitted BERT had the highest score, ranking second overall amongst all participants.

In subtask B the highest scoring models on the validation set was the soft voting classifier with a score of 0.64, closely followed by RNN and CNN 0.63. BERT-Base, Uncased performed surprisingly poorly and achieved a score of 0.59.

The soft voting classifier scored the highest on the test set and ranked 16th overall.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
SVC	0.7252	0.8105
Logistic Regression	0.7867	0.8453
BERT-Large	**0.8153**	**0.8547**

Table 2: Results on the test set for Sub-task A.

System	F1 (macro)
SVC	**0.642**
RNN	0.633
CNN	0.631
DPCNN	0.630
Logistic Regression	0.629
MLP	0.614
FastText	0.612
BERT-Base	0.599
Nave Bayes	0.596
SVM	0.576

Table 3: Results on the validation set for Sub-task B.

In subtask C BERT-Base, Uncased was by far the best individual model, achieving a score of 0.64, surpassing its closest contender (Multi-Layered Perceptron) by approximately 0.045. The third model which we submitted was the soft voting classifier with a score of 0.60.

BERT significantly outperformed every other submitted model, securing us first place in subtask C.

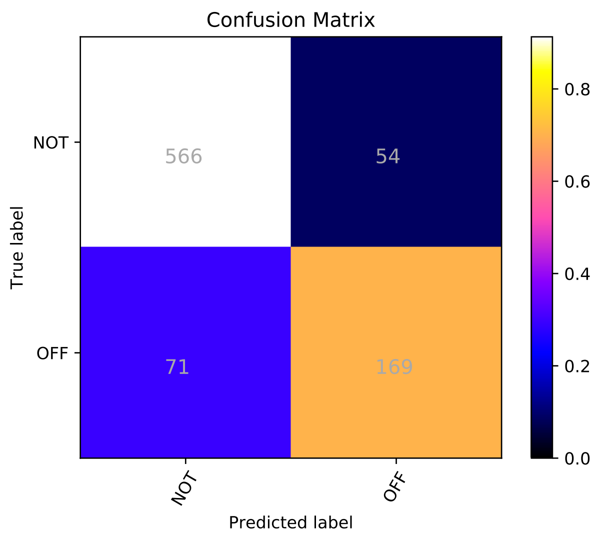

Figure 1: Sub-task A, vradivchev anikolov CodaLab BERT

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
RNN	0.6354	0.7667
SVC	**0.6674**	**0.8208**
CNN	0.6248	0.7833

Table 4: Results on the test set for Sub-task B.

System	F1 (macro)
BERT-Base	**0.644**
SVC	0.603
MLP	0.595
Logistic Regression	0.590
RNN	0.586
CNN	0.571
FastText	0.570
DPCNN	0.568
Nave Bayes	0.567
SVM	0.546

Table 5: Results on the validation set for Sub-task C.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
BERT-Base	**0.6597**	**0.7277**
MLP	0.5591	0.6808
SVC	0.6107	0.6948

5 Conclusion

Google's BERT model proved to be a powerful tool for text classification. Not only did it outperform common models on the validation set, but based on the results from the test set it did so without overfitting on the data.

Abstract

The paper describes the systems submitted to OffensEval (SemEval 2019, Task 6) on 'Identifying and Categorizing Offensive Language in Social Media' by the 'NIT_Agartala_NLP_Team'. A Twitter annotated dataset of 13,240 English tweets was provided by the task organizers to train the individual models, with the best results obtained using an ensemble model composed of six different classifiers. The ensemble model produced macro-averaged F_1-scores of 0.7434, 0.7078 and 0.4853 on Subtasks A, B, and C, respectively. The paper highlights the overall low predictive nature of various linguistic features and surface level count features, as well as the limitations of a traditional machine learning approach when compared to a Deep Learning counterpart.

1 Introduction

Offensive language has been the scourge of the internet since the rise of social media. Social media provides a platform for everyone and anyone to voice their opinion. This has empowered people to make their voices heard and to speak out on global issues. The downside to this, however, is the misuse of such platforms to attack an individual or a minority group, and to spread hateful opinions. Pairing this with the perceived anonymity the internet provides, there has been a massive upswing in the use of social media for cyberbullying and hate speech, with technology giants coming under increased pressure to address the issue.

Most of what we may be interested in detecting can be broadly labelled as hate speech, cyberbullying or abusive use of swearing. The union of these three subsets form what can be identified as 'Offensive Language on Social Media'. However, what we consider offensive is often a grey area, as is evident by the low inter-annotator agreement rates when labelling data for offensive language (Waseem et al., 2017b).

Detecting offensive language has proven to be difficult, due to the broad spectrum in which language can be used to convey an insult. The nature of the abuse can be implicit — drawing from sarcasm and humour rather than offensive terms — as well as explicit, by making extensive use of traditional offensive terms and profanity. It does not help that the reverse is also entertained, with profanity often being used to imply informality in speech or for emphasis. Coincidentally, these are also the reasons why lexical detection methods have been unfruitful in classifying text as offensive or non-offensive.

The OffensEval 2019 shared task (Zampieri et al., 2019b) is one of several endeavours to further the state-of-the-art in addressing the offensive language problem. The paper describes the insights obtained when tackling the shared task using an ensemble of traditional machine learning classification models and a Long Short-Term Memory (LSTM) deep learning model. Section 2 first discusses other related approaches to detecting hate speech and offensive language. Then Section 3 describes the dataset and Section 4 the ideas and methodology behind our approach. Section 5 reports the results obtained, while Section 6 discusses those results with a particular eye towards the errors committed by the models. Finally, Section 7 sums up the key results and points to ways the work can be extended.

2 Related Work

Most datasets for offensive language detection represent multiclass classification problems (Davidson et al., 2017; Founta et al., 2018; Waseem and Hovy, 2016), with the annotations often obtained via crowd-sourcing portals, with varying degrees of success. Waseem et al. (2017b) state that annotation via crowd-sourcing tends to work best when the abuse is explicit (Waseem and Hovy, 2016), but is considerably less reliable when considering implicit abuse (Dadvar et al., 2013; Justo et al., 2014; Dinakar et al., 2011). They propose a typology that can synthesise different offensive language detection subtasks. Zampieri et al. (2019a) expand on these ideas and propose a hierarchical three-level-annotation model, which is used in the OffensEval 2019 shared task. Another issue is whether the datasets should be balanced or not (Waseem and Hovy, 2016), since there are much fewer offensive comments than benign comments in randomly sampled real-life data (Schmidt and Wiegland, 2017).

Classical Machine learning algorithms have been wielded to some success in automated offensive language detection, mainly Logistic Regression (Davidson et al., 2017; Waseem and Hovy, 2016; Burnap and Williams, 2015) and Support Vector Machines (Xu et al., 2012; Dadvar et al., 2013). Recently, however, deep learning models have outperformed their traditional machine learning counterparts, with both Recurrent Neural Networks (RNN) — such as LSTM (Pitsilis et al., 2018) and Bi-LSTM (Gao and Huang, 2017) — and Convolutional Neural Networks (CNN) having been used. Gambäck and Sikdar (2017) utilised a CNN model with word2vec embeddings to obtain higher F_1-score and precision than a previous logistic regression model (Waseem and Hovy, 2016), while Zhang et al. (2018) combined a CNN model with a Gated Recurrent Unit (GRU) layer. Malmasi and Zampieri (2018) used an ensemble system much like ours to separate profanity from hate speech, but reported no significant improvement over a single classifier system.

In terms of features, simple bag of words models have proven to be highly predictive (Waseem and Hovy, 2016; Davidson et al., 2017; Nobata et al., 2016; Burnap and Williams, 2015). Mehdad and Tetreault (2016) endorsed the use of character n-grams over token n-grams citing their ability to glaze over the spelling errors that are frequent in online texts. Nobata et al. (2016); Chen et al. (2012) showed small improvements by including features capturing the frequency of different entities such as URLs and mentions, with other features such as part-of-speech (POS) tags (Xu et al., 2012; Davidson et al., 2017) and sentiment scores (Van Hee et al., 2015; Davidson et al., 2017) also having been used (Schmidt and Wiegland, 2017). More recently, meta information about the users have been suggested as features, but no consistent correlation between user information and tendency for offensive behaviour online has been shown, with Waseem and Hovy (2016) claiming gender information leading to improvements in classifier performance, but with Unsvåg and Gambäck (2018) challenging this and reporting user-network data to be more important instead. Wulczyn et al. (2017) concluded that anonymity leads to an increase in the likelihood of a comment being an attack.

3 Data

The training dataset used for the shared task, the Offensive Language Identification Dataset (Zampieri et al., 2019a), contains 13,240 tweets, with each tweet having been annotated on the basis of a hierarchical three-level model. An additional 860 tweets were used as the test set for the shared task. The three levels/subtasks are as follows:

A – Whether the tweet is offensive (OFF) or non-offensive (NOT).

B – Whether the tweet is targeted (TIN) or untargeted (UNT).

C – If the target is an individual (IND), group (GRP) or other (OTH; e.g., an issue or an organisation).

The dataset does not have an equal number of offensive and non-offensive tweets. Only about one-third of the tweets are marked offensive, to partially account for the fact that most online discourse mainly is non-offensive. The corpus exhibits a larger number of male (∼3000) than female pronouns (∼2500), but is reasonably balanced.

Noticeably, the annotators were very conservative in their classification of tweets as non-offensive. It is unclear whether this was due to a more strict definition provided by the task organisers. For example, it is not immediately clear why tweets such as:[1] *"@USER Ouch!" (23159)*, *"@USER He is a beast" (50771)*, and *"@USER That shit weird! Lol" (31404)* were annotated as offensive.

The annotators furthermore seemed to disagree over the cathartic and emphatic use of swearing, as in *"@USER Oh my Carmen. He is SO FRICK-*

[1]In the examples, tweet IDs are given in parenthesis.

ING CUTE" (39021), *"@USER GIVE ME A FUCKING MIC" (60566)*, and *"@USER why are you so fucking good." (80097)*. These tweets do not really seem to be offensive except for them containing varying degrees of profanity. However, this is inconsistent, with some other tweets annotated not offensive, as expected: *"@USER No fucking way he said this!" (47427)*, and *"@USER IT'S FUCKING TIME!!" (59465)*, although most tweets that contained profanity were included in the offensive class.

Another thing to note is a large amount of political criticism within the tweets in the corpus. Whether it be left wing or right wing, extreme cases seem to be correctly annotated as offensive, while a healthy amount of criticism and political discourse correctly is annotated as non-offensive. The dataset also exhibits a dearth of racist tweets.

4 Methodology

Initially, a suite of features was composed based on those used successfully in previous work such as Waseem and Hovy (2016), Davidson et al. (2017), Nobata et al. (2016) and Burnap and Williams (2015): surface-level token unigrams, bigrams, and trigrams, weighted by TF-IDF; POS tags obtained through the `CMU tagger`[2] (Gimpel et al., 2011), which was specifically developed for the language used on Twitter; sentiment score assigned using a pre-trained model included in `TextBlob`[3]; and count features for URLs, mentions, hashtags, punctuation marks, words, syllables, and sentences.

`Scikit-learn`[4] (Pedregosa et al., 2011) was used as the primary library for modelling and training. L1-regularised Logistic Regression and a Linear Support Vector Classifier stood out initially as the best models. Further experimentation displayed that while those two models exhibited the highest accuracy, their recall of offensive tweets in subtask A and of untargeted insults in subtask B were lower than other classifiers provided in the Scikit-learn library, such as the Passive-Aggressive (PA) classifier (Crammer et al., 2006) and stochastic gradient descent (SGD).

Further exploration showed that the classifiers were not in agreement on certain tweets. This led to the idea of a vote-based ensemble model built on the following five classifiers combined by plurality voting (Kuncheva, 2004): L1-regularised Logistic Regression, L2-regularised Logistic Regression, Linear SVC, SGD, and PA. The ensemble model exhibited the best results in subtasks A and B. In subtask C, the multi-class classification problem and a severe reduction of the size of the training set led to much lower macro-averaged F_1-scores, with the ensemble model performing badly. A deep learning approach, based on an LSTM architecture (Hochreiter and Schmidhuber, 1997), was adopted specifically for this subtask. The model used a 200 dimensional `GloVe embedding`[5] pre-trained on 2 billion tweets (Pennington et al., 2014), with trainability set to False. The embedding layer was followed by a 1D convolution layer with 64 output filters and a Rectified Linear Unit (ReLU) activation function. The output of this layer was down-sampled using a max pooling layer of size 4. These inputs were fed into an LSTM layer of 200 units and subsequently a dense layer of 3 units with a softmax activation function. The model used the 'Adam' optimiser and the categorical cross entropy loss function. Due to the less amount of data, overfitting was quite common on as few as 3 epochs. Therefore, the model benefited from larger dropout values (up to 0.5). This model exhibited a better result than the ensemble model in subtask C, although only by a small margin.

5 Results

The experiments were run in three stages. First, before choosing the models, a mini ablation study was carried out on how various features affected the accuracy and F_1-score metrics of different models. The selected models were then optimised on the training set, before being evaluated on the test dataset.

5.1 Feature Engineering

The initial ablation study was carried out on a small sample space of models: the Linear SVC and L1/L2-penalised Logistic Regression. The results are represented in Table 1.

The ablation analysis revealed that surface-level token/character n-grams are by far the most predictive of the features. An interesting observation is the significantly improved recall of offensive tweets when character n-grams are included.

Table 2: Test set results (macro-F_1 and accuracy) for all subtasks, with class baselines ("All X").

However, the best F_1-score/accuracy was never achieved with the character n-gram model, and hence only token n-grams were included on the final feature list. Other features provided only small improvements in accordance with previous observations (Wiegand et al., 2018). The addition of POS information seems to cause a reduction in performance, so this feature was dropped, except for in subtask C, where a small positive effect could be observed. Furthermore, artificially balancing the classes by modifying class weights helped alleviate the low recall issue to some extent.

5.2 Training Set

A 10-fold cross-validation was performed on each model used in the ensemble, with the metrics obtained in each fold averaged to obtain a median for each model's performance on the dataset. These initial results were obtained only for subtask A, to decide which models would be a part of the ensemble. Most models used in the ensemble exhibited similar accuracy, but varied in the recall of offensive tweets. It was also observed that models with the higher recall of offensive tweets exhibited equivalently lower recall of non-Offensive tweets. These observations are graphically represented in Figure 1. Small improvements in F_1-score and accuracy were achieved while using the **ensemble model (F_1-score: .7338 and Accuracy: .7720)** over any other single classifier model.

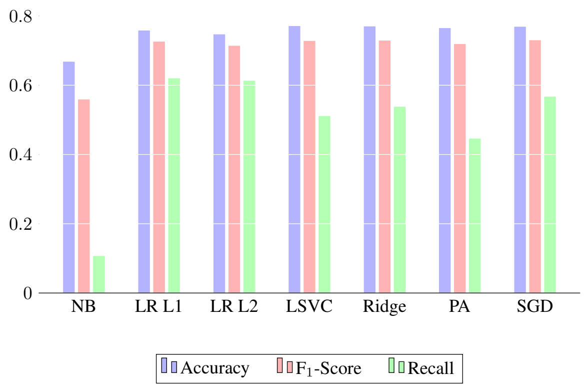

Figure 1: Performance of individual classifiers

5.3 Test Set

After the models were trained, their performance was measured on a separate set of 860 unseen tweets. All F_1-scores provided by the OffensEval organising team were macro-averaged. Baselines for each metric were also provided.

Subtask A: The best single model, Linear SVC came in at .7369 F_1-score and .8012 accuracy, while the ensemble model achieved a slightly improved .7434 F_1 and .8023 accuracy, as highlighted in Table 2. Most models used in the ensemble exhibited similar F_1 and accuracy, but recall of offensive tweets varying in the 0.4–0.7 range, with models with high offensive recall exhibiting equivalent decrease in recall of non-offensive tweets. On the unseen test data, the ensemble model reached a .5792 recall on offensive tweets and .8887 on non-offensive tweets.

Subtask B: This subtask represented a highly imbalanced dataset, with the number of targeted instances (213) dwarfing the number of untargeted instances (27). Here the ensemble model performed the best by far, while the different individual models exhibited high disparity on separation into the two classes. Though the ensemble at .7079 exhibited the highest F_1-score, its accuracy still trailed behind the baseline targeted (TIN) accuracy by a small margin (.8833 vs .8875). The recall of the targeted and untargeted (UNT) tweets were .9343 and .4815, respectively.

Subtask C: Subtask C entailed multi-class classification over the target type of insult. This was the only subtask which exhibited improvement through the inclusion of POS data. As seen in Table 2, the ensemble model achieved .4854 F_1 and .6291 accuracy. The LSTM network provided better results, coming in at .5056 F_1-score and .6385 accuracy, when using a 200-dimensional GloVe embedding. In this subtask, as expected, classification of the minority class, OTH, proved to be the most troublesome. Both the ensemble model and the LSTM exhibited very low recall on that class: .0571 and .0857, respectively. The recall of the IND and GRP classes were .7800 and .6923, respectively.

6 Error Analysis

This section gives a short qualitative analysis of the misclassifications in each subtask and hypothesises potential reasons for the errors.

Subtask A: As seen in Figure 2a, the ensemble model had more difficulty identifying offensive tweets than the non-offensive ones. As also noted in previous work by Davidson et al. (2017) and others, we see that the classifier finds it difficult to identify offensive tweets that lack profanity such as *"@USER Get back on your peanut farm old man" (24726)* and *"@USER She is such a witch. All she needs is a broom" (49813)*. The classifier also faced issues in classifying political discourse, as it may have learned trends of words such as 'MAGA', 'Trump', 'Liberals' and 'Conservatives' being appearing relatively often under the OFF (offensive) label. This leads to misclassification of tweets such as *"@USER Up next: liberals calling us out for calling him guilty." (59807)* and *"@USER there is a point where even liberals must question motives" (15788)* as offensive.

Subtask B: Due to the highly imbalanced data set, the minority class (UNT) as expected accounted for most of the misclassifications, as seen in Figure 2b. The simple trend deduced was that tweets with pronouns such as 'she', 'your', 'he', and 'I' were biased to be classified as targeted (TIN). This leads to misclassification of untargeted insults such as, *"@USER @USER Still no excuse... Where TF are her parents??? They are using him &amp; he is using her" (10641)* and *"@USER If someone is being too nice to you at happy hour and asking probing questions about what you do at Pub Citizen....make sure to troll them and say you're with Antifa or something." (58699)*, *"@USER I hate him im so fucking sorry" (91969)*. The opposite is also true, with targeted insults that contain no pronouns being misclassified as untargeted: *"@USER Google go to hell!" (52798), "@USER and bale is shit" (47806).*

Subtask C: Most misclassification in this subtask occurred on the Other (OTH) label; see Figure 2c. Here most tweets labelled OTH were classified under the Group (GRP) class, due to close similarity between the two labels. Consider the following examples: *"@USER @USER Because 45% of Americans are too lazy to vote. Non-voters skew liberal. And too many liberals who do vote throw their vote away on 3rd party losers. Next question?" (82171)* and *"@USER @USER @USER @USER Connections are vital with all of the crap Twitter forces on conservatives." (89193)*. Both these tweets are classified as GRP insults, probably due to the presence of terms such as 'Americans', 'liberals', and 'conservatives' that tend to relate to groups, while actually being annotated as OTH as they address an issue rather than a group.

There were also a considerable number of misclassifications of OTH class tweets as IND. These misclassifications are justified on similar grounds. Examples include *"@USER Google go to hell!" (52798)*, and *"@USER get your shit together" (18315)*.

7 Conclusion

The idea of a hierarchical classification of offensive language is a step in the right direction in reducing the ambiguity existing between various similar subtasks. It is yet to be seen, however, how effective this method would be in synthesising more specific subsets of offensive language. For example, the cyberbullying subtask instances may yield either OFF, TIN or IND labels at each level of classification, but we are unaware of how effectively models developed for the OffensEval subtask perform on cyberbullying data sets. Some issues that have plagued offensive language detection — such as the problem of ambiguity and overlap between various subtasks — could effectively be solved if the idea of hierarchical classification achieves what it sets out to do.

Consistent with previous work, we find that it is difficult to classify non-offensive tweets containing profanity and offensive tweets lacking profanity. We also found that a similar issue persists with tweets that are politically motivated and valid criticism incorrectly classified as offensive and similarly, political hate incorrectly classified as non-offensive.

On the topic of selecting a classification model, it is noteworthy that even a simple and crude deep learning model such as the one used here can obtain better results than a more polished ensemble model. Except for surface level n-grams, most features are not as predictive as we would like them to be.

The data analysis showed that even though the annotators of the OLID data set were experienced with the platform, there still exist quite a few cases of erroneous classification by the annotators, just as noted for other datasets (Waseem and Hovy, 2016; Davidson et al., 2017; Nobata et al., 2016), for which amateur annotators were found unreliable.

Offensive language detection has proven to be a more layered issue than was initially expected, but with various developments in research the task seems surmountable. Future work must focus on building upon previous endeavours, to reduce the redundancy between subtasks and publications. The OffensEval shared task is a significant step forward in achieving this goal and we look forward to seeing how future research will be affected by the work that has been done here.

Abstract

This paper proposes a system for OffensEval (SemEval 2019 Task 6), which calls for a system to classify offensive language into several categories. Our system is a text based CNN, which learns only from the provided training data. Our system achieves 80 - 90% accuracy for the binary classification problems (offensive vs not offensive and targeted vs untargeted) and 63% accuracy for trinary classification (group vs individual vs other).

1 Introduction

Background. Social media (e.g. Twitter, Facebook) is widely used today. For example, 68% of all Americans report owning a Facebook account in 2018 (Smith and Anderson, 2018), while 71% of Americans (within the ages of 18-24) report using Twitter. Online gaming is a second popular use of the internet, reaching upwards of 80 - 100 million monthly users depending on game (Goslin, 2018). These uses demonstrate the internet as a way for humans to connect with others. However, connecting with others can carry a downside. More than 1 in 3 young people have been cyberbullied online (cyb, 2018), this extends to around half of teens. Besides cyberbullying, offensive language, on a public forum, can cause users to stay away from certain platforms. Because of this, companies have increased their efforts to remove offensive language from their platforms (Terdiman, 2018). With the large amount of traffic these platforms see, a purely manual approach to detecting/removing offensive language is impossible, which means an automated approach is needed to help. OffensEval (Zampieri et al., 2019b) provides a community driven opportunity to build such systems. We approach this problem of classifying offensive tweets with a CNN architecture trained on the provided training dataset.

2 Proposed Approach

Our system is a variation of a Convolutional Neural Network (CNN), which was chosen since it has seen success previously with classification tasks

CNN Infrastructure. We experimented with two different Convolutional Neural Networks. The first whose architecture is based on the CNN originally proposed in (Kim, 2014) (CNN 1), and the second a combination of multiple CNNs (CNN 2). We further discuss each of these CNNs and their comparison on the training data. The visual structure for CNN 1 and CNN 2 can be found in figure 1 and figure 2 respectively.

Preprocessing. Both CNN 1 and CNN 2 begin by preprocessing the text of the tweet. As noted in section 3, URLs and user mentions are already denoted as URL and USER. Basic cleaning of the text is applied, includes removal of punctuation, converting text to lowercase, and filtering of stopwords via NLTK's stopword list[1]. Finally, all separated words are tokenized via nltk's tokenize() function[2].

Embedding Layer. CNN 1 and CNN 2 encode the text of a tweet as a word embedding with dimension j. We experimented with several j arriving at j = 100. Word embeddings for Non-Out of Vocabulary (OOV) words are obtained from Glove (Pennington et al., 2014) which has been trained on Twitter data[3]. Experiments were also conducted with Glove common crawl data, but no visible improvement was found. OOV words are randomly initialized as a word embedding. The embedding layer takes in i word embeddings of length j, where the i word embeddings are combined in the same sequential order as they appear in the tweet. We choose i as the length of the

[1]nltk.org/api/nltk.corpus.html
[2]nltk.org/api/nltk.tokenize.html
[3]nlp.stanford.edu/projects/glove/

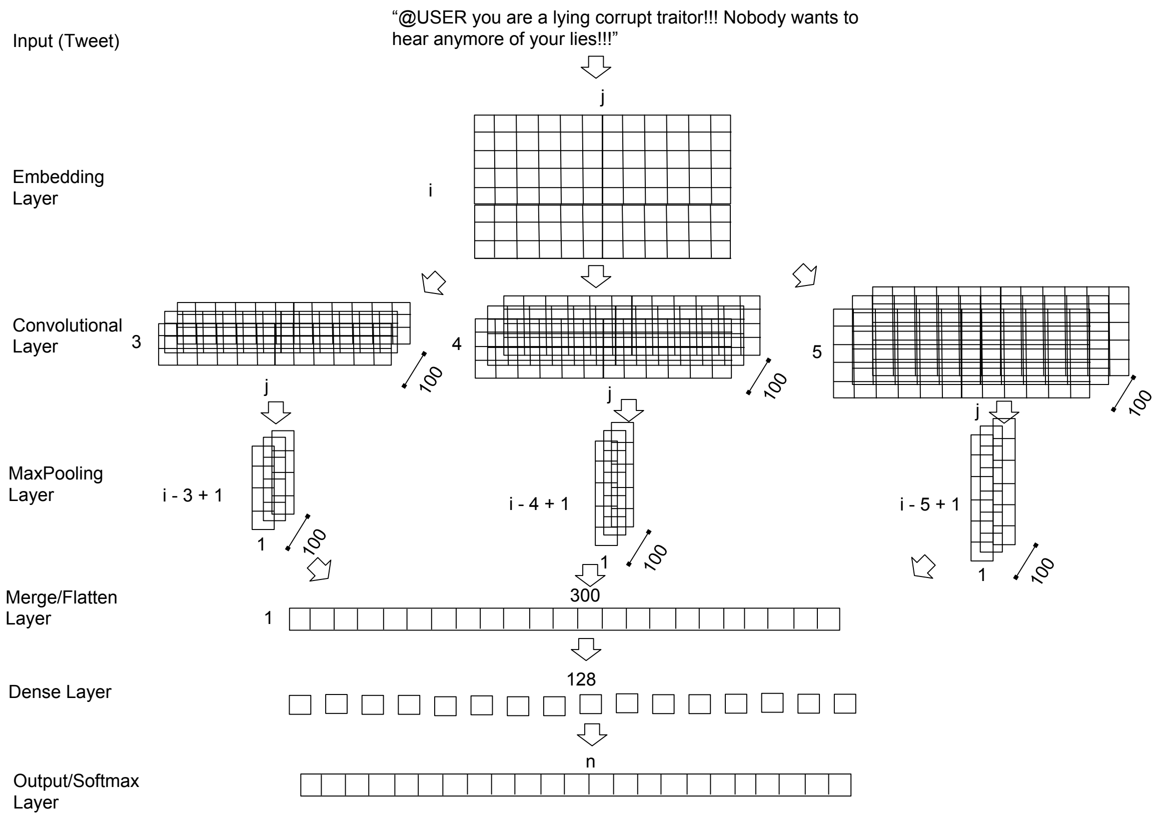

Figure 1: CNN 1 's Architecture

longest tweet (i.e. number of words after preprocessing). Any tweets less than *i* length are padded with zero embeddings at the end. CNN 1 and CNN 2 differ at this point and will be examined separately.

CNN 1 **Convolutional Layer.** CNN 1 applies three $k \times j$ convolutional windows to the embedding layer: a 3 x *j*, a 4 x *j*, and a 5 x *j* window. Applying each window to the embedding layer results in a $(i - k + 1) \times 1$ output, where k = {3,4,5} and corresponds to the length of the window. 100 filters of each window are applied to the embedding layer resulting in 100 $(i - k + 1) \times 1$ outputs for each *k*.

CNN 1 **Max pooling/Merge Layer** A max pooling of size $(i - k + 1) \times 1$ is applied to each separate filter output from the convolutional layer. The resulting outputs from all three max pooling streams are merged together then flattened to a 300 neuron layer.

CNN 1 **Dense Layer/Output Layer** The flattened layer is fed into a dense layer consisting of 128 neurons. ReLu is chosen as the activation function. Finally, the output of the dense layer is passed to the output layer of size *n* where *n* = number of classes. The output layer uses a softmax function as activation.

CNN 2 **Convolutional Layer.** CNN 2 applies three sets of three convolution windows to the embedding layer, each window in the format $k \times j$. The first set of convolution windows are $k = [2, 3, 4]$, the second are $k = [3, 4, 5]$, and third are $k = [4, 5, 6]$. Similar to CNN 1 , applying these filters results in a $(i - k + 1) \times 1$ output, and 100 filters exist for each *k* for each set of windows.

CNN 2 **Max pooling/Merge Layer.** Max pooling, in this instance, behaves similarly to CNN 1 . However, instead of merging all the pooled layers, only those in the same set are merged. This results in three separate flattened 300 neuron layers.

CNN 2 **Separate Dense layers** The three separate merged layers are fed through two dense layers consisting of 128 neurons each. ReLu activation function is used for all dense layers. Each merged layer is fed to their own respective dense layers. The second dense layers are finally merged together.

CNN 2 **Final Dense/Output Layers** The merged layer is fed through two more 128 dense layers with ReLu activation. Finally, the result is

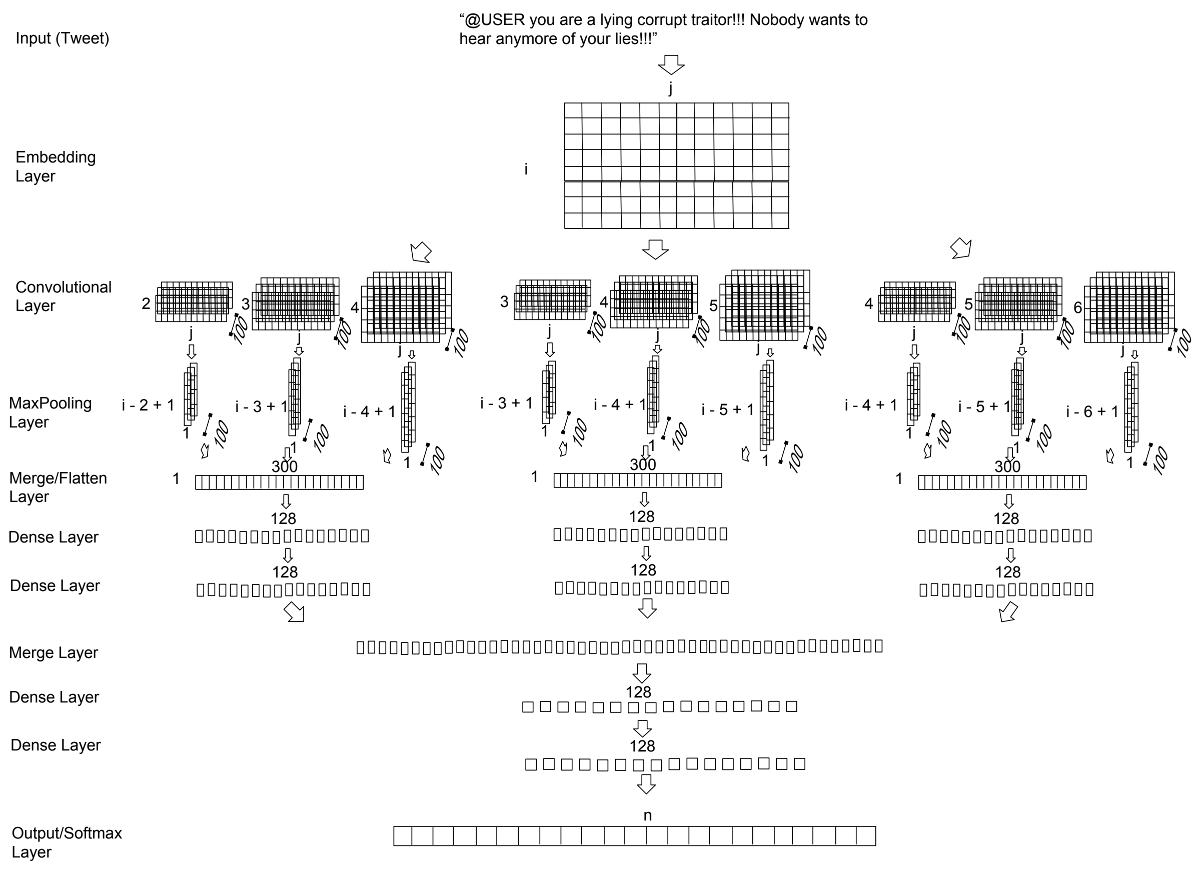

Figure 2: CNN 2 's Architecture

fed to the output layer of size n with softmax activation.

Hyperparameters/Training We experimented with different epochs and batch sizes and ended up finding epochs=30 and batch size = 50 worked best for our models. The only data trained on was the training data provided. More on this data in section 3. The system was implemented with Keras[4] and Tensorflow as the backend.

3 Dataset

Training Set. The data collection methods used to compile the dataset provided in OffensEval is described in Zampieri et al. (2019a). The training data set provided consists of 13,240 tweets. Each tweet, consists of up to three classifications, which correspond to subtasks further described in section 4. The classifications are as follows:

i. OFF - This post contains offensive language or a targeted (veiled or direct) offense

ii. NOT - This post does not contain offense or profanity.

iii. TIN - A post containing an insult or threat to an individual, a group, or others

iv. UNT - A post containing non-targeted profanity and swearing.

v. IND - The target of the offensive post is an individual: a famous person, a named individual or an unnamed person interacting in the conversation.

vi. GRP - The target of the offensive post is a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or something else.

vii. OTH - The target of the offensive post does not belong to any of the previous two categories (e.g., an organization, a situation, an event, or an issue)

A tweet which is classified as OFF, can be further classified into TIN or UNT. If classified as TIN, the tweet can be further classified into IND, GRP, or OTH. A breakdown of the frequency of each class label can be found in table 1.

[4]https://keras.io/

OFF				NOT
4400				8840
TIN			UNT	
3876			524	
IND	GRP	OTH		
2407	1074	395		

Table 1: A breakdown of frequency of labels of tweets, the classes underneath are further classifications of classes above (e.g. a tweet labeled IND is also labeled TIN and OFF)

Test Set. The test set provided follows the same classification rules as training and consists of 860 tweets. The 860 tweets can be classified into OFF or NOT, then 240 OFF tweets can be classified as TIN or UNT, and finally 213 TIN tweets can be classified as IND, GRP or OTH.

4 Subtasks

OffensEval divided the overall task of identifying/classifying offensive language into three subtasks, subtask A, B, and C.

Subtask A. Subtask A requires a system to classify tweets as either offensive (OFF) or not offensive (NOT). An example of a tweet marked as OFF (in provided training):

@USER you are a lying corrupt traitor!!! Nobody wants to hear anymore of your lies!!!.

An example of a tweet marked as NOT:

@USER Buy more icecream!!!.

A more expanded look at the training data can be found in section 3.

Subtask A Results. As our system only trained on the provided gold standard, this data set was used to gauge the effectiveness of our two systems. Five fold cross validation was used for predicting training data. The results for subtask A on training data can be found in table 2. CNN 1 and CNN 2 achieve similar results, an accuracy of 0.7468 and 0.7555, and a macro F1 score of 0.7130 and 0.7114, respectively. The results for our systems' performance on OffensEval test data subtask A can be found in table 3. As with the training data, CNN 1 and CNN 2 perform similarly on this task, with CNN 1 achieving 0.8 accuracy and a macro F1 score of 0.73.

Subtask B. Subtask B requires further classification of OFF tagged into two categories, targeted (TIN) and untargeted (UNT). An example of untargeted tweet is:

System	Acc.	Pr.	Re.	F1
CNN 1	0.7469	0.7145	0.7117	0.7130
CNN 2	0.7555	0.7256	0.7036	0.7114

Table 2: Subtask A Training Data Results, Pr.=Macro Precision, Re.=Macro Recall, F1=Macro F1 Score

System	Acc.	Pr.	Re.	F1
CNN 1	0.7988	0.7552	0.7175	0.7314
CNN 2	0.7767	0.7250	0.7379	0.7306
All NOT	0.7209			0.4189
All OFF	0.2790			0.2182

Table 3: Subtask A Test Results, Pr.=Macro Precision, Re.=Macro Recall, F1=Macro F1 Score. All OFF, NOT are baselines where that specific label was assigned to all tweets.

@USER @USER My favourite part of this is watching all the conservatives lose their minds as usual. Once again the Democrats a re being mean to us boo-hoo. LOL.

An example of targeted:

@USER You are a complete knob! It's ppl like you who are messing up this country. More details on data in section 3.

Subtask B Results. The results for cross validation on subtask B's training data are found in table 4. CNN 2 achieves a greater accuracy over CNN 1 on this subtask, 0.8723 compared to 0.8222, but still achieves a smaller macro F1 score of 0.5673 compared to 0.5827. Subtask B test results for our systems are found in table 5. Similar to training, CNN 2 outperforms CNN 1 in accuracy, 0.8958 to 0.8750, but achieves a similar trend in macro F1 scores, 0.6511 and 0.6528.

Subtask C. Subtask C requires further classification of those tweets tagged are targeted (TIN), into three classes, Individual (IND), Group (GRP), and Other (OTH). Examples:

IND tweet -*@USER You are a complete knob! It's ppl like you who are messing up this country*

GRP tweet - *@USER Assuming liberals are unarmed would be a grave mistake by the deplorables.*

System	Acc.	Pr.	Re.	F1
CNN 1	0.8222	0.5815	0.5839	0.5827
CNN 2	0.8723	0.6442	0.5545	0.5673

Table 4: Subtask B Training Data Results, Pr.=Macro Precision, Re.=Macro Recall, F1=Macro F1 Score

System	Acc.	Pr.	Re.	F1
CNN 1	0.8750	0.6732	0.6385	0.6528
CNN 2	0.8958	0.7478	0.6179	0.6511
All TIN	0.8875			0.4702
All UNT	0.1125			0.1011

Table 5: Subtask B Test Results, Pr.=Macro Precision, Re.=Macro Recall, F1=Macro F1 Score. All TIN, UNT are baselines where that specific label was assigned to all tweets.

System	Acc.	Pr.	Re.	F1
CNN 1	0.6925	0.5372	0.5224	0.5282
CNN 2	0.6772	0.5147	0.5136	0.5140

Table 6: Subtask C Training Data Results, Pr.=Macro Precision, Re.=Macro Recall, F1=Macro F1 Score

OTH tweet - *@USER Shooting in USA is so common no one is talking about gun control any more.*

More details on subtask C data in section 3.

Subtask C Results. The results for subtask C's cross validation on training data can be found in table 6. CNN 1 slightly outperforms CNN 2 in this task, achieving an accuracy of 0.6925 over 0.6772 and a macro F1 score of 0.5282 over 0.5140. Subtask C's test data results can be found in table 7. As subtask C is a three class problem (compared to the two class problem of A, B), the accuracy and macro F1 scores are lower overall. As with training, CNN 1 slightly outperforms CNN 2 in both accuracy, 0.6291 to 0.6197, and macro F1 score, 0.5061 to 0.4939.

5 Discussion

Systems outperform single labels. On test data, for all three subtasks, our system outperforms the baseline, provided by organizers, for assigning a single label for all tweets. Outperforming the best baseline (labeling tweets with highest frequent label) in terms of F1 by 0.32 in subtask A, 0.18 in subtask B, and 0.29 in subtask C. Outperformances in accuracy are seen in all three subtasks as well.

System	Acc.	Pr.	Re.	F1
CNN 1	0.6291	0.5513	0.5148	0.5061
CNN 2	0.6197	0.5079	0.5014	0.4939
All GRP	0.3662			0.1787
All IND	0.4695			0.2130
All OTH	0.1643			0.0941

Table 7: Subtask C Test Results, Pr.=Macro Precision, Re.=Macro Recall, F1=Macro F1 Score. All GRP, IND, OTH are baselines where that specific label was assigned to all tweets.

		NOT	OFF	
Key	NOT	559	61	620
	OFF	112	128	240
		System		860

Table 8: CNN 1 's Confusion matrix for subtask A

		TIN	UNT	
Key	TIN	201	12	213
	UNT	18	9	27
		System		240

Table 9: CNN 1 's Confusion matrix for subtask B

Results follow data distribution. The test confusion matrices for the higher scoring system (CNN 1), for subtask A, B, and C, can be found in table 8, table 9, and table 10 respectively. Training data for OFF and NOT make up 67% and 33% respectively. For test data, the percentages are 28% for OFF and 78% for NOT. As expected, our system identifies better identifies NOT (559/620 tweets) compared to OFF (128/240 tweets). Similar results occur for subtask B, TIN (201/213) compared to UNT(9/27), and subtask C, GRP (33/78) compared to (95/100) compared to (6/35). These results all follow distribution of training data, which might point to lack of training data for poorer results for smaller classes since deep learning systems depend on a good amount of training data.

Added complexity of CNN 2 **adds little to no improvement.** Although CNN 2 shows greater performance in accuracy on the training data for subtasks A and B, the performance does not follow through in the test data, as CNN 1 outperformed CNN 2 in subtask A and C for accuracy and all

		GRP	IND	OTH

	OTH	12	17	6	35
			System		213

Table 10: CNN 1 's Confusion matrix for subtask C

three subtasks for macro F1 score. Although CNN 2 performs slightly worse, this may not be due to the structure itself, CNN 2 is currently trained the traditional way (updates all weights as once) but it may be necessary for the branches to be trained separately. This requires further testing in the future.

6 Related Work

Offensive language detection and classification has become increasingly relevant in recent years with the rise of social media. Subsequently, researchers have also begun to look at aggression, cyberbullying, hate speech, and abusive language identification.

Cyberbullying. Cyberbullying detection has been approach by several teams. Dinakar et al. (2011) show that binary classifiers for individual labels outperforms multi-label classifiers. Xu et al. (2012) demonstrate that social media is a rich environment for studying cyberbulling with NLP. Dadvar et al. (2013) show the effectiveness of including context around a comment.

Abusive Language. Abusive language has also seen increase in study. Nobata et al. (2016) construct a machine learning algorithm and test with different lexical features, outperforming at the time state-of-the-art methods. Mubarak et al. (2017) expand abusive language identification to Arabic social media. Fišer et al. (2017) propose a legal framework, dataset and anotation schema for abusive online language in Slovene. Su et al. (2017) propose a system which can not only detect, but also rephrase abusive language in Chinese. Waseem et al. (2017) propose breaking abusive language identification into further subtasks. Founta et al. (2018) leverage crowd sourcing to produce a large (80,000) annotated data set of abusive Twitter language.

Hate speech. Hate speech identification has come to the forefront for research as it deals with current hot button issues (e.g. racism, sexism). Schmidt and Wiegand (2017) and Fortuna and Nunes (2018) compile a surveys of current hate speech detection.

Other teams have brought to question how we view and handle hate speech. Ross et al. (2016) show the difficulty of annotating hate speech and propose handling classification as non-binary. Malmasi and Zampieri (2017) establish lexical baselines for hate speech detection by applying supervised classification methods and Malmasi and Zampieri (2018) show the problems which can arise when distinguishing profanity from hate speech. ElSherief et al. (2018) further look to understand hate speech by looking into the target of hate speech (i.e. at a individual or more general group).

Machine learning classifiers are leveraged in this field as well. Kwok and Wang (2013) employ a machine learning classifier to identify racist tweets. Burnap and Williams (2015) test a machine learning system on different n-gram features to identify hate speech on Twitter. Tulkens et al. (2016) use hate speech dictionaries along with support vector machines to identify racism on Dutch social media. Schofield and Davidson (2017) demonstrate three standard methods for producing features for text classification, targeting specifically the problem of automatic hate speech identification.

Subsequently, deep learning is seen in hate speech detection as well. Djuric et al. (2015) train and leverage comment embeddings to help identify hate speech. Gambäck and Sikdar (2017) show the effectiveness of convolutional neural networks (CNN) when identifying hate speech. Zhang et al. (2018) identify hate speech using a convolution-GRU based deep neural network.

Offensive Language. Offensive language identification aims to broaden the scope of negative language identification. Wiegand et al. (2018) proposed and ran a GermEval task similar to OffensEval, which had participants classify offensive language as offensive or other, then further classify the offensive tagged language.

7 Conclusion/Future Work

We have proposed and tested two different CNN architectures for identifying offensive language. Future work would aim to improve the current CNN design by testing different word windows and training techniques. Furthermore, since deep learning performs better with large amounts of training data, increasing the training data, perhaps even with silver standards if not gold, should help further improve the system's predictions.

Abstract

The paper presents a system developed for the SemEval-2019 competition Task 5 *hat-Eval* Basile et al. (2019) (team name: *LU Team*) and Task 6 *OffensEval* Zampieri et al. (2019b) (team name: *NLPR@SRPOL*), where we achieved 2^{nd} position in Subtask C. The system combines in an ensemble several models (LSTM, Transformer, OpenAI's GPT, Random forest, SVM) with various embeddings (custom, ELMo, fastText, Universal Encoder) together with additional linguistic features (number of blacklisted words, special characters, etc.). The system works with a multi-tier blacklist and a large corpus of crawled data, annotated for general offensiveness. In the paper we do an extensive analysis of our results and show how the combination of features and embedding affect the performance of the models.

1 Introduction

In 2017 two-thirds of all adults in the United States have experienced some form of online harassment (Duggan, 2017).[1] This, together with various episodes of online harassment, boosted research on the general problem of recognizing and/or filtering offensive language on the Internet. Still, recognizing if a sentence expresses hate speech against immigrants or women, understanding if a sentence is offensive to a group of people, an individual or others – these tasks continue to be very difficult for neural networks and machine learning models to accomplish. In order to do this, various implementations have been proposed; for the most successful recent approaches see Pitsilis et al. (2018); Founta et al. (2018); Wulczyn et al. (2017); Waseem and Hovy (2016); Park and Fung (2017); Davidson et al. (2017). Most of them use various combination of features to recognize these characteristics.

This article presents a system that we have implemented for recognizing if a sentence is offensive. The system was developed for two SemEval-2019 competition tasks: Task 5 *hatEval* "Multilingual detection of hate speech against immigrants and women in Twitter" Basile et al. (2019) (team name: *LU Team*) and Task 6 *OffensEval* "Identifying and categorizing offensive language in social media" (Zampieri et al., 2019b) (team name: *NLPR@SRPOL*). Table 1 shows the results that we achieved with our system in the SemEval-2019 competitions.

Competition	Placement
Task 6-A	8th position
Task 6-B	9th position
Task 6-C	2nd position
Task 5-A	8th position (ex aequo)

Table 1: SemEval-2019 results.

In order to create a highly accurate classifier, we combined state-of-the-art AI with linguistic findings on the pragmatic category of impoliteness (Culpeper, 2011; Jay and Janschewitz, 2008; Brown and Levinson, 1987). We achieved this by deciding on the factors that point to the impoliteness of a given expression (for the blacklists) or the entire sentence (for corpus annotation). Such factors led us to divide the blacklist into "offensive" and "offensive in context", as most linguistic studies of impoliteness focus on various aspects of the context. Furthermore, linguistic research made it possible to arrive at a maximally general definition of offensiveness for the crowdsourced annotators.

[1] Due to the topic of the SemEval-2019 Tasks 5 and 6, the present paper contains offensive expressions spelled out in full. These are solely illustrations of the problems under consideration. They should not be interpreted as expressing our views in any way.

The article is organized as follows. Section 2 presents the current state of the art for offensive sentence classification. Section 3 explains the architecture of our system (features, models and ensembles). Section 4 describes the datasets and how they were created. Section 5 shows the results of the SemEval-2019 tasks in detail, motivating which combination of features and models was the best. Finally, section 6 offers conclusions together with our plans for future research.

2 Related work

In recent years, the problem of recognizing if a sentence is offensive or not has become an important topic in the machine learning literature. The problem itself has different declinations depending on the point of view. Currently there are three main areas of research in this topic in the machine/deep learning community:

1. Distinguishing offensive language from non-offensive language;
2. Solving biases in deep learning systems;
3. Recognizing more specific forms of offensivness (e.g. racism, sexism etc.).

The main problem with each of the tasks is the amount of data available to researchers for experimenting with their systems. This – together with the fact that it is difficult to clearly define what is offensive/racist/sexist or not – makes the three problems listed above very difficult for a deep learning system to solve.

Articles have showed that there is a strong bias in text and embeddings, and have tried to solve this bias using different techniques (Zhao et al., 2018; Dixon et al.; Bolukbasi et al., 2016). Furthermore, thanks to a dataset defined in Waseem and Hovy (2016) and Waseem (2016), various works have gone in the direction of recognizing sexism and racism in tweets (Pitsilis et al., 2018; Park and Fung, 2017).

Another field of work was recognizing offensiveness in the Wikipedia internal discussion forum dataset (Wulczyn et al., 2017). This dataset has led to other articles making systems for distinguishing between offensive and non-offensive language (Founta et al., 2018; Pitsilis et al., 2018; Kumar et al., 2018; Gröndahl et al., 2018; Li, 2018; Park and Fung, 2017; Aken et al., 2018).

Linguistic expertise enhanced the functionality at two stages: sentence annotation (described in detail in Section 4) and active creation of blacklists (Section 3). The completion of these tasks breaks new ground, as there exist no corpus linguistic studies on the generality of offensive language, to the best of our knowledge. Recent approaches of narrower scope are Dewaele (2015) and McEnery (2006).

3 System description

Our system is composed of three major elements, described below:

- Features – common to all models;
- Various models – neural networks or not;
- Ensemble.

3.1 Features

This section describes the features that we used and explains their role. We implemented the following features:

- Number of blacklisted words in the sentence;
- Number of special characters, uppercase characters, etc.;
- A language model taught to recognize offensive and not offensive words.

Blacklisted We used two kinds of blacklisted expressions: "offensive" and "offensive in context". The "offensive in context" expressions are offensive in specific contexts and unoffensive otherwise, e.g. *bloody* or *pearl necklace*. This dictionary was compiled by crowdsourcing and contains about 2,300 words (+ variations). The blacklist consists of swear words, invectives, profanities, slurs and other impolite expressions.

Special characters, uppercase, etc. We checked the graphemic characteristics of the written text and we gave this as a feature to the model. We mainly used the non user related features defined in Founta et al. (2018).

Language model Inspired by the work of Yu et al. (2018), we decided to train a language model on both offensive and non-offensive words. For this purpose, we trained two character based language models, one on the offensive dictionary (described above) and the other from a corpus of non-offensive words. After training them we used the difference in perplexity of each input word as a feature for the model.

3.2 Models

We trained various models and then combined them in an ensemble. This section outlines the models that were part of the ensemble.

Embeddings Both the Neural networks and the machine learning models used embeddings. We used the following embeddings: ELMo (Peters et al., 2018), fastText (Bojanowski et al., 2017), custom embeddings, and Universal Sentence Encoder (Cer et al., 2018). For fastText, we used the 1 million word (300d) vectors trained on Wikipedia 2017, below called fastText 1M.

The custom embedding was built by training a fastText embedding on our corpus. We then combined the 1M fastText embeddings with these custom embeddings using Truncated SVD after concatenating their columns (this was done inspired by the work (Speer et al., 2017)). Building custom embeddings was important for the offensive word classification because the original version of the fastText 1M embeddings contained around 50% of the words in the corpus while after adding the custom embeddings, only 30% of the words were out of the vocabulary. Below, this combination of embeddings is called "combined".

Neural networks We used two types of neural network models:

- LSTM models (Hochreiter and Schmidhuber, 1997);
- Transformer models (Vaswani et al., 2017).

For both models, we used multi-head attention and we tried different embeddings. In most cases, the Transformer models had better results than the LSTM models, and this is what we used in the submissions. The parameters of the models are described in Appendix A.1. In both models, the Features described in Section 3.1 are concatenated to the output of the model.

OpenAI GPT One of the models that we used was the OpenAI GPT (Radford et al., 2018). We used the GPT model in its original form, without changing any parameters. Our results show that this model works very well when there is enough data for finetuning. However, small classes – as in Task 6 Subtask C – pose a problem (see Section 5).

Machine learning models We used two machine learning models:

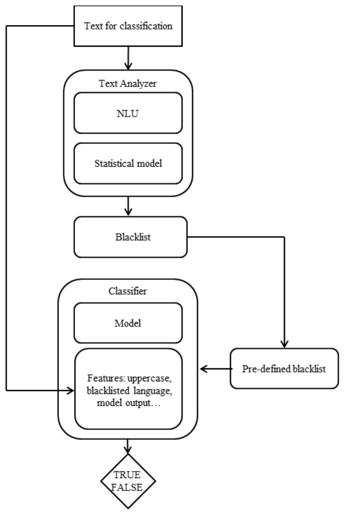

Figure 1: Pipeline for the offensive sentence classifier.

- Random forest;
- SVM.

For these models, we built a pipeline where:

- In a first step we either compute the embeddings of the sentences or get the Td-Idf score.
- In a second step we concatenate the result of the first step with the Features described in Section 3.1 (if used).
- We run the classifier.

As embeddings we used only the Universal Encoder, and with good results.

Ensemble For the ensemble we used a voting classifier with soft voting (based on the probability returned by each model). For each subtask, we show which combination of models gave the best results.

The pipeline for the entire offensive sentence classifier is shown in Figure 1.

4 Data/Datasets

4.1 Preprocessing

Preprocessing plays a crucial role in the analysis of potentially offensive sentences, because most inputs use highly non-standard language. Hence, preprocessing was mainly focused on normalizing the language for simplifying the model work. We applied the following preprocessing:

- Substituting user names with <USER> tokens;
- Removing all links;
- Normalizing words and letters;

- Normalizing spacing and non-standard characters;
- Over/Downsampling of the classes;

After the preprocessing, we split by space and used each token as an input to the models.

Normalizing words and letters We have a dictionary containing common spelling variants of words found in our corpus. We used this to change words to the "canonical" form. Examples of such variants can be seen in Table 2.

Word	Common variants
fuck	fvck, fok, fucc, phuk
nigger	n1gga, n1gr, niigr, nuggah, nigg3r
boob	booob, boooooob
motherfucker	Mutha Fukker, Motha Fuker
ass	a55, 455 ("leetspeak" variants)
assclown	ẫšs̡ĺσẇη (vulgarity obfuscation)

Table 2: Common spelling variants.

Over/Downsampling For each Task/Subtask, we systematically oversampled the classes to obtain a balanced dataset. This was especially important for Task 6/Subtask C, which introduced 3 highly unbalanced classes. For most subtasks we did two things at the same time:

- Downsampled the majority class when there was too much difference from the other classes;
- Oversampled the minority class after downsampling.

4.2 Datasets

In this section we give a high level overview of the datasets we used for training our models for the SemEval-2019 tasks. Detailed statistics are presented in Appendix A.2. For training the model, we used several openly available datasets:

- *Hate Sonar* gathered from Twitter (Davidson et al., 2017);
- 2 related hate speech datasets from Twitter (Waseem and Hovy, 2016), (Waseem, 2016);
- Insulting internet comments (Impermium, 2012);
- Attacking, aggressive, toxic and neutral comments from Wikipedia Talk Pages (Wulczyn et al., 2017);
- *Vulgar Twitter* (Cachola et al., 2018);

our own custom-built corpora and datasets provided by the SemEval organizers.

From the sources listed above, we added a total of 20,399 sentences to the SemEval-2019 corpus for Task 5, and 97,759 sentences to the one for Task 6.

Custom Offensive language corpus Our custom dataset was built by crowdsourcing and by crawling content from the Internet. The dataset is balanced, with 49,179 not offensive and 48,580 offensive comments. Around half of the dataset was labeled by linguists, who were asked to look for "general offensiveness". This could take various forms:

- Expletives, swear-words, offensive terms;
- Rude meaning;
- Meaning that is harsh politically/ethically/ emotionally, and hence expression of hate/ disgust/disrespect;
- Uncomfortable topics related to the human genitals in a gross way;
- Hate speech, sarcasm, sexism, racism, violence, etc.;
- Discussion of drug use or other illegal actions;
- For any other reasons, children should not have access to the sentence.

To each sentence, the linguists assigned one of the three labels:

- OFF – offensive sentence,
- NOT – not offensive sentence,
- Nonsense – random collection of words or non-English (removed from the corpus).

In cases of disagreement between linguists, we chose the most popular label, if applicable, or obtained an expert annotation. We calculated Fleiss' kappa for inter-annotator agreement (Fleiss, 1971), which extends Cohen's kappa to more than two raters (Cohen, 1960). For random ratings Fleiss' $\kappa = 0$, while for perfect agreement $\kappa = 1$. Our κ was equal to 0.62, which falls in the "substantial agreement" category, according to Landis and Koch (1977).

The remaining part of the corpus was assessed automatically with a blacklist-based filter.

Dataset for Task 6 The OLID dataset (Zampieri et al., 2019a) contains Offensive and Not Offensive sentences. The Offensive sentences are further categorized into:

- TIN – targeted insults and threats,
- UNT – untargeted.

and the targeted (TIN) category was further subdivided into:

- IND – individual target,
- GRP – group target,
- OTH – a target that is neither an individual nor a group.

Our full offensive language corpus, described in the previous subsection, was used for this task. The OFF sentences were further annotated for the two categories while the NOT sentences were not further annotated. All the additional classes were added automatically by a wordlist-based annotator.

Dataset for Task 5 The dataset for Task 5 (Basile et al., 2019) contained the classes:

- HATE – hate speech against women or immigrants,
- NOHATE – no hate speech against women or immigrants.

together with other subclasses. Given that we participated in the Task 5 Subtask A, we annotated our corpus only with these two labels. Using a mixture of automated and manual annotation, we were able to add around 30k sentences from our dataset for this task.

5 Results

SemEval In Table 3 we show the average F1 of our models for all the SemEval-2019 Tasks and Subtasks. These results were obtained by using an ensemble of models and in Table 4 we show which model was used inside which ensemble. The acronyms used in the table correspond to:

- **GPT** : OpenAI's GPT model
- **RF**: Random Forest
- **T**: Transformer model
- **U**: Universal encoder
- **EL**: ELMo embeddings
- **CO**: Combined embeddings (see 3.1 for an explanation of this)
- **F**: Features.

Given the short amount of time, during the SemEval competition we were unable to test all the combinations of models and data preparation types to choose the best combination for the Ensemble. We thus selected the models in the ensemble by experimenting with part of the models. This is the main reason why only one model used in Task 5 contains additional features (the TELUF model).

Ensemble	Competition	Macro F1
6-A	Task 6-A	0.80
6-B	Task 6-B	0.69
6-C	Task 6-C	0.63
5-A	Task 5-A	0.51

Table 3: SemEval-2019 results breakdown.

Task	6-A	6-B	6-C	5-A
GPT	✓		✓*	✓
RF	✓	✓	✓	✓
RF+U	✓	✓		✓
T+EL	✓		✓	✓
T+CO+U	✓		✓*	✓
T+EL+U+F				✓

Table 4: Ensemble detail. The models marked with * have been trained with an unbalanced dataset.

After the competition, we tried the models contained in the Ensembles on all the tasks; detailed results are presented in Table 9 in the Appendix. It is important to note though that the results in the Appendix cannot be directly compared with the ones of the SemEval competition because although the models were the same, the Test data was different (the golden data has not been released yet).

From the results we clearly see that we have two "data regimes": in the *low data regime* (Task 6 Subtask B and C), Random forest (with or without the Universal embeddings) is the best choice. However, in *the big(ger) data regime*, Fine tune is the best model. Also in the low data regime each model works best with a different data preparation strategy: GPT with unbalanced data, the Transformer with oversampled and downsampled data while Random forest with oversampled data.

Ablation studies In this part we show the results of ablation studies on the transformer and random forest models. In this study, we want to understand how far the final result was influenced by the linguistically based features and preprocessing we defined in this article. All the results obtained in this section have been computed on a Test set

Model	Task 6 A	Task 6 C
T + CO	0.73	0.44
T + CO + U	0.71	0.52
T + CO + F	**0.75**	0.45
T + CO + U + F	0.74	0.47
RF	0.7	**0.54**
RF + F	0.68	0.43
RF + U	0.72	0.48
RF + U + F	0.69	0.38

Table 5: Macro F1 for selected Transformer models with different combinations of features

created from the Train set shared in the SemEval-2019 tasks (as in Appendix A.3). As we discussed in the previous section, the Tasks were characterized by a "low" (Task 6 C) and a "big" data regime (Task 6 A), thus we compare the ablation study results for these two extreme regimes.

In a first study we wanted to understand how the features influenced the results. For this reason, we tried some combinations of Features, Embeddings and Models on both Task 6 Subtask A and Task 6 Subtask C; the relevant macro F1 results are shown in Table 5. The table shows that, in the big data regime, the Random Forest works best when only the Universal Encoder is used, while the Transformer model improves its performance when the features are added. On the other hand, in the low data regime, we see that the plain Random Forest outperforms all the other combinations. This is probably because the more things we add, the more the model needs to learn, and with little data this is simply not possible.

In a second study we wanted to understand how much the normalization defined in Section 4.1 affected the performance of the model. For this reason, we trained again the best models in Table 5 for both Subtasks with an unnormalized version of the dataset. The results are that for Subtask A, the model **T + CO + F** F1 decreased from 0.75 to 0.73 while for Subtask C, the **RF** F1 decreased from 0.54 to 0.44.

The results of this section seem to point to the fact that the features we added and the normalization we used are beneficial for the performance of the models. Further work will be devoted to understanding this point though.

6 Conclusions

The article presented our approach to making a classifier recognizing offensive expressions in text. It showed how our architecture is suitable for multiple (related) offensive sentence classification tasks. It also showed how we built the features and the data that the model used for learning. Thanks to our system, we were 2^{nd} in the SemEval-2019 Task 6/Subtask C. In the article we also showed with ablation studies that the linguistic features proposed and the embeddings added improve the performance of the models we used.

In the future, we will extend our system to recognize a wider set of features. We are currently working on analyzing the linguistic differences between the offensive corpus and the non-offensive corpus. Specifically, we think that by analyzing the differences, we should be able to build a "white-list" of terms that can be used as features that will help the classifier understand which sentences are less likely to be offensive.

A Supplementary Materials

A.1 Model parameters

The following parameters were used for all LSTM and Transformer models in the results Section 5:

- keep probability: 0.8;
- LSTM units: 100;
- L2 regularization: 0;
- fully connected size: 256 or 128;
- multihead attention:
  - attention size: 5 or 2,
  - attention head: 4

For GPT, we used a learning rate of 6.25e-5 and an L2 regularization of 0.01.

A.2 Data

In Table 6 we show the amount of data that was contained in our corpus (overall). In Table 7 and 8 we show the data for Task 5 and Task 6. For a description of how these corpora were built and annotated, see Section 4.2.

Source	NOT	OFF	Total
Custom corpus	16,545	12,938	29,483
Kaggle	2,629	3,463	6,092
Twitter	917	23,438	24,355
Wikipedia	29,088	8,741	37,829
Total	49,179	48,580	97,759

Table 6: Statistics for our offensive language corpus. The Kaggle dataset was collected by Impermium (2012). The Twitter dataset was compiled from 4 sources: Davidson et al. (2017), Cachola et al. (2018), Waseem and Hovy (2016) and Waseem (2016). The Wikipedia dataset was collected by Wulczyn et al. (2017).

Class	Total
HATE	16,508
NOHATE	11,154

Abstract

This paper presents our submission for the SemEval shared task 6, sub-task A on the identification of offensive language. Our proposed model, C-BiGRU, combines a Convolutional Neural Network (CNN) with a bidirectional Recurrent Neural Network (RNN). We utilize word2vec to capture the semantic similarities between words. This composition allows us to extract long term dependencies in tweets and distinguish between offensive and non-offensive tweets. In addition, we evaluate our approach on a different dataset and show that our model is capable of detecting online aggressiveness in both English and German tweets. Our model achieved a macro F1-score of 79.40% on the SemEval dataset.

1 Introduction

The ever-increasing amount of user-generated data introduces new challenges in terms of automatic content moderation, especially regarding hate speech and offensive language detection. User content mostly consists of microposts, where the context of a post can be missing or inferred only from current events. The challenge of automatic identification and detection of online aggressiveness has therefore gained increasing popularity in the scientific community over the last years.

Several recent workshops and conferences such as TRAC (Kumar et al., 2018), ALW2 (Fišer et al., 2018), and GermEval (Wiegand et al., 2018) show the growing importance of this subject. The SemEval 2019 shared task 6 (Zampieri et al., 2019b) further addresses this topic by introducing the Offensive Language Identification Dataset (OLID), which consists of tweets, labeled with a three-level annotation model (Zampieri et al., 2019a). Sub-task A is composed of a binary classification problem of whether a tweet in the dataset is offensive or not. Sub-task B focuses on different categories of offensive language and the goal of sub-task C is to identify the targeted individual of an offensive tweet.

In the following paper, we present our contribution to sub-task A. After the related work section, we outline our conducted experiments in section 3 and further describe the used baseline model, as well as the submitted model. In section 4 we report the results of our experiments on the OLID dataset and the additionally used GermEval dataset. Section 5 discusses our results and section 6 concludes our work and describes possible future work.

2 Related Work

Several methods and models have been presented in literature over the last decade to address the predicament of identifying hate speech, offensive language, and online aggressiveness. In the following section, we present the most notable contributions related to our work.

The tweets collected by Davidson et al. (2017) were divided into Hate, Offensive, and Neither. Their proposed algorithm uses unigram, bigram, and trigram tokens as features, weighted by the respective TF-IDF, as well as Part-of-Speech (POS) tagging and different metrics to determine the readability and sentiment of a tweet. Logistic-regression and linear SVM result in the best performance for a wide range of assessed classifiers. Nobata et al. (2016) collected comments from Yahoo! Finance and News articles over a time period of one year and labeled them as either 'Abusive' or 'Clean'. They experimented with various different features, including n-gram, linguistic, syntactic, and distributional semantics features.

Various approaches utilized deep learning models for text categorization. Zhang et al. (2015) proposed a character-level convolutional network for text classification on large-scale datasets. Their network uses 1-dimensional convolutional filters to extract features from different character embeddings. Gambäck and Sikdar (2017) further experimented with convolutional networks in the context of online hate speech classification. Their research work compares different types of convolutional models, namely character-level, word vectors with a pretrained word2vec (w2v) model, randomly generated word vectors, and w2v in combination with character n-grams. The results of their experiments suggest that w2v embeddings are the most suitable for this task. Zhang et al. (2018) suggest an architecture similar to our network, where a convolutional filter extracts features from pretrained word embeddings. After max pooling, the feature maps are processed using a unidirectional GRU. Their model is compared to a bag-of-n-gram model on various multi-class hate speech datasets and shows promising results. A detailed survey on different architectures, methods and features for offensive language detection is provided by Schmidt and Wiegand (2017).

3 System Description

In addition to Twitter data provided by the organizers of the SemEval shared task, we further evaluate our approach on German tweets from the GermEval (2018) shared task. The OLID dataset contains 13,240 tweets, with 4,400 offensive and 8,840 non-offensive tweets (66.77% offensive, 33.23% non-offensive). Similarly, the GermEval dataset contains 5,009 tweets, divided into 1,688 offensive and 3,321 non-offensive tweets (66.30% offensive, 33.70% non-offensive). To compensate for the imbalanced class distributions and weigh each class equally, we choose the macro averaged F1-score of both classes as our main evaluation metric. From both data sets we use 10% of our tweets as test set. The remaining tweets are split into 90% training set and 10% validation set. We conduct a stratified 10-fold cross-validation on the training and validation set to prevent overfitting and to validate our model.

The pretrained w2v model, which is used to initialize the weights of our embedding layer, resulted from the work of Godin et al. (2015). The w2v model for the GermEval dataset originates from our previous work (2018).

For comparison to our proposed model, a token bag-of-n-gram model composed of unigrams, bigrams, and trigrams weighted by their TF-IDF is used as baseline approach. We subsequently analyze the performance of different classifiers on the resulting feature space.
We have used the packages *keras*, *scikit-learn*, *gensim*, and *nltk* for preprocessing and the implementation of our models.

3.1 Preprocessing

Tweets are first tokenized and converted to lowercase. We constrain repeated character sequences to length 3 and replace all longer character sequences. HTML character encodings are replaced by their corresponding literal or token representation (e.g. '*&amp;*' translates to '*and*'). Tokens are further split if they enclose a set of special characters ('\', '/', '&', '-'). Since hashtags are often used to replace contextually important words mid-sentence, we split hashtags in the actual hash-symbol and the following string to keep the semantic information of a hashtag (e.g. '*Brainless #Liberal Stooge Ocasio-Cortez*').

3.2 Baseline Model

A TF-IDF bag-of-words model as baseline approach is chosen to evaluate the performance of our model. We limit our feature space to the 10,000 most frequently used unigrams, bigrams, and trigrams in a corpus. Furthermore, we stem each token in the preprocessing phase and remove stopwords. We compare the performance of several classifiers, namely multinomial Naive Bayes (NB), SVM, Decision Tree (DT), and Logistic Regression (LogR) and conduct a grid search to optimize our hyper-parameters.

3.3 C-BiGRU

After the preprocessing step, we construct a dictionary which maps all unique tokens to their number of occurrences in the respective corpus. Tokens which appear only once in a corpus are disregarded and treated as unknown token. As a next step, we construct the weighting matrix $W^{m \times dim}$ for our embedding layer, where dim is the dimension of the used w2v model and m the number of unique tokens $t_i, i \in \{1, ..., m\}$. The word vector of t_i is stored in W if the token is represented in the w2v model. If t_i has no pretrained word vector, we generate a random vector drawn from the uniform distribution within $\left[-\sqrt{\frac{6}{dim}}, \sqrt{\frac{6}{dim}}\right]$ as suggested by He et al. (2015). We fix the maximum length of a sentence to 150 tokens, longer sequences are clipped at the end and shorter sequences are padded with a masking token.

The convolutional layer of our classifier consists of $(k \times 128)$ 1-dimensional filters, where k is the number of different window sizes. These window sizes range from 2 to 5 and allow the extraction of n-gram features. The padding of the input is kept constant, resulting in the same output sequence length as the input. We further choose ReLu as activation function. The resulting feature maps are concatenated and passed towards the recurrent layer.

Gated Recurrent Units (GRU) as initially proposed by Cho et al. (2014) are used in RNNs to capture long-term dependencies of input sequences. Similar to Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997) GRU are able to overcome the vanishing gradient problem by using a gating mechanism. GRU have shown to achieve comparable results to LSTM in sequence modeling tasks and are able to outperform the latter on smaller data sets (Chung et al., 2014). The recurrent layer in our model consists of a bidirectional GRU, where the concatenated feature maps, which resulted from the convolutional layer, are used as input for the GRU layer. Simultaneously, the reversed copy of the input sequence is used for the second GRU layer. Both GRU layers return a hidden state for each processed feature map. The output of both layers is then concatenated. We set the length of the returned hidden states to 64 for both layers, resulting in an output space of (150×128) neurons.

Afterwards, a global max pooling layer reduces the output space to (1×128) nodes. The following fully-connected layer consists of 32 neurons, which connect to a single output neuron. The output neuron utilizes the *sigmoid* activation function.

To additionally prevent overfitting, we include two dropout layers with a dropout rate of 0.2; one after the embedding layer and another one after the fully-connected layer. Furthermore, we adopt early stopping and use 10% of the training data as validation split. We use cross entropy as error function for our model and the optimizer 'adam' to update our network weights (Kingma and Ba, 2014). The batch size for the gradient update is set to 32. A schema of our proposed model is illustrated in Figure 1.

4 Results

For the comparison model, the SVM performs best on the OLID dataset with an F1-score of 70.22% averaged over a 10-fold cross-validation. The SVM also shows the best results on the GermEval dataset with an F1-score of 66.61%. The evaluation on the test set results in 66.78% F1-score for the GermEval gold test set. The evaluation of the baseline model for the OLID gold test set is not possible at the time of writing, since the gold test data have not yet been released.

The C-BiGRU achieved a 76.28% F1-score on the OLID and a 71.13% F1-score on the GermEval dataset on average over a 10-fold cross-validation. On the OLID gold test set, our model achieved an F1-score of 79.40%. The evaluation on the GermEval gold test data resulted in a 72.41% F1-score. An overview of all results can be found in Table 1. Figure 2 shows the confusion matrix of our submitted predictions for the SemEval shared task.

	Baseline		C-BiGRU	
	CV	gold	CV	gold
OLID	70.22%	-	76.28%	79.40%
GermEval	66.61%	66.78%	71.13%	72.41%

Table 1: All results in table form (CV = cross-validation; gold = gold test set).

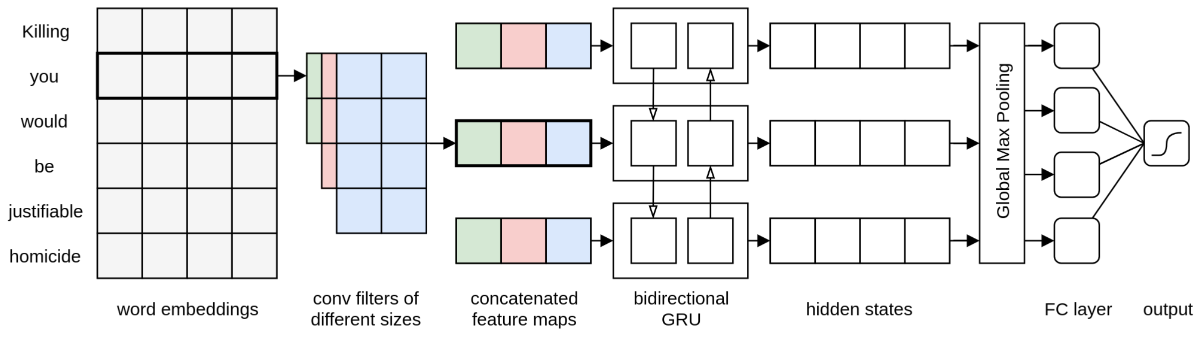

Figure 1: Representation of the proposed classifier.

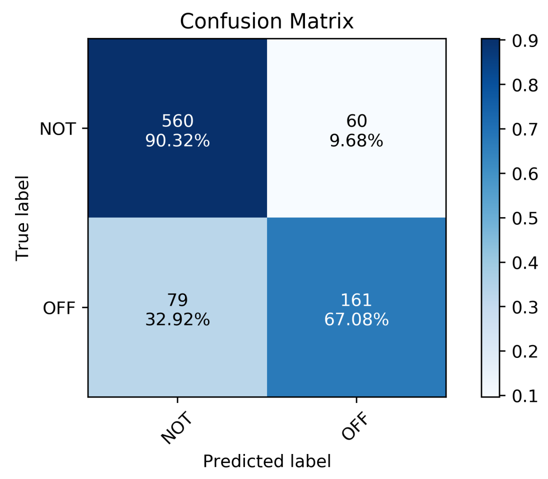

Figure 2: Confusion Matrix of the OLID gold test set, sub-task A. Depicted are instances and normalized values.

5 Discussion

The presented model continues our work on the identification of offensive German tweets (2018). We were able to improve our proposed model by adjusting the architecture of the recurrent layer in our neural network. By using a bidirectional GRU instead of a unidirectional LSTM, we are able to capture past and future information about the input sequence and exploit the better performance of GRU networks on smaller datasets. Furthermore, we return the hidden states for each feature map instead of returning only the last hidden state. This allows us to extract higher-level sequentially dependent features from each concatenated feature map.

Our experiments show that our suggested model outperforms the baseline model on both datasets. The difference between the F1-scores for the English and German dataset might be attributed to the smaller size of the German training set, which contains only about 5,000 tweets. The discrepancy between the results of our cross-validation and achieved score on the OLID test set might be explained by the small amount of test tweets, which may lead to imprecise results for the submitted runs.

By utilizing w2v as features, we are able to limit extensive and language specific preprocessing.

> “@USER Lolol God he is such an a**hole.”

In this example, the vector representation of “a**hole” has a high cosine similarity (0.63) to the vector representation of “asshole”, which allows our model to classify this tweet as offensive. On the contrary, our approach falls short when confronted with indirect insults.

> “@USER @USER Im sure the air that he is breathing is also bad.”

Our model wrongly predicts a non-offensive tweet in this instance.

The detection of offensive, hateful, racist, and/or sexist user behavior in social media still proves to be a challenge. Even for humans, it can be problematic to identify offensive microposts, since these posts can be ambiguous and dependant on the personal mindset of a reader. Ross et al. (2017) show that it can be difficult to measure the agreement of annotators about hate speech in the light of the European refugee crisis. They conclude that instead of a classification problem, a regression model with an average offensiveness score of multiple annotators might be more suitable for this task. Furthermore, it can be difficult to grasp the full context of an arbitrary tweet. With only excerpts of a conversation, the context and true intention of the author may be difficult to determine.

6 Conclusion and Future Work

In this paper, we describe our submitted model for the SemEval shared task 6 and evaluation methods for the identification of online aggressiveness in social media microposts. Our model achieves good results in the two evaluated datasets. For the OLID dataset which contains English tweets, a macro F1-score of 79.40% is reached, while our network resulted in an F1-score of 72.41 % on the GermEval dataset, which consists of German tweets.

We plan to evaluate our approach on more datasets to further investigate the potential of our model for different languages. One such set is the TRAC dataset, which contains aggression-annotated Facebook posts and comments in Hindi. Furthermore, we want to examine whether additional features such as character-level embeddings or POS tagging will improve our results. Inclusion of figurative language detection has proved to enhance many NLP tasks, such as argument mining and so-called hidden hate speech (Mitrović et al., 2017), which is also one of our future directions.

Abstract

The rise of social media has made information exchange faster and easier among the people. However, in recent times, the use of offensive language has seen an upsurge in social media. The main challenge for a service provider is to correctly identify such offensive posts and take necessary action to monitor and control their spread. In this work, we try to address this problem by using sophisticated deep learning techniques like LSTM, Bidirectional LSTM and Bidirectional GRU. Our proposed approach solves 3 different Sub-tasks provided in the SemEval-2019 task 6 which incorporates identification of offensive tweets as well as their categorization. We obtain significantly better results in the leader-board for Sub-task B and decent results for Sub-task A and Sub-task C validating the fact that the proposed models can be used for automating the offensive post-detection task in social media.

1 Introduction

Social media has revolutionized the way of communication among the people. It is an instant communication medium which connects people all over the world and shares their views. But, some people misuse this freedom by using the offensive language through posts or comments to defame, insult or target an individual or a group of individuals. The mainstream media have reported various cases of suicide and depression due to trolling and cyberbullying in social media. Hence it becomes worrisome for the corporates, government organizations and security agencies to either stop or mitigate this type of behavior of the users. Manually it is impossible to check the negative behavior of users due to the volume, velocity and variety of data coming from the social networks. Hence there is an utmost need to develop a system which automatically identifies and categorizes the offensive language in social networks. To tackle these issues SemEval-2019 (Zampieri et al., 2019b) aimed exactly at that need and organized a task in identifying and categorizing offensive language in social media. This task is divided into three Sub-tasks.
Sub-task A - Offensive language identification.
Sub-task B - Categorization of offense types.
Sub-task C - Offense target identification.
All the three Sub-tasks are related to each other. In Sub-task A, we have to identify whether a given set of tweets is offensive or not. It is a binary classification task based on tweet text. In Sub-task B, the main challenge is to categorize the tweets which are offensive in Sub-task A into targeted or untargeted. Sub-task C is comparatively challenging than other two Sub-tasks due to the multi-class nature. Its goal is to identify the tweets which are targeted in Sub-task B and categorized those tweets into individual, group or others.
Our approach for the SemEval-2019 task 6 (identifying and categorizing offensive language in social media) comprises of deep learning models: Bidirectional LSTM, Bidirectional GRU and standard LSTM. These are popularly used deep learning sequence models applied in many text classification tasks. We used the pre-trained word level embedding GloVe (Global Vectors for Word Representation) to get vector representations for words that appeared in tweets and used these representations as features for training the models. To check the performance of models, 10 fold cross-validation was applied on the given training data. We compared the results of the above-mentioned models with various baselines such as Logistic Regression, Support Vector Machine, Gradient Boosting and XGBoost. The baseline models are reasonably good but they have poor classification Accuracy as compared to deep learning models. This paper presents the description of our approaches and results for SemEval-2019 task 6.

2 Related Work

This section discusses some existing work related to identifying and categorizing offensive language in social media. Researchers have applied various computational methods to deal with hate speech, aggression, offensive language, racist and sexist language, and cyberbullying.

Hate Speech: Detection of hate speech is modeled in (Zhang et al., 2018). The authors applied CNN and GRU deep neural networks along with pre-trained Google Word2vec word embedding to detect the hate speech on Twitter. (Zhang and Luo, 2018) proposed Skip Gram Extraction CNN (SKIP-CNN) deep neural network model to identify hate speech present in social media text. It is discussed in this paper that hate speech lacks distinctive and unique features in a dataset which is hard to discover. The proposed model serves as a feature extractor for capturing the semantics of hate speech in social media.

Aggression: A method to detect aggression in social media is proposed in (Madisetty and Desarkar, 2018). The authors applied CNN, LSTM and Bidirectional LSTM on Facebook comment dataset. The output of these three deep learning models are used as an input to the majority based ensemble method for detection of aggression in social media. Another paper (Kumar et al., 2018) presents the system description report of shared task on identification of aggression in social media as a part of the 1st workshop on trolling, aggression and cyberbullying (TRAC1). The aggression annotated dataset of Facebook posts and comments in English and Hindi language were provided to the participants for training and validation. Six models out of the top ten best performing models were trained using LSTM, Bidirectional LSTM, CNN, and RNN deep neural networks.

Racist and Sexist Language: (Davidson et al., 2017) focused on classifying homophobic and racist tweets as hate speech and sexist remarks tweets as offensive. They use Logistic Regression with L2 regularization to predict the class membership. (Pitsilis et al., 2018) proposed an ensemble LSTM deep learning classifier that utilizes the user behavior metric to show each user viewpoint towards racism and sexism captured by their tweeting history.

Cyberbullying: (Dadvar et al., 2013) studied about the Cyberbullying detection. They combine individual comments, user characteristics and user profile information for training the Support Vector Machine classifier. It is also reported that the addition of user history with text features improves cyberbullying detection accuracy. (Rafiq et al., 2018) proposed a multi-stage cyberbullying detection mechanism by two novel components. First is dynamic priority scheduler which drastically reduces the classification time, and second is incremental classification method which is highly responsive regarding time to raise alerts.

Until now there have been many publications and studies on offensive language, aggression and hate speech in social media. Examples include (Wiegand et al., 2018), (ElSherief et al., 2018) and (Fortuna and Nunes, 2018). All these methods have some pros and cons associated with them. Therefore this paper proposed the idea of using deep learning sequence models for better accuracy in results for SemEval-2019 task 6.

3 Methodology and Data

In this section, we first describe the dataset used in the competition and then we explain the description of approaches used for solving the problem.

3.1 Dataset Used

The dataset provided by the task organizers is OLID (Offensive Language Identification). The details of data and annotation are available in (Zampieri et al., 2019a). For Sub-task A, this dataset contains tweets labeled into the following two categories: offensive (OFF) and not offensive (NOT). For Sub-task B, tweets are labeled into the following two categories: targeted input (TIN) and untargeted (UNT). For Sub-task C, the given tweets are classified into the following three categories: group (GP), individual (IND) and others (OTH). Out of 13,240 training samples of Sub-task A, 4404 samples have been allocated to Sub-task B and 3,877 samples have been allocated to Sub-task C. All the tweets are in English language. The statistics of the dataset and some instances of tweets with their labels are shown in Table 1 and Table 2.

	Training Set samples	Testing Set samples
Sub-task A	13240	860
Sub-task B	4404	240
Sub-task C	3877	213

Table 1: Statistics of the offensive dataset

Tweet	Sub-task A	Sub-task B	Sub-task C
Its not my fault you support gun control.	NOT	-	-
Someone should'veTaken" this piece of shit to a volcano.	OFF	UNT	-
you are a lying corrupt traitor!!! Nobody wants to hear anymore of your lies!!! #DeepStateCorruption.	OFF	TIN	IND
Kind of like when conservatives wanna associate everyone to their left as communist antifa members?	OFF	TIN	GRP
why report this garbage. We don't give a crap.	OFF	TIN	OTH

Table 2: Some tweets from the training dataset with their labels.

3.2 Methodology

Here we discuss our proposed approach in details. Our initial approach was to check with standard machine learning algorithms like Logistic Regression (Hosmer Jr et al., 2013), Random Forest (Xu et al., 2012), Support Vector Machines (Chang and Lin, 2011), XGBoost (Chen and Guestrin, 2016) and Gradient Boosting (Natekin and Knoll, 2013). We use TF-IDF vectorization for vectorizing our text and then apply the above-mentioned algorithms for the model development. Performance of these algorithms were not quite acceptable as it gave low Accuracy in results. To overcome above mentioned issues, we use deep learning algorithms for classifying the text. First we convert the text into vector representations with the help of GloVe (Pennington et al., 2014) word level embeddings and then use these representations as an input to the deep learning models described in the subsequent sections for classification tasks.

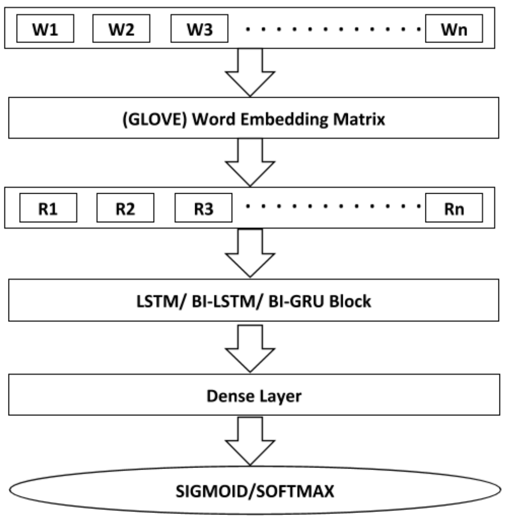

Figure 1: Architecture of the proposed deep learning models.

The multi-layered architecture of our approach presented in Figure 1. It comprised of various components in the form of layers. Since the data is in the form of text and the first step is to vectorize the text. To achieve this, we first make the tokens of the text W1, W2, W3,..., Wn and apply pre-trained GloVe word embeddings to get vector representations R1, R2, R3,..., Rn from it. Next layer can be LSTM, Bidirectional LSTM or Bidirectional GRU Block described in the next subsections. To overcome the problem of overfitting, we add a small amount of dropout. Finally, we use a Dense layer and Softmax/Sigmoid layer to get the output of the models.

3.2.1 Long Short Term Memory (LSTM)

We first try LSTM (Hochreiter and Schmidhuber, 1997) which have been used successfully in many text classification tasks (Madisetty and Desarkar, 2018). LSTM is special kind of RNN which captures the long contexts and long-range dependencies very efficiently in the sentences and takes care of the vanishing gradient problem of RNN (Lipton et al., 2015) with the help of carefully regulated structures named gates. The main components of the LSTM model are input gate, forget gate, output gate and candidate memory state. All these gates are single layered neural networks with the Sigmoid activation function except candidate memory state which uses tanh as the activation function.

3.2.2 Gated Recurrent Unit (GRU)

Gated Recurrent Unit (Tjandra et al., 2016) is an improvisation over LSTM. They also take care of the vanishing gradient problem of the RNN and tries to capture long-range connections better but with a less number of gates than LSTM. This leads to a less amount of parameters for the model which enables a faster and efficient model development in comparison to the LSTM based model.

The main components of GRU are reset gate, update gate and current memory content. Similar to LSTM, both reset gate and update gate are single layered neural networks with the Sigmoid activation function except current memory content which use tanh as the activation function. The basic function of the reset gate is to determine how much of the past information to be lost whereas the update gate decides how much of the information the model should pass to the next states.

3.2.3 Bidirectional LSTM and GRU

Both LSTM and GRU uses sequential information of the textual data for the processing and capture much longer range dependencies. But, the catch is that they use the sequence of only one direction while the Bidirectional version of the same considers a reverse copy of the provided input. In certain problems, this reversal helps to a better feature understanding and improved model performance.
In our work, we mainly use standard LSTM and Bidirectional version of both LSTM and GRU for the model developments. The detailed experimental setup is described in the next section.

4 Experimental Setting

For implementing the models, we use Keras (Ketkar, 2017) and Scikit-learn (Pedregosa et al., 2011) python framework libraries. The experimental details and model configuration are shown in Table 3. For the effectiveness of models, we add a small proportion of dropout. For GRU model, we specify the number of Recurrent Units. In terms of training, we use categorical cross Entropy as a loss function with ADAM as the optimization function. All the models are tested using 10 fold cross-validation.

Model Configuration	**Value**
sentences_length	32
batch_size	64
recurrent_units (for GRU)	64
dense_size	16
dropout_rate	0.5
number of epochs	300

Table 3: Configuration of the proposed models.

4.1 Impact of Batch Size on Model Performance

We checked our proposed approach with three different batch_sizes 64, 128 and 256 to check its impact on model performance. It is found experimentally that batch_size 64 provides optimal results.

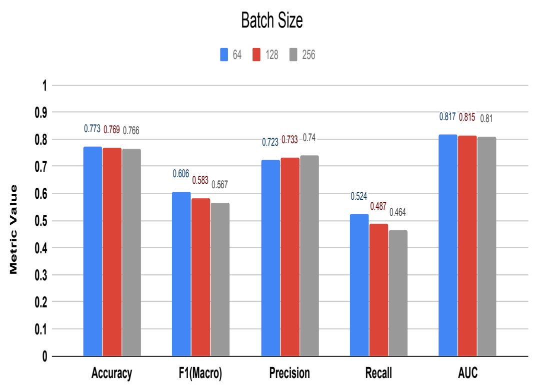

Figure 2: Performance comparisons with different batch Sizes.

Performance metrics: The official evaluation metric for all the three Sub-tasks are the macro-averaged F1 score. For additional analysis, we use the Accuracy, Precision, Recall and ROC-AUC.

5 Results and Discussions

This section contains the detailed experimental results that we performed on the proposed models including the baselines. It is quite familiar that multiple baselines approaches are helpful for comparing the performance of models on validation sets. To observe this, we apply various computational models on the training data released for Sub-task A so that we figure out which models give better results on the training data. Table 4 presents each model results in terms of Accuracy, F1(Macro), Precision, Recall and Roc-Auc score. It is evident from this Table that the deep learning models like LSTM, Bidirectional LSTM and Bidirectional GRU with GloVe word embeddings outperformed TF-IDF based machine learning algorithms. The LSTM model provides better results in terms of Accuracy among all the models. Bidirectional LSTM provides better results in terms of F1 macro and the Random Forest with TF-IDF gives better results in terms of Precision. The Bidirectional GRU provides better results for Recall matrix. The standard LSTM and Bidirectional LSTM performs equally good in terms of ROC-AUC.

Classifier	Accuracy	F1(Macro)	Precision	Recall	ROC-AUC
Logistic Regression + TF-IDF	0.7610	0.5563	0.5070	0.4463	0.6832
Random Forest + TF-IDF	0.7567	0.5189	**0.7718**	0.3908	0.6662
SVM with linear Kernel + TF-IDF	0.7658	0.5579	0.7613	0.4403	0.6853
Xgboost + TF-IDF	0.7323	0.5248	0.6493	0.4403	0.6601
Gradient Boosting + TF-IDF	0.7525	0.5750	0.6785	0.4988	0.6897
BI-LSTM + GloVe	0.7686	**0.6089**	0.7026	0.5459	**0.8100**
BI-GRU + GloVe	0.7524	0.6021	0.6501	**0.5672**	0.7963
LSTM + GloVe	**0.7695**	0.5942	0.7191	0.5081	**0.8100**

Table 4: Results of the proposed deep learning approaches including baselines on the Sub-task A training data using 10-fold cross validation

5.1 Results for Sub-task A

The official results of our proposed models on the test set for Sub-task A is shown in Table 5. As it is evident from these results that Bidirectional GRU performed better than other two deep learning models with F1 Score of 0.69. To analyze the correct label of a tweet, we also show the confusion matrix which shows correct class predictions along diagonal lines. Our team ranked 74 out of 104 participating teams.

System	**F1 (macro)**	**Accuracy**
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
BI-LSTM	0.6617	0.7535
BI-GRU	**0.6992**	**0.7744**
LSTM	0.6785	0.7477

Table 5: Results for Sub-task A (Binary Classification)

5.2 Results for Sub-task B

As comparison to Sub-task A, the official results for Sub-task B shown in Table 6 are significantly better. Our team ranked 7 out of 76 participating teams with F1 Score of 0.69. Again the Bidirectional GRU outperforms both LSTM and Bidirectional LSTM deep learning models in terms of F1 and Accuracy.

System	**F1 (macro)**	**Accuracy**
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
BI-LSTM	0.6511	0.8958
BI-GRU	**0.6997**	**0.9**
LSTM	0.6455	0.8917

Table 6: Results for Sub-task B (Binary classification)

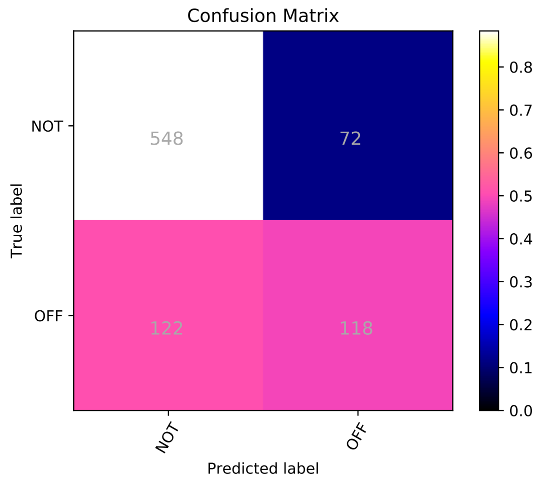

Figure 3: Confusion Matrix shows results for Sub-task A using Bidirectional GRU

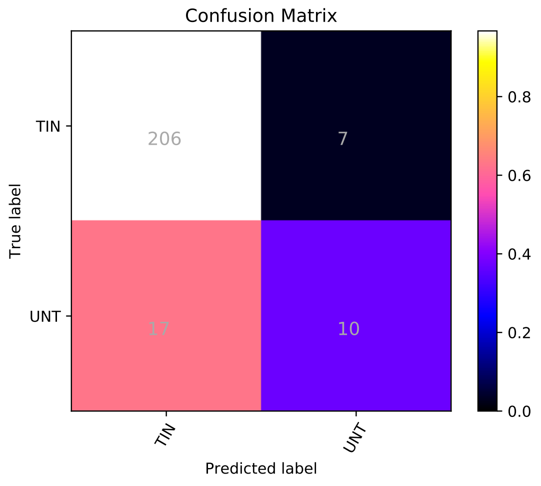

Figure 4: Confusion Matrix shows results for Sub-task B using Bidirectional GRU

5.3 Results for Sub-task C

Table 7 presents our results on the test set for Sub-task C. For this multi-class classification challenge, the results are lower as compared to other two Sub-tasks. All the participating teams had a lower performance with highest F1 score of 0.66, demonstrating the difficulty of the Sub-task. Our team ranked 41 out of 65 participating teams and Bidirectional LSTM give better results with F1 score of 0.49.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
BI-LSTM	**0.4903**	**0.6056**
BI-GRU	0.4635	0.5775
LSTM	0.4810	0.6197

Table 7: Results for Sub-task C (Multi-Class Classification)

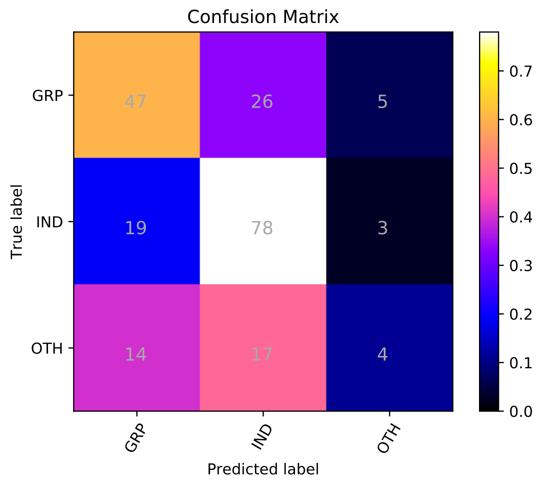

Figure 5: Confusion Matrix shows results for Sub-task C using Bidirectional LSTM

5.4 Class Label results

Besides the combined results of our proposed models on the test set for three Sub-tasks, we also present per class results in Tables 8, 9 and 10. The results in these tables show how well our models performed on each class label.
Table 8 shows each class label results for Sub-task A which comprises of two classes offensive (OFF) and not offensive (NOT). Bidirectional GRU performed better on both classes with F1 score of 0.54 and 0.84 respectively validating the fact that offensive class are relatively difficult to classify.
Table 9 shows each class label results for Sub-task B which comprises of two classes targeted input (TIN) and untargeted (UNT). Bidirectional GRU performed better on both classes with F1 score of 0.94 and 0.45 respectively which shows that untargeted class are much harder to classify.
Table 10 shows each class label results for Sub-task C which is a multi-class classification challenge having three classes individual (IND), group (GRP) and others (OTH). LSTM provides better results with F1 score of 0.72 and 0.63 for both (IND) and (GRP) classes while Bidirectional LSTM performed better on (OTH) class with F1 score of 0.17, justifies that (OTH) class is relatively harder to classify.

6 Conclusion

In this paper, we address the challenge of identification of offensive tweets as well as their categorization. Our proposed approach comprises of three deep learning based techniques for efficient classification of offensive posts in social media. In this work, we show that applying word embedding over social media text followed by the application of a sequence to sequence models like LSTM, Bidirectional LSTM and Bidirectional GRU leads to a better classification of the text. This proposed approach can also be incorporated in an end-to-end framework. Overall, our approach provides an efficient way of text classification in social media. For future work, we want to include character-based embeddings along with pre-trained word level embeddings for better representation of text. Also, the addition of attention layer to the deep networks sometimes increases performance even further.

Abstract

Offensive language has an impact across society. The use of social media has aggravated this issue among online users, causing suicides in the worst cases. For this reason, it is important to develop systems capable of identifying and detecting offensive language in text automatically. In this paper, we developed a system to classify offensive tweets as part of our participation in SemEval-2019 Task 6: OffensEval. Our main contribution is the integration of lexical features in the classification using the SVM algorithm.

1 Introduction

In recent years, with the emergence of social media, the user-generated content on the Web has grown exponentially. This content has the potential to be transmitted quickly, reaching anywhere in the world in a matter of seconds. Due to the exchange of ideas between users, we find not only positive comments, but also a wide diffusion of aggressive and potentially harmful content. Consequently, this type of remarks affects millions of online users. In fact, it has been reported that these incidents have not only created mental and psychological agony to the online users, but have forced people to deactivate their accounts and, in severe cases like cyberbullying, to commit suicides (Hinduja and Patchin, 2018). One of the strategies used to deal with aggressive behavior in social media is to monitor or report this type of content. However, this strategy is not entirely feasible due to the huge amount of data that is generated daily by users. Therefore, it is necessary to develop systems capable of identifying this type of content on the Web.

In order to tackle this problem, firstly it is important to define the toxic language. The toxic language can be broadly divided into two categories: hate speech and offensive language (Cheng, 2007; Davidson et al., 2017; Gaydhani et al., 2018). According to Cambridge Dictionary, hate speech is defined as "public speech that expresses hate or encourages violence towards a person or group based on something such as race, religion, sex, or sexual orientation". Offensive language is defined as the text which uses hurtful, derogatory or obscene terms made by one person to another person.

In this paper, we present the system we developed as part of our participation in SemEval-2019 Task 6 OffensEval: Identifying and Categorizing Offensive Language in Social Media) (Zampieri et al., 2019b). In particular, we participated in subtask A: Offensive language identification. It is a binary classification task and consists of identifying if a post contains or not offense or profanity language.

The rest of the paper is structured as follows. In Section 2, we explain the data used in our methods. Section 3 introduces the lexical resources used for this work. Section 4 presents the details of the proposed systems. In Section 5, we discuss the analysis and evaluation results for our system. We conclude in Section 6 with remarks on future work.

2 Data

To run our experiments, we used the English dataset provided by the organizers in SemEval19 Task 6 OffensEval: Identifying and Categorizing Offensive Language in Social Media (Zampieri et al., 2019a).

The datasets contain tweets with five fields. Each tweet comprises an identifier (id), the tweet text (tweet), field for subtask A (subtask_a), field for subtask B (subtask_b) and field for subtask C (subtask_c). Since we have only participated in sub-task A, we are interested in the fields id, tweet and subtask_a.

In sub-task A, we are interested in the identification of offensive tweets and tweets containing any form of (untargeted) profanity. In this sub-task, there are 2 categories in which the tweet could be classified:

(NOT) Not Offensive - This post does not contain offense or profanity.

(OFF) Offensive - This post contains offensive language or a targeted (veiled or direct) offense. In the annotation, this category includes insults, threats, and posts containing profane language and swear words.

During pre-evaluation period, we trained our models on the train set, and evaluated our different approaches on the trial set. During evaluation period, we trained our models on the train and trial sets, and tested the model on the test set. Table 1 shows the number of tweets per class for English language used in our experiments.

Dataset	NOT	OFF	Total
Train	8840	4400	13,240
Trial	243	77	320
Test	-	-	860

Table 1: Number of tweets per class in OffensEval dataset.

3 Resources

For this subtask A, we used different lexicons that we explain in detail below.

VADER (Valence Aware Dictionary and sEntiment Reasoner) (Gilbert, 2014). The VADER sentiment lexicon is a rule-based sentiment analysis tool. This is sensitive both to the polarity and the intensity of sentiments expressed in social media contexts, and is also generally applicable to sentiment analysis in other domains. VADER has been validated by multiple independent human judges. The tool return four values: positive, negative, neutral and compound. The first three scores represent the proportion of text that falls in these categories. The compound score is computed by summing the valence scores of each word in the lexicon, adjusted according to the rules, and then normalized between -1 (most extreme negative) and +1 (most extreme positive).

Offensive/Profane Word List (von Ahn, 2009). A list of 1,384 English terms (unigrams and bigrams) that could be found offensive. The list contains some words that many people won't find offensive, but it's a good start for anybody wanting to detect offensive or profane terms.

4 System Description

In this section, we describe the systems developed for the subtask A in OffensEval task. During our experiments, scikit-learn machine learning in Python library (Pedregosa et al., 2011) was used for benchmarking. A general scheme of the system can be seen in Figure 1.

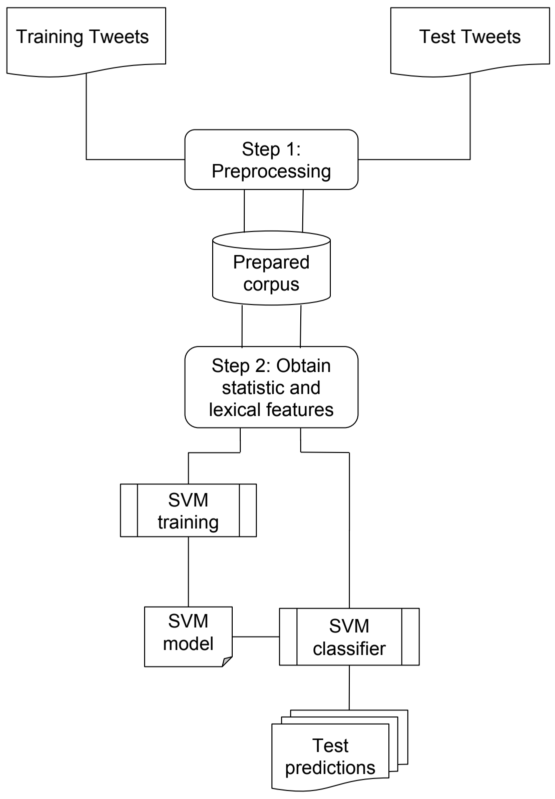

Figure 1: Systems architecture.

4.1 Data Preprocessing

In first place, we preprocessed the corpus of tweets provided by the organizers. We applied the following preprocessing steps: the documents were tokenized using NLTK, the URLs and mentions users are removed and all letters were converted to lower-case.

4.2 Feature Extractor

Converting sentences into feature vectors is a focal task of supervised learning based sentiment analysis. Therefore, the features we chose in our system can be divided into two parts: statistic features and lexical features.

- **Statistic features**. We employed the features that usually perform well in text classification: Term Frequency (TF) taking into account unigrams.
- **Lexical features**. As we explained in Section 3, we used two lexicons to obtain our features in the following way:
    1. **VaderSentiment**. We use the sentiment.vader module[1] provided by the Natural Language Toolkit (NLTK). With this module, we analyze each sentence and we obtained a vector of four scores: negative sentiment, positive sentiment, neutral sentiment and compound polarity.
    2. **Offensive/Profane Word List**. We checked the presence of each word of offensive/profane word list in the tweet and if it exists we assigned 1 as Confidence Value (CV). Then, we summed the CV of all the words finding in the tweet and this value is divided for the total number of words of tweet. As a result, we obtained a parameter that will be used as a feature applied for the classifier.

4.3 Classifier

The concatenation of the features described before are applied for the classification using the SVM algorithm. We selected the Linear SVM formulation, known as C-SVC and the value of the C parameter was 1.0.

5 Analysis of results

During the pre-evaluation phase we carried out several experiments and the best experiment were taken into account for the evaluation phase. The system has been evaluated using the official competition metric, the macro-averaged F1-score. The metric has been computed as follows:

$$\text{Macro-F1} = \frac{2 * \text{Macro-Prec} * \text{Macro-Rec}}{\text{Macro-Prec} + \text{Macro-Rec}} \quad (1)$$

The results of our participation in the subtask A of OffensEval task during the evaluation phase can be seen in Table 2.

[1]https://www.nltk.org/_modules/nltk/sentiment/vader.html

Class	precision	recall	f1-score
NOT	0.81	0.95	0.88
OFF	0.77	0.44	0.56
avg / total	0.8	0.81	**0.79**

Table 2: System test results per class in subtask A of OffensEval task.

User name (ranking)	Macro-F1
pliu19 (1)	0.83
DA-LD-Hildesheim (22)	0.78
fmplaza (68)	**0.72**
gretelliz92 (80)	0.67
AyushS (102)	0.42

Table 3: System Results per participating team in subtask A of OffensEval task.

In relation to our results, it should be noted that we achieve better score in case of the class NOT offensive (F1: 0.88). However, our system is not able to classify well the OFF class (F1: 0.56). This issue may be due to overtraining for the NOT class since as we can see in the Table 1 of Section 2, around 67% of the total tweets belong to that class in the training set in comparison to 33% of OFF class.

With respect to other users, we were ranked in the 68th position as can be seen in Table 3.

6 Conclusions and Future Work

In this paper, we present the system we have developed as part of our participation in SemEval-2019 Task 6: OffensEval: Identifying and Categorizing Offensive Language in Social Media. Specifically, we have participated in subtask A. To solve this task, we have developed a classifier system based on SVM incorporating lexical features from a polarity lexicon and a offensive/profane word list.

Our next study will focus on exploring more features from lexicons because in SemEval-2018 Task 1 (Mohammad et al., 2018), most of the top-performing teams relied on features derived from existing affective lexicons. Also, we will continue working on classifying offensive tweets because today it is a very important task due to the large amount of offensive data generated by users on the Web and we need to prevent the serious consequences it can have on other users.

Abstract

Offensive language identification (OLI) in user generated text is automatic detection of any profanity, insult, obscenity, racism or vulgarity that degrades an individual or a group. It is helpful for hate speech detection, flame detection and cyber bullying. Due to immense growth of accessibility to social media, OLI helps to avoid abuse and hurts. In this paper, we present deep and traditional machine learning approaches for OLI. In deep learning approach, we have used bi-directional LSTM with different attention mechanisms to build the models and in traditional machine learning, TF-IDF weighting schemes with classifiers namely Multinomial Naive Bayes and Support Vector Machines with Stochastic Gradient Descent optimizer are used for model building. The approaches are evaluated on the OffensEval@SemEval2019 dataset and our team SSN_NLP submitted runs for three tasks of OffensEval shared task. The best runs of SSN_NLP obtained the F1 scores as 0.53, 0.48, 0.3 and the accuracies as 0.63, 0.84 and 0.42 for the tasks A, B and C respectively. Our approaches improved the base line F1 scores by 12%, 26% and 14% for Task A, B and C respectively.

1 Introduction

Offensive language identification (OLI) is a process of detecting offensive language classes (Razavi et al., 2010) such as slurs, homophobia, profanity, extremism, insult, disguise, obscenity, racism or vulgarity that hurts or degrades an individual or a group from user-generated text like social media postings. OLI is useful for several applications such as hate speech detection, flame detection, aggression detection and cyber bullying. Recently, several research work have been reported to identify the offensive languages using social media content. Several workshops such as TA-COS[1], TRAC[2] (Kumar et al., 2018a), Abusive Language Online[3] and GermEval (Wiegand et al., 2018) have been organized recently in this research area. In this line, OffensEval@SemEval2019 (Zampieri et al., 2019b) shared task focuses on identification and categorization of offensive language in social media. It focuses on three subtasks namely offensive language detection, categorization of offensive language and offensive language target identification. Sub_Task_A aims to detect text as offensive (OFF) or not offensive (NOT). Sub_Task_B aims to categorize the offensive type as targeted text (TIN) or untargeted text (UNT). Sub_Task_C focuses on identification of target as individual (IND), group (GRP) or others (OTH). Our team SSN_NLP participated in all the three subtasks.

2 Related Work

Several research work have been reported since 2010 in this research field of hate speech detection (Kwok and Wang, 2013; Burnap and Williams, 2015; Djuric et al., 2015; Davidson et al., 2017; Malmasi and Zampieri, 2018; Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018; ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018; Mathur et al., 2018). Schmidt and Wiegand (2017) & Fortuna and Nunes (2018) reviewed the approaches used for hate speech detection. Kwok and Wang (2013) used bag of words and bi-gram features with machine learning approach to classify the tweets as "racist" or "nonracist". Burnap and Williams (2015) developed a supervised algorithm for hateful and antagonistic content in Twitter using voted ensemble meta-

[1] http://ta-cos.org/
[2] https://sites.google.com/view/trac1/home
[3] https://sites.google.com/site/abusivelanguageworkshop2017/

classifier. Djuric et al. (2015) learnt distributed low-dimensional representations of social media comments using neural language models for hate speech detection. Davidson et al. (2017) used n-gram (bigram, unigram, and trigram) features with TF-IDF score along with crowd-sourced hate speech lexicon and employed several classifiers including logistic regression with L1 regularization to separate hate speech from other offensive languages. Malmasi and Zampieri (2018) used n-grams, skip-grams and clustering-based word representations as features with ensemble classifier for hate speech detection. ElSherief et al. (2018) performed linguistic and psycholinguistic analysis to detect the hate speech is either "directed" towards a target, or "generalized" towards a group. Gambäck and Sikdar (2017) used deep learning using CNN models to detect the hate speech as "racism", "sexism", "both" and "non-hate-speech". They used character 4-grams, word vectors based on word2vec, randomly generated word vectors, and word vectors combined with character n-grams as features in their approach. Zhang et al. (2018) used convolution-GRU based deep neural network for detecting hate speech.

Many research work have been carried out in aggression detection (Aroyehun and Gelbukh, 2018; Madisetty and Desarkar, 2018; Raiyani et al., 2018; Kumar et al., 2018b). Aroyehun and Gelbukh (2018) & Raiyani et al. (2018) used LSTM and CNN respectively to detect aggression in text. Kumar et al. (2018b) presented the findings of the shared task on aggression identification which aims to detect different scales of aggression namely "Overtly Aggressive", "Covertly Aggressive", and "Non-aggressive". Madisetty and Desarkar (2018) used CNN, LSTM and Bi-LSTM to detect the above scales of aggression. Waseem et al. (2017) & Park and Fung (2017) presented the methodologies on abusive language identification using deep neural networks.

Research on identifying offensive languages has been focused on non-English languages like German (Wiegand et al., 2018), Hindi (Kumar et al., 2018b), Hinglish: Hindi-English (Mathur et al., 2018), Slovene (Fišer et al., 2017) and Chinese (Su et al., 2017). Wiegand et al. (2018) presented an overview of GermEval shared task on the identification of offensive language that focused on classification of German tweets from Twitter. Kumar et al. (2018b) focused on the shared task to identify aggression on Hindi text. Mathur et al. (2018) applied transfer learning to detect three classes namely "nonoffensive", "abusive" and "hate-speech" from Hindi-English code switched language. Fišer et al. (2017) presented a framework to annotate offensive labels in Slovene. Su et al. (2017) rephrased profanity in Chinese text after detecting them from social media text.

3 Data and Methodology

In our approach, we have used OLID dataset (Zampieri et al., 2019a) given by OffensEval@SemEval2019 shared task. The dataset is given in *.tsv* file format with columns namely, ID, INSTANCE, SUBA, SUBB, SUBC where ID represents the identification number for the tweet, INSTANCE represents the tweets, SUBA consists of the labels namely Offensive (OFF) and Not Offensive (NOT), SUBB consists of the labels namely Targeted Insult and Threats (TIN) and Untargeted (UNT) and SUBC consists of the labels namely Individual (IND), Group (GRP) and Other (OTH). The dataset has 13240 tweets. All the instances are considered for Sub_Task_A. However, we have filtered and considered the data that are labelled with "TIN/UNT" and "IND/GRP/OTH" for Sub_Task_B and Sub_Task_C respectively by ignoring the instances labelled with "NULL". Thus, we have obtained 4400 and 3876 instances for Sub_Task_B and Sub_Task_C respectively. We have preprocessed the data by removing the URLs and the text "@USER" from the tweets. Tweet tokenizer [4] is used to obtain the vocabulary and features for the training data.

We have employed both traditional machine learning and deep learning approaches to identify the offensive language in social media. The models that are implemented for the three sub-tasks are given in Table 1.

In deep learning (DL) approach, the tweets are vectorized using word embeddings and are fed into encoding and decoding processes. Bidirectional LSTMs are used for encoding and decoding processes. We have used 2 layers of LSTM for this. The output is given to softmax layer by incorporating attention wrapper to obtain the OffensEval class labels. We have trained the deep learning models with a batch size 128 and dropout 0.2 for 300 epochs to build the model. We have em-

Tasks	Models	Description
Task A	Task_A_DL_NB	Deep learning with Normed Bahdanau attention
	Task_A_DL_SL	Deep learning with Scaled Luong attention
Tak B	Task_B_DL_NB	Deep learning with Normed Bahdanau attention
	Task_B_DL_SL	Deep learning with Scaled Luong attention
	Task_B_TL_MNB	Traditional Machine Learning with Multinomial Naive Bayes
Task C	Task_C_DL_NB	Deep learning with Normed Bahdanau attention
	Task_C_DL_SL	Deep learning with Scaled Luong attention
	Task_C_TL_SVM	Traditional Machine Learning with Support Vector Machine and Stochastic Gradient Descent optimizer

Table 1: Models for the Tasks

ployed two attention mechanisms namely Normed Bahdanau (NB) (Sutskever et al., 2014; Bahdanau et al., 2014) and Scaled Luong (SL) (Luong et al., 2015, 2017) in this approach. These two variations are implemented to predict the class labels for all the three sub tasks. These attention mechanisms help the model to capture the group of input words relevant to the target output label. For example, consider the instance in Task C: “we do not watch any nfl games this guy can shove it in his pie hole”. This instance clearly contains the offensive slang “pie hole” and about watching the “nfl games”. The attention mechanism captures these named entities or group of words and correctly map to the label “GRP”. Also, it is evident from the earlier experiments (Sutskever et al., 2014; Thenmozhi et al., 2018) that bi-directional LSTM with attention mechanism performs better for mapping input sequences to the output sequences.

In traditional learning (TL) approach, the features are extracted from the tokens with minimum count of two. The feature vectors are constructed using TF-IDF scores for the training instances. We have chosen the classifiers namely Multinomial Naive Bayes (MNB) and Support Vector Machine (SVM) with Stochastic Gradient Descent optimizer to build the models for Task B and Task C respectively. These classifiers have been chosen based on the cross validation accuracies. The class labels namely “TIN/UNT” and “IND/GRP/OTH” are predicted for Task B and Task C using the respective models.

4 Results

We have evaluated our models using the test data of OffensEval@SemEval2019 shared task for the three sub tasks. The performance was analyzed using the metrics namely precision, recall, macro-averaged F1 and accuracy. The results of our approaches are presented in Tables 2, 3 and 4 for Task A, Task B and Task C respectively. We have obtained the best results for Task_A_DL_SL, Task_B_DL_NB, Task_C_TL_SVM models for Task A, Task B and Task C respectively.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
Task_A_DL_NB (527733)	0.5166	0.614
Task_A_DL_SL (527740)	**0.5341**	**0.6349**

Table 2: Results for Sub-task A.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
Task_B_DL_NB (532649)	**0.4800**	**0.8375**
Task_B_DL_SL (532651)	0.4558	0.8375
Task_B_TL_MNB (532654)	0.4558	0.7792

Table 3: Results for Sub-task B.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
Task_C_DL_NB (536200)	0.2462	**0.4507**
Task_C_DL_SL (536201)	0.2663	0.4178
Task_C_TL_SVM (536203)	**0.3001**	0.4178

Table 4: Results for Sub-task C.

The attention mechanism Scaled Luong performs better when more data is available for training. Normed Bahdanau attention mechanism performs better even for a small dataset. However, deep learning gives poor results than traditional learning approach for Task C, because only 3876 instances were considered for model building. The deep learning model could not learn the features appropiately due to less domain knowledge imparted by the smaller data set. Thus, traditional learning performs better with the given data size when compared to deep learning for Task C. The confusion matrix for our best run in the three sub tasks are depicted in Tables 5, 6 and 7. These tables show that the true positive rate of "NOT", "TIN" and "IND" classes are good as the number of samples for those classes are more in training set. Our approaches show improvement over the base line systems for all the three tasks. We have obtained 12% and 14% improvement on F1 and accuracy respectively for Task A when compared with the base line. For Task B, we have obtained 26% and 34% improvement on F1 and accuracy respectively. Also, Task C results have been improved by 14% and 7% for F1 and accuracy when compared to base line results.

	OFF	NOT
OFF	73	147

Table 7: Confusion Matrix for Task_C_TL_SVM.

5 Conclusion

We have implemented both traditional machine learning and deep learning approaches for identifying offensive languages from social media. The approaches are evaluated on OffensEval@SemEval2019 dataset. The given instances are preprocessed and vectorized using word embeddings in deep learning models. We have employed 2 layered bi-directional LSTM with Scaled Luong and Normed Bahdanau attention mechanisms to build the model for all the three sub tasks. The instances are vectorized using TF-IDF score for traditional machine learning models with minimum count two. The classifiers namely Multinomial Naive Bayes and Support Vector Machine with Stochastic Gradient Descent optimizer were employed to build the models for sub tasks B and C. Deep learning with Scaled Luong attention, deep learning with Normed Bahdanau attention, traditional machine learning with SVM give better results for Task A, Task B and Task C respectively. Our models outperform the base line for all the three tasks. The performance may be improved further by incorporating external datasets (Kumar et al., 2018a; Davidson et al., 2017), lexicons and dictionaries.

Abstract

This paper summarizes the participation of Stop PropagHate team at SemEval 2019. Our approach is based on replicating one of the most relevant works on the literature, using word embeddings and LSTM. After circumventing some of the problems of the original code, we found poor results when applying it to the HatEval contest (F1=0.45). We think this is due mainly to inconsistencies in the data of this contest. Finally, for the OffensEval the classifier performed well (F1=0.74), proving to have a better performance for offense detection than for hate speech.

1 Introduction

In the last few years, several evaluation tasks in the context of hate speech detection and categorization have been created. Some of these tasks include e.g., EVALITA (Bosco et al., 2018) and TRAC-1 (Kumar et al., 2018). These type of initiatives promote the development of different but comparable solutions for the same problem, within a short period of time, which is an interesting contribution for a research field. In this paper, we describe the participation of team "Stop PropagHate" in the HatEval and OffensEval tasks of SemEval 2019.

The main goal of both tasks is to improve the classification of Hate Speech and Offensive Language. Some of the works in the literature achieve a very competitive performance, e.g. Badjatiya et al. (2017) obtain an F1 score of 0.93 when using deep learning for classifying hate speech in one of the most commonly used baseline datasets (e.g. Waseem (2016)). In this context, we have a specific objective with our approach: we aim to reproduce a state-of-the-art classifier as described in the literature of this topic.

We choose to reproduce the study by Badjatiya et al. (2017), not only because of the good performance of the developed models, but also because in this work the authors published their code. Considering the amount of parameters available for definition and tuning in a machine learning classification pipeline, a precise and extensive definition of an experiment's parameters is not simple and is hardly ever provided. Thus, having the code of the experiment is the best way to understand not only which steps were conducted, but also how those steps were indeed executed. This is a highly cited paper, which can be regarded as an indicator of its relevance in the area.

In this paper, we describe our journey in the process of replication and the results achieved when applying this classifier in both shared tasks. The paper is structured as follows: Section 2 briefly reviews the literature, Section 3 presents our methodology, Section 4 describes the tasks and preliminary experiences with the data, Section 5 shows our official results in the shared tasks, and we report the conclusions of our work in Section 6.

2 Related Work

Previous research in the field of automatic detection of hate speech and offensive language can give us insight on how to approach this problem. Two surveys summarize previous research and conclude that the approaches rely frequently on Machine Learning techniques (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018). Different methods are used, such as word and character n-grams (Liu and Forss, 2014), perpetrator characteristics (Waseem and Hovy, 2016) or "othering language" (Burnap and Williams, 2016). Word embeddings (Djuric et al., 2015) are often used in this field because they can feed deep learning classification algorithms and obtain high performances. Usually, when traditional Machine

Learning classifiers are used, the most frequent algorithms are SVM (Del Vigna et al., 2017) and Random Forests (Burnap and Williams, 2014), but Deep Learning techniques are quickly gaining ground in the area (Yuan et al., 2016; Gambäck and Sikdar, 2017; Park and Fung, 2017). Different studies proved that deep learning algorithms outperform previous approaches (Mehdad and Tetreault, 2016; Park and Fung, 2017; Badjatiya et al., 2017; Del Vigna et al., 2017; Pitsilis et al., 2018; Founta et al., 2018; Zhang et al., 2018; Gambäck and Sikdar, 2017).

Other sources of solutions are previous shared tasks. For EVALITA, the best performing system achieved an F1 score of 0.83 on Facebook data and 0.80 on Twitter data. The best team tested three different classification models: one based on a linear SVM, another one based on a 1-layer BiLSTM and a 2-layer BiLSTM which exploits multi-task learning with additional data. For TRAC-1, the system that achieved the best performance with a F1 value of 0.64 used an LSTM and resorted to translation as a data augmentation strategy.

During the last 2 years, many articles have been published in this area, and one of the main focal points is to find accurate classifiers for the detection and characterization of hate speech. One main dataset is now used (Waseem, 2016), allowing performance comparison between systems. However, it is still not trivial to compare and reproduce the different approaches. Machine learning classification systems involve a long, complex set of steps and parameters and not every paper gives clear and transparent specifications. A precise specification is fundamental for replicating and improving a system.

With this idea in mind, we tried to replicate a paper with promising results as a baseline for our work. We found a paper which describes several classifiers with good performance and that also provides a GitHub repository for the code of the classifiers (as stated before, the work from Badjatiya et al. (2017). In this paper, the authors propose and use different methods. They investigate three neural network architectures applied to the problem of automatic hate speech detection: CNN, LSTM and FastText. In each one of the methods they initialize the weights with either random embeddings or GloVe embeddings. They use a dataset with messages classified as containing sexist hate speech, racist or none (Waseem, 2016). Additionally, they use 10-fold cross validation. The set of experiments achieving better performance consists in using a deep learning architecture, then taking the weights of the last layer and feeding it into a standard machine learning classifier. More particularly, embeddings learned from LSTM model were combined with gradient boosted decision trees and led to the best performance (F1 score of 0.93).

Regarding our specific approach in this shared task, the main research question of our work concerns if it is possible to replicate the results of the aforementioned paper. After trying to replicate their results, we then apply the approach to the two new datasets provided by the shared tasks.

In the next sections, we present our methodology and approach to these shared tasks.

3 Methodology

For conducting this study, we follow a methodology of 10-fold cross-validation with holdout validation (Chollet, 2017). This consists in dividing the data into two sets. One part of the data is used for cross-validation and parameter tuning with grid search on several classification parameters. The second part of the data is used for estimating the performance of this model when applied to classify new data.

In terms of pipeline, we tried to replicate the study by Badjatiya et al. (2017), and we started by downloading the version of the code[1] in December 2018. We then faced some difficulties that we list here:

- Unspecified versions of Python and of some of the used libraries.
- The authors use the fact that they provide the code as a reason not to specify the parameters in detail.
- The code contains only some of the classifiers described in the paper. The set of classifiers using xgBoost together with deep learning as features were not provided. These are the classifiers with the best performance.
- No validation data is hold out for the model to be tested after the tuning during the cross validation.

[1] https://github.com/pinkeshbadjatiya/twitter-hatespeech

- In the provided code, the 10-fold cross-validation procedure has a bug. With a more detailed analysis of the code we have found out that the method used for classification is train_on_batch from Keras[2], that runs a single gradient update on a single batch of data. Successive calls to this method are done through the 10 iterations of the cross-validation procedure, without instantiating a new model. This means that, during the 10 iterations, the model will successively update the gradient values without resetting it. The effect of using 10-fold cross-validation is then eliminated because only in the first iteration the testing is conducted in data never seen previously by the model. As a consequence of this problem, we can see that the successive values of F1 score found in the 10 iterations increases every time. See Table 1 for the specific F1 score values per cross-validation phase.

CV Iteration	Macro F1
1	0.76
2	0.78
3	0.8
4	0.83
5	0.87
6	0.88
7	0.89
8	0.91
9	0.92
10	0.89
Average	**0.89**

Table 1: F1 score over the different iterations of the cross-validation procedure. Experiment conducted for replicating the paper from Badjatiya et al. (2017).

In order to overcome these limitations, we provide all the information required to replicate the experiment. We use Python 3.6, Keras (Chollet et al., 2018), Gensim (Řehůřek and Sojka, 2010) and Scikit-learn (Pedregosa et al., 2011) as main libraries, and we make available our project and code[3].

The following subsections describe specific indications on how we implement each step performed by our system.

[2]Line 204 at the file `https://github.com/pinkeshbadjatiya/twitter-hatespeech/blob/master/lstm.py`

[3]`https://github.com/paulafortuna/SemEval_2019_public`

3.1 Text pre-processing

In terms of text pre-processing, we remove stop words using Gensim, and punctuation using the default string library. We transform our tweets to lower case.

3.2 Feature extraction

Regarding the features that we use in our experiment, we extract Glove Twitter word embeddings, sentiment and frequencies of words from Hatebase. The last is a set of features developed in our work. In Table 2 we present an overview of the features.

Used features	Dimensions	Abbreviation
Glove twitter word embeddings	200	glove
Sentiment Vader	4	sentiment
Hatebase	2	hatebase

Table 2: Experiment features.

3.2.1 Word embeddings

Regarding the pre-trained word embeddings, we use Twitter Glove pre-trained word embeddings with 200 dimensions. We then use the methods provided by Keras to map each token in the input to an embedding.

3.2.2 Sentiment Features

Another set of features that we use is the sentiment analysis provided by the Vader library (Hutto and Gilbert, 2014). We extract the negative ('neg'), neutral ('neu'), positive ('pos') and compound ('compound') dimensions. Each text is then represented as a 4-dimensional vector with these values.

3.2.3 Hatebase Features

Finally, we use word frequencies from the Hatebase platform (Hatebase, 2019). This platform provides different data regarding hateful words usually connected to hate speech. For each method, we count two set of words:

- Hateful words - corresponds to one or two words and are defined as "terms" in Hatebase (e.g. bitch);
- Hate topic words - corresponds to a definition of the hateful terms and are defined as "hateful meaning" (e.g. a human female). We excluded the stop words and counted for each message if there would be any reference to

words used to explain hatebase terms, so that we could approximate reference to hate related topics.

For every message, we store the frequencies of total hateful words in the text and also the frequencies of hate topic words.

3.3 Classification

Regarding the classifiers we used LSTM and xgBoost.

3.3.1 Deep Learning

For the deep learning model, we used LSTM as implemented in the code from the paper by Badjatiya et al. (2017). This contains an Embedding Layer with the weights from the word embeddings extraction procedure, an addtional LSTM layer with 50 dimensions, and dropouts at the end of both layers. We used Adam as optimizer, binary cross-entropy as loss function, 10 epochs and 128 for batch size. With this model we classify the data into binary classes and we save the last layer before the classification to extract 50 dimensions for giving it as input to the xgBoost algorithm, in a similar manner as described in the paper we are replicating. Additionally, we tested with higher dimensionality, but we find no improvement when we kept the remaining parameters.

3.3.2 xgBoost

We used the gradient boosting algorithm from the Python library xgboost (Chen and Guestrin, 2016). In terms of parameters, we used the default except for the eta and gamma. In this case we conducted a grid search combining several values of both (eta: 0, 0.3, 1; and gamma: 0.1, 1, 10). Additionally, we ran all the possible combinations of the three available sets of features: hatebase words frequencies, sentiment, and weights extracted from the LSTM model.

4 Tasks, systems and results

We conduct different experiments following the procedure described in Section 3.

4.1 Standard Dataset

In our methodology, we use a standard dataset (Waseem, 2016), so that we could compare our results with the original paper we are replicating.

4.1.1 Data

We randomly divided the data into 90% training and 10% testing datasets, having 15,214 messages for training and 1,691 messages for testing.

4.1.2 Results for Tuning and Validation

In Table 3 we present the results of the experiments with the baseline dataset. Some patterns of the results are in accordance with the original study (Badjatiya et al., 2017). Indeed, classifying the data with xgBoost after extracting 50 dimensions with the LSTM brought improvement when compared to directly classify it with LSTM. However, the results presented here are far from the 0.93 reported in the original paper. We obtained an F1 score of 0.72 using cross validation and 0.78 using the test set, when combining LSTM last layer with sentiment, hatebase, and xgBoost as classifier. One explanation for the differences between our results and the cited paper can be the fact that in this experiment we developed and classified hate speech as binary classes and for that we converted the sexism and racism, to a single hate speech class. On the other hand, the original work was conducted with the three original classes of the dataset. Another possible explanation may be the different problems found in the code, mainly the bug in the cross-validation. The results reported in the original paper may be classification models that were not tested in new data, and can be overfitted.

We can also conclude that the sentiment and hatebase features did not work well for our classification tasks either when used alone or together with the 50 dimensions extracted from the LSTM last layer to feed the xgBoost model.

4.2 HatEval (Task 5)

The proposed task (Basile et al., 2019) consists in the detection of Hate Speech targeting immigrants and women in Twitter, using texts in Spanish and English. There are two different tasks but our team participated only in the first. In Task A, the teams predict whether a tweet is hateful or not hateful as a binary classification task. This task is composed of two different subtasks, one in English and another in Spanish. The systems are evaluated and ranked using macro averaged F1 score.

4.2.1 Data

All the data provided for the competition was collected from Twitter and manually annotated via the Figure Eight crowdsourcing platform. The data is organized and especially released for the competition. More specifically, there are two datasets including tweets about hate against women and immigrants, in English and Spanish. The task dataset contains 9,000 messages for training, 1,000 messages for testing during developing phase and 3,000 messages for final testing and evaluation of the different teams.

4.2.2 Results for Tuning and Validation

Our team participated in the Task A for English and, during the model development phase, achieved the results presented in Table 4. We obtained similar results when applying the classifier to this dataset, when compared to the baseline dataset. Again, using the xgBoost to classify and the 50 dimensions of the last layer of LSTM as features, brought improvement. We achieved an F1 score of 0.75 using cross validation and 0.68 using the test set. We noticed that in the baseline the testing results improve, when compared to the cross-validation while when using the HatEval dataset those results decreased.

4.3 OffensEval (Task 6)

In OffensEval (Zampieri et al., 2019b), there are three sub-tasks and one of the main goals is to take into account the type and target of offenses. Our team participated in the Task A, about Offensive language identification. Again, Classification systems in all tasks are evaluated using the macro-averaged F1 score.

4.3.1 Data

The data used for the contest were previously presented in another work (Zampieri et al., 2019a). Participants were allowed to use external resources and other datasets for this task. Our team received 13,240 messages for training, 320 messages for testing during model development phase, and 860 messages for final testing and ranking of the different teams.

4.3.2 Results for Tuning and Validation

Our team participated in Task A and, during the model development phase, achieved the results presented in Table 5. We obtained similar results to the baseline dataset and HatEval contest. Again, using the xgBoost to classify brought improvement when compared to just use LSTM to directly classify the data (F1 score of 0.78 using cross validation and 0.80 using the test set). Additionally, we can see that the classification of Offensive discourse achieved a better performance, when compared to the classification of hate speech in previous tasks. This may indicate that offensive language is easier to identify when compared with hate speech, which is consistent with previous studies (Kumar et al., 2018).

5 Shared Task Results

In Table 6 we present the results of the team "Stop PropagHate" in the two contests. Regarding the HatEval, we conclude that the results drastically dropped in the F1 metric from 0.77 in the testing phase to 0.45 in the contest. We believe that this result is due to the sampling procedure used for building the datasets, we noticed that the training was conducted with a very balanced dataset which is an uncommon situation for hate speech automatic detection. We also find strange that the winning team only achieved 0.65 which is a result much lower than the current state of art (F1 of around 0.80). The low performances of the systems and our drop in score from the development phase indicates that there should be important differences in the evaluation dataset with respect to the training material. However, we checked the proportion of hate speech in both datasets and it is equivalent (around 42%).

For the OffensEval task, we achieved more consistent results in all the phases, with a F1 of 0.74 more similar to the 0.80 from the testing phases. The consistency in this case might indicate that the evaluation set is similar to the training material. The winner of the competition scored 0.83, so we can see that our approach is not far from that performance.

6 Conclusion

In this paper, we entered a shared task in the field of hate speech detection and characterization. Our approach was based on replicating one of the most relevant works on the state-of-the-art literature. One of our initial conclusions was that it was not possible to replicate the study and the results we aimed at. Our main difficulty was the lack of specification of the method. Additionally, the incomplete available code contained a bug that brought doubt on the validity of the reported results in the original paper. This allowed us to see the importance of sharing code in this field. This is the

Features	**Classifier**	**Number of features**	**Parameters**	**CV training F1 macro**	**testing F1 macro**

Number of teams	67	103
1st place (F1)	0.65	0.83
last place (F1)	0.35	0.17

Table 6: Achieved performance in the shared tasks. Model 1 corresponds to the original classifier from the replicated paper (LSTM 50d + xgBoost). Model 2 corresponds to the same as Model 1 plus adding hatebase features, and finally, Model 3 corresponds to the same as Model 1 plus adding hatebase and sentiment features.

only way to exactly replicate the reported results to then apply the same approach in other scenarios. A posteriori, we received an answer from the authors explaining that the available GitHub repository does not correspond to the final version of the project. Nevertheless, the it remained not updated at the moment of the submission of this paper. Another work could also not replicate this results (Lee et al., 2018).

After circumventing some of the aforementioned problems of the original code, we explained our specific version and used it to enter the shared task. We show that using the same classifier we found poor results when applied to the HatEval contest. Due to the results achieved on the baseline dataset and testing set before contest, we think this is due to inconsistencies between the characteristics of the training set and the final test set. Finally, for the OffensEval we believe that the classifier performed well, and with a better performance for offense detection than for hate speech.

Acknowledgments

This work was partially funded by the Google DNI grant Stop PropagHate.

Abstract

Task 6 of SemEval 2019 involves identifying and categorizing offensive language in social media. The systems developed by TECHSSN team uses multi-level classification techniques. We have developed two systems. In the first system, the first level of classification is done by a multi-branch 2D CNN classifier with Google's pre-trained Word2Vec embedding and the second level of classification by string matching technique supported by offensive and bad words dictionary. The second system uses a multi-branch 1D CNN classifier with Glove pre-trained embedding layer for the first level of classification and string matching for the second level of classification. Input data with a probability of less than 0.70 in the first level are passed on to the second level. The misclassified examples are classified correctly in the second level.

1 Introduction

The growth of social media networks in recent days has been phenomenal and Twitter is no exception. However, this rapid growth of social media also poses a serious challenge of maintaining ethics in social media because of the degradation of moral values in society. Offensive micro tweets are generated on a daily basis targeting a particular person, organization, race, caste, community, religion, gender and so forth. For this reason, our task for the SemEval2019 (Zampieri et al., 2019b) mainly focuses on the detection of offensive language in tweets and classify them.

In Subtask-A, we tried to classify the tweets into two classes, namely offensive and non-offensive. The offensive tweets in the Subtask-A are then categorized in Subtask-B into targeted and untargeted tweets, where targeted tweets are aimed at a specific person, organization, religion or political parties. Further, Subtask-C deals with the fine-grained classification of offensive tweets into three classes viz person, organization and others.

The training dataset provided by the organizers contains 13240 tweets. The given dataset is used as the preliminary dataset to train our model. In addition, Impermium dataset from Kaggle and TRAC dataset are added to improve the accuracy of the model. We have also used a dictionary of offensive words in the second level of classification. Manually classifying the tweets is ambiguous and highly subjective, and is one of the biggest challenges. The mix of colloquial slang in tweets, veiled references, missing data, usage of symbols and emojis are further hurdles that lowered the prediction accuracy (Founta et al., 2018).

2 Related Work

Many researchers in the field of Artificial Intelligence and Natural Language Processing have been working to detect offensive speech in tweets using sentiment analysis. Pang et al. (2002) used a three level classification system with Naive Bayes classifier in the first level, Multinomial Updatable Naive Bayes in the second level and a rule based classifier named DTNB in the third level. The second level of classification increased the accuracy by 7% while the third level results showed an improvement in performance by a 6% rise in accuracy. The results were boosted by the usage of an insulting and abusive language dictionary.

Stammbach et al. (2018) developed an ensemble model of Convolutional Neural Network (CNN), Recurrent Neural Network (RNN) and CNN+RNN that gave a macro averaged F1-score of 77.7%, 78.6% and 77.6% respectively on 10-

fold cross validation. It is stated that the correct words generated by the spell-checker did not occur in the embeddings and this might be one of the reasons for the low performance of the model. Che et al. (2017) presented a review of the recent deep neural networks used for text classification and a comparison of word embeddings to Support Vector Machine (SVM) classifiers. It points out that a critical issue with CNN is the restriction of a fixed input size and hence the inability to handle sentences of variable length as input, and therefore, focuses on RNN. It is also mentioned that n-grams with syntactic and semantic information achieve significantly better results than the standard n-grams.

(Le and Mikolov, 2014) uses paragraph vectors instead of Bag-of-Words (BOW) feature representation and reduces the classification error by approximately 39%. Dinakar et al. (2011) and ElSherief et al. (2018) discuss the problem of overlapping classes in target identification. Malmasi and Zampieri (2018) discuss the various challenges in discriminating hate, offensive and non-offensive text using ensemble techniques and stacked generalization meta learning methods.

Razavi et al. (2010) discuss about the multilevel classification for flame detection using complement naive Bayes on first level to select discriminative features and multinomial updatable naive Bayes classifier on second level to enhance the model with new features for adaptive learning. They have used rule-based classifier named DTNB (Decision Table/Naive Bayes hybrid classifier) as the last level to classify the text into Flame/Not.

3 Methodology and Data

The task of classifying offensive tweets is difficult as it needs to discover the intention of the user. Moreover, people who follow the chatting convention use offensive words to express their feelings. The architecture diagram for the offensive text classification is shown in Figure 1.

3.1 Acquiring Datasets

The classifier can make a well-informed decision if we procure and supply more data to it. For good performance, deep learning requires sufficiently large amount of data. Therefore, in addition to the dataset given by Zampieri et al. (2019a), we also compiled a variety of datasets for our tweet classification. We have added the TRAC training dataset (Kumar et al., 2018) consisting of online posts from Facebook, the Impermium Dataset of Kaggle (Impermium, 2013), and used a comprehensive list of known offensive words banned by Google in all their different forms. TRAC dataset is based on multiclass classification (OAG, CAG, NAG). We have considered OAG and CAG class labels as OFF label and NAG as NOT for the subtask A.

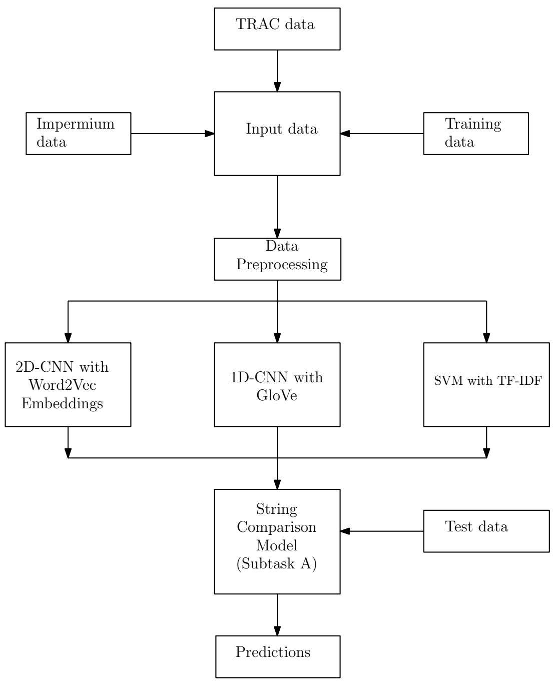

Figure 1: Architecture of Proposed System

3.2 Data Preprocessing

Data preprocessing critical for the success of any machine learning solution. The given dataset shows many signs of irregularities which is a classic signature of any collection of tweets. Normalizing the data involves flattening the dimensions of data into textual form. The dataset is cleaned and processed using functions from NLTK and spacy toolkit.

During preprocessing, we

(a) remove URLs,
(b) annotate emojis, emoticons,
(c) convert uppercase to lowercase,
(d) expand contractions,
(e) remove stopwords,
(f) remove special characters,
(g) remove accented characters,
(h) reduce lengthened words,
(i) lemmatize text, and

(j) remove extra whitespace

Among the steps listed above, step (e) is omitted for subtask-B and subtask-C, since stopwords are significant for target identification.

3.3 Model Description

We classified the text using these three models and compare the results:

1. 2D-CNN with Word2Vec Learned Embeddings
2. 1D-CNN with GloVe
3. SVM with BOW

3.3.1 2D-CNN with Word2Vec Learned Embeddings

Even though it is unconventional to use a two dimensional convolutional network to work on text sequences, it has proved its usefulness quite satisfactorily (Prusa and Khoshgoftaar, 2017). The model is built by taking the pre-trained Google's Word2Vec weights and learn more with the following additional layers.

1. Input layer
2. Embedding layer
3. Convolutional layer with kernel size 2
4. Convolutional layer with kernel size 3
5. Convolutional layer with kernel size 4
6. Respective pooling layers for CNN layers
7. Fully connected dense layer
8. Output layer

We have used an embedding layer which learns the weights of the embedding matrix during training. The bigrams, trigrams and fourgrams of the words are obtained by applying filters and kernels of the right size on the embedding layer output. After applying the filters, a max pooling operation is performed on each CNN layer to scale down the output vectors into dense feature vectors, each of size 100. The three dense vectors are concatenated and flattened into a single dense vector of size 300 in the fully connected layer. The final output is obtained through a dense layer with 2 output units.

The main ideabehind the concatenation of the word grams is to compute n-grams in parallel, add them together and extract as much information as possible from the vectors. This enables the classifier to learn and understand the relationships between the underlying words. The parameters for the model are as set as follows: sequence length of the model is 43, learning rate is set as 0.001 and dropout is set as 0.5, Softmax activation function for output layer and Relu activation function in other layers.

3.3.2 1D-CNN with GloVe

GloVe embeddings with 1 million word vectors of 200 dimension from twitter is used as an alternative method to create the embedding matrix of the embedding layer in the network. We used a conventional convolutional neural network in single dimension and extracted the skip-grams in parallel by using filters of size 2, 3 and 4, each vector of size 100, in three different branches and concatenated them to form one flattened dense vector of size 300. We have used 100 filters and dropout value as 0.2. Softmax activation function is used in output layer and Relu function is used in other layers. To increase the representational power of the neural network, a couple of dense layers are added before the final output layer. This model has fewer trainable parameters, takes less time to train, yet performs on par with 2D-CNN.

3.3.3 SVM with Bag-Of-Words

We implemented a Support Vector Machine using Term Frequency-Inverse Document Frequency (TF-IDF) model and found it to be as good as neural networks. The input document is converted into binary vectors using TF-IDF method. These feature vectors are fed as input to the SVM which uses a linear function as the kernel. The confusion matrix for SVM is shown in Table 1. Linear SVM is found to be better for text classification since most of the text classification problems are linearly separable (Joachims, 1998). For our model, BOW vector size is 98807.

		Actual	
		OFF	NOT
Predicted	OFF	689	618
	NOT	75	1880

Table 1: Linear SVM with TF-IDF model

3.3.4 Logistic Regression and RNN Models

We also trained Logistic Regression (Davidson et al., 2017) and RNN + LSTM (Long Short-Term Memory) models (Pitsilis et al., 2018). Table 2 shows macro average F1-scores for the various models developed. These models do not perform well compared to CNN and SVM. We used 75%

Model Used	F1 (Macro)
1D-CNN with GloVe	**0.751**
2D-CNN with Word2Vec	0.740
Linear SVM with TF-IDF	0.722
RNN+LSTM and GloVe	0.719
Logistic Regression with BoW	0.703
RNN+LSTM and Word2Vec	0.702

Table 2: Comparison of F1-scores of the Models Used

of the instances for training and 25% for testing the accuracy of the models.

The Logistic Regression using count vectorization model predicts more offensive tweets correctly than the previous models specified here. However, since the model could not classify non-offensive tweets effectively, its performance is low. The reason is that the bag of words model using count vectorization does not take the context or the semantics of the tweet into account and hence contextually non-offensive tweets with an offensive word in them are misclassified. Table 3 shows the confusion matrix for logistic regression model.

		Actual	
		OFF	NOT
Predicted	OFF	831	476
	NOT	250	1705

Table 3: Logistic Regression using BoW

3.3.5 Second Level Classification for Subtask-A

Most of the models we have described in the paper classify non-offensive tweets more correctly than offensive ones. To overcome the misclassification of offensive tweets, a second level of classification using string comparison model is done. Tweets predicted offensive with a probability less than 0.70 are passed on to a string comparison model which checks for any occurrence of offensive words. As an aid, a dictionary of 1384 words is constructed with the offensive words banned by Google and a list of bad words. This two level classification system proves to be very effective and increases the performance of the system by 5% in the macro average F1-score. The second level of classification is used to find whether the tweet is offensive or not. There is no need for a second level in subtasks B and C since they do not involve this classification.

4 Results

Table 4 shows the accuracy (Acc) results for subtask A. Three models were developed and tested for the given dataset. 2D-CNN model with enhanced dataset has better F1 score for both offensive and non-offensive tweets in comparison to the 2D-CNN with given dataset alone and 1D-CNN. 1D-CNN has better accuracy than other models. Since the given dataset is biased, some models classify non-offensive tweets more correctly than offensive tweets. Such a model has better accuracy than other models, but lower F1 score.

System	F1 (macro)	Acc
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
2D-CNN (28000 Data)	**0.7382**	0.8058
2D-CNN (13240 Data)	0.7351	0.8035
1D-CNN	0.7281	**0.8174**

Table 4: Results for Subtask A

Table 5 shows the results for subtask B. We developed SVM and 2D-CNN model for subtask B. SVM classifies tweets into targeted and untargeted ones more effectively than 2D-CNN model.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
SVM with TF-IDF	**0.6602**	**0.8208**
2D-CNN	0.5588	0.775

Table 5: Results for Subtask B

Table 6 shows the results for subtask C. SVM with TF-IDF, 1D-CNN with GloVe and 2D-CNN with learned Word2Vec embeddings are used to build models for subtask C. 1D-CNN model has better F1 macro score than other models.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
SVM with TF-IDF	0.5095	**0.6808**
1D-CNN	**0.5633**	0.6714
2D-CNN	0.4846	0.6479

Table 6: Results for Subtask C

The confusion matrix for the best model in subtasks A, B and C are shown in Figure 2, 3 and 4 respectively.

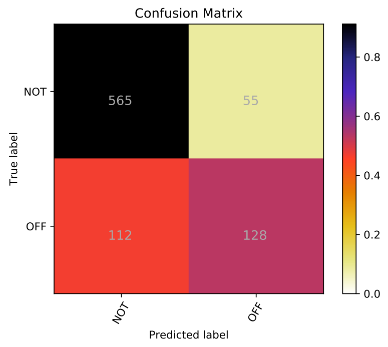

Figure 2: SubTask A: Confusion Matrix for 2D-CNN with Word2Vec embeddings

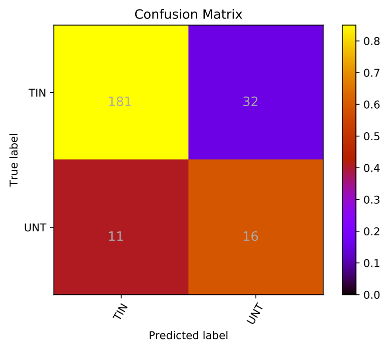

Figure 3: Subtask B: Confusion Matrix for SVM with bag of words model

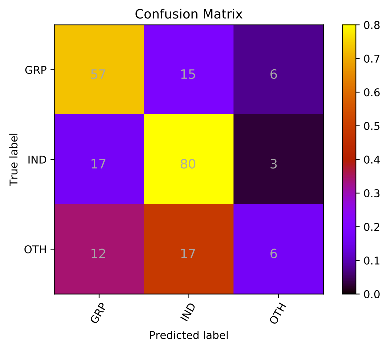

Figure 4: SubTask C: Confusion Matrix for 1D-CNN with GloVe

5 Conclusion

We have built three models for the tasks of offensive language detection and classification in tweets. The models are 2D-CNN with Word2Vec learned embeddings, 1D-CNN with GloVe and SVM with TF-IDF. All the models use data preprocessed with NLTK, which we think is an important factor for improved accuracy. In addition, we also made use of a dictionary of offensive and banned words for a second level of classification.

Meaning of a tweet varies with an individual's perception and cannot be judged by simple conventional models. This is one reason for the reduced precision of classification. The concepts of irony, sarcasm, humor and other tones of a conversation are too intuitive and implicit for the models to detect them accurately. We intend to investigate further by adding multiple hidden layers and building complex network structure which will, in parallel, look for the tell-tale signs of the target tone of the tweets.

1D-CNN model achieved less F1-score in the target identification (subtask C) than in subtasks A and B, due to smaller dataset, which can improved by augmenting the dataset.

Abstract

This system paper is a description of the system submitted to "SemEval-2019 Task 6", where we had to detect offensive language in Twitter. There were two specific target audiences, immigrants and women. The language of the tweets was English. We were required to first detect whether a tweet contains offensive content, and then we had to find out whether the tweet was targeted against some individual, group or other entity. Finally we were required to classify the targeted audience.

1 Introduction

Offensive language is pervasive in social media. Individuals frequently take advantage of the perceived anonymity of computer-mediated communication, using this to engage in behavior that many of them would not consider in real life. Online communities, social media platforms, and technology companies have been investing heavily in ways to cope with offensive language to prevent abusive behavior in social media.

One of the most effective strategies for tackling this problem is to use computational methods to identify offense in user-generated content (e.g. posts, comments, microblogs, etc.). This topic has attracted significant attention in recent years of various Natural Language analysts.

The SemEval 2019 task 6 (Zampieri et al., 2019b) was a classification task where we were required to classify a tweet, as hate speech or otherwise. However, there were some additional challenges presented, which involved automatic categorization of offense target types and the specific detection of the target audience, namely, women or immigrants.

The task was divided into three parts. In the first subtask our system categorized the instances into `OFF` and `NOT`. In the second subtask our system categorized instances into `TIN` and `UNT` while in the third subtask systems should categorize instances into `IND`, `GRP`, and `OTH`.

To solve the task in hand we built a bidirectional LSTM based neural network for prediction of the classes present in the provided dataset.

The paper has been organized as follows. Section 2 describes a brief survey on the relevant work done in this field. Section 3 describes the data, on which, the task was performed. The methodology followed is described in Section 4. This is followed by the results and concluding remarks in Section 5 and 6 respectively.

2 Related Work

Papers published in the last two years include the surveys by Schmidt and Wiegand (2017) and Fortuna and Nunes (2018). The paper by Davidson et al. (2017) presenting the Hate Speech Detection dataset were used in (Malmasi and Zampieri, 2017) and a few other recent papers such as (ElSherief et al., 2018; Gambäck and Sikdar, 2017; Zhang et al., 2018).

A proposal of typology of abusive language sub-tasks is presented in (Waseem et al., 2017). For studies on languages other than English see work by Su et al. (2017) on Chinese and Fišer et al. (2017) on Slovene. Finally, for recent discussion on identifying profanity vs. hate speech see the work by Malmasi and Zampieri (2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

Previous editions of related workshops are TA-COS[1], Abusive Language Online[2], and TRAC[3] and related shared tasks such as GermEval (Wiegand et al., 2018) and TRAC (Kumar et al., 2018).

3 Data

The dataset that was used to train the model is the OLID dataset (Zampieri et al., 2019a). It was collected from Twitter; the data being retrieved the data using the Twitter API by searching for keywords and constructions that are often included in offensive messages. The vast majority of content on Twitter is not offensive so different strategies were tried to keep a reasonable number of tweets in the offensive class amounting to around 30% of the dataset.

The dataset provided consisted of tweets in their original form along with the corresponding labels. Subtask A consisted of the labels `OFF` and `NOT`; subtask B consisted of the labels `TIN` and `UNT`; and finally subtask C consisted of the labels `IND`, `GRP` and `OTH`.

Label	**Meaning**
OFF	Tweet containing offensive language
NOT	Tweet not containing offensive language
TIN	Tweet containing profanity and targeted against individual/group/others
UNT	Tweet with profanity, but non-targeted
IND	Offensive tweet targeting an individual
GRP	Offensive tweet targeting a group
OTH	Offensive tweet targeting neither group or individual

Table 1: Meaning of the labels used in the dataset

The dataset had 14100 instances which were divided into 13240 training data instances and 860 test data instances.

A	**B**	**C**	**Train**	**Test**	**Total**
OFF	TIN	IND	2407	100	2507
OFF	TIN	OTH	395	35	430
OFF	TIN	GRP	1074	78	1152
OFF	UNT	-	524	27	551
NOT	-	-	8840	620	9460
All			13240	860	14100

Table 2: Distribution of the labels in the dataset

4 Methodology

Our approach was to convert the tweet into a sequence of words and then run a neural-network based algorithm on the processed tweet.

The first stage in our pipeline was to preprocess the tweet. This consisted of the following steps:

1. Removing mentions
2. Removing punctuation
3. Removing URLs
4. Contracting white space
5. Extracting words from hash tags

The last step consists of taking advantage of the Pascal Casing of hash tags (e.g. `#PascalCasing`). A simple regex can extract all words; we ignore a few errors that arise in this procedure. This extraction results in better performance mainly because words in hash tags, to some extent, may convey sentiments of hate. They play an important role during the model-training stage.

We treat the tweet as a sequence of words with interdependence among various words contributing to its meaning. Hence we use an bidirectional LSTM based approach to capture information from both the past and future context.

Our model is a neural-network based model. First, the input tweet is passed through an embedding layer which transforms the tweet into a 128 length vector. The embedding layer learns the word embeddings from the input tweets. This is followed by two bidirectional LSTM layers containing 64 units each. This is followed by the final output layer of neurons with softmax activation, each neuron predicting a label as present in the dataset. For subtasks 1 and 2, it contains 2 neurons for predicting `OFF/NOT` and `TIN/UNT` respectively; for subtask 3 it contains 3 neurons for predicting `IND/GRP/OTH`. Between the LSTM and output layers, we add dropout with a rate of 0.5 as a regularizer. The model is trained using the Adam optimization algorithm with a learning rate of 0.0005 and using crossentropy as the loss.

We note that the dataset is highly skewed in nature. If trained on the entire training dataset without any validation, the model tends to completely overfit to the class with higher frequency as it leads to a higher accuracy score.

To overcome this problem, we took some measures. Firstly, the training data was split into two parts; one for training and one for validation comprising 70 % and 30 % of the dataset respectively. The training was stopped when two consecutive epochs increased the measured loss function value for the validation set.

Secondly, class weights were assigned to the different classes present in the data. The weights were approximately chosen to be proportional to the inverse of the respective frequencies of the classes. Intuitively, the model now gives equal weight to the skewed classes and this penalizes tendencies to overfit to the data.

In general, we took 0.5 as the boundary between predictions of 0 and 1 — essentially rounding the predicted values. However, for subtask B, we try different values for this parameter (`thresh`) to achieve better results. Values less than `thresh` are converted to 0 while the remaining values are converted to 1.

5 Results

We have included the automatically generated tables with our results. We have also included some baselines generated by assigning the same labels for all instances. For example, "All OFF" in subtask A represents the performance of a system that labels everything as offensive. We have used this for comparison.

We have also added the relevant confusion matrices that were provided together with the results.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
BiLSTM	0.4650	0.5651

Table 3: Sub-task A, garain CodaLab 528038 (Bi-Directional LSTM)

6 Conclusion

Here we have presented a model which performs satisfactorily in the given tasks. The model is based on a simple architecture. There is scope for improvement by including more features (like those removed in the preprocessing step) to increase performance. Another drawback of the model is that it does not use any external data other than the dataset provided which may lead to poor results based on the modest size of the data. Related domain knowledge may be exploited to obtain better results.

University of Tübingen, Germany
{mkannan,lstein}@sfs.uni-tuebingen.de

Abstract

We describe our system (TüKaSt) submitted for Task 6: Offensive Language Classification, at SemEval 2019. We developed multiple SVM classifier models that used sentence-level dense vector representations of tweets enriched with sentiment information and term weighting. Our best results achieved F1 scores of 0.734, 0.660 and 0.465 in the first, second and third sub-tasks respectively. We also describe a neural network model that was developed in parallel but not used during evaluation due to time constraints.

1 Introduction

We live in a day and age where social media pervades through every aspect of lives. Constant growth of social media platforms and rapid exposure to them are changing how human communication is perceived and working (Sticca and Perren, 2013). As much as social media and the general web help its users stay connected and informed, misuse of these channels grows with them. As long as anonymity continues to play a central role in online interactions, one must contend with individuals and entities who feel empowered to behave aggressively for that very reason (Burnap and Williams, 2015). Recent events have forced social media platforms to take a renewed interest in limiting the negative influence of such users for commercial and practical reasons. However, the sheer size of data on social media makes it impossible to manually observe, thereby calling the creation of systems that automatically detect potentially offensive content.

The SemEval 2019 - OffensEval Shared Task (Zampieri et al., 2019b) is aiming exactly at that need, calling for system able to detect offensive language in social media data. The task is split into three sub-tasks: Detecting offensive language, determining whether it is offensive directly towards a target, and target specification. This paper follows our approach of applying both traditional and more sophisticated neural models to the task of offensive text classification.

2 Preprocessing

All tweets were converted to lowercase and tokenised. Stop-words were removed unconditionally, but hashtags and user mentions were removed during the training of certain model variants.

3 Training Data

The SVM models were trained and evaluated exclusively on the training data provided by Zampieri et al. (2019a) with ten-fold cross-validation. For the RNN models, we also used the trail data that was provided before the start of the training phase. The samples were shuffled before each training run, and a 80-20 split was performed to generate training and validation sets.

300-dimensional, pre-trained FastText embeddings (Mikolov et al., 2018) were used to train the SVM models. The FastText embeddings were chosen due to their subword-information (Bojanowski et al., 2017), making it easier to deal with social media data, which is prone to contain spelling errors and abbreviations. 100-dimensional Glove vectors trained on the Twitter corpus (Pennington et al., 2014) were used to initialise the word embeddings in the RNN models.

For sentiment data, we used the Vader sentiment lexicon (Gilbert, 2014) to retrieve polarity scores for each word in the vocabulary. Scores range from -4 (extremely negative) to +4 (extremely positive). A neutral score of zero was assigned to out-of-vocabulary words.

4 Models

4.1 Support Vector Machines Classifier

Support Vector Machines (SVMs) have been used successfully in many classification problems concerning natural language (Aggarwal and Zhai, 2012). In the proceedings of the First Workshop on Trolling, Aggression and Cyberbullying, Kumar et al. (2018) report on several teams using SVMs to identify aggressive texts. Moreover, SVMs with traditional features can still outperform neural networks in natural language tasks (Medvedeva et al., 2017; Çöltekin and Rama, 2017, 2018). However, traditional features like TF-IDF, character and word n-grams, bag of words/n-grams, and sentiment lookups dominate the majority of models used for identifying aggressive language.

Contrasting the use of traditional features used in natural language processing is the prominent research on neural networks using dense vector representations (word embeddings) as input. Since embeddings are able to capture syntactic and semantic features and represent them in a distributed manner, it makes them perfect for language modelling (Bojanowski et al., 2017). We chose to experiment with embeddings in SVMs for this classification task in order to keep pre-processing and feature-engineering to a minimum. Moreover, we wanted to see how the SVM could improve with the dense representations over sparse representations. However, we also experimented with combinations of continuous features and traditional features in some of our models.

The SVM models' dense sentence representation was composed by summing the respective embeddings of every word in the tweet and normalising over the length of the tweet. We chose not to weight them by their TF-IDF scores to achieve an even combination of all constituents. Mikolov et al. (2013) report that adding vectors in a linear fashion yields meaningful phrase representations.

For the first of three SVM models (**combined_fixed**), we created vectors for the TF-IDF and the retrieved sentiment values in the following manner: The TF-IDF vectors were constructed with length $|V|$, where V is the vocabulary constructed from the corpus and each dimension is corresponding to a specific word in the model's vocabulary. The sentiment vector was constructed with length $|V'|$, where V' corresponds to the Vader lexicon (Gilbert, 2014) and each dimension corresponds to a specific word in the lexicon. Both vectors were initialised with zeros and respective dimensions were replaced with the retrieved/computed values. Both vectors were then appended to the dense sentence representation.

The second model (**combined_positioned**) was trained with a word-order sensitive representation of the aforementioned features. Both the TF-IDF vector and the sentiment vectors were constructed with length $|word\_count(t)|$, where t is the longest tweet in the trainings set and where each the dimension corresponds to the word encountered at the respective index in the tweet. The third and final SVM model was only trained on the composed sentence embeddings (**emb_only**).

4.2 Recurrent Neural Classifier

In addition to the SVM classifier, we parallelly trained a recurrent neural classifier using both Long Short-Term Memory (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (Cho et al., 2014) cells.

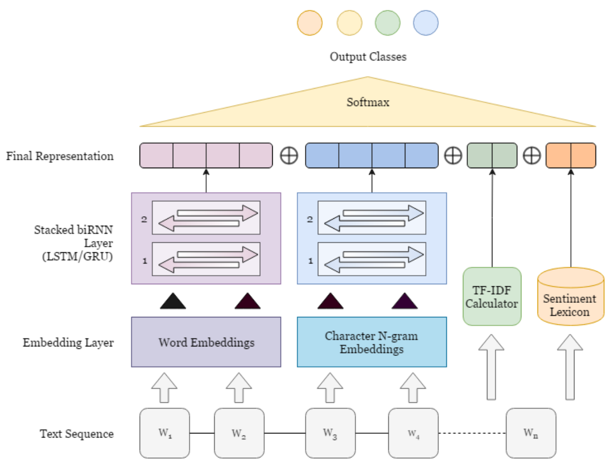

Figure 1: RNN Classifier Architecture.

The architecture of our model is illustrated in figure 1. It accepts token and character n-gram sequences as inputs. The embedding layer consists of individual embedding matrices for each input type. The word embedding matrix is initialised with pre-trained word embeddings while the character embedding matrix is randomly initialised, both of which are subsequently learned as parameters of the model during the training phase.

The embedding sequence is used as the input to a stacked bi-directional RNN layer. We used both LSTM (with peepholes) and GRU cells for the individual units in each RNN layer (trained as separate models). Dropout is additionally added to each layer during the training phase. The hidden states of the forward and backward RNNs of the top-most layer are concatenated to produce the sentential representation of the sequence. This is performed for both types of input sequences.

In addition to the output of the biRNN layers, we calculate TF-IDF (Term Frequency - Inverse Document Frequency) scores for all words in the corpus. This lets us construct a fixed-length dense vector of normalised TF-IDF values for each tweet. Similarly, we use a sentiment lexicon to lookup human-assigned polarity scores of individual words and construct a second fixed-length vector with sentiment information for each tweet.

The outputs of the above components are concatenated into a single, final representation. We expect the TF-IDF and sentiment vectors to encode relevant information about the importance of discriminating words in the input sequence. This final representation is used as the logits for a SoftMax layer that outputs the predicted label of the tweet.

5 Parameters & Training

We used *sklearn-kittext* (Pedregosa et al., 2011) to build our SVM models. For both Sub-task A and B, a binary classifier was trained and for Sub-task C a one-versus-one, multi-class classifier was trained on the three different labels. All three models use sklearn's default RBF-kernel with `C`=2 and `gamma`=0. The final hyper-parameters used by the neural classifier are listed in table 7. Training was performed with early stopping.

During our initial tests, the neural network classifier particularly had trouble generalising to the training data. We found that the class imbalance in the data caused the classifier to be biased towards the majority class and to over-fit the training data. To mitigate this, we weighted the output of the loss function with the ratios of the different classes in each dataset and performed L2 regularisation on the losses of each mini-batch.

6 Results

The results that follow are those only those of the SVM models evaluated during the evaluation phase of the OffenEval task (Zampieri et al., 2019b). Since we were unable to train the RNN classifier in time for the official evaluation phase, we will instead be reporting the scores of the classifier on the validation set (mean and best macro-F1 scores and their corresponding accuracies) in section A.

The model using the sentence embedding on its own is denoted by **emb_only**, the combination of sentence embedding and multiple-hot TF-IDF and sentiment vectors by **combined_fixed** and the position sensitive combination of the vectors by **combined_positioned**.

For Sub-task B and C, all three models were submitted and for sub-task A, only the **emb_only** and the **combined_fixed** were submitted.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
combined_fixed	**0.7340**	**0.7942**
emb_only	0.7127	0.7849

Table 1: Results for Sub-task A.

The results for Sub-task A (Table 1) reveal a slight improvement for adding traditional features to the dense sentence representation. This improvement is likely to be due to the sentiment vector, whose values should be very discriminative for tweets containing offensive language. Nevertheless, this information should be encoded in the embeddings as well.

For Sub-task B (Table 2) and Sub-task C, the **emb_only** model actually outperforms the combined vectors. This might be due to the fact that tasks are more fine-grained than Task A and these nuances are captured by the word embeddings, while the sentiment and TF-IDF vectors end up contributing more to the noise than information in the signal. Nevertheless, the SVM seems to be able to handle the data from the composed sentence embeddings quite well.

System	**F1 (macro)**	**Accuracy**
All TIN baseline	0.4702	**0.8875**
All UNT baseline	0.1011	0.1125
combined_positioned	0.6470	0.8
combined_fixed	0.4702	**0.8875**
emb_only	**0.6602**	0.8208

Table 2: Results for Sub-task B.

System	**F1 (macro)**	**Accuracy**
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
combined_positioned	0.4421	**0.5305**
combined_fixed	0.4213	0.4695
emb_only	**0.4652**	0.5164

Table 3: Results for Sub-task C.

The results obtained for Sub-task B reveal that the model trained on **combined_fixed** performs remarkably badly when evaluated on the F1 score. Moreover, the accordance on Accuracy with the All-TIN-Baseline indicates that our model over-fits the training data and classifies all samples as being targeted, which is actually the case. This problem and general performance could probably be improved by spending more time on hyper-parameter training.

The per-class scores of the best performing model in each sub-task are listed in tables 4-6.

	Precision	Recall	F1-score	Samples
NOT	0.8413	0.8806	0.8605	620
OFF	0.6493	0.5708	0.6075	240

Table 4: Per-class performance in Sub-task A, SVM model *combined_fixed*

	Precision	Recall	F1-score	Samples
TIN	0.9427	0.8498	0.8938	213
UNT	0.3333	0.5926	0.4267	27

Table 5: Per-class performance in Sub-task B, SVM model *emb_only*

	Precision	Recall	F1-score	Samples
GRP	0.5306	0.6667	0.5909	78

OTH	0.1837	0.2571	0.2143	35

Table 6: Per-class performance in Sub-task C, SVM model *emb_only*

7 Conclusion

In this paper, we demonstrate the use of both Support Vector Machine models and Recurrent Neural models to classify offensive tweets. We show how sentential representations derived from word and character n-gram embeddings can be enriched by including term salience and sentiment information for certain tasks. For more fine-grained tasks, dense vector representations of sentences work well with SVM classifiers. While our results show that traditional methods still outperform neural network models, there is much room for improvement. Future work could investigate the use of more sophisticated mechanisms like attention to potentially increase performance even further.

Table 7: RNN Model Hyper-parameters

A.1 Recurrent Neural Classifier Validation Results

The *-hm* suffix denotes the models that were trained on tweets from which hash tags and user mentions were removed. *-aux* denotes the models that did not use the fixed-length TF-IDF and sentiment vectors in the final representation. In all other models, both of the aforementioned features were preserved. We also report the validation results of the SVM models for comparison.

In Sub-task A (Table 8), the full-LSTM model with TF-IDF and sentiment vectors scored best, followed very closely by the model without hashtags or user mentions. Removing the auxiliary vectors resulted in a net decrease in performance, which shows that sentiment and [term] salience-related information do indeed help the model learn and generalise better. Interestingly, removing hash tags/mentions along with the auxiliary vectors increased performance relative to the previous case. The GRU scored the lowest; this could potentially be attributed to its weakness with long-distance dependencies.

The full-LSTM model continued to outperform the other models in Sub-task B (Table 9) as well. Removing hash tags and user mentions caused a more substantial drop in performance compared to the first sub-task. This follows logically as the given task is to identify targetted tweets; removing information that is intrinsically indicative of the same results in a worse-performing model. Removing the auxiliary vectors causes performance to drop further, further corroborating their informativity. And as before, the GRU finished in the last place.

Sub-Task C (Table 10) saw a reversal of roles between the GRU and full-LSTM models. Between the different variants of the LSTM-based models, the general trend seen in Sub-task A re-emerged. It must, however, be noted that all models performed poorly at this sub-task. We conjecture that this is partly due to the limited amount of training data available for this sub-task. It is also likely that the chosen architecture of the classifier is not sophisticated enough to model the non-linearities in the training data.

Abstract

This article presents our approach for detecting a target of offensive messages in Twitter, including Individual, Group and Others classes. The model we have created is an ensemble of simpler models, including Logistic Regression, Naive Bayes, Support Vector Machine and the interpolation between Logistic Regression and Naive Bayes with 0.25 coefficient of interpolation. The model allows us to achieve 0.547 macro F1-score.

1 Introduction

Nowadays aggressive language on social media occurs more and more often. Categories of hate speech can be very diverse and can deal with a wide range of issues such as misogyny, sexual orientation, religion and immigration. Such types of speech can be found in posts in social networks, in Internet discussions, in comments on various articles and in responses to posts of famous persons.

This problem is receiving increasing amounts of attention and researchers are making attempts to build systems capable of recognizing such kinds of aggressive speech, offenses and insults in social networks.

This article presented our approach to hate speech detection, which we used for the challenge SemEval-2019 Task 6: OffensEval - Identifying and Categorizing Offensive Language in Social Media (Zampieri et al., 2019a ; Zampieri et al., 2019b).

The task consisted of three sub-tasks and proposed to investigate the data extracted from Twitter for creating a classification system.

Sub-task A had the aim to identify offensive language and there were 860 unmarked English tweets for testing. The post had to be non offensive if it did not contain any offense or profanity.

The main goal of the Sub-task B was to categorize offensive posts from Sub-task A (there were 240 English tweets for testing) to different offensive types:

- Targeted Insults and Threats in cases when a post insults or treats to an individual, a group or an organization;

- Untargeted in cases where a post has a non-targeting profanity and swearing.

Sub-task C focused on offense target identification. There were 213 English tweets which were marked as offensive in Sub-task A and Targeted Insult and Threats in Sub-task B for testing. The classification was for three different groups:

- Individual, when the target of the offensive post was a person;

- Group, when the target of the offensive message was a group of people considered as a unit;

- Other, when the target of the offensive tweet did not belong to any of the previous categories (e.g., a situation, an event, or another issue).

There are two datasets in English and in Spanish languages for analysis, and our team worked with English only. The training dataset included 13200 tweets, 4400 of them were offensive ones, 3876 messages were labeled as 'Target Insult and Threats' and 524 ones as 'Untargeted'. We focused our efforts on Sub-task C only, and the training dataset for it consisted of 2407 'individual' offensive posts, 1074 'group' ones and 395 tweets marked as 'other'.

The paper is organized as follows. Some relevant related works in the area are described in Section 2. Section 3 presents the preprocessing we applied for the dataset and the methodology we used for the model creating. In Section 4 the results are described and analyzed. In Section 5 we summarize our work and plan some steps for the future researches.

2 Related Work

Today there are a lot of promising works in the area of the hate speech recognition As was shown in (Fasoli et al., 2015), offensive language can be very diverse and the level of the messages offensiveness can depend on the context and the relationships between users who take part in the conversation.

For example, insults delivered in a sexual context are less offensive in cases where there is a conversation between partners. Some slurs have more offensive meaning in cases of conversations between a superior and a subordinate compared with conversations between friends and some groups of slurs are more acceptable then others.

Expanding the point that offensive speech is heterogeneous, the work (Clarke and Grieve, 2017) presented results which showed that there is a difference between racist and sexist posts: the sexist messages were more interactive (more personal) and more attitudinal (with authors opinion) than racist ones. From this article we can make a conclusion that the most popular linguistic feature in offensive language are question marks and question DO (when a sentence stars with the word do).

The work (Saleem et al., 2017) demonstrated that messages may not include slurs, but still be offensive. The authors took as training dataset messages from potentially vulnerable communities (like groups of Afro-American and plus-size users) and messages from haters of these communities (not included slurs only) and showed that the system of hate speech recognition based on traditional methods like Logistic Regression could indicate insult meaning on the posts without slurs. .

In addition, this work shows that it is possible to test dataset from one source using training set from another one. Authors checked this fact, used the training dataset from one source and the testing dataset from the another source. The results were quite good and it is allow us to say that it could be useful to add to our training dataset some comments from another social media to make predictions better.

At the Automated Misogyny Detection (AMI) Shared Tasks IBEREVAL-2018 (Fersini et al., 2018) and EVALITA-2018 (Caselli et al., 2018), some interesting approaches for offensive language detecting were presented. The main goal in these challenges was to detect misogynistic tweets and to classify tweets for different groups depending on a misogyny type (stereotypes and objectification, dominance, derailing, sexual harassment and threats of violence and discredit) and an insults target (the idea of this type of classification was to recognize misogynous tweets which offend a specific person and tweets which insult a group of people).

In (Pamungkas et al., 2018) it was shown that the results of the model based on Support Vector Machine were quite good and in the research (Frenda et al., 2018) the ensemble of models allow to achieve a high level of accuracy. In work (Shushkevich and Cardiff, 2018) it was presented the ensemble of Logistic Regression. Support Vector Machine and Naive Bayes model which shown quite good results.

It is necessary to add that models based on neural networks show good results of offensive language recognition, as it was shown in (Badjatiya et al., 2017), where the authors created the model based on Long Short-Term Networks (LSTMs) which use internal memory for capture the long range dependencies in sentences and it could be important for the hate speech detection. This approach allowed them to achieve very high results in sexist and racist tweets detection in comparison with classifiers such as Logistic Regression, Random Forest, SVMs and Gradient

Boosted Decision Trees (GBDTs).

3 Methodology and Data

As the preprocessing step we:

- converted the words to the lower case;

- used TF-IDF (Term Frequency - Inverse Document Frequency) for the vectorization;

- marked emojis with the word 'EMOJI';

- labeled some combinations of symbols like '!!! ' and '??? ', because they look like emotional expressions and could be presented as emojis too, and replaced them with the word 'EMOJI'

Our model presents an ensemble of some classic machine learning models:

- The model based on Logistic Regression (LR) (Wright, 1995; Genkin et al., 2007), this type of classifiers apply an exponential function to a lineal combination of objects extracted from the data.

- The model based on Naive Bayes (NB), whose advantages are an absence of big training dataset and speed calculations requirement (Hi and Li, 2007).

- The model presented an interpolation between LR and NB with 0.25 coefficient of interpolation as a form of regulation: trust NB unless the LR. This type of interpolation was shown in (Wang and Manning, 2012) where NB was combined with Support Vector Machine, but in our case the combination LR+NB worked better.

- The model based on Support Vector Machine (SVM), the effectiveness of which in the work with texts was described in (Joachims, 2002).

We blended all above-described models into one which indicated the belonging of a tweet to the classes according to the rule: we summarized probabilities of belonging to all three classed which all four models presented and divided this number by 4. A post was assigned a class with the highest average probability.

4 Results

The predicted results of F1-macro for the all 5 models are presented in Table 1.

As it shown the Blended model achieves the highest score (0.68), so we could conclude that our hypothesis was correct and an ensemble of models presented the best results for the task of offense target identification.

Also, the model which combine Logistic Regression and Naive Bayes achieves good result (0.65), and the worst model for this type of classification was Logistic Regression one.

The results of the challenge are presented in Table 2. Overall Accuracy for the test set was equal to 0.6478 and Macro-F1 was 0.547.

As we can see, the macro F1-score is less when predicted with the training dataset macro F1-score by 0.133, and this difference could be connected with the small number of tweets for training. Also it should be noted, that the results of classification have a strict correlation with the number of testing examples: the IND classifier works better then GRP one and much better then OTH classifier, because in the testing dataset there were more data about individual target of offenses then about group and other targets.

5 Conclusion

To sum up, we created an ensemble of models, which allow as to achieve quite good results being placed 25th out of a total of 65 participants. We showed that the idea of blending simple models based on Logistic Regression, Naive Bayes and Support Vector Machine gives a perspective in the area of hate speech recognition in the identification of the target of offensive messages.

As the next steps in our research, we are planning to expand the preprocessing step and use some dictionaries and lists of offensive language, which could help us to achieve better results. We also intend to additional data for the training datasets.

It is interesting to add, that in these datasets all links were replaced with URL and all usernames

Model	F1 (macro)
Logistic Regression	0.50
Naive Bayes	0.63
LR+NB	0.65
Support Vector Machine	0.60
Blended Model	**0.68**

Table 1: Results for each model with training dataset for the Subtask C

Type of classification	F1-score
GRP	0.6047
IND	0.7615
OTH	0.2759
avg/totall	**0.6243**

Table 2: Results of the classification with testing dataset for the Subtask C

in tweets were replaced with USER. It could be useful to investigate, for example, links, which were mentioned in offensive messages. It could be possible to expand our dataset in cases when link was a respond for another offensive post or we could lable tweets which have links for a blocked content.

In this challenge we faced the problem of the an insufficient quantity of tweets to make our classifier work better: for example, for the class Other there were only 395 post for training. We believe that an increase in the volume of data could make our modeling more effective, and external data sources could be helpful. Also, we intend to experiment with the use of LSTMs.

Abstract

We examine learning offensive content on Twitter with limited, imbalanced data. For the purpose, we investigate the utility of using various data enhancement methods with a host of classical ensemble classifiers. Among the 75 participating teams in SemEval-2019 sub-task B, our system ranks 6th (with 0.706 macro F_1-score). For sub-task C, among the 65 participating teams, our system ranks 9th (with 0.587 macro F_1-score).

1 Introduction

With the proliferation of social media, millions of people currently express their opinions freely online. Unfortunately, this is not without costs as some users fail to maintain the thin line between freedom of expression and hate speech, defamation, ad hominem attacks, etc. Manually detecting these types of negative content is not feasible, due to the sheer volume of online communication. In addition, individuals tasked with inspecting such types of content may suffer from depression and burnout. For these reasons, it is desirable to build machine learning systems that can flag offensive online content.

Several works have investigated detecting undesirable (Alshehri et al., 2018) and offensive language online using traditional machine learning methods. For example, Xiang et al. (2012) employ statistical topic modelling and feature engineering to detect offensive tweets. Similarly, Davidson et al. (2017) train multiple classifiers (e.g., logistic regression, decision trees, and support vector machines) to detect hate speech from general offensive tweets. More recently, deep artificial neural networks (i.e., deep learning) has been used for several text classification tasks, including detecting offensive and hateful language. For example, Pitsilis et al. (2018) use recurrent neural networks (RNN) to detect offensive language in tweets. Mathur et al. (2018) use transfer learning with convolutional neural networks (CNN) for offensive tweet classification on Twitter data.

Most of these works, however, either assume relatively balanced data (traditional classifiers) and/or large amounts of labeled data (deep learning). In scenarios where only highly imbalanced data are available, it becomes challenging to learn good generalizations. In these cases, it is useful to employ methods with good predictive power for especially minority classes. For example, methods capable of enhancing training data (e.g., by augmenting minority categories) are desirable in such scenarios. In the literature, some works have been undertaken to address issues of data imbalance in language tasks. For example, Mountassir et al. (2012) propose different undersampling techniques that yield better performance than common random undersampling on sentiment analysis. Along similar lines Gopalakrishnan and Ramaswamy (2014) propose a modified ensemble based bagging algorithm and sampling techniques that improve sentiment analysis. Further, Li et al. (2018) present a novel oversampling technique that generates synthetic texts from word spaces.

In addition to data enhancement, combining various classifiers in an ensemble fashion can be useful since different classifiers have different learning biases. Past research has shown the effectiveness of ensembling classifiers for text classification (Xia et al., 2011; Onan et al., 2016). Omar et al. (2013), for example, study the performance of ensemble models for sentiment analysis of Arabic reviews. Da Silva et al. (2014) exploit ensembles to boost the accuracy on twitter sentiment analysis. Wang and Yao (2009) demonstrate the utility of combining sampling techniques with ensemble models for solving the data imbalance problem.

In this paper, we describe our submissions to SemEval-2019 task 6 (OffenseEval) (Zampieri et al., 2019b). We focus on sub-tasks B and C. The Offensive Language Identification Dataset (Zampieri et al., 2019a), the data released by the organizers for each of these sub-tasks, is extremely imbalanced (see Section 2). We propose effective methods for developing models exploiting the data. Our main contributions are: (1) we experiment with a number of simple data augmentation methods to alleviate class imbalance, and (2) we apply a number of classical machine learning methods in the context of ensembling to develop highly successful models for each of the competition sub-tasks. Our work shows the utility of the proposed methods for detecting offensive language in absence of budget for performing feature engineering and/or small, imbalanced data.

The rest of the paper is organized as follows: We describe the datasets in Section 2. We introduce our methods in Section 3. Next, we detail our models for each sub-task (Sections 4 and 5). We then offer an analysis of the performance of our models in Section 6, and conclude in Section 7.

2 Data

As mentioned, *OffenseEval* is SemEval-2019 task 6. The task is focused on identifying and categorizing offensive language in social media and involves three different sub-tasks. These are:

- **Sub-task A** is offensive language identification, e.g. classifying the given tweets into *offensive* or *non-offensive*. In our work, we only focus on sub-tasks B and C and so we do not cover sub-task A further.

- **Sub-task B** is automatic categorization of offensive content types, which involves categorizing tweets into *targeted* and *untargeted* threats. The dataset for this sub-task consists of 4,400 tweets (3,876 *targeted* and 524 *untargeted*). Table 1 provides one examples of each of these two classes.

- **Sub-task C** is offense target identification and includes the 3 classes of targets. These classes are in the set {*individual, group, others*}. The dataset for this sub-task consists of 3,876 tweets (2,407 *individual*, 1,074 *group*, and 395 *other*). We similarly provide one example for each of these classes in Table 1.

We use 80% of the tweets as our training set and the remaining 20% as our validation set for both sub-tasks B and C. We also report our best models on the competition test set, as returned to us by organizers. Table 2 provides statistics of our data for sub-tasks B and C.

3 Methods

3.1 Pre-Processing

We utilize a simple data pre-processing pipeline involving lower-casing all text, filtering out URLs, usernames, punctuation, irrelevant characters and emojis, and splitting text into word-level tokens.

3.2 Data Intelligence Methods

We employ multiple machine learning methods and combine them with different sampling and data generation techniques to enhance our training set. From a data sampling perspective, the most common approaches to deal with imbalanced data is random oversampling and random undersampling (Lohr, 2009; Chawla, 2009). Learning with these basic techniques is usually effective due to possibly reducing model bias towards the majority class. We employ a number of data sampling techniques, as described next.

Random oversampling technique randomly duplicates the minority samples to obtain a balanced dataset. Despite the naive approach, this method is reported to perform well (as compared to other sophisticated oversampling methods) in the literature. One major drawback of this method is that it does not add any new data to the training set (since it only duplicates minority-class training data) (Liu et al., 2007).

Synthetic minority over-sampling (SMOTE) is a sophisticated oversampling technique where synthetic samples are generated and added to the minority class. For each data point, one of k minority class neighbours is randomly selected and the new synthetic point is a random point on the line joining the actual data point and this randomly selected neighbour. This method has been shown to be effective compared to some other oversampling methods (Chawla et al., 2002; Batista et al., 2004).

Random undersampling removes instances from the majority class in a random manner to ob-

Task	Label	Example
Sub-task B	targeted	*Liberals are all Kookoo !!!*
	untargeted	*Dont believe the hype.*
Sub-task C	individual	*Good move...he is the big loser*
	group	*The Liberals are mentally unstable!!*
	other	*Google go to hell!*

Table 1: Examples of each class in sub-tasks B and C

Task	Label	Train	Dev	Total
Sub-task B	targeted	3,101	775	3,876
	untargeted	419	105	524
Sub-task C	individual	1,925	482	2,407
	group	859	215	1,074
	other	316	79	395

Table 2: Distribution of classes over our data splits

tain a balanced dataset. One possible disadvantage of this method is that it might remove valuable information from training data since, due to its randomness, it does not pay consideration to the data points removed (Liu et al., 2007).

kNN-based undersampling is an alternative undersampling technique (Mani and Zhang, 2003) which uses distance between points within a class. We use three different methods to select near-miss samples, as described in Mani and Zhang (2003). **NearMiss-1** selects majority class samples whose average distance to three closest minority class samples is smallest. In **NearMiss-2**, the samples of the majority class are selected such that their average distances to three farthest samples of minority class are smallest. **NearMiss-3** picks a given number of the closest majority class samples from each minority class sample, which guarantees every minority class sample is surrounded by some majority class points. Mani and Zhang (2003) choose the majority class samples whose average distances to the three closest minority class samples are farthest.

Synthetic Data Generation. We experiment with adding information to the minority class by generating synthetic samples employing a word2vec-aided paraphrasing technique. Initially, we train a word2vec model on the entire training data and use this word2vec model to generate samples for the minority class by randomly replacing words in tweets (with a probability of 0.9). We randomly pick one word from k word2vec most similar words. We fix k=5 words and probability value as 0.9, but these are hyperparameters that can be optimized. In this way, we generate a balanced dataset in an attempt to overcome the problem of imbalance. In this technique, we draw inspiration from (Li et al., 2018) where authors propose a sentiment lexicon generation method using a label propagation algorithm and utilize the generated lexicons to obtain synthetic samples for the minority class by randomly replacing a set of words with words that have similar semantic content.

3.3 Classifiers

We apply a number of machine learning classifiers that are proven to work well for text categorization. Namely, we use logistic regression, support vector machines (SVM) and Naive Bayes. We also experiment with boosting algorithms such as random forest, AdaBoost, bagging classifier, XGBoost, and gradient boosting classifier. We deploy ensembles of our best performing models in two ways: (1) ensembles based on majority rule classifiers that use predicted class labels for majority rule voting and (2) soft voting classifiers that predict the class label based on the argmax of the sums of the predicted probabilities of various classifiers.

4 Sub-Task B Models

For sub-task B, we have one minority class, so we generate samples for this minority class to obtain a new, balanced dataset. We use this balanced data as well as the the imbalanced (ORG) dataset for our first iteration of experiments. The goal of iteration is to identify the best (1) input n-gram settings (explained next), (2) classifier (from our classifiers listed in Section 3.3, and (3) sampling techniques (listed in 3.2). For **n-gram settings**, we use a combination of bag of words and TF-IDF to extract features from the tweets and run with unigrams and all different combinations of unigram, bigrams, trigrams, and four grams. We run on all combinations across all the three variables above (n-grams, classifiers, and sampling methods) on both the imbalanced (ORG) and balanced datasets. Since our datasets are small, this iteration of experiments is not very costly. We acquire best results on the balanced dataset, identifying the combination of unigrams and bigrams as our best n-gram settings, XGBoost as the best classifier, and SMOTE as the best sampling technique. We provide these best results in Table 3 in Macro-F1 score. We use two baselines. Baseline 1 is the majority class in training data (i.e., *targeted* offense class, 0.46827 Macro F_1-score). The second baseline is the best model with no data sampling, a logistic regression model. The best model, XGBoost with SMOTE sampling, acquires an F_1-score of 0.61248. This is a sizeable gain over the baselines. We now describe how we leverage ensembles to improve over this XGBoost model.

Sampling Type	**Sampling Technique**	**Macro F1**
NA	**Baseline 1**	0.46827
	Baseline 2	0.5547
Oversampling	**Random Oversampling**	0.56705
	SMOTE	**0.61248**
Undersampling	**Random Undersampling**	0.49739
	Near Miss-1	0.32533
	Near Miss-2	0.4376
	Near Miss-3	0.46158

Table 3: **Sub-Task B:** XGBoost performance with sampling methods. Baseline 1 is our majority class in training data. Baseline 2 is a logistic regression model with no data sampling.

4.1 Ensembles for Sub-Task B

Our best performance with the XGBoost model in the previous section was acquired with SMOTE oversampling. However, we note that oversampling in general performed better than other sampling methods. For this reason, we experiment with a number of ensemble methods across our two oversampling techniques (SMOTE and random oversampling [ROS]). We provide our best results from this iteration of experiments (for both the dev and the competition test set) in Table 4. In addition to the same XGBoost model reported earlier (in Table 3, reproduced in Table 4), we identify and report our two best models: (1) **Model A**: An ensemble with soft voting over XGBoost, AdaBoost, and logistic regression with random oversampling (ROS) and (2) **Model B**: The average of our XGBoost model (with SMOTE) and the best model with synthetic oversampling (which is a Naive Bayes classifier). We submitted the three models in Table 4 to the competition. Although Model B performs best on the dev set, it was model A that performed highest on the competition test set. This suggests that the dev and test sets are different in some aspects. Importantly, even though the three models in Table 4 perform comparably on dev, only the ensemble models (Model A and Model B) seem to generalize better on the test set. This further demonstrates the utility of ensembles on the task.

5 Sub-Task C Models

Sub-Task C is 3-way classification, with 2 minority classes. Again, we run all our classifiers with unigram and bigram combinations across all sampling methods (including no sampling) on this imbalanced dataset. In addition, we use 4 different configurations to generate samples for each of the two minority classes to obtain 4 balanced datasets. `C1` is created with random oversampling of the two minority classes; `C2` is created with synthetic oversampling of the two minority classes; `C3` is created with random oversampling of minority class *group* (GRP) and synthetic oversampling of minority class *other* (OTH); and `C4` is random oversampling of minority class OTH and synthetic oversampling of minority class GRP.

We report our best results in Table 5, with two baselines: Baseline 1 is the majority class in training data and Baseline 2 is our best model without sampling (a logistic regression classifier). Our best model on C2 is a logistic regression classifier, whereas our best models on C1, C3, and C4 are acquired with the same soft voting ensemble in Table 4 (an ensemble of logistic regression, AdaBoost, and XGBoost).

Our next step is to investigate whether we can further improve performance by averaging classification probabilities of models described in Table 5. The result of this iteration is shown in Table 6. Models in Table 6 are the 3 models we submitted to the SemEval-2019 competition, which are as

Dataset	Models	Targeted			Untargeted			
		Precision	**Recall**	**F1**	**Precision**	**Recall**	**F1**	**Macro F1 score**
DEV	**XGBoost (SMOTE)**	0.90158	**0.95742**	**0.92866**	**0.42105**	0.22857	0.2963	0.61248
	Model A	0.90945	0.89419	0.90176	0.30508	0.34286	**0.32287**	0.61231
	Model B	**0.94065**	0.90447	0.9222	0.26667	**0.37838**	0.31285	**0.61753**

Table 4: **Sub-Task B:** Best ensemble model results. We reproduce XGBoost results from Table 3 for comparison.

Sampling	Type	Best Model	Macro F1
NA	NA	Baseline-1	0.21300
	NA	Baseline-2	0.51580
Sampling	**C1**	**Model 1**	**0.56822**
	C2	Log Reg	0.54319
	C3	Model 1	0.54665
	C4	Model 1	0.56216

Table 5: **Sub-Task C:** Best results with various sampling methods.

follows: **Model 1**: our best model with C1; **Model 2**: a prediction based on the average of classification probabilities of the best classifiers on C1, C2, and C4; **Model 3**: the prediction acquired from the average of tag probabilities of the best classifiers on C1 and C4. Table 6 shows that performance of all the models on the dev set is very comparable, with model 3 performing slightly better than the two other models. Similarly, results of the three models are not very different on the competition test set.

6 Model Analysis

In order to further understand the results on the test set, we investigate the predictions made by our models across the two sub-tasks. For the purpose, we provide simple visualizations of the confusion matrices of predictions acquired by our best models as released by organizers.

Sub-Task B. Figure 1 shows that our model has higher precision for the targeted threats, which is also clear from Table 4 presented earlier. Figure 1 also shows that our model has slightly higher false negatives as compared to false positives. In other words, the chances of our model mislabeling a *targeted* tweet as *untargeted* is slightly higher as compared to predicting an *untargeted* tweet as *targeted*.

Sub-Task C We visualize model errors in Figure 2. Figure 2 shows that our model has

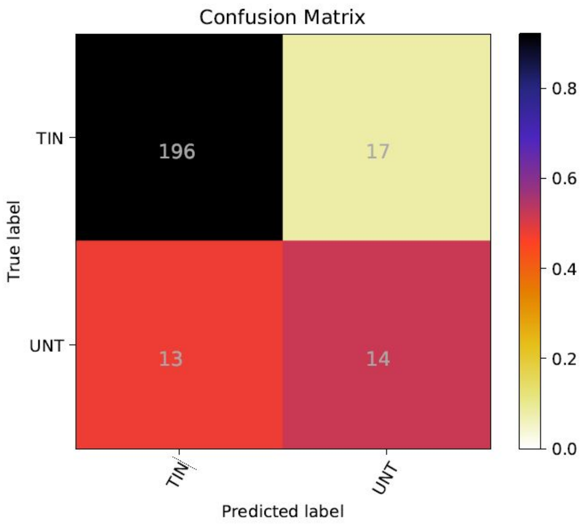

Figure 1: Confusion matrix of soft voting ensemble model (Model A in Table 4) for Sub-Task B.

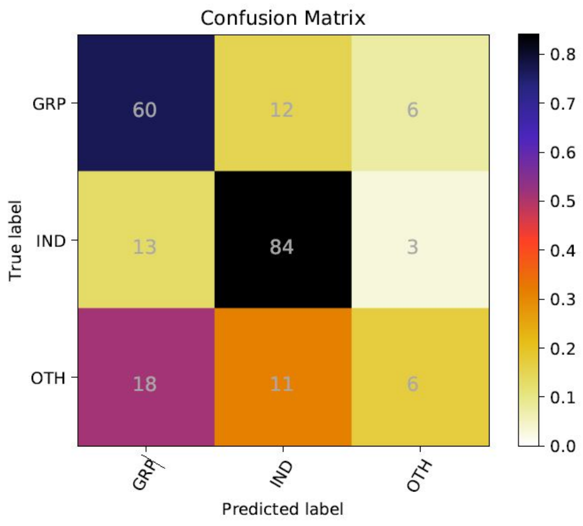

Figure 2: Confusion matrix of soft voting ensemble model (Model 1 in Table 6) for Sub-Task C.

Dataset	Models	GRP	IND	OTH	Macro F1 score

Table 6: **Sub-Task C:** Results of our 3 final submitted models

higher precision for the *group* (GRP) and *individual* (IND) categories, but only higher recall for the *other* (OTH) class. Again, this means that the chances of our model predicting a GRP tweet or IND tweet as OTH is much higher as compared to OTH tweet being predicted as IND or GRP. In other words, the model is biased towards predicting one of the two categories GRP and IND

7 Conclusion

In this paper, we described our contributions to OffenseEval, the 6th shared task of SemEval-2019 . We explored the effectiveness of different sampling techniques and ensembling methods combined with different classical and boosting machine learning algorithms. We find simple data enhancement approaches (i.e., sampling techniques) to work well, especially when coupled with the right ensemble methods. In general, ensemble models decrease errors by leveraging the different strengths of the various underlying models and hence are useful in absence of balanced data.

Abstract

We present a neural network based approach of transfer learning for offensive language detection. For our system, we compare two types of knowledge transfer: supervised and unsupervised pre-training. Supervised pre-training of our bidirectional GRU-3-CNN architecture is performed as multi-task learning of parallel training of five different tasks. The selected tasks are supervised classification problems from public NLP resources with some overlap to offensive language such as sentiment detection, emoji classification, and aggressive language classification. Unsupervised transfer learning is performed with a thematic clustering of 40M unlabeled tweets via LDA. Based on this dataset, pre-training is performed by predicting the main topic of a tweet. Results indicate that unsupervised transfer from large datasets performs slightly better than supervised training on small 'near target category' datasets. In the SemEval Task, our system ranks 14 out of 103 participants.

1 Introduction

The automatic detection of hate speech, cyberbullying, abusive, aggressive or offensive language has become a vital field of research in natural language processing (NLP) during recent years. Especially in social media, the tone of conversations escalates in a disturbing way that often threatens a free, democratic and argumentative discourse of users. Concerning the tremendous amount of digital texts posted on platforms such as Twitter, Facebook or in comments sections of online newspapers, automatic approaches to offensive language detection are of high relevancy for moderation and filtering of content as well as for studying the phenomenon of offensive language use in social media at large scale.

To take account of this development, a shared task on "offensive language detection" was conducted at the SemEval 2019 workshop. This paper describes our approach to the shared task 6 (OffensEval) as organized and described in detail by Zampieri et al. (2019b). The task contains three hierarchically ordered sub-tasks: Task A requires a classification of tweets into either offensive (OFF) or not offensive (NOT), Task B subdivides all offensive tweets into either targeted insults (TIN) or generally offensive expressions not targeted to any specific entity (UNT), and Task C finally asks to assign one out of three specific target labels to all targeted insults: groups (GRP, e.g. ethnic groups), individuals (IND, e.g. a politician or a specific Twitter user), or other (OTH, e.g. the media industry). The dataset consisting of 14,100 examples (13,240 in the training set, 860 in the test set) was annotated via crowdsourcing (Zampieri et al., 2019a). Each tweet was labeled by at least two annotators who must reach an agreement of at least 66% for including the tweet in the dataset. The dataset is characterized by a high imbalance of label distributions, especially for Tasks B and C.

There are several challenges for automatic offensive language detection that render simple dictionary-based approaches unusable. First, label distribution in the dataset is highly skewed for all sub-tasks. Although offensive language is a growing problem for social media communication, it still accounts for only a small fraction of all content posted. Second, language characteristics in social media pose a severe challenge to standard NLP tools. Misspellings, slang vocabulary, emoticons and emojis, as well as ungrammatical punctuation must be taken into account for a successful solution. Third, offensive language is highly context-dependent. For instance, swear words are often used to mark overly positive emotion ("This is fucking great!!!"), and actually neutral and descriptive sentences can be conceived as derogatory if they refer to a specific individual ("@Barack-

Obama he is a Muslim").

Our approach to the OffensEval shared task is based on two main contributions: First, we introduce a BiGRU-3CNN neural network architecture in combination with pre-trained sub-word embeddings that are able to handle social media language robustly. Second, we investigate two types of knowledge transfer: supervised and unsupervised pre-training. Supervised pre-training of our neural network architecture is performed as multi-task learning of parallel training of five different NLP tasks with some overlap to offensive language detection. Unsupervised transfer learning is performed with a thematic clustering of a large dataset of unlabeled tweets via LDA. After shortly referencing related work (Section 2), we introduce both approaches in detail in Section 3 and present the results in Section 4.

2 Related Work

Two recent survey papers, Schmidt and Wiegand (2017) and Fortuna and Nunes (2018), summarize the current state of the art in offensive language detection and related tasks such as hate speech or abusive language detection. Specifically for offensive language detection, the paper by Davidson et al. (2017) introduced a publicly available dataset which was reused in (Malmasi and Zampieri, 2017, 2018; ElSherief et al., 2018; Zhang et al., 2018) as well as in our approach of supervised pre-training.

A predecessor of our transfer learning approach has already successfully been applied at GermEval 2018 (Wiegand et al., 2018), a shared task on offensive language detection in German language tweets. In our paper (Wiedemann et al., 2018), we tested different types of knowledge transfer and transfer learning strategies. We further found that latent semantic clusters of user handles in tweets (e.g. user accounts run by media companies or politicians) are a very helpful feature to predict offensive language since they provide valuable context information how to interpret otherwise ambiguous tweets. Unfortunately, this feature cannot be used for the SemEval 2019 Task 6 since user mentions have all been unified to the token '@USER' in the training data. Thus, we base our approach on the best performing transfer learning strategy from Wiedemann et al. (2018) but implement several minor improvements, which will be described in detail in the following.

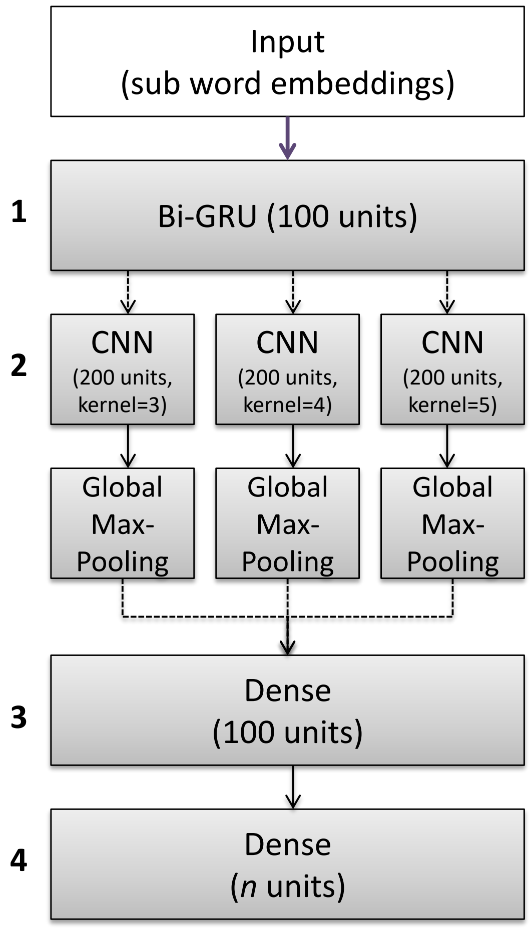

Figure 1: BiGRU-3-CNN model architecture. We use a combination of recurrent and convolutional cells for learning. As input, we rely on (sub-)word embeddings. Dashed lines indicate dropout with rate 0.5 between layers. The last dense layer contains n units for prediction of the probability of each of the n classification labels per sub-task.

3 Methodology

We utilize a neural network architecture for text classification with randomly initialized weights as a baseline, and together with two types of pre-training layer weights for transfer learning: supervised and unsupervised pre-training. Evaluation for model selection is performed via 10-fold cross-validation to determine submission candidates for the SemEval shared task.

Preprocessing: Tweets are tokenized with an extended version of the NLTK (Bird et al., 2009) tweet tokenizer. In addition to correct tokenization of emoticons and shortening of repeated character sequences (e.g. '!!!!!!') to a maximum length of three, we separate # characters as individual token from hashtags. If hashtags contain camel casing, we split them into separate tokens at each uppercase letter occurrence (e.g. '#DemocratsForPeace' is tokenized into '# democrats for peace'). Finally, all tokens are reduced to lower case. In order to account for atypical language, we use sub-word embeddings to represent the input of token sequences to our model. FastText embeddings (Bojanowski et al., 2017) are derived from character n-grams and, thus, provide meaningful word vectors even for words unseen during training, misspelled words and words specifically used in the context of social media such as emojis. We utilize a pre-trained model for the English language published by Bojanowski et al. (2017).

Model architecture: We employ a neural network architecture implemented with the Keras framework for Python[1] as shown in Fig. 1. It combines a bi-directional Gated Recurrent Unit (GRU) layer (Cho et al., 2014) with 100 units followed by three parallel convolutional layers (CNN), each with a different kernel size $k \in 3, 4, 5$, and a filter size 200. The outputs of the three CNN blocks are reduced by global max-pooling and concatenated into a single vector. This vector is then fed into a dense layer with LeakyReLU activation producing a final feature vector of length 100, which is forwarded into the prediction layer (softmax activation). For regularization, dropout is applied to the recurrent layer and to each CNN block after global max-pooling (dropout rate 0.5). For training, we use categorical cross-entropy loss and the Nesterov Adam optimization with a learning rate of 0.002. To account for imbalance in the training set, we set class weights to pay more attention to samples from the under-represented class in the loss function.

Supervised Pre-training: Instead of end-to-end text classification based on a random initialization of the parameters weights of our model, we seek to increase performance from knowledge transfer. For the supervised approach, we pre-train the model weights in a multi-task learning setup with related semantic categories. Instead of one prediction layer (see layer 4 in Fig. 1), we use m prediction layers connected to layer 3 to train m tasks in parallel. The following four publicly available datasets were compiled into one training set: offensive language tweets by (Davidson et al., 2017), flamewar comments from the Yahoo news annotated corpus (Napoles et al., 2017), sentiments of tweets from (Go et al., 2009), aggressive tweets and Facebook comments from the TRAC shared task (Kumar et al., 2018). A fifth dataset was compiled from about 30,000 randomly sampled tweets in our unsupervised background collection (see next Section) containing either a happy or an angry emoji. The merged dataset contains ca. 115k partially labeled instances for pre-training from which a sample of 5k was used as validation set. Missing labels for the combined set were filled by training a separate model for each of the m individual tasks on the respective dataset and predict a label for each instance in the other four datasets. Multi-task pre-training is performed with a batch-size of 256 for 15 epochs.

Unsupervised Pre-training: For the unsupervised approach, we utilize a large background corpus of tweets that were collected from the Twitter streaming API in 2018. Since the API provides a random fraction of all tweets (1%), language identification is performed to filter for English tweets only. From this tweet collection, we sample 20 million non-duplicate tweets containing at least two non-URL tokens as our background corpus. As a pre-training task, we first compute a Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) with $K = 1,000$ topics to obtain semantic clusters of our background corpus.[2] From the topic-document distribution of the resulting LDA model, we determine the majority topic id for each tweet as a target label for prediction during pre-training our neural model. Pre-training of the neural model is performed with a batch-size of 256 for 10 epochs.

Transfer learning: Once the neural model has been pre-trained, we can apply it for learning our actual target task. For this, we need to remove the final prediction layer of the pre-trained model (i.e. Layer 4 in Fig. 1) and add a new dense layer for prediction of one of the actual label sets. To prevent the effect of "catastrophic forgetting" of pre-trained knowledge during task-specific model training, we apply a specific layer weight freezing strategy as suggested in Wiedemann et al. (2018). First, the newly added final prediction layer is trained while all other model weights re-

[1]https://keras.io

[2]For LDA, we used Mallet (http://mallet.cs.umass.edu) with Gibbs Sampling for 1,000 iterations and priors $\alpha = 10/K$ and $\beta = 0.01$.

Task	No transfer	Supervised	Unsupervised
A	76.26	**77.46**	77.36
B	58.87	**61.24**	60.57
C	56.66	54.16	**58.26**

Table 1: Model selection (cross-validation, macro-F1)

main frozen. Training is conducted for 15 epochs. After each epoch performance is tested on the validation set. The best performing model state is then used in the next step of fine-tuning the pre-trained model layers. Employing a bottom-up strategy, we unfreeze the lowest layer (1) containing the most general knowledge first, then we continue optimization with the more specific layers (2 and 3) one after the other. During fine-tuning of every single layer, all other layers remain frozen and training is performed again for 15 epochs selecting the best performing model at the end of each layer optimization. In a final round of fine-tuning, all layers are unfrozen.

Ensemble: For each sub-task A, B and C, the cross-validation results in 10 best performing models from transfer learning per configuration. For submission to the shared task, we select the model with the highest average performance across all folds. Moreover, as a simple ensemble classification, predictions of these 10 models on the test set instances are combined via majority vote.

4 Results

Model selection: To compare different types of pre-training for knowledge transfer, we use the official shared task metric macro-averaged F1. Table 1 displays the averaged results of 10-fold cross-validation for all three tasks with no transfer as baseline compared to supervised transfer from multi-task learning and pre-training on unsupervised LDA clustering. The results indicate that transfer learning is able to improve performance for offensive language detection for all tasks. With the exception of supervised transfer for task C, the relative improvements are larger the smaller the training datasets get for each of the hierarchically ordered tasks. In general, for the lower level tasks B and C, a severe performance drop can be observed compared to task A.

The comparison between unsupervised and supervised pre-training delivers a mixed result. While the performance of the supervised transfer approach slightly exceeds the unsupervised approach for task A and B, for task C, containing only very small numbers of positive examples for each class in the training dataset, the unsupervised approach clearly beats the network pre-training by supervised near-target category tasks. Supervised transfer even fails to beat the baseline of no transfer learning at all. We assume that this type of pre-training tends to over-fit the model if there is only little training data to learn from. Unsupervised pre-training on very large datasets, in contrast, better captures generic language regularities which is beneficial for arbitrary categories.

System	F1 (macro)	Accuracy
Task A		
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
Supervised	**0.7887**	**0.8372**
Unsupervised	0.7722	0.8337
Task B		
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
Unsupervised	**0.6608**	**0.8917**
Task C		
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
Unsupervised	**0.5752**	**0.6761**

Table 2: Official test set performance results

Shared task submissions: Table 2 displays our best official results of ensemble classifications submitted to the shared tasks A, B, and C. A systematic comparison between the two compared approaches of pre-training would have required submission of two classifications per sub-task, one for supervised and one for unsupervised pre-training. Unfortunately, the official shared task website only allowed for three submissions per sub-task[3]. This policy led to the decision to submit only variations / repeated runs of the best classifier we had until the task submission deadline.

Our supervised pre-training approach ranks 14 out of 103 for sub-task A. For sub-tasks B and C, only classifiers pre-training with the unsupervised approach have been submitted. They rank 21 out of 75 for B, and 13 out of 65 for C (see

[3]Also, the official test set was not released yet, so we cannot report a systematic comparison at this point.

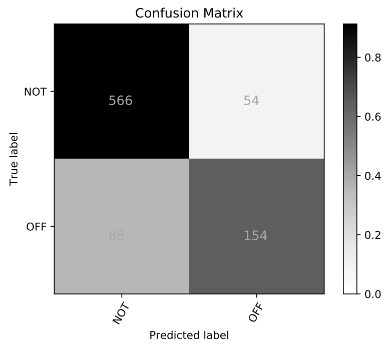

Figure 2: Sub-task A, supervised

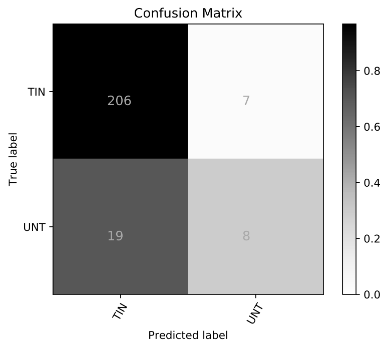

Figure 3: Sub-task B, unsupervised

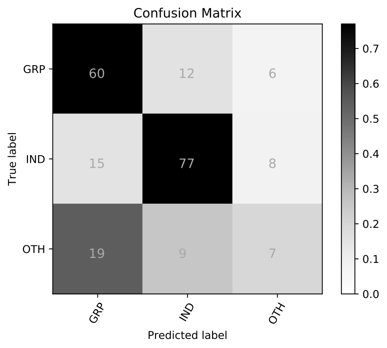

Figure 4: Sub-task C, unsupervised

Zampieri et al. (2019b) for a detailed comparison of all submissions). Fig. 2 to 4 show confusion matrices for the three best runs. The ratio between false positives and false negatives for sub-task A is fairly balanced. False positives mainly comprise hard cases where, for instance, swear words are used in a non-offensive manner. In the highly unbalanced annotations for sub-task B, more tweets were wrongly predicted as targeted insults than true yet unpredicted targeted insults. Here we observe many cases which contain offensive language and some mentioning of individuals or groups but both are not directly linked. A similar situation, where actually characteristics of two categories are contained in a tweet, can be observed for task C in which the classifier falsely predicts a group target instead of 'other'.

5 Conclusion

We systematically compared to types of knowledge transfer for offensive language detection: supervised and unsupervised pre-training of a BiGRU-3-CNN neural network architecture. The former uses a set of near-target category labeled short texts while the latter relies on a very large set of unlabeled tweets. On average, our system performs among the top 20% of all submissions of the OffensEval 2019 shared task. From our experiments, we can draw the following three main conclusions:

- Supervised pre-training with annotated near-target category data is beneficial if the target training data is fairly large.
- Unsupervised pre-training with unlabeled data from LDA clustering processes improves learning for arbitrary tasks even for fairly small target training datasets.
- For unsupervised pre-training, the benefit of transfer learning compared to the baseline without transfer is larger the smaller the target training dataset gets.

In future work, we plan to further investigate the differences between the two types of transfer learning by systematically investigating the influence of different near-target category datasets, and unsupervised topic clustering methods other than LDA for pre-training deep neural network architectures.

Abstract

This paper describes the UM-IU@LING's system for the SemEval 2019 Task 6: OffensEval. We take a mixed approach to identify and categorize hate speech in social media. In subtask A, we fine-tuned a BERT based classifier to detect abusive content in tweets, achieving a macro F_1 score of 0.8136 on the test data, thus reaching the 3rd rank out of 103 submissions. In subtasks B and C, we used a linear SVM with selected character n-gram features. For subtask C, our system could identify the target of abuse with a macro F_1 score of 0.5243, ranking it 27th out of 65 submissions.

1 Introduction

With the increased influence of social media on modern society, large amounts of user-generated content emerge on the internet. Besides the exchange of ideas, we also see an exponential increase of aggressive and potentially harmful content, for example, hate speech. If we consider the amount of user-generated data, it is impractical to manually identify the malicious speech. Thus we need to develop methods to detect offensive speech automatically through computational models. However, this task is challenging because natural language is fraught with ambiguities, and language in social media is extremely noisy. Here we present our method to automatically identifying offensive content in tweets.

We primarily focus on detecting whether a tweet contains offensive content or not (subtask A), and then determining the target of the offensive content (subtask C). For subtask A, we use pre-trained word embeddings by fine-tuning the BERT model (Devlin et al., 2018) for detecting offensive tweets. For subtasks B and C, BERT did not perform well, either because of limited training data or because we did not find the appropriate hyperparameters. Thus we use an SVM classifier with character n-grams as features. We accidentally flipped the predicted labels in our submission to subtask B, which is why we do not report results of subtask B here. Among all teams participating in OffensEval, our models ranks 3rd out of 103 on subtask A and 27th out of 65 on subtask C. (see Zampieri et al., 2019b).

2 Related Work

Detecting offensive language online is becoming more and more important (Schmidt and Wiegand, 2017; Founta et al., 2018; Malmasi and Zampieri, 2018). To build an effective classifier, one of the major problems is to find the appropriate features. Normally, two types of features are utilized: surface features like n-grams and word representations trained by neural network. Most offensive language classifiers are trained on different types of surface features with approaches like SVM (Malmasi and Zampieri, 2018; Arroyo-Fernández et al., 2018), Random Forest (Burnap and Williams, 2015), and Logistic Regression (Davidson et al., 2017). Recently, word embeddings trained in neural networks have been shown to achieve good performance in offensive language identification tasks (Badjatiya et al., 2017). Benchmarks of the first shared task on aggression identification (Kumar et al., 2018) show that half of the top 15 systems are trained on neural networks.

Using pre-trained word embeddings for feature extraction has been shown to be highly effective in multiple NLP tasks. Traditional word embeddings are extracted from shallow neural networks trained on a large swathes of texts required to learn the contextual representations of words. Examples include skip-grams (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). However, these embeddings are learned from an aggregation of all possible word contexts, which may gloss over semantic nuances in representations.

Recent models like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018) significantly advanced the state-of-the-art in language modeling by learning context-sensitive representations of words. ELMo goes beyond word embeddings by learning representations that are functions of the entire input sentence (Peters et al., 2018). However, ELMo is still considered shallow with two bidirectional LSTM layers, and more recent transformer based language models such as the OpenAI Generative Pre-trained Transformer (GPT) (Radford et al., 2018) and Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) have been extended to a depth of up to twelve layers. The OpenAI GPT is still a unidirectional language model while BERT is trained to be bidirectional with two novel prediction tasks, Masked LM and Next Sentence Prediction. The pre-trained BERT model has been shown to give significant improvements in a series of downstream tasks over ELMo and OpenAI GPT (Devlin et al., 2018).

However, identifying offensive language is not a simple task. Challenges during identification include but are not limited to the fact that surface language features fail to capturing subtle semantic difference, and the shortage of undisputed annotated data (Malmasi and Zampieri, 2018). Most of previous studies focus on distinguishing between offensive and non-offensive language (Kwok and Wang, 2013; Djuric et al., 2015), which is the goal of subtask A in the current shared task. But part of challenge consists of the intertwined nature of such messages having negative connotations and profanity. Dinakar et al. (2011) show that it is important to tease these two factors apart. Malmasi and Zampieri (2018) first address the issue of distinguishing hate speech from general profanity.

3 Methodology and Data

The subtasks in the shared task are rather different. In subtask A, the goal is to identify offensive tweets; in subtask B and C, the aim is to distinguish targeted and untargeted offense and to classify the targeted ones into different types. Subtask A requires sensitivity to subtle changes in word meaning in context while the other subtasks are more categorical in nature. However, both suffer from data sparsity. Therefore, we decided, backed by empirical validation on the trial data, to utilize different methods for the subtasks, namely, BERT embeddings for subtask A, and an SVM classifier for subtasks B and C.

The data collection method used to compile the dataset in OffensEval is described by Zampieri et al. (2019a). We used the official training data and trial data provided by the shared task to train the classifier. Our implmentations can be found at: https://github.com/zytian9/SemEval-2019-Task-6.

3.1 Subtask A: Identifying Abusive Content

The goal of subtask A is to identify whether a tweet contains offensive content by training a model to perform binary classification. There are 13,240 tweet instances in the training data, in which each instance has been labeled as either 'offensive' ('OFF') or 'not offensive' ('NOT'). The model takes a tweet as input and predicts the corresponding label of that tweet. We used the trial data as development data.

3.1.1 Model Details

For subtask A, we trained a classifier by fine-tuning a pre-trained BERT Transformer (Devlin et al., 2018) with a linear layer for text sequence classification on top.

The input sentences[1] were first tokenized with the BERT basic tokenizer to perform punctuation splitting, lower casing and invalid characters removal. Then this was followed by WordPiece tokenization (Wu et al., 2016) to split words into subword units, in accordance with the original BERT approach (Devlin et al., 2018). The maximum sequence length was defined as 80, with shorter sequences padded and longer sequences truncated to this length. The order of the input sequence was represented by the learned positional embeddings. The input representation for each tweet is the sum of these token, segment, and position embeddings. As only one sentence serves as input, only the sentence A embeddings are used as the segment embeddings (Devlin et al., 2018).

We selected the $\text{BERT}_{\text{base-uncased}}$ as the underlying BERT model. The $\text{BERT}_{\text{base}}$ consists of 12 Transformer blocks, 12 self-attention heads, and 768 hidden dimension with a total parameters of 110M. It was trained on the BookCorpus (800M words) and the English Wikipedia (2,500M

[1]In BERT, a "sentence" can be a text sequence of arbitrary length. In our case, a "sentence" refers to a tweet even if it may span multiple linguistic sentences.

words). Though the BERT$_{\text{large}}$ model was reported to outperform the BERT$_{\text{base}}$ in a variety of tasks, training and fine tuning BERT$_{\text{large}}$ was too computationally intensive given the time limit. Thus we used BERT$_{\text{base}}$ for accelerated training. The BERT$_{\text{base}}$ model includes a special classification embedding `[CLS]` at the beginning of every sentence, and this token in the final layer was extracted as the aggregate sequence representation for the current classification task. Then a linear layer of 768 dimensions was added on top of BERT$_{\text{base}}$, using the `[CLS]` embeddings of the whole input sequence to predict a binary label. Binary cross-entropy was used as the loss function to fine-tune the classifier.

3.1.2 Implementation

The neural network was implemented in PyTorch (Paszke et al., 2017), and we used the tokenizer, pretrained WordPiece, and positional embeddings and pre-trained BERT from the library `pytorch-pretrained-bert`[2]. Following the recommendation for fine-tuning in the original BERT approach (Devlin et al., 2018), we trained our classifier with a batch size of 32 for 2 epochs. The dropout probability was set to 0.1 for all layers. Adam optimizer was used with a learning rate of 2e-5. The training was carried out on an Nvidia 1070Ti GPU; only taking about 6 minutes in total.

3.2 Subtask B: Categorizing Offense Types

For subtasks B and C, we adopted an SVM classifier. For these two tasks, the BERT classifier performed close to the baseline on the trial data. This could be caused by the limited amount of the training data for these two tasks or inappropriate selection of hyperparameters. Thus, we built a linear SVM classifier to identify the offense type and target.

Subtask B requires the distinction between targeted and untargeted offense. We used an SVM classifier with selected character n gram features for subtask B. For the trial data of subtask B, the classifier achieved a macro F_1 score of 0.5333 and accuracy of 0.5714; both of them considerably higher than the baseline. But since the labels of two classes were accidentally flipped in our submission, our results were not competitive. We also reconstructed test F_1 from the flipped confusion matrix. If the labels were not flipped, the test F_1 should be 0.5946.

3.3 Subtask C: Identifying the Target of Abuse

Subtask C requires the classifier to identify three types of offense target, 'Individual' ('IND'), 'Group'('GRP') and 'Other'('OTH'). The training set is rather imbalanced: The minority class OTH constitutes around 10 percent of all the instances, and only occurs once in the trial data. We originally were planning to use the same approach as for subtasks A. However, experiments on the trial data showed a weak performance. For this reason, we decided to use a linear SVM classifier to identify the offense target with three sub-classes since previous studies indicate that SVM classifiers perform well on classification tasks and at par with deep neural networks when features are well selected (Founta et al., 2018; Kumar et al., 2018). For this classifier, we used the Scikit-learn (Pedregosa et al., 2011) implementation, and we used only the training data provided by the shared task.

3.3.1 Model Details

Given that character-level n-gram could reduce the effect of spelling errors and variations in tweets (Schmidt and Wiegand, 2017), we used a bag of character n-grams (with n ranging from 2 to 7 characters) as features in order to characterize the users' language features as robustly as possible. Since in subtask C, we need to identify different types of offense target, we assume that named entity information will be effective for identifying target types. Named entities information was extracted by spaCy, which is based on the entity types from OntoNotes 5 corpus[3]. Given that this task aims to identify three types of targets, namely individual, group and other, we used the named entity information by classifying all the entity types into three major types and counting the number of each type separately. The first type only includes PERSON entities, the second type consists of entity types related to a group sense, for example ORG, NORG, and GPE, and the last type includes all occurrences of the other entity types.

Nobata et al. (2016) found that linguistic features such as tweet length, average word length,

$\text{BERT}_{\text{base-cased}}$	0.8094	0.8500
$\text{BERT}_{\text{base-multiling-unc.}}$	0.4300	0.7625
$\text{BERT}_{\text{base-multiling-cased}}$	0.8179	0.8718

Table 2: Results on the trial data for subtask A.

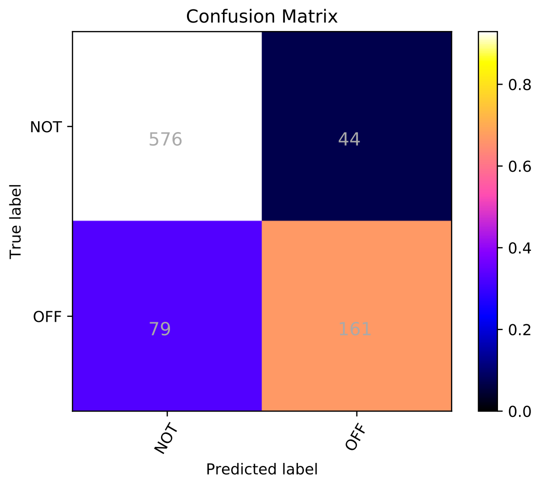

Figure 1: The UM-IU@LING confusion matrix for subtask A.

number of punctuation, number of discourse connectives can be useful for detecting abusive language. In this study, we adopt 9 features from their work. Besides the n-gram features, named entity, and linguistic features, we also adopted emoji and emoticons as additional features, which have been shown to be useful in sentiment analysis tasks (Kouloumpis et al., 2011; Shiha and Ayvaz, 2017). Emoticons are extracted using the s regular expressions by C. Potts[4]. We also added three emoji sentiment features, which consist of the positive, negative, and overall sentiment scores based on the Emoji Sentiment Ranking (Novak et al., 2015).

We performed feature selection for the n-gram features using a filtering approach with information gain, which has proven to be effective in social media sentiment classification (Kübler et al., 2018).

Our final submission is a linear SVM classifier (C=0.1, squared-hinge loss function) with 1000 selected character n-grams of length 2-7. Adding linguistic and emoji features resulted in small gains on the trial data and was that not considered useful for the official version.

4 Results

4.1 Subtask A

Our best result for subtask A along with the official baselines are summarized in Table 1. The BERT classifier achieved a macro F_1 score of 0.8136, clearly exceeding the baseline of 0.4189 and ranking the system 3rd out of 103 submissions. This demonstrates that our model can effectively identify whether a given tweet contains offensive content or not. The confusion matrix in Figure 1 further illustrates the error pattern of our classifier, which more often misclassified offensive tweets as being not offensive. One explanation of the results may be the classifier's preference for the majority class. But it is possible that our classifier may not capture some of the subtle nuances in meaning and contexts. However, the results also show that the macro F_1 score is only about 4.5 percent points lower than the accuracy (0.8136 vs. 0.8570). This is a clear indication that the classifier is successful in modeling the minority class of offensive tweets.

4.1.1 Ablation Analysis

We performed an ablation analysis on our BERT classifier using the training and the trial data. First, we retrained the classifier by varying the learning rate. The macro F_1 dropped to the baseline of 0.4318 with a learning rate of either 2e-8 or 2e-3, which indicates that the system is sensitive to change in learning rates.

The selection of sequence length only has a minimal influence on the final performance, with a tendency for longer sequence length to improves prediction accuracy: Setting the input sequence length to 60 reduces the macro F_1 minimally to 0.8212, and decreasing the input length to 40 decreases the macro F_1 to 0.8126.

Table 3: Misclassified examples for subtask A from the trial data. Usernames are anonymized.

There are several versions of pre-trained $\text{BERT}_{\text{base}}$[5]. We compared the performance of these different versions of $\text{BERT}_{\text{base}}$ and the results are summarized in Table 2. Generally, these variants of $\text{BERT}_{\text{base}}$ tend to give similar performance but $\text{BERT}_{\text{base-uncased}}$ achieved the best performance on the trial data. It is unclear why $\text{BERT}_{\text{base-multilingual-uncased}}$ did not learn to perform the task beyond the baseline. Additional hyperparameter tuning might be necessary in this case. Overall, these results demonstrate that though BERT can give superior performance in detecting hate speech, it is somewhat sensitive to the change of hyperparameters. We also find that the SVM classifier achieved a higher accuracy on the trial data, but there is a significant drop in macro F_1 when compared with the BERT model. This shows that the BERT model performs better on the minority class.

4.1.2 Error Analysis

We show examples of misclassified tweets in Table 3. In example 263, the BERT classifier failed to identify the offensive word "F". It is common for people to use euphemisms to tone down swear words in certain situations. The classifier could miss these word variants, especially when the word variant is the only offensive word in the given tweet. For tweet 50, the word "sucks" is the only word that is often used offensively. However, the given tweet is not offensive because the author only describes their mood instead of insulting someone else. These misclassifications seem to indicate that the classifier reacts to trigger words with negative connotations but may not be capable of interpreting the words with respect to the larger context.

When examining the prediction errors, we consistently noticed that the BERT classifier is highly effective in identifying tweets with words that are negative or offensive in most linguistic contexts. The real challenge is that not all tweets containing negative or potentially insulting words are offensive; there are subtle differences between a negative opinion and an insult towards someone. However, the model cannot distinguish these subtle differences in meaning in the proper cultural or socio-political contexts. Additionally, it is not robust enough to detect swear word variants or atypical spellings common in social media.

$\text{SVM}_{\text{char+ling+emoji+entity}}$	0.3901	0.7742

Table 5: Results on the trial data for subtask C.

4.2 Subtask C

Table 4 shows our best result for subtask C in comparison to the official baselines. The macro F_1 score of the SVM classifier is 0.5243, which is considerably higher than the baseline and ranks the system 27th out of 65 submissions. The confusion matrix in Figure 2 indicates that our classi-

ID	Tweet	Label	Prediction
17	@User Obama fed the country shit sandwiches for 8 years. Maybe Jim just has his addled mind confused about dates and who fed who what..	GRP	IND
22	@User The Catholic Church is really screwed up. Nothing new here.	GRP	OTH
31	@User Yeah thanks to your Nobel Emmy award winning idiot chief flip flopping on everything from Iran to gun control.	IND	GRP

Table 6: Misclassified examples from the trial data for subtask C.

fier performed well on identifying the IND class, was effective for the GRP class, but often failed to distinguish the OTH class from the other two classes. This clearly shows that the sparsity of training data for the minority class OTH affects the performance of our classifier negatively.

The performance of the classifier with different features is shown in Table 5. Since there are only 31 instances in the trial set and it is rather imbalanced, we can see that the highest accuracy is reached by classifying all examples as IND, i.e., the all IND baseline. Even though none of the classifiers outperformed the baseline in terms of accuracy, all the classifiers achieved significantly higher macro F_1 scores, which shows that they are better at identifying the other two classes. After adding linguistic and emoji features, the character n-gram model showed a slight improvement in macro F_1 score and achieved the highest accuracy along with the simple character n-gram model. But both macro F_1 and accuracy dropped when entity information was added.

Table 6 presents examples of misclassified tweets in the trial set. In example 17, two persons are mentioned, “Obama” and “Jim’, and both of them are insulted, however not as a group but individually. The classifier labeled this example as IND. In example 22, the classifier is misguided by the word ’Church’ and wrongly classifies it as OTH. Example 31 is similar to example 17. Here, there are two potential targets, ’Nobel Emmy award winning idiot’ and ’Iran’ that could trigger the group sense, which significantly affects the classifier’s judgment.

The errors analysis indicates that the classifier has the ability to distinguish individual and group targets, but it fails to capture the relation between different entities and sometimes misidentifies the target category of offensive language.

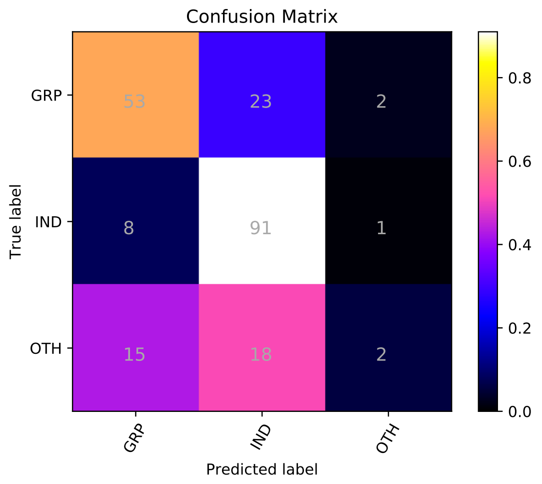

Figure 2: Confusion matrix for the SVM classifier for subtask C.

5 Conclusion

In this study, we report our systems for OffensEval subtasks A and C. In subtask A, we trained a neural network based classifier by fine-tuning the pre-trained $\text{BERT}_{\text{base}}$ model to detect offensive tweets. In subtask C, we used a linear SVM with character n-gram features to identify the target of hate speech.

The evaluation results indicate that our system is capable of detecting offensive language robustly, and it has a good chance of identifying the target. However, there is room for improvement. In the future, in order to capture subtle meaning and overcome the data sparsity, we plan to take syntactic and semantic features into consideration and investigate the combination of selected surface features and pre-trained word embeddings.

Abstract

In this paper, we present a system description for the SemEval-2019 Task 6 submitted by our team. For the task, our system takes tweet as an input and determine if the tweet is offensive or non-offensive (Sub-task A). In case a tweet is offensive, our system identifies if a tweet is targeted (insult or threat) or non-targeted like swearing (Sub-task B). In targeted tweets, our system identifies the target as an individual or group (Sub-task C). We used data pre-processing techniques like splitting hashtags into words, removing special characters, stop-word removal, stemming, lemmatization, capitalization, and offensive word dictionary. Later, we used keras tokenizer and word embeddings for feature extraction. For classification, we used the LSTM (Long short-term memory) model of keras framework. Our accuracy scores for Sub-task A, B and C are *0.8128*, *0.8167* and *0.3662* respectively. Our results indicate that fine-grained classification to identify offense target was difficult for the system. Lastly, in the future scope section, we will discuss the ways to improve system performance.

1 Introduction

In recent years, there has been a rapid rise in social media platforms and surge in the number of users registering in order to communicate, publish content, showcase their skills and express their views. Social media platforms like Facebook and Twitter have millions of registered users influenced by the countless user-generated posts on daily basis (Zeitel-Bank and Tat, 2014). While on one hand social media platforms facilitate the exchange of views, effective communication and can be seen as a helping mode in crisis. On the other hand, they open up the window for anti-social behavior such as bullying, stalking, harassing, trolling and hate speech (Malmasi and Zampieri, 2018; Wiegand et al., 2018; ElSherief et al., 2018; Zhang et al., 2018). These platforms provide the anonymity and hence aid users to indulge in aggressive behavior which propagates due to the increased willingness of people sharing their opinions (Fortuna and Nunes, 2018).

This aggression can lead to foul language which is seen as "offensive", "abusive", or "hate speech", terms, which are used interchangeably (Waseem et al., 2017). In general, offensive language is defined as derogatory, hurtful/ obscene remarks or comments made by an individual (or group) to an individual (or group) (Wiegand et al., 2018; Baziotis et al., 2018). The offensive language can be targeted towards a race, religion, color, gender, sexual orientation, nationality, or any characteristics of a person or a group. Hate Speech is slowly plaguing the social media users with depression and anxiety (Davidson et al., 2017; Zhang et al., 2018), which can be presented in the form of images, text or media such as audio, video, etc. (Schmidt and Wiegand, 2017).

Our paper presents the data and task description followed by results, conclusion and future work. The purpose of Task 6 is to address and provide an effective procedure for detecting offensive tweets from the data set provided by shared task report paper (Zampieri et al., 2019b). The shared task is threefold. The Sub-task A ask us to identify whether the given tweet is offensive or non-offensive. In Sub-task B offensive tweets are to be classified as targeted (person/group) or non-targeted (general). Sub-task C ask us to do classification of the offensive tweets into individual, group or others. We apply the LSTM with word embeddings in order to perform the multi-level classification.

2 Related Work

Technological giants like Facebook, Google, YouTube and Twitter have been investing a significant amount of time and money towards the detection and removal of offensive and hate speech posts that give users a direct or indirect negative influence (Fortuna and Nunes, 2018). However, lack of automation techniques and ineffectiveness of manual flagging has lead to a lot of criticism for not having potent control for the problem (Zhang et al., 2018). The process of manual tagging is not sustainable or scalable with the large volumes of data exchanged in Social media. Hence, the need of the hour is to do automatic detection and filtering of offensive posts to give the user quality of service (Fortuna and Nunes, 2018).

The problem of automatic Hate Speech Detection is not trivial as offensive language may or may not be meant to insult or hurt someone and can be used in common conversations. Different language contexts are rampant in social media (Davidson et al., 2017). In recent years, linguistics, researchers, computer scientists, and related professionals have conducted research towards finding an effective yet simple solution for the problem. In papers, (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018), authors survey the state of the art methods along with the description of the nature of hate speech, limitations of the methods proposed in literature and categorization of the hate speech. Further, authors mainly classified the features as general features like N-grams, Part-Of-Speech (POS) and sentiment scores and, specific features such as othering language, the superiority of in-group and stereotype. In (Silva et al., 2016), authors list categories of hate speech and possible targets examples.

The research carried over the years has employed various features and classification techniques. The features include the bag of words (Greevy and Smeaton, 2004; Kwok and Wang, 2013), dictionaries, distance metrics, N-grams, IF-IDF scores, and profanity windows (Fortuna and Nunes, 2018). Authors in (Davidson et al., 2017) used a crowdsourced hate speech lexicon to collect tweets and train a multi-class classifier to distinguish between hate speech, offensive language, and non-offensive language. The authors in paper (Waseem et al., 2017) presents a typology that gives the relationship between various sub-tasks such as cyber-bullying, hate speech, offensive, and online abuse. They synthesize the various literature definitions and contradiction together to emphasize the central affinity among these sub-tasks. In (Gambäck and Sikdar, 2017), authors used a Convolutional Neural Network model for Twitter hate speech text classification into 4 classes: sexism, racism, both sexism-racism and neither. Similar approaches using deep learning have been employed in (Agrawal and Awekar, 2018; Badjatiya et al., 2017) for detecting hate speech and cyberbullying respectively.

Authors in (Zhang et al., 2018) have proposed Deep Neural Network (DNN) structures which serve as a feature extractor for finding key semantics from hate speech. Prior to that, they emphasize the linguistics of hate speech, that it lacks discriminative features making hate speech difficult to detect. Authors in (ElSherief et al., 2018) have carried out the analysis and detection of the hate speech by classifying the target as directed towards a specific person/identity or generalized towards a group of people sharing common characteristics. Their assessment states that directed hate consists of informal, angrier and name calling while generalized hate consists of more religious hate and use of lethal words like murder, kills and exterminate.

3 Problem Statement

In Task 6, three level offensive language identification is described as three Sub-tasks A, B and C. For Sub-task A, tweets were identified as offensive (tweet with any form of unacceptable language, targeted/non-targeted offense) or not offensive. For Sub-task B, the offensive tweets are further categorized into targeted or non-targeted tweets. The targeted offense is made for an individual or group while the untargeted offense is a general use of offensive language. Later for Sub-task C, targeted tweets are further categorized according to the target, individual, group or others. This step by step tweet classification will lead to the detailed categorization of offensive tweets.

4 Data

The data collection methods used to compile the dataset used in OffensEval are described in Zampieri et al. (2019a). The OLID dataset collected from Twitter has tweet id, tweet text, and labels for Sub-task A, B, and C. We have also used Offensive/Profane Word List (Ahn, 2019) with *1,300+* English terms that could be found offensive for lexical analysis of tweets to see check probability of tweet being offensive if a tweet has an offensive word.

4.1 Data Pre-processing

The data is raw tweet data from Twitter and hence data cleaning and pre-processing is required. We used the following steps for data pre-processing:

1. Split hashtags over Capital letters: In this step hashtags are divided into separate words (for example, "#TweetFromTheSeat" will be converted to "Tweet from the seat"). Generally, while writing hashtags multiple words are combined to form single hashtag, where each word is started with a capital letter. Here, we take advantage of this property of hashtag and generate a string of words from it.

2. Remove special characters: In this step we removed all special characters from the tweet and resultant tweet will contain only alphabets and number. In Twitter domain "#" is important special character. Splitting of hashtags,"#Text" into "#" and "Text", retains the purpose of the hashtags after removal of "#" . Other special characters (for e.g. ",", ".","!", etc) are not much informative for given context.

3. Removal of stop-words, Stemming and Lemmatization: In this step we used NLTK (Loper and Bird, 2002) list of stop-words to remove stopwords, classic Porter Stemmer (Porter, 1980) for stemming and NLTK (Loper and Bird, 2002) Word Net Lemmatizer for lemmatization.

4. Capitalization: This is the last step for data pre-processing and all characters are converted to capital letters. In Twitter domain uppercase characters are said to portray expression, but this is not true for all cases. Also, keeping cases intact may lead to over-fitting during training.

5. Embedding "Offensive": This is an optional step. We used offensive word list (Ahn, 2019) to find offensive words in the tweet. Later for tweets with matched offensive words were embedded with "Offensive" as a word.

5 System Description

We used a four-layer neural network with each layer detailed below:

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
LSTM (5,0.2)	**0.7382**	**0.8128**

Table 1: Results for Sub-task A.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	**0.8875**
All UNT baseline	0.1011	0.1125
LSTM (5,0.2)	0.5925	0.8167
LSTM (20,0.2)	0.5291	0.6125
LSTM (20,0.2) and word list	**0.6171**	0.7667

Table 2: Results for Sub-task B.

The first layer of our network is an embedding layer, which takes tokens as inputs (each sentence is converted into index sequences using tokenizer). This layer convert sequences to dense vector sequences generating embedding table used by the next layer. We used tokenizer for top *1000* words and embedding dimension of *128* for our system. The second layer is SpatialDropout1D layer which helps promote independence between feature maps. We used *0.1* as rate or Fraction of the input units to drop. This layer is mainly used to covert multi-dimensional input to one-dimensional input using dropout method.

Third layer is LSTM (Hochreiter and Schmidhuber, 1997) layer with dropout and recurrent dropout as *0.2*. This layer serves as a recurrent neural network layer which was only for short term memory. LSTM (long short-term memory) takes care of longer dependencies. The dimension of LSTM hidden states is *200* for our system. Finally, we used a dense layer with Softmax function for binary classification in-case of Sub-task A and B, and three class classification for Sub-task C. The dimension of the dense layer is *200*.

For hyperparameter selection, we used different train and validation splits. The batch size is *64*, and the maximal training epoch is varied with different system ranging from *5* to *50* (Performance was decreasing for higher epochs). We used RMSProp as the optimizer for network training. The performance is evaluated by macro-averaged F1-score and Accuracy by task organizers.

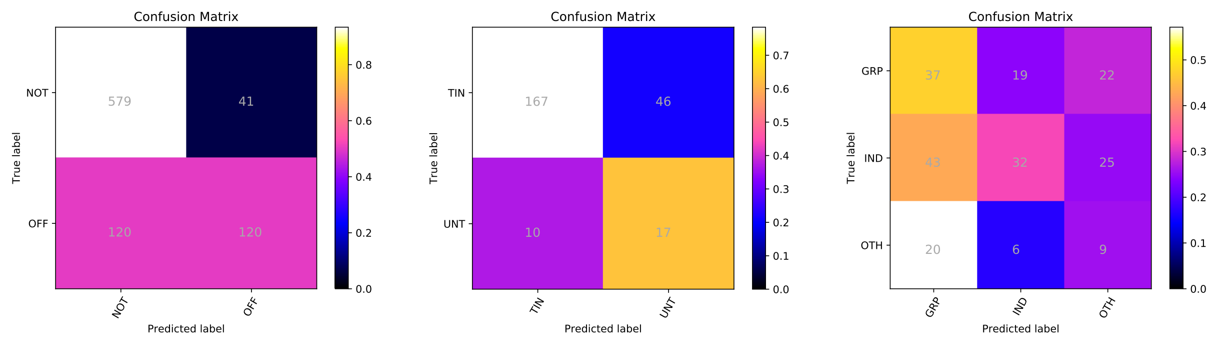

Figure 1: a) Sub-task A, LSTM (epoch=5, dropout= 0.2), b) Sub-task B, LSTM (dropout=0.2, epochs=20), c) Sub-task C, LSTM(dropout=0.2, epochs=50)

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	**0.4695**
All OTH baseline	0.0941	0.1643
LSTM (20,0.2) and word list	0.1849	0.1878
LSTM (50,0.2)	**0.3404**	0.3662
LSTM (50,0.2) and word list	0.2832	0.3521

Table 3: Results for Sub-task C.

6 Results

Tables 1, 2 and 3 shows F1 (macro) and Accuracy scores for the submitted systems. We can see that for all the sub-tasks our system has F1 (macro) and as described in (Zampieri et al., 2019a) F1 (macro) is used for performance analysis by task coordinators. Best results are highlighted in bold ink in tables and confusion matrix for them is also shown in Figure 1 for Sub-tasks A, B and C. In **Sub-task A** we achieved *0.8128* and *0.7382* as accuracy and F1 respectively. For this task we submitted only one system with LSTM network dropout *0.2* and *5* epochs. For **Sub-task B** we submitted three runs but, the best performance is achieved by system with LSTM dropout of *0.2*, *20* epochs and offensive word list described in Section 4. Later in **Sub-task C** we submitted three runs and best performance was LSTM with *50* epochs and *0.2* dropout.

7 Conclusion

In this paper we used LSTM network to identify offensive tweets and categorize offense in subcategories as described in Section 3 for Task 6: Identifying and Categorizing Offensive Language in Social Media. We used an embedding layer followed by LSTM layer for tweet classification. Three tasks of OffensEval Sub-task A, B, and C were of varied difficulty level. The main reason can be decreasing amount of data for each of them, where Sub-task A has more data followed by Sub-task B categorizing offensive tweets identified by Sub-task A and, Sub-task C categorizing targeted offense identified by Sub-task B. Data was also unbalanced leading to more importance for majority class but after applying cost function we found that accuracy was decreased with increased errors in identification of majority class.

8 Future Work

For future work, we would like to use additional datasets like TRAC-1 data (Kumar et al., 2018), (Davidson et al., 2017), and would collect data from Twitter to get diverse data. To be consistent with substantial research done in recent years we want to employ a combination of textual features like the bag of words n-grams, capitalized characters, sentiment scores, e.t.c. Also, we want to focus more on specific features like semantics and linguistic features intrinsic to hate/offensive rather than just generic text-based features. For that, we want to use character level deep LSTM which can be used to extract the semantic and syntactic information. Finally, we want to explore more about the similarities and dissimilarities between the profanity and hate speech, establishing more profound way of extracting features in order to make the detection system more responsive.

UTFPR at SemEval-2019 Task 6: Relying on Compositionality to Find Offense

Gustavo Henrique Paetzold
Universidade Tecnológica Federal do Paraná / Toledo-PR, Brazil
ghpaetzold@utfpr.edu.br

Abstract

We present the UTFPR system for the OffensEval shared task of SemEval 2019: A character-to-word-to-sentence compositional RNN model trained exclusively over the training data provided by the organizers. We find that, although not very competitive for the task at hand, it offers a robust solution to the orthographic irregularity inherent to tweets.

1 Introduction

Text classification tasks can take a wide variety of forms, and some of them, such as sentiment and emotion analysis, have managed to grab a lot of attention from researchers in recent years. More recently, however, the public's growing engagement in debates on the topics of free speech and politics has led the Natural Language Processing (NLP) and Machine Learning (ML) communities to take an interest in classification tasks related to identifying and categorizing patterns of profanity, hate speech and offense. The prominence of shared tasks held on these topics, such as those of Fersini et al. (2018) and Wiegand et al. (2018), are great examples of the research community coming together to attempt to create more reliable solutions for these challenges.

While hate speech is commonly characterized by specific slurs and other offensive expressions that convey prejudice against a certain group or individual, offensive speech is often more challenging to identify because it encompasses a more broad spectrum of language, featuring expressions that do not necessarily convey prejudice (Malmasi and Zampieri, 2018). Technologies that identify these types of patterns could, for instance, help a social media platform on profiling users and take appropriate action whenever someone breaks user agreements and/or terms of use.

Identifying offensive language within the content of social media platforms is particularly challenging, since this type of content is usually littered with irregular orthography, meta-characters, slang and others. Since a lot of the effort from the research community focuses on identifying offensive language in social media platforms, an NLP approach for such a task must be able to overcome those hurdles in some way. Some of the preferred methods for handling the orthographic irregularity of social media content are using word embeddings trained over tweets (Rozental et al., 2018) or regularizing unusual spellings (Bertaglia and das Graças Volpe Nunes, 2017), but neither of them ensure that every possible orthographically irregular word will be understood by the NLP model in question. Recently, however, there have been a lot of contributions that present compositional neural models that learn numerical representations of words based on the sequence of characters that compose them (Kim et al., 2016; Ling et al., 2015; Balazs et al., 2018; Paetzold, 2018). These models have been demonstrated to be both effective in text classification, and robust when faced with orthographic irregularity.

In this paper, we present the UTFPR system submitted to the OffensEval shared task of SemEval 2019, which employs compositional neural models to identify offensive language in tweets. In the following sections we describe the task (section 2), our model (section 3) and experiments (sections 4 to 5).

2 Task Summary

The UTFPR systems described herein are a contribution to the OffensEval shared task held at the SemEval 2019 workshop (Zampieri et al., 2019b). In this shared task, participants were tasked with creating innovative classifiers capable of identifying and categorizing offensive tweets. This shared tasks has 3 sub-tasks:

- **Task A:** Binary classification task that consists in judging whether a tweet is offensive or not.
- **Task B:** Binary classification task that consists in identifying whether or not an offensive tweet was targeted towards a specific person or group.
- **Task C:** Consists in identifying whether an offensive tweet was targeted at a person, group or something else (3-class classification).

We decided to focus our efforts on Task A exclusively. The organizers provided participants a training set with $13,240$ instances, a trial set with 320, and a test set with 860. Each instance is composed of a tweet and its respective labels for tasks A, B and C. The datasets were annotated by humans of undisclosed background (Zampieri et al., 2019a).

3 The UTFPR Model

As we have previously mentioned, ours is a compositional Recurrent Neural Network (RNN) inspired by the ones introduced by Ling et al. (2015) and Paetzold (2018). Our RNN learns word representations based on the sequence of characters that compose them, then learns sentence representations based on the word representations previously learned. Figure 1 illustrates the architecture of our model in detail.

The model takes as input a potentially offensive tweet. It first produces character embeddings for the characters of each word in the sentence, then passes them through a sequence of bidirectional RNN layers in order to produce character-to-word numerical representations for them. These word representations are then passed onto another sequence of bidirectional RNN layers, which in turn produce a single word-to-sentence numerical representation for the sentence. A dense layer connected to a softmax layer produces the final binary class, which can be OFF (for offensive) and NOT (for not offensive).

Because the dataset provided for training is rather small, we suspected that the character-to-word representations produced through this training data would not be reliable enough for the task. Because of that, we decided to train two different model variants:

- **UTFPR-Scratch:** The model depicted in Figure 1 trained from scratch over the shared task's training set exclusively.
- **UTFPR-Reuse:** The same model depicted in Figure 1, except instead of training its character-to-word RNN layers from scratch along with the rest of the model, they are taken from a similar compositional model pre-trained by Paetzold (2018) over a much larger dataset for the Emotion Analysis shared task held at WASSA 2018 (Klinger et al., 2018). The training set of the WASSA 2018 shared task has $153,383$ instances, each composed of a tweet with a target emotion word replaced with a [#TRIGGERWORD#] marker, and an emotion label that could be either joy, sad, disgust, anger, surprise, or fear.

The architecture of our models is identical, and their specifications are:

- **Size of character embeddings:** 15
- **RNN layer type:** Gated Recurrent Units
- **RNN layer depth:** 2 (for all layers sets)
- **RNN layer size:** 60 (for all layers)
- **Dropout proportion:** 25%
- **Loss function:** Cross-entropy
- **Framework used:** PyTorch[1]

We chose to use the PyTorch framework due to the fact that it employs dynamic computational graphs, and hence they do not require us to set a fixed maximum size for the words in the dataset. This feature of PyTorch only allows us to create a much more flexible model that can handle any word size, but also disregards the needs for padding.

To train our models, we split the training set into a training portion ($10,000$ instances) and a development portion ($3,240$ instances). The models were left training for hundreds of iterations, and after each iteration a version of each model was saved. The final selected models were the ones with the lowest attained error on the development

[1]https://pytorch.org

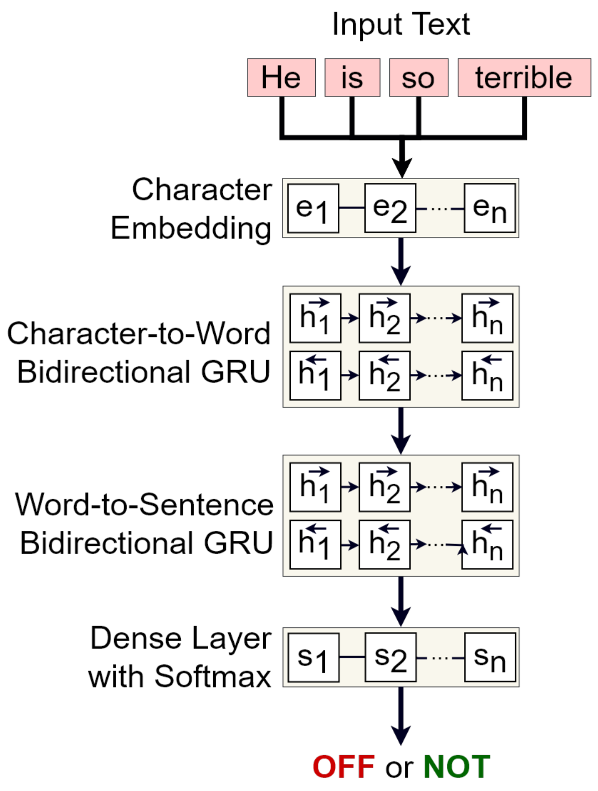

Figure 1: Architecture of the UTFPR system.

portion of the data. We conducted a preliminary evaluation over the trial set to determine which of the variants to submit. The macro-averaged F-scores, which are illustrated in Table 2, show that using pre-trained character-to-word RNN layers actually compromised the performance of our model in this instance, hence we opted to submit the UTFPR-Scratch variant.

System	F-score
UTFPR-Scratch	0.770
UTFPR-Reuse	0.599

Table 1: Macro-averaged F-scores for the trial set

4 Performance on Shared Task

The systems submitted to the shared task were evaluated through their macro-averaged F1-score. The results on Table 2 showcase the results obtained by UTFPR-Scratch, as well as the top 3 and bottom 3 systems submitted to Task A. As it can be noticed, our system did not perform very well, placing 93rd out of 103 teams. The confusion matrix of UTFPR-Reuse in Figure 3 shows that the main reason behind this poor showing was the large amount of false negatives predicted. Upon inspecting the labels predicted, we found that the UTFPR-Scratch system would predict offense mostly for tweets with a lot of profanity and with hashtags associated with the Donald Trump administration, such as “#BuildTheWall”.

Rank	System	F-score
1	pliu19	0.829
2	anikolov	0.815
3	lukez	0.814
93	UTFPR	0.528
101	hamadanayel	0.458
102	magnito60	0.422
103	AyushS	0.171

Table 2: Macro-averaged F-scores for the trial set

5 Robustness Assessment

As we’ve already mentioned, one of the main advantages of compositional RNN models that learn word representations from character sequences is the fact that they handle low-frequency and out-of-vocabulary words in an elegant way, since they are able to produce a numerical representation for any word. Because of that, these models tend to be much more resilient when presented with noisy

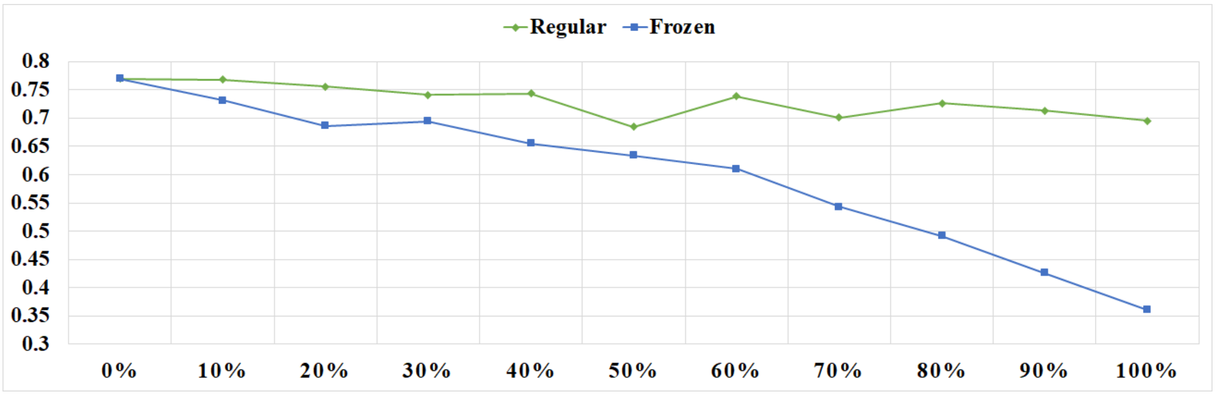

Figure 2: Results of our robustness experiments. The vertical and horizontal axes presents macro-averaged F-scores and the percentage of words with noise introduced to them, respectively. The dots represent the scores obtained by the regular UTFPR-Scratch model and a frozen version that treats all words outside of the training set as out-of-vocabulary words.

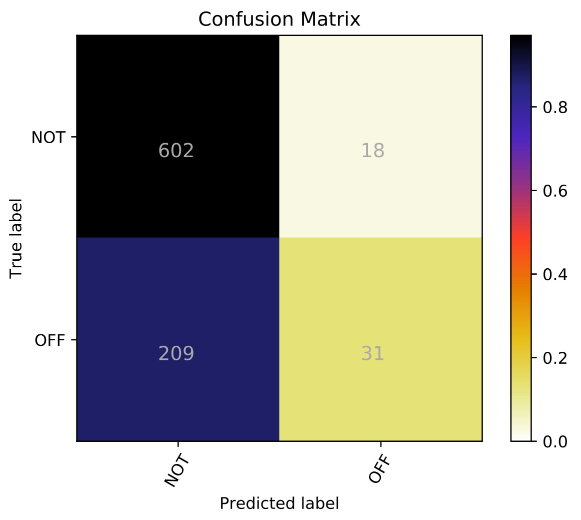

Figure 3: Confusion matrix of the UTFPR-Scratch model on the test set.

input that differs considerably from the input presented during training.

In this experiment, we assess the robustness of our UTFPR models. First, we generated "jammed" versions of the shared task's trial set (since the test set was not made available) with increasing volumes of noise introduced to them. To create a jammed test set, we simply added a noise-inducing modification to $N\%$ randomly selected words of each sentence. The modifications were randomly selected between either removing a randomly selected character form the word (50% chance) or duplicating it (50% chance). We created 11 jammed versions by using $0 \leq N \leq 100$ in intervals of 10. Words with a single character that were subjected to removal were simply discarded from the sentence.

We compared the regular UTFPR-Scratch model (Regular) with a modified version with frozen character-to-word RNN layers (Frozen). The frozen version only produces a numerical representation of a word if it is present in the training set, otherwise, it produces a vector full of 1's signaling an out-of-vocabulary word. The results in Figure 2 show that using the frozen version is much less robust than the regular model, specially when the input sentence has 70% or more of its words out of the training set vocabulary.

6 Conclusions

In this paper we presented the UTFPR system for the OffensEval shared task held at SemEval 2019, which is a compositional RNN model that learns numerical representations of words based on its characters. Our experiments reveal that, although our model is not very competitive for this task specifically (placing 93rd out of 103 participants), it offers a very robust solution to the problem of out-of-vocabulary words. Inspecting the model's output we found that the main cause for its poor performance was the fact that it learned a bias towards the "not offensive" label, which caused it to predict a lot of false negatives. Also, we found that our model was actually better at identifying profanity and controversial topics rather than offense itself. In the future, we intend to explore combining our numerical word representations with richer semantic features in order to train more reliable compositional models for this task.

7 Acknowledgments

We gratefully acknowledge the support of NVIDIA Corporation with the donation of the Titan V GPU used for this research.

Abstract

With the growth in the usage of social media, it has become increasingly common for people to hide behind a mask and abuse others. We have attempted to detect such tweets and comments that are malicious in intent, which either targets an individual or a group. Our best classifier for identifying offensive tweets for SubTask_A (Classifying offensive vs. non-offensive) has an accuracy of 83.14% and a f1-score of 0.7565 on the actual test data. For SubTask_B, to identify if an offensive tweet is targeted (If targeted towards an individual or a group), the classifier performs with an accuracy of 89.17% and f1-score of 0.5885. The paper talks about how we generated linguistic and semantic features to build an ensemble machine learning model. By training with more extracts from different sources (Facebook, and more tweets), the paper shows how the accuracy changes with additional training data.

1 Introduction

Internet is now accessed by over half of the world's population [1]. In fact, almost 1 million new users are added each day. With social media platforms, people find it a lot easier to get away with the abuse they spew around, in comparison to the offline world. This brings a lot of onus on the Social Network websites to tackle such activities. Majority of the countries have laws to control hate speech which puts tremendous pressure on the concerned websites to curb such activities. Since manual monitoring or defining a specific rule-set might be time consuming, an ensemble machine learning approach has been discussed to avoid complexity and increase interpretability.

The paper focuses on providing solutions to SubTask_A and SubTask_B for the SemEval 2019 competition. Previous works and papers focus on identifying if a tweet is offensive or not. Here, in addition to that, it is identified if an offensive tweet is targeted towards a particular individual or a group *(SubTask_B)*. Such granular information would help the Social Media to make better decisions.

2 Related Work

This issue has gathered a lot of attention over the past few years with various types of hate speech detection models.

Papers published in the last two years include the surveys by Schmidt and Wiegand (2017) and Fortuna and Nunes (2018) where the authors extract features from the text like sentiment, linguistic features, utilize different lexical resources to tag an offensive tweet, and another paper by Davidson et al. (2017) presenting the Hate Speech Detection data set used in Malmasi and Zampieri (2017) where the authors perform a three way classification - Hate Speech, Offensive and None. By classifying these, the authors talk about specific patterns related to offensive terms. It is found that the usage of cuss words like b*tch and n*gga is fond in both offensive and casual setting, while f*ggot and n*gger were predominantly used in hateful contexts. One of the major takeaways was that lexical methods are effective to identify potentially offensive terms, but are inaccurate at identifying hate speech Other work include: ElSherief et al. (2018); Gambäck and Sikdar (2017); Zhang et al. (2018).

A proposal of typology of abusive language sub-tasks is presented in Waseem et al. (2017) where the author talks about how an offensive tweet can be categorized into four segments - Explicit, Implicit, Directed and Generalized abuse.

These help in creating segment wise features to capture them separately. Finally, methods in identifying profanity vs. hate speech is talked by Malmasi and Zampieri (2018). This work highlighted the challenges of distinguishing between profanity, and threatening language which may not actually contain profane language.

The description of the current task is presented in detail in Zampieri et al. (2019b), which clearly provides the context and underlying problem statement for this paper.

3 Data

For this project, the data set provided by the organizers of OffensEval 2019 was used.The data collection methods used to compile the data set used is described in Zampieri et al. (2019a). The data set consisted of 13,241 records of training observations with the following types of response variables : 1) If a tweet is offensive or not 2) If an offensive tweet is targeted towards an individual (IND) or a group (GRP).

To validate if the performance would increase, an additional data source was also used. The main hypothesis behind including the data was that more data would result in a better accuracy. So, the data set that closely aligned with the current objective was considered for the analysis. This data set was used as a part of the competition organized by TRAC [2]. This contained the response variable with the categories - 'Covertly Aggressive', 'Overtly Aggressive' and 'Non Aggressive'. To maintain consistency with the current data set, 'Covertly Aggressive' and 'Overtly Aggressive' were tagged as 'Offensive' and the rest as 'Not Offensive'.

Including both the data sets, there were a total of 25,239 observations.

The distribution of variables of the original data set is as follows,

SubTask_A: Offensive (33%), and Non-offensive (67%). **SubTask_B:** Out of the 33% offensive tweets, it is seen that there are Targeted (88%), and Untargeted (12%)

4 Methodology

The Methodology involved two sub-works - Feature Engineering and Ensemble Model building.

[2] https://sites.google.com/view/trac1/shared-task/

Various features were extracted to get the semantics of the words and tweets.

4.1 Feature Engineering

Character n-grams
Inspired from earlier works, character n-grams were used especially to tackle misspelled words or words without spaces like 'fu*koff' and 'fu*kasdf'. In both of these cases, character 4-gram would detect the sub-word 'fu*k'.

Word n-grams
Apart from using just 1-gram, 3-gram and 4-gram really helped in identifying the context of the tweet and focus on words like *'not good'* where 'not' negates the next word.

Cuss-word Dictionary and Profanity Checker
A list of cuss words were scraped from *www.noswearing.com.* This helped in identifying such cuss words in tweets which occurred only once or twice in the whole corpus. Profanity checker libraries like *profanity* were also used along with the scraped list. These helped in creating features like *cuss-word count* and *cuss-word position*.

GloVe Embedding
The use case of GloVe embedding were two-fold. One, average embedding could be found for a tweet which can then be used as a feature space. Two, once the top-30 features were obtained from the initial training, GloVe model was used to find most similar words to them thereby creating a feature representing potential offensive terms.

Part of Speech
Parts of Speech of the tweets were extracted using spaCy, especially the pronouns which could be used for identifying an individual *(SubTask_B).*

Others
Other features like tweet polarity (positive, negative or neural score), of hash-tags, of user tags were also used.

4.2 Model Building

Required pre-processing steps like stop-word removal (high and low frequency), stemming, case correction were done. Post which, various features as mentioned above were generated.

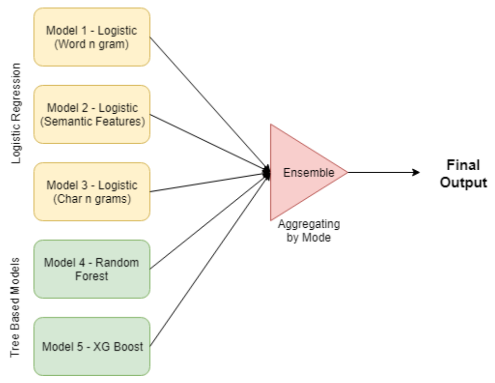

Figure 1: Final Model Architecture

An Ensemble Model was then built by aggregating the results of 5 different models with varying feature set provided as input to each model.

Logistic Regression

Three basic logistic regression models with L2 regularization were developed:

Model 1 was built with Bag of Words (1 - 4 grams) which amounted to 107,445 number of features

Model 2 was built with Tweet Polarity, Word Embedding, Cuss Word Count, and Cuss Word Position

Model 3 was built with character - 4 grams. Various tests with cross validation were performed to arrive at this result with a final count of 100,122 features

Tree Based Models

Model 4 was built using Random forest with Bag of Words (1,2,3,4 grams) containing a total feature size of 107,237.

Model 5 using XG Boost, with Bag of Words (1,2,3,4 grams) containing a feature size of 107,237.

The combined architecture looked as follows,

Vote count was made to arrive at the final decision using the outputs from each of these models

5 Results

5.1 Results - SubTask_A

Model results with respect to the validation data set (part of the training sample) are discussed here. Results of the validation data set with respect to the 80-20 split are shown,

Ensemble Model was able to perform with an accuracy gain of 1.5% with respect to the best individual model *(Model 1)*

Similarly, the results for the model using the given data with an addition of training data provided by TRAC are,

Model	*Accuracy*	*F1 (macro)*
Model1 - Logistic (BOW)	0.78	0.73
Model 2- Logistic (Semantic features)	0.77	0.70
Model 3 - Logistic (Char n gram)	0.76	0.71
Model 3 - Random Forest (BOW)	0.77	0.70
Model 4 - XG Boost (BOW)	0.77	0.71
Ensemble Model	**0.80**	**0.74**

Table 1: Results for SubTask_A without additional data

Model (Additional Data)	*Accuracy*	*F1 (macro)*
Model1 - Logistic (BOW)	0.73	0.72
Model 2- Logistic (Semantic features)	0.70	0.69
Model 3 - Logistic (Char n gram)	0.72	0.71
Model 3 - Random Forest (BOW)	0.71	0.69
Model 4 - XG Boost (BOW)	0.71	0.71
Ensemble Model	**0.74**	**0.73**

Table 2: Results for SubTask_A with additional data

Comparing the results, it can be seen that addition of data in fact reduces the model accuracy.

Features Analysis- Logistic Regression

For better intuitive understanding, top features from logistic regression model trained without additional data were extracted to understand what words constitutes a tweet to be offensive,

Variable	**Coefficient**
stupid	1.798
sucks	1.513
Cuss_word	1.453
crap	1.415
clown	1.274
idiots	1.274
bitch	1.272
sex	1.231

Table 3: Coefficients with higher values

It is clear that words like stupid, sucks, crap and idiots increases the probability of a tweet to be offensive. However, it has been identified that some non-offensive tweets are mis-classified as offensive just because of the presence of such words.

Looking at the coefficients with least weights, it is seen that although the above words have a mild negative connotation, majority of their use-cases are not in an offensive setting which makes a tweet with these to have higher probability of non-offensive class.

Validating the results using actual test data:

Variable	Coefficient
bad	-1.57
mean	-1.08
woman	-1.02
brexit	-0.87
hell	-0.84
fact	-0.76
holy shit	-0.72
pissed	-0.70

Table 4: Coefficients with lower values

The results using ensemble model were submitted to the competition and compared against the actual test data. The table shows the baseline results and the model's performance

System	Accuracy	F1 (macro)
All NOT baseline	0.7209	0.4189
All OFF baseline	0.2790	0.2182
Ensemble - No additiona data	**0.8314**	**0.7565**
Ensemble with additional data	0.8093	0.7433

Table 5: SubTask_A result on actual test data

It was surprising to see that by training the model with additional data, model's accuracy decreased by 3%. This can be mainly attributed to the difference in data sources and difference in response variable definition.

The results between the models trained with and without additional data are to be compared to see the difference between them. Looking at the tweets tagged as Offensive by Model without additional data, but as non-offensive by the other : *@USER Zuckerberg lies.*, *SerenaWilliams is so full of herself...she is just as painful to watch as to listen to...*, and *"50 Cent Calls Out Joe Budden's Bullshit"" On Instagram URL URL.* Looking at the tags, it can be hypothesized that words like 'lies','painful' and 'bullshit' which had very high positive score (offensie), got reduced because of the additional data where these words were not used in an offensive setting. Difference in usage of such words is the reason behind reduction in prediction accuracy for new tweets.

Confusion Matrix

The primary problem is seen with predicting the offensive tweets, where almost half of them are were predicted incorrectly, while a majority of the non-offensive tweets are predicted correctly.

Error Analysis

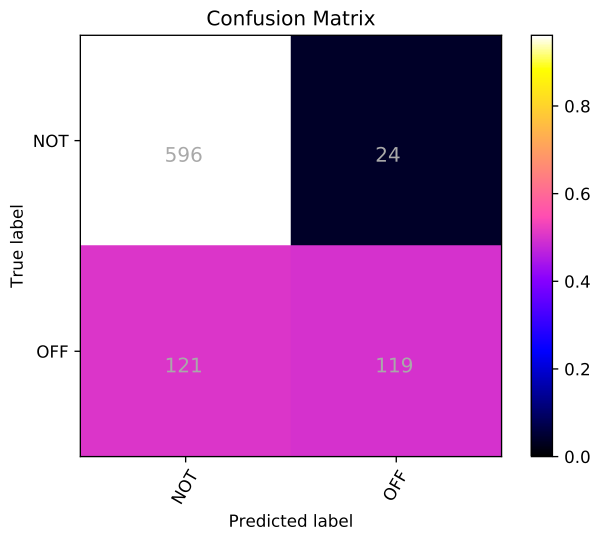

Figure 2: SubTask_A, Ensemble - No additional data

Analyzing the two cases of mis-classification,

i) Offensive tweet tagged non-offensive - While a few of the tweets target an individual or a group, many of them seem to be ambiguous like - *"@USER @USER @USER @USER Kick the absolute shite out of the car", "@USER @USER @USER @USER Yes. Yes he is!"*, and *"Shits about to Hit the Fan. MAGA URL"*

ii) Non offensive being tagged as offensive - The most common reason is the presence of cuss word in a non-offensive sense. Examples are - *Am I a dickhead ???? Probably yes,@USER I've already listened to it like 5 times it's so fucking well made* More features related to the sequence of the sentence, and dependency parsing might help in understanding the syntactic structure

5.2 Results - SubTask_B

The model architecture remained similar to the earlier SubTask, except that Model 2 was trained with additional features like **Parts of Speech** to help detect the target.

The cross-validation results obtained are,

Model (SubTask_B)	*Accuracy*	*F1 (macro)*
Model1 - Logistic (BOW)	0.87	0.46
Model 2- Logistic (Semantic features)	0.87	0.46
Model 3 - Logistic (Char n gram)	0.87	0.45
Model 3 - Random Forest (BOW)	0.86	0.46
Model 4 - XG Boost (BOW)	0.87	0.46
Ensemble Model	**0.88**	**0.47**

Table 6: Results for SubTask_B with no additional data

It is clear that the ensemble model performs bet-

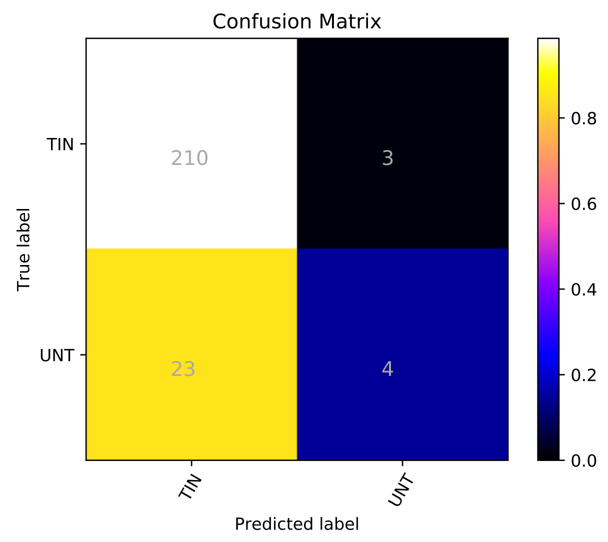

Figure 3: SubTask_B,Confusion matrix for final model

ter than all the other individual models. Now, assessing the performance on actual test data,

System	Accuracy	F1 (macro)
All TIN baseline	0.8875	0.4702
All UNT baseline	0.1125	0.1011
Ensemble Model	0.8917	0.5885

Table 7: SubTask_B result on actual test data

Confusion Matrix

Looking at the confusion matrix in Figure 3, the main issue is seen with predicting a targeted tweet, where almost all of them are predicted incorrectly. This can be ascribed to insufficient number of features that would identify an individual or organization.

6 Conclusion

The proposed ensemble model leverages the best of each of the individual models, where each of the models was experimented with a varying set of features. Some features like word and character n-grams, tweet polarity, cuss word count were more helpful in capturing offensive tweets. The performance for SubTask_B is not appreciable because less number of features related to identifying a target were used. With our best scores for SubTask_A, we were placed 36th out of 103 participants, and were placed 42nd out of 75 submissions in the SemEval-2019 competition. The top team achieved a F1(macro) score of 0.829 in SubTask_A, while we obtained 0.756. Similarly, for SubTask_B the top team had a F1(macro) score of 0.755, while we obtained 0.588. Features like identifying the presence of a person's name using nltk libraries, and the presence of an individual or an organization using Named Entity Recognition with spaCy is highly recommended for further studies.

Moreover, there was a pattern associated with the coefficients having least weights - most of them had a slightly negative connotation. This can justified because of the overall theme of tweets used for training, as most of them were inclined towards *politics*. This lead to overall less number of 'positive words'. Having **more training examples** especially with a range of tweet polarity from more positive to more negative would help in building better models. As seen from our results, an additional data set should be in the same space (Twitter data) to avoid worse performance.

Talking about the offensive tweet categories, there are four types - explicit, implicit, targeted at individuals and groups. The techniques mentioned in this paper using a variety of feature engineering tries to capture most of these categories. However, advanced syntactic features should be introduced to capture patterns like *"Pronoun-Verb-Cuss_word"*. Especially, if a exploratory data analysis is performed on analyzing the patterns of Parts of Speech in offensive tweets, it would help in building additional useful variables.

The main goal of this paper is to show that simpler models which have understandable features can produce good results. More complex methods like introducing polynomial or intricate features, deep learning models using Recurrent Neural Network are other approaches for potentially better accuracy but at the risk of losing interpretability. In conclusion, it is believed that with additional robust features as discussed earlier, the current ensemble machine learning model's performance might increase. Moreover, such features would also be really helpful in interpreting why a tweet could be offensive, which will help in taking necessary actions and remedial measures for social media companies.

Abstract

This document describes the submission of team YNU-HPCC to SemEval-2019 for three Sub-tasks of Task 6: Sub-task A, Sub-task B, and Sub-task C. We have submitted four systems to identify and categorise offensive language. The first subsystem is an attention-based 2-layer bidirectional long short-term memory (BiLSTM). The second subsystem is a voting ensemble of four different deep learning architectures. The third subsystem is a stacking ensemble of four different deep learning architectures. Finally, the fourth subsystem is a bidirectional encoder representations from transformers (BERT) model. Among our models, in Sub-task A, our first subsystem performed the best, ranking 16th among 103 teams; in Sub-task B, the second subsystem performed the best, ranking 12th among 75 teams; in Sub-task C, the fourth subsystem performed best, ranking 4th among 65 teams.

1 Introduction

Identifying offensive language (Zampieri et al., 2019b) on Twitter is a particularly challenging task because of the informal and creative writing style, with the improper use of grammar, figurative language, misspellings and slang, etc. In previous attempts of the task, OffensEval was generally tackled using hand-crafted features and/or sentiment lexicons by feeding them to classifiers such as Support Vector Machines (SVM). These approaches require a laborious feature-engineering process, which may also need domain-specific knowledge, usually resulting in both redundant and missing features. However, in recent years, artificial neural networks for feature learning have achieved good results in this field (Christos Baziotis, 2017).

SemEval-2019 Task 6 consists of three Sub-tasks (Symeon Symeonidis, 2017):

- Sub-task A: Offensive language identification;
- Sub-task B: Automatic categorisation of offense types;
- Sub-task C: Offense target identification.

In this document, we present four systems that competed at SemEval-2019 Task 6 (Zampieri et al., 2019b). The first model is a 2-layer BiLSTM, equipped with an attention mechanism. The second is voting scheme that combines a 2-layer BiLSTM, Capsule Network, 2-layer bidirectional gated recurrent unit (BiGRU), and the first model. The third model is a stacking scheme that combines a 2-layer BiLSTM, Capsule Network, 2-layer bidirectional gated recurrent unit (BiGRU), and the first model. In addition, the above three models, for the word representation, we have used the glove vector. The fourth model is BERT-BASE (Jacob Devlin, 2018), which was released last year by Google AI Language.

The remainder of this document is organised as follows. The related work is described in Section 2. Section 3 reports our methodology and data. Section 4 reports our result. The conclusions are summarised in Section 5.

2 Related Work

In recent years, with the rapid development of social media, the use of aggressive and offensive language as well as hate speech has gradually increased. To tackle this problematic behaviour, one of the most common strategies is to train systems capable of recognising them and either deleting them or setting them aside for human moderation.

Aggression can be divided into three categories: overt aggression, covert aggression, and non-aggression (Kumar et al., 2018). Last year, in a shared task, several participants used deep neural networks and traditional machine learning methods for aggression identification. The best performing systems in this competition used deep-learning approaches based on convolutional neural networks (CNN), BiLSTM, and long short-term memory (LSTM). Offensive Language is commonly defined as hurtful, derogatory or obscene comments made from one person to another. Currently, there is an increasing amount of such language online. Manually monitoring these posts would incur significant costs (Mathur et al., 2018). Therefore, the automatic identification of suspicious posts has emerges as a trend. In recent years, many researchers have studied the use of deep-learning and traditional machine learning methods for this purpose. Their results indicate that, although several deep-learning approaches produce good scores, traditional supervised classifiers can produce similar scores. Word embeddings, character n-grams and lexicons of offensive words are popular features, but all three components are not necessary for a robust system. Ensemble methods mostly help (Wiegand et al., 2018). Many previous studies still tend to equate offensive language and hate speech. However, through this method, we may erroneously classify many people as hate speakers by failing to differentiate between commonplace offensive language and genuine hate speech (Davidson et al., 2017; Fortuna and Nunes, 2018). In recent years, the recognition of hate speech has mainly focused on deep-learning methods, such as CNNs (Gambäck and Sikdar, 2017) and Convolution-GRU (Zhang et al., 2018).

3 Methodology and Data

3.1 Data

The datasets contain data from Twitter and were provided by the organisers. For Sub-task A, Sub-task B, and Sub-task C, the available datasets (Zampieri et al., 2019a) comprised all the training and testing data. In addition, because the organisers did not provide development, we decided to split 0.2 from the training as development. Table 1 shows the data provided by the organisers.

As shown in Table 1, there the data of the three Sub-tasks shows a significant imbalance.

A	B	C	Train	Test	Total
OFF	**TIN**	**IND**	2,407	100	2,507
OFF	**TIN**	**OTH**	395	35	430
OFF	**TIN**	**GRP**	1,074	78	1,152
OFF	**UNT**	—	524	27	551
NOT	—	—	8,840	620	9,460
ALL			13,240	860	14,100

Table 1: Distribution of label combinations in the data

3.2 Preprocessing

Initially, we received the training and testing data that had been preprocessed by the organisers. Subsequently, on this basis, we preprocessed the training and testing data again and finally applied it to a neural network. For preprocessing, we removed and replaced strings from the tweets that did not show any sentiments, irregularities, or abbreviations. We also removed duplicates and Unicode strings. These were implemented as follows:

- Removing consecutive duplicates while retaining one item: we found that some instances of text were duplicates, e.g. ”????” $\rightarrow$ ”?”.

- Replacing the emojis on Twitter with the corresponding English definition and replacing abbreviations: There were several emojis in the data conveying different emotions. In addition, the abbreviations in the data also restrict the corresponding emotional categories, e.g. ”don’t” $\rightarrow$ ”do not”.

- Replacing irregular words: we found that there were many irregular words in the data, e.g. ”bro” $\rightarrow$ ”brother”.

- Removing some punctuation: preliminary experiments showed better results when we removed some punctuation; however, we detected emotive punctuation signs such as ”!” and ”?” and retained them.

- Converting lowercase: the final tweets were converted to lowercase (after detecting words that had all of their character capitalised, which were retained).

- Using Stanford toolkit: After comparing the use of the word segmentation in the NLTK and Stanford toolkits, we finally decided to use the Stanford toolkit, because of its better performance.

3.3 System

For SemEval-2019 Task 6, we used five basic models:

- **BiLSTM**: BiLSTM is a combination of forward LSTM (LSTM is an artificial recurrent neural network (RNN) architecture; a common LSTM unit comprises a cell, an input gate, an output gate, and a forget gate.) and backward LSTM. Because BiLSTM can better represent bidirectional semantic dependencies, it is often used to model contextual information in natural language processing. In the three Sub-tasks, after several trial comparisons and time factors, we finally selected a 2-layer BiLSTM. In addition, the parameters of our model were chosen to maximise development performance: in Sub-task A, we initialised the hidden dimension, recurrent dropout, and batch size as 120, 0.25, and 128, respectively; in Sub-task B, we initialised the hidden dimension, recurrent dropout, and batch size as 120, 0.25, and 100, respectively; and in Sub-task C, we initialised the hidden dimension, recurrent dropout, and batch size as 140, 0.35, and 64, respectively.

- **BiGRU**: similarly, BiGRU is a combination of forward GRU (GRU, a variant of LSTM, has a simpler structure than LSTM and works well; there are only two gates in the GRU model, namely the update gate and the reset gate) and backward GRU. For the three Sub-tasks, we used a 2-layer BiGRU. The parameters of our model were chosen to maximise development performance: in Sub-tasks A and B, we initialised the hidden dimension, recurrent dropout, and batch size as 120, 0.25, and 100, respectively; in Sub-task C, we initialised the hidden dimension, recurrent dropout, and batch size as 120, 0.25, and 128, respectively.

- **BiLSTM with attention**: For this, an attention layer was added to the 2-layer BiLSTM. In BiLSTM, we used the output vector of the last time sequence as the feature vector and then performed softmax classification. The attention layer is used to first calculate the weight of each time sequence, then take the weighted sum of all the time sequence vectors as feature vectors, and finally perform softmax classification. Similar to the previous models, the parameters of our model were as follows: in Sub-tasks A and B, we initialised the hidden dimension, recurrent dropout, and batch size as 120, 0.25, and 256, respectively; in Sub-task C, we initialised the hidden dimension, recurrent dropout, and batch size as 180, 0.3, and 128, respectively.

- **Capsule Network**: In the deep-learning model, the spatial patterns are summarised at the lower level, thus helping represent the concept of higher layers. For example, when a CNN models spatial information, it needs to copy the feature detector, which reduces the efficiency of the model. However, spatially insensitive methods are inevitably limited by rich text structures (such as the preservation of word location information, semantic information, and grammatical structure), which are difficult to encode effectively and lack text expression ability. Hinton et al. (Sara Sabour, 2017) proposed a Capsule Network, which replaces a single neuron node of a traditional neural network with a neuron vector and trains this new neural network through dynamic routing, effectively improving the shortcomings of the above two methods. The parameters of our model were as follows: in Sub-tasks A and B, we initialised the hidden dimension, batch size, and routing as 64, 120, and 15, respectively; in Sub-task C, we initialised the hidden dimension, batch size, and routing as 64, 140, and 15, respectively.

- **BERT**: The BERT model is a language model proposed by Google based on a bidirectional transformer. It is quite different from ELMo (Peters et al., 2018). In existing pre-training models (including word2vec and ELMo), word vectors are generated. This type of pre-training model belongs to domain transfer. The GPT (Karthik Narasimhan and Sutskever, 2018), BERT, etc. proposed in recent years are all examples of model migration. Furthermore, the BERT model combines the pre-training model with the downstream task model. In other words, it is still utilised when performing downstream tasks, and text classification tasks are naturally supported. The model does not need to be modified when performing text classification tasks. The BERT model has two versions on the English datasets, namely Base and Large, and we used the Base version. The parameters of our model were as follows: transformer blocks (L) was set as 12, hidden size (H) as 768, number of self-attention heads (A) as 12, total parameters as 110M, train batch size as 32, predict batch size as 8, and learning rate as 0.00002.

For the four models of BiLSTM, BiGRU, BiLSTM with attention, and Capsule Network, first, the processed Twitter text was converted into a word vector matrix. Then the word vector matrix was processed by the embedded layer. Subsequently, the word vector matrix was converted to a computable vector matrix. Finally, the four models could utilise the vector matrix for training and prediction.

3.4 K-Fold Cross-Validation

We know from Section 3.1 that data imbalance exists in the public datasets published by the organisers. This would lead to unstable or inaccurate experimental results. To manage this problem, we used k-fold (k = 5) cross-validation: the training sample was randomly partitioned into 5 equal sized subsamples. Of the 5 subsamples, a single subsample was retained as validation data to test the model, and the remaining 4 subsamples were used as training data.

4 Results

4.1 Task A

Sub-task A includes 13240 training instances and 860 testing instances, as well as OFF and NOT labels. We used four models for predictions on the testing sets. These four models were BERT (system ID: 528280), voting (system ID: 528117), stacking (system ID: 528015), and BiLSTM with attention (system ID: 528232). In the voting model, we performed soft voting ensemble on four basic models: BiLSTM, BiGRU, BiLSTM with attention, and Capsule Network. In the stacking model, we performed stacking ensemble on four basic models: BiLSTM, BiGRU, BiLSTM with attention, and Capsule Network. Our team results according to those provided by the task organisers are shown in Table 2. Among the results of the four models submitted by our team, the BiLSTM with attention model performed the best, and its F1 (macro) was 0.7877. The accuracy was 0.843, ranking 16th among all participants. In addition, from the confusion matrix in Figure 1, it is observed that when the classifier predicts two classes of labels, namely NOT and OFF, it is more specific to the NOT label, and the precision for the NOT label is higher than that for the OFF label.

System ID	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
528015	0.7258	0.7872
528117	0.7817	0.836
528280	0.7667	0.8174
528232	0.7877	0.843

Table 2: Results for Sub-task A

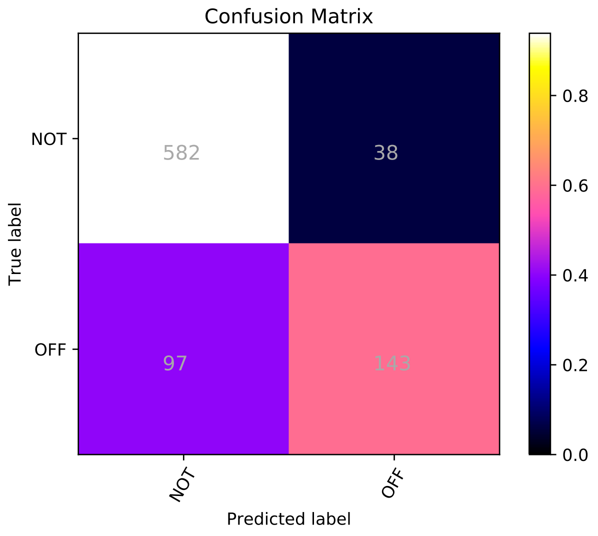

Figure 1: Sub-task A, YNU-HPCC CodaLab 528232

4.2 Task B

Sub-task B continues on the OFF label of Sub-task A. It includes 4400 training instances and 240 testing instances, as well as TIN and UNT labels. We used BERT (system ID: 533313), voting (system ID: 533291), and BiLSTM with attention (system ID: 533311) for predictions on the testing sets. The results of our team according to those provided by the task organisers are shown in Table 3. Among the results of the three models submitted by our team, the voting model performed best; its F1 (macro) was 0.6811, its accuracy was 0.8625, and it ranked 12th among all participants. Similar to the previous Sub-task, the confusion matrix in Figure 2 indicates that, for the TIN and UNT labels, the classifier is more sensitive to TIN labels. In terms of precision, the value for the TIN label is also higher than that for the UNT label.

System ID	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
533291	0.6811	0.8625
533311	0.6248	0.7833
533313	0.6530	0.8375

Table 3: Results for Sub-task B

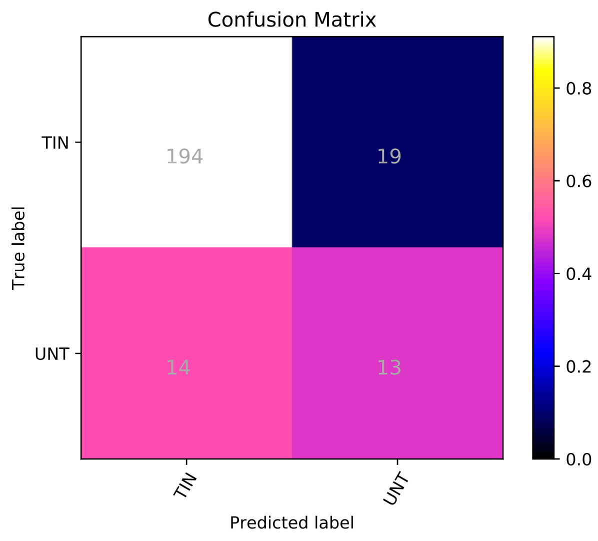

Figure 2: Sub-task B, YNU-HPCC CodaLab 533291

4.3 Task C

Sub-task C continues on the TIN label of Sub-task B. It includes 3876 training instances and 213 testing instances, as well as IND, OTH, and GRP labels. We used BERT (system ID: 536705) and voting (system ID: 537472) for predictions on the testing sets. The results of our team according to those provided by the task organisers are shown in Table 4. Among the results of the two models submitted by our team, the BERT model performed the best; its F1 (macro) was 0.6212, its accuracy was 0.7089, and it ranked 4th among all participants. Additionally, as shown in Figure 3, among the IND, OTH, and GRP labels, the highest recall and precision are for the IND labels, and the lowest are for the OTH labels.

For the three Sub-tasks, misclassifications of the classifier are likely due to data imbalance.

System ID	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
536705	0.6212	0.7089
537472	0.5377	0.6667

Table 4: Results for Sub-task C

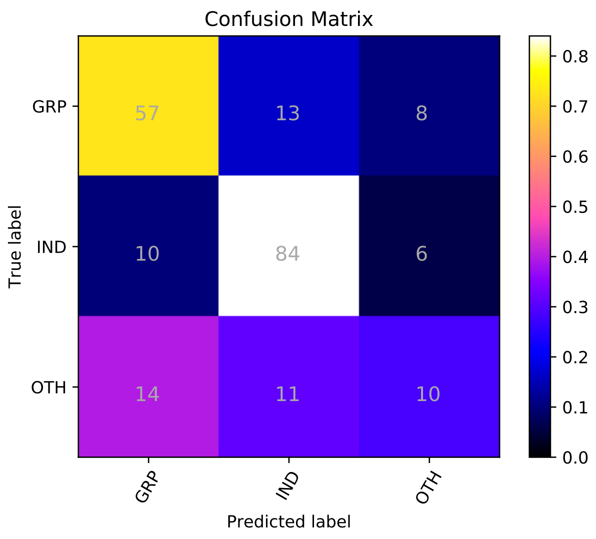

Figure 3: Sub-task C, YNU-HPCC CodaLab 536705

5 Conclusion

Identifying and categorising offensive language is a task that is drawing increasing attention. In this document, we described our four models submitted for Task 6 of the SemEval-2019 Workshop, which involved identifying and categorising offensive language on Twitter. These four models comprise not only traditional neural network models but also popular language models. Our model exhibited good performance in terms of the experimental results. In the three Sub-tasks, there appears to be significant room for improvement compared to the top-ranked participating systems. Therefore, in future work, we will focus on using more word embedding methods and managing data imbalance issues.

Abstract

This paper describes the system submitted to SemEval 2019 Task 6: OffensEval 2019. The task aims to identify and categorize offensive language in social media, we only participate in Sub-task A, which aims to identify offensive language. In order to address this task, we propose a system based on a K-max pooling convolutional neural network model, and use an argument for averaging as a valid meta-embedding technique to get a meta-embedding. Finally, we use a cyclic learning rate policy to improve model performance. Our model achieves a Macro F1-score of 0.802 (ranked 9/103) in the Sub-task A.

1 Introduction

In the past ten years, with the popularity of the Internet, social media platforms such as facebook and twitter have gradually become important tools for people's daily communication, and users can publish their own content on these platforms. As the number of people interacting on social media platforms increases, online aggression language behavior also grows, and now it has become a major source of social conflict.

Semeval 2019 Task 6 is proposed for identifying online offensive languages (Zampieri et al., 2019b). Its goal is to use computational methods to identify offense, aggression and hate speech in user-generated content on online social media platforms. We can prevent abuse of offensive language by using this approach in social media platforms. This task gives us some data from the social media platform, and classifies the content through computational analysis.

In this competition, we only participate in Subtask A: identification of offensive language. For this task, we use a deep learning method to build a K-max pooling convolutional neural network model which uses convolutional neural networks of different filters to extract features and preserves k largest eigenvalues during the pooling phase. We use two different pre-training vector models (fastText and Glove) to obtain a more accurate meta-embedding with a simple averaging technique (Coates and Bollegala, 2018). In addition, we have adopted a Cyclic Learning Rate (CLR) strategy (Smith, 2017), which avoids the process to find the optimal learning rate, and the learning rate varies within a reasonable interval rather than monotonically. Unlike the Adative Learning Rate, the CLR does not require additional calculations.

The rest of the paper is structured as follows: In section 2, we describe some of the relevant research work. In section 3, we describe the task data and how to build the model. In section 4, we describe the experimental results.

2 Related Work

In recent years, offensive language has prevailed in social media, and people are increasingly interested in identifying offensive speech, especially on social media platforms. This topic has attracted the attention of a large number of researchers in industry and academia. The field of Hate Speech Automatic Detection in the text has unquestionable social impact potential, especially in online communities and digital media platforms (Fortuna and Nunes, 2018). In this section, we will review some of the studies and briefly discuss their findings.

Dinakar et al. decomposed the overall detection problem into detection of sensitive topics, incorporated itself into the text classification subquestion, and solved the problem of text cyberbullying detection by constructing a separate topic-sensitive classifier(Dinakar et al., 2011). Burnap et al. used probabilities, based on the combination of rules and space-based classifiers and voting element classifiers to predict the possible spread of network hatred in Twitter data samples (Burnap and Williams, 2015). Kwok et al. used supervised machine learning methods to obtain tagged data from different Twitter accounts in an inexpensive way, and to learn the binary classifiers of the "racist" and "nonracist" tags (Kwok and Wang, 2013). Gambäck et al. built a convolutional neural network model based on word2vec embedding(Gambäck and Sikdar, 2017). And a new method for deep neural networks based on convolution and gated recursive networks was proposed by Zhang et al. (Zhang et al., 2018). In the field of research on hate speech, originally Xu et al. introduced the social study of bullying and formulated it as NLP tasks(Xu et al., 2012), then Ross et al. suggested that the existence of hate speech should not be considered as a binary yes or no decision, and the evaluator needs a more detailed commentary(Ross et al., 2016), and now ElSherief et al. believed that it is necessary to further deepen the understanding of online hate language to determine whether the target is individual or group (ElSherief et al., 2018).

3 Methodology and Data

3.1 Data description

In this task, we only use the official training data set for training and trial data set to verify. The official data provided by OLID is mainly from Twitter (Zampieri et al., 2019a). In Sub-task A, the purpose is to distinguish whether the tweet is offensive, so the data is divided into two categories: Not Offensive (NOT): Posts that do not contain offensive or defamatory; and Offensive (OFF): This category includes insults, threats, and posts that contain defamatory or cursed words. The training data set has a total of 13240 tweets, in which there are 8840 of NOT and 4400 of OFF, the ratio is about 2:1. The data is slightly unbalanced, but we have not dealt with the data imbalance problem.

3.2 K-max pooling CNN model

Our network architecture is shown in Figure 1. It is a variant of the CNN model structure proposed by Yoon Kim (Kim, 2014). Next we explain the details of our system.

- **Input layer:** This layer mainly inputs all the preprocessed text data into the model.

- **Embedding layer:** Converting text into word embeddings represents each word of the text with a d dimensional vector by using a pre-trained word vector model.

- **Convolutional layer:** In this layer, the obtained word vectors are subjected to convolution operations to obtain multiple feature maps. The specific operation is: a sentence contains L words, each of which has a dimension of d after the embedding layer, and forms a $L * D$ sentence representation by splicing L words. There are several convolution kernels in the convolutional layer, the size of which is $N * d$, and N is the filter window size. The convolution operation is to apply a convolution kernel to create a new feature in a matrix that is spliced by words. Its formula is as follows:

$$C_l = f(w * x_{(l:l+N-1)} + b) \qquad (1)$$

where l represents the lth word, c_l is the feature, w is the convolution kernel, b is the bias term, and f is a nonlinear function. After the convolution operation of the whole sentence, a feature map is obtained, which is a vector of size $L + N - 1$.

- **Pooling layer:** The main function of this layer is to perform dimensionality reduction on the features of filter to form the final feature with a K-max pooling operation, which takes the value of the scores in Top K among all the feature values, and retains the original order of these feature values. Obviously, K-max Pooling can express the same type of feature multiple times, that is, it can express the intensity of a certain type of feature; In addition, because the relative order of these Top K eigenvalues is preserved, it should be said that it retains part of the position information. However, this location information is only the relative order between features, not absolute location information. For example: "I think the scenery in this place is not bad, but there are too many people." Although the first half reflects the positive emotions, the global text expresses the negative emotions, and K-max pooling can capture such information.

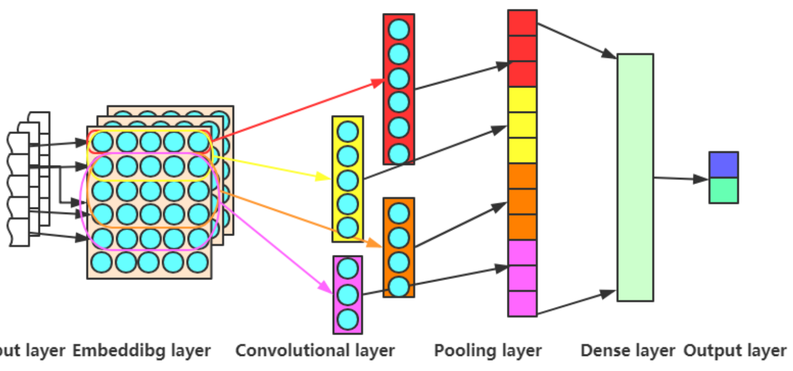

Figure 1: The architecture of K-max pooling CNN model

- **Fully connected layer:** In this model architecture, there are two layers of fully connected layers. The first layer receives the feature vectors obtained by the pooling layer, and the last layer is used for classification and prediction.

3.3 Word embedding

We use two different pre-trained word embeddings, fastText and Glove. FastText is provided by Mikolov et al. (Mikolov et al., 2018), it is a 2 million word vector trained using subword information on Common Crawl with 600B tokens, and its dimension is 300. Glove is provided by Jeffrey Pennington et al. (Pennington et al., 2014), it is a 2.2 million word vector trained using subword information on Common Crawl with 840B tokens, and its dimension is also 300.

We use a mathematical mean of the word vectors by fastText and Glove to produce a high performance word vector. Since the principles between fastText and Glove are different, the word vector representation of the same word is also slightly different, and the average embedding set retains semantic information through preservation of the relative distances between words (Coates and Bollegala, 2018).

3.4 CLR

In this article, we use the cyclic learning rate strategy provided by Leslie N . Smith (Smith, 2017), which is a new method of setting the global learning rate. The advantage is that it avoids a lot of experiments to find the optimal learning rate and can be faster. We set the base learning rate and the maximum learning rate so that the learning rate fluctuates cyclically within this interval. The wave method we use is exp_range, which is a triangle loop that scales the loop magnitude by a factor while keeping the initial learning rate constant.

4 Experiment and results

4.1 Data preprocessing

Text from tweets are inherently noisy. Tweets are processed using tweettokenize tool. Cleaning the text before further processing helps to generate better features and semantics. We perform the following preprocessing steps.

- The “#” symbol is removed and the word itself is retained for hashtags.
- All of “@user” is replaced with username. Username mentions, i.e. words starting with “@”, generally provide no information in terms of sentiment. Hence such terms are removed completely from the tweet.
- Repeated full stops, question marks and exclamation marks are replaced with a single instance with a special token ”repeat” added.
- All contractions are split into two tokens(e.g.: “it’s” is changed to “it” and “is”).
- Emoticons (for example, ‘:(’, ‘:)’, ‘:P’ and emoji etc) are replaced with their own meanings by emotion lexicons.
- Lemmatization, restoring language vocabulary to general form (can express complete semantics) by WordNetLemmatizer.
- Tokens are converted to lower case.

4.2 Experiment setting

We use 4-fold cross validation on the training data, because in this experiment we experimented with cross-validation of different k values, and found that the 4-fold cross-validation effect is the best. In addition the batch size is to 512 and the epoch to 20. In our model, the dimension of embeding is 300. Between the embedding layer and the convolution layer we add the SpatialDropout1D layer with a value of 0.2. In the convolution layer, we set up four convolution kernels of different window sizes, which are 1, 2, 3 and 4, the number of filters is 180, the kernel initializer is $normal$, the activation function is $relu$; in the pooling layer we set the k value to 3. Before the fully connected layer, we add a dropout layer, and the rate is 0.6. The activation function of the final output layer is $sigmoid$ for binary classification. The loss function of this model is $binary\ crossentropy$, and the optimizer is $adam$.

For the cyclical learning rate, we set the base learning rate to 0.001, the maximum learning rate to 0.002, the step size to 300, and the scaling factor gamma to 0.99994.

4.3 Result analysis

This Sub-task A is to evaluate the classification system by calculating the marco F1 score. According to the official ranking of Sub-task A, our model has a marco F1 score of 0.8024, ranked 9th, and our result is much higher than the official baseline. The results of the official baseline and our model are shown in Table 1.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
Our model	**0.8024**	**0.8453**

Table 1: Results for Sub-task A

The confusion matrix of our model prediction results in Sub-task A is shown in Figure 2. There are 620 NOT tags in the test dataset, and 240 OFF tags. As can be seen from the confusion matrix, our model has a lot of OFF prediction errors into NOT, about 32% of OFF are predicted to be NOT, while only about 9% of NOT are predicted to be OFF.

4.4 Influence of Word Embedding

The effect of the average meta-embedding technique is shown in Table 2. In this table, the results of fastText, Glove, the word vector generated by concatenating fastText and Glove and the vector

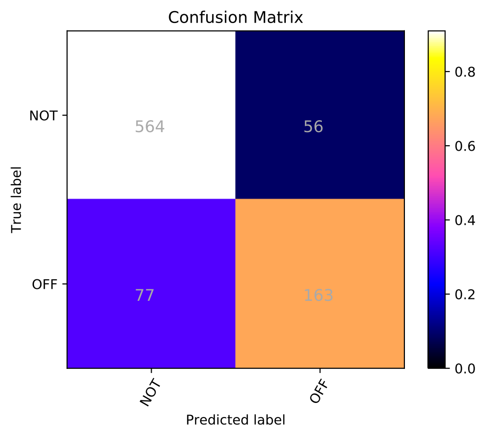

Figure 2: Confusion matrix of K-max pooling CNN model for Sub-task A

generated by the average meta-embedding technique are compared, and the result is obtained in the trial data set. The results show that this average meta-embedding technique can improve the performance of the model.

word vector	F1 (macro)
fastText	0.8138
Glove	0.7895
concatenated	0.8165
average meta-embedding	**0.8242**

Table 2: Influence of word embedding in trial data set for Sub-task A

As can be seen from Table 2, the concatenated can also improve the performance of the model, but increases the dimension of word embeddings to 600. While the meta-embedded dimension will not exceed the maximum dimension existing in the source embedding.

5 Conclusion

In this paper, we present a K-max pooling convolutional neural network model based on average meta-embedding technology for offensive language detection, which relies solely on the data sets provided to generate competitive results. However, the data imbalance problem will affect the performance of the model, which makes the model prediction tend to be biased towards a high amount of data. In the future work, we will strengthen the processing of data imbalance problems, and try to extract some NER features from the data to further improve the performance of the model.

Zeyad at SemEval-2019 Task 6: That's Offensive! An All-Out Search For An Ensemble To Identify And Categorize Offense in Tweets

Zeyad El-Zanaty
Faculty of Engineering
Alexandria University
zeyadzanaty@gmail.com

Abstract

The objective of this paper is to provide a description for a classification system built for SemEval-2019 Task 6: OffensEval. This system classifies a tweet as either offensive or not offensive (Sub-task A) and further classifies offensive tweets into categories (Sub-tasks B - C). The system consists of two phases; a brute-force grid search to find the best learners amongst a given set and an ensemble of a subset of these best learners. The system achieved an F1-score of 0.728, ranking in subtask A, an F1-score score of 0.616 in subtask B and an F1-score of 0.509 in subtask C.

1 Introduction

In OffensEval we break down offensive content into three sub-tasks taking the type and target of offenses into account. Sub-task A - Offensive language identification; In this sub-task we are interested in the identification of offensive posts and posts containing any form of (untargeted) profanity. In this sub-task there are 2 categories in which the tweet could be classified Not Offensive - This post does not contain offense or profanity. Non-offensive posts do not include any form of offense or profanity. Sub-task B - Automatic categorization of offense types; In this sub-task we are interested in categorizing offenses. Tweets are labeled from one of the following categories Targeted Insult - A post containing an insult or a threat to an individual, group, or others; Untargeted - A post containing non-targeted profanity and swearing. Posts containing general profanity are not targeted but they contain non-acceptable language. On the other hand, insults and threats are targeted at an individual or group. Sub-task C - Offense target identification. Finally, in sub-task C we are interested in the target of offenses. Only posts which are either insults or threats are included in this sub-task. The three categories included in sub-task C are the following: Individual - The target of the offensive post is an individual: a famous person, named individual or an unnamed person interacting in the conversation. Group - The target of the offensive post is a group of people considered as a unity due to the same ethnicity, gender or sexual orientation, political affiliation, religious belief, or something else. Other The target of the offensive post does not belong to any of the previous two categories (e.g. an organization, a situation, an event, or an issue).(Zampieri et al., 2019b)

To work with such complicated tasks our approach is an exhaustive one. We try combinations of many techniques in pre-processing, feature extraction and classification while tuning their hyper-parameters to find the best models with the leading F1-scores. With the gained information an ensemble of the top three models is formed to get the optimum result. Along side to this approach we try a deep-learning method with a simple 1D - CNN consisting of 3 convolutional layers and a softmax layer just to compare results.

2 Related Work

Offensive language on social media hardly remains unnoticed. Contents involving hateful messages vary from hate speech to group-based racism and could target anyone irrespective of their status, identity, location and so forth. Even when it is not materialized into a hate-motivated crime, the damage is done victims are being labeled, marginalised and exposed to negative stereotyping. The overall consequences of online hate can be the dehumanisation of individuals or groups of individuals. The need for proper strategies to tackle hate speech on social media

Proceedings of the 13th International Workshop on Semantic Evaluation (SemEval-2019), pages 823–828
Minneapolis, Minnesota, USA, June 6–7, 2019. ©2019 Association for Computational Linguistics

is unquestionable. The core focus of the thesis is not to find a solution to the challenge, but rather to identify central problems that have contributed to the formation of the existing reality. To unrave the contributing factors, a holistic analysis of both international human rights principles regarding hate speech and the practical application of those standards is necessary.(Schofield and Davidson, 2017)

There have been many studies and publication on the topic of offensive language and hate speech over the last few years. Examples on such studies include (Davidson et al., 2017), (Malmasi and Zampieri, 2017), (ElSherief et al., 2018), (Gambäck and Sikdar, 2017), (Zhang et al., 2018). Also there have been challenges on how to distinguish profanity from hate-speech presented by (Malmasi and Zampieri, 2018).

3 Methodology and Data

The used dataset in this assignment is the one provided in SemEval-2019 task 6. The dataset has been collected from Twitter. It was retrieved by searching offensive terms that could be present in a tweet. It consists of 14,100 tweets in total. It was annotated using crowdsourcing. The gold labels were assigned taking the agreement of three annotators into consideration. No correction has been carried out on the crowdsourcing annotations. The dataset was presented in two phases; Training data: already labeled tweets used to train the classifiers. Each tweet was provided with a binary classification label and an index. Testing data: unlabeled tweets to test the classifiers against. Zampieri et al. (2019a).

The system is a combination of three essential layers. First, pre-processing which is a necessary step in NLP as textual data could and most likely is not clean, thus will affect further stages and create an incoherent model. Second, feature extraction or vectorization, which translates words to a number or a series of numbers with different weights to represent this word. Finally, classification, features extracted from the previous step is fed into a learner and a model is created that could classify tweets.

For our approach we implemented a heap of pre-processors, vectorizers and classifiers and with the help of brute-froce search ranked all the resulting models according to their F1-scores. All implemented techniques are available in Table 1. For the implementation see: `github.com/zeyadzanaty/offenseval`

Phase	Implemented Techniques
Pre-processing	Stopwords Removal Lemmatization - Stemming
Feature Extraction	TFIDF - Count - Word Embedding
Classification	KNN - Naive Bayes - Decision Trees - SVM -Random Forest Logistic Regression - MLP

Table 1: Multiple techniques implemented in our system.

3.1 Pre-processing

A tweet contains many unwanted data that would take extra computational power and decrease the accuracy of the model. So, noise removal and some normalization techniques must be applied to the corpus in-order to generate more consistent models. **Stopword Removal** is a noise removal method by filtering words that dont have significance in the context of the sentence, without them the semantics of the tweet wont be affected. **Lemmatization** is the process of getting the linguistic root of a word. First, words are part-of-speech tagged , then converted to their roots. **Stemming** is the process of stripping a word of it's prefixes and suffixes using the porter-stemmer algorithm (Porter, 1980).

For this step, a list of all combinations of pre-processing techniques is used. For example it would look something like: [(Stopwords Removal), (Stowords Removal, Lemmatization), (Stopwords Removal, Stemming), (Lemmatization), etc..]

3.2 Feature Extraction

Now that we've got our clean, almost noise-free textual data, we cant simply feed a classification model a bunch of text words, most models only work with numerical data. This is where we convert words to numerical features using

one the methods mentioned below to create our classification-ready data.
We use three word embedding models of embedding dimension 100 (which gave adequate results after experimenting with other dimensions) along side to the standard **TFIDF/Count** models.

- Word2Vec model trained on our dataset.(Mikolov et al., 2013)
- fastText model trained on our dataset.(Joulin et al., 2016)
- Pre-trained GloVe model trained on 2 Billion tweets - 27 Billion tokens - 1.2 million vocabulary.(Pennington et al., 2014)

All three models mentioned are zero-padded with the maximum length of a tweet present in the dataset to resolve the uneven dimensionality issue. A list of all techniques is initialized for later usage in the search for the best model.

3.3 Classification and Tuning

This is where all the previous work comes together for the final phase of the system. Seven models where chosen and tuned using sci-kit learns (Pedregosa et al., 2011) GridSearchCV, which does a cross validation search on a list of hyper-parameters for a given model. The parameters grids that were tested are available in Table 2.

Model	Parameters Grid
KNN	n_neighbours: [1, 3, 5, 7]
Naive Bayes	fit_prior: [True, False]
SVM	C: [0.1,10,100] kernel: [rbf, poly]
Decision Trees	criterion: [gini, entropy]
Random Forest	n_estimators: [10 - 200]
Logistic Regression	penalty : [l2] solver: [sag, lbfgs, newton]
MLP	activation:[tanh, relu] solver: [sgd,adam, lbfgs]

Table 2: Classification models and their corresponding parameters to tune.

Again, a list of classifiers and their parameters grids is initialized to tune them with a 3-fold cross validation.

3.4 All-Out Search

This is the body of all the work. We try every possible combination of pre-processing, vectorization and classification to ensure the output has the best possible F1-score for the given subtask. We start by cleaning the data using a certain combination of pre-processors, then extracting features using one of the vectorizers and finally to complete the pipeline, tune a classifier's hyper-parameters on the resulting data-matrix. And repeat for the next combination.

```
1: procedure SEARCH($preprocessors$, $vectorizers$, $classifiers$)
2:     $models \leftarrow \{\}$
3:     for $prp \in preprocessors$ do
4:         clean-data(prp)
5:         for $vec \in vectorizers$ do
6:             vectorize-data(vec)
7:             for $clf \in classifiers$ do
8:                 $models[clf] \leftarrow tune(clf)$
9:     $sort(models)$
```

The resulting set 'models' is a set of each classifier and a list of parameters and their corresponding preprocessors, vectroizers and F1-scores. The results could be plotted to help visualize the performance of each model seen in Figure 1, which

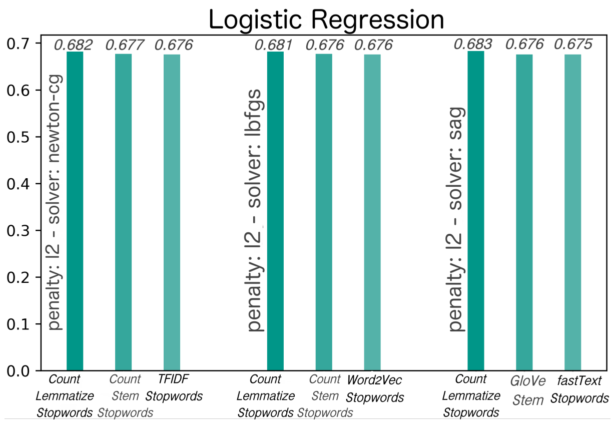

Figure 1: F1-scores of logistic regression model on subtask A, each bar is a model with it's own pre-processing, vectorizer and parameters.

shows the top 3 models for the logistic regression classifier. Each 3 bars represent the hyper-parameters combination and the top 3 combinations of pre-processing and vectorization. The best F1-score (0.683) came from a pre-processing of stopwords removal followed by lemmatization, a count vectroizer and hyper-parameters [penalty: l2, solver: sag]. Following this search, now that

Subtask	Phase	1st	2nd	3rd
A	Pre-processing	Stopwords Removal & Lemmatization	Stopwords Removal & Stemming	Lemmatization
	Vectorization	Count	Count	Count
	Classification	Logistic Regression	Naive Bayes	Random Forest
B	Pre-processing	Lemmatization	Lemmatization	Stopwords-Removal
	Vectorization	TFIDF	TFIDF	GloVe-Embeddings
	Classifiaction	Naive Bayes	Random Forest	MLP
C	Pre-processing	Lemmatization	Stopwords Removal	Stemming
	Vectorization	Count	Count	Count
	Classification	Random Forest	Logistic Regression	Naive Bayes

Table 3: Top 3 models for each subtask, these 3 models will form an ensemble to enhance the performance.

we have the scores of each model, we can model an ensemble of the top 3 models to give us a better overview of the data available in Table 3. And just to add an extra layer we can re-tune the classifier parameters in case of any error that could have appeared in the previous step.

4 Results

We submitted with a couple of models, for subtask A, an ensemble of the three top models mentioned in Table 3, the Random Forest model and a 1-D CNN. The ensemble did its best in subtask A but the Random Forest (RF) model came a very close second. Results can be viewed in Table 4, and confusion matrix Figure 2.

System	F1 (macro)	Accuracy
All NOT baseline	0.4189	0.7209
All OFF baseline	0.2182	0.2790
Ensemble	**0.7289**	**0.8151**
Random Forest	0.7143	0.8128
1D-CNN	0.5506	0.6977

Table 4: Results for Sub-task A. The ensemble approach gave the best results.

As for subtask B, the ensemble submission unfortunately failed, but it didn't look good anyway. The best model was as simple Naive Bayes (NB)-TFIDF model which got a very good F1-score of 0.887. Results can be viewed in Table 5, and confusion matrix Figure 3.

System	F1 (macro)	Accuracy
All TIN baseline	0.4702	0.8875
All UNT baseline	0.1011	0.1125
1D-CNN	0.4436	0.5542
Naive Bayes	**0.6161**	**0.8542**

Table 5: Results for Sub-task B. The best performer was a simple TFIDF - Naive Bayes model.

Finally, for subtask C, we chose to let go of the CNN model as it didn't get an acceptable result, and went for the ensemble, which got the best accuracy but came second for F1-scores and the RF model which also got a good accuracy but a poor F1-score, and the best model was a logistic regression-count model with an F1-score of 0.5093. Results can be viewed in Table 6, and confusion matrix Figure 4.

System	F1 (macro)	Accuracy
All GRP baseline	0.1787	0.3662
All IND baseline	0.2130	0.4695
All OTH baseline	0.0941	0.1643
Ensemble	0.4973	0.6479
Random Forest	0.4763	0.6432
Logistic Regression	**0.5093**	**0.6056**

Table 6: Results for Sub-task C. The ensemble got the best accuracy but, LR got a better F1-score.

Looking at these results, we hypothesize that the systems performance can be improved by combining all word embedding features instead of using them individually. It was also remarkable that the for most subtasks a simple Naive Bayes - TFIDF model came close to being the best amongst all others. We also believe better results can be achieved if there was the dataset was more balanced and having more offensive tweets, and if we had sufficient time to perform grammar checking on the tokens and other operations that can reduce noise. The problem of out-of-vocabulary (OOV) words which we unfortunately didn't attempt to solve, could be later be solved by using a character-level embedding model rather than a word embedding one.

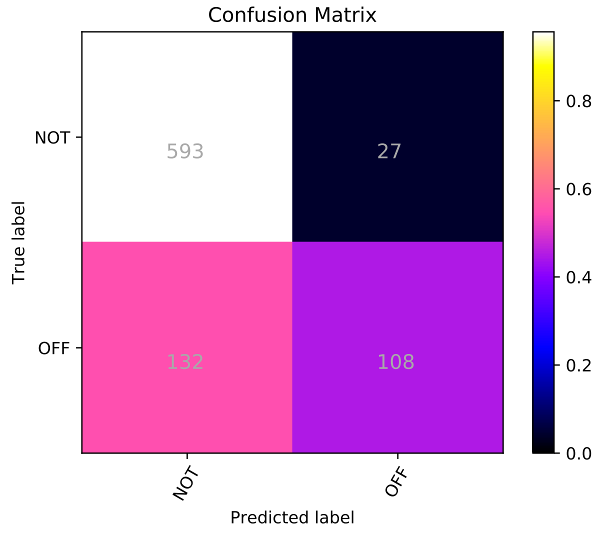

Figure 2: Sub-task A, Ensemble of LR-NB-RF

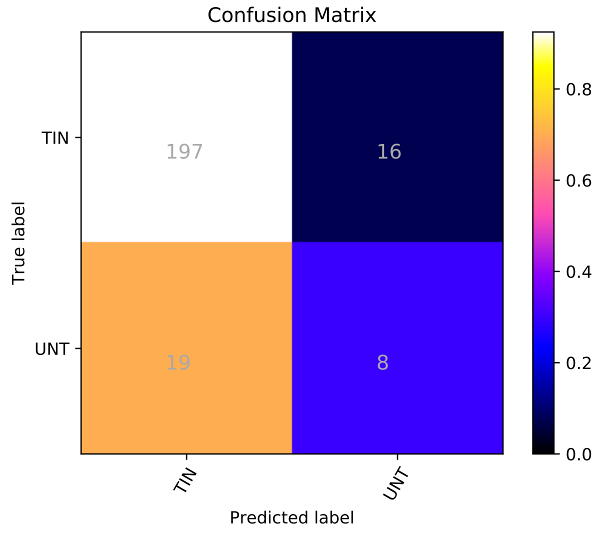

Figure 3: Sub-task B, Naive Bayes - TFIDF - Lemmatization

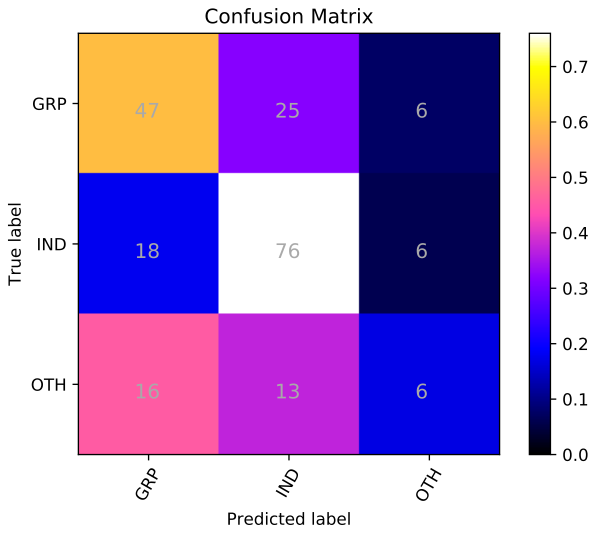

Figure 4: Sub-task C, Logistic Regression - Count - Stopwords Removal

5 Conclusion

This paper describes our offensive tweets identification and categorization system that was built in the framework of SemEval-2019 Task 6. We used a brute-force search technique to find the best model that could be generated from a list of prepocessing techniques, feature extraction models and classifiers and got an F1-sore of 0.728 in subtask A, 0.6161 in subtask B and 0.5093 in subtask C. In future work, we aim to focus more on word embedding features by concatenating all 3 word vector models and experiment with character-level/sentence-level models.

Abstract

Hyperpartisan news is news that takes an extreme left-wing or right-wing standpoint. If one is able to reliably compute this meta information, news articles may be automatically tagged, this way encouraging or discouraging readers to consume the text. It is an open question how successfully hyperpartisan news detection can be automated, and the goal of this SemEval task was to shed light on the state of the art. We developed new resources for this purpose, including a manually labeled dataset with 1,273 articles, and a second dataset with 754,000 articles, labeled via distant supervision. The interest of the research community in our task exceeded all our expectations: The datasets were downloaded about 1,000 times, 322 teams registered, of which 184 configured a virtual machine on our shared task cloud service TIRA, of which in turn 42 teams submitted a valid run. The best team achieved an accuracy of 0.822 on a balanced sample (yes : no hyperpartisan) drawn from the manually tagged corpus; an ensemble of the submitted systems increased the accuracy by 0.048.

1 Introduction

Yellow journalism has established itself in social media, nowadays often linked to phenomena like clickbait, fake news, and hyperpartisan news. Clickbait has been its first "success story" (Potthast et al., 2016): When the viral spreading of pieces of information was first observed in social networks, some investigated how to manufacture such events for profit. Unlike for "natural" viral content, however, readers had to be directed to a web page containing the to-be-spread information alongside paid-for advertising, so that only teasers and not the information itself could be shared. Then, to maximize their virality, data-driven optimization revealed that teaser messages which induce curiosity, or any other kind of strong emotion, spread best. The many forms of such teasers that have emerged since are collectively called clickbait. New publishing houses arose around viral content, which brought clickbait into the mainstream. Traditional news publishers, struggling for their share of the attention market that is a social network, adopted clickbait into their toolbox, too, despite its violation of journalistic codes of ethics.

The content spread using clickbait used to be mostly harmless trivia—entertainment and distraction to some, spam to others—, but in the wake of the 2016 United States presidential election, "fake news" came to widespread public attention. While certainly not a new phenomenon in yellow journalism, its viral success on social media was a surprise to many. Part of this success was then attributed to so-called hyperpartisan news publishers (Bhatt et al., 2018), which report strongly in favor of one political position and in fierce disagreement with its opponents. Clinging to hyperpartisanship often entails stretching the truth, if not breaking it with fake news, whose highly emotional content makes them spread exceptionally fast, like clickbait.

Given the hype surrounding fake news, activists, industry, and research are now paying a lot of attention to mitigating the problem, such as trying to check facts in news items. Clickbait and hyperpartisan news, however, have been less studied. In previous work, we sought to help close this gap from both ends: for clickbait detection (Potthast et al., 2016), part of our group created a large-scale evaluation dataset (Potthast et al., 2018b) and set up an ongoing competition for the best detection approach (Potthast et al., 2018a). For hyperpartisan news detection (Potthast et al., 2018c), we teamed up to follow a similar approach that led to the Hyperpartisan News Detection task at SemEval-2019. This paper reports on the results of this task.

2 Task Definition

We define hyperpartisan news detection as follows:

> Given the text and markup of an online news article, decide whether the article is hyperpartisan or not.

Hyperpartisan articles mimic the form of regular news articles, but are one-sided in the sense that opposing views are either ignored or fiercely attacked. We deliberately disregard the distinction between left and right, since previous work has found that, in hyperpartisan form, both are more similar to each other in terms of style than either are to the mainstream (Potthast et al., 2018c). The challenge of this task is to unveil the mimicking and to detect the hyperpartisan language, which may be distinguishable from regular news at the levels of style, syntax, semantics, and pragmatics.

3 Data

Our focus is on news articles published online, and we provide two datasets with this task. One has 1,273 articles, each labeled manually, while the second, larger dataset of 754,000 articles is labeled in a semi-automated manner via distant supervision at the publisher level. These datasets are further split into public and private sets. We released the public set for the model training, tuning, and evaluation,[1] while the unreleased private set is used to enable blind, cloud-based evaluation.

As online news articles are published mainly in the HTML format, both datasets use a unified HTML-like format (see Figure 1). We restricted the markup for the article content to paragraphs (`<p>`), links (`<a>`), and quotes (`<q>`). We distinguished *internal* links to the other pages of the same domain, from which we removed the href-attribute value to avoid classifiers fitting to them; and links to *external* domains, for which we kept the attribute. An XML schema that exactly specifies the format is distributed along the datasets.

3.1 Dataset Annotated By Article

We gathered a crowdsourced dataset of 1,273 articles, each labeled manually by 3 annotators (Vincent and Mestre, 2018). These articles were published by active hyperpartisan and mainstream websites and were all assured to contain political news. Annotators were asked to rate each article's bias on the following 5-point Likert scale:

[1]https://doi.org/10.5281/zenodo.1489920

1. No hyperpartisan content
2. Mostly unbiased, non-hyperpartisan content
3. Not Sure
4. Fair amount of hyperpartisan content
5. Extreme hyperpartisan content

We removed all articles from the dataset with low agreement score and the aggregated rating of "not sure" (see Vincent and Mestre for more details). We then binarized the labels to hyperpartisan (average rating of 4 or 5) and not (average rating of 1 or 2). The final by-article set achieved an inter-annotator agreement of 0.5 Krippendorff's alpha. Of the remaining 1,273 articles, 645 were published as a training dataset, whereas the other 628 (50% hyperpartisan and 50% not) were kept private for the evaluation. To ensure that classifiers could not profit from overfitting to publisher style, we made sure there was no overlap between the publishers of the articles between these two sets.

3.2 Dataset Annotated By Publisher

To allow for methods that require huge amounts of training data, we compiled a dataset of 754,000 articles, each labeled as per the bias of their respective publisher. To create this dataset, we cross-checked two publicly available news publisher bias lists compiled by media professionals from BuzzFeed news[2] and Media Bias Fact Check.[3] The former was created by BuzzFeed journalists as a basis for a news article, whereas the latter is Media Bias Fact Check's main product. While both lists contain several hundred news publishers, they disagree only for nine, which we removed from our dataset.

We then crawled, archived, and post-processed the articles available on the publishers' web sites and Facebook feeds. We archived all articles using a specialized tool (Kiesel et al., 2018) that removes pop-overs and similar things preventing the article content from being loaded. After filtering out publishers that did not mainly publish political articles or had no political section to which we could restrict our crawl, we were left with 383 publishers. For each of the publishers' web sites we wrote a content-wrapper to extract the article content and relevant meta data from the HTML DOM. We then removed all articles that were too short to contain news,[4] that are not written in English,

[2]https://github.com/BuzzFeedNews/2017-08-partisan-sites-and-facebook-pages

[3]https://mediabiasfactcheck.com

[4]Based on manual inspection of a hundred short articles, we set the threshold to 40 words.

```

New York Times.  Leslie, author of <a href="" type="internal">Deep Water:  The Epic
Struggle Over Dams, Displaced People and the Environment</a>, highlights the threat
posed by poorly maintained and increasingly failing dams around the country:</p>
<p>Unlike, say, waterways and sanitation plants, a majority of dams - 56 percent of
those inventoried - are privately owned, which is one reason dams are among the
country’s most dangerous structures.  Many private owners can’t afford to repair
aging dams; some owners go so far as to resist paying by tying up official repair
demands in court or campaigning to weaken state dam safety laws.</p>
<p>Kinda makes you want to find out what is upstream.</p> </article>
```

Figure 1: Example of a non-hyperpartisan article in our dataset. An archived version of the original article is available at https://web.archive.org/web/20121006194050/https://grist.org/article/remember-the-dams/.

or that contain obvious encoding errors. The final dataset consisted of 754,000 articles, split into a public training set (600,000 articles), a public validation set (150,000 articles) and a non-public test set (4,000 articles). Like for the by-article dataset, we ensured that there is no overlap of publishers between the sets. Each set consists of 50% articles from non-hyperpartisan publishers and 50% articles from hyperpartisan publishers, the latter again being 50% from left-wing and 50% from right-wing publishers.

4 Fairness and Reproducibility

In this shared task, we asked participants to submit their software instead of just its run output. The submissions were executed at our site on the test data, enabling us to keep the test data entirely secret. This has two important advantages over traditional shared task setups: first, software submission gives rise to blind evaluation; and second, it maximizes the replicability and the reproducibility of each participant's approach. To facilitate software submission and to render it feasible in terms of work overhead and flexibility for both participants and organizers, we employ the TIRA Integrated Research Architecture (Potthast et al., 2019).

A shortcoming of traditional shared task setups is that typically the test data are shared with participants, albeit without ground truth. Although participants in shared tasks generally exercise integrity and do not analyze the test data other than running their software on it, we have experienced cases to the contrary. Such problems particularly arise in shared tasks where the stakes are higher than usual; when monetary incentives are offered or winning results in high visibility. A partial workaround is to share the test data only very close to the final submission deadline, minimizing analysis opportunities. But if sharing the test data is impossible for reasons of sensibility and proprietariness, or because the ground truth can be easily reverse-engineered, a traditional shared task cannot be held.

Another shortcoming of traditional shared tasks (and many computer science publications in general) is their lack of reproducibility. Although sharing the software underlying experiments as well as the trained models is easy, and although it would greatly aid reproducibility, this is still rare. Typically, all that remains after a shared task are the papers and datasets published. Given that shared tasks often establish a benchmark for the task in question, acting normative for future evaluations, this outcome is far from optimal and comparably wasteful. All of the above can be significantly improved upon by asking participants not to submit their software's run output, but the software itself. However, this entails a significant work overhead for organizers, especially for larger tasks.

In order to mitigate the work overhead, we employ TIRA. In a nutshell, TIRA implements evaluation as a service in the form of a cloud-based evaluation platform. Participants deploy their software into virtual machines hosted at TIRA's cloud, and then remotely control the machines and the software within, executing it on the test data. The test data are available only within the cloud, and made accessible on demand so that participants cannot access it directly. At execution time, the virtual machine is disconnected from the internet, copied, and only the copy gets access to the test data. Once the automatically executed software terminates, its run output is saved and the virtual machine copy is destroyed so as to prevent data leaks. This way, all submitted pieces of software can be archived in working condition, and be re-evaluated at a later time, even on new datasets.

5 Participating Systems

This task attracted a very diverse and interesting set of solutions from the participating teams. The teams employed very different sets of features, a wide variety of classifiers, and also employed the large by-publisher dataset in different ways. Around half of the submissions used hand-crafted features. In the following, we give an overview of the submitted approaches. For a more readable and condensed form, we only use the team names here, which were chosen from fictional journalistic characters or entities (see Table 1 for references).

5.1 Features

The teams that participated in this task employed a variety of features, including standard word n-grams (also unigrams, i.e., bag-of-words), word embeddings, stylometric features, HTML features like the target of hyperlinks, and a meta data feature in the form of the publication date.

N-Grams Most teams that used hand-crafted features also included word n-grams: Pioquinto Manterola and Tintin used them as their only features. Character and part-of-speech n-grams were, for example, used by Paparazzo.

Word embeddings Many teams integrated word embeddings into their approach. Frequently used were Word2Vec, fastText, and GloVe. Noticeably, Tom Jumbo Grumbo relied exclusively on them. Bertha von Suttner relied on ELMo embeddings (Peters et al., 2018), which have the advantage of modeling polysemy. Where the aforementioned word embeddings all rely on neural networks, Doris Martin employed a document representation based on word clusters as part of their approach.

BERT (Devlin et al., 2018), which jointly conditions on both left and right context in all layers, is a rather new technique that was used by several teams. Peter Parker directly applied a freely available pre-trained BERT model to the task, whereas Howard Beale and Clint Buchanan trained their own BERT models on the by-publisher dataset and then performed fine-tuning on the by-article dataset. Despite the fine-tuning, Howard Beale reported overfitting issues for this strategy. Going one step further, Jack Ryder and Yeon Zi integrated BERT in their neural network architectures.

Stylometry Many teams used stylometric features including punctuation and article structure (Steve Martin, Spider Jerusalem, Fernando Pessa, Ned Leeds, Carl Kolchak, Orwellian Times), readability scores (Ned Leeds, Pistachon, Steve Martin, Orwellian Times, D X Beaumont), or psycholinguistic lexicons (Ned Leeds, Spider Jerusalem, Steve Martin, Pistachon). Borat Sagdiyev employed a self-compiled list of trigger words that contains mostly profanities. They noticed that such words are used more often in hyperpartisan articles.

Emotionality Several teams used sentiment and emotion features, either based on libraries (Borat Sagdiyev, Steve Martin, Carl Kolchak) or lexicons (Spider Jerusalem, D X Beaumont). Notably, Kermit the Frog uses sentiment detection only. Vernon Fenwick and D X Beaumont used subjectivity and polarity metrics as features.

Named entities Borat Sagdiyev used named entity types as features. In preliminary tests only the type of "nationalities or religious and political groups" was found to be predictive.

Quotations A few teams treated quotations separately. Whereas Spider Jerusalem and Borat Sagdiyev created separate features from quotations, the Ankh Morpork Times filtered them out for not necessarily representing the views of the author.

Hyperlinks Only few teams considered hyperlinks. Both Borat Sagdiyev and Steve Martin used external lists of partisan web pages to count how often an article links to partisan and non-partisan pages. They assume that articles tend to link other articles on the same side of the political spectrum.

Publication date Based on the conjecture that months around American elections could see more hyperpartisan activity, Borat Sagdiyev used the publication month and year as separate features.

5.2 Classifiers

While many different classifiers were used overall, neural networks were the most frequent, which mirrors the current trend in text classification.

The most popular type of neural networks among the participants were convolutional ones (CNNs), which employ convolving filters over neighboring words. Many teams cited the architecture by Kim (2014). Xenophilius Lovegood added a second layer to their CNN in order to encode more information about the articles, using both available and custom-learned embeddings. While Pioquinto Manterola experimented with a CNN, it suffered from overfitting and was thus not used for the final submission. Peter Brinkmann built a submission using available embeddings. Brenda Starr combined a CNN with a sentence-level bidirectional recurrent neural network and an attention mechanism to a complex architecture. A similar approach was employed by the Ankh Morpork Times. An ensemble of three CNN-based models was used by Bertha von Suttner. Steve Martin used a character bigram CNN as part of their approach.

Next to CNNs, long short term memory networks (LSTM) were employed by Kit Kittredge and Miles Clarkson. The latter extended the network with an attention model. Moreover, Joseph Rouletabille used the hierarchical attention network of Yang et al. (2016).

Besides neural networks, a wide variety of classifiers were used. A few teams opted for SVMs (e.g., the Orwellian Times), others for random forests (e.g., Fernando Pessa), linear models (e.g., Pistachon), the Naive Bayes model (e.g., Carl Kolchak), XGBOOST (Clark Kent), Maxent (Doris Martin), and rule-based models (Harry Friberg). Morbo used ULMFit (Howard and Ruder, 2018) to adapt a language model pre-trained on Wikipedia articles to the articles and classes of this task.

5.3 Usage of the By-publisher Dataset

The submitted systems can also be distinguished by whether and how they used the large, distantly-supervised by-publisher dataset. Though much larger than the by-article set, its labels are noisy, whereas the opposite holds for the by-article dataset. One of the key challenges faced by many teams was how to train a powerful expressive model on the smaller dataset without overfitting. Most teams made use of the larger dataset in some form or another. A challenge faced by some of the teams was that the test split of the by-article dataset was balanced between classes, whereas the corresponding training dataset was not.

Several systems trained the whole or part of their system on the by-publisher dataset. Some extracted features like n-grams (e.g., Sally Smedley), word clusters (Doris Martin), or neural network word embeddings (e.g., Clint Buchanan). Others used the larger dataset to perform hyperparameter search (e.g., Miles Clarkson). Many teams trained their models using the by-publisher dataset only (Pistachon, Joseph Rouletabille, Xenophilius Lovegood, Peter Brinkmann, and Kit Kittredge).

To reduce the noise in the distantly-supervised data, some teams used only a subset of it. Yeon Zi, Borat Sagdiyev and the Anhk Morpork Times fitted a model on the by-article dataset and ran it on the by-publisher one: the articles of the by-publisher dataset that were misclassified by this model, were presumed to be noisy and filtered out.

6 Results

A total of 42 teams completed the task, representing more than twenty countries between them, including India, China, the USA, Japan, Vietnam, and many European countries. Table 1 shows the accuracy, precision, recall, and F_1 score for each team, sorted by accuracy. This task used accuracy as the main metric to represent a filtering scenario. The accuracy scores ranged from 0.462 up to 0.822.

The results show a range of trade-offs between precision and recall and the resulting F_1 scores. The highest F_1 was 0.821 with a precision of 0.815 and a recall of 0.828; the highest precision was 0.883 with a recall of 0.672 (F_1: 0.763); and the highest recall was 0.971 with a relatively low precision of 0.542 (F_1: 0.696).

6.1 Methods Used by the Top Teams

While the winning team, Bertha von Suttner, used deep learning (sentence-level embeddings and a convolutional neural network) the second-placed team, Vernon Fenwick, took a different approach and combined sentence embeddings with more domain-specific features and a linear model. Out of the top five teams, only two used "pure" deep learning models of neural networks without any domain-specific, hand-crafted features, showing no single method has a clear advantage over others.

Bertha von Suttner used a model based on ELMo embeddings (Peters et al., 2018) and trained on the by-article dataset. After minimal preprocessing, a pre-trained ELMo was applied onto each token of each sentence, and then averaged, to obtain average sentence embeddings. The sentence embeddings were later passed through a CNN, batch-normalized, followed by a dense layer and a sigmoid function to obtain the final probabilities. The final model was an ensemble of the 3 best-performing models of a 10-fold cross-validation. The authors tried to include the by-publisher dataset, but found in their preliminary tests no approach to profit from the large data.

Table 1: For each team and dataset, the performance of the submission that reached the highest accuracy is shown. If a team published their code, the 🔗 links to the respective repository. We forked all repositories for archival.[6]

The second and third best teams used linear models as their main predictor and embeddings as features, training on the by-article dataset only. Vernon Fenwick extracted sentence embeddings with the Universal Sentence Encoder (USE) (Cer et al., 2018), while Sally Smedley used BERT to generate contextual embeddings. Both teams also employed hand-crafted, domain-specific features. Vernon Fenwick extracted article-level and sentence-level polarity, bias, and subjectivity, among others, while Sally Smedley used the by-publisher dataset to extract key discriminative phrases, which they later looked up in the training data.

6.2 Overall Insights

The results reveal several insights into the suitability of different features and approaches for the task of hyperpartisan news detection.

Word-embeddings have been reported to be a very efficient feature by many teams. Tom Jumbo Grumbo achieved an accuracy of 0.806 with GloVe embeddings and a classifier trained on the by-article dataset. The application of a pre-trained BERT model by Peter Parker performed very poorly (acc. 0.503). However, the same BERT embeddings were used for great effect by Sally Smedley, using techniques like word-dropout and informative phrase identification (acc. 0.809).

[6]https://github.com/hyperpartisan-news-challenge

Also standard word n-grams were found to be suitable for the task, though not as strong as embeddings. While n-grams where used in several well-performing approaches, Pioquinto Manterola reached an accuracy of 0.704 with unigrams alone.

Several teams reported an increase in accuracy through sentiment or similar features (e.g., Borat Sagdiyev). Kermit the Frog used sentiment detection alone to reach an accuracy of 0.621.

Besides textual features, a few teams also analyzed HTML and article meta-features. Borat Sagdiyev performed a detailed analysis in this regard, which helped them to achieve the highest precision of all teams. For example, they found that both the publication date and the number of links to known hyperpartisan pages could each improve the overall accuracy by about 0.01 to 0.02.

Of the top teams, only Sally Smedley used the by-publisher dataset, and only to select n-grams. Based on the reports of several teams, the utilization of this dataset thus seems more difficult than we expected. We conjecture that this is due to the mis-classification of what should be the most informative articles: non-hyperpartisan articles from mainly hyperpartisan publishers, and hyperpartisan articles from non-hyperpartisan publishers. These articles are especially suited to distinguish features that identify hyperpartisanship from features that identify publisher style. While we assumed that the advantages of big data would outweigh this drawback, the results suggest that it might be more worthwhile to put effort in larger datasets where each article is annotated separately. Still, some teams managed to use the by-publisher dataset as a large dataset of in-domain texts. For example, Clint Buchanan reported that pre-training embeddings on the by-publisher dataset increased the accuracy of their system on the by-article dataset.

Moreover, the ranking of teams for the two test datasets is quite different. Bertha von Suttner, who ranked first for by-article, reached only rank eight for the by-publisher dataset. Conversely, Tintin, who optimized for by-publisher, ranked first there but only 27th for the by-article dataset. This discrepancy highlights the unexpected large differences between the datasets.

7 Meta-Classification Task

Inspired by successes of meta classifiers in past SemEval tasks (e.g., Hagen et al. (2015)), we enabled and encouraged participants to devise meta

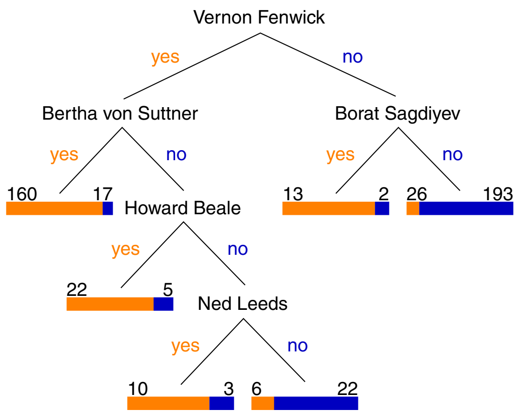

Figure 2: Meta-classification decision tree J48-M10 learned on the predictions of the submitted systems (hyperpartisan: yes or no; by-article dataset). The numbers show the training class-distribution at the leafs.

classifiers that learn from the classifications of the submitted approaches. For this meta-classification task, we split the test datasets further into new training (66%) and test sets (33%). We again made sure that there are an equal amount of non-hyperpartisan and hyperpartisan articles, as well as an equal share of left-wing and right-wing articles within the hyperpartisan sets. Furthermore, we again assured that no publisher had articles in both the training and the test sets. An instance in these datasets corresponds to the classifications (hyperpartisan or not) of the best-performing software of each team (42 classifications for the by-article dataset and 30 for the by-publisher one) of one article from the original test data.

We provide two simple classification systems for baselines, majority voting and an out-of-the-box decision tree, which both outperform the best single submitted software and which were both outperformed by the meta-classifiers submitted. Majority voting refers to a system that outputs the classification (hyperpartisan or not) that the most base classifiers selected. As it does not learn a decision boundary, it is—strictly speaking—not a meta classifier. For the decision tree, we used the J48 implementation of WEKA (Frank et al., 2016). We tested two variants: standard settings (*J48-M2*) and restricting leaf nodes to contain at least 10 articles (*J48-M10*) to force a simpler decision tree. Simpler trees often generalize better to unseen data.

Figure 2 shows the J48-M10 tree for the by-article dataset. For every leaf of the tree, more than 75% of the corresponding training articles are from the same class. This shows that even with as few as 5 decision nodes, the training set

Team or system name	Acc.	Prec.	Recall	F_1
Fernando Pessa	**0.899**	0.895	**0.904**	**0.900**
Spider Jerusalem	**0.899**	0.903	0.894	0.899
Majority Vote	0.885	0.892	0.875	0.883
J48-M10	0.880	**0.916**	0.837	0.874
J48-M2	0.856	0.863	0.846	0.854
Bertha von Suttner alone	0.851	0.901	0.788	0.841

Table 2: Accuracy, precision, recall, and F_1-measure for the by-article meta learning test dataset.

could be fitted reasonably well. The meta classifier was thus able to use the submitted systems as predictive and distinct features, which shows that some submitted systems performed well on some articles where other systems did not and vice versa. Even more, the 5 systems employed by the meta-classifier are all within the top 10 systems of the task, which shows that there is considerable variation even among the top performers. This is reasonable, given the variety of approaches used.

In addition to our approaches, two teams submitted their own classifiers in the short time span they had. Fernando Pessa used a random forest classifier trained on the single predictions as well as the average vote. Spider Jerusalem used a weighted majority voting algorithm, where they weighted each single prediction by the precision of the respective classifier on the training set.

Table 2 shows the performance of the approaches on the meta learning test dataset. Note that the best single system, Bertha von Suttner, reaches an increased accuracy of 0.851 on the meta learning test set. This is due to variations in the small dataset. Still, all ensemble approaches reach a higher accuracy. The majority voting approach reaches an accuracy of 0.885, and thus outperforms the J48 classifiers. This is somewhat surprising, but shows that there is a lot to gain by integrating also the systems that performed less well—team Fernando Pessa came to a similar insight in their paper (Cruz et al., 2019). The approaches of the two participants performed very similar, despite their methodological differences, and outperformed the majority vote. They managed to achieve an accuracy 0.048 points above Bertha von Suttner and therefore a considerable increase in performance.

We also repeated the experiments for the by-publisher dataset, but could not produce decisive results there, yet. We assume that this is due to most teams focusing on the other dataset and both datasets being more different than expected.

8 Conclusion

This paper reports on the setup, participation, results, and insights gained from the first task in hyperpartisan news detection, hosted as Task 4 at SemEval-2019. We detailed the construction of both a manually annotated dataset of 1,273 articles as well as a large dataset of 754,000 articles, compiled using distant supervision. Moreover, it provides a systematic overview of the 34 papers submitted by the participants, insights gathered from single teams, by comparing their approaches, and by an ad-hoc meta classification.

Through the use of TIRA (Potthast et al., 2019), we were able to establish a blind evaluation setup, so that future approaches can be compared on same grounds. For this, we continue to accept new approaches in ongoing submissions.[7] Moreover, through the use of TIRA we can directly evaluate the submitted approaches on new datasets for hyperpartisan news detection, provided they are formatted like the datasets presented here.

Very promising results were achieved during the task, with accuracy values above 80% on a balanced test set—and even up to 90% using meta classification on all submissions. Like in many other NLP tasks, word embeddings could be used to great effect, but hand-crafted features also performed well. The differences between the two employed datasets were larger than anticipated, which suggests a focus on by-article annotations in the future. A larger dataset of this kind will probably assist in improving the accuracy of future models even beyond the already very good level.

It thus seems that hyperpartisan news detection is already sufficiently developed to take the next step and demand human-understandable explanations from the approaches. The most obvious use cases of hyperpartisan news detectors are for filtering articles, which always requires a careful handling to avoid unwarranted censorship. Especially in the current political climate, it therefore seems necessary that hyperpartisanship detectors not only reach a high accuracy, but also reveal their reasoning.

Acknowledgements

Our thanks go out to all participating teams; your contributions made this task a success. We hope we have been able to do your work justice, and are looking forward to doing so in the future. Our special thanks go out to the SemEval organizers for providing perfect organizational support.

Abstract

This paper describes the participation of team "bertha-von-suttner" in the SemEval2019 task 4 Hyperpartisan News Detection task. Our system[1] uses sentence representations from averaged word embeddings generated from the pre-trained ELMo model with Convolutional Neural Networks and Batch Normalization for predicting hyperpartisan news. The final predictions were generated from the averaged predictions of an ensemble of models. With this architecture, our system ranked in first place, based on accuracy, the official scoring metric.

1 Introduction

Hyperpartisan news is typically defined as news which exhibits an extremely biased opinion in favour of one side, or unreasoning allegiance to one party (Potthast et al., 2017). SemEval-2019 Task 4 on "Hyperpartisan News Detection" (Kiesel et al., 2019) is a document-level classification task which requires building a precise and reliable algorithm to automatically discriminate hyperpartisan news from more balanced stories.

One of the major challenges of this task is that the model must have the ability to adapt to a large range of article sizes. In one of the training data sets, the *by-publisher* corpus, the average article length is 796 tokens, but the longest document has 93,714 tokens. Most state-of-the-art neural network approaches for document classification use a token sequence as network input (Kim, 2014; Yin and Schütze, 2016; Conneau et al., 2016). This implies either a high computational cost when a very large maximum sequence length is used to fully represent the longest articles, or alternatively potentially a significant loss of information if the sequence length is restricted to a manageable number of initial tokens from the document.

In this paper, we introduce the **E**LMo **S**entence **R**epresentation **C**onvolutional (ESRC) Network. We first pre-calculate sentence level embeddings as the average of ELMo (Peters et al., 2018) word embeddings for each sentence, and represent the document as a sequence of such sentence embeddings. We then apply a lightweight convolutional Neural Network (CNN), along with Batch Normalization (BN), to learn the document representations and predict the hyperpartisan classification.

Two types of data set have been made available for the task. The *by-publisher* corpus contains 750K articles which were automatically classified based on a categorization of the political bias of the news source. This dataset was split into a training set of 600K articles and a validation set of 150K articles, where all the articles in the validation set originated from sources not in the training set. The second set, *by-article*, contains just 645 articles which were labelled manually. The final evaluation (Potthast et al., 2019) was carried out on a dataset of 628 articles which were also labelled manually.

We created several models based on the two datasets and evaluated them using cross-validation on the *by-article* training set (as the final test set was not available to the participants and it was only available for a maximum of three evaluations). In order to investigate the usefulness of the *by-publisher* training data for training a model that performs well on the manually annotated *by-article* corpus, we experimented with various kinds of pre-training and fine-tuning, and found that any kind of use of the *by-publisher* corpus was actually harmful and decreased the usefulness of the model. A CNN model which used ELMo-based sentence embeddings to represent the article, and was trained on the *by-article* set only,

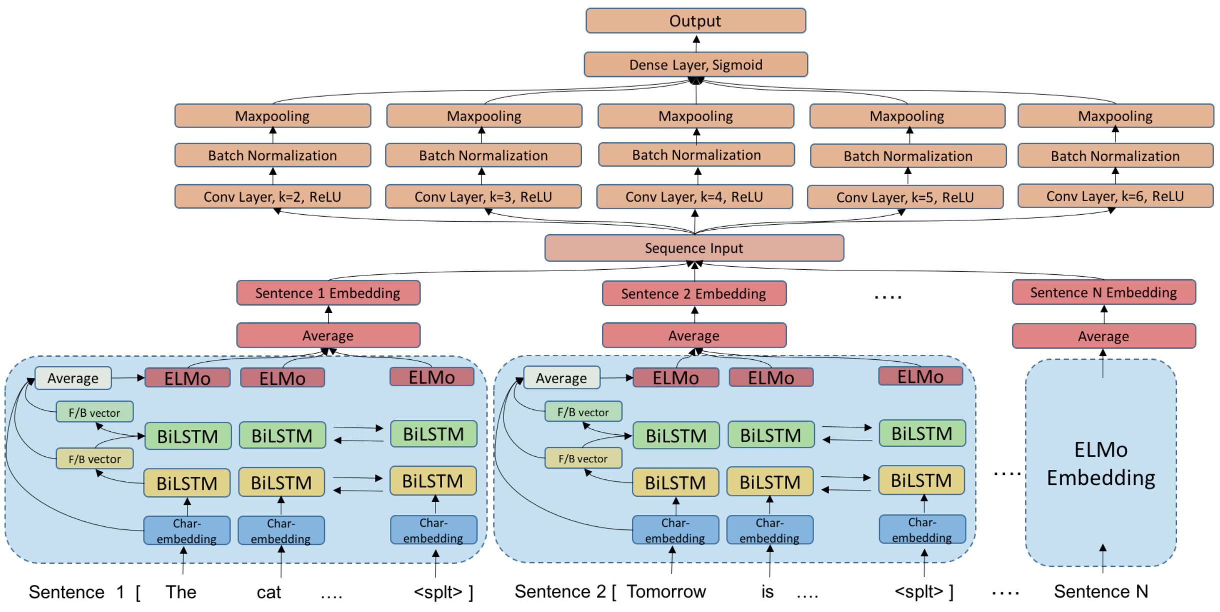

Figure 1: System architecture, *F/B vector* denotes Forward/Backward hidden state from BiLSTM layers.

turned out to outperform all other attempts.

2 System Description

In our model, we represent each article as a sequence of sentence embeddings, where each sentence embedding is calculated as the averaged word embeddings generated from a pre-trained ELMO model. The network consists of 5 parallel convolutional layers with kernel sizes 2,3,4,5,6 and 512 output features, each followed by a ReLU non-linearity, batch normalization, and max-pooling. All the results of the max-pooling layers are combined and go through a final fully connected layer with a sigmoid activation function for the final binary classification. Our model architecture is shown in Figure 1.

2.1 Data

The maximum, mean, and minimum numbers of tokens in the *by-article* corpus are: 6470, 666, 19 respectively, and in the *by-publisher* are: 93714, 796, 10 respectively. This makes it impractical to directly use word level representations as the input for our models. As a simple and easy to calculate compromise between representing the details of the article and as much of a longer article as possible, we represent the article as a sequence of sentence embeddings which are calculated as the average of the word embeddings of a sentence. This can be done using any pre-trained word embeddings and does not require a large training set for training or pre-training, so can be easily applied to even the small *by-article* corpus. To form the input sequence for our network, a maximum of the 200 initial tokens per sentence was used for each sentence embedding and a maximum of 200 sentences was used per article. The title of the article was used as the first article sentence for each document.

2.2 Preprocessing

Our model is character-based, which enabled us to only perform minimal pre-processing. We extract the title and article text from the original XML representation. All the original HTML paragraphs in the text cause a sentence break; the remaining text paragraphs have been split into sentences using `Spacy`. The original case of the text was maintained.

Whitespace is normalized to a single space between tokens; numbers are replaced by a special number token; and all punctuation and other special characters are preserved as input to the pre-trained ELMo model.

2.3 Deep Contextualized Word Representation

Traditionally, the input to CNNs is a set of pre-trained word vectors such as Word2Vec (Mikolov et al., 2013), Glove (Pennington et al., 2014), or Fasttext (Bojanowski et al., 2017). In our model, we use the AllenNLP library to generate ELMo embeddings, in which the word representation is learned from character-based units as well as contextual information from the news articles. These character-based word representations allow our model to pick up on morphological features that word-level embeddings could miss, and a valid word representation can be formed even for out-of-vocabulary words. Furthermore, ELMo uses two bi-directional LSTM (Gers et al., 1999) layers to learn the contextual information from the text, which makes it capable of disambiguating the same word into different representations based on its context.

We use the original[2] pre-trained ELMo model to output three vectors for each word. Each vector corresponds to a layer output from the ELMo pre-trained model. Then, we take the average of all three vectors to form the final word vector, and compute the sentence vector by averaging the word vectors in the sentence.

2.4 Convolutional Layers

We combine 5 convolutional layers for different kernel sizes. Each layer is then followed by a non-linear activation function ReLU.

2.5 Batch Normalization

Batch Normalization (BN) is a method for reducing internal covariate shift in neural networks (Ioffe and Szegedy, 2015). BN normalizes the input distribution by subtracting the batch mean and dividing by the batch standard deviation, so that the ranges of input distribution between each layer stay the same. This allows the model to have a higher learning rate, so that the training speed is accelerated. It also reduces overfitting by decreasing the dependence of weight initialization between each layer. The original paper suggested that BN should be applied before the activation layer, but we apply it after the activation layer, after observing better performance in our model this way round. We also applied weighted moving-mean and moving-variance to avoid updating the mean and variance so aggressively in the mini-batch during training time.

2.6 Fully Connected Layer

We perform max-pooling on the output of the batch-normalization layers. Then the outputs of the max-pooling for all convolution layers are combined to form the input to a fully connected layer, which maps to a single output, followed by the Sigmoid function for the binary classification task.

[2] `elmo_2x4096_512_2048cnn_2xhighway`

3 Experiments and Results

The generated ELMo embedding contains three vectors for each word, where each vector corresponds to one of the output layers from the pre-trained model. We average the three vectors to generate word representations which contain morphological and contextual information, and compute the sentence vectors by averaging all the word vectors in each sentence. We take a maximum of 200 words for each sentence and a maximum of 200 sentences for each article. If a document has fewer than 200 sentences, we pad the number of sentences out to 200.

Our models are built by using the Keras library with a Tensorflow backend. All the results are shown in Table 1. The table shows for each model the accuracy obtained on the *by-article* training set, and for the submitted models, the *by-publisher* test set, and the hidden *by-article* test set (which unlike the other two, was not available to participants).

In order to investigate the correlation between the two datasets, we first built the `ESRC-publisher` model which is trained on a randomly selected 100K out of the 750K articles from the *by-publisher* corpus, as it is impractical to generate ELMo embeddings for the entire corpus. We also fine-tuned the `ESRC-publisher` model based on the *by-article* set to obtain the `ESRC-publisher-article` model by freezing the weights of all but the last layer of the model. Finally we trained the `ESRC-article` model only on the *by-article* set, one version without and one version (`ESRC-article-BN`) with the additional batch normalization (BN) layer. The accuracy for the `ERC-publisher` model is from evaluating on the whole `by-article` training set, while all other evaluations on the `by-article` training set were carried out using a 10-fold cross validation. However, because of the very limited size of that corpus, the evaluation part of each fold was also used for early stopping and model selection within each fold.

For the evaluation on the hidden test set, we selected the best three models from the 10-folds, according to the accuracy on the evaluation set of each fold to form an averaged ensemble model, `ESRC-article-BN-Ens`.

For comparison, the table also shows the results for an earlier version of the model, `GloVe-article`, which used GloVe word embeddings (6 billion words, 300 dimensional) to represent up to the first 400 words of the article and did not use batch normalization.

Models	**By-Article Training**
GloVe-article	0.7963
ESRC-publisher	0.5643
ESRC-publisher-article	0.8189
ESRC-article	0.8182
ESRC-article-BN	0.8387
ESRC-article-BN-Ens	**0.8404**
Submitted Models	**By-Article Test**
GloVe-article	0.7659
ESRC-article-BN-Ens	0.8216
Submitted Models	**By-Publisher Test**
GloVe-article	0.6435
ESRC-article-BN-Ens	0.5947

Table 1: System comparison (accuracy).

The parameters in our models are as follows: we used 5 convolutional layers with kernel sizes ($k = 2, 3, 4, 5, 6$) and 512 output features. The momentum in the batch normalization is set to 0.7.[3] We used the default Adam algorithm as the optimizer, and Binary Cross-Entropy as the loss function. The batch size was set to 32 and the fixed number of epochs used was 30. The final best model after 30 epochs was used.

4 Discussion and Conclusion

The `ESRC-publisher` model performs extremely badly on the *by-article* evaluation data. Even fine-tuning the `ESRC-publisher` model on the *by-article* corpus produces models which perform worse than a model that is trained only on the *by-article* data. This confirms results from earlier experiments with simpler models that any use of the *by-publisher* data only hurts the model. We assume that the algorithm used for assigning the labels to this dataset just does not reflect any information about hyperpartisan articles sufficiently to be helpful. For this reason, the `GloVe-article` model also outperforms the ESRC-article-BN-Ens model on the by-publisher dataset.

A quick manual inspection of the data showed that the source of an article is insufficient by far to identify articles as hyperpartisan or not. It would be interesting to know how the algorithm used for creating the *by-publisher* corpus actually performs on the *by-article* corpus. To get maximum performance on the *by-article* dataset, we therefore decided to completely ignore the *by-publisher* data for our final model. The use of BN also showed significant improvement.

Since we use a CNN with a comparatively large number of parameters in relation to the size of the training set which is rather small, we expect significant variance in the generated models and therefore use the average of an ensemble of several models for the final predictions.

[3]This was determined by exploring values from 0.1 to 0.9 at an earlier stage of the experiments and kept, so it may not be the optimal value.

Abstract

Since the first RumourEval shared task in 2017, interest in automated claim validation has greatly increased, as the danger of "fake news" has become a mainstream concern. However automated support for rumour verification remains in its infancy. It is therefore important that a shared task in this area continues to provide a focus for effort, which is likely to increase. Rumour verification is characterised by the need to consider evolving conversations and news updates to reach a verdict on a rumour's veracity. As in RumourEval 2017 we provided a dataset of dubious posts and ensuing conversations in social media, annotated both for stance and veracity. The social media rumours stem from a variety of breaking news stories and the dataset is expanded to include Reddit as well as new Twitter posts. There were two concrete tasks; rumour stance prediction and rumour verification, which we present in detail along with results achieved by participants. We received 22 system submissions (a 70% increase from RumourEval 2017) many of which used state-of-the-art methodology to tackle the challenges involved.

1 Introduction

1.1 Background

Since the first RumourEval shared task in 2017 (Derczynski et al., 2017), interest in automated verification of rumours has deepened, as research has demonstrated the potential impact of false claims on important political outcomes (Allcott and Gentzkow, 2017). Living in a "post-truth world", in which perceived truth can matter more than actual truth (Dale, 2017), the dangers posed by unchecked market forces and cheap platforms, as well as poor ability by many readers to discern credible information, are evident. As a result the importance of educating young people about critical thinking is increasingly emphasised.[1]. Moreover the European Commission's High Level Expert Group on Fake News provides tools to empower users and journalists to tackle disinformation as one of the five pillars of their recommended approach.[2] Platforms are increasingly motivated to engage with the problem of damaging content that appears on them, as society moves toward a consensus regarding their level of responsibility. Independent fact checking efforts, such as Snopes[3], Full Fact[4], Chequeado[5], are also becoming valued resources (Konstantinovskiy et al., 2018). Zubiaga et al. (2018) present an extensive list of projects. Effort so far is often manual, and struggles to keep up with the large volume of online material.

Within NLP research the tasks of stance classification of news articles and social media posts and the creation of systems to automatically identify false content are gaining momentum. Work in credibility assessment has been around since 2011 (Castillo et al., 2011), making use initially

Veracity prediction. Example 2:

u1: OMG. #Prince rumoured to be performing in Toronto today. Exciting! [false]

Table 1: Examples of source tweets with veracity value

of local features. Fact checking is a broad complex task, challenging the resourcefulness of even a human expert. Claims such as ”we send the EU 350 million a week” which is partially true would need to be decomposed into statements to be checked against knowledge bases and multiple sources. Ways of automating fact checking has inspired researchers (Vlachos and Riedel, 2015) and has resulted in a new shared task FEVER.[6] Other research has focused on stylistic tells of untrustworthiness in the source itself (Conroy et al., 2015; Singhania et al., 2017). Rumour verification is a particular case of fact checking. Rumours are *“circulating stories of questionable veracity, which are apparently credible but hard to verify, and produce sufficient skepticism and/or anxiety so as to motivate finding out the actual truth”* (Zubiaga et al., 2016). One can distinguish several component to a rumour resolution pipeline such as rumour detection, rumour tracking and stance classification, leading to the final outcome of determining the veracity of a rumour (Zubiaga et al., 2018). Thus what characterises rumour verification compared to other types of fact checking is time sensitivity and the importance of dynamic interactions between users, their stance and information propagation. Initial work on rumour detection and stance classification (Qazvinian et al., 2011) was succeeded by more elaborate systems and annotation schemas (Kumar and Geethakumari, 2014; Zhang et al., 2015; Shao et al., 2016; Zubiaga et al., 2016). Vosoughi (2015) demonstrated the value of making use of propagation information, i.e. the ensuing discussion, in rumour verification. Stance detection is the task of classifying a text according to the position it takes with respect to a statement. Research supports the importance of this subtask as a first step to veracity identification. (Ferreira and Vlachos, 2016; Enayet and El-Beltagy, 2017). Crowd response, stance and the details of rumour propagation feature in the work by Chen et al. (2016) as well as the most successful system in RumourEval 2017 (Enayet and El-Beltagy, 2017), and the highest performing systems in RumourEval 2019.

1.2 Datasets for rumour verification

The UK fact-checking charity Full Fact provides a roadmap[7] for development of automated fact checking. They cite open and shared evaluation as one of their five principles for international collaboration, demonstrating the continuing relevance of shared tasks in this area. Shared datasets are a crucial part of the joint endeavour. Datasets for rumour resolution are still relatively few, and likely to be in increasing demand. In addition to the data from RumourEval 2017, the dataset released by Kwon et al. (2017) is also suitable for veracity classification. It includes 51 true rumours and 60 false rumours, where each rumour includes a stream of tweets associated with it. Twitter 15 and 16 datasets (Ma et al., 2018) contain claim propagation trees and combine tasks of rumour detection and verification in one four-way classification task (Non-rumour, True, False, Unverified). A Sina Weibo corpus is also available (Wu et al., 2015), in which 5000 posts are classified for veracity, but responses are not available. Partially generated statistical claim checking data is now becoming available in the context of the FEVER shared task, mentioned above, but is not suitable for this type of work. Twitter continues to be a highly relevant platform for rumour verification, being popular with the public as well as politicians. RumourEval 2019 also includes Reddit

[6]https://sheffieldnlp.github.io/fever/

[7]https://fullfact.org/media/uploads/full_fact-the_state_of_automated_factchecking_aug_2016.pdf

data, thus providing more diversity in the types of users, more focussed discussions and longer texts.

1.3 RumourEval 2017 vs 2019

RumourEval 2019 furthers progress on stance detection and rumour verification, both still unbested NLP tasks. They are currently moderately well performed for English short texts (tweets), with data existing in a few other languages (notably as part of IberEval). In 2019, many more teams took part, demonstrating the rising relevance of the tasks. Specifically, as in 2017, RumourEval 2019 comprises two subtasks:

- In subtask A, given a source tweet, tweets in a conversation thread discussing the claim are classified as either supporting, denying, querying or commenting on the rumour mentioned by the source tweet
- In subtask B, the rumour introduced by the source tweet that spawned the discussion is classified as true, false or unverified.

In 2017 we had two variants of the task, a closed and an open one.

- In the open variant, a system could consider the source tweet itself, the discussion as well as additional background information.
- In the closed variant, only the source tweet and the ensuing discussion were used by systems.

Eight teams entered subtask A, achieving accuracies ranging from 0.635 to 0.784. In the open variant of subtask B, only one team participated, gaining an accuracy of 0.393 and demonstrating that the addition of a feature for the presence of the rumour in the supplied additional materials does improve their score. Five teams entered the closed variant of task B, scoring between 0.286 and 0.536. Only one of these made use of the discussion material, specifically the percentage of responses querying, denying and supporting the rumour but scored joint highest on accuracy and achieved the lowest RMSE. A variety of machine learning algorithms were employed. Among traditional approaches, a gradient boosting classifier achieved the second best score in task A, and a support vector machine achieved a fair score in task A and first place in task B. However, deep learning approaches also fared well; an LSTM-based approach took first place in task A and an approach using CNN took second place in task B, though performing less well in task A. Other teams used different kinds of ensembles and cascades of traditional and deep learning supervised approaches.

For 2019 we wanted to encourage participants to be more innovative in the information they make use of, particularly in exploiting the output of task A in their task B approaches.

We extended the challenges through the addition of new data and by including Reddit posts.

In order to encourage more information-rich approaches, we combined variants of subtask B into a single task, allowing participants to use additional material. This was selected to provide a range of options whilst being temporally appropriate to the rumours in order to mimic the conditions of a real world rumour checking scenario.

1.4 Subtask A - SDQC support classification

Related to the objective of predicting a rumour's veracity, and as a first step in a rumour verification pipeline, Subtask A deals with the complementary objective of tracking how other sources orient to the accuracy of the rumourous story. A key step in the analysis of the surrounding discourse is to determine how other users in social media regard the rumour (Procter et al., 2013). Given a source post containing a rumourous claim and a conversation thread discussing the rumour as input, the objective is to label each of the posts in the conversation thread with respect to their stance towards the rumour.

Success on this task supports success on task B by providing additional context and information; for example, where the discussion ends in a number of agreements, it could be inferred that human respondents have verified the rumour. In this way, task A provides an intermediate challenge in which a larger number of data points can be provided. See Table 2 for an example conversation thread and refer to Derczynski et al. (2017) for more details about the task definition.

1.5 Subtask B - Veracity prediction

As in RumourEval 2017 (Derczynski et al., 2017), the goal of subtask B is to predict the veracity of a given rumour, where the latter is presented in the form of a post reporting an update associated with a newsworthy event. Given such a claim as input,

 u2: @u1 Apparently a hoax. Best to take Tweet down. [deny]
 u3: @u1 This photo was taken this morning, before the shooting. [deny]
 u4: @u1 I dont believe there are soldiers guarding this area right now. [deny]
  u5: @u4 wondered as well. Ive reached out to someone who would know just to confirm that. Hopefully get response soon. [comment]
   u4: @u5 ok, thanks. [comment]

Table 2: Examples of tree-structured threads discussing the veracity of a rumour, where the label associated with each tweet is the target of the SDQC support classification task.

plus additional data such as stance data classified in task A and any other information teams chose to use from the selection provided, systems return a label describing the anticipated veracity of the rumour. Examples are given in Table 1. In addition to returning a classification of true, or false, a confidence score was also required, allowing for a finer grained evaluation. A confidence score of 0 should be returned if the rumour is unverified.

2 Data & Resources- RumourEval 2019

The data are structured as follows. Source posts introduce a rumour, and may be true, false or unverified. These are accompanied by an ensuing discussion (tree-shaped) in which users support, deny, comment or query (SDCQ) the rumour in the source text. This is illustrated in figure 1 with an example rumour about Putin. Note that source posts also need to be annotated for stance, as the way a post presents a rumour usually gives stance information also. For example, when introducing a rumour, an implicit "support" stance may be present, in that the rumour is assumed to convey valid information. In the Reddit data, rumours were often introduced with an implicit "query", as they were presented for discussion/debunking.

The RumourEval 2017 corpus contains 297 source tweets grouped into eight breaking news events, and a total of 7100 discussion tweets. This became training data in 2019, and was augmented with new Twitter test data and new Reddit material. The Reddit material was split into training and test sets. Each are discussed in turn below.

In RumourEval 2017 along with the tweet threads, we also provided additional context that participants could make use of (Derczynski et al., 2017). However, only one system had made use of this additional context. Due to lack of time such context data was not provided in RumourEval 2019 but we would look into re-introducing this in future editions of the task.

2.1 English Twitter data about natural disasters

The additional English Twitter testing data is about natural disasters. In such events, where chaos dominates the situation, rumours are spread on various issues and false rumours have the potential to increase the chaos. Detecting such false rumours are important to plan actions that will

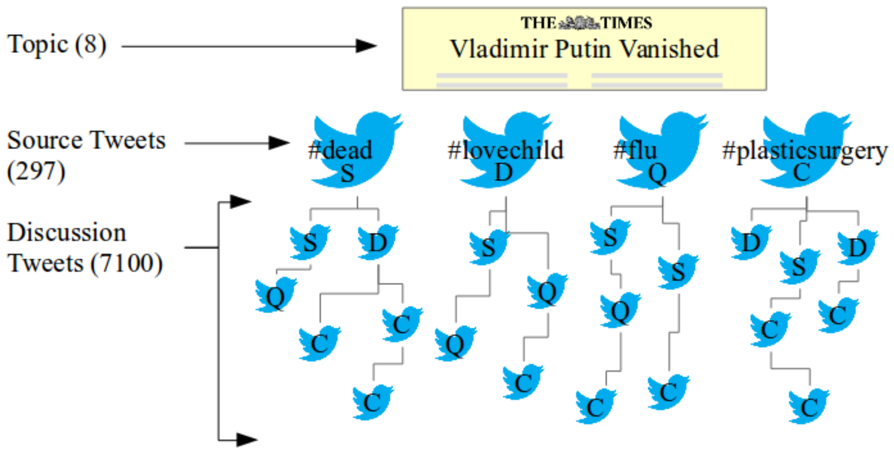

Figure 1: Structure of the first rumours corpus

eliminate the additional negative impact on the already existing chaotic situation. Therefore, for this year we decided to introduce such a dataset as test data. To collect this dataset rumours about natural disasters were chosen manually through Snopes.com and Politifact.com: we searched manually for rumours about known natural disasters such as hurricanes, floods, etc. If the search returned some results, we quickly scanned this result list for social media posts (specifically tweets) that people had created about the disaster and which had been verified by the debunking web-site.

Once we collected the rumour introducing tweets (the source tweets) we aimed to collect also the cascades, i.e. the reactions/replies to the source tweet. The replies encode the reactions (stance information) of other users to the rumour and can be of importance when verifying the rumour. To collect the replies we used an existing scraper (Zubiaga et al., 2016). The number of source tweets of different veracities and replies of different stances are given in Tables 3 and 4.[8]

2.1.1 Annotation of new English Twitter data

As noted above a rumour consists of a source tweet and a thread of tweets that respond to the source one, where the source tweet contains the rumour. The veracity of each source tweet is already known a priori. However, the dataset is missing stance labels for the replies. To get also the stance labels we performed annotation through crowd sourcing. Zubiaga et al. (2016) distinguish between the following stance labels for each replying tweet: supporting, denying, questioning and commenting.

Following the same strategies and design reported by Zubiaga et al. (2016) we posted our datasets for stance annotation to FigureEight (F8)[9]. We applied a restriction so that annotation could be performed only by people from the USA and UK. We also made sure that each annotation was performed maximum by 10 annotators and that an annotator agreement of min. 70% was met. Note if the agreement of 70% was met with fewer annotators then the system would not force an annotation to be done by 10 annotators but would finish earlier. The system requires 10 annotators if the minimum agreement requirement is not met. Each annotator saw five source tweets on a page. The source tweets were accompanied by replying tweets followed by the stance labels to choose from. Each page showed also instructions and definitions about the stance labels. We paid for each tweet annotation 3 US Dollar Cents.

The agreement among the annotators is directly taken from F8s aggregated scores and is computed based on percentage agreement. On the entire dataset we have 76.2% agreement.

We also computed the distribution of stances provided for the replying tweets (see Tables 3 and 4). As we see from the tables, overall the distribution of stances is skewed towards the comment category. This is also the case with the PHEME dataset reported by Zubiaga et al. (2016).

[8]The labels were taken from the debunking web-sites. As in the RumourEval2017 test data the false rumours dominate. However, unlike the previous dataset the number of unverified rumours is proportionally smaller compared to the other two classes. In the 2017 dataset the test data included 12 false rumours, 8 true and 8 unverified ones.

[9]www.figure-eight.com

2.2 Reddit Data

Rumours were identified on Reddit by manually searching debunking forums and current affairs forums to identify suitable threads. Reddit discussions are deeper than Twitter discussions, with often a complex conversational structure exploring the topic. They are usually introduced by a post implicitly querying the rumour, unlike Twitter rumours which are more often presented as valid information and therefore the source tweets usually support the rumour. The Reddit material is less time-sensitive than the Twitter material, and may discuss long-standing conspiracy theories, for example. Threads were downloaded using a bespoke script.

2.2.1 Annotation of Reddit discussions

Since the Reddit discussions are complex, there is more of a danger that careless annotators won't distinguish between posts that disagree with the immediately preceding comment and posts that disagree with the rumour. A response such as "absolutely!" might therefore get a high agreement from annotators who all made the mistake of annotating it as "support", even if it was in response to a preceding comment which denied the rumour. To avoid this, an extensive quiz of 51 test questions was used to ensure that annotators understood the task properly. Reddit threads tend to be longer and more diverse, leading to a more challenging task as discussion may be only loosely related to the main topic, leading to a preponderance of "comments" (88% overall compared with 67% in the Twitter data). Tables 3 and 4 give totals in training and test data for both tasks alongside the figures for Twitter data.

Up to five judgements were collected, or an agreement of 0.7, whichever came first. Since Reddit annotators were highly trained by the time they were accepted on the task, this was found sufficient. Four US dollar cents per post was offered, which is higher than usual for a Figure Eight task, in order to attract annotators to this relatively hard task. The final macro-agreement for the entire Reddit set is 78%, and an average of 3.84 annotations annotated each item. For "support" items, more annotations were required, at 4.22 on average, and a lower macro agreement was achieved of 67%. Similarly for deny items, 4.04 judgements were obtained on average and a macro agreement of 63% was achieved. For query items, 4.36 judgements on average were obtained and a macro agreement of 64% was achieved.

	Supp.	**Deny**	**Query**	**Com.**	**Total**
Twitter Train	1004	415	464	3685	5568
Reddit Train	23	45	51	1015	1134

Total Test	157	146	93	1476	1872
Total Task A	1184	606	608	6176	8574

Table 3: Task A corpus

	True	**False**	**Unver.**	**Total**
Twitter Train	145	74	106	325
Reddit Train	9	24	7	40
Total Train	154	98	113	365
Twitter Test	22	30	4	56
Reddit Test	9	10	6	25
Total Test	31	40	10	81
Total Task B	185	138	123	446

Table 4: Task B corpus

For Task B, rumours were annotated for veracity with the aid of Snopes and similar sites. This is a change from RumourEval 2017, where manually-annotated veracity was assigned. Instead, we used community experts working professionally in a range of organisations to construct the Task B veracity judgments. The volume of data was also significantly extended beyond e.g. the 21 stories in the test set of RumourEval 2017 Task B.

3 Evaluation

In task A, stance classification, care must be taken to accommodate the skew towards the "comment" class, which dominates, as well as being the least helpful type of data in establishing rumour veracity. Therefore we used macro-averaged F1 to evaluate performance on task A.

In task B participants supply a true/false classification for each rumour, as well as a confidence score. Macro-averaged F1 was again the score of choice to evaluate the overall classification. For the confidence score, a root mean squared error (RMSE, a popular metric that differs only from the Brier score in being its square root) was calculated relative to a reference confidence of 1. Unverified rumours were considered correctly annotated if they received a confidence score of zero regardless of true/false classification.

The previous RumourEval task used accuracy as the evaluation metric, but that approach allowed higher scores to be obtained through less sensitivity to minority classes. For the stance task, 80% of test items were comments, and this is the least interesting class. For the verification task, class imbalance is not so extreme, with 50%"false" in the dataset and close to 40% "true" (the remainder are "unverified").

Whilst participants weren't evaluated on accuracy for task A, we note that generally speaking, teams that obtained higher macro F1 scores also obtained higher accuracies, and that around 50% of the teams obtained accuracies higher than might be obtained simply by assigning all items to the comment class (majority baseline). However, the correlation between accuracy and macro F1 was only 0.47, and use of macro F1 revealed that three teams surged ahead. For task B, where class imbalance was less pronounced, the relationship between accuracy and macro F1 was much closer, with a correlation of 0.87, though again, F1 was the better differentiator. Interestingly, RMSE showed a stronger relationship with macro F1 than with accuracy (correlations -0.92 vs -0.77).

User or Team name	Subtask B, MacroF	Subtask B, RMSE	Subtask A, Macro F

4 Baselines

We provided participants with our implementation of several baseline systems[10], described below.

4.1 Stance classification baseline

For subtask A we released a Keras (Chollet et al., 2015) implementation of branchLSTM, the winning system of RumourEval 2017 Task A (Kochkina et al., 2017). This system uses the conversation structure by splitting it into linear branches. It is a neural network architecture that uses LSTM layer(s) to process sequences of tweets, outputting a stance label at each time step. Each tweet is represented by the average of its word vectors [11] concatenated with a number of extra features. This baseline was outperformed by 3 submitted systems (BLCU NLP, BUT-FIT, eventAI).

4.2 Veracity classification baselines

For subtask B we provided two baselines.

1. A model which is an extension of branchLSTM (Kochkina et al., 2018) uses the same features as the stance classification system but produces a single output per branch. The veracity prediction for the thread is then decided using majority voting over per-branch outcomes.

2. The NileTMRG baseline (Enayet and El-Beltagy, 2017) is a linear SVM that uses a bag-of-words representation of the source tweet, concatenated features defined by the presence of URL, presence of hashtag and proportion of supporting, denying and querying tweets in the thread. In our implementation of NileTMRG e use the branchLSTM model to obtain stance labels for the tweets in the testing set rather than the model originally used in (Enayet and El-Beltagy, 2017).

Baseline systems in subtask B were outperformed by the winning system eventAI (outperforms both baselines) and a late submission by FINKI NLP (outperforms NileTMRG and reaches similar result to branchLSTM, see Table 5). If participants made their own run of the baseline sys-

[11]We are using word2vec (Mikolov et al., 2013) model pretrained on the GoogleNews dataset (300d)

tems, their outcome might differ from ours due to variation in random seeds, package versions and hardware used.

5 Participant Systems and Results

We have had 22 system submissions at RumourEval 2019 (70% up from RumourEval 2017), confirming the significant increase in interest in this area. All submissions tackled subtask A (Rumour SDQC) and 13 systems attempted both tasks (more than a 100% increase). The participating systems and the results achieved can be found in Table 5. Note that system ranking is presented according to macro-F1 score in subtask B, which is considered the core task and the more challenging of the two. As in RumourEval 2017 subtask A was the more popular task of the two and whilst participation in both tasks has significantly increased, it is still the case that systems seem to focus and do better in one of the two tasks. Specifically, the best performing system in substask B (eventAI) ranked third in subtask A and the best performing system in subtask A (BLCU NLP) ranked fourth in subtask B. Three systems outperformed the branchLSTM subtask A baseline (BLCU NLP, BUT-FIT, eventAI), whereas almost all systems outperformed the majority baseline macro-F1 in this task. In subtask B, over 60% of systems outperformed the majority baseline in macro-F1, two systems outperformed the NILETMRG baseline (eventAI,FINKI-NLP–late) and one system (eventAI) beat both the NILETMRG and branchLSTM baselines.

The trend for neural approaches has demonstrably increased with almost all systems adopting a neural network (NN) architecture for their models, with the exception of the best performing system in subtask B (eventAI), which implemented an ensemble of classifiers (SVM,RF,LR), including a NN with three connected layers, where individual post representations are created using an LSTM with attention. This also considered a range of other features and postprocessing module to find similarities between source tweets. A similar ensemble model also considering sophisticated features and feature selection using RF would have ranked second in this task (FINKI-NLP, submitted late) as it outperformed the NILETMRG baseline. The second best performing system in subtask A (BUT-FIT) uses an ensemble of BERT (Devlin et al., 2018) models, which allows the pre-training of bidirectional representations to provide additional context. They experiment with different parameter settings and if the model increased overall performance it was added to the classifier. Interestingly the best performing system in task A (BLCU-NLP) and the third best (CLEARumor) also use pre-trained contextual embedding representations with BLCU-NLP using OpenAI GPT (Radford et al., 2018) and ClEARumor using ELMo (Peters et al., 2018). While most systems use single tweets or pairs of tweets (source-response) as their underlying structure to operate on, BLCU-NLP employ an inference chain-based system for this paper. Thus they consider the conversation thread starting with a source tweet, followed by replies, in which each one responds to an earlier one in time sequence. They take each conversation thread as an inference chain and concentrate on utilizing it to solve the problem of class imbalance in subtask A and training data scarcity in subtask B. They also have augmented the training data with external public datasets. Other popular neural models among participants include BiLSTM and LSTM. Judging from the approaches of two best performing systems in each of subtask A and B (BLCU-NLP and eventAI respectively) one could infer that: (1) for subtask A considering the sequence of earlier posts is important to identifying correctly the stance of a post towards the rumour (2) for rumour verification it is more important to consider a variety of different features.

6 Conclusion

We evaluated multiple teams in the tasks of rumour stance detection and rumour veracity evaluation. Interest in these tasks continues to increase, driving performance of systems higher and pushing the sophistication of systems, which are now often using state-of-the-art neural network methods and beyond. Further challenges include use of the rich context available, in terms of both time, conversation, and broader discourse during the evolution of rumours. Additionally, we need to work better with other languages. While we tried to make more available in this task, framing the task and annotating the data proved challenging and demanding. On the other hand, leaving stance detection just to English leaves the majority of the world without this important technology.

Abstract

This paper describes our system for SemEval 2019 RumorEval: Determining rumor veracity and support for rumors (SemEval 2019 Task 7). This track has two tasks: Task A is to determine a user's stance towards the source rumor, and Task B is to detect the veracity of the rumor: true, false or unverified. For stance classification, a neural network model with language features is utilized. For rumor verification, our approach exploits information from different dimensions: rumor content, source credibility, user credibility, user stance, event propagation path, etc. We use an ensemble approach in both tasks, which includes neural network models as well as the traditional classification algorithms. Our system is ranked 1st place in the rumor verification task by both the macro F1 measure and the RMSE measure.

1 Introduction

Social media platforms, such as Twitter, Reddit and Facebook, do not always poses authentic information. Rumors sometimes may spread quickly over these platforms (Castillo et al., 2011; Derczynski and Bontcheva, 2014; Qazvinian et al., 2011). A rumor may be defined as a statement whose truth value is unverified or deliberately false (Qazvinian et al., 2011). Rumors usually spread fear or even euphoria, and they may confuse people and cause them to make wrong decisions. Therefore, rumor detection has gained great interest recently. In this paper, we describe the approaches we used in SemEval 2019 RumourEval: Determining rumor veracity and support for rumors (SemEval 2019 Task 7). This task has two subtasks: Task A - user stance classification and Task B - rumor verification.

Stance classification is to determine the attitude of the author of a post message towards a target (Mohammad et al., 2016). In task A, we focus on stance classification of messages towards the truthfulness of rumors in Twitter or Reddit conversations. Each conversation is defined by a source post that initiates the conversation, and a set of replies to it, which form a conversation thread. The goal is to classify each post into one of the four categories: supporting, denying, querying or commenting (SDQC). For this task, we use an ensemble approach, which combines the prediction results from both the traditional learning models, such as SVM, and a neural network model, using the language features extracted from the message text. Task B predicts the veracity of a rumor: true, false, or unverified (i.e., its veracity cannot be verified based on the given information). Each rumor consists of a source post that makes a claim, and a set of replies, directly or indirectly towards the source post. We also employed an ensemble approach on this task, which uses multiple models together to do the veracity prediction.

For more details about these two tasks, please check the task description paper from the task organizers (Gorrell et al., 2019).

2 Related Studies

Rumor detection on social media has been a popular research topic in recent years. The early exploration of this issue started from two special case studies on rumor propagation during natural disasters like earthquakes and hurricanes (Gupta et. al., 2013; Mendoza et al., 2010). Many existing algorithms (Liu et al., 2015; Wu et. al., 2015; Yang et. al., 2012) for debunking rumors followed the work of Castillo et al. (2011). They studied information credibility and proposed a set of features that are able to retrospectively predict if an event is credible.

Stance classification is also an active research area that has been studied in previous work (Lukasik et al., 2016; Zubiaga et al., 2016; Kochkina et al., 2017). A time sequence classification technique has been proposed for detecting the stance against a rumor (Lukasik et al., 2016). Zubiaga et al. (2016) used sequence of label transitions in tree-structured conversations for classifying stance.

Several studies have applied neural networks on the verification of rumors (Ma et al., 2016; Kochkina et al., 2017; Ma et al., 2017); They mainly focus on analyzing the information propagation structure, and have not utilized much information on user credibility. User stance plays an important role in rumor detection. Recent works have employed multi-task learning approaches to jointly learn stance detection and veracity prediction, in order to improve classification accuracy by utilizing the interdependence between them (Ma et al.,; 2018; Kochkina et al., 2018).

3 System Description

We first describe the data set, the word embedding, our message representation method, and then our systems for the two tasks.

Data set quality: Regarding the annotation of the data set, as the task description already pointed out: the overall inter-annotator agreement rate of 63.7% showed the task to be challenging, and easier for source tweets (81.1%) than for replying tweets (62.2%). This means that there are many conflicting or inconsistent labels. This will confuse the learning based models, and make the model and prediction result unstable. When we analyzed the training data set, we found many such examples. To make the labels more consistent, we run an analysis to find the posts that are basically the same or highly similar, but their labels are different. We then mark these posts, and use the same label, the one labeled on the majority of these posts, on them during training. The similarity between two posts is calculated by cosine measure, and the post/message embedding is used in the calculation. The similarity threshold for being considered as similar posts is empirically set as 0.75.

Word embeddings: A popular word embedding data set used by many previous studies is one that is created from Google news articles using word2vec (Mikolov et al., 2013). Because the data in this task are social media messages, mainly tweets, we think a embedding model built specifically from tweets will be more appropriate. Therefore, we used tweets collected from Twitter to train a word embedding model. Only English tweets are used, and about 200 million tweets are used to build the embedding model. Totally, 3 billion words are processed, and word embeddings are generated for 3.5 million unique terms using the word2vec model (Mikolov et al., 2013) and data from (Li et al, 2017). In this task, although some messages are from Reddit, they are similar to tweets, in terms of language style and message structure, since both are social media messages.

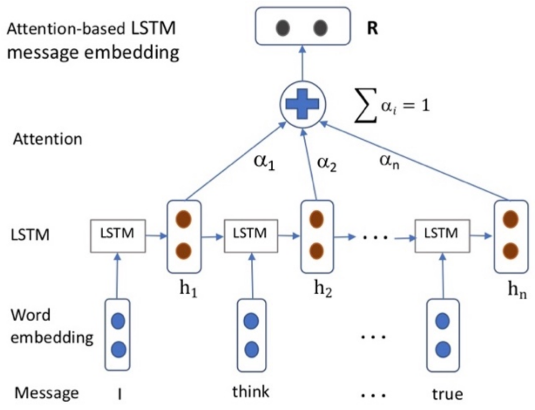

Figure 1. Message embedding based on the attention-based LSTM

Message representation: A tweet (or Reddit message) is usually very shot, consisting of only one sentence. In our models where a whole post is used, such as the stance detection, a message embedding is used as the message representation. We generate the message representation through an attention-based LSTM network for messages that have only one sentence. A post is first preprocessed, such as removing URLs, before it is fed into the LSTM network. Figure 1 shows the network structure for generating the message embedding.

3.1 Stance Detection

Similar to (Kochkina et al., 2017), we use a set of features that include the word embeddings and features generated from the message. They are listed below:

- **Message role:** it is the source message or a reply.
- **Message embedding**: this the message representation presented in Figure 1.
- **Presence of link**: has at least one link or not
- **Link type**: the types of the links. Types include image, video, and article.
- **Relation to source message**: whether this is a reply to the source message
- **Stance of parent message**: if this is a reply message, then the stance of the message it

replies to. In other words, we also check the stance of a message's parent in the propagation path.

- **Similarity with the source message**: Measured by cosine similarity using message embedding.
- **Punctuations**: we check if it has a question mark or exclamation mark.
- **Content length**: the message length after removing links and mentions
- **Mentions:** if the mentions are special accounts, e.g. @cnn, @theonion
- **Hashtags:** if it contains some special hashtags, e.g. #fakenews, #lying

These features are used by the following classification modules: A neural network model. The message embedding and other features are concatenated together and fed into the neural model, which consists of two fully connected layers and a softmax layer for the final label output; Models based on SVM, Random Forest and Logistic Regression, respectively; A rule based model.

The rule-based model handles some special case. Two examples are: 1. For source tweet stance: by default, label the source message as *support*, except A. if it is a Reddit message and it has "debunk this", then label it as *query*. B. if the source message has a question mark, and the sentence has the pattern of asking a question, label it as *query*. For example, the Yes/No questions: "did, do, does, have, has, am, is, are, can, could, may, would, will", and the WH-questions: "what, why, how, when, where", and the as well as their negations. 2. If the message is very short, and mainly contains a couple of keywords or hashtags expressing a very strong opinion, e.g. *#fakenews* or *"not true"*, then a corresponding label is assigned to it.

3.2 Rumor Verification

Our approach for rumor verification utilizes rumor information from several dimensions: text content, user credibility information, rumor propagation path, user stance, etc. Text content is utilized by almost all the previous studies on rumor verification. According to the deception style theory, the content style of deceptive information that aims to deceive readers should be somewhat different from that of the truth, e.g., using exaggerated expressions. An early study from (Castillo et al., 2011) uses many text features in their model. These features and other additional text features are also used in other studies (Liu et al., 2015; Enayet and El-Beltagy, 2017; Ma et al., 2017). Many previous studies have shown that user credibility information is very important in rumor verification (Castillo et al., 2011; Yang et al., 2012; Gupta et al., 2012; Liu et al., 2015; Li et al., 2016; Liu and Wu, 2018). Based on 421 false rumors and 1.47 million related tweets, Li et al. (2016) study various semantic aspects of false rumors, and analyze their spread and user characteristics. Their study shows that user credibility information is a good indicator for judging the credibility of a rumor story. To verify a rumor, we analyze the information from several dimensions:

- **Source content analysis**: whether the source message has links pointing to an article, video or image; length of the source message after removing URLs and mentions; number of named entities, verbs and nouns in the source message; whether the source message contains time expression.
- **Source account credibility:** the following information are considered: is a news agent account; profile has link pointing to top domains; account type: individual or organization (company, government agent, organization); profile has location information; profile has description; profile has image; profile has profession information; is verified user; number of followers, number of posts authors, account age, etc. How they are generated is similar to (Liu et al, 2015).
- **Source account credibility score**: calculated from the information listed in the *Source account credibility* category, and normalized to 0 to 1 (Liu et al, 2015).
- **Reply account credibility:** the profile information to check are similar to the ones in the Source account credibility category.
- **Reply account credibility score:** calculated from the information in the *Reply account credibility category*, and normalized to 0 to 1.
- **Stance of the source message:** get from Task A
- **Stance of replies**: percentage of each stance type; the overall stance score for each stance class, calculated by integrating each reply's account credibility score with its stance.
- **Rumor topic domain**: the topic area of the rumor, e.g. politics, business, science, etc. (Liu et al., 2015; Li et al., 2016).

These data are fed into different models for veracity prediction.

Propagation path analysis: Rumors spread through social media in the form of shares and re-shares of the source post and shared posts, resulting in a diffusion cascade or tree. Each source message has many replies, and they are either direct replies, or replies to other messages in the conversion thread. Take the rumors on Twitter as an example, the training data set contains 327 tweet rumors, and these rumors have 4017 branches and 5570 tweets, which means we have quite a lot replies that are not toward directly to the source message. The structure of the conversion thread is important for understanding the real stance of the user of a reply. For example, given a message "This is fake" and a reply to this message " I totally agree", if we do not know the reply is toward to the first message, then we will give a wrong label "support" to this reply. But actually this reply is denying the rumor claim. This is very important in rumor verification.

Models: We also use the ensemble approach in this task, where multiple models are used to predict rumor veracity, and stacking is employed for the final decision. Similar to the stance detection, we have following classification modules: A neural network model. All the features described above are concatenated together and fed into the neural model, which consists of two fully connected layers and a softmax layer for the final veracity prediction; Three models based on SVM, Random Forest and Logistic Regression, respectively; and a post-processing module that is described below.

Post-processing module

In this component, we consider some special characteristics of rumors and the data sets. We built some simple modules in this components, which may change the prediction results in previous steps. Some of them are described below:

Topics with multiple rumors: Some topics have multiple rumors, and in most cases, the rumors from the same topic have the same veracity, i.e. they are all true, false or unverified. To utilize this characteristic, for a given topic, after each rumor is processed and a prediction is generated, we use this post-process to re-evaluate their veracities, to see if any of them needs to be changed. The rumors from the same topic may or may not talk about the same claim, although in many cases, they are. We calculate the cosine similarity between two source posts, if it is greater than the threshold (set as 0.65 empirically), then the two rumors are considered as basically talking about the same claim, and their veracities are set as the same value. In similarity calculation, a source message is represented by its embedding, already described in previous section. The final veracity is chosen based on the distribution of the veracity values in these rumors, and their corresponding confidence scores.

Rumors originated from special accounts: due to the limited size of training data and annotation quality, some patterns or knowledge may not be caught by the trained models. But when we analyzed the data set, we found some patterns or signals that can provide very strong evidence on rumor veracity, especially for the false rumors. For example, TheOnion is a website usually publishing satirical news and opinions. A source message from this account usually is a false rumor. We check the source post and also the replies in the conversation thread, to see if there is evidence that the claim is from certain special accounts. Another example: if a rumor is from a very credible source, such as news agency NPR or a government agency, then it is very likely its veracity is true.

Rumors debunked or endorsed by special accounts: Similar to the last point, we also check the replies of a source messages, to see if some special accounts have expressed very strong opinion on that claim. For example, if a response is from Snopes.com, a rumor verification website, and it says "#fakenews", or its response is cited by a post in the conversation thread, we can confidently classify this rumor as false. The account information are obtained by analyzing the training data.

Rumor Veracity	Precision	Recall	F measure
True	0.733	0.710	0.721
False	0.828	0.600	0.696
Unverifies	0.227	0.500	0.313
Average	0.596	0.603	0.577

Table 1. Rumer verification result

4 Experiments and Results

The evaluation metric of Task A is the average macro F measure of the four stance categories. Task B uses two evaluation metrics: the average macro F measure of the three veracity types, and also RMSE. Regarding the model training, for the neural network model, the stochastic gradient descent, shuffled mini-batch, AdaDelta update, back-propagation and dropout are used. The word embeddings were fine-tuned during the training process.

For the stance detection task, the result of our system is 0.578 , based on the macro F measure of SDQC. Table 1 shows the rumor detection result of our system. It shows that the unverified category got a very low precision, 0.227, and consequently, its F value is also pretty low, which is 0.313. And this value drags down the average F value of the three categories to 0.577.

Abstract

We present SemEval-2019 Task 8 on *Fact Checking in Community Question Answering Forums*, which features two subtasks. Subtask A is about deciding whether a question asks for factual information vs. an opinion/advice vs. just socializing. Subtask B asks to predict whether an answer to a factual question is true, false or not a proper answer. We received 17 official submissions for subtask A and 11 official submissions for Subtask B. For subtask A, all systems improved over the majority class baseline. For Subtask B, all systems were below a majority class baseline, but several systems were very close to it. The leaderboard and the data from the competition can be found at http://competitions.codalab.org/competitions/20022.

1 Overview

The current coverage of the political landscape in both the press and in social media has led to an unprecedented situation. Like never before, a statement in an interview, a press release, a blog note, or a tweet can spread almost instantaneously. The speed of proliferation leaves little time for double-checking claims against the facts, which has proven critical in politics, e.g., during the 2016 presidential campaign in the USA, which was dominated by fake news in social media and by false claims.

Investigative journalists and volunteers have been working hard to get to the root of a claim and to present solid evidence in favor or against it. Manual fact-checking is very time-consuming, and thus automatic methods have been proposed to speed-up the process, e.g., there has been work on checking the factuality/credibility of a claim, of a news article, or of an information source (Ba et al., 2016; Zubiaga et al., 2016; Ma et al., 2016; Castillo et al., 2011; Baly et al., 2018).

The process starts when a document is made public. First, an intrinsic analysis is carried out in which check-worthy text fragments are identified. Then, other documents that might support or rebut a claim in the document are retrieved from various sources. Finally, by comparing a claim against the retrieved evidence, a system can determine whether the claim is likely true or likely false (or unsure, if no strong enough evidence either way could be found). For instance, Ciampaglia et al. (2015) do this using a knowledge graph derived from Wikipedia. The outcome could then be presented to a human expert for final judgement.[1]

For our two subtasks, we explore factuality in the context of Community Question Answering (cQA) forums. Forums such as StackOverflow, Yahoo! Answers, and Quora are very popular these days, as they represent effective means for communities around particular topics to share information. However, the information shared by the users is not always correct or accurate. There are multiple factors explaining the presence of incorrect answers in cQA forums, e.g., misunderstanding of the question, ignorance or maliciousness of the responder. Also, as a result of our dynamic world, the truth is time-sensitive: something that was true yesterday may be false today. Moreover, forums are often barely moderated and thus lack systematic quality control.

Here we focus on checking the factuality of questions and answers in cQA forums. This aspect was ignored in recent cQA tasks (Ishikawa et al., 2010; Nakov et al., 2015, 2016a, 2017a), where an answer is considered GOOD if it addresses the question, irrespective of its veracity, accuracy, etc.

[1]As of present, fully automatic methods for fact checking still lag behind in terms of quality, and thus also of credibility in the eyes of the users, compared to what high-quality manual checking by reputable sources can achieve, which means that a final double-checking by a human expert is needed.

Q: HI ;; IF WIFE IS UNDER HER HUSBAND'S SPONSORSHIP AND IS WILLING TO COME QATAR ON VISIT; HOW LONG SHE CAN STAY AFTER EXTENDING THE VISA EVERY MONTH? I HAVE HEARD ITS NOT POSSIBLE TO EXTEND VISIT VISA MORE THAN 6 MONTHS? CAN U PLEASE ANSWER ME.. THANKZZZ...

a_1: Maximum period is 9 Months....

a_2: 6 months maximum

a_3: This has been answered in QL so many times. Please do search for information regarding this. BTW answer is 6 months.

Figure 1: Example from the *Qatar Living* forum.

Figure 1 presents an excerpt of an example from the Qatar Living Forum, with one question and three answers selected from a longer thread. According to SemEval-2016 Task 3 (Nakov et al., 2016a), all three answers would be considered GOOD since they are formally answering the question. Nevertheless, a_1 contains false information, while a_2 and a_3 are correct, as can be established from an official government website.[2]

Checking the veracity of answers in a cQA forum is a hard problem, which requires putting together aspects of language understanding, modelling the context, integrating several information sources, uisng world knowledge and complex inference, among others. Moreover, high-quality automatic fact-checking would offer better experience to users of cQA systems, e.g., the user could be presented with veracity scores, where low scores would warn the user not to completely trust the answer or to double-check it.

2 Related Work

Fact-checking of answers was not studied before in the context of community Question Answering, apart from our own recent work (Mihaylova et al., 2018). Yet, in the context of cQA and general QA, there has been work on *credibility* assessment, which has been modelled primarily at the feature level, with the goal of improving GOOD answer identification. A notable exception are (Nakov et al., 2017b; Mihaylov et al., 2018), where credibility was a task on its own right. However, *credibility* is different from *veracity* (our focus here) as it is a subjective perception about whether a statement is credible, rather than actually truthful.

Jurczyk and Agichtein (2007) modelled author authority using link analysis. Agichtein et al. (2008) looked for high-quality answers using PageRank and HITS, in addition to intrinsic content quality, e.g., punctuation and typos, syntactic and semantic complexity, and grammaticality.

Lita et al. (2005) studied three qualitative dimensions for answers: source credibility (e.g., does the document come from a government website), sentiment analysis, and contradiction compared to other answers. Su et al. (2010) looked for verbs and adjectives that cast doubt. Banerjee and Han (2009) used language modelling to validate the reliability of an answer's source. Jeon et al. (2006) focused on non-textual features such as click counts, answer activity level, and copy counts. Pelleg et al. (2016) curated social media content using syntactic, semantic, and social signals. Unlike this research, we (*i*) target factuality rather than credibility, (*ii*) address it as a task in its own right, and on a specialised dataset.

Information credibility was also studied in social computing. Castillo et al. (2011) modeledd user reputation. Canini et al. (2011) analyzed the interaction of content and social network structure. Morris et al. (2012) studied how Twitter users judge truthfulness. Lukasik et al. (2015) used temporal patterns to detect rumors, and Zubiaga et al. (2016) focused on conversations.

Other authors have been querying the Web to gather support for accepting or refuting a claim (Popat et al., 2016; Karadzhov et al., 2017b). In social media, there has been research targeting the user, e.g., finding malicious users (Mihaylov and Nakov, 2016; Mihaylova et al., 2018; Mihaylov et al., 2018), *sockpuppets* (Maity et al., 2017), *Internet water army* (Chen et al., 2013), and *seminar users* (Darwish et al., 2017).

Finally, there has been work on credibility, trust, and expertise in news communities (Mukherjee and Weikum, 2015). Dong et al. (2015) proposed that a trustworthy source is one that contains very few false claims. Recent work has also focused on evaluating the factuality of reporting of entire news outlets (Baly et al., 2018, 2019).[3] However, none of this work was about QA or cQA.

[2]http://portal.moi.gov.qa/wps/portal/MOIInternet/departmentcommittees/visasentrypermeits/

[3]Knowing the reliability of a medium is important when fact-checking a claim (Popat et al., 2017; Nguyen et al., 2018) and when solving article-level tasks such as "fake news" and click-bait detection (Hardalov et al., 2016; Karadzhov et al., 2017a; Pan et al., 2018; Pérez-Rosas et al., 2018).

3 Subtasks and Data Description

SemEval-2019 Task 8 has two subtasks:

- **Subtask A:** Given a question from a cQA forum, predict whether this question asks for factual information vs. opinion/advice vs. just socializing.

- **Subtask B:** Given a factual question from a cQA forum, together with its answer thread, predict whether each answer provides true vs. false vs. non-factual information as a response to the question.

3.1 Data and Resources

We retrieved the data from the Qatar Living web forum[4]. We then cleaned it and we annotated it with the labels described in Sections 3.2 and 3.3.

For subtask A, we annotated the questions using Amazon Mechanical Turk[5]. To ensure high quality of the annotation, we went through all annotations and manually double-checked them.

For subtask B, we did not use an external annotation service, but instead we annotated all the data ourselves. Each answer was processed by three independent annotators, and we made sure we had proof for the label from reliable sources on the Web. Then, the annotations were consolidated after a discussion until agreement was achieved for each example.

All data is freely available under a Creative Commons Attribution 3.0 Unported (CC BY 3.0) license, and is accessible on the competition's website[6].

In addition to the provided annotated data, we also allowed the participants to use unlabelled data from the Qatar Living forum footnote`http://alt.qcri.org/semeval2016/task3/data/uploads/QL-unannotated-data-subtaskA.xml.zip`, as well as additional external resources, which they had to mention explicitly in their submissions.

Note that the class distribution in the training, development and test sets differs, especially for Subtask B. The reason for this is the way the data was prepared. The different datasets (training, development and test) were prepared on stages, because of the very time-consuming data annotation process.

[4]`http://www.qatarliving.com`
[5]`http://www.mturk.com/`
[6]`http://competitions.codalab.org/competitions/20022`

For each dataset annotation stage, we had to choose between releasing all the available annotated data or aim at releasing sets with similar label distribution. At the end, we decided to release the available data, although we were aware that this would result in releasing sets with different distribution and, in some cases, unbalanced categories.

3.2 Training Data for Subtask A

To create the dataset for the task, we chose to augment a pre-existing dataset for cQA with factuality annotations; this allowed us to stress the difference between (*a*) distinguishing a good vs. a bad answer, and (*b*) distinguishing a factually-true vs. a factually-false one. In particular, we added annotations for factuality to the CQA-QL-2016 dataset from SemEval-2016 Task 3 on Community Question Answering (Nakov et al., 2016a).

In CQA-QL-2016, the data is organized in question–answer threads (from the Qatar Living forum). Each question has a subject, a body, and meta information: question ID, date and time of posting, user name and ID, and category (e.g., *Computers and Internet* and *Moving to Qatar*).

We analyzed the forum questions and we defined three categories, related to their factuality. We then annotated the questions using Amazon Mechanical Turk. The three factuality categories are as follows:

∗ FACTUAL: The question asks for factual information, which can be answered by checking various information sources, and it is not ambiguous (e.g., "*What is Ooredoo customer service number?*").

∗ OPINION: The question asks for an opinion or an advice, not for a fact. (e.g., "*Can anyone recommend a good Vet in Doha?*")

∗ SOCIALIZING: Not a real question, but rather socializing/chatting. This can also mean expressing an opinion or sharing some information, without really asking anything of general interest. (e.g., "*What was your first car?*")

Table 1 shows the distribution of the labels for the question labels in the training, in the development and in the testing datasets. Overall, there are 1118, 239 and 953 questions annotated with the above-described labels.

Label	Train	Dev	Test
FACTUAL	311	62	299
OPINION	563	126	167
SOCIALIZING	244	51	487
TOTAL	**1118**	**239**	**953**

Table 1: **Subtask A:** Distribution of the factuality labels for the questions.

Label	Train	Dev	Test
TRUE	166	29	34
FALSE	135	31	45
NONFACTUAL	194	52	231
TOTAL	**495**	**112**	**310**

Table 2: **Subtask B:** Distribution of the factuality labels for the answers.

3.3 Training Data for Subtask B

For subtask B, we annotated for veracity the answers to the questions with a FACTUAL label for subtask A. Note that in CQA-QL-2016, each answer has a subject, a body, meta information (answer ID, user name, and ID), the question that it answers, and a judgement about how well it answers the question of its thread (GOOD , BAD or POTENTIALLY USEFUL).

We annotated the GOOD answers for factuality based on the assumption that a GOOD answer means it provides factual information, whether it is true or false. All BAD and POTENTIALLY USEFUL answers are automatically considered as NON-FACTUAL. The factuality labels are described as follows:

∗ FACTUAL – TRUE: The answer is True and can be proven with an external resource. (**Q:** *"I wanted to know if there were any specific shots and vaccinations I should get before coming over [to Doha]."*; **A:** *"Yes there are; though it varies depending on which country you come from. In the UK; the doctor has a list of all countries and the vaccinations needed for each."*).[7]

∗ FACTUAL – FALSE: The answer gives a factual response, but it is False and this can be proven using an external resource. (**Q:** *"Can I bring my pitbulls to Qatar?"*; **A:** *"Yes you can bring it but be careful this kind of dog is very dangerous."*).[8]

∗ FACTUAL – PARTIALLY TRUE: The answer contains more than one claim, and only some of these claims could be manually verified. (**Q:** *"I will be relocating from the UK to Qatar [...] is there a league or TT clubs / nights in Doha?"*; **A:** *"Visit Qatar Bowling Center during thursday and friday and you'll find people playing TT there."*).[9]

∗ FACTUAL – CONDITIONALLY TRUE: The answer is True in some cases, and False in others, depending on some conditions that the answer does not mention. (**Q:** *"My wife does not have NOC from Qatar Airways; but we are married now so can i bring her legally on my family visa as her husband?"*; **A:** *"Yes you can."*).[10]

∗ FACTUAL - RESPONDER UNSURE: The person giving the answer is not sure about the veracity of his/her statement. (e.g., "*Possible only if government employed. That's what I heard.*")

∗ NON-FACTUAL: When the answer does not provide factual information to the question; it can be an opinion or an advice that cannot be verified. (e.g., "*Its better to buy a new one.*").

We further discarded answers whose factuality was very time-sensitive and it makes no sense to check whether the statements are true or false (e.g., "*It is Friday tomorrow.*", "*It was raining last week.*").

Moreover, many answers are arguably somewhat time-sensitive, e.g., "*There is an IKEA in Doha.*" is true only after IKEA opened, but not before that. In such cases, we just used the present situation as a point of reference. We further discarded the answers for which the annotators could not find any information.

[7]The answer is factually true and this can be seen at http://wwwnc.cdc.gov/travel/destinations/traveler/none/qatar

[8]The answer is incorrect since pitbulls are included in the list of breeds banned in Qatar. See http://canvethospital.com/pet-relocation/banned-dog-breed-list-qatar-2015/

[9]The place mentioned in the answer has table tennis, but we do not know on which days. See http://www.qatarbowlingfederation.com/bowling-center/

[10]This answer can be true, but this depends upon some conditions. See http://www.onlineqatar.com/info/dependent-family-visa.aspx

Ultimately, we consolidated the above fine-grained labels into the following coarse-grained labels, which we used for subtask B:

∗ FACTUAL – TRUE: Contains answers with proven true, non-contradictory statements. This includes the answers with the label FACTUAL – TRUE from above. This label is used for answers one can trust as a true statement.

∗ FACTUAL – FALSE: Contains answers with statements that are proven to be false or not completely true. This includes answers with the following fine-grained factuality labels: FACTUAL – FALSE, FACTUAL – PARTIALLY FALSE, FACTUAL – CONDITIONALLY TRUE, FACTUAL – RESPONDER UNSURE. We also use this label for answers that contain a statement for which the person giving the answer expresses uncertainty in the claim.

∗ NON-FACTUAL: These are either non-factual statements or statements that could be factual, but no information about them could be found, i.e., we could find no way to check whether the statement was true or false. This category also includes some statements that have been incorrectly annotated as a GOOD answer. It also includes the very time-sensitive statements described before, such as "*It is Friday tomorrow?*". The BAD and the POTENTIALLY USEFUL answers from CQA-QL-2016 also fall in this category.

As we have mentioned above, we have annotated the answers to the FACTUAL questions selected from the Qatar Living forum. We targeted very high quality annotation, and thus we did not use crowd-sourcing, as a pilot experiment has shown that the task was very difficult and that it was not possible to guarantee that Turkers would do all the necessary verification and gather evidence from trusted sources. Instead, all examples were first annotated independently by three of us, and then, we carefully discussed *each example* to come up with a final label. The distribution of the labels on the training, on the development, and on the testind dataset are shown in Table 2[11].

[11]Although not very big, our dataset is larger than datasets used for similar problems, e.g., Ma et al. (2015) experimented with 226 rumors for rumor detection, and Popat et al. (2016) used 100 Wiki hoaxes for credibility assessment of textual claims.

3.4 Evaluation

Both subtasks are three-way classification problems. In subtask A, the questions were to be classified as FACTUAL, OPINION, or SOCIALIZING. Similarly, in subtask B there were also three target categories for the answers: FACTUAL - TRUE, FACTUAL - FALSE, and NON-FACTUAL.

We further scored the submissions based on Accuracy, macro-F1, and average recall (AvgRec).[12] For subtask B, we also report mean average precision (MAP), where the FACTUAL - TRUE instances were considered to be positive, and the remaining ones were negative. The official evaluation measure for both subtasks was Accuracy.

4 Participants and Results

We received 17 official submissions for Subtask A and 11 official submissions for Subtask B. Below we report the evaluation results.

Table 3 presents the results for subtask A on question classification. The results are based the official submissions in the evaluation phase. In this subtask, all of the submitted systems managed to improve over the majority class baseline, and several teams achieved similarly good results. Whenever a number of teams achieve the same result with respect to the main evaluation measure, i.e., Accuracy, we rank them according to the F1 score, and then by AvgRec if a tie still appears.

Table 4 presents the results based on the evaluation phase on the test set for predicting answer factuality labels. This subtask was more difficult as the majority class baseline was very high due to label unbalance. No team managed to improve over that baseline, but several teams had results that were very close to it.

5 Discussion

In the evaluation phase of the competition, the participants had to specify one official submission and were allowed up to two contrastive submissions. In the post-evaluation phase, they could upload an unlimited number of contrastive submissions. Below, we will only discuss the official submissions. The contrastive submissions, the ablation studies, and the experiments with different techniques are described by the participants in their respective system description papers.

[12]Average recall has some attractive properties and has been used in previous SemEval tasks, e.g., (Nakov et al., 2016b; Rosenthal et al., 2017).

Table 4: **Subtask B:** Results for answer classification based on the official submissions, evaluated on the test set.

The best system for Subtask A was by team Fermi (IIIT Hyderabad). They used Google's Universal Sentence representation (Cer et al., 2018), and XGBoost (Chen and Guestrin, 2016).

The best system for Subtask B was by team AUTOHOME-ORCA (Autohome Inc. and Beijing University of Posts and Telecommunications), who used BERT (Devlin et al., 2019).

They achieved their best results by using an ensemble, and by also using question meta-information (category and subject) in addition to the question and the answer text. They concatenated the category, the subject and the body of the questions into the first part separated by [SEP]. The replier's username and statement were concatenated as the second part. The two parts separated by [SEP] were pushed into the BERT model for answer classification. Then, based on the sequential outputs of the BERT model, some variant methods such as average-pooling, and bi-LSTM were adopted to produce the final results. To tackle the problem with insufficient training data, they further used data augmentation based on translation with Google Translate: in particular, they performed consecutive English-Chinese and Chinese-English translation to generate more synthetic training data.

Overall, the submitted systems for the two subtasks used a number of pre-processing steps to clean the text of the question and of the answer. As shown by the DOMLIN team, the pre-processing of the data turns out to be crucial. They reported up to 5% improvement in terms of accuracy when cleaning the unannotated forum data before fine-tuning a BERT model. Common preprocessing steps included removing or replacing the URLs, the numbers, the punctuation, the symbols, spell-checking, expansion of contractions, HTML tags, etc. DUTH also used lemmatization and stopword removal.

The submitted systems used a wide range of strategies for training their models. A sizable part of the systems used manually crafted features such as linguistic, syntactic, stylistic, and semantic features. Moreover, the systems used task-specific information such as answer ranking and rating. ColumbiaNLP also computed an average cosine similarity of one answer with respect to the other answers in the thread for subtask B, assuming that bad answers would differ substantially from the remaining answers.

While some of the approaches used character and word n-gram information, the teams also used word- and sentence-level embeddings. CodeForTheChange evaluated different classification algorithms fed with Skip-Thought vectors, and ultimately found that neural networks performed best for both subtasks with either concatenation or averaging over the vectors of the available texts. Fermi performed evaluation of different embedding models - InferSent, Concatenated Power Mean Word Embedding, Lexical Vectors, ELMo and The Universal Sentence Encoder, used in subtask A to feed an XGBoost classifier. ColumbiaNLP used ULMFiT, but performed additional unsupervised tuning of the language model on questions, answers and question-answer pairs from the Qatar Living Forum. TMLab's system used the Universal Sentence Encoder.

A common neural network architecture was LSTM, where YNU-HPCC combined LSTM with an attention mechanism. TueFact used comment chain embeddings. Other machine learning algorithms that participants tried include Random Forest, Adaboost, Perceptron, and SVM, inter alia.

While for question classification (subtask A), all the necessary information was contained in the question text and in the metadata, subtask B required additional resources. Most teams used the provided additional unannotated forum data in order to pre-train their language models or to extract more data with weak supervision (DOMLIN). Furthermore, several teams used other means for data augmentation such as SQuAD (BLCU NLP) or external Web information (SolomonLab).

6 Conclusion

We have described SemEval 2019 Task 8 on Fact Checking in Community Question Answering Forums. We received 17 and 11 submissions for Subtask A and B, respectively. Overall, subtask A (question classification) was easier and all submitted systems managed to improve over the majority class baseline. However, Subtask B (answer classification) proved to be much more challenging, and no team managed to improve over the majority class baseline, even though several teams came very close. For this latter subtask, using external resources and preprocessing proved to be crucial.

Acknowledgments

This research is part of the Tanbih project,[13] which aims to limit the effect of "fake news", propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the Qatar Computing Research Institute (QCRI), HBKU and the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL).

Abstract

Fact checking is an important task for maintaining high quality posts and improving user experience in Community Question Answering forums. Therefore, the SemEval-2019 task 8 is aimed to identify factual question (subtask A) and detect true factual information from corresponding answers (subtask B). In order to address this task, we propose a system based on the BERT model with meta information of questions. For the subtask A, the outputs of fine-tuned BERT classification model are combined with the feature of length of questions to boost the performance. For the subtask B, the predictions of several variants of BERT model encoding the meta information are combined to create an ensemble model. Our system achieved competitive results with an accuracy of 0.82 in the subtask A and 0.83 in the subtask B. The experimental results validate the effectiveness of our system.

1 Introduction

The Community Question Answering (CQA) forums are gaining more and more popularity because they can offer great opportunity for users to get appropriate answers to their questions from other users. Meanwhile, the accumulated massive questions and answers in CQA forums present a new challenge to provide valuable information for users more effectively. Therefore, researchers have shown an increased interest in CQA systems (Srba and Bielikova, 2016; Wang et al., 2018), aiming to facilitate efficient knowledge acquisition and circulation. Specifically, a large portion of researches mainly focus on the two tasks: find relevant questions to a new question to reuse corresponding answers (*Question Retrieval*), and search for relevant answers among existing answers to other questions (*Answer Selection*).

Despite a great deal of research on CQA, there are relatively few studies focusing on the quality of questions and answers. Actually, the credibility of answers is an important aspect, which can directly affect the user experience for CQA forums. In order to check the veracity of answers automatically, some recent works (Karadzhov et al., 2017; Mihaylova et al., 2018) attempt to utilize external sources and extract appropriate features for classification. Considering the importance of information veracity in CQA forums, the fact checking of answers is still an issue that is worth investigating further.

Therefore, the SemEval-2019 task 8 aims to conduct fact checking in CQA forums. In order to detect the veracity of answers, it is necessary to identify whether the questions are factual firstly. The task is comprised of two subtasks: the subtask A is targeted to identify whether a question is asking for factual information, an opinion/advice or socializing. Given factual questions, the subtask B is aimed to determine whether the corresponding answers are true, false or not factual.

In order to address the SemEval-2019 task 8, we propose a system based on the BERT model (Devlin et al., 2018). In our system, we extend BERT for integrating some meta information of questions into the BERT encoder, and generate an ensemble model from some potential classification models to achieve very competitive results. To be specific, in subtask A, two outputs of fine-tuned BERT classifiers are obtained from subjects and bodies of questions respectively. Then by combining both outputs with the length of questions as features, the AdaBoost method (Schapire, 1999) is utilized to boost the performance of question classification. As for subtask B, while encoding additional meta information (category and subject of questions) into BERT model, we adopt the bagging method for some variants of BERT model produced by adding additional layers. The experimental results in both subtasks demonstrate the effectiveness of our system.

The rest of our paper is organized in the following way. The related work about CQA is summarized in Section 2. Section 3 gives a more detailed description of our system. The results and analysis of experiments are demonstrated in Section 4. Finally, Section 5 presents the main conclusions.

2 Related Work

So far, most studies about CQA mainly pay attention to two tasks: *Question Retrieval* and *Answer Selection*. In previous works, some traditional methods treat questions or answers as bag of words and measure their similarities based on weighted matching between the words (Robertson et al., 1994) or translation probability learning from language model (Xue et al., 2008). In fact, similar questions often are not phrased with exactly same words, but related words, while there is very little token overlap between questions and answers. These methods essentially consider the question or answer as a bag of words, neglecting semantic information. So it is not surprising that the performance of traditional methods is not very well on aforementioned tasks. Recently, the neural-based models (He et al., 2015; Feng et al., 2015; Tan et al., 2016; Bachrach et al., 2017; Tay et al., 2018), which can capture some semantic relations, are proposed and become mainstream in the research about CQA gradually. The basic idea behind them is to learn the representation of questions and answers based on CNN or LSTM models, then conduct text matching by regarding both tasks as classification or learning to rank.

Furthermore, there are also public CQA datasets and competitions available, which promote relevant researches substantially. The public datasets are collected from various CQA websites, including Quora[1] , Yahoo! Answers[2], Qatar Living[3], etc. As for competitions, there is a kaggle competition[4] to identify the duplicated question pairs collecting from the Quora website. In SemEval-2015 Task 3 ”Answer Selection in Community Question Answering” (Nakov et al., 2015), it is mainly targeted on the answer selection task. And there is a more comprehensive competition in SemEval-2016 Task 3 (Nakov et al., 2016) designed for both Question Retrieval and Answer Selection, which is consisted of four subtasks: Question-Comment Similarity, Question-Question Similarity, Question-External Comment Similarity and Reranking the correct answers for a new question. In contrast, in SemEval-2017 task 3 (Nakov et al., 2017), a new duplicate question detection subtask is incorporated on the basis of the SemEval-2016 Task 3.

Although much work has been done in CQA researches, few attentions have been paid on improving the quality of questions and answers. In order to detect true factual answers automatically, Karadzhov et al. (Karadzhov et al., 2017) propose a general framework using external sources, which adopts the LSTM model (Hochreiter and Schmidhuber, 1997) to learn text representation of answers and external sources. Mihaylova et al. (Mihaylova et al., 2018) extract features from multiple aspects (the answer content, the author profile, the rest of the community forum and external authoritative sources) and demonstrate the effectiveness of fact checking of answers. At the same time, the lack of large-scale dataset also restricts the progress on fact checking in CQA forums further.

Recently, there are some of key milestones in the NLP field, such as ELMo (Peters et al., 2018), ULMFiT (Howard and Ruder, 2018), OpenAI GPT (Radford, 2018) and BERT (Devlin et al., 2018). These large-scale models have provided great performance on various NLP tasks, which can be pre-trained on a massive corpus of unlabeled data, and then fine-tuned to downstream tasks. Especially, the BERT model has achieved state-of-the-art results on a variety of language tasks, which allows us to obtain significantly higher performance than models that are only able to leverage a small task-specific dataset. Therefore, we build a system based on the BERT model for the SemEval2019 task 8 and achieve satisfactory results.

3 System Description

3.1 System Overview

The pipeline of our system is shown in Figure 1. Firstly, original input files with questions and answers are preprocessed, including removing redundant information (e.g., HTML tags, URLs and strings exceeding maximum length limit) and extracting the structured contents and

[1]https://www.quora.com
[2]https://answers.yahoo.com
[3]https://www.qatarliving.com
[4]https://www.kaggle.com/c/quora-question-pairs

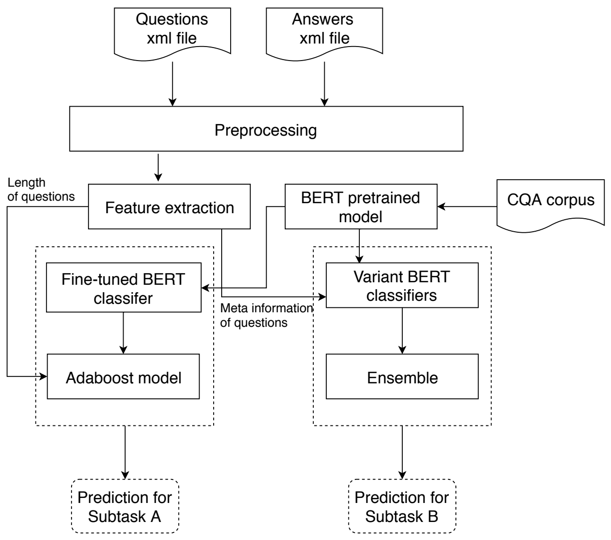

Figure 1: Pipeline of our system.

Label	Subject of questions	Body of questions
Opinion	e.g., *does anyone know good dentist?*	e.g., *can anybody recommend me a dentist? a good one.*
Factual	e.g., *when is eid gonna start?*	e.g., *when will eid start? like holidays*
Socializing	e.g., *What do you like about the person above you?*	e.g., *Hello people...let's play this game...you have to write something good about the person whose 'post' is above you on QL.You can write anything and you can write multiple times. For ex;the person who will respond to my post will write about me ;) and so on. This will be fun...*

Table 1: Samples of questions with different labels.

meta information. Secondly, some important features are obtained from structured information, such as the length and category of questions. Thirdly, based on the pre-trained BERT model released by Google[5], we conduct unsupervised training on specific CQA corpus further to make the model more suitable for the following classification tasks. Finally, the pre-trained BERT model and extracted features are fed into two subsystems to obtain predictions for the subtask A and the subtask B respectively. In the subsystem for subtask A (detailed in Subsection 3.2), the AdaBoost model is adopted to predict the classification of questions by combining the outputs of fine-tuned BERT classifier and the feature of length of questions. In the subsystem for subtask B (described in Subsection 3.3), some variant BERT models which encode meta information of questions are combined to generate an ensemble model for predication of labels of answers.

3.2 Subsystem for Subtask A

In this Subsection, the subsystem for subtask A is described in detail below.

Firstly, the subject and body of questions are encoded into two BERT models separately for fine-tuning on the question classification. The different inputs for both BERT models are represented as

$$[CLS] + text1 + [SEP]$$
$$[CLS] + text2 + [SEP]$$

where $text1$ and $text2$ are the subject and body of question respectively.

Secondly, the outputs of two fine-tuned BERT models are concatenated with the length of questions' body as features for classification. As illustrated in Table 1, it is rather intuitive that the body length of questions for socializing is inclined to be longer than ones for factual or opinion. Therefore, it is reasonable to consider the body length of questions as a suitable feature for classification. In addition, the results of each BERT model are probabilities of questions belonging to different classes (Factual, Opinion and Socializing). Then the feature vector x_{vector} for question classification is represented as follows

$$x_{vector} = [P_s1, P_s2, P_s3, P_b1, P_b2, P_b3, L_b] \quad (1)$$

where P_s1, P_s2, P_s3 are the output of a BERT model encoding the question subject. Similarly, P_b1, P_b2, P_b3 are the output of another BERT model encoding the question body, and L_b is the body length of a question.

Finally, based on the generated feature vector x_{vector}, the AdaBoost algorithm is adopted to obtain the final results of classification. AdaBoost is a typical Boosting algorithm that aims to convert a set of relative weak classifiers to a strong classifier. Therefore, the performance of classification can be strengthened by considering additional length feature, compared to the one that the BERT models

[5]https://github.com/google-research/bert

have achieved.

3.3 Subsystem for Subtask B

The Subsection describes the details of the subsystem for subtask B as follows.

Firstly, the subject and body of question, corresponding reply (i.e., answer) and meta information of question are combined to generate sequences for BERT encoders. In order to identify the true factual reply, the content of corresponding questions and auxiliary information (e.g., the category of question, username of a questioner or replier) should be necessary for classifiers. So in the subsystem, we investigate the influence of different information for the classification performance (see Table 4 for details), including the subject of question (F-subject), the usernames of questioner and replier (F-username) and the category of question (F-category). Ultimately, the text of answer and the information of F-subject and F-category are employed for our BERT based models. The generated sequence for inputs of models are represented as following:

$$[CLS] + text1 + [SEP] + text2 + [SEP]$$

We use [SEP] to separate between the information of question and answer. $text1$ is composed of F-subject, F-category and the body of question separated by the special symbol ($\sim$), while $text2$ is the text of corresponding reply.

Secondly, based on the generated sequences as inputs, we design three different categories of BERT based models for ensemble. As shown in

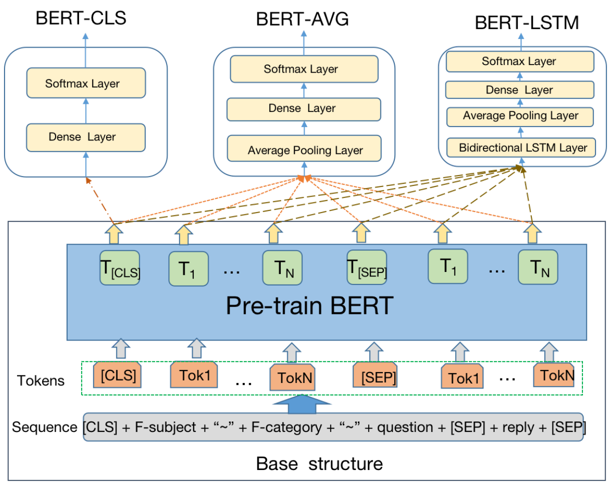

Figure 2: Architecture of BERT based models.

Figure 2, the specific structures of the three kinds of models are described as follows:

- *BERT-CLS*. The final hidden state for the first token [CLS] in the input is employed for fine-tuning the pre-trained BERT model by adding a classification layer and a standard softmax.

- *BERT-AVG*. Different from BERT-CLS, the final hidden states for all tokens are utilized for classification by conducting an average pooling, and then adding a full connected layer and a standard softmax.

- *BERT-LSTM*. Compared with BERT-AVG, a Bi-LSTM network is added between the pooling layer and the pre-trained BERT encoder. It must be noted that we only obtain the outputs of BERT encoder and the parameters of BERT encoder are not updated when training.

Thirdly, we select a set of competitive classifiers in the training process by the three kinds of BERT based models respectively. The method of five-fold cross-validation is employed. To be specific, the original samples are randomly divided into five sub-samples with equal size. And one of the five sub-samples is retained for validating the performance of classifier, and the rest of four sub-samples are used as training data. For each kind of BERT based model, the cross-validation process is repeated five times and each time no more than five optimal classifiers are obtained. Therefore, we get a total of sixty-five competitive classifiers filtered by certain threshold value on accuracy metric from three kinds of BERT based models for ensemble.

Finally, an effective integration strategy is applied to produce a strong classifier for the subtask. There are two candidate integration strategies:

- *Strategy 1 (Vote-ensemble)*: Each classifier casts a vote, the label of a sample is decided according to the majority of votes.

- *Strategy 2 (Distribution-ensemble)*: If the number of votes for any label exceeds one-half of the total number of classifiers, the sample is classified as the corresponding label. Otherwise, the label of the sample will be determined by considering the actual label distribution of the training data and the label distribution of votes together. For example, if one sample's votes for different labels are very close, then the sample is classified as the label with the largest proportion of data distribution.

At last, the strategy 2 is employed in our subsystem because it seems that Distribution-ensemble strategy is more robust for variance error, especially for small dataset, which will be discussed in Subsection 4.2 further.

4 Experiment

4.1 Dataset

The dataset is organized in question-answer threads from the Qatar Living forum. Each question, which is annotated by labels: Opinion, Factual and Socializing, has a subject, a body and meta information including question ID, category, posting time, user's ID and name. And each answer, which is classified as Factual-True, Factual-False and Non-Factual, has a body and meta information (answer ID, posting time, user's ID and name). The detailed statistics of the dataset in this task are illustrated in the task description paper (Mihaylova et al., 2019).

4.2 Experimental Results and Analysis

As for pre-training the BERT model, it is trained based on the BERT-Base-Cased model by the forum corpus provided by organizer[6]. The training batch size is 32, the number of train steps is 1e+5 and the learning rate is 2e-5. The detailed experimental results for both subtasks are described as following.

4.2.1 Results for Subtask A

In the subsystem for subtask A, the AdaBoost algorithm is employed to boost the performance on question classification. The number of estimators for the AdaBoost method is 10. To evaluate the performance of question classification, we compare our proposed method against the following models:

- Text-CNN (Kim, 2014): a simple CNN with one layer of convolution on top of word vectors. The subject and body of each question are concatenated as the input of Text-CNN model. When training, the number of epoch is 80, the initial learning rate is 0.001 and the dropout rate is set to 0.4.

- BERT without pre-training: the BERT-Base cased model release by Google. The input of the model is the concatenation of the subject and the body of each question with the symbol [SEP], which is represented as follows:

$$[CLS] + text1 + [SEP] + text2 + [SEP]$$

  $text1$ and $text2$ are the subject and body of a question separately. When training the model, the batch size of training is 32, the initial learning rate is 2e-5 and the number of epoch is 9.

- BERT with pre-training: the BERT model pre-trained by CQA corpus. The settings of hyper-parameters is the same as the BERT model without pre-training.

Models	Acc. (Dev)	Acc. (Test)
Text-CNN	0.6569	0.6502
BERT without pre-training	0.6862	0.7370
BERT with pre-training	0.7197	0.7922
Our method	**0.7283**	**0.8181**

Table 2: Performance of different models in the subtask A.

The comparison results are shown in Table 2. From the table, it can be observed that the accuracy of the Text-CNN model is much lower than the other three BERT-based models. Even if only the BERT model without pre-training is used to predict the final result, it is 2.93% and 8.68% higher than Text-CNN model on development dataset and test dataset, respectively. Considering the size of dataset is relative small, it seems to demonstrate the potential advantage of BERT based models. Compared with the BERT model without pre-training, the BERT model with pre-training has 3.35% and 5.52% increase respectively. It is illustrated that the step of pre-training the BERT model is very important. Furthermore, the accuracy achieved by our method is 0.86% and 2.59% higher than the one by the BERT with pre-training model on two datasets separately. It shows that the AdaBoost algorithm can make better use of the probability outputs from the fine-tuned BERT models for prediction. What's more, the body length of questions can be considered as an effective feature for training model and predicting results.

[6]http://alt.qcri.org/semeval2016/task3/data/uploads/QL-unannotated-data-subtaskA.xml.zip

4.2.2 Results for Subtask B

In the experiments for subtask B, the three kinds of BERT based models are implemented with TensorFlow and trained with Adam optimizer. The maximum length of sequence is set to 150 and the batch size is 4. The initial learning rates are 3e-5 for parameters of BERT encoder and 1e-3 for others.

Models	Acc.(Dev)	Acc.(Test)
BERT-AVG	0.6732	–
BERT-CLS	0.6667	–
BERT-LSTM	0.656	–
Vote-ensemble	0.6693	0.7935
Distr.-ensemble	**0.6845**	**0.8322**

Table 3: Performance of different models in the subtask B.

The experimental results of different kinds of models are shown in Table 3. From the table, it can be observed that the BERT-AVG model achieves the best performance in the three single models. By conducting average pooling operation on final hidden states of all tokens, the BERT-AVG model can capture more semantic information than the BERT-CLS model which can only pay attention to the hidden state of the [CLS] token. As for the BERT-LSTM model, it performs the worst, which may be caused by the highest model complexity and the lack of adequate training dataset, resulting in somewhat overfitting. In addition, it is indicated that ensemble models can obtain higher accuracy than single models and the strategy of Distribution-ensemble is more robust than the strategy of Vote-ensemble. This is because that when the numbers of votes for different labels are close to each other, it is difficult to identify the correct class only by the majority. By considering actual classification distribution in training dataset additionally, the Distribution-ensemble can show its potential advantage.

Feature	Acc.(Dev)
Baseline	0.6559
+F-category	0.6606(+0.47)
+F-username	0.6547(-0.12)
+F-subject	0.6642(+0.83)
+F-category, +F-subject	**0.6667(+1.08)**

Table 4: Performance of different features on development dataset in the subtask B. "+" means to add current features to the main feature.

In order to explore the effectiveness of different information for classification, a series of experiments based on the BERT-CLS model are conducted. The baseline model (BERT-CLS) is established only by encoding the information of the body of question and the corresponding answer. Therefore, the influence of other information can be discussed individually. By considering different information, the performance of the model validated on development dataset is shown in Table 4. It is observed that the F-username can not contribute to the increase of accuracy, which may be caused by existing many anonymous users in the forum. By encoding the information F-subject and F-category into the model, it can achieve the best performance.

5 Conclusion

Detecting the veracity of answers is vital to maintain high quality information in CQA forums. In order to address this problem, a system based on BERT model is developed for participating in the SemEval-2019 Task 8. In the system, the meta information of questions is encoded into the BERT model and an ensemble with multiple variants of BERT model are produced to accomplish better performance. In subtask A, we utilize the AdaBoost algorithm to the features that is consisted of fine-tuned results of BERT models and length of questions. In subtask B, after encoding the auxiliary information of questions and answers into the BERT model, fine-tuned BERT model and two variant models by adding average-pooling or LSTM layers are combined to reduce the variance error. Finally, our system achieved great performance with an accuracy of 0.82 and 0.83 in the two subtasks respectively.

To our surprise, the system has impressive results in the subtask B without using external sources. It may be explained by the potential advantage of BERT model over other models only trained on a small task-specific dataset. In the future, we will explore to retrieve relevant information from the Web efficiently and then integrate the external information into our BERT based model.

Abstract

We present the pilot SemEval task on Suggestion Mining. The task consists of subtasks A and B, where we created labeled data from feedback forum and hotel reviews respectively. Subtask A provides training and test data from the same domain, while Subtask B evaluates the system on a test dataset from a different domain than the available training data. 33 teams participated in the shared task, with a total of 50 members. We summarize the problem definition, benchmark dataset preparation, and methods used by the participating teams, providing details of the methods used by the top ranked systems. The dataset is made freely available to help advance the research in suggestion mining, and reproduce the systems submitted under this task.

1 Introduction

State of the art opinion mining systems provide numerical summaries of sentiments and tend to overlook additional descriptive and potentially useful content present in the opinionated text. We stress that such content also encompass information like suggestions, tips, and advice, which is otherwise explicitly sought by the stakeholders. For example, hotel reviews often contain room tips, i.e., which room should be preferred in a hotel. Likewise, tips on restaurants, shops, sightseeing, etc. are also present within the hotel reviews. On the other hand, platforms like Tripadvisor[1], which collect hotel and restaurant related opinions, request the reviewers to fill up the room tips section in addition to the hotel review. Likewise, sentences expressing advice, tips, and recommendations relating to a target entity can often be present in text available from different types of data sources, like blogs, microblogs, discussions, etc. Such sentences can be collectively referred to as suggestions. With the increasing availability of opinionated text, methods for automatic detection of suggestions can be employed for different use cases. Some example use cases are the extraction of suggestions for brand improvement, the extraction of tips and advice for customers, the extraction of the expressions of recommendations from unstructured data in order to aid recommender systems, or the summarisation of suggestion forums where suggestion providers often tend to provide context in their responses (Figure 1) which gets repetitive over a large number of responses relating to the same entity. The task of automatic identification of suggestions in a given text is referred to as *suggestion mining* (Brun and Hagege, 2013).

Studies performed on suggestion mining have defined it as a sentence classification task, where class prediction has to be made on each sentence of a given text, classes being *suggestion* and *non suggestion* (Negi, 2016). State of the art opinion mining systems have mostly focused on identifying sentiment polarity of the text. Therefore, suggestion mining remains a very less explored problem as compared to sentiment analysis, specially in the context of recent advancements in neural network based approaches for feature learning and transfer learning.

As suggestion mining is still an emerging research area, it lacks benchmark datasets and well defined annotation guidelines. A few early works were mostly rule based methods, mainly targeted towards the use case of extracting suggestions for product improvements (Brun and Hagege, 2013; Ramanand et al., 2010; Moghaddam, 2015). In our prior work, we performed early investigations on the problem definition and datasets, aiming for the statistical methods which also require benchmark train datasets in addition to the evaluation

How can we improve the tenant admin features O365?

3,051 votes

Allow the admin to pin custom tiles to the app launcher for all users in the tenant

With the newly released update it is now easy for an admin to add a custom tile to the My Apps page. However, as an admin you still can't add this custom tile to the app launcher for any user except yourself.

For several companies it would be nice if you gave the admin the ability to add tiles directly to the app launcher for all users. For example when you want to link to the time management tool, public website etc.

123 comments · Apps and App Launcher · Flag idea as inappropriate...

Barbara Feldon (Office 365 Customer Experience, Microsoft) responded

Great news! This capability is included in in the recently updated Office 365 Roadmap entry: "Admin App Launcher Customization Tools" which can be found in the "In Development" section.

https://products.office.com/en-us/business/office-365-roadmap.

Figure 1: A post from the suggestion forum for Microsoft developers

datasets(Negi and Buitelaar, 2015; Negi et al., 2016). A few other works also evaluated statistical classifiers (Wicaksono and Myaeng, 2012; Dong et al., 2013), which employed mostly manually identified features, however only two other works (Wicaksono and Myaeng, 2012; Dong et al., 2013) provided their datasets. Suggestion mining still lacks well defined annotation guidelines, a multi-domain and cross-domain approach to the problem and benchmark datasets, which we address in our recent work (Negi et al., 2018). Therefore, we introduce this pilot shared task to disseminate suggestion mining benchmarks and evaluate state of the art methods for text classification on domain specific and cross domain training scenarios. The datasets released as a part of the shared task include the domains hotel reviews and software developers suggestion forum (see Table 1).

Suggestion mining faces similar text processing challenges as other sentence or short text classification tasks related to opinion mining and subjectivity analysis, such as stance detection (Mohammad et al., 2016), or tweet sentiment classification (Rosenthal et al., 2015). Some of the observed challenges in suggestion mining are elaborated below:

- **Class imbalance:** Usually, suggestions tend to appear sparsely among opinionated text, which leads to higher data annotation costs and results in a class distribution bias in the trained models.

- **Figurative expressions:** Text from social media and other sources usually contains figurative use of language, which demands pragmatic understanding from the models. For example, 'Try asking for extra juice at breakfast - its 22 euros!!!!!' is more of a sarcasm than a suggestion. Therefore, a sentence framed as a typical suggestions may not always be a suggestion and vice versa. A variety of linguistic strategies used in suggestions also make this task interesting from a computational linguistics perspective and labeled datasets can be leveraged for linguistic studies as well.

- **Context dependency:** In some cases, context plays a major role in determining whether a sentence is a suggestion or not. For example, 'There is a parking garage on the corner of the Forbes showroom.' can be labeled as a suggestion (for parking space) when it appears in a restaurant review and a human annotator gets to read the full review. However, the same sentence would not be labeled as a suggestion if the text is aimed to describe the surroundings of the Forbes showroom.

- **Long and complex sentences:** Often, a suggestion is expressed in either one part of a sentence, or it is elaborated as a long sentence, like, *'I think that there should be a nice feature where you can be able to slide the status bar down and view all the push notifications that you got but you didn't view, just like*

Source	Sentence	Label
Hotel reviews	Be sure to specify a room at the back of the hotel.	suggestion
Hotel reviews	The point is, don't advertise the service if there are caveats that go with it.	non-suggestion
Suggestion forum	Why not let us have several pages that we can put tiles on and name whatever we want to	suggestion
Suggestion forum	It fails with a uninformative message indicating deployment failed.	non-suggestion

Table 1: Examples of suggestions found in reviews and the labels assigned to the suggestion sentences

android and IOS, but the best part is that it fixes many problems like when people wanted a short cut to turn WiFi on and off and data on and off so that would be a nice feature to have 2'. This poses challenges to the training of algorithms in terms of learning effective features, as well as for certain pre-processing steps like part of speech tagging.

Investigating the development of high performance suggestion mining systems could drive the engagement of both, commercial entities (like brand owners) as well as the research communities, working on problems such as opinion mining, supervised learning, or representation learning. A suggestion mining component can empower both, public and private sectors, to extract and leverage suggestions which are constantly expressed on various online platforms like Twitter[2] , TripAdvisor, or Reddit[3] for developing innovative services and products.

2 Task Definition

The early rule based approaches towards suggestion mining assumed that suggestions are always expressed using standard expressions like 'I recommend', 'I suggest that', 'You should', and created small evaluation datasets which were labeled in-house (Brun and Hagege, 2013; Ramanand et al., 2010). Only two of the previous studies released training datasets, which cover travel discussion forums (Wicaksono and Myaeng, 2013) and microblogs (Dong et al., 2013), while the review datasets from the previous works remain proprietary (Ramanand et al., 2010; Moghaddam, 2015). In our recent work, we perform a qualitative analysis of datasets from different sources, which includes investigation of linguistic properties of suggestions, relationship between sentiments and suggestions, and a laymans perception of suggestions (Negi, 2019). We also observed a low inter-annotator agreement in labeling sentences as suggestions and non-suggestions, and formulate a typology for sentences in context to suggestion detection, and design an annotation procedure based on this typology (Negi et al., 2018; Negi, 2019). For this shared task, we extend datasets from our previous studies, following the same task description and annotation method.

The Oxford dictionary defines suggestion as, *An idea or plan put forward for consideration*, and some of the listed synonyms of suggestions are *proposal, proposition, recommendation, advice, hint, tip, clue*. Many linguistic studies define how suggestions should be expressed in a standard use of language. However, in the context of text mining, we are dealing with user generated text on the web, which can be associated with multiple contexts, like the end user, domain etc. We observed in our layman annotation study, context may affect an annotator's judgment. In the absence of context, different annotators associate different contexts to a candidate sentence. We observed that the following concepts form an integral part of defining a suggestion in the context of suggestion mining and proposed an empirically driven and context-based definition of suggestions.

- **Surface structure:** Different surface structures (Chomsky, 1957; Crystal, 2011) can be used to express the underlying intention of giving the same suggestion. For example, *The nearby food outlets serve fresh local breakfast and are also cheaper* and *You can also have breakfast at the nearby food outlets which are cheaper and equally good.*

- **Context:** When dealing with specific use cases, context plays an important role in distinguishing a suggestion from a non-suggestion. Context may be present within

[2]https://www.twitter.com
[3]https://www.reddit.com

a given sentence. It can be a set of values corresponding to different variables that are provided explicitly and in addition to a given sentence. One or more of the following variables can constitute the context:

Domain: In this work, we refer to the source of a text as *domain*, which should not be considered in-line with the standard definition of domain. For example, in this shared task, we used hotel and suggestion forum domains.

Source text: The text in the entire source document to which a sentence belongs may also serve as a context, giving an insight into the discourse where the suggestion appeared.

Application or use case: Suggestions may sometimes be sought only around a specific topic, for example, room tips from hotel reviews. Suggestions can also be selectively mined for a certain class of users, for example, suggestions for future customers. All non-relevant suggestions in the data may be regarded as non-suggestions in this case.

Given that

- s denotes the surface structure of a sentence,
- C denotes additional context provided with s, where the context can be a set of values corresponding to certain variables, and
- $a(s, C)$ denotes the annotation agreement for the sentence, and t denotes a threshold value for the annotation agreement,

we write $S(s, C)$ to denote the *suggestion function*, which is defined as

$$S(s,C) = \begin{cases} Suggestion, & \text{if } a(s,C) \geq t \\ Non\text{-}suggestion, & \text{if } a(s,C) < t. \end{cases} \quad (1)$$

Depending on the choice of C, and, hence, on the value of $a(s, C)$, we identify four categories of sentences that a suggestion mining system is likely to encounter.

Explicit suggestions. *Explicit suggestions* are sentences for which S always outputs *Suggestion*, whether C is the empty set or not. They are like the *direct* and *conventionalised* forms of suggestions as defined by (Martínez Flor, 2005). It may also be the case that such sentences have a strong presence of context within their surface form, as in illustrated by *If you do end up here, be sure to specify a room at the back of the hotel.*

Explicit non-suggestions. These are the sentences for which S always outputs *Non-suggestion*, whether C is the empty set or not. For example, *Just returned from a 3 night stay.*

Implicit suggestions. These are sentences for which S outputs *Non-suggestion* only when C is the empty set. Typically, implicit suggestions do not posses the surface form of suggestions but the additional context helps the readers to identify them as suggestions. For example, *There is a parking garage on the corner of Forbes, so its pretty convenient* is labeled as a suggestion by the annotators when the context is revealed as that of a restaurant review. A sentence such as *Malahide is a pleasant village-turned-dormitory-town near the airport* can be considered as a suggestion given that it is obtained from a travel discussion thread for Dublin. These kind of sentences are observed to have a lower inter annotator agreement than the above two categories.

Implicit non-suggestions. These are sentences for which S outputs *Suggestion* only when C is an empty set. Typically, an implicit non-suggestion posses the surface form of suggestions but the context leads readers to identify them as non-suggestions. Such sentences may contain sarcasm. Examples include *Do not advertise if you don't know how to cook* appearing in a restaurant review and *The iPod is a very easy to use MP3 player, and if you can't figure this out, you shouldn't even own one* appearing in a MP3 player review.

The proposed categories provide the flexibility to change the scope of classes in a well defined manner, as well as to define context as per the application and use case. Based on the above four categoriese can define the scope of suggestion and non-suggestion classes for suggestion mining tasks. For open domain and cross domain suggestion mining, we proposed to limit the scope of suggestions to the *explicit suggestions*. Therefore, we set the definition of suggestion for this shared task as:

Let s be a sentence. If s is an explicit suggestion, assign the label *Suggestion*. Otherwise, assign the label *Non-suggestion*.

3 Dataset Annotation

A two phase annotation methodology, as proposed in our previous works (Negi et al., 2018; Negi, 2019) is followed.

3.1 Phase 1: Crowdsourced Annotations

This phase is performed using paid crowdsourcing, where each sentence is annotated by multiple layman annotators, and the set of annotators do not necessarily remain the same for all the sentences. We used Figure Eight[4] to collect layman annotations.

Annotators were also provided with the context, i.e. source text from where the sentence is extracted. They were simply asked to choose to label a sentence as suggestions if it contained expressions of suggestion, advice, tip, and recommendation. We aimed to collect implicit and explicit suggestions in this phase.

For quality control, before being allowed to perform a job, the annotators were presented with a set of test sentences which are similar to the actual questions except that their answers have already been provided by us to the system. We also submitted the explanation behind the correct answer. This way the test questions serve two purposes: test the annotators competency and understanding of the job, and train the annotator for the job. Crowdflower recommends certain best practices to prepare effective test questions.[5]. We submitted 30 test questions for each dataset. Each starting annotator was presented with 10 test questions, and only the annotators achieving an accuracy of 70% or more were allowed to proceed with the job. If an annotator passed the test and started the job, the remaining unseen test questions were presented to them in between the regular sentences without being notified. One sentence out of every 8 was a hidden test question. The accuracy score of a contributor on test questions is referred to as *Trust score* in a job. If an annotator's trust score dropped below a certain threshold during the course of the annotation, the system did not allow them to proceed further with the job. This threshold score was set to 70% in our case.

In addition to the hidden test questions, a minimum time for each annotator to stay on one page of the job was set. We set this time to 40 seconds (5 seconds on average for each sentence). If annotators appeared to be faster than that, they were automatically removed from the job. We restricted access to annotators from countries where English is a popular language and that are also likely to have a large crowdsourcing workforce. Most of the annotators came from Australia, Canada, Germany, India, Ireland, the United Kingdom, and the USA.

Annotation agreement: Crowdflower's *confidence* score describes the level of agreement between multiple contributors and the confidence in the validity of the result at the same time, we used a threshold confidence score of 0.6. However, it can be the case that a sentence is very ambiguous and cannot achieve the confidence score even after a large number of workers answered it. A maximum limit to the number of annotators is set in such case, and no further judgements are collected even if the threshold confidence is not reached. We set this limit to 5 annotators. Sentences that do not pass the confidence threshold of 0.6 are not included in the dataset.

3.2 Phase 2: Expert Annotations

This phase is performed by two in-house expert annotators, who are provided with the detailed annotation guidelines as compared to the phase 1 annotation guidelines, and the annotators are familiar with the problem definition and the task at hand. However, the annotators are not provided with the source text in this case. Phase 2 of the annotation is only applied to sentences that were labeled as suggestions in Phase 1, which drastically reduces the number of annotations to be performed in Phase 2.

Annotation Agreement: The inter-annotator agreement for Phase 2 was calculated by having two annotators label a subset of sentences for each domain (50 sentences). Cohen's kappa coefficient was used to measure the inter-annotator agreement. The remainder of the data instances were annotated by only one annotator. The fol-

Subtask	Domain	Suggestion/Non-suggestion			IA agreement (phase 2)
		Training	Trial Test	Test	
A	Software developer suggestion forums (Uservoice)	1428 / 4296	296 / 742	87/746	0.81
B	Hotel reviews (Trip Advisor)	448 / 7086	404 / 3000	348/476	0.86

Table 2: Details of released datasets

lowing guidelines were provided to the annotators in Phase 2 :

- The intent of giving a suggestion and the suggested action or recommended entity should be explicitly stated in the sentence. *Try the cup cakes at the bakery next door* is a positive example. Other explicit forms of this suggestion could be: *I recommend the cup cakes at the bakery next door* or *You should definitely taste the cup cakes from the bakery next door*. An implicit way of expressing the suggestion could be *The cup cakes from the bakery next door were delicious*.

- The suggestion should have the intent of benefiting a stakeholder and should not be mere sarcasm or a joke. For example, *If the player doesn't work now, you can run it over with your car* would not pass this test.

Following are some of the scenarios of conflicting judgments observed in this phase of annotation:

- In the case of suggestion forums for specific domains, like a software developer forum, domain knowledge is required to distinguish an implicit non-suggestion from an explicit suggestion. Consider, for example, the two sentences, *It needs to be an integrated part of the phones functionality, that is why I put it in Framework* and *Secondly, you need to limit the number of apps that a publisher can submit with a particular key word*. The first sentence is a description of already existing functionality and is a context sentence in the original post, while the second is suggestion for a new feature.

- No concrete mention of what is being advised such as in *It'd be great if you would work on a solution to improve the situation*.

- At times, there was a confusion between information (fact) or suggestion (opinion). For example, *You can get a ticket that covers 6 of the National Gallery sites for only about US$10*.

In the final dataset, the sentences that are labeled as suggestions in Phase 2 of the annotation process are labeled as suggestions, while all other sentences are labeled as non-suggestions.

4 SemEval 2019 Shared Task

This is the pilot shared task on suggestion mining, the task is set as a binary sentence classification task, where the classes are suggestion and non-suggestion. As explained previously, explicit suggestions are deemed as the suggestion class, and rest of the sentences are considered as non-suggestions. The task is further split into two subtasks, named as A and B. Participating teams were to participate in at-least one of the two subtasks.

Datasets: Table 2 lists the details of the currently datasets released under this task and the inter-annotator agreement in the phase 2 of annotations. The class distribution is retained as obtained from a random sample of the source dataset used for annotation.
Software suggestion forum: The sentences for this dataset were scraped from the Uservoice platform[6]. Uservoice provides customer engagement tools tobrands, and therefore hosts dedicated suggestion forums for certain prod-ucts. The Feedly mobile application forum and the Windows developer forum are openly accessible. A sample of posts were scraped and split into sentences using the Stanford CoreNLP toolkit. Many suggestions are in the form of requests, which is less frequent in other domains. The text contains highly technical vocabulary related to the software which is being discussed.
Hotel reviews: Wachsmuth et al. (2014) provide a large dataset of hotel reviews collected from the TripAdvisor website[7]. They segmented the

[6]https://www.uservoice.com/
[7]https://www.tripadvisor.com/

reviews into statements so that each statement has only one sentiment label and have manually labeled the sentiments. Statements are equivalent to sentences, and comprise of one or more clauses. We further annotated these segments as *suggestion* and *non-suggestion*.

Sub-Task A: Train and test dataset belong to the same domain. The provided domain is suggestion forum sentences for software developers. Title of the posts are excluded, which are at times summary of the suggestion.
Sub-Task B: No training dataset is provided, and the test dataset belongs to a different domain than the subtask A, i.e. hotel reviews. The participants could use the training dataset from subtask A. Participants were not allowed to use the trial test set for subtask B as a training dataset, however they were allowed to use trial test set as a validation dataset.
Additional resources: Participants were allowed to use additional language resources, with one exception. Participants will be prohibited from using additional hand labeled training datasets for any of the domain.
Evaluation Metrics: Classification performance of the submitted systems if evaluated on the basis of F-1 score for the positive class, i.e. the *suggestion* class, which ranges from 0 to 1.
Precision suggestion (P_{sugg}): The fraction of instances which are actually suggestions out of the ones which are predicted as suggestions.
P_{sugg} = True Positives / (True Positives + False Positives)

Recall suggestion (R_{sugg}): The fraction of suggestion class instances which are correctly identified out of the total number of suggestions.
R_{sugg} = True Positives / (True Positives + False Negatives)

F1 score for the suggestion class is:
$F1_{sugg} = 2 * (P_{sugg} * R_{sugg}) / (P_{sugg} + R_{sugg})$

Baseline System A rule based classifier is employed using the existing rules from some of the related works, the rules which were dependent on the domain specific variables were excluded from the baseline. Table 4 provides the rules used in the baseline system.

Trial vs Test phase: A trial test dataset was released prior to the final test/evaluation dataset. The class distribution in the trial set was deliberately balanced in order to not bias the participants towards a specific class distribution for the evaluation phase, and keep the class distribution of trial set different from that of the final test set. This was because the trial test dataset labels were released prior to the final evalaution phase, and it was used as a validation dataset by the participants.

5 Participating Systems

A total of 33 teams participated in the evaluation phase, where all teams participated in the subtask A, and 16 of these also participated in subtask B. This number is lower than the trial phase submissions, where a total of 50 teams submitted their results on trial test dataset. Out of 33, 20 teams also submitted their system description papers. A summary of these 20 systems is provided in Table 3, listing results and corresponding methods. The highest F-score achieved was reasonably high i.e. 0.78 for subtask A, given a very low number of suggestion sentences in the test dataset 2. The highest F-score for subtask B was 0.858, where the ratio of suggestion and non-suggestion sentences in the test set was higher than subtask A.

Top 3 systems: BERT (Devlin et al., 2018) pre-trained language model remains the common method in the top three systems submitted in subtask A, which is one of the state of the art statistical language models. However, the most interesting results are provided by the best performing system in subtask B, which uses a rule based classifier, where rules comprise of both words and POS tags. The devised rule-based classifier (Potamias et al., 2019) assigns confidence scores to sentences on the basis of lexical patterns organised in pre-specified categories and lexical lists corresponding to each subtask. This rule based system also performed fairly well in subtask A, where it achieved rank 5.

Transfer and Unsupervised Learning: While a variety of pre-trained word embeddings and language models were employed, BERT remains the most popular means of transfer learning in the submitted systems, where 7 out of top 13 systems for subtask A used BERT.
For subtask B, only two systems used additional

Table 4: Rules for the baseline system

domain specific unlabeled data, i.e. hotel reviews, and were ranked as 3 and 5. All other submissions for subtask B relied on pre-trained word embeddings and language models.

Class Imbalance: Given that there was a major difference in the class distribution between training, trial test, and final test datasets, a minority of the top ten systems explicitly handle class imbalance by methods like oversampling (team MIDAS) and assigning weights to the predicted probability which are in proportion to the class distribution of the training data (team Yimmon). Other top 10 systems performed fairly well without any additional configuration for class imbalance in their classifiers.

Types of Classifiers: All systems except two used statistical classifiers, with most of them using neural network classifiers. Classifier ensembles also remain a favoured approach among the top ten systems. The neural network classifiers clearly outperformed SVM, Naive Bayes and Logistic regression. For subtask B, rule based classifier seem to do fairly well. The state of the art deep learning classifiers achieved a similar performance without any manual feature engineering, as compared to the carefully hand crafted rules.

6 Summary

We organised the pilot shared task on suggestion mining, which was framed as a binary text classification task, with two subtasks representing domain dependent and cross-domain/open domain evaluation. The task achieved a high level of participation, and most importantly a wide coverage in terms of methods and algorithms. The approaches covered automatically learned rule, carefully crafted linguistic features and rules, SOTA neural network classifiers, and SOTA transfer learning approaches. This shared task acted as a catalyst in pushing forward the state of the art for Suggestion Mining which otherwise received We plan to extend the task in future years with larger datasets, and the problem framed as the extraction of suggestion sentences from source texts in place of sentence classification. The problem definition here a better availability of document level context as compared to the sentence level context.

Abstract

This paper presents our system to the SemEval-2019 Task 9, Suggestion Mining from Online Reviews and Forums. The goal of this task is to extract suggestions such as the expressions of tips, advice, and recommendations. We explore Bidirectional Encoder Representations from Transformers (BERT) focusing on target domain pre-training in Subtask A which provides training and test datasets in the same domain. In Subtask B, the cross domain suggestion mining task, we apply the idea of distant supervision. Our system obtained the third place in Subtask A and the fifth place in Subtask B, which demonstrates its efficacy of our approaches.

1 Introduction

In SemEval2019 Task 9, participants are required to build a model which can classify given sentences into suggestion and non-suggestion classes. We participate in two sub-tasks: domain specific suggestion mining task (Subtask A[1]) and cross domain suggestion mining task (Subtask B[2]). In Subtask A, the test dataset belongs to the same domain as the training and development datasets. These datasets are extracted from the suggestion forum for windows platform. In Subtask B, training and test datasets belong to separate domains. More specifically, the domain of the training dataset is entries from the windows forum and that of the test dataset is hotel reviews. Example sentences used in these tasks are listed in Table 1. For a description of these tasks please refer to (Negi et al., 2019).

Subtask A can be viewed as a binary text classification task. Recently, pre-training models, such as OpenAI GPI (Radford et al., 2018) and BERT (Devlin et al., 2018), have gained much attention with their ability to improve a number of downstream tasks. These models are pre-trained using unlabeled corpora and then fine-tuned on labeled datasets. We apply BERT to this task because it has achieved state-of-the-art performance in several text classification tasks. The difference to the original BERT model is that we further pre-train BERT model using an unlabeled corpus related to this domain. More concretely, we extract documents from a windows forum and run additional steps of pre-training using these documents, starting from the pre-trained BERT model.

Subtask A (windows platform)
P: xbox dev mode companion work ipv6 please...
N: I do not want to convert MSIs.
Subtask B (hotel review)
P: If you can, upgrade to an Ocean Front Room.
N: it doesn't have a very clean look.

Table 1: Example sentences in the test dataset. **P** means a positive sentence, i.e. suggestion sentence and **N** denotes a negative sentence, i.e. non-suggestion sentence.

In Subtask B, we apply the idea of distant supervision which has been firstly proposed by (Mintz et al., 2009). Distant supervision is a weakly supervised learning framework which tries to automatically generate noisy training examples. Specifically, we use the rule based system which is provided by the task organizer for creating a noisy training dataset and train the model based on them.

Our system significantly outperforms baseline methods on two subtasks. These results demonstrate its efficacy of our approaches, target domain pre-training in Subtask A and distant supervision in Subtask B.

[2]https://competitions.codalab.org/competitions/19956

2 System Description

Our model is built using a recent development of pre-training model, BERT. In the following, we describe details of this model first and then explain our systems in Subtask A and Subtask B.

2.1 BERT

BERT, proposed by (Devlin et al., 2018), has been shown to improve several tasks such as sentiment classification, calculating semantic textual similarity task, and recognizing textual entailment task. This model consists of several Transformer models (Vaswani et al., 2017) whose parameters are pre-trained on unlabeled corpora, Wikipedia and BooksCorpus (Zhu et al., 2015). Pre-training consists of two tasks, masked language modeling and next sentence prediction, and trained models of these unsupervised tasks are available.[3]

For the classification task, we added one layer to output predictions, suggestion or non-suggestion. These model parameters were then fine-tuned based on the labeled training dataset.

2.2 Subtask A

Subtask A is a classical document classification task, where training/development/test datasets consist of the same domain. The data has been collected from feedback posts on universal windows platform. We mainly use BERT in this task, however, in the following we describe several techniques to improve the score.

2.2.1 Target Domain Pre-training

The major difference between BERT and our system is the target domain pre-training. Typically, BERT training consists of two parts: pre-training on the general domain corpus and fine-tuning on the target task. On the other hand, our system consists of three training steps: pre-training on the general domain corpus, pre-training on the target domain corpus, and fine-tuning on the target task. More concretely, we further pre-train the model using a task specific unlabeled corpus scraped from the universal windows platform developer feedback site.[4] These documents are split into sentences and the model is then trained on two unsupervised tasks (i.e. masked language modeling and next sentence prediction). We should note here that we use officially provided pre-trained parameters as initial model parameters and further train the model based on target domain documents to obtain better network parameters.

This target domain pre-training can be considered as a similar framework of Universal Language Model Fine-Tuning (ULMFiT), proposed by (Howard and Ruder, 2018). In their framework, the model is firstly trained on general domain corpus to capture general features. In addition, the model is further trained on target task data to learn task specific features, and fine-tuned on the target task. This procedure is similar to our system. In other words, our work can be viewed as the extension of BERT model by using the idea of ULMFiT.

2.2.2 Model Averaging

(Reimers and Gurevych, 2017) showed that training deep neural network is sensitive to the initial weights and (Che et al., 2018) showed the effectiveness of ensembling models trained with different initialization. Furthermore, (Devlin et al., 2018) empirically showed that ensembling BERT models trained with different pre-training checkpoint leads to performance improvement. We follow this work and train three models with different pre-training checkpoint, then ensemble these models by simply averaging output scores.

2.3 Subtask B

Subtask B is cross-domain suggestion mining, where train and development datasets belong to windows platform domain, while the test dataset belongs to the hotel review domain. In this task, we do not use the datasets provided in Subtask A, because we find that models trained on these datasets tend to have poor performance (see also Sec. 3.2.2). We instead apply the paradigm of distant supervision.

Distant supervision is a framework to generate noisy annotated data automatically and use them as a training dataset. This idea has been firstly proposed by (Mintz et al., 2009) and well studied in the field of relation extraction (Riedel et al., 2010; Hoffmann et al., 2011).

2.3.1 Rule Based Labeling

For distant supervision, the initial labeling method is needed. In this work, we make use of the officially provided baseline method as an initial labeling tool. This system is based on a rule based

	Subtask A			Subtask B		
	Train	Dev	Test	Train	Dev	Test
Suggestions	2,085	296	87	-	404	348
Non Suggestions	6,415	296	746	-	404	476
All	8,500	592	833	-	808	824

Table 2: Statistics of datasets.

method. For example, if a specific word such as ”suggest” is in the sentence, then the sentence is predicted as a suggestion sentence. For more details, please see the code in the official repository.[5]

2.3.2 Model Training Procedure

After the labeled corpus is generated, we trained a model using this corpus. Here, we do not label all of the unlabeled sentences via the rule based system. Instead, we split the sentences into several pieces and label one of them by using the rule based system. A model is trained on the noisy labeled dataset and we label another piece through the trained model. We apply this procedure iteratively until the model is trained on the last piece. More specifically, our training procedure can be summarized as follows:

1. We prepare the unlabeled hotel review corpus and split it into N pieces (corpus C_1, C_2, C_3, ..., C_N).
2. We apply the baseline method which is provided by the task organizer to the corpus C_1 and treat predicted labels as true labels.
3. The model is then trained using the labeled corpus C'_1.
4. We apply the trained model to the corpus C_2 and treat predicted labels as true labels.
5. A new model is trained using the labeled corpus C'_2 and labels of sentences in C_3 are predicted by this model.
6. We iteratively apply the above procedure until the model is trained on the corpus C_N.

3 Experiments

Table 2 shows the statistics of datasets which are used in Subtask A and Subtask B. These datasets are available at the official repository.[6] For evaluating systems, F1 score for the positive class, i.e. the suggestion class, is employed.

[5]https://github.com/Semeval2019Task9/Subtask-B/blob/master/semeval-task9-baseline.py

[6]https://github.com/Semeval2019Task9

System	Dev F1	Test F1
Baseline	0.721	0.267
BERT BASE (Single)	0.845	0.731
BERT BASE (Sgl. + Tgt.)	0.866	0.755
BERT LARGE (Single)	0.867	0.737
BERT LARGE (Sgl. + Tgt.)	0.882	0.759
BERT LARGE (Ens. + Tgt.)	0.890	0.776

Table 3: Results of Subtask A. **Single** or **Sgl.** denotes the single model and **Ens.** means the ensembled models. **Tgt.** denotes the pre-training on the target domain corpus.

3.1 Subtask A

3.1.1 Settings

We employed the official BERT model. We used both BASE model which has 12 Transformer layers, 12 self-attention heads, and 768 hidden size, and LARGE model which has 24 Transformer layers, 16 self-attention heads, and 1024 hidden size. There are 110 million parameters in total in BASE model and 340 million parameters in LARGE model.

As for the target domain pre-training, we obtained the windows review corpus and split it into sentences using NLTK.[7] The number of scraped documents is 2,325 and we used these documents as the unlabeled corpus for further pre-training the BERT model.

3.1.2 Results and Discussions

Table 3 shows the results of the experiment. Here, the baseline method is a rule based method as explained in Sec. 2.3.1. From Table 3, we can conclude the following four things:

First, BERT LARGE model outperformed BERT BASE model despite of the small size of the dataset. In general, it has been known that increasing the model size leads to an improvement on large scale tasks such as machine translation, and this does not be applied to small scale tasks

[7]https://www.nltk.org/

except for (Devlin et al., 2018). They showed a similar tendency in another small scale task. These results demonstrate that large size models improve results not only on large scale tasks but also on small scale tasks, if the model has been well pre-trained.

Second, the effect of the target domain pre-training is not trivial. The improvement can be observed in both BASE and LARGE model. In BASE model, the F1 score is pushed from 0.845 to 0.866 in the development dataset and from 0.731 to 0.755 in the test dataset. In LARGE model, the score is improved from 0.867 to 0.882 in the development dataset and from 0.737 to 0.759 in the test dataset. These results show that better models are produced by target domain pre-training even if we do not have large, domain-specific documents.

Third, ensembling models leads to further performance improvement.

Fourth, Test F1 score is much lower than Dev F1 score. This has also been observed by other teams. In concrete, many teams have achieved over 0.850 F1 score on the development dataset, however, no team has achieved over 0.800 F1 score on the test dataset. It might have something to do with the small size of the development dataset size or the difference in the label distribution.

3.2 Subtask B

3.2.1 Settings

In Subtask B, we got unlabeled hotel review documents provided by (Wachsmuth et al., 2014).[8] We split documents into sentences using the NLTK package and randomly extracted 500,000 sentences. These sentences were further split into 5 pieces.

We firstly ran the baseline method and automatically labeled 100,000 sentences. These sentences were used as a training dataset to train the machine learning model. We used the BERT BASE model and set the default hyperparameters except for the training epochs. To avoid over-fitting, we trained the model for only one epoch.

As described in Sec. 2.3, another 100,000 sentences were automatically labeled using the trained model and we trained a new model using this labeled data. We iteratively applied this procedure and submitted results predicted by the final model.

[8]http://argumentation.bplaced.net/arguana/data

System	Dev F1	Test F1
Baseline	0.774	0.732
BERT BASE (windows)	0.308	0.419
BERT BASE (1st model)	0.800	0.785
BERT BASE (5th model)	0.817	0.793

Table 4: Results of Subtask B. **BERT BASE (windows)** is the model trained on windows corpus provided in Subtask A.

3.2.2 Results and Discussions

Table 4 shows the results of the experiment. As you can see in Table 4, BERT BASE (windows), the model trained on the other domain corpus, shows poor performance while the baseline method has achieved a much better score. This motivated us to apply the idea of distant supervision.

The model based on distant supervision significantly outperformed the baseline model. This result shows that the distant supervision idea can be applied successfully in the cross domain suggestion mining task. Furthermore, we can see that our iterative approach leads to more performance improvement (from 0.800 to 0.817 in the development dataset and 0.785 to 0.793 in the test dataset). We currently do not know why the F1 score has been improved, however, one interpretation could be that our iterative framework avoids over-fitting to the one model and learns more general decision boundaries. A detailed study of this effect is future work.

4 Conclusion

This paper explains our submission to SemEval2019 Task 9, Subtask A and Subtask B. We explored BERT models focusing on the target domain pre-training in Subtask A and the idea of the distant supervision in Subtask B. Our approach obtained the third place in Subtask A and the fifth place in Subtask B.

In the future, we will further investigate the effect of these approaches in other tasks.

Abstract

We report on the SemEval 2019 task on math question answering. We provided a question set derived from Math SAT practice exams, including 2778 training questions and 1082 test questions. For a significant subset of these questions, we also provided SMT-LIB logical form annotations and an interpreter that could solve these logical forms. Systems were evaluated based on the percentage of correctly answered questions. The top system correctly answered 45% of the test questions, a considerable improvement over the 17% random guessing baseline.

1 Overview

Over the past four years, there has been a surge of interest in math question answering. Research groups from around the globe have published papers on the topic, including MIT (Kushman et al., 2014), University of Washington (Hosseini et al., 2014; Koncel-Kedziorski et al., 2015), National Institute of Informatics, Japan (Matsuzaki et al., 2014), University of Illinois (Roy and Roth, 2015), Microsoft Research (Shi et al., 2015; Upadhyay and Chang, 2016), Baidu (Zhou et al., 2015), Arizona State University (Mitra and Baral, 2016), KU Leuven (Dries et al., 2017), Carnegie Mellon University (Sachan et al., 2017), Tencent (Wang et al., 2017), and DeepMind (Ling et al., 2017).

Math question answering has several attractive properties that have rekindled this interest:

1. It is easy to evaluate. Usually there is a single correct answer for a given question, either numeric or multiple-choice.

2. In order to achieve robust results, systems require some (explicit or implicit) semantic representation of the question language. Consider the first question in Figure 1. The correct answer (11) has a subtle relationship to the other quantities mentioned in the text (3 and 15). There is no obvious shortcut (like word association metrics on a bag-of-words representation of the question) to guessing 11.

3. Math questions exhibit interesting semantic phenomena like cross-sentence coreference and indirect coreference (e.g. in the geometry question from Figure 1, "the third side" refers to a triangle introduced in a previous sentence).

Closed-vocabulary algebra: Suppose 3x + y = 15, where x is a positive integer. What is the difference between the largest possible value of y and the smallest possible value of x, assuming that y is also a positive integer?

Open-vocabulary algebra: At a basketball tournament involving 8 teams, each team played 4 games with each of the other teams. How many games were played at this tournament?

Geometry: The lengths of two sides of a triangle are $(x-2)$ and $(x+2)$, where $x > 2$. Which of the following ranges includes all and only the possible values of the third side y? (A) $0 < y < x$ (B) $0 < y < 2x$ (C) $4 < y < 2x$

Figure 1: Example math questions from different genres.

This task sought to unify the somewhat divergent research efforts and to address certain recognized data issues that have developed in the nascent

phase of this subfield. We discuss these issues in the next section.

2 Existing Resources

Existing datasets are either scraped from the web and filtered (Kushman et al., 2014; Hosseini et al., 2014; Roy and Roth, 2015; Shi et al., 2015) or crowdsourced (Ling et al., 2017).

The scraped datasets have been observed to be narrow in semantic scope, and to exhibit considerable lexical overlap from question to question (Koncel-Kedziorski et al., 2015; Roy and Roth, 2016). Also, they tend to be curated to showcase proposed models (e.g. by requiring every quantity present in the semantic representation to be explicitly mentioned in the question).

DeepMind (Ling et al., 2017) provided a public, large-scale dataset called AQuA, consisting of approximately 100,000 questions. This dataset was created by using crowdsourcing to augment a nucleus of web-scraped questions. Unfortunately, the result is extremely redundant and noisy. Figure 2 shows a typical excerpt from the sorted list of AQuA questions. Note the amount of repeated boilerplate and the low quality of the language. While AQuA may prove useful for training, it is inappropriate as an evaluation set.

3 Resource: Train/Test Data from Math SAT practice tests

Over the course of the Euclid project (Hosseini et al., 2014; Seo et al., 2014, 2015; Koncel-Kedziorski et al., 2015; Hopkins et al., 2017) at the Allen Institute for Artificial Intelligence, we curated a sizable collection of practice exams for Math SAT study guides. These were originally used as training and test in a paper that appeared at EMNLP (Hopkins et al., 2017). At the time, this dataset consisted of 648 training questions (12 practice tests) and 1082 test questions (21 practice tests). For this task, we expanded the training set to include 2778 training questions (over 50 practice tests).

Because the data is a compilation of SAT practice exams in their entirety, its distribution of topics corresponds to (at least one authority's idea of) the breadth of knowledge expected of an incoming college student. It is curated by impartial third parties (the study guide publishers) and is thus not a priori biased towards any particular model. The language is high quality and diverse.

3.1 Data Collection Process and Format

First, practice exams were scanned from physical printed copies of SAT study guides by Kaplan, McGraw-Hill, and the Princeton Review, among others. We also processed official PDF practice exams issued by the College Board. Then, trained workers manually encoded each exam as a LaTeX document, attempting to preserve the original formatting as much as possible. PDFs generated from the LaTeX documents were compared against the original scans to ensure quality and corrections were made as necessary.

Finally, the LaTeX documents were automatically converted into the JSON format shown in Figure 3. Diagrams from the exams are stored as Portable Network Graphics (PNG) files in a com-

mon directory. If a question refers to a diagram, then this is captured by the "diagramRef" field. Not all questions are multiple-choice. For non-multiple choice questions, the "answer" field contains the answer itself (as a string) rather than the choice key.

3.2 Subtasks

The Math SAT contains three broadly discernible subcategories (examples of which are provided in Figure 1):

1. **Closed-vocabulary algebra (approximately 44% of the questions):** Algebra word problems described with a circumscribed mathematical vocabulary. Note that the language and semantics can still be quite involved (see the first example in Figure 1).

2. **Open-vocabulary algebra (approximately 20% of the questions):** Algebra word problems described with an open-ended vocabulary, often involving real-world situation descriptions.

3. **Geometry (approximately 31% of the questions):** In contrast to the algebra subdomains, these often involve diagrams and thus require methods that perform joint reasoning over language and images, e.g. (Seo et al., 2014).

As part of the digitization process described in the previous section, we have also tagged the questions based on this categorization. A small minority (approximately 5%) of questions do not fall into any of these categories.

This categorization provides the basis for three subtasks: (1) closed algebra QA, (2) open algebra QA, and (3) geometry QA. Note that the algebra subtasks do not involve diagrams (algebra questions involving diagrams are classified into the small "other" category). Table 1 shows the number of questions collected, organized by subtask.

4 Additional Resource: Logical Forms for Closed Algebra

To make it easier for researchers to build systems, we provided logical form annotations for a majority of the training questions in the closed algebra subtask, as well as an engine that solves these logical forms. The logical form language was introduced in (Hopkins et al., 2017). Figure 4 shows an example logical form for the question "The sum of a two-digit number and its reverse is 121. What is the number?" The logical form language adopts

```
(declare-const q Number)
(assert (= (Count (Digits q)) 2))
(assert (= 121 (Sum q (Reverse q))))
(assert (Query q))
```

Figure 4: Logical form annotation for the question "The sum of a two-digit number and its reverse is 121. What is the number?"

the popular SMT-LIB syntax (Barrett et al., 2017), to facilitate language expansion and the building of alternate engines.

As part of the SemEval task, we provided:

- Logical form annotations for 50% of the closed algebra training data.
- Thorough documentation of the logical form language.
- An interpreter that can solve all provided annotations.

The logical form interpreter is an extended version of the one described in (Hopkins et al., 2017). This interpreter is written in Scala. We provide Scala, Java, and Python APIs.

Note: the logical form annotations and interpreter were provided to help lower the barrier to entry, but participants were not required to use them.

5 Evaluation Methodology and Baseline

For each subtask, the main evaluation metric was simply question accuracy, i.e. the number of correctly answered questions. We provided a Python script that took as input a list of JSON datum { id: <id>, response: "<response>" }, where <id> is the integer index of a question and <response> is the guessed response (either a choice key or a numeric string). Its output was the number of correct responses divided by the total number of questions in the subtask.

While the main evaluation metric included no penalties for guessing, we also computed a secondary metric that implements the actual evaluation metric used to score these SATs. This metric is the number of correct questions, minus 1/4 point for each incorrect guess. We include this metric to challenge participants to investigate high-precision QA systems.

For each subtask, we provided a simple Python baseline that reads in a JSON file containing the evaluation questions, and randomly guesses a choice key for each multiple choice question, and "0" for each numeric-answer question.

To train their systems, participants were permitted to use the following public resources: (a) the provided SAT training data and annotations, (b) data collected in MAWPS (Koncel-Kedziorski et al., 2016), (c) AQuA. Participants were also welcome to use standard public corpora for training word vector representations, language models, etc.

6 Evaluation

Table 2 shows the teams (and their affiliations) that submitted systems that beat the baseline in at least one task. Tables 3, 4, 5, and 6 compares the performance of these systems. The AiFu systems (Ding et al., 2019) outperformed the other entries by a wide margin.

6.1 The AiFu System

The AiFu system (Ding et al., 2019), like other math question answering systems designed for complex domains (Shi et al., 2015; Hopkins et al., 2017), followed the architecture in Figure 5. First, a natural language question is transformed into a logical form via a "translator" (semantic parser), then this logical form is given to a symbolic solver (after a suitable format conversion).

Like the previous semantic parsing approaches, the AiFu semantic parser is engineered manually, using the training set as a guide.

AiFu also incorporates a neural network-based system trained to guess the answer to a multiple choice question based on its question word sequence. Although this system does not work well independently, it boosts the performance of the overall system when used as a fallback for questions that go unanswered by the symbolic system.

The AiFu team submitted two variants of their system, referred to in the comparison tables as AiFu 1 and AiFu 2.

6.2 The ProblemSolver System

The ProblemSolver system (Luo et al., 2019) combines two approaches.

The first approach is a neural sequence-to-sequence translator that maps a question, e.g. "If $x + 345 = 111$, what is the value of x", to a response, e.g. "-234". Because the provided data is insufficiently large for training the sequence-

to-sequence model, they use data augmentation methods to increase the data size to over 600K questions.

The second approach is an adaptation of the arithmetic tree approach of (Roy and Roth, 2015) to Math SAT question answering.

The combination of these techniques provides a minor improvement over the random guessing baseline.

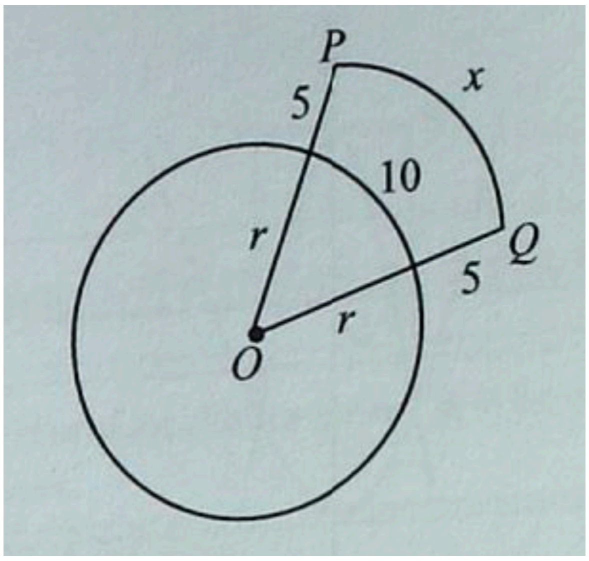

Figure 6: Example diagram accompanying the question "In the circle above, the length of an arc is 10, and there are two radii shown extended by 5 units outside the circle. If the length of arc Q is x, what must x equal?"

7 Discussion

Lately, math question answering seems to have bifurcated into two distinct approaches:

1. Simple, elegant machine learning approaches that work mainly on narrowly-scoped datasets with considerable redundancy.

2. Engineering-heavy, rule-based approaches that significantly outperform ML approaches on more realistic datasets, but are laborious to scale to new domains.

This SemEval task provides additional examples of these two approaches. As NLP researchers, we could focus on narrow-scope datasets for the time being[1], improving the performance of scalable ML approaches on these datasets. However the challenges presented by more difficult datasets, like the Math SAT data provided in this task, are intriguing and important. For instance:

How do we synthesize information that comes from heterogenous sources (e.g. from text and diagrams)?

Many of the geometry questions require a generalized notion of coreference resolution that spans language and vision. Figure 6 shows an example diagram that accompanies the question "In the circle above, the length of an arc is 10, and there are two radii shown extended by 5 units outside the circle. If the length of arc Q is x, what must x equal?". It remains an open question how to reliably resolve textual references like "the circle above" and "two radii shown" with diagram components. (Seo et al., 2014, 2015) provide a starting point for this area, but their dataset consisted of less than 100 diagrams. Hopefully our larger resource can help spur research into this research question.

How can machine learning be leveraged to reduce (or eliminate) the burden of engineering semantic parsers for complicated domains?

Given that the only techniques that have so far found success on Math SAT question answering (Hopkins et al., 2017; Ding et al., 2019) have involved semantic parsers with engineered rules, it suggests that one path forward might be to use machine learning to facilitate the engineering or elicitation of such rules for low-resource QA domains.

How do we create ML systems for diverse datasets for which we do not (and will never have) millions of training instances?

Despite the huge industry surrounding the Math SAT, it was still challenging to find and digitize over 50 distinct practice exams. Having millions of instances is not feasible. We argue that there will always be a long tail of domains for which we do not have millions of training instances, and we need ways to induce performant systems on this scale of data.

8 Conclusion

We have digitized over 70 SAT practice exams as a resource for driving research in math (and low-resource) question answering. We have also provided logical form annotations for approximately half of the closed-vocabulary algebra questions in the training data. The top system in our competition, AiFu, correctly answered 45% of the test questions, compared to a random guessing baseline of 17%. Our data and logical forms are available at https://github.com/allenai/semeval-2019-task-10, subject to the terms and conditions specified in that repository.

[1]Indeed, this seems to be the prevailing opinion of the hundredsome task participants who abandoned the task after obtaining the data.

Abstract

`AiFu` has won the first place in the SemEval-2019 Task [10] - "Math Question Answering"(Hopkins et al.) competition. This paper is to describe how it works technically and to report and analyze some essential experimental results.

1 Introduction

Recently, math question answering has attracted a lot of attention in the AI community, both in academia and in industry (Matsuzaki et al., 2017) (Wang et al., 2017) (Huang et al., 2016) (Wang et al., 2018) (Hosseini et al., 2014)(Huang et al., 2018a) (Huang et al., 2018b) (Kushman et al., 2014) (Liang et al., 2017) (Mitra and Baral, 2016) (Zhou et al., 2015) (Roy and Roth, 2017)(Hopkins et al., 2017). On one side, it raises a difficult yet workable challenge for the current development of AI research. In order to tackle this challenge, one has to integrate and advance many subareas in AI including knowledge representation and reasoning, machine learning, natural language understanding and image understanding. On the other side, math question answering itself has important commercial value in the AI+Education industry.

Against this backdrop, SemEval-2019 organizes a competition on math question answering, namely Task 10 (Hopkins et al.). In this task, an opportunity is provided for Math Question-Answering systems to test themselves on a benchmark that consists of many math questions collected from the US Math Scholastic Achievement Test (SAT).

We have implemented a prototype system, called `AiFu`, to tackle this challenge, and it has won the first place at the end. `AiFu` is an integrated system that combines the state-of-the-art approaches from many important subareas in AI, and more importantly, it also develops and justifies some new ideas and techniques.

This paper is to describe how `AiFu` works technically and to report and analyze some essential experimental results. In the next section, we go through the technical details of `AiFu` that consists of many essential components including representation, reasoning and natural language understanding. In Section 3, we report our experimental results and shed new insights on why `AiFu` works in some cases but not in others. Finally, we conclude this paper and point out some future directions.

2 Method

Figure 1 depicts the overall architecture of `AiFu`. Given a mathematical question, a translator is used to convert it into its internal representation, which is sent to an encoder to further convert it into a math representation that can be directly used by the SMT solver Z3 (De Moura and Bjørner, 2008). Finally, by calling Z3, the solution of the original mathematical question is obtained.

2.1 Internal Representation

We use an internal representation language, called Verb Connection Formula (VCF), to bridge the gap between mathematical questions and their formal mathematical counterparts.

VCF is based on assertional logic (Zhou, 2017), in which all mathematical objects are formalized as either individuals (constants and variables), or concepts, or operators (functions and relations). For instance, the natural language sentence "the integer x equals to 3" is transformed to "Integer(x), Equal(x,3)" in VCF, where "x" and "3" are individuals, "Integer" is a concept and "Equal" is a Boolean operator, i.e., relation. Meta level mathematical concepts such as equation and inequality are represented as concepts in VCF too. For instance, an equation $9 + 3^{n+2} = m$ in the question is transformed to "Equation(9+3**(n+2)=m)" in VCF, and an inequality $xyz \neq 0$ is transformed into "Inequality(x*y*z!=0)". VCF uses the symbol $:-$ for representing the implication relationship between statements. For instance, the VCF representation of the natural language sentence "When n is a positive integer, $9 + 3^{n+2} = m$" is "(Equation(9+3**(n+2)=m)):-(Positive(n),Integer(n))".

2.2 Translator

The translator transforms mathematical questions to corresponding statements in VCF.

Segmentation and POS tagging: Our translator uses the Stanford NLP parser (Chen and Manning, 2014) for segmentation and POS tagging. In order to handle Math questions, we introduce two new POS taggers, namely "FORM" for indicating Math formula and "VAL" for indicating variable. For example, the result of POS tagging of "When n is a positive integer, $9 + 3^{n+2} = m$" is "When/WRB n/VAL is/VBZ a/DT positive/JJ integer/NN ,/PUNCTUATION $9 + 3^{n+2} = m$/FORM".

Semantic parsing:

We adopt a top-down rule-based template approach for semantic parsing, i.e., translating math questions in English to statements in VCF. As shown in Table 1, we consider five basic clause types, corresponding to five syntactic structures respectively.

Type	Description	Examples
LEAF	a single word	"If","percent", "of"
NOUN	entity with adjunct words	"125 percent"
PREP	relation with multiple entities	125 percent of x
PRED	clause with operators	"125 percent of x is 150"
CONJ	causal connection between two clauses	"if 125 percent of x is 150,what is x percent of 75"

Table 1: Clause types

Algorithm 1 illustrates how to construct the semantic parsing tree for each sentence in the question from top to down. The root must be the sentence itself. Each node is assigned with one of the five types according to hand-crafted rule-based templates. Based on which, we decompose it into several child nodes correspondingly as different clause types result in different kinds of decomposition according to the templates. Note that each leaf node must be assigned with LEAF.

Algorithm 1: Semantic parsing algorithm

```
   input : a sentence in the question
   output: a list of VCF statements
1  root = original sentence;
2  Stack = Empty;
3  VCF_Stack = Empty;
4  Stack.push(root);
5  while Stack is not Empty do
6      current_node = Stack.pop();
7      templates = get_valid_templates(current_node);
8      template = choose_template(templates);
9      current_node.VCF_template = get_VCF_template(template);
10     VCF_Stack.push(current_node);
11     nodes = get_child_nodes(template,current_node);
12     for node in nodes do
13         current_node.child_nodes.add(node);
14         if type(node) != LEAF then
15             Stack.push(node);
16         end
17     end
18 end
19 while VCF_Stack is not Empty do
20     current_node = VCF_Stack.pop();
21     current_node.VCF=get_VCF_from_template_and_child_node();
22 end
23 return $root.VCF$
```

Figure 2 illustrates a semantic parsing tree example, in which each node is associated with one of the five basic types. According to this semantic parsing tree, we compute the resulting VCF statements from bottom to up recursively. For instance, the node "125 percent/NOUN" is converted into "NumberPer-

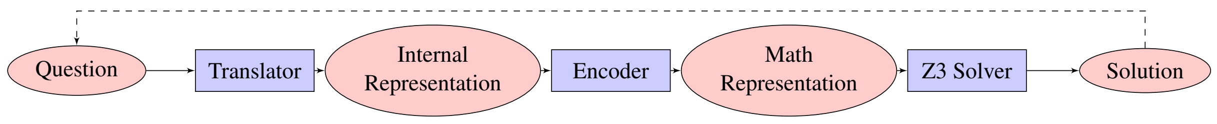

Figure 1: The architecture of `AiFu`

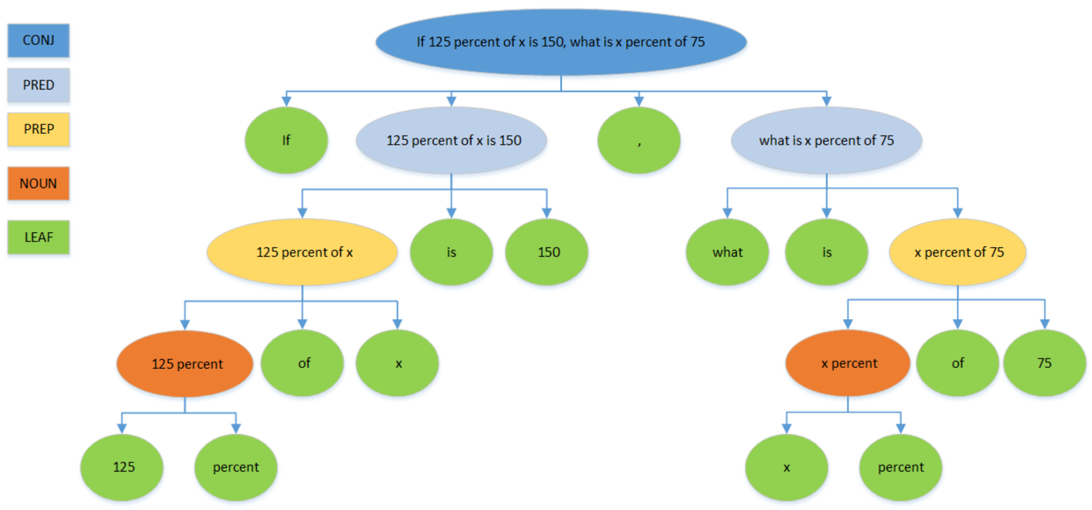

Figure 2: Semantic parsing tree: a case study

cent(125)", while the node "What is x percent of 75/PRED" is converted into "NumberPercent(x), Of(75,x,rs_a), Be(rs_b,rs_a), What(rs_b)". Finally, the root node, i.e., the original sentence, is converted into "(NumberPercent(x), Of(75,x,rs_a), Be(rs_b,rs_a), What(rs_b)) :- (NumberPercent(125), Of(x,125,rs_c), Be(rs_c,150))".

2.3 Encoder

The encoder further converts statements in VCF to formulas that can be accepted by Z3. Again, we use a rule based template approach for this purpose. There are two types of encoding templates. One is used to unify all different kinds of concepts/operators in VCF to a set of predefined concepts/operators that are accepted by Z3. For instance, a VCF statement "add(3,5,x)" is normalized as "Equal(3+5,x)". While the operator "add" is not a Z3 acceptable one, "Equal" and "+" are. Another type of template is to unify new entities that are created by VCF. For instance, the sentence "x is an integer" is converted to VCF statements "Be(rs_a,x),Integer(rs_a)" in the translator, which is further encoded as "Integer(x)" in the encoder by unifying the two entities "x" and "rs_a". At first glance, it seems tedious to introduce extra entities in the translator. However, this is exactly the reason why we need an intermediate representation language VCF because machines cannot directly understand what "x is an integer" really means.

By using the encoding templates, the VCF statements obtained in Figure 2 is converted into "Var: x:Real, Equations: x*125% = 150, Target: x%*75", which can be directly sent to the Z3 solver.

A large portion of SAT math questions can be done in this way, thus are suitable to use Z3 as the solver. Nevertheless, for some mathematical concepts such as progression, set, list and odd/even numbers, we need to make extra effort to formalize them in the modulo theory linear arithmetic. For instance, Odd(x) ("x is an odd number") can be converted into Equation($x\%2 = 1$). While the former cannot be directly encoded in linear arithmetic, the latter can.

2.4 Z3 Solver

Similar to some previous approaches (Hopkins et al., 2017), we also call the Z3 solver[1] as our reasoning engine. Z3 is a widely used Satisfiability Modulo Theories (SMT) solver, for solving problems that are represented in classical logic augmented with modulo theories, e.g., linear arithmetic.

However, Z3 has inherited difficulties on solving nonlinear equations, e.g., $3\sqrt{x} - 7 = 20$. In

[1]https://github.com/Z3Prover/z3

this case, we use SymPy [2] (Meurer et al., 2017), a Python library for symbolic mathematics, as the backup.

2.5 More on Geometry and Open Categories

For answering geometry questions, one has to understand diagrams. For this purpose, we first use the Optical Character Recognition (OCR) tool pytesseract[3] to obtain character information. Then, we follow the combined text and diagram understanding approach GeoS (Seo et al., 2015).

Understanding open-vocabulary algebra questions is a critical challenge. At first glance, it seems that the SAT open-vocabulary algebra subdataset is quite similar to Math23k (Wang et al., 2017). Hence, we attempted to use a Seq2Seq approach (Wang et al., 2017) that transforms math questions directly to their corresponding mathematical meanings. However, this attempt was not successful, mainly because of the following two reasons. First, questions in Math23k are much simpler. Second, Math23k is much larger in terms of volume.

Hence, we shifted back to a rule-based approach. We first use SVM to classify the type of questions. Based on which, regular expressions are used to transform questions in natural languages to statements in VCF, similar to that for the closed category described above. It turns out that its performance is slightly better than the Seq2Seq approach, yet still far from satisfactory.

2.6 Sub-symbolic System

We call the framework (see Figure 1) described above the "symbolic system" as it mainly uses a symbolic approach. However, some math questions remain unsolved. Hence, we also implement a guess system as a complementary counterpart. A simple guess system would be just a random guesser. Nevertheless, in `AiFu`, we use a neural-network based sub-symbolic approach, called the "sub-symbolic system" instead based on sentence embedding.

We treat the math question answering problem as a classification problem. We combine the question as well as a candidate choice into one sentence, and use a sentence embedding approach InferSent (Conneau et al., 2017) to embed it into a vector of 4096 dimensions. Then, we construct a simple four-layer fully-connected feed-forward neural network, in which the input is the 4096-dimension sentence embedding, the output is the 5 classes of answers and the two hidden layers both contain 1024 nodes. Finally, we train the network with the training dataset provided by the organizer.

3 Results

Table 2 reports the overall final results of `AiFu` on the test dataset. "Symb" is the symbolic system described from Sections 2.2 to 2.5, "Sub-S" is the sub-symbolic system described in Section 2.6, and "Integ" is the integrated system `AiFu` that combines them both by answering those questions not answered by the symbolic system with the sub-symbolic system. While "Acc" refers to the standard accuracy, "Pena Acc" refers to the penalized accuracy by deducting 0.25 points each for a wrong answer.

All in all, `AiFu` achieves an overall accuracy of 45% as well as an overall penalized accuracy of 36%. In particular, on the closed-vocabulary algebra category, it achieves a relatively high accuracy 70% (66% for penalized accuracy in contrast). The symbolic system plays a more critical role as it alone achieves 63% on answering closed-vocabulary algebra questions. More importantly, the symbolic system has a very high precision of 96%, thus has almost no penalization on all categories. In addition, unlike the sub-symbolic system, the symbolic system is fully explainable. However, it can be observed that all of these systems still perform poor on the Geometry and the open categories, especially when measured by penalized accuracy.

Table 3 illustrates the semantic parsing accuracy rate on closed-vocabulary algebra questions. It can be observed that, on the training and development datasets, we can achieve a relatively high accuracy of 84%. Nevertheless, it drops down to 71% on the test dataset. This is mainly because of the generalizability issue of templates.

In order to further analyze the genrealizability issue of templates, we consider the effects on the number of templates. Figure 3 shows how the template number affects the semantic parsing accuracy. It can be observed that, on the training dataset, the accuracy rates rapidly goes up to 50 % by the first 400 templates, then reaches 70% by 900 templates. Then, it slowly climbs up to 80% with 500 templates more. However, the growth

Development	84% (187/222)
Test	71% (326/459)

Table 3: Semantic parsing accuracy

Error Analysis	Training
Non-linear question	19%
Contain math concept	49%
Contain definition	9%
Other tricky question	23%

Table 4: Questions that cannot be solved by Z3

rate drops down dramatically afterwards, making it very difficult to improve. The main reason is that SAT math questions have many long-tail questions that cannot be covered by ordinary templates.

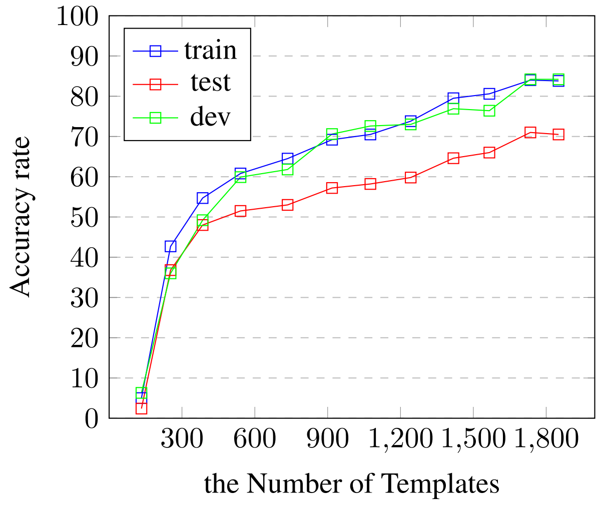

Figure 3: Effects on the number of templates

There are some questions that can be correctly parsed by our translator and encoder but failed to be solved by Z3. Among all, nearly 12% (100 out of 846) belong to this case in the training dataset. We further analyze their features. Among them, 49% need to use new math concepts, e.g., prime number, that cannot be represented in Z3. Around 19% of the questions are non-linear equations, which are very difficult for Z3. Finally, there are 9% of the questions need to define new objects, and the rest 23% are other kinds of tricky questions.

4 Conclusion

In this paper, we presents `AiFu`, a system that has won the first place in the SemEval-19 "Math Question Answering" competition. `AiFu` is a combined system that enhances a symbolic system with a sub-symbolic guesser. In `AiFu`, the symbolic system plays the most vital role, which itself can achieve a relatively high accuracy with many merits on closed-vocabulary algebra questions. Many state-of-the-art approaches are used and integrated in `AiFu`. Some new techniques are proposed including our new internal representation language VCF and our template structures.

For future work, the most important task is to improve the translator, which is the bottleneck, especially on geometry and open-vocabulary algebra questions. We believe that new foundations are needed, possibly requiring a deep integration of symbolic and sub-symbolic approaches.

Abstract

We present the SemEval-2019 Task 12 which focuses on toponym resolution in scientific articles. Given an article from PubMed, the task consists of detecting mentions of names of places, or toponyms, and mapping the mentions to their corresponding entries in GeoNames.org, a database of geospatial locations. We proposed three subtasks. In Subtask 1, we asked participants to detect all toponyms in an article. In Subtask 2, given toponym mentions as input, we asked participants to disambiguate them by linking them to entries in GeoNames. In Subtask 3, we asked participants to perform both the detection and the disambiguation steps for all toponyms. A total of 29 teams registered, and 8 teams submitted a system run. We summarize the corpus and the tools created for the challenge. They are freely available at https://competitions.codalab.org/competitions/19948. We also analyze the methods, the results and the errors made by the competing systems with a focus on toponym disambiguation.

1 Introduction

Toponym resolution, also known as geoparsing, geo-grounding or place name resolution, aims to assign geographic coordinates to all location names mentioned in documents. Toponym resolution is usually performed in two independent steps. First, toponym detection or geotagging, where the span of place names mentioned in a document is noted. Second, toponym disambiguation or geocoding, where each name found is mapped to latitude and longitude coordinates corresponding to the centroid of its physical location. Toponym detection has been extensively studied in named entity recognition: location names were one of the first classes of named entities to be detected in text (Piskorski and Yangarber, 2013). Disambiguation of toponyms is a more recent task (Leidner, 2007).

With the growth of the internet, the public adoption of smartphones equipped with Geographic Information Systems and the collaborative development of comprehensive maps and geographical databases, toponym resolution has seen an important gain of interest in the last two decades. Not only academic but also commercial and open source toponym resolvers are now available. However, their performance varies greatly when applied on corpora of different genres and domains (Gritta et al., 2018). Toponym disambiguation tackles ambiguities between different toponyms, like Manchester, NH, USA vs. Manchester, UK (Geo-Geo ambiguities), and between toponyms and other entities, such as names of people or daily life objects (Geo-NonGeo ambiguities). Additional linguistic challenges during the resolution step may be metonymic usage of toponyms, "91% of the US didn't vote for either Hilary or Trump" (a country does not vote, thus the toponym refers to the people living in the country), elliptical constructions, "Lakeview and Harrison streets" (the phrase refers to two street names Lakeview street and Harrison street), or when the context simply does not provide enough evidences for the resolution.

Although significant progress has been made in the last decade on toponym resolution, it is still difficult to determine precisely the current state-of-the-art performances (Leidner and Lieberman, 2011). As emphasized by several authors (Tobin et al., 2010; Speriosu, 2013; Weissenbacher et al., 2015; Gritta et al., 2018; Karimzadeh and MacEachren, 2019), the main obstacle is that few corpora of large size exist or are freely available. Consequently, researchers create their own (limited) corpora to evaluate their system, with the known drawbacks and biases that this implies.

Moreover, one corpus is not sufficient to evaluate a toponym resolver thoroughly, as the domain of a corpus strongly impacts the performance of a resolver. A disambiguation strategy can be optimal on one domain and damaging on another. In (Speriosu, 2013), Speriosu illustrates that toponyms occurring in historical literature will tend to resolve within a local vicinity, whereas toponyms occurring in international press news refer to the most prominent places by default. Otherwise additional information is provided to help the resolution (ex. Paris, the city in Texas).

In this article we first define the concept of toponym and detail the subtasks of this challenge (Section 3). Then, we summarize how we acquired and annotated our data (Section 4). In Section 5, after describing the evaluation metrics, we briefly describe the resources and the baseline system provided to the participants. In the last Section 6 we discuss the results obtained and the potential future direction for the task of toponym resolution.

2 Related Work

The *Entity Linking* task aims to map a name of an entity with the ID of the corresponding entity in a predefined Knowledge database (Bada, 2014). Entity linking has been largely studied by the community (Shen et al., 2015). Toponym resolution is a special case of the entity linking task where strategies dedicated to toponyms can improve overall performances. Three main strategies have been proposed in the literature. The first exploits the linguistic context where a toponym is mentioned in a document. The vicinity of the toponym often contains clues that help the readers to interpret it. These clues can be other toponyms (Tobin et al., 2010), other named entities (Roberts et al., 2010), or even more generally, specific topics associated more often with a particular toponym than with others (Speriosu, 2013; Adams and McKenzie, 2013; Ju et al., 2016). The second strategy relies on the physical properties of the toponyms to disambiguate their mentions in documents. The population heuristic or the minimum distance heuristic are popular heuristics using such properties. The population heuristics disambiguates toponyms by taking, among the ambiguous candidates, the candidate with the largest population, whereas the minimum distance heuristic disambiguates all toponyms in a document by taking the set of candidates that are the closest to each other (Leidner, 2007). A recent heuristic computes from Wikipedia a network expressing important toponyms and their semantic relation with other entities. The network is then used to disambiguate jointly all toponyms in a document (Hoffart and Weikum, 2013; Spitz et al., 2016). The last strategy is less frequently used as it depends on metadata describing the documents where toponyms are mentioned. These metadata are of various kinds, but they all indicate, directly or not, geographic areas to help interpret toponyms mentioned in documents. Such metadata can be geotagging of social media posts (Zhang and Gelernter, 2014) or external databases structuring the information detailed in a document (Weissenbacher et al., 2015). These three strategies are complementary and can be unified with machine learning algorithms as shown by (Santos et al., 2015) or (Kamalloo and Rafiei, 2018).

3 Task Description

The definition of toponym is still in debate among researchers. In its simpler definition, a toponym is a proper name of an existing populated place on Earth. This definition can be extended to include a place or geographical entity that is named, and can be designated by a geographical coordinate[1]. This encompasses cities and countries, but also lakes or monuments. In this challenge we consider the extended definition of toponyms and exclude all indirect mentions of places such as "30 km north from Boston", as well as metonymic usage and elliptical constructions of toponyms.

Subtask 1: Toponym Detection Toponym detection consists of detecting the text boundaries of all toponym mentions in full PubMed articles. For example, given the sentence `An H1N1 virus was isolated in 2009 from a child hospitalized in Nanjing, China.`, a perfect detector, regardless how, would return two pairs encoding the starting and ending positions of Nanjing and China, *i.e.* (64, 70) and (73, 77). Despite major progress, toponym detection is still an open problem and it was evaluated in a separate subtask since it determines the overall performance of the resolution. Toponym mentions missed during the detection cannot be disambiguated (False Negative, FN) and, inversely,

[1] https://unstats.un.org/unsd/geoinfo/UNGEGN/

phrases wrongly detected as toponyms will received geocoordinates during the disambiguation (False Positive, FP). Both FNs and FPs degrade the quality of the overall resolution.

Subtask 2: Toponym Disambiguation The second subtask focuses on the disambiguation of the toponyms only. In this subtask, all names of locations in articles are known by a disambiguator but not their precise coordinates. The disambiguator has to select the GeoNames IDs corresponding to the expected places among all possible candidates. GeoNames[2] is a crowdsourced database of geospatial locations and freely available. Following with our previous example, given the position of Nanjing in the sentence, a perfect disambiguator, regardless how, would have to choose among 12 populated places named Nanjing located in China in GeoNames and return the entry 7843770 in GeoNames. The disambiguator has to infer the expected place based on all information available in the article and not only based on the sentence. This subtask allows one to measure the performance of the disambiguation algorithms independently from the performances of the toponym detector used upstream.

Subtask 3: End-to-end, Toponym Resolution The last subtask evaluates the toponym resolver as it would be when deployed in real-world applications. Only the full PubMed articles are given to the resolver and all toponyms detected and disambiguated by the resolver are evaluated.

4 Data and Resources

4.1 A Case Study: Epidemiology of Viruses

The automatic resolution of the names of places mentioned in textual documents has multiple applications and, therefore, has been the focus of research for both industrial and academic organizations. For this challenge, we chose a scientific domain where the resolution of the names of places is key: epidemiology.

One aim in epidemiology might be to create maps of the locations of viruses and their migration paths, a tool which is used to monitor and intervene during disease epidemics. To create maps of viruses, researchers often use geospatial metadata of individual sequence records in public databases such as NIH's GenBank (Benson et al., 2017)[3]. The metadata provides the location of the infected host. With more than 3 million virus sequences[4], GenBank provides abundant information on viruses. However, previous work has suggested that geospatial metadata, when it is not simply missing, can be too imprecise for local-scale epidemiology (Scotch et al., 2011). In their article Scotch et al., 2011 estimate that only 20% of GenBank records of zoonotic viruses contain detailed geospatial metadata such as a county or a town name (zoonotic viruses are viruses able to infect naturally hosts of different species, like rabies). Most GenBank records provide generic information, such as Japan or Australia, without mentioning the specific places within these countries. However, more specific information about the locations of the viruses may be present in articles which describe the research work. To create a complete map, researchers are then forced to read these articles to locate in the text these additional pieces of geospatial metadata for a set of viruses of interest. This manual process can be highly time-consuming and labor-intensive.

This challenge was an opportunity to assess the development and evaluation of automated approaches to retrieve geospatial metadata with finer level of granularity from full-text journal articles, approaches that can be further transferred or adapted to resolve names of places in other scientific domains.

4.2 Corpus Collection

Our corpus is composed of 150 full text journal articles downloaded from the subset of PubMed Central (PMC) in open access[5]. All articles in this subset of PMC are covered by a Creative Commons license and free to access. We built our corpus using three queries on GenBank.

Subset A: For the first 60 articles, we downloaded 102,949 GenBank records that were linked to NCBI taxonomy id 197911 for influenza A. The downloaded records were associated with 1,424 distinct PubMed articles and 598 of them had links

[2] https://www.geonames.org/

[3] For this competition we chose to work with PubMed articles and the GenBank database as they provide more complete and detailed information for epidemiology than public health reports.

[4] Last accessed April 2019 with the query: https://www.ncbi.nlm.nih.gov/nuccore/?term=txid10239[Organism:exp]

[5] https://www.ncbi.nlm.nih.gov/pmc/tools/openftlist/

to an open access journal article in PubMed Central (PMC). We randomly sampled 60 articles from this set of 598 articles for manual annotation.

Subset B: We selected 60 additional articles by expanding our search to GenBank records linked to influenza B and C, rabies, hantavirus, western equine encephalitis, eastern equine encephalitis, St. Louis encephalitis, and West Nile virus. Our query returned a total of 544,422 GenBank records. We randomly selected a subset of records associated with 1,915 unique open access PMC articles. From these 1,915 articles, we randomly selected for toponym annotation a stratified sample of 60 articles, where strata were based on the number of GenBank records associated with the articles.

Subset C: We completed our corpus with 30 biomedical research articles to decrease bias and increase the generalizability of our corpus beyond toponym mentions in virus related research articles. From the 1,341 research articles returned by the search in PMC of the journal titles with the Article Attribute of Open access, we randomly selected 30 articles from top epidemiology journals, as determined by their impact factor in September 2018.

Since the 60 articles from Subset A had been used in our prior publications (Weissenbacher et al., 2015, 2017), we kept them all for training. We randomly selected half of the articles from Subset B and Subset C for training and left the second half for testing. The resulting corpus of 105 articles for training and 45 for testing was used for all three subtasks of the competition. The corpus is available for download on the Codalab used for the competition: `https://competitions.codalab.org/competitions/20171#learn_the_details-data_resources`.

4.3 Annotation Process

To perform the annotation, we manually downloaded the PDF versions of the PMC articles and converted them to text files using the freely available tool, Pdf-to-text[6]. We formatted the output to be compatible with the BRAT annotator[7] (Stenetorp et al., 2012). We manually detected and disambiguated the toponyms using GeoNames. We annotated toponyms in titles, bodies, tables and captions sections of the documents. We removed contents that would not contain virology-related toponyms, such as the names of the authors, acknowledgments and references, this was done manually. In cases where a toponym could not be found in GeoNames, we set its coordinates to a special value N/A. Prior to beginning annotation, we developed a set of annotation guidelines after discussion among three annotators. The resulting guidelines are also available in the Codalab of the competition. Two annotators were undergraduate students in biomedical informatics and biology, respectively, and our senior annotator has a M.S. in biomedical informatics.

Two annotators annotated independently 58 articles of Subset B to estimate the inter-annotator agreement. Since the detection task is a named-entity recognition task, we followed the recommendations of Rothschild and Hripcsak (2005) and used precision and recall metrics to estimate the inter-annotator rate. The inter-annotator agreement rate on the toponym detection was .94 precision (P) and .95 recall (R) which indicates a good agreement between the annotators. The inter-annotator agreement rate on the toponym disambiguation was 0.857 Accuracy. Subset C was also annotated by two annotators, although not independently, to ensure the quality of the annotation of all documents occurring in the test set of the competition.

The corpus contains a total of 1,506 distinct toponyms for a total of 8,360 occurrences. 1,228 of these toponyms occur in only one document (a document may include multiple occurrences). The average number of occurrences for a toponym is 5.5 with *China* being the most mentioned toponym with a total of 417 occurrences. The average ambiguity is about 26.3 candidates per toponym which is comparable to the average ambiguity found in existing corpora (Speriosu, 2013). The location *San Antonio* was the most ambiguous with 2633 possible candidates. 232 toponyms (531 occurrences) were not found in GeoNames using a strict match, this was caused by multiple reasons, like misspellings, non standard-abbreviations, missing entries in GeoNames, etc. 142 countries and continents are mentioned in our corpus with a total of 3,105 occurrences. The resolution of country and continent names are easier than other places but they represent only 37% of the total of the occurrences, making our corpus challenging.

5 Evaluation

5.1 Toponym Resolution Metrics

When a gold standard corpus and a toponym resolver are aligned on the same geographical database, here the database GeoNames, the standard metrics of precision, recall and F-measure can be used to measure the performance of the resolver. For this challenge, we report all results by using two common variations of these metrics: strict and overlapping measures. In the strict measure, resolver annotations are considered matching with the gold standard annotations if they hit the same spans of text; whereas in overlapping measure, both annotations match when they share a common span of text.

We computed the P and R for toponym detection with the standard equations: $Precision = TP/(TP+FP)$ and $Recall = TP/(TP+FN)$, where TP (True Positive) is the number of toponyms correctly identified by a toponym detector in the corpus, FP (False Positive) the number of phrases incorrectly identified as toponyms by the detector, and FN (False Negative) the number of toponyms not identified by the detector.

To evaluate the toponym disambiguation, we modified the equations computing the P and R used for toponym detection in order to account for both detection and disambiguation errors. The precision of the toponym disambiguation is given by the equation: $Pds = TCD/TCD + TID$, where TCD is the number of toponyms correctly identified and disambiguated by the toponym disambiguator in the corpus and TID is the number of toponyms incorrectly identified or incorrectly disambiguated in the corpus. The recall of the toponym disambiguation was computed by the equation: $Rds = TCD/TN$, where TN is the total number of toponyms in the corpus. F1ds is the harmonic mean of Pds and Rds. Since the resolvers competing and the gold corpus annotations were aligned on GeoNames, toponyms correctly identified were known by a simple match between the place IDs retrieved by the resolvers and those annotated by the annotators.

5.2 Baseline System

We released an end-to-end system to be used as a strong baseline. This system performs sequentially the detection and the disambiguation of the toponyms in raw texts. To detect the toponyms the system uses a feedforward neural network described in (Magge et al., 2018). The disambiguation of all toponyms detected is then performed using a common heuristic, the population heuristic. Using this heuristic, the system always disambiguates a toponym by choosing the place which has the highest population in GeoNames. The baseline system can be downloaded from the Codalab website of the competition. We also made available to the participants a Rest service to search a recent copy of GeoNames, the documentation and the code to deploy the service locally can be found on the Codalab website.

6 Systems

6.1 Results

Twenty nine teams registered to participate in the shared-task and eight teams submitted. 21/8/13 submissions from 8/4/6 teams were included in the final evaluations of sub-task 1/2/3 respectively. All systems which attempted to resolve the toponyms in Subtask 3 opted for a pipeline architecture where the detection and the disambiguation steps were performed independently and sequentially. Table 1 summarizes the characteristics of the systems along with their use of external resources. Tables 2, 3 and 4 presents the performances for each team. Team DM_NLP achieved the best performances on all sub-tasks (Wang et al., 2019).

Toponym Detection: With all systems but one, Deep Recurrent Neural Networks were the most commonly used and efficient technology to detect toponyms in our corpus. Their architectures varied with respect to the integration of character embedding layers, mechanisms of attention, integration of external features (such as POS tagging or other Named Entities) or the choice of a general or in domain corpus for pre-training their word and sentence embeddings. In our epidemiological corpus, toponyms were not only mentioned in the body of the articles but also in tables. And interestingly, top ranked systems detected the toponyms with two different algorithms, one dedicated to the body and one to the tables of the articles. The top ranking system outperformed other competitors for Subtask 1 significantly, with a margin of 4 points separating it from the second ranked system, even though the same technology was used. Both teams used dedicated algorithms for bodies and tables but Team DM_NLP implemented several strategies to improve the pre-training of their

Table 2: Results of the toponym detection task, Subtask 1.

system which, according to their ablation study (Wang et al., 2019), proved to be effective[9]. Note that the performance of the first system is close to our IAA for toponym detection.

Toponym Disambiguation: All systems relied on handcrafted features to disambiguate toponyms. Their features described the lexical context of the toponyms and their importance. The importance of the toponyms was estimated by the frequencies of the candidates in the training data or by their populations. While the two top ranked systems combined such features with machine learning, SVM for UniMelb and a gradient boosting algorithm for DM_NLP, others just encoded them into hard rules leading to suboptimal disambiguation.

6.2 Analysis

We analyzed a sample of errors to understand the remaining challenges for toponym disambiguation systems based on the results of Sub-task 2. We randomly selected 10 articles and analyzed 103 mentions of toponyms disambiguated incorrectly by all systems. We manually found 5 distinct categories of errors. For the largest category of errors, with 62 cases, the systems missed context clues used by the authors of the articles to convey the correct interpretation of the toponym and chose the wrong candidates. Such clues include the mention of a country in the header of a table or the explicit mention of a district after an ambiguous toponym. 17 errors were due to the systems not complying with the guidelines, selecting instead populated places or cities when the expected choices were toponyms with a higher administrative level. 8 candidates were not found in GeoNames by strict or fuzzy matching because of their surface forms. These were unconventional abbreviations, rare acronyms or words split by a hyphen. Despite our efforts to limit annotation errors, 15 were found in our sample[10]. The last error was a toponym where the choice made by the annotators can be argued.

[9]Team QWERTY did not describe their system at the time of writing. We were therefore unable to compare it with other systems.

[10]Since we analyzed entire articles, this count includes multiple mentions of the same toponym repeatedly annotated with the same error

7 Conclusion

In this paper we presented an overview of the results of SemEval 2019 Task 12 which focuses on toponym resolution in scientific articles. Given an article from PubMed, the task consists of detecting all mentions of place names, or toponyms, in the article and mapping them to their corresponding entry in GeoNames, a database of geospatial locations. All systems resolved the toponyms in our corpus sequentially, detecting the toponyms before disambiguating them. Among the 21 systems submitted for toponym detection, neural network based approaches were the most popular and the most efficient to detect toponyms with scores approaching the Inter-Annotator agreement. One key to success for the top ranked systems was to design two different algorithms to detect toponyms in the body and in the tables of the articles. The disambiguation of the toponyms remains challenging. Despite a clever use of rules or machine learning to combine features describing the lexical context of the toponyms and their importance from the 4 competing systems, the strict macro F1ds score of .82 of the best system signals space for improvement. Our analysis of common disambiguation errors reveals that it is still difficult for the systems to capture linguistic evidence in the context of the toponyms that dictate their disambiguation, causing 60% of the errors of the systems. The end-to-end performance of the best toponym resolver was .77 F1ds strict macro, a score high enough for scientists to benefit from automation to reduce their workload when extracting toponyms from the voluminous and quickly growing literature, while still leaving room for technical improvement.

Abstract

This paper describes DM-NLP's system for toponym resolution task at Semeval 2019. Our system was developed for toponym detection, disambiguation and end-to-end resolution which is a pipeline of the former two. For toponym detection, we utilized the state-of-the-art sequence labeling model, namely, BiLSTM-CRF model as backbone. A lot of strategies are adopted for further improvement, such as pre-training, model ensemble, model averaging and data augment. For toponym disambiguation, we adopted the widely used searching and ranking framework. For ranking, we proposed several effective features for measuring the consistency between the detected toponym and toponyms in GeoNames. Eventually, our system achieved the best performance among all the submitted results in each sub task.

1 Introduction

The toponym resolution task is aimed to detect toponyms in scientific papers and link them to entities in a geographical knowledge base (GeoNames[1] in this task). A toponym is a proper name of a place or geographical entity that is named, and can be designated by a geographical coordinate, including cities, countries, lakes or monuments.

We developed an end-to-end toponym resolution system (for subtask 3) which is a pipeline of toponym detection (for subtask 1) and disambiguation (for subtask 2). We model the detection task as a Named Entity Recognition (NER) and address it with popular sequence labeling framework. For disambiguation task, we adopted the searching and ranking framework which is widely used in Entity linking task.

Toponym is a special type of entity similar to the location entity in the general NER task. Thus, the well-studied NER models may be effective for detecting toponyms. The most successful NER models (Chen et al., 2006; Lample et al., 2016; Huang et al., 2015; Yao and Huang, 2016) are sequence labeling models, including the traditional CRF (Conditional Random Field (Lafferty et al., 2001)) and some variants of RNNs (Recurent Neural Networks) proposed recently, like LSTM-CRF, BiLSTM-CRF, BiLSTM-CNN-CRF, etc. In this paper, We utilize the most popular model, i.e., BiLSTM-CRF for toponym detection. Beyond the model, a prevalent pre-training embedding named ELMo is used after fine-tuning. Model averaging and model ensemble are used for avoiding overfitting. Data sets from other NER tasks are exploited to augment the training data. We also proposed a dictionary based method for detecting toponyms in tables separately. Since tables have some peculiarities, i.e., well formatted yet without meaningful context for toponyms in them.

Toponym disambiguation can be seen as a variant of entity linking (EL) problem, which links entity mentions in articles to entities in knowledge base (KB) like Wikipedia. A typical EL system consists of candidate entity generation and ranking as well as unlinkable mention prediction (Shen et al., 2015). The major challenge is that the KB of toponym lacks of background information other than toponym names, types and coordinates. Therefore, we follow the typical EL method (Hoffart et al., 2011) for toponym disambiguation and propose a classification based ranking method. Specifically, We recast the problem as a binary classification task asking that whether a toponym in GeoNames is a link for given toponym. If more than one positives exist, they are ranked according to their confidence scores. Coupled with the classifier, We introduce many features which measure the consistency between toponyms effectively, including name string similarity, candidate

[1] https://geonames.org

attributes, contextual features and mention list features.

Our contributions to this task can be summarized as follows:

- Proposing an approach to process tables separately from the main body.
- Proposing a novel data augment approach to exploit external data.
- Designing many novel and effective features for disambiguation.

2 Methodology

2.1 Overview

Our system for toponym resolution consists of toponym detection and disambiguation. The former is based on a sequence labeling model and is enhanced with pre-training, model ensemble and data augment. The later is a two-stage approach which obtains candidates by searching and does disambiguation via classification.

2.2 Toponym Detection

A scientific article usually contains a main body and tables. Detecting toponyms in these two types of content are different due to toponyms in tables lack of contextual information. Consequently, we adopt two different approaches.

2.2.1 Detection in Main Body

We recast the problem the Toponym Detection in main body as a Named Entity Recognition task and we make use of the BiLSTM-CRF model with the contextual information as input. To alleviate over-fitting, we apply model averaging training strategies. Finally, a voting method is utilized to benefit from multiple models.

Input Information Based upon our previous work (Ma et al., 2018) on sequence labeling, our system incorporates four types of linguistic information: Part-of-Speech (POS) tags, NER labels, Chunking labels and ELMo (Peters et al., 2018). The former three are generated by open source tools. In detail, we use Stanford CoreNLP (Manning et al., 2014) to annotate POS tags and NER labels, and use OpenNLP [2] to annotate Chunking labels. These information are represented as distributional vectors which are randomly initialized and trained with the entire model. ELMo

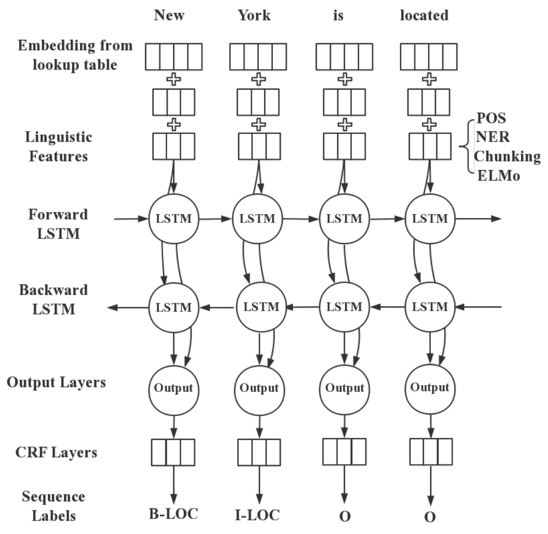

Figure 1: Architecture of BiLSTM-CRF model

is a deep contextualized word representation that models both complex characteristics of word use, and how these uses vary across linguistic contexts. These word vectors are learned functions of the internal states of a deep bidirectional language model (biLM), which is pre-trained on a large corpus of texts. We fine tuned ELMo on the weakly labeled data provided by the organizers, so that the vectors will be adapted to this domain.

BiLSTM-CRF Model As illustrated in Figure 1, the entire model consists of five layers: word representation layer, input layer, feature extraction layer, output layer and CRF layer. The word representation layer is a group of BiLSTM with shared parameters. Each BiLSTM corresponds to a word. The BiLSTM takes a sequence of character (characters in a word) embedding as input and concatenates the final hidden states (forward and backward) as the representation of the word. Designing a neural network architecture with character representation as input is appealing for several reasons. Firstly, words which have the same morphological properties (like the prefix or suffix of a word) often share the same grammatical function or meaning. Secondly, a character-level analysis can help to address the out-of-vocabulary problem, Thirdly, capitalization may provide additional information. A recent study (Lample et al., 2016) has shown that BiLSTM is an effective approach to extract morphological information from characters of words, and consequently help to improve the performance

[2]`https://opennlp.apache.org/`

in NER and POS tagging.

The input layer generates the final representation of each word by concatenating three types of vectors, the pre-trained word embedding, the word vector given by the character BiLSTM and the vector of linguistic information (POS label, NE label, chunking label and ELMo vector).

The feature extraction layer is another BiLSTM. RNNs are well-studied solutions for a neural network to process variable length input and have a long term memory. As a variant of RNNs, the long-short term memory (LSTM) unit with three multiplicative gates allows highly non-trivial long-distance dependencies to be easily learned. Therefore, we use a bidirectional LSTM network as proposed in (Graves et al., 2013) to efficiently make use of past features (via forward states) and future features (via backward states) for a specific time frame.

The output layer is a fully connected feed forward network which outputs the probability distribution over all labels.

The CRF Layer is use on the top to decode the appropriate label sequence. For sequence labeling tasks, such as POS tagging or NER, the adjacent labels are often strongly related (e.g. I-ORG cannot follow B-PER or I-LOC in NER tasks like CoNLL2003). CRF model is good at modeling these constraints.

Model Averaging Random initialization and shuffling order of training sentences introduce randomization when training a model. During our experiments, we found that model predictions vary considerably even when the same pre-trained data and parameters are used. In order to utilize the power of model ensemble and avoid overfitting problem, we use a script provided by tensor2tensor to average values of variables in a list of checkpoint files generated by BiLSTM-CRF networks.

Ensemble By using different pre-trained word embeddings or using different linguistic information, we trained multiple models, we apply an average voting strategy to compute the final decision of our system from all models. Experimental result shows that voting indeed boosts the overall performance.

2.2.2 Detection in Tables

As important components of a scientific article, tables have specific formats:

- They usually begin with the word 'Table'.
- The first line is called the header which indicates the meaning of each column.
- All rows follow the schema defined by the header of the tables.

According to our analysis of the training data, many toponyms are mentioned in tables. Nevertheless, the contexts of these toponyms differ significantly from contexts of toponyms in main body. The later are always meaningful sentences. As a result, performances may drop significantly if a model trained to recognize toponyms in the sentences of the main body is used to recognized toponyms occuring in tables. Thus, we propose a novel approach for detecting toponyms in tables which are processed separately with details as follows:

1. Analyze the mean and variance of words counts (split by space), within a window of text. Decreasing the size of window until the variance is smaller than a threshold.
2. If the word 'Table' is found in the context of the window, take the n-gram within this window as toponym if it exists in GeoNames database.

2.2.3 Postprocess

Rule based postprocessing is applied in the end of the detection step to avoiding errors which occur frequently in development set. The following rules are applied to a toponym for generating possible corrections, which are confirmed and used to replace the original mention by figuring out whether a correction exists in GeoNames.

- If a word of locality, such as eastern, appears before a toponym within three words, we correct the candidate predicted by adding the word of locality to the toponym.
- If a toponym ends with a suffix word (e.g., Province) which indicates an administrative division, we make a candidate correction by removing the suffix when the suffix occurs in a predefined black list.
- If an abbreviation appears after a toponym and the abbriviation consists of of all the capital letters of the words composing the name of the toponym, we include the abbreviation as a new candidate toponym.

2.3 Toponym Disambiguation

Our approach for disambiguation has two stages. First, we retrieve possible candidate toponyms from GeoNames database using a search engine with a toponym mention as query. Second, a binary classifier with carefully designed features are applied to each candidate to figure out whether it is the appropriate place that the mention refers to.

2.3.1 Candidate Generation

This stage is based on an offline search engine implemented with Lucene[3]. All GeoNames records were indexed in advance. Then, we search the index with the toponym mentions given by the detection module as queries. In order to ensure higher recall rate, we addressed the alias issue. We expand the query by alternate names and enable fuzzy matching searching.

Alternative names of given toponym mentions are obtained by the following ways:

1. Alternative names recorded in GeoNames dump files, including allCountries, alternatenames, countryInfo.

2. Abbreviations of state names in America given by Wikipedia[4].

3. Alternative names mined by pattern matching from the article where the mention appeared. For example, by using the pattern '<mention>, (<abbr>)' we can get the alternate name 'RSA' of mention 'Republic of South Africa' from sentence 'Republic of South Africa, (RSA)'.

Fuzzy matching is enabled since there are some incorrect spellings in source articles which lead to empty results. However, fuzzy matching introduces noises, so it is enable only if the original query recalls nothing.

2.3.2 Candidate Ranking

We formulate the candidate ranking problem as a binary classification problem. Given a mention detected, several potential candidates are retrieved during candidate generation stage. We take every mention and a candidate pair as input for a binary classifier to decide whether the mention refers to the candidate. We consider the classification confidence as the candidate ranking score $score\langle m, e\rangle$ to select the most likely candidate. To deal with context-poor KB problem, we design information rich features and use the ensemble of model strategy.

Features We divide all the features into four groups, i.e., Name String Similarity, Candidate Attributes, Contextual Features and Mention List Features.

1. **Name String Similarity** Following previous work (Shen et al., 2015), we developed features capturing similarity between the candidate's and the mention's name, including Exact Match, Mention Substring of Candidate, Candidate Substring of Mention, Mention Starts Candidate Name, Candidate Starts Mention Name, Jaccard Similarity, Levenshtein Similarity. All names are lowercased in advance and the name of candidate may change into its alternate names if exist.

2. **Candidate Attributes** This set of features are based on target KB's (GeoNames) records and capture some priority of candidate, including Popularity, Number of Ancestors, Code Level.

3. **Contextual Features** Inspired by previous work (Guo et al., 2013), We designed this set of features to measure the contextual similarity between the mention and the candidate. Firstly, for mentions, we take multiple levels of context around mentions in documents as mention-side context, including sentenceparagraph and document level. Secondly, since target KB (GeoNames) lacks context information, we resort to Wikipedia to request candidate's page via API [5]. Considering computation efficiency and avoiding the noise introduced by whole wiki page, we just use the summary (first description paragraph) of the page as candidate-side context, instead of multiple levels. Finally, Bag-of-words representation is employed to mention-side and candidate-side context. Several similarity methods have been explored, including word overlap, cosine similarity and Jaccard similarity.

4. **Mention List Features** We found that the true candidate (or it's ancestor candidates)

[3]https://lucene.apache.org/

[4]https://en.wikipedia.org/wiki/List_of_U.S._state_abbreviations

[5]https://github.com/goldsmith/Wikipedia

may also refer to another mention in the same document. This makes sense because toponyms often co-occur with their child or parent toponyms in medical articles or just occur repeatedly in the same document. We developed so called Mention Neighbors Features, which take all mentions in a document as mention list. Similar to mention-side context, every mention has its sentence, paragraph, and document mention list. We encode the relationship between multi-level mention lists and by checking whether the candidate name, its ancestor name or alternate names occur in the mention lists. This set of features can capture the coherence to some extent.

Classification Model We use LightGBM (Ke et al., 2017) as our base model, which gets higher performance compared with other gradient boosting models such as gbdt, xgboost and more traditional models like LR and SVM.

Ensemble & Stacking We select different hyper parameters of LightGBM to build a set of base models. Hyper parameters vary in number of estimators, number of leaves, and learning rate. Furthermore, We add a soft-vote classifier as model ensemble, which returns the class label as argmax of the sum of predicted probabilities. Based on all the base models (several LightGBMs, two vote classifiers), we apply a model stacking strategy that takes the outputs (probabilities and labels) of all base models as input and train a simple linear classifier called stacking model and return the stacking model output as the final output.

3 Experiments

3.1 Toponym Detection

3.1.1 Dataset and Settings

Given 105 medical papers from PubMed Central[6] for developing system, we randomly divided the data into training, development and test set by a ratio of 5:1:1. To avoiding instability of experimental results, we repeat this process 5 times and yield different distributions. All the results shown below are average values among these five distributions.

Data Augment The official training data is smaller than the dataset used in general NER task. Therefore, we expanded the training data by selecting external data from CONLL2003 and ontonotes5.0. Sentence containing GPE or LOC entities were selected. A binary classifier [7] was applied to distinguish the external sentences from the official sentences and outputs a confidence score. If the score lower than a threshold, in other words, the external sentence is similar to the official sentence, we add the external sentence into training data. Finally, we obtained 8000 extra training sentences, about 32% of the total training data.

Preprocessing Articles are segmented into sentences by NLTK and segmentation errors are corrected based on NER results (generated by CoreNLP). For example, ”St. Louis” is split by ’.’ incorrectly. But it is a location according to NER Results.

3.1.2 Ablation Study

Table 1 shows the ablation study of the detection model. As mentioned above, the baseline model is a Char-LSTM-LSTM-CRF model (Lample et al., 2016). We tried two types of pre-trained embeddings, GloVe (Pennington et al., 2014) and PubMed [8]. Since the PubMed is trained on in-domain data, it achieves better results. Thus, all the rest results are based on embeddings trained on PubMed dataset.

Among the four linguistic information, adding ELMo yields the most improvement, while adding the other three yield a little. we successfully use voting, a simple ensemble method to take advantage of multiple models trained by using different linguistic information, and it works.

All techniques proposed contribute to the performance according to the results. Bring in more training data indeed works but the improvement is feeble. Processing tables separately increases the recall since there are many tables containing toponyms.

The best result is obtained by leveraging all the approaches in combination, it outperforms the baseline model significantly.

3.2 Toponym Disambiguation

3.2.1 Dataset and Settings

Data The distributions of articles is the same as those experiments of Toponym Detection. Exter-

[6] `https://www.ncbi.nlm.nih.gov/pmc/`

[7] The training data for this classifier is obtained by mixing the official and external sentences with source information kept. The threshold is chosen by intuition.

[8] trained on PubMed and Wikipedia articles, downloaded from `http://bio.nlplab.org/`

Model		Precision	Recall	F1-score
Baseline+PE	GloVe	85.61	82.81	84.19
	PubMed	87.60	83.24	85.37
Baseline+PE+LF	POS	87.73	83.19	85.40
	NER	87.38	83.55	85.42
	Chunking	87.92	83.47	85.64
	ElMo	89.40	88.34	88.87
Baseline+PE+LF+ME		89.63	88.51	89.06
Baseline+PE+DA		88.25	83.73	85.93
Baseline+PE+TP		88.36	84.78	86.53
Baseline+PE+PP		87.96	83.41	85.62
+All		**90.69**	**89.74**	**90.21**

Table 1: Experiment results of Detection. Abbreviations: DA, Data Augment; PPE, Pubmed Pre-trained Embedding; PP, Post Process; TP, Table Process; LF, Linguistic Features; ME, Model Ensemble

nal data is not included since they contains no annotation for disambiguation task.

Hyper-parameters LightGBM models trained with different hyper-parameters constitute the base model set. The number of estimators varies from 200 to 800, number of leaves from 30 to 50, and the learning rate takes one of 0.05, 0.1. Variance threshold is set as 0.9 at feature selection phase.

3.2.2 Candidate Ranking Results

Table 2 shows the experimental results. We compare the baseline method, single LightGBM model, soft-vote method, and stacking method. The baseline method take the candidate with most population as output.

From Table 2, we can see the LightGBM model beat the baseline method, and model combination strategy improve the performance further. We take outputs of all LightGBM models and soft-vote model as input samples for training a stacking LR model and get the best performance of 89.85%.

For the final run in competition, we chose the stacking method and retrained all base models on the entire train set and predicted on the test set.

3.2.3 Ablation Study

We also conducted an ablation study to investigate the impact of each group of features. From Table 3, we can see Name String Similarity is far below the baseline method(80.45%) and and using the population as a feature is a strong heuristic in fact. Although attribute features take the population as one feature but the classifier using these features still fail to beat the baseline. A reasonable explanation is some other attributes act as noise.

Not surprisingly, Contextual Features play a great role and bring an essential improvement surpassing the baseline. Interestingly, Mention List features, allow a bigger progress over Contextual Features. We think they capture the particularity of toponym disambiguation and some coherence.

Model	Prec.	Rec.	F1
baseline	79.96	80.94	80.45
lightGBM-single	89.30	87.03	88.15
soft-vote	89.44	87.83	**88.63**
stacking	90.57	89.14	**89.85**

4 Conclusion and Future works

This paper introduces our system for toponym resolution which is a pipeline of sequence labeling model based detection and classification model based disambiguation. More works are worthy to be done in the future, such as developing a more sophisticated approach for detection toponyms in table, adopting graph-based disambiguation methods and address this task in an end-to-end manner.

(olgapapa,georgekordopatis,markzampoglou,papadop,ikom)@iti.gr

Abstract

In the effort to tackle the challenge of Hyperpartisan News Detection, i.e., the task of deciding whether a news article is biased towards one party, faction, cause, or person, we experimented with two systems: i) a standard supervised learning approach using superficial text and bag-of-words features from the article title and body, and ii) a deep learning system comprising a four-layer convolutional neural network and max-pooling layers after the embedding layer, feeding the consolidated features to a bi-directional recurrent neural network. We achieved an F-score of 0.712 with our best approach, which corresponds to the mid-range of performance levels in the leaderboard.

1 Introduction

The emerging issue of online disinformation has lately attracted the public attention and is perceived as a major risk for democracy and society. Media content (text, images, videos) is often disseminated on the Internet with the purpose of manipulating public opinion. Hyperpartisan news detection is a problem arising as a result of the intention of publishers to influence readers in favour of a given party, idea or person. The SemEval 2019 Task 4 (Kiesel et al., 2019) seeks solutions to this challenge, in particular text-based approaches that can detect hyperpartisan news articles.

We experimented with two approaches: i) a standard supervised learning approach using superficial text and bag-of-words features, and ii) a deep learning system. We deployed the developed systems on TIRA (Potthast et al., 2019) (a platform that supports software submissions) and its evaluation was conducted on unseen news articles. The results of our submissions, which are presented in Table 1, are promising, yet there is still considerable room for improvement. Our best resulting approach was the deep learning system, which scored an F-score of 0.712. The implemented approaches are described below along with additional experiments that were conducted on the provided training and validation datasets.

2 Data

The dataset provided by the organizers of the task (Kiesel et al., 2019) consists of news articles, half of which are labelled as hyperpartisan. It is split into two sets, the training and the validation set, where for each article the article title, body and published date are provided. The training set consists of 500.000 news articles and it is used as training set for the presented experiments and the provided validation set (150.000 news articles) is used for validating the approaches. A small dataset of 645 news articles, manually annotated, is also provided but not used in the following experiments neither as training nor as validation data. For the evaluation phase, two small datasets of 628 and 4000 articles are provided. The first, called by-article test dataset, is labeled through crowdsourcing on an article basis while the latter, named by-publisher test dataset, is labeled by the overall bias of the publisher as provided by BuzzFeed journalists and MediaBiasFactCheck.com.

A pre-processing step is applied on both the article title and body in order to clean the text and prepare it for the subsequent machine learning steps. The Natural Language Toolkit (NLTK) (Bird et al., 2009) was used to implement this step. First, the text is split into sentences and then each sentence is split in tokens. Lemmatization is applied on each token in order to group together the inflected forms of a word and subsequently remove the stop words based on a list of commonly agreed stop words provided by the NLTK.

	By article test set			By publisher test set		
	Precision	Recall	F-score	Precision	Recall	F-score
SuCla	0.556	0.643	0.596	0.535	0.809	0.644
BOW	0.542	**0.971**	0.696	**0.627**	0.808	0.706
DL	**0.592**	0.895	**0.712**	0.608	**0.860**	**0.712**

Table 1: Evaluation results on the two unseen test sets provided by SemEval-2019 Task 4.

3 Proposed Approach

We experimented with three approaches:

- **SuCla:** a simple classifier based on *superficial* features extracted from the article text (e.g. *number of words*, *contains pronouns*, *number of explanation marks*) and building supervised machine learning models;
- **BOW:** a 'bag-of-words' text classifier;
- **DL:** a deep learning system based on convolutional neural networks (CNN) (LeCun et al., 2015) and recurrent neural networks (RNN) (Medsker and Jain, 1999).

These are further detailed in the next sections.

In the experiments reported here, the training set was used for building the models and the validation set for calculating the evaluation measures: precision, recall and F-score[1]. The decision threshold is set to 0.5 where probabilities ≥ 0.5 indicate hyperpartisan articles and < 0.5 non hyperpartisan. Regarding the submissions to the task through the TIRA platform, training was conducted offline by concatenating the training and validation sets as input and then, the trained models were deployed to TIRA to classify the new, unseen news articles.

3.1 Superficial Features Classifier (SuCla)

This simple approach is an adaptation of the one introduced in (Boididou et al., 2018), which was used to assess the credibility of Twitter posts. We extracted a set of superficial features from the article title, which are a subset of the *tweet-based* features presented in (Boididou et al., 2018). These are listed in Table 2. In (Boididou et al., 2018), further information about the Twitter user who posted the tweet was used, but such information is not available for the article publisher in this task.

We extracted the title-based features on the training and validation sets. The extracted 15-dimensional feature vectors were first normalized in the [0,1] range and then fed to a Radial Basis Function (RBF) kernel SVM. The model parameters were calculated using a grid searching method. The software was deployed to TIRA and evaluated on the unseen articles of the test set. The normalization of test article features was conducted using the scaling parameters computed from the training set. Then, articles were classified as hyperpartisan or not with a score in the [0,1] range: the higher the score the more likely the article is hyperpartisan. The precision, recall and F-measure of this run are presented in Table 1 for the two test sets of unseen articles (by-pyblisher and by-article). The resulting F-scores of 0.596 and 0.644 for the by-article and by-publisher test set respectively indicate that this approach performs better than random but requires more distinctive features to further improve the accuracy.

#	Title-based features
01	Text length
02	Number of words
03	Contains question mark (Boolean)
04	Contains exclamation mark (Boolean)
05	Contains 1st person pronoun (Boolean)
06	Contains 2nd person pronoun (Boolean)
07	Contains 3rd person pronoun (Boolean)
08	Number of uppercase characters
09	Number of positive sentiment words
10	Number of negative sentiment words
11	Number of slang words
12	Has : symbol (Boolean)
13	Number of question marks
14	Number of exclamation marks
15	Number of nouns

3.2 Bag-of-words Classifier (BOW)

A text item, in our case the article title or body, can be represented as a vector of word occurrences. This is the well-known and widely used 'bag-of-words' (BOW) model. For building the BOW, we

[1]https://en.wikipedia.org/wiki/Precision_and_recall

	Precision		Recall		F-measure	
	Title	Body	Title	Body	Title	Body
MNB	0.54	0.54	0.66	0.79	0.59	0.65
RF	0.56	0.54	0.74	0.68	0.64	0.60
LR	0.58	0.56	0.79	0.81	**0.67**	0.66

Table 3: Evaluation results for Bag of Words on article title and body. Three classifiers are evaluated: Multinomial Naive Bayes (MNB), Random Forest (RF) and Logistic Regression (LR).

started with the clean text resulting from the pre-processing step described in Section 2 and counted the number of occurrences of each word from two vocabularies that were created based on the training set, and had a size of 64,663 and 364,359 words for the title and the body respectively. Three classifiers were evaluated: a) Multinomial Naive Bayes (MNB), b) Random Forest (RF) and c) Logistic Regression (LR). The obtained test results are presented in Table 3. According to it, LR outperforms the other two, irrespective of whether the article title or body is used as input. The resulting F-scores are 0.67 (title) and 0.66 (body). The BOW counts the number of times a word appear in the text of an article (term frequency) regardless of its appearance in other articles. In addition, we applied the Term Frequency-Inverse Document Frequency (TF-IDF), which adapts the term weight in relation to the times that this term appears in all articles. However, the resulting F-score of 0.58 (title) and 0.66 (body) for LR indicated that classification performance would suffer. Additionally, in the attempt to take advantage of both the title and body text, we implemented a fusion step based on averaging the prediction scores of the individual models. As a result, a minor increase of the F-score to 0.69 was obtained at the expense of additional complexity.

The LR classifier was finally trained on the full set of articles (both training and validation sets) and article title. The new BOW model was deployed to TIRA to classify the unseen news articles. This led to slightly better results as presented in Table 1. Compared to the SuCla approach, the BOW performance is significantly better, especially on the by-article dataset.

3.3 Deep Learning System (DL)

An overview of the employed network architecture, which was devised for the task, is presented in Figure 1.

The input to the network is the vectorized form of the articles' title and body. The input text is pre-processed as described in Section 2. An additional step is applied in order to form the text so that the inputs to the network have the same shape for each article. More specifically, for each article we retain the first 64 sentences, and for each sentence the first 64 words. This results in a (64x64)-dimensional tensor that is provided as input to the network. Zero padding is applied in order to fill missing words and/or sentences.

The input of the network is provided to an Embedding layer, to map each word of the input text to a *word embedding*. We used the pre-trained FastText word embeddings (Mikolov et al., 2018) of size 300. The weights of this layer are not updated during learning. In that way, we overcome the limitation of a bounded vocabulary, imposed by the training set, and the network can process words outside the training sets since they exist in the vocabulary of FastText. The output of this layer is a tensor of (64x64x300) for each article.

Then, we apply multiple convolution filters with different kernel sizes on the output of the Embedding layer. In that way, the network can capture word sequence structure in different granularity levels. The convolutional layers are used with kernel sizes of (1x1), (1x3), (1x5), and (1x7) and in combination with a ReLU activation function. The output of each convolutional layer is a (64x64x128)-dimensional tensor. The outputs of the four convolutional layers are then concatenated on the channel axis (the last tensor dimension) to form a (64x64x512)-dimensional tensor per article. Finally max-pooling is performed over the word axis, i.e., the maximum value per channel and sentence is extracted. To this end, the Embedding and Convolutional layers of the network capture word-level information from the article text.

After max-pooling on the outputs of the Convolutional layers, the (64x512)-dimensional tensors are given to a bidirectional Recurrent Neural Network (bi-RNN) (Schuster and Paliwal, 1997) that

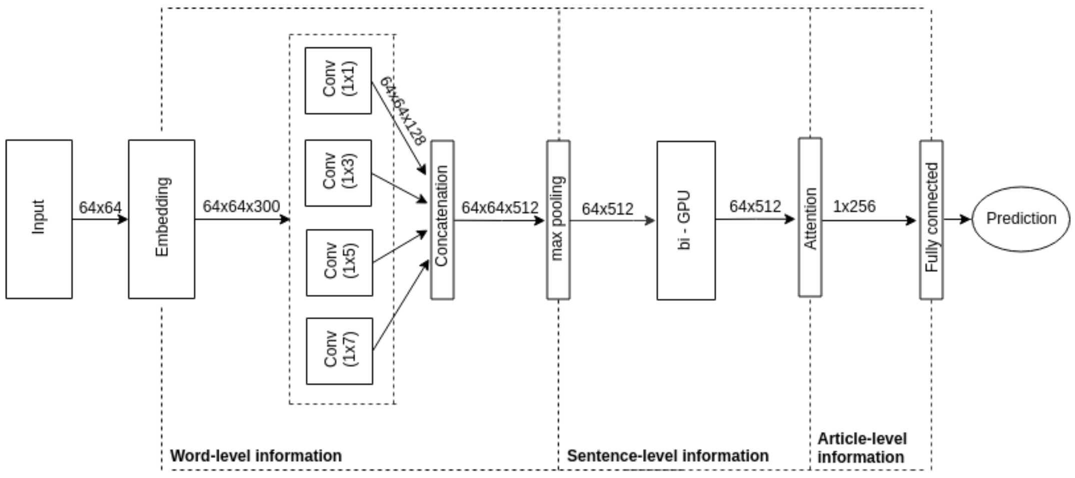

Figure 1: The deep learning architecture developed for classifying a news item as hyperpartisan or not.

calculates sentence vectors by taking into account the neighbor sentences. More precisely, for every article sentence i, the hidden vector h_i summarizes the neighbor sentences around sentence i but still focuses on that sentence. We employed the bidirectional Gated Recurrent Units (bi-GRU) (Cho et al., 2014) as the recurrent unit of the bi-RNN, which is an improved version of the standard recurrent unit. The output of the bi-GRU layer is provided to an attention mechanism (Yang et al., 2016) that weights each sentence vectors based on their similarity to a sentence-level context vector, and then averages the weighted vectors to single vector. The result of the Attention layer is a (1x256)-dimensional vector.

At the final stage, the network captures article-level information. The output of the Attention layer is fed to a fully connected layer to get the final prediction of the network. In this layer, we apply Sigmoid activation to map the output to the [0,1] range, which represents the probability of the article being hyperpartisan. Finally, the network is trained with the binary cross-entropy loss function, weight decay with a $5 * 10^{-4}$ regularization factor, Adam (Kingma and Ba, 2014) optimizer, and 10^{-3} learning rate. Training is done for 100 epochs with a batch size of 32 articles, and the best network is selected based on the performance on the validation set.

This method performs better than the other two approaches, achieving an F-score of 0.712 (Table 1) for both test sets.

3.4 Ideal Fusion

We implemented an ideal fusion method in order to examine the complementarity between the three proposed approaches. This is a theoretical scheme (oracle) which takes the outputs of the individual approaches and selects the correct classifier: at least one model needs to classify correctly an article. An F-score of 0.85 is achieved on the validation set, far better than the individual classifiers accuracy (SuCla: 0.51, BOW: 0.67, DL: 0.65) indicating that the models bring complementary information, which make them good components of a combined model.

4 Conclusions

This paper summarized our participation in SemEval-2019 Task 4, where we aimed at the challenge of Hyperpartisan News Detection. We tried to approach the problem from the perspective of standard supervised learning techniques, as well as more complex deep learning approaches. While none of the methods gave groundbreaking results, our set of experiments and observations provides a solid basis for future research on the problem. In particular, we intend to conduct more extensive analysis on the annotated data and extract patterns that will be more representative and distinctive for the problem at hand. Moreover, we will consider combining the three proposed approaches with the aim of creating a stronger and more accurate combined model. The significant increase in performance of the ideal fusion method points out the benefits of such a strategy.

Abstract

This paper summarizes our contribution to the Hyperpartisan News Detection task in SemEval 2019. We experiment with two different approaches: 1) an SVM classifier based on word vector averages and hand-crafted linguistic features, and 2) a BiLSTM-based neural text classifier trained on a filtered training set. Surprisingly, despite their different nature, both approaches achieve an accuracy of 0.74. The main focus of this paper is to further analyze the remarkable fact that a simple feature-based approach can perform on par with modern neural classifiers. We also highlight the effectiveness of our filtering strategy for training the neural network on a large but noisy training set.

1 Introduction

In the era of misinformation, the challenge of differentiating reality from frames, facts from opinions, is becoming increasingly important. Concepts such as *Fake News*, *Fact Checking* or *Post-Truth Era*, generally unknown a few years ago (Lewandowsky et al., 2017), started to play an important part in media, academic papers and even in Natural Language Processing (NLP) tasks (Rashkin et al., 2017; Shu et al., 2017; Wang, 2017). Nowadays, strongly opinionated news stories can offer biased information, as is the case with hyperpartisan articles. A text is considered hyperpartisan when it is highly polarized towards an extreme position. Potthast et al. (2018) analyzed hyperpartisanism in relation to fake news, to discover that a very similar writing style could be associated both with right-wing and left-wing polarized stories. This shared style of biased articles was different from that of mainstream articles. Task 4 in SemEval 2019 (Kiesel et al., 2019) consisted in a classification challenge where news articles had to be sorted out as hyperpartisan or non-hyperpartisan. Our approach addressed this challenge via two different models, which included 1) an SVM classifier based on word embeddings averages and handcrafted linguistic features and 2) a recurrent BiLSTM neural network classifier trained on filtered data. The reason and process for filtering data will be explained in section 3.2.

Word embeddings have remained central to the state-of-the-art approaches in NLP since the introduction of Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014) models. In addition to modelling word meaning, embeddings can also be applied to longer units of significance, such as phrases, sentences, paragraphs or entire documents (Le and Mikolov, 2014). However, although such vector representations often enable the best results in a variety of NLP challenges, some tasks still benefit from linguistically inspired approaches. In fact, recent work has proved how linguistic features and stylometry could improve the performance of deep learning techniques. The already mentioned work in Hyperpartisan and Fake News detection (Potthast et al., 2018) applied stylometry based on linguistic features to identify strongly biased articles. Bag of words, stop words, part of speech and readability scores are some of the features analyzed by the authors. They also focus on quotes, measuring their length and counting their appearances in a text. Rhetorical questions or the appearance of personal pronouns, among many others linguistic features, also helped to classify suspicious vs trusted news posts on Twitter (Volkova et al., 2017). The number of adverbs or swear words has also been used for fact checking purposes (Rashkin et al., 2017). Inspired by these previous works and their results, these linguistic features are some of the ones we apply in our first model.

The second model is based on word embeddings as input for a neural network. Specifically, we used a Convolutional Neural Network (CNN) combined with a Bidirectional Long-Short Term Memory (BiLSTM) network. The main novelty of this approach lies in the preprocessing step which filters the training data. This strategy is used because the bulk of the training data only provides a weak supervision signal, which we found too noisy to use directly.

2 Data

The data provided for this task consisted of a training set of 645 news articles, manually labeled as hyperpartisan or non-hyperpartisan. In addition to this gold standard data, a larger dataset of 600,000 training articles and 150,000 validation articles was provided. These complementary documents were labeled automatically depending on their source media. If the media was considered hyperpartisan, the article was labeled as such, but without analyzing its content. These automatically tagged articles also included further labels (referring to the publisher rather than the article itself), which have not been used in our system. Our first model exclusively relied on the manually labeled articles (645) for training, while the second model also took advantage of the larger set of weakly labeled articles (750000).

3 Our Approach

The dataset was preprocessed by changing the text to lower case and then applying tokenization. For our first model, sentence tokenization was applied and articles were preprocessed with part-of-speech tagging (PoS), using the NLTK library (Bird et al., 2009). While Potthast et al. (2018) kept and analyzed quotes in texts, we chose to delete them in both datasets. Our first experiments showed that, in a small number of cases, keeping quotes drove our system to misclassification because while an article could quote hyperpartisan statements of others, the document itself did not necessarily have an extreme position towards a topic or event. In both approaches, we only considered the main text of the article, discarding its title.

3.1 Model 1: Combining Document Embeddings with Linguistic Features

Document embeddings were built for each article. For doing so, we first computed embeddings for all sentences by averaging the pre-trained GloVe vectors (Pennington et al., 2014) for all the words occurring in them. To this end, we used the uncased Common Crawl pretrained GloVe embeddings, with 300 dimensions and a vocabulary of 1.9 million words. The average of all the sentences in an article was then computed to obtain a single vector representation of the news article. To complement this document vector, we identified a number of document-level discriminant linguistic features to classify a text as hyperpartisan or non-hyperpartisan. The selected features are as follow:

- **`excl`**: total number of exclamation marks
- **`quest`**: total number of question marks
- **`adj`**: percentage of tokens which are adjectives
- **`adv`**: percentage of tokens which are adverbs
- **`insults`**: total number of insults or swear words[1]
- **`first_pers`**: total number of times that the first person personal pronoun *I* was used
- **`sent_length`**: average length of sentences
- **`min_sent`**: length of the shortest sentence
- **`max_sent`**: length of the longest sentence

These feature values were concatenated with the document vector to provide the input for a linear SVM classifier.

To experiment with different configurations of our method, we used the 645 manually labeled articles with 5-fold cross-validation. Document embeddings and linguistic features vectors were considered both separately and concatenated as input for different classifiers, namely Random Forest, Logistic Regression and Support Vector Machine (SVM), with different parameters. In all cases, we used the implementations from the Scikit-Learn Machine Learning Library (Pedregosa et al., 2011). After testing the different options, a concatenated vector of document embeddings and linguistic features as input for an SVM proved to ob-

[1] A file containing swear words and insults was provided as input for a swear words count function. The file was created with a list of such words extracted from https://www.digitalspy.com/tv/a809925/ofcom-swear-words-ranking-in-order-of-offensiveness/, and then augmented with 2,500 similar insults coming from their *word2vec* nearest neighbours.

tain the best results. We finally trained our combined model as a linear SVM on the entire set of 645 gold standard documents.

3.2 Model 2: Neural Text Classification

Neural networks need large amounts of data to be able to learn. The small dataset of 645 manually labeled articles was clearly too small to train a competitive neural network model. However, we noticed that the large training set of 750K documents, which was labeled based on the publisher, was too noisy, yielding a performance which was far worse than that of the first model. We attempted to surmount this issue via a two-step strategy, in which we first trained a classifier on the small training set, which we used to filter the larger but noisy training set. The goal was to automatically extract from the 750K labeled-by-publisher articles only those which were correctly predicted as hyperpartisan or non-hyperpartisan by this initial classifier. The strategy which we found to perform best was the following:

1. Using half of the 645 labeled articles, we trained three classifiers:
    - a linear SVM based on the linguistic feature set described in Section 3.1,
    - a linear SVM based on the document embedding
    - and a standard neural classifier using a convolutional layer followed by a bi-LSTM layer (CBLSTM).

    The two first classifiers were included after they had been tested in our first model, and with the parameters previously explained. The choice of using a combination of CNN and LSTM for our third classifier stems from previous work where either or both architectures combined proved to be useful in document classification (Kim, 2014; Xiao and Cho, 2016). Concerning the choice of hyperparameters, we used 100 convolutional filters of size 5, and one-token strides. The output of the CNN layer was then passed to a max-pooling layer (where pool size was set to 4), and this output was passed to a bidirectional LSTM layer which produces two 100d vector outputs, which after concatenation, were passed to a final 2d softmax layer. We implemented this model using the *keras*[2] library.

2. We then trained a meta-classifier on the remaining half of the 645 articles, which used the predictions of these three individual classifiers as features, and which finally generated a final prediction. For this meta-classifier we used a linear SVM.

3. Once trained, the meta-classifier was applied to the 750K labeled-by-publisher articles. Whenever the ground-truth label agreed with the prediction of our metaclassifier, the article was retained in our filtered dataset.

4. Through this process, we obtained around 150K refined labeled articles that we used for training another CBLSTM, replicating the same process and parameters used in step 1. This last refined model was the one applied to the test set.

4 Analysis

We will focus our analysis on the first model, given that its result is perhaps most surprising. We observed that exclamation and question marks were present in non-hyperpartisan and mainstream articles, but a high occurrence of these features is nonetheless clearly correlated with hyperpartisanism. Adjectives and adverbs tended to be more frequent in hyperpartisan texts as well. Insults or swear words were extremely scarce in non-hyperpartisan articles, so their presence is a strong indicator for hyperpartisanism. The personal pronoun *I* denotes a personal text, and for this reason is more common in strongly opinionated articles. Average sentence length was not found to be particularly informative. On the other hand, we found that the shortest sentences in hyperpartisan articles tend to be shorter than those in non-hyperpartisan articles. In a similar way, the longest sentences were also slightly longer in extreme news stories. These results have been summarized in Table 1.

Further experiments to assess the discriminatory power of each linguistic feature were performed, although these took place after the submission for this SemEval task. A 5-fold cross validation on the 645 gold-standard articles dataset was applied to estimate the performance of the model in each case. As can be seen in Table 2, the linguistic features on their own are sufficient for achieving an accuracy of 66%. Combining them with document embeddings, the results reached 73.2%. However, a deeper analysis showed that

[2]https://keras.io/

	Hyp.	Non Hyp.
excl (avg)	1.30	0.63
quest (avg)	2.43	1.20

sent_length (avg)	22.47	24.43
min_sent(median)	2.00	4.00
max_sent(median)	52.00	47.00

Table 1: Linguistic features extracted from 645 articles dataset.

some linguistic features were actually deteriorating the general performance of the system. For instance, the linguistic features model alone performed better when `excl` were not accounted for. On the other hand, `insults`, `adj` and `adv`, respectively, were the most discriminant features, leading to the biggest drop in performance when discarded. Here, we would like to highlight that, surprisingly, the feature `adv` reduces the performance of the combined model, where eliminating it allows the system to reach 75% of accuracy. The feature `first_person` is also reducing the score of the combined system. However, whenever we omitted two or more linguistic features, the performance of the combined model dropped below 72.7%, which is the accuracy achieved by the document vectors on their own. Therefore it seems safe to conclude that our linguistic features share some information that, combined, provide complementary evidence for document embeddings.

5 Results and Discussion

Both our systems obtained around 74% accuracy in SemEval 2019 task 4: Hyperpartisan News Detection under the team name of Ankh-Morpork Times (Potthast et al., 2019). This constitutes an improvement of 28 percentage points over the provided baseline. In the SemEval competition, our team got the 16th position out of 42 participants. Our main contribution was to show that a simple approach, based on document embeddings and linguistic features, can obtain the same accuracy as a typical neural text classifier.

Overall, there are several lessons learned from our participation in this task, which we will try to develop in future work. For example, we confirmed that, although the community tends to rely on the performance of word vectors, linguistic features can complement word vector based representations in a meaningful way in text classification. In addition, further analysis in our work showed that we could have improved our performance with a better selection of linguistic features. Therefore, for future work, we aim at providing a more reliable model which takes into account more complex linguistic features. For instance, we believe that looking at sentences' modality and sentiment, as well as assessing the polarity of adjectives and adverbs in a text, should give valuable extra information for the task.

As a secondary contribution, we also proposed a technique for filtering noisy data. It is known that neural networks perform well for large training sets, but sometimes a large accurately labeled dataset cannot be obtained. To this end, we created a meta-classifier trained on a smaller gold standard dataset and applied to larger, noisy data for obtaining a filtered higher-quality training set.

6 Namesake

Ankh-Morpork is the biggest city in the Discworld, the fictional world that gives name to the famous fantasy book series by Sir Terry Pratchett. And Ankh-Morpork Times is its first, biggest and most famous newspaper, and covers in a peculiar and surreal way the no less surreal events happening in this flat world. And sometimes, we must admit, with quite a hyperpartisan point of view.

Abstract

In this paper, we present a news bias prediction system, which we developed as part of a SemEval 2019 task. We developed an XGBoost based system which uses character and word level n-gram features represented using TF-IDF, count vector based correlation matrix, and predicts if an input news article is a hyperpartisan news article.

Our model was able to achieve a precision of 68.3% on the test set provided by the contest organizers. We also run our model on the BuzzFeed corpus and find XGBoost with simple character level N-Gram embeddings to be performing well with an accuracy of around 96%.

1 Introduction

The problem of hyperpartisan news detection (Potthast et al., 2018) is based on predicting whether a news article is biased towards a specific political wing or not. The problem falls under the category of classification problems, and the task is to classify an article as being extremely one-sided or not. A closely related problem is that of fake new detection wherein the task is to analyze the veracity of an article, and classify it based on some predefined degrees of truthfulness.

Our problem has a high societal relevance, since one-sided news poses a great threat to democracy, particularly in the context of conducting fair elections. In this paper, we discuss our approach to solving this problem used during the contest *Hyper Partisan News Detection*, a competition task at SemEval 2019 (Kiesel et al., 2019).

More formally, our problem definition is:

Definition 1 (Hyperpartisan News Detection) *We are given a set of news articles A, where each article a_i is marked with two labels: a Boolean label hyperpartisan h_i which indicates if article a_i is biased towards a political wing, and a bias label $b_i \in$ {left, right, left-center, right-center, least} which indicates which wing the article is biased towards. If h_i = True, then $b_i \in$ {left, right}; if h_i = False, then $b_i \in$ {least, left-center, right-center}. The objective is to learn a classifier **C** which predicts the hyperpartisan label h_j for an unknown news article a_j.*

In this work, we identify the role of various traditional NLP features in determining the degree of partisanship. We utilise standard term-frequency and inverse document frequency vector features computed for uni, bi and tri-grams obtained from the corpus. We do this feature extraction at both character and word level and then train a gradient boosted decision tree as a classifier for identifying partisanship. We also compare other methods of classification such as SVM, KNN, Naive Bayes and Logistic Regression for the task using the same vector features. Furthermore, experiments exploiting the metadata information were also performed (explained in detail in the scalar features in section 3.2).

The experiments were performed on two corpora, the BuzzFeed corpus (created in (Potthast et al., 2018)) and the training corpus released by the task organisers (the SemEval corpus). Further we also discuss the results obtained on the final test corpus released for the final evaluation of the task in section 4.1. Due to computation infeasibility over the larger training corpus, we do not compute vector features for the SemEval corpus.

2 Related Work

The work done on hyperpartisan and fake news detection can be broadly classified into three categories – knowledge-based (Etzioni et al., 2008; Ginsca et al., 2015), context-based (Long et al.,

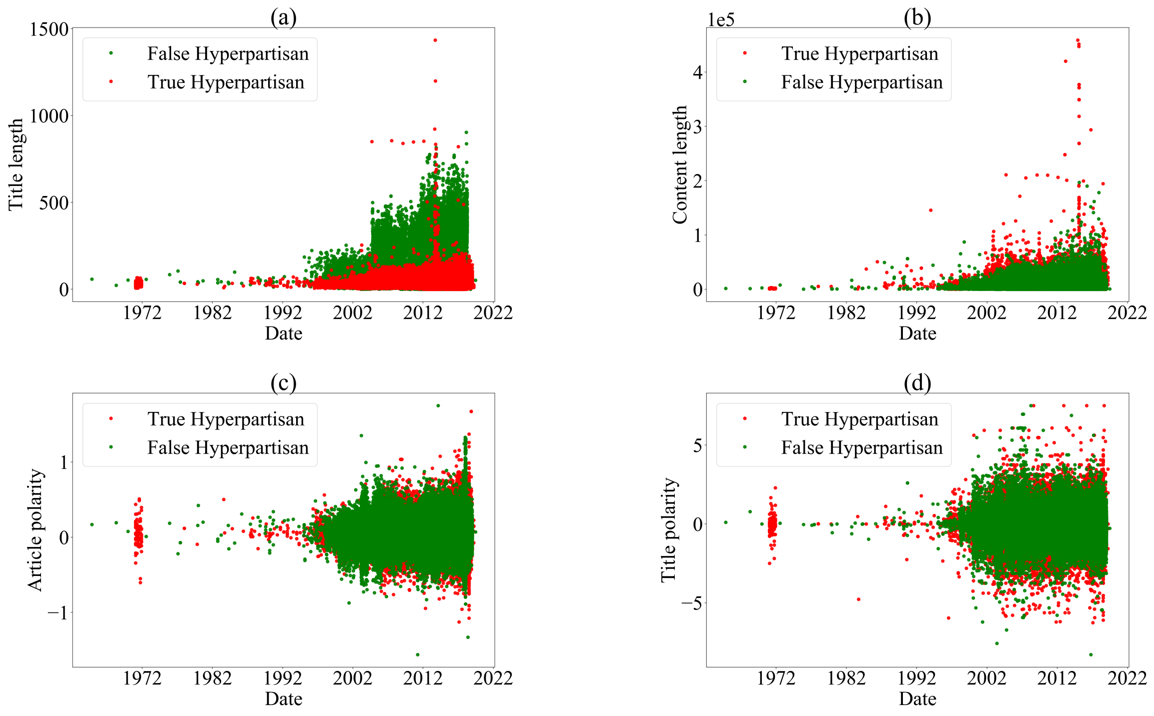

Figure 1: Variation in feature value w.r.t. time for true and false hyperpartisan articles in SemEval Corpus (a) Title length w.r.t. time (b) Content length w.r.t. time (c) Article polarity value w.r.t. time (d) Title polarity value w.r.t time . Red and green colors depict articles from hyperpartisan publishers and other publishers respectively.

2017a; Mocanu et al., 2015), and style-based (Bourgonje et al., 2017).

While the knowledge-based and context-based features may take some time to detect hyperpartisanship (after the news starts spreading on social media), the style-based features can be used to detect partisanship of a news article well in time before the damage happens (Potthast et al., 2018).

For exploiting style based features, (Long et al., 2017b) uses deep learning based methods, and (Shu et al., 2017) performs fake news detection on social media data using a data mining oriented approach.

2.1 Baseline

We take as our baseline the work done by (Potthast et al., 2018). Their work uses the author's writing style as features to detect hyperpartisanship. The stylometric features used in their work include POS-unigrams, POS-bigrams, POS-trigrams, char-unigrams, char-bigrams, char-trigrams, stopword-uniGrams, stopword-bigrams, stopword-trigrams, general inquirer categories, readability scores, quotation ratio, link amount and average paragraph length. A random forest classifier was used to make predictions.

We use their classifier as the baseline for the BuzzFeed corpus. For the SemEval corpus, we use the random baseline provided in the task as our baseline. The baseline results are mentioned in Tables 1 and 3 for both the datasets.

3 Methodology

In this section, we describe the dataset, the features that we selected and the models we trained using the selected features. A visual overview is shown in Figure 2.

3.1 Corpus

We used two corpora, which we name as BuzzFeed corpus and SemEval corpus.

BuzzFeed corpus: This corpus was produced by the baseline work. The dataset comprised 1,627 articles that were manually checked by four BuzzFeed journalists. Of these, 826 articles belong to the main-stream category of publishers, 256 belong to the left-wing category of publishers, and the remaining 545 to the right-wing category of publishers.

SemEval corpus: This corpus has been released for the SemEval 2019 Task 4 on Hyperpartisan News Detection. It comprises 800,000

Table 2: Scalar features results.

training articles and 200,000 test articles. These articles are annotated based on the publisher of the articles.

3.2 Feature Selection

Prior to the selection of features, we pre-processed our datasets to clean the text in articles to handle the encoding errors, perform text normalisation and stop word removal. The features we selected can be categorized into two categories, viz. scalar features and vector features. We train two sets of models, one for each category of features.
Scalar features: Here, we select four features, all used at the same time since they encode different information:

- Article length: This feature denotes the length of the articles in terms of the number of characters.
- Title length: The title length features denotes the length of the title of an article in terms of the number of characters.
- Article polarity: The article polarity denotes the sentiment score of the article text in the range $[-1, 1]$. A score value less than zero implies a negative sentiment, and a positive sentiment otherwise.
- Title polarity: Similar to the article polarity, the title polarity feature denotes the sentiment score of the article title in the range $[-1, 1]$.

Vector features: These include three kinds of features (considered separately since they encode the same information):

- Word count vectors: The count vector for a document denotes the vector of counts of words in the document from the set of possible words in a corpus/vocabulary.
- Word level n-gram vectors: The word level vector for a document denotes the vector of tf-idf values of words level n-grams in the document. We used unigrams, bigrams and trigrams for this feature.
- Character level n-gram vectors: The character vector for a document denotes the vector of counts of character level ngrams. For this feature too, we use unigrams, bigrams and trigrams.

Visual inspection of the data: In Figure 1 we provide a visual insight into the corpus based

Dataset	Method	Precision	Recall	F1 score	Accuracy
By Article	Ours	68.3	17.8	28.3	**54.8**

By Publisher	Ours	56.5	17.0	26.1	**51.95**
	Baseline	51.1	51.1	50.0	50.5

Table 3: Results for the submitted model.

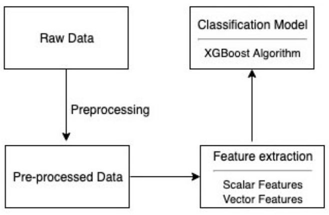

Figure 2: System Overview.

on the features selected. The figure depicts scatter plots showing variation in feature values w.r.t. time for both true and false hyperpartisan articles.

3.3 Models Used

We use the following learning models for our scalar features of the BuzzFeed corpus: K Nearest Neighbours (KNN), Gaussian Naive Bayes (GNB), Random Forest (RF), Logistic Regression (LR) and Support Vector Machine (SVM). For the vector features of the BuzzFeed corpus, we use: KNN, GNB, RF, LR, SVM and XGBoost (XGB).

4 Experiments

We divide this section into three parts – experimental setup, results on the BuzzFeed corpus, and results on the SemEval corpus.

4.1 Experimental Setup

The article polarity and title polarity features were computed using SentiWordNet[1] (Baccianella et al., 2010). All the vector features were computed using the scikit-learn package. To split the data into training and testing sets, we used 5-fold cross-validation.

4.2 Results on the BuzzFeed Corpus

The results for the scalar features for models trained on the BuzzFeed corpus are shown in Table 2a(a). The RF model performs the best with an accuracy of 74%. The scalar features, however, are insufficient in beating the baseline. We therefore train models on our vector features. The results for the vector features are shown in Table 1.

As evident from table 1 and 2a(a), vector features perform much better and are able to beat the baseline (Table 1) easily.

Various sections in Table 1 represent the results when using different kinds of vector representations as features, with character level n-grams yielding the top results.

4.3 Results on the SemEval Corpus

Results on the SemEval corpus are shown in Table 2b(b). From all models, KNN performs the best, followed by RF, SVM, and GNB (in that order).

Since computing vector features and tf-idf features was computationally infeasible on this corpus, we did not train the vector features, however, based on our observations from buzzfeed dataset (i.e the character level vectors outperforming all others), we trained a supervised classifier using FastText (Joulin et al., 2016), (Bojanowski et al., 2016). The accuracy achieved for this model is 65%.

The results of our model using all the scalar features on the final evaluations (testing by article and testing by publisher corpus) of this competition are shown in Table 3. These results show that our model suffered from the inability to draw out more of the relevant results (low recall).

5 Conclusion

In this work, we have explored traditional sets of features and models for the Hyper-partisan News Detection problem. We worked on two corpora, of which one has been used in the state-of-the-art literature. For this corpus, we beat the baseline and achieve a remarkable accuracy of 96%. For the other corpus, we achieve an accuracy of 65% (with a fast text character level embedding based model).

From the results of the contest (Table 3), we were able to beat the baseline easily. Though our system did not achieve as high accuracy as other systems, we observe that this is due to a bad recall, i.e even though the features that we selected

[1]https://github.com/anelachan/sentimentanalysis

are very useful for the model to produce relevant results, it cannot capture some of the correct results.

6 Code and Reproducibility

We provide all our code for both Buzzfeed and Semeval Corpus as a github repository located at https://github.com/virresh/hyperpartisan-semeval19-task4 . The same code was uploaded on TIRA (Potthast et al., 2019) and run for submission to the contest.

Abstract

In a world of information operations, influence campaigns, and fake news, classification of news articles as following hyperpartisan argumentation or not is becoming increasingly important. We present a deep learning-based approach in which a pre-trained language model has been fine-tuned on domain-specific data and used for classification of news articles, as part of the SemEval-2019 task on hyperpartisan news detection. The suggested approach yields accuracy and F1-scores around 0.8 which places the best performing classifier among the top-5 systems in the competition.

1 Introduction

In today's polarized media and political landscapes, the challenge of determining whether a news article is biased or not is highly topical. In the hyperpartisan news detection task (Kiesel et al., 2019) of the International Workshop on Semantic Evaluation (SemEval) 2019, the task is to predict whether a given news article text follows a hyperpartisan (extreme one-sided) argumentation or not, i.e., whether it exhibits blind or prejudiced allegiance to one party, cause, or person (Potthast et al., 2019). As part of this challenge, participating research teams got access to two datasets:

1. **by-publisher**: A well-balanced dataset consisting of 750,000 articles in which the data have been labeled by the overall bias of the *publisher*, as provided by journalists or fact-checking sites.

2. **by-article**: A smaller dataset consisting of 645 articles for which crowdsourcing workers have agreed on the labeling of the *articles* as being hyperpartisan (37%) or not (63%). A similar but more well-balanced test dataset (to which the participating teams have not got direct access) has been used for evaluating the accuracy, precision, recall, and F1-score of systems developed by the participating research teams.

In this system description paper we present the results for the two participating research teams from the Swedish Defence Research Agency (FOI): 1) **dick-preston** and 2) **morbo**.

The teams contributed with separate systems for the early-bird deadline and for the final submission. In the early phase we used traditional machine learning classifiers such as logistic regression and support vector machines (SVMs), built upon traditional text features such as word and character n-gram term frequencies (weighted with inverse document frequency). These classifiers have been used as baselines to which more "modern" NLP classifiers have been compared. For the final submission both teams made use of transfer learning-based Universal Language Model Fine-Tuning (ULMFiT) models. The difference in the teams' final systems is the percentage of data used for training/validation splits when fine-tuning the models and the number of epochs for which the models were trained. Despite that only a few hundred examples were used for fine-tuning the pre-trained ULMFiT-models, accuracies and F1-scores of approximately 0.8 were achieved on the unseen test data. This resulted in a fifth place for the team **dick-preston** and seventh place for the team **morbo** out of 42 participating teams, as reported on the competition leaderboard[1].

The rest of this paper is structured as follows. In Section 2, we present the machine learning algorithms and features which have been used for building the hyperpartisan news article classifiers used in the competition. In Section 3 we outline

[1]https://pan.webis.de/semeval19/semeval19-web/leaderboard.html

the conducted experiments, present the used hyperparameters, and describe the obtained results. Finally, we present overall conclusions and discuss ideas for future work in Section 4.

2 Method

In the early phase of the competition, both FOI teams experimented with traditional machine learning algorithms such as Naïve Bayes, logistic regression, and support vector machines (SVMs), taking sparse text features such as word and character n-grams as input. These methods have been used as baselines to which more novel algorithms have been compared. The FOI baseline methods are briefly presented in Section 2.1.

For the final system submission we have used more "modern" NLP methods. More specifically, Universal Language Model Fine-Tuning (ULMFiT) was utilized. ULMFiT is a natural language processing (NLP) transfer learning algorithm introduced in (Howard and Ruder, 2018). ULMFiT is one of several language model-based transfer learning algorithms developed in 2018 which have been shown to yield state-of-the-art results on several NLP tasks. Approaches such as ELMo (Peters et al., 2018), OpenAI GPT (Radford et al.), and BERT (Devlin et al., 2018) have arguably received more attention than ULMFiT, but we selected to implement our final systems using ULMFiT due to its straightforward implementation in the fastai library[2], and its promising results also on small datasets (Howard and Ruder, 2018). ULMFiT is presented in more detail in Section 2.2.

2.1 Baseline Classifiers

As baseline classifiers we have made use of traditional "shallow" machine learning algorithms like logistic regression, SVMs, etc. An extensive list of the tested algorithms can be found in the experiment descriptions in Section 3. A detailed explanation of such classifiers is outside the scope of this paper but we refer the interested reader to (Hastie et al., 2001) for an excellent introduction to such approaches.

As input features to our baseline classifiers we have used term frequencies of n-grams. In the most basic case of 1-grams (unigrams), this means that for each token in the dataset (tested on character as well as word level) we count the number of times the specfic token (e.g., the word "Trump") appears. In the case of 2-grams (bigrams) we do the same, but then for pairs of tokens (e.g., "President Trump"). To account for tokens which appear frequently in all kinds of news articles (thereby making them less valuable for prediction of the target class) we weigh the term frequencies by their inverse document frequency. Various strategies such as only including the most frequently occuring tokens have also been utilized. Details of which strategies that have been tested in our experiments are given in Section 3.

2.2 ULMFiT

As the basis of our ULMFiT models we have used a pre-trained language model trained on the English Wikitext-103 (Merity et al., 2016), which in total consists of more than 28,000 preprocessed Wikipedia articles and over 100 million words. The pre-trained language model consists of a word embedding layer connected to a three-layered unidirectional left-to-right AWD-LSTM (Merity et al., 2017). The AWD-LSTM utilizes several regularizations strategies such as a DropConnect mask on the hidden-to-hidden recurrent weights and variable length backpropagation through time (BPTT) sequences. Given a sequence of N tokens, a left-to-right language model can be used to compute the probability of the sequence of tokens:

$$P(t_1, t_2, \ldots, t_N) = \prod_{k=1}^{N} P(t_k | t_1, t_2, \ldots, t_{k-1}) \tag{1}$$

Language models are powerful in that they can "teach themselves" a lot about language by simply letting them iteratively predict the next word in a sequence on large amounts of (otherwise unlabeled) training data. Throughout this process, the parameters in the ULMFiT AWD-LSTM layers implicity learn about both syntax and semantics as these are helpful for predicting the next word in a sequence.

In next step, the pre-trained language model has been fine-tuned on the 645 articles in the manually crowdsourced **by-article** dataset. The reason for this fine-tuning is that the news articles most likely stem from a different data distribution, compared to the Wikipedia articles on which the language model originally have been trained. During the language model fine-tuning, discriminative learning and slanted triangulated learning rates (SLTR) was used, as outlined in the original

[2]https://github.com/fastai/fastai

ULMFiT paper (Howard and Ruder, 2018). The language model could most likely have been improved upon more by making use of the larger **by-publisher** dataset. However, we were interested in how good the ULMFiT model would perform on a very limited dataset.

In the last step, the fine-tuned language model has been augmented with two linear blocks separated by a rectified linear unit (ReLU) activation function. The last linear block consists of just two output nodes with a softmax activation, giving as output a probability of the current news article being hyperpartisan or not given the fine-tuned model. Regularization in the form of dropout and batch normalization is applied to the linear blocks in order to allow for better generalization. Moreover, gradual unfreezing is used in order to avoid catastrophic forgetting, a phenomenon which previously has been common when trying to fine-tune pre-trained language models.

3 Experiments and Results

For the first part of the competition we experimented with baseline classifiers to which we later on could compare the classification accuracy of more advanced algorithms on hold-out validation datasets constructed from the training data. The experiments with the baseline classifiers were performed using scikit-learn, while latter experiments have been carried out using various deep learning frameworks (including TensorFlow and Keras). The final ULMFiT classifier implementations and experiments have been carried out using PyTorch and the fastai library.

3.1 FOI Baseline Classifier Experiments

We first experimented with a number of simple classifiers which were used as baselines:

- SVM (LinearSVC)
- Logistic Regression
- Random Forest
- Gradient Boosting
- Naïve Bayes
- NBSVM

We used scikit-learn to conduct a grid-search over various hyperparameters for these classifiers in order to find suitable optimized baseline models. In this section we will focus on the hyperparameters of the SVM classifier and its input features as this performed the best among the evaluated classifiers.

A consistent result for all the tested classifiers was that they performed better when creating the n-gram features described in last section from the text context of the news articles rather than only using the shorter titles. As input to the classifier we combined the 1000 word unigrams and bigrams ranked highest in terms of TF-IDF and the 1000 character unigrams and bigrams ranked highest in terms of TF-IDF. For the SVM we used a linear kernel and the regularization parameter C was set to 0.38. Using these parameters we obtained a weighted F1-score of 0.78 when applying stratified 10-fold cross validation on the training data. When the same model was trained on 100 % of the training data and submitted for evaluation on the test data as part of the early-bird deadline we obtained an accuracy of 0.77. This is a rather strong baseline as it would have resulted in a top-10 result in the final leaderboard (if the final FOI classifiers would not have been submitted).

3.2 FOI ULMFiT Classifier Experiments

The embedding layer of our ULMFiT classifiers uses word embeddings with an embedding size of 400. For the sequential linear layers that have been attached to the pre-trained LSTM layers we have used a momentum of 0.1 for the BatchNorm and a dropout probability p of 0.2 for the first linear layer and 0.1 the last linear layer. We have gradually unfreezed different blocks of the model to avoid catastrophic forgetting. Different slanted learning rates and number of training epochs have been used for the different submitted FOI classifiers, but we have in general found learning rates around 0.01 to work well for fine-tuning just the last layer, and then using lower magnitude learning rates when unfreezing earlier layers.

We evaluated the fine-tuned ULMFiT classifiers by splitting the available **by-article** dataset into a training set (85 %) and a validation set (15 %). This was attempted on a few random splits for which we consistently reached accuracies on the validation set over 0.95. In the end we submitted models trained on 85 % and 100 % of the training data but the one trained on 85 % performed the best, probably due to overfitting of the other model (which is natural since it was hard to know how

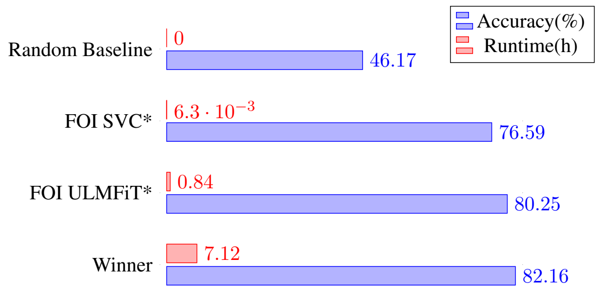

Figure 1: Accuracy and runtime of FOI classifiers in comparison to a random baseline and the winner of the hyperpartisan news detection competition.

many epochs the model should be trained for when not having any separate validation data to evaluate on). When the best performing model was submitted for evaluation on the test set it obtained an accuracy of 0.80 which resulted in a fifth place in the final leaderboard.

In Figure 3.2 we compare the accuracy and running time of our best performing ULMFiT classifier on the test data and contrast them to the corresponding measures for our FOI linear SVM classifier, a random baseline provided by the task organizers, and the classifier developed by the winning team. As can be seen, the accuracy of the ULMFiT classifier is marginally lower than the winning classifier, while the running time seems to be much lower[3].

4 Conclusions

In this paper we have described the ULMFiT classifiers developed by the FOI teams **dick-preston** and **morbo** for the SemEval-2019 challenge of hyperpartisan news article detection. By first fine-tuning a pre-trained language model on the texts and titles of a small dataset consisting of 645 news articles and then fine-tuning two additional linear blocks on humanly annotated labels of these articles, we have achieved accuracy and F1-scores around 0.80 on the task organizers' test dataset. The obtained accuracies resulted in a fifth and seventh place, respectively, out of a total of 42 research teams who submitted their classifiers to the competition. This demonstrates the applicability of novel transfer learning approaches such as ULMFiT to domains for which only very limited amounts of data is available. To the best of our knowledge, this is the first time on which ULMFiT has been attempted on such a small dataset.

[3]The submissions were evaluated on a rather slow virtual machine (Potthast et al., 2018) which impact the running times.

4.1 Future Work

The obtained results could have been improved upon by utilizing the larger available **by-publisher** training set for improving the fine-tuning of the language model on the target domain. It is also possible that this larger dataset could have been used for further fine-tuning of the classifier.

Another interesting idea for future research on this dataset would be to train a classifier based on Google AI's BERT, which make use of a deep bidirectional transformer instead of a multi-layered LSTM.

Doris Martin at SemEval-2019 Task 4: Hyperpartisan News Detection with Generic Semi-supervised Features

Rodrigo Agerri
IXA NLP Group, University of the Basque Country UPV/EHU
rodrigo.agerri@ehu.eus

Abstract

In this paper we describe our participation to the Hyperpartisan News Detection shared task at SemEval 2019. Motivated by the late arrival of Doris Martin, we test a previously developed document classification system which consists of a combination of clustering features implemented on top of some simple shallow local features. We show how leveraging distributional features obtained from large in-domain unlabeled data helps to easily and quickly develop a reasonably good performing system for detecting hyperpartisan news. The system and models generated for this task are publicly available.

1 Introduction

The definition of hyperpartisan according to the Hyperpartisan News Detection shared task at SemEval 2019 (Kiesel et al., 2019) is the following: "Given a news article text, decide whether it follows a hyperpartisan argumentation, i.e., whether it exhibits blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person".[1] Putting it simply, the task is, given a news article, to decide whether such document is hyperpartisan (true) or not (false). This task is related to the Stance Detection (Mohammad et al., 2016) and automatic detection of fake news (Pérez-Rosas et al., 2018) tasks, which are getting increasing attention within the Natural Language Processing community (Potthast et al., 2018). In this sense, it could be the case that hyperpartisanism is conveyed by some elements of fake news within the article, usually with the objective of spreading propaganda and manipulate readers towards a particular stance on a specific topic.

The SemEval 2019 task 4 aims to address the problem of hyperpartisan news detection at document level, without trying to distinguish specific elements or indicators of hyperpartisanism in each article. Two sets of data were released to participants. The first part (*bypublisher*) is annotated at publisher level. This means that if a publisher is thought to be spreading hyperpartisan news, then all its articles are annotated as hyperpartisan. The *bypublisher* set contains 750K articles divided in 600K documents for training and a validation set of 150K documents. The second part (*byarticle*) has been annotated at article level via crowdsourcing and consists of 645 articles for training and 628 documents for the test. The test set is hidden in TIRA (Potthast et al., 2019) and it is used for the official evaluation scores of the task. It should be noted that, unlike the *byarticle* test set, the *byarticle* training set was not balanced (407 false vs 238 true).

We address this task using an existing document classification system, mostly due to the fact that we joined the task just a week before the final submission deadline. However, and despite the lack of time to implement specific features for the task, we obtained quite good results with a simple and very general feature set in which the most meaningful feature was the use of pre-trained clusters obtained from the English Wikipedia and the Gigaword 5th edition. Out of 42 participants, our official submission obtained 0.737 accuracy whereas the winner of the task scored 0.822.

In addition to our official participation, in this paper we also describe a second round of experiments performed after the official submission deadline. The objective was to establish whether using clusters trained on domain-specific data would improve the results with respect to those obtained by using clusters based on general domain text such as Wikipedia and Gigaword. As it turned out, this second round of experiments allowed us to considerably improve the results

[1] https://pan.webis.de/semeval19/semeval19-web/index.html

(0.761) with respect to our official scores in the task (0.737), confirming that training clusters on domain-specific data, although smaller, helps to address the hyperpartisan news detection task.

2 Methodology

We parsed the given data in XML format extracting the title and the document body for training. We experimented with the original corpus version and with a cleaned (HTML tags removed) and tokenized version. All the pre-processing was done using the IXA pipes tools (Agerri et al., 2014).

Our system learns language independent models which consist of a set of local, shallow features complemented with semantic distributional features based on clusters obtained from a variety of out-of-domain and domain-specific data sources. We show that our approach, despite the lack of hand-engineered, language- and task-specific features, obtains competitive results in the hyperpartisan news detection task.

For the official results we trained only on the *byarticle* training set. The best settings of our system were chosen via 5-fold cross validation. The chosen models and software were uploaded to TIRA (Potthast et al., 2019) to annotate and evaluate the test data. For the official runs, we used pre-trained clusters from the Wikipedia and the English Gigaword, as described by Agerri and Rigau (2016).

For the second round of experiments, we used the large *bypublisher* data set and a Fake News Kaggle set[2] in order to train clusters. The motivation was to test whether using data sources closer to the task domain, as opposed to using general text data from Wikipedia and Gigaword, helped to obtained better word representations for this task.

3 ixa-pipe-doc

Our document classification system is *ixa-pipe-doc*, which aims to establish a simple and shallow feature set, avoiding any linguistic motivated features, with the objective of removing any reliance on costly extra gold annotations (POS tags, lemmas, semantics) and/or cascading errors if automatic language processors are used. The underlying motivation is to obtain robust models to facilitate the development of document classification systems for several languages, datasets and domains while obtaining state of the art results.

[2] https://www.kaggle.com/c/fake-news

The system consists of: (i) Local, shallow features based mostly on orthographic, word shape and n-gram features plus their context; (ii) three types of simple clustering features, based on unigram matching; (iii) publicly available gazetteers, such as sentiment lexicons. Specifically, *ixa-pipe-doc* implements, on top of the local features, a combination of word representation features: (i) Brown (1992) clusters, taking the 4th, 8th, 12th and 20th node in the path; (ii) Clark (2003) clusters and, (iii) Word2vec (Mikolov et al., 2013) clusters, based on K-means applied over the extracted word vectors using the skip-gram algorithm. The implementation of the clustering features looks for the cluster class of the incoming token in one or more of the clustering lexicons induced following the three methods listed above. If found, then we add the class as feature. The Brown clusters only apply to the token related features, which are duplicated.

ixa-pipe-doc, as a component of IXA pipes, includes a simple method to combine various types of clustering features induced over different data sources or corpora. This method has already obtained state of the art results in several tasks such as newswire Named Entity Recognition (Agerri and Rigau, 2016) and Opinion Target Extraction (Agerri and Rigau, 2019), both in out-of-domain and in-domain evaluations.

Clusters of words provide denser document representations. Although still a one-hot vector representation, the dimensions of the representation gets reduced to the number of clustering classes used. This is done by mapping the words in the document to the words in each of the clustering lexicons thereby obtaining a denser representations than the traditional one-hot representation based bag of words (Turian et al., 2010).

Finally, *ixa-pipe-doc* learns supervised models via the Maxent algorithm (Ratnaparkhi, 1999). To avoid duplication of efforts, the system uses the Apache OpenNLP project implementation of Maxent [3] customized with the features described in this section.

4 Experiments

We train ixa-pipe-doc with the default parameters, performing 100 iterations with a 5 count cutoff.[4]

[3] http://opennlp.apache.org/

[4] Only features that occur more than 5 times are considered (Ratnaparkhi, 1999).

Features	F1 True	F1 False	Accuracy
token	0.655	0.810	0.755
char26	0.643	0.806	0.749
pref04	0.662	0.810	0.757
token + pref04	0.669	0.809	0.758
token + char26	0.652	0.807	0.752
pref04 + char	0.655	0.812	0.757
(local) Token + char26 + pref04	0.665	0.813	0.759
local + CW600	0.672	0.814	0.763
local + W2VG200	0.674	0.817	**0.766**
local + CW600+W2VG200	0.671	0.816	**0.764**

Table 1: 5-fold cross validation for official results on the *byarticle* training set. CW600: Clark Wikipedia 600 clusters; W2VG200: Word2vec Gigaword 200 clusters.

Features	Accuracy	P	R	F1
Local + W2VG200	**0.737**	0.754	**0.704**	**0.728**
Local + CW600+W2VG200	0.714	**0.773**	0.608	0.680

Table 2: Official results on TIRA test set. CW600: Clark Wikipedia 600 clusters; W2VG200: Word2vec Gigaword 200 clusters.

We only tested three types of **local features** which were already implemented in the system: the current token, the character ngrams of each token (2:6 range) and word prefixes (0-4 characters of each token).

Due to our late arrival to the task, we combined the best local features with our pre-trained clusters from Wikipedia and Gigaword for the official results described in section 4.1. For the second round of experiments of section 4.2, we used the clusters trained using the *bypublisher* and Fake News datasets. The number of clusters trained with each algorithm and data source was the following: 100-800 clusters using the Clark and Word2vec methods, and 1000 classes with the Brown algorithm. The best combination of features were obtained by performing every possible permutation between them in a 5-fold cross validation setting using the *byarticle* training data.

4.1 Official Results

Table 1 provides the 5-fold cross validation results used to choose the two best runs that we submitted for testing on TIRA. As it can be seen, the performance for the *true* and the *false* classes greatly differ. This could be due to the unbalanced nature of the *byarticle* training set or because classifying articles that are hyperpartisan is actually more difficult.

The official results obtained by our system are shown in Table 2. These results show that the main weakness of the system is its lower recall. The local features used usually obtain high precision and lower recall whereas the clustering features reduce sparsity thereby improving the recall. The exception was the Brown clusters, which were detrimental to performance. This is consistent with previous experiments using clusters trained in out-of-domain data (Agerri and Rigau, 2019). Finally, although TIRA did not show the results per class (true or false) we believe that our system reproduced, for the official test data, the behaviour observed in the cross validation experiments.

Therefore, our results seem to indicate that the data used in our pre-trained clusters, Wikipedia and Gigaword, does not allow us to create good word representations for the hyperpartisan news data. Still, it can be said that our official results were promising, obtaining 0.737 versus the 0.822 accuracy of the best system.[5]

4.2 Second Round

This second round of experiments consisted of replacing the out-of-domain cluster lexicons from Wikipedia and Gigaword with those trained on the *bypublisher* and Fake News data. These are the "local + clusters" models in Table 3, which shows the results of performing 5-fold cross validation

[5]https://pan.webis.de/semeval19/semeval19-web/leaderboard.html

Features	F1 True	F1 False	Accuracy
local + W2VHP300	0.675	0.819	0.769
local + W2VFN400	0.670	0.813	0.761
local + W2VHP300+W2VFN400 (clusters)	0.677	0.825	0.773
local + clusters + polarity	0.675	0.824	0.772
local-token + clusters	0.677	0.826	0.774
local-token + clusters + polarity	**0.678**	**0.827**	**0.775**

Table 3: 5-fold cross validation for the second round of results on the *byarticle* training set. W2VHP300: Word2vec Hyperpartisan bypublisher 300 clusters; W2VFN400: Word2vec Fake News 400 clusters.

Features	Accuracy	P	R	F1
local	0.707	**0.768**	0.592	0.669
local + W2VHP300+W2VFN400 (clusters)	0.754	0.719	0.834	0.772
local + clusters + polarity	0.754	0.717	**0.840**	**0.774**
local-token + clusters	0.756	0.731	0.808	0.768
local-token + clusters + polarity	**0.761**	0.734	0.818	0.774

Table 4: Second round results. W2VHP300: Word2vec Hyperpartisan bypublisher 300 clusters; W2VFN400: Word2vec Fake News 400 clusters.

on the *byarticle* training set in order to choose the best models for testing.

Furthermore, Table 3 reports the results of three additional experiments: (1) adding three polarity lexicons to the *local* + *clusters* model; (2) removing the current token feature from the *local* feature set (*local-token* + *clusters*) and, (3) adding the three polarity lexicons to experiment (2). The motivation of removing the current token feature was to see if that helped the system to generalize better over unseen words. The features based on polarity add a polarity value (positive or negative) if a word in training or testing gets matched in one of the three polarity lexicons used. More specifically, we used three different lexicons (Hu and Liu, 2004; Riloff and Wiebe, 2003; Mohammad et al., 2009), resulting in three different features for each token. As in the previous section, in this phase we realized that our system consistently performs much better, for every experiment, for the "false" class. Experimenting with a balanced training set is left for future work.

As we expected, using domain-specific clustering-based word representations substantially improved the recall results, which in turn led to substantial improvements in terms of accuracy and F1 score. This improvements are reflected also on the evaluation on the test data hidden in TIRA. Thus, Table 4 reports considerable gains obtained by using clustering features in terms of recall with respect to the model based on local features only. The final reported score is 0.761 in accuracy, still lower than the top score in the task (0.822), but a significant result obtained by the simple method of providing better word representations (closer to the task domain) based on clustering. The improvements of this second round of experiments are larger in terms of F1 score, which goes up to 0.774, closer to the winner's F1 score of 0.809.

Most importantly, our experiments show that our system, even though generic, simple and lacking task-specific features, allows to easily obtain competitive results for a document classification task such as hyperpartisan news detection.

5 Concluding Remarks

This paper describes our first experiments on the Hyperpartisan News Detection task organized at SemEval 2019 (Kiesel et al., 2019). We aim to improve our work in the task by using other techniques such as denser word representations based on continuous vectors (word embeddings) and deep learning architectures for document classification. We would also like to investigate the relation with other tasks such as Stance Detection (Mohammad et al., 2016) and automatic detection of fake news (Pérez-Rosas et al., 2018). The system and models can be found in `https://github.com/ixa-ehu/ixa-pipe-doc`.

Duluth at SemEval-2019 Task 4: The Pioquinto Manterola Hyperpartisan News Detector

Saptarshi Sengupta and **Ted Pedersen**
Department of Computer Science
University of Minnesota
Duluth, MN 55812, USA
{sengu059,tpederse}@d.umn.edu

Abstract

This paper describes the Pioquinto Manterola Hyperpartisan News Detector, which participated in SemEval–2019 Task 4. Hyperpartisan news is highly polarized and takes a very biased or one–sided view of a particular story. We developed two variants of our system, the more successful was a Logistic Regression classifier based on unigram features. This was our official entry in the task, and it placed 23rd of 42 participating teams. Our second variant was a Convolutional Neural Network that did not perform as well.

1 Introduction

Social media has become a vital source of news for many people. It makes it possible to share useful information widely and in a timely fashion, and yet can also be misused to spread biased, misleading, or dangerous content.

Hyperpartisan news is a particular worry in that it is premised on absolute allegiance to one particular point of view, and seeks to reinforce potentially misinformed opinions held by its readers. This has led to very real consequences in this world. A tragic example can be found in Myanmar, where Buddhist ultranationalists relied on social media to spread hyperpartisan and fake news in order to promote hatred and violence against different Muslim communities (Fink, 2018).

While related, Hyperpartisan news is not the same as fake news. The former shows a high degree of bias, whereas the latter is more so an outright fabrication. However, the techniques applied to detecting both are similar. For example, Pérez-Rosas et al. (2018) detected fake news by training Support Vector Machines using ngrams, punctuation, and measures of readability. (Tacchini et al., 2017) used *likes* of articles as features for building a Logistic Regression classifier for fake news detection. Potthast et al. (2018) identified hyperpartisan news through the use of style and readability features, and also employed a technique known as *unmasking* (Koppel et al., 2007) to distinguish between hyperpartisan and mainstream news.

2 Task Description

SemEval–2019 Task 4 (Kiesel et al., 2019) challenged participants to detect whether an article is hyperpartisan (H) or mainsteam (M). As such it represents a binary classification task. The task organizers provided training data, and so we elected to take a supervised learning approach.

There were two datasets provided by the organizers (Kiesel et al., 2018). The *by-article* data is a smaller corpus of 645 news articles that have been manually assigned to H (238 articles) or M (407 articles). There was also the much larger *by-publisher* data set with 750,000 articles where classifications were made based on the source of an article. Making classifications in this way is possible since certain publishers are known to be providers of hyperpartisan content. For our experiments we elected to use the by-article data, but plan to investigate the potential of the by-publisher data in future work.

3 Methodology

We created two systems for the task.[1] The first was a Logistic Regression (LR) classifier trained on unigram features, and the second a Convolutional Neural Network (CNN) with word embeddings created from the training data.

During the development phase of our systems we carried out 10-fold cross validation on the *by-article* training data in order to tune both our LR and CNN systems.

[1] https://github.com/saptarshi059/SemEval2k19-Task4-UMD

3.1 Logistic Regression

Logistic Regression (LR) is a widely used method for supervised learning. Each feature is assigned a positive or negative weight which indicates the contribution of that feature to the overall classification of the system. We carried out our experiments using *scikit-learn* (Pedregosa et al., 2011), a Machine Learning toolkit for Python.

Our first step was to preprocess the text. This consisted of converting all text to lowercase, and removing stopwords and non-alphanumeric characters.

Next, a word by article matrix was generated for the training data. For our purposes words are defined as space separated strings. Any word that occurred less than 12 times in the training data was removed and not considered a feature. We arrived at this cutoff via our cross validation experiments, where this value led to the most accurate results (although other nearby values were nearly as accurate).

Our LR model was trained using the default settings for scikit-learn. We relied on the default *liblinear* algorithm (Fan et al., 2008) to optimize the loss function, since it is known to be effective with smaller amounts of training. data[2]

3.2 Convolutional Neural Network

Our initial focus was on our LR approach. However, the task allowed for two entries per team, and so we decided to include a CNN given its history of success in text classification tasks (e.g., (Liu and Wu, 2018)). We used *keras* (Chollet et al., 2015), a Python toolkit for Deep Learning that provides a wrapper around TensorFlow.

Our CNN approach was also based on unigrams, although each unigram was represented by an embedding created from the training data. We started with an existing CNN for text classification[3] and made a few adjustments to some of the hyperparameters. The maximum input vector size was set to 10,000, our embeddings were of length 100, and we trained our model for 100 epochs. We used *Adam* to optimize the loss function and a *GlobalMaxPooling1D* layer to reduce the size of the input feature vectors.

We did not experiment with these hyperparameters extensively, but instead relied on what we found to be fairly common settings and defaults provided by *keras*.

[3]https://realpython.com/python-keras-text-classification/

Model	**Accuracy**	**P**	**R**	**F1**
LR	0.70	0.74	0.63	0.68
CNN	0.58	0.87	0.18	0.30

Table 1: Final Evaluation Results.

4 Experimental Results

The formal task evaluation was carried on virtual systems provided by the organizers using the TIRA system (Potthast et al., 2019). We trained both our LR and CNN on the entire by-article training corpus and saved the resulting models to disk (so they could be ported over to the evaluation system).

We decided to use LR and CNN as our two entries to the task, since during our development phase they had very similar results on 10-fold cross validation : LR accuracy was 0.77 ± 0.06 while CNN was at 0.75 ± 0.05.

However, on the official evaluation run (using a held out set of test data the systems had never seen), the CNN performed poorly and only attained accuracy of 0.58. LR on the other hand reached accuracy of 0.70 and so was selected by the organizers as our official entry to the task. Other evaluation metrics including Precision (P), Recall (R), and F1 are shown in Table 1.

The confusion matrix for our LR system is shown in Table 2 and for the CNN system in Table 3. In these matrices the distribution of correct or gold standard answers are shown in the columns (with sums 314) and the system predictions are shown across in the rows. While the evaluation phase test data is balanced between the classes H and M, the by-article training data was not (238 H versus 407 M).

Table 2 shows that LR predicted a somewhat more balanced distribution of classes (266 H vs. 362 M), which is reflected in the relatively similar Precision and Recall scores found in Table 1. However, Table 3 shows that the CNN produced a much more skewed result (67 H vs. 561 M) which led to very high Precision for the CNN (0.87) while the Recall was extremely low (0.18).

We hypothesize that the difference between the distribution of classes in the training versus evaluation data at least partially explains this result. Given more examples of mainstream news (M),

	H	M	
H	197	69	266
M	117	245	362
	314	314	628

Table 2: LR Confusion Matrix.

	H	M	
H	58	9	67
M	256	305	561
	314	314	628

Table 3: CNN Confusion Matrix.

both models learned this class more thoroughly and so tended to classify articles into this category.

The LR model appears to be more robust in that it performed at approximately the same level of accuracy both during development phase cross validation and the final evaluation round (despite the difference in the distribution of classes).

The CNN on the other hand appears to have been very negatively affected by the shift in the distribution of classes from training to evaluation data, and performed significantly worse on the evaluation data as compared with cross validation on the training set. We are uncertain as to the causes of the CNN result. It is important to note that the by-article data is relatively small and that this may put the CNN at a disadvantage. We also noticed that the accuracy of the CNN on the training data was 1.00 and much lower on the evaluation data, which is a common sign of overfitting.

5 Feature Analysis

An appealing quality of Logistic Regression is that it is somewhat transparent and allows us to see which features are contributing more to classification decisions. Table 4 shows the top 30 features for LR based on the weights learned from the training data. Positive weights are associated with the hyperpartisan (H) class, and negative weights indicate the mainstream (M) class. We've put the words with negative weights in upper case to improve readability, however remember in our data that all text was lower cased.

While the highly weighted individual features are of interest, it is important to remember that Logistic Regression performs classification based on the combined weight of all the features present in an article. As a result a single highly weighted feature for one class may be overridden by the presence of multiple lesser weighted values for the other class.

Table 4: Top 30 LR features : positive weights associated with H, negative with M.

The data for this task consists of articles from 2016 – 2018, starting around the time of the 2016 US presidential election, where Donald Trump defeated Hillary Clinton after a bitterly contested campaign.

In general the top features contain many terms associated with elections or political figures. We note a few more person names among the top 30 features for the H class (5) versus the M class (3). These features are in bold face in Table 4. It is significant to note that one of the person names that appears as a hyperpartisan feature is Hitler, suggesting that he may have been used as a basis for comparison in such articles. The name Arpaio refers to a controversial sheriff in Arizona who ran for re-election in 2016 (and was defeated). Maria is Hurricane Maria, which devastated Puerto Rico in September 2017. The recovery from this natural disaster became a political issue and so its use as a feature in hyperpartisan news seems likely.

The mainstream features (in upper case) include Donald and Twitter. Candidate (and now President) Trump is well known as an enthusiastic Twitter user, so these features would certainly occur in mainstream news coverage. Jesse Watters is a Fox News reporter who hosts a person on the street style interview program which drew some news coverage. Jeff Sessions was an early supporter of Donald Trump and became Attorney General after the election and so was often in the news.

6 Error Analysis

We divided the by-article training data into a set of 585 training examples and 60 test instances (30 from each class). We used this data to train and evaluate our LR classifier. We categorized our results as True Positive (H classified as H), True Negative (M classified as M), False Positive (M classified as H), and False Negative (H classified as M). Below we discuss an article from each category, where each is identified via (by-article id number, word count).

True Positive (1, 259): This article takes a mocking and sarcastic tone regarding President Trump's campaign promises to fix infrastructure. It points out that Hurricane Maria (H feature) did extensive damage but that Trump was indifferent because Puerto Rico did not vote for him. This is an obvious example of hyperpartisan news.

True Negative (14, 225): Ivana Trump, Donald's ex-wife, talks about his punctuality in his personal and professional life. The article is very matter of fact and simply describes her observations without embellishment or bias, and is pretty clearly mainstream.

False Positive (4, 929): This is a very long article that was classified as H despite not having any obvious signs of bias. Rather it compares the unsettled state of America now with the very turbulent year of 1968. However, the article uses many rare and emotional words such as *nihilism*, *malady*, and *hysteria* which may have caused it to be classified as hyperpartisan.

False Negative (2, 189): This is a highly opinionated response to Joyce Newman's (Democrat) stance on gun control. It is a very emotional piece, however, it also provides facts and figures to bolster the position of the author. We believe it is the latter which caused the LR to (incorrectly) classify it as mainstream.

We also noticed that the 30 H articles in our test data had on average much larger word counts (1,178.9) versus the 30 M articles (503.4). (Potthast et al., 2018) used average paragraph length as a feature when detecting H news, and this seems like it would have been a useful feature in this task as well.

7 Future Work

There are numerous possible directions for future work. We are interested in exploring the use of the much larger by-publisher training data. This could be of particular assistance in improving the results from CNNs. We also plan to revisit our preprocessing steps and perform named entity recognition since proper nouns represent important information for this problem.

We would also like to explore variations in our feature sets for LR. In our current experiments we do not have any requirement that a feature occur in a certain minimum number of articles (in addition to occurring at least 12 times). As a result we noticed several features that occurred many times in just a few articles were strongly weighted and yet would be unlikely to generalize well. We would also like to explore the use of *TF-IDF* in place of simple frequency counts for feature selection.

Finally, our error analysis suggested that hyperpartisan news tends to use emotional language as well as unusual or rare words. Given this we are interested in the possibilities offered by sentiment analysis, as well as the inclusion of structural and style features.

8 Namesake

Pioquinto Manterola is a fictional journalist created by Paco Ignacio Taibo II. He is a central character in *The Shadow of a Shadow* (Ignacio Taibo II, 1991) and *Returning as Shadows* (Ignacio Taibo II, 2003). These novels are set in Mexico City, the first in 1922 and the second in 1941-1942. In both stories Manterola is teamed with a poet to investigate mysterious circumstances that lead to uncovering even more complex and sinister wrongdoing. As such he seemed an appropriate namesake for our team in this task.

Abstract

This paper describes our system (Fermi) for Task 4: Hyper-partisan News detection of SemEval-2019. We use simple text classification algorithms by transforming the input features to a reduced feature set. We aim to find the right number of features useful for efficient classification and explore multiple training models to evaluate the performance of these text classification algorithms. Our team - **Fermi**'s model achieved an accuracy of 59.10% and an F1 score of 69.5% on the official test data set.

In this paper, we provide a detailed description of the approach as well as the results obtained in the task.

1 Introduction

Hyper-partisan refers to a person or a group's tendency to be extremely partisan or biased towards a person or a group and specifically towards a political person or a political party. With the tremendous increase in citizen-based journalism, where anyone can create a website and post his (biased) views, there is a new phenomenon called fake news and it's potential role in affecting the election results, and has the ability to modify and impact the public's perception towards various people, companies and political parties. These kind of 'news' are usually one-sided, inflammatory, emotional and mostly woven around untruths. Combined with the proliferation of social media platforms, these 'fake news' signals get amplified and may potentially mask the signal of the real news. The fake news phenomenon hype has caused irreparable loss to many politicians, companies and in some cases involved the death of fellow citizens.

While Social media platforms can be used for constructive ideas, a small group of people can propagate their notions including hatred or affinity towards or against an individual, or a group or a race to the entire world in a few seconds. This necessitates the need to come up with computational methods to identify hyper-partisan news in user generated content.

Using computational methods to identify hyper-partisan news has been gaining attention in recent years as evidenced in (Potthast et al., 2018).

2 Related Work

In this section, we briefly describe other work in this area.

Hyper-partisan news detection is a new area and to the best of the knowledge of the authors, not much work has been done in this area. However, a close and related task is that of fake news detection. (Pérez-Rosas et al., 2017) use linguistic features to distinguish between fake and legitimate news content. (Wang, 2017) collect a decade long manually labelled sor statements in various context from a political fact checking website and create fake news classifiers using surface level linguistic patterns. (Tschiatschek et al., 2018) leverage crowd signals for detecting fake news. (Long et al., 2017) tackles the problem of fake news through multi-perspective speaker profiles.

Papers published in the last two years include the surveys by (Zhou and Zafarani, 2018), (Zhou et al., 2019) and (Shu et al., 2017), the paper by (Kumar and Shah, 2018).

A shared task on Hyper-partisan News detection(Kiesel et al., 2019) was announced as part of the annual workshop SemEval 2019. The task was to find if the given news article text and classify if it follows a hyper-partisan argumentation, i.e., whether it exhibits blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person.

3 Methodology and Data

The data collection methods used to compile the data set in Hyperpartisan news detection is described in (Kiesel et al., 2019). We tackle the problem of identifying a piece of news as hyperpartisan or not by formulating it as a text classification problem. We use bag of words representation to transform the individual documents into vectors. After the transformation, we reduce the number of dimensions by using chi-square feature selection technique. In this method, the chi-square statistics between every feature variable and the target variable are computed, and then the existence of a relationship between the variables and the target is calculated. If the target variable is independent of the feature variable, that feature variable is not useful for prediction. If the two are dependent, then that feature variable is very important. In text classification, the feature selection is the process of selecting a specific subset of the terms of the training set and using only them in the classification algorithm. The feature selection process takes place before the training of the classifier. We use Random Forest Classifier from scikit-learn[1] machine learning library to generate models on these reduced features. The number of estimators in all the experiments is 20. All other parameters are default.

Our results on the different number of important features have been mentioned and described in the results section.

We haven't used any external datasets to augment the data for training our models.

No of features	F1 (macro)	Accuracy
200	0.39	0.51
400	0.40	0.51
600	0.42	0.51
800	0.44	0.52
1000	**0.46**	**0.52**

Table 1: *Dev* set Accuracy and Macro-F1 scores on labels by publisher dataset.

Dataset	F1 (macro)	Accuracy
Labels-by-article	0.69	0.59
Labels-by-publisher	0.66	0.61

Table 2: *Test set* Accuracy and Macro-F1 scores.

[1]https://scikit-learn.org/

4 Results and Analysis

Table 2 shows the dev set macro-averaged F-1 and accuracy for different number of important features.

We notice that the best performance was bagged by the model which uses 1000 features with Random Forest. We submitted this best model for evaluation on the test data and Table 4 shows the results.

The potential applications of this work show how different number of important features affect the performance of the classification task.

5 Future Work

Due to some constraints on the TIRA[2] platform, we were unable to use state-of-the-art deep learning techniques for text classification, which gained immense popularity in the past few years. In the future, we would like to explore transfer learning and deep learning algorithms to create models for and evaluate their performance for this task.

Abstract

We use various natural processing and machine learning methods to perform the Hyperpartisan News Detection task. In particular, some of the features we look at are bag-of-words features , the title's length, number of capitalized words in the title, and the sentiment of the sentences and the title. By adding these features, we see improvements in our evaluation metrics compared to the baseline values. We find that sentiment analysis helps improve our evaluation metrics. We do not see a benefit from feature selection. Overall, our system achieves an accuracy of 0.739, finishing 18th out of 42 submissions to the task. From our work, it is evident that both title features and sentiment of articles are meaningful to the hyperpartisanship of news articles.

1 Introduction

In 2019, Task 4 of the SemEval Workshop asked participants to automatically identify hyperpartisan texts (Kiesel et al., 2019). Hyperpartisan news detection is the problem of building a classifier using natural language processing techniques in order to label news articles as either hyperpartisan or neutral in content bias. Hyperpartisan articles, in this case, can be defined as articles which are very polarized and extremely biased towards one political party. This task is quite relevant in today's political climate, with reports of "fake news" articles heavily influencing votes and people's support of some candidates running for government offices. The issue is especially egregious because these biased news articles are informing political opinions of people who believe them to be factual and impartial, with no easy way to remove or detect hyperpartisan news articles. This is also a non-trivial task, as hyperpartisan news is not extremely explicit in its bias, and even human readers do not always agree on which articles should be classified as hyperpartisan or what about those articles merits such a classification. There is no one unifying feature of hyperpartisan news, and even news publishers which do produce hyperpartisan news are not guaranteed to *only* publish hyperpartisan news. Therefore, each article must be evaluated for its degree of hyperpartisanship, along many different axes of measurements.

A functional and accurate hyperpartisan news detector would be useful for social media sites and other carriers of news to make sure that their news content is unbiased, and to be able to detect and perhaps remove or block sources of hyperpartisan news. Facebook, for example, has been under great public scrutiny due to the quantity and popularity of hyperpartisan news on its site. Hyperpartisan news detection could also be useful for researchers seeking to understand the scope and impact of hyperpartisan news on the 2016 presidential election and how it can continue to inform voters today and in future elections.

2 Previous Work

Hyperpartisan news detection has become a popular application of natural language processing due to its relevance in contemporary politics. Specifically, there has been research to hash out what features are prevalent in hyperpartisan articles. Buzzfeed conducted a manual analysis of nine different pages on Facebook: three that were mainstream news, three that were hyperpartisan left, and three hyperpartisan right (Silverman et al., 2018). They rated every post as mostly false, mixture of true and false, mostly true, or not factual, for posts like memes or jokes. They determined that hyperpartisan articles on both the left and the right side have more in common with each other than with articles in the mainstream, and detecting whether or not an article was hyperpartisan was easier than detecting the actual orientation of the bias (Potthast et al., 2017). Likewise, in our application, we build a hyperpartisan news detector which labels hyperpartisanship but not whether an article is left- or right-leaning.

Fake news, which hyperpartisan sites are more likely to produce, tends to have certain qualities about its titles that make them distinct (Horne and Adali, 2017). These qualities are longer titles, simpler, more readable vocabulary words, and multiple words in the title which are all capitals. We use these qualities to inform our feature extraction of the article title, extracting the length of titles, the average length of title words, and the number of words in all capitals and adding these features to our larger feature matrix.

Polarity indicates how positive or negative a text may be, or the direction of the bias, while subjectivity indicates how strongly the text represents an opinion versus an objective fact, or the magnitude of the bias (Liu, 2010). We hypothesize that hyperpartisan news articles will carry relatively strong observable opinionation in comparison to non-hyperpartisan articles, so we use the two metrics of subjectivity and polarity as an addition to the other features in our feature matrix.

In this vein, one past study used sentiment analysis on the comment sections of articles about the Trayvon Martin case. It determined that more well known commentators tended to have stronger sentiment in their comments (Ignatow et al., 2016), implying that sentiment is a useful metric for analyzing opinions on the World Wide Web. Another study that used sentiment analysis on social media data showed that sentiment analysis was a key technique for extracting features of an opinion, allowing the researchers to propose models for simulating and forecasting online opinions (Kaschesky et al., 2011). This research in particular was interesting, because it covers a similar area of interest as hyperpartisan news detection. That is, it examines the far-reaching effects of political opinions and their proliferation on the World Wide Web, and also uses similar natural language processing techniques to extract information about these opinions. This tells us that sentiment analysis is an important tool for computational analysis of political opinions.

3 Methodology

Our model was trained and tested on the pre-labeled dataset provided by the SemEval group and the basis of our approach was a bag-of-words model. In order to improve upon the bag-of-words model and integrate some known salient features of hyperpartisan news, we also included headline features as well as sentiment analysis scores of the articles.

3.1 Data Set

To train our model, we use training data provided by the SemEval 2019 Hyperpartisan News Detection task organizers (Kiesel et al., 2019). These data come in the form of news articles given in XML format. Each article was given with title and article body text, and had labels provided in a separate file to indicate whether they had been flagged as hyperpartisan.

This data came in two distinct training sets as provided by the task organizers. The larger of the two sets, with about 800,000 labeled articles, was labeled by publisher; that is, publishers were grouped by whether they were known to be hyperpartisan in general, and the corresponding label was applied to all articles by a given publisher. A smaller set, comprising around 650 articles, was entirely hand-labeled; that is, human readers determined on an article-by-article basis whether a given article should be labeled as hyperpartisan.

It should be noted here that the smaller set labels are more true to what is expected of this task. Specifically, it is more of interest to us whether we can detect hyperpartisanship of articles based on how humans would judge it. Though the labeling by publisher is useful for obtaining a larger data set, it introduces some error due to the possibility that hyperpartisan sources may sometimes publish non-hyperpartisan articles and vice versa. Despite the advantages of the hand-labeled data set, its small size makes it much less feasible as a training set, so we also made substantial use of the larger set as we were tuning our model.

The content of each article was pre-processed with the Python library `spaCy` to tokenize and sentence-segment the text (AI, 2016–).

3.2 Feature Extraction

We used a bag-of-words approach to use for our main set of features, using a vocabulary of common English words. Unknown words were ignored. We filtered out 100 stop words, and used a vocabulary of 30,000 words.

We also included features from the titles, as certain qualities about the titles in hyperpartisan articles may be different than mainstream articles. We included the number of words in the title, hypothesizing that long titles can often indicate the article is misleading, or very biased. We included the number of fully capitalized words, which can often indicate that the article is not mainstream. Finally, we added a feature for the average length of the words in the title, as some research shows that hyperpartisan or biased articles tend to use more short, easily understood, words to appeal to the average reader (Horne and Adali, 2017).

We used the Python library TextBlob to do sentiment analysis on the articles and their titles (Loria, 2018). TextBlob has a sentiment analysis tool that provides both the subjectivity and polarity of a given sentence. We found the average subjectivity and average polarity of all the sentences in the article and used it as a feature. We also used the sentiment subjectivity and polarity of the article's title as a feature.

As our vocabulary used for extracting bag-of-words features was quite large, we used the built-in `SelectKBest` feature selection class provided by scikit-learn (Pedregosa et al., 2011) to narrow down the set of features we were using. However, testing with adjusting the parameters for feature selection did not seem to yield better results than simply using all possible features, so our final system made used of all of the available features.

3.3 Classifier

We feed our features to a multinomial naive Bayes (NB) classifier in scikit-learn (Pedregosa et al., 2011). For comparison to a baseline, we also use a majority-class dummy classifier.

4 Results

Table 1 shows the results of training with 10-fold cross-validation for each of our classifiers. As expected, the dummy classifier did not perform well. It represents a majority class baseline, though, and is useful for comparison purposes.

Our evaluation metrics improved with adding sentiment analysis and features of the title. Our final model does better than all of our previous models for every metric, including the dummy classifier, multinomial naive Bayes on BoW features, and adding title features. With an F-measure of 0.800, our precision and recall are well-balanced, and both are around 80%.

On the hand labeled SemEval test set, we achieved an accuracy of 0.739 and an F1 score of 0.745. Overall, our system ranked 18th out of 42 by accuracy, and 11th by F1 measure.

5 Discussion

We can infer from the results of our system that the features we extracted from the text, such as title features and sentiment, were significant and correlated to the hyperpartisanship of articles. This was expected, as the design of our classifier was based on previous work which determined that such features were useful for detecting bias in text. Since we combined different aspects of other studies, we were able to build upon previous findings and gain a more holistic view of hyperpartisan news articles Since this is the first offering of the SemEval Hyperpartisan News Detection task, we see our work as providing a foundation for future groups to build on as they attempt to fine-tune and improve a classifier for this important task.

There are still many questions regarding hyperpartisan news identification that remain unanswered. For example, it would be interesting to incorporate bigrams or trigrams of words instead of just using the bag-of-words approach. We also hypothesize that noun phrase chunks would be indicative of hyperpartisanship due to the ubiquity of certain controversial noun phrases in current media. The temporal nature of these features presents a unique challenge, though,

We could also use sentiment analysis in other ways. For instance, instead of just taking the average subjectivity and average polarity, it might also be interesting to find the percentage of sentences with a absolute value of polarity above a certain threshold. This could indicate an article is hyperpartisan if there are a lot of sentences that are above some threshold for polarity, that is, very opinionated sentences either strongly positive or strongly negative.

It would also be interesting to be able to look into the comment sections of the articles and determine if the sentiment of the comments can indicate hyperpartisanship. It seems probable that hyperpartisan articles would tend to attract more hyperpartisan viewers than mainstream articles would, and these people would have similarly strong opinions and be willing to voice them. The alignment of the comments may not even be aligned with the article, as the article may attract people from the other side, looking to critique or complain about the article. This data was not available for the SemEval task, but polarity and subjectivity also seem

Classifier	Accuracy	Precision	Recall	F-measure
DC: most frequent	0.553	0.553	1.0	0.712
NB (BoW only)	0.552	0.61	0.297	0.401
+title features	0.556	0.615	0.315	0.417
+sentiment features	0.793	0.781	0.820	0.800

like they would be useful metrics to extract from article comments.

In addition to the comments, it would be interesting to analyze how often the articles were shared, viewed, commented on, or in other ways interacted with. As the Buzzfeed study showed, hyperpartisan articles and articles that may not be entirely true tended to get more shares than non-partisan, as these are more interesting and inflammatory, and so this may be another feature that would have helped determine the hyperpartisanship of the article (Silverman et al., 2018).

Trying different classifiers would also be an appropriate next step. We focused on feature selection above experimenting with different classifiers because we believed that feature selection would give more meaningful insights into the nature of hyperpartisan articles than merely optimizing a classifier, but both are likely necessary to successfully identifying hyperpartisan articles.

6 Namesake

Our system is named after Carl Kolchak, the main character from the television series *Kolchak: The Night Stalker*, which aired in 1974-75. On the show, Kolchak investigated mysterious cases that had been abandoned by the police. We believe the unlikely and often unbelievable scenarios encountered by Kolchak would have been likely fodder for fake and hyperpartisan news during its time, and hope that our system will contribute to a community effort to automatically separate truth from fiction (Wikipedia contributors, 2019).

Figure 1: Darren McGavin, who portrayed Carl Kolchak in the TV Series *Kolchak: The Night Stalker* (ClassicBecky, 2011).

Abstract

We investigate the recently developed Bidirectional Encoder Representations from Transformers (BERT) model (Devlin et al., 2018) for the hyperpartisan news detection task. Using a subset of hand-labeled articles from SemEval as a validation set, we test the performance of different parameters for BERT models. We find that accuracy from two different BERT models using different proportions of the articles is consistently high, with our best-performing model on the validation set achieving 85% accuracy and the best-performing model on the test set achieving 77%. We further determined that our model exhibits strong consistency, labeling independent slices of the same article identically. Finally, we find that randomizing the order of word pieces dramatically reduces validation accuracy (to approximately 60%), but that shuffling groups of four or more word pieces maintains an accuracy of about 80%, indicating the model mainly gains value from local context.

1 Introduction

SemEval Task 4 (Kiesel et al., 2019) tasked participating teams with identifying news articles that are misleading to their readers, a phenomenon often associated with "fake news" distributed by partisan sources (Potthast et al., 2017).

We approach the problem through transfer learning to fine-tune a model for the document classification task. We use the BERT model based on the implementation of the github repository *pytorch-pretrained-bert*[1] on some of the data provided by Task 4 of SemEval. BERT has been used to learn useful representations for a variety of natural language tasks, achieving state of the art performance in these tasks after being fine-tuned (Devlin et al., 2018). It is a language representation model that is designed to pre-train deep bidirectional representations by jointly conditioning on both left and right context in all layers. Thus, it may be able to adequately account for complex characteristics as such blind, prejudiced reasoning and extreme bias that are important to reliably identifying hyperpartisanship in articles.

We show that BERT performs well on hyperpartisan sentiment classification. We use unsupervised learning on the set of 600,000 source-labeled articles provided as part of the task, then train using supervised learning for the 645 hand-labeled articles. We believe that learning on source-labeled articles would bias our model to learn the partisanship of a source, instead of the article. Additionally, the accuracy of the model on validation data labeled by article differs heavily when the articles are labeled by publisher. Thus, we decided to use a small subset of the hand-labeled articles as our validation set for all of our experiments. As the articles are too large for the model to be trained on the full text each time, we consider the number of word-pieces that the model uses from each article a hyperparameter.

A second major issue we explore is what information the model is using to make decisions. This is particularly important for BERT because neural models are often viewed like black boxes. This view is problematic for a task like hyperpartisan news detection where users may reasonably want explanations as to why an article was flagged. We specifically explore how much of the article is needed by the model, how consistent the model behaves on an article, and whether the model focuses on individual words and phrases or if it uses more global understanding. We find that the model only needs a short amount of context (100 word pieces), is very consistent throughout an article, and most of the model's accuracy arises from locally examining the article.

In this paper, we demonstrate the effectiveness

[1] https://github.com/huggingface/pytorch-pretrained-BERT

of BERT models for the hyperpartisan news classification task, with validation accuracy as high as 85% and test accuracy as high as 77% [2]. We also make significant investigations into the importance of different factors relating to the articles and training in BERT's success. The remainder of this paper is organized as follows. Section 2 describes previous work on the BERT model and semi-supervised learning. Section 3 outlines our model, data, and experiments. Our results are presented in Section 4, with their ramifications discussed in Section 5. We close with an introduction to our system's namesake, fictional journalist Clint Buchanan, in Section 6.

2 Related Work

We build upon the Bidirectional Encoder Representations from Transformers (BERT) model. BERT is a deep bidirectional transformer that has been successfully tuned to a variety of tasks (Devlin et al., 2018). BERT functions as a language model over character sequences, with tokenization as described by Sennrich et al. (2016). The transformer architecture (Vaswani et al., 2017) is based upon relying on self-attention layers to encode a sequence. To allow the language model to be trained in a bidirectional manner instead of predicting tokens autoregressively, BERT was pretrained to fill in the blanks for a piece of text, also known as the Cloze task (Taylor, 1953).

Due to the small size of our training data, it was necessary to explore techniques from semi-supervised learning. Dai and Le (2015) found pre-training a model as a language model on a larger corpus to be beneficial for a variety of experiments. We also investigated the use of self-training (Zhu, 2005) to increase our effective training dataset size. Lastly, the motivation of examining the effective context of our classification model was based on Brendel and Bethge (2019). It was found that much higher performance than expected was achieved on the ImageNet dataset (Li Fei-Fei et al., 2009) by aggregating predictions from local patches. This revealed that typical ImageNet models could acquire most of their performance from local decisions.

3 Methodology

Next, we describe the variations of the BERT model used in our experiments, the data we used, and details of the setup of each of our experiments.

3.1 Model

We adjust the standard BERT model for the hyperpartisan news task, evaluating its performance both on a validation set we construct and on the test set provided by Task 4 at SemEval. The training of the model follows the methodology of the original BERT paper.

We choose to experiment with the use of the two different pre-trained versions of the BERT model, *BERT-LARGE* and *BERT-BASE*. The two differ in the number of layers and hidden sizes in the underlying model. *BERT-BASE* consists of 12 layers and 110 million parameters, while *BERT-LARGE* consists of 24 layers and 340 million parameters.

3.2 Training and Test Sets

We focus primarily on the smaller data set of 645 hand-labeled articles provided to task participants, both for training and for validation. We take the first 80% of this data set for our training set and the last 20% for the validation set. Since the test set is also hand-labeled we found that the 645 articles are much more representative of the final test set than the articles labeled by publisher. The model's performance on articles labeled by publisher was not much above chance level.

Due to an intrinsic limitation of the BERT model, we are unable to consider sequences of longer than 512 word pieces for classification problems. These word pieces refer to the byte-pair encoding that BERT relies on for tokenization. These can be actual words, but less common words may be split into subword pieces (Sennrich et al., 2016). The longest article in the training set contains around 6500 word pieces. To accommodate this model limitation, we work with truncated versions of the articles.

We use the additional $600,000$ training articles labeled by publisher as an unsupervised data set to further train the BERT model.

3.3 Experiments

We first investigate the impact of pre-training on *BERT-BASE*'s performance. We then compare the performance of *BERT-BASE* with *BERT-LARGE*. For both, we vary the number of word-pieces from each article that are used in training. We perform tests with 100, 250 and 500 word pieces.

We also explore whether and how the BERT models we use classify different parts of each individual article. Since the model can only consider a limited number of word pieces and not a full article, we test how the model judges different sections of the same article. Here, we are interested in the extent to which the same class will be assigned to each segment of an article. Finally, we test whether the model's behavior varies if we randomly shuffle word-pieces from the articles during training. Our goal in this experiment is to understand whether the model focuses on individual words and phrases or if it achieves more global understanding. We alter the the size of the chunks to be shuffled (N) in each iteration of this experiment, from shuffling individual word-pieces ($N = 1$) to shuffling larger multiword chunks.

4 Results

Our results are primarily based on a validation set we constructed using the last 20% of the hand-labeled articles. It is important to note that our validation set was fairly unbalanced. About 72% of articles were not hyperpartisan and this mainly arose because we were not provided with a balanced set of hand-labeled articles. The small validation split ended up increasing the imbalance in exchange for training on a more balanced set. The test accuracies we report were done on SemEval Task 4's balanced test dataset.

4.1 Importance of Pre-training

Our first experiment was checking the importance of pre-training. We pre-trained BERT-base on the 600,000 articles without labels by using the same Cloze task (Taylor, 1953) that BERT had originally used for pre-training. We then trained the model on sequence lengths of 100, 250 and 500. The accuracy for each sequence length after 100 epochs is shown in 1 and is labeled as UP (unsupervised pre-training). The other column shows how well *BERT-base* trained without pre-training. We found improvements for lower sequence lengths, but not at 500 word pieces. Since the longer chunk should have been more informative, and since our hand-labeled training set only contained 516 articles, this likely indicates that BERT experiences training difficulty when dealing with long sequences on such a small dataset. As the cost to do pre-training was only a one time cost all of our remaining experiments use a pre-trained model.

Max Seq Len	BERT-base	BERT-base + UP
100	76.7	79.8
250	75.9	82.9
500	79.1	75.2

Table 1: Validation accuracy for BERT-base with and without Unsupervised Pre-training (UP).

We evaluated this model on the *SemEval 2019 Task 4: Hyperpartisan News Detection* competition's **pan19-hyperpartisan-news-detection-by-article-test-dataset-2018-12-07** dataset using TIRA (Potthast et al., 2019). Our model, with a maximium sequence length of 250, had an accuracy of 77%. It had higher precision (83.2%) than recall (67.8%), for an overall F1-score of 0.747.

4.2 Importance of Sequence Length

Next, we further explore the impact of sequence length using *BERT-LARGE*. The model took approximately 3 days to pre-train when using 4 NVIDIA GeForce GTX 1080 Ti. On the same computer, fine tuning the model on the small training set took only about 35 minutes for sequence length 100. The model's training time scaled roughly linearly with sequence length. We did a grid search on sequence length and learning rate.

Table 2 shows that the model consistently performed best at a sequence length of 100. This is a discrepancy from *BERT-BASE* indicating that the larger model struggled more with training on a small amount of long sequences. For our best trained *BERT-LARGE*, we submitted the model for evaluation on TIRA. Surprisingly, the test performance (75.1%) of the larger model was worse than the base model. The experiments in (Devlin et al., 2018) consistently found improvements when using the large model. The main distinction here is a smaller training dataset than in their tasks. The experiments in the remaining sections use the same hyperparameters as the optimal *BERT-LARGE*.

4.3 Model Consistency

Due to the small training dataset, we tried self-training to increase our effective training set. We trained the model for 40 epochs. For the remaining 60 epochs, after each epoch we had the model make predictions on five slices of 500 unlabeled

Max Seq Len \ Learning Rate	5e-7	1e-6	1.5e-6	2e-6	2.5e-6	3e-6
50	78.3	80.6	79.8	79.1	79.1	77.5
100	83.7	83.7	86.1	86.1	85.3	84.5
150	77.5	79.8	81.4	80.6	79.8	79.8
200	81.4	80.6	79.8	84.5	83	81.4

Table 2: Validation Accuracy on *BERT-LARGE* across sequence length and learning rate.

articles. If an article had the same prediction for more than four slices, we added it to the labeled training data. The model always added every article to the training set, though, since it always made the same prediction for all 5 slices. This caused self-training to be ineffective, but also revealed that the model's predictions were very consistent across segments of a single article.[3]

4.4 Effective Model Context

Finally, we investigate whether the model's accuracy primarily arose from examining words or short phrases, or if the decisions were more global. We permuted the word pieces in the article at various levels of granularity. At the finest level (permute_ngrams = 1), we permuted every single word piece, forcing the model to process a bag of word pieces. At coarser levels, ngrams were permuted. As the sequence length for these experiments was 100, permute_ngrams = 100 corresponds to no permutation. The results can be found in 3.

permute_ngrams	Validation Accuracy
1	67.4
2	62.8
3	75.2
4	83.0
5	76.0
10	82.2
20	76.7
50	79.8
100	84.5

Table 3: *BERT-LARGE* across permute_ngrams.

Accuracy drops a lot with only a bag of word pieces, but still reaches 67.4%. Also, most of the accuracy of the model (within 2%) is achieved with only 4-grams of word pieces, so the model is not getting much of a boost from global content.

[3]We also tried training a model that averaged its predictions across multiple slices. This turned out to be slightly worse, likely due to the model's high consistency.

5 Discussion

Our successful results demonstrate the adaptability of the BERT model to different tasks. With a relatively small training set of articles, we were able to train models with high accuracy on both the validation set and the test set.

Our models classified different parts of a given article identically, demonstrating that the overall hyperpartisan aspects were similar across an article. In addition, the model had significantly lower accuracy when word pieces were shuffled around, but that accuracy was almost entirely restored when shuffling around chunks of four or more word pieces, suggesting that most of the important features can already be extracted at this level.

In future work, we we would like to make use of the entire article. Naively, running this over each chunk would be computationally infeasible, so it may be worth doing a full pass on a few chunks and cheaper computations on other chunks.

6 Namesake

Figure 1: Jerry verDorn as Clint Buchanan.

Our system is named after Clint Buchanan[4], a fictional journalist on the soap opera *One Life to Live*. Following the unbelievable stories of Clint and his associates may be one of the few tasks *more* difficult than identifying hyperpartisan news.

Abstract

We use the 600 hand-labelled articles from SemEval Task 4 (Kiesel et al., 2019) to hand-tune a classifier with 3000 features for the Hyperpartisan News Detection task. Our final system uses features based on bag-of-words (BoW), analysis of the article title, language complexity, and simple sentiment analysis in a naive Bayes classifier. We trained our final system on the 600,000 articles labelled by publisher. Our final system has an accuracy of 0.653 on the hand-labeled test set. The most effective features are the Automated Readability Index and the presence of certain words in the title. This suggests that hyperpartisan writing uses a distinct writing style, especially in the title.

1 Introduction

Hyperpartisan news is becoming more mainstream as online sources gain popularity. Hyperpartisan news is news written from an extremely partisan perspective, such that the goal is reinforcing existing belief structures in the party's ideology rather than conveying facts. Such hyperpartisan writing tends to amplify political divisions and increase animosity between opposing political ideologies. Hyperpartisan news sources also output fake news at startling rates (Silverman et al., 2016). Automatic detection of fake news is difficult, but detecting hyperpartisan news can help, and it can also expose biases in journalism. This task is challenging to automate because it is even difficult for humans: fake and biased news articles get shared on social media at high rates, and even labels that were hand-generated by professionals have errors (Silverman et al., 2016). We attempt to use various features of political news articles to train a multinomial Naive Bayes classifier to complete this task. We use a set of bag-of-words (BoW) features for words appearing in the title of each article, and for words appearing in the article text. With these features, we identified a set of words that characterize hyperpartisan writing. We also considered complexity features such as type-to-token ratio and automated readability index. Based on the performance of these features we attempt to answer the question of whether hyperpartisan writing is more or less complex than non-hyperpartisan writing. A successful classifier could be very useful in today's society. For example, it could be used to create a browser plug-in to check online articles for political bias in real time as the user reads. People on social media could use it to verify the legitimacy of a political article before sharing it with their followers. Encouraging people to share factual news rather than inflammatory hyperpartisan articles would hopefully improve communication between opposing parties and create a more informed population.

The rest of this paper begins with a description of previous work on the related task of fake news detection in Section 2. We then describe our model and features in Section 3, and our results in Section 4. Section 5 discusses some lessons learned with respect to what features are most useful in identifying hyperpartisan news, and Section 6 closes with a brief description of our system's namesake, fictional magazine editor D.X. Beaumont.

2 Previous Work

Since the 2016 election, there has been a lot of interest in fake news, which is closely related to the hyperpartisan news we focus on. Our approach to the hyperpartisan news task leverages lessons learned in prior work on fake news detection, and explores the extent to which that work is successful in a different but related task. Fake news detection has been widely studied (e.g., the survey paper by Fuhr et al. (Fuhr et al., 2018)), and we base many of our classifier's features on previous studies of fake news.

The content of fake and real news articles differ substantially. Fake news articles have been found to require a lower reading level than real news articles, to be less technical, and to use more personal pronouns. Further, their titles tend to be longer, use more proper nouns, and use more words that are all capitalized (Horne and Adali, 2017). Our work differs in that we were trying to determine whether an article is hyperpartisan, which is similar to but not the same as identifying fake news articles. In particular, a hyperpartisan news article may be factually correct (i.e., not contain any mistruths) but still be written with a hyperpartisan slant. We hypothesize, nonetheless, that the stylistic features that distinguish between real and fake news may be useful in identifying hyperpartisan news articles. Potthast, et. al., also showed that there are significant stylistic differences between hyperpartisan and mainstream news articles (Potthast et al., 2017). Consequently, we include reading level and features of each article's title as features in our model.

The success of these features on identifying fake news motivates our decision to focus on article titles as a differentiating feature, and to include reading level in the set of features available to our model.

Perez-Rosa et al. also examine fake news articles to create a classifier for them (Prez-Rosas et al., 2018). Their results identify additional features related to text readability, with fake news articles tending to be written at a lower reading level than real news articles. We incorporate features from their work, including *Average Word Length*, *Type-Token-Ratio*, and *SMOG Readability Formula* .

3 Methodology

Each article's content and title was tokenized using `spacy`'s default English model (AI, 2016–).

We use a multinomial naive Bayes classifier from `scikit-learn`, extracting a large number of features and then using feature selection to reduce the number of features available to our classifier.

3.1 Features

We make use of features related to the words in the article as a whole, the title of the article, sentiment, and text complexity.

Bag of Words Features: Using a vocabulary of 30,000 words, we count the number of times each vocabulary word occurs in the full article text. We then drop a fixed number stop words, selected automatically by frequency. We experimented with both 50 and 100 stop words, and the run of our system that was submitted to the SemEval task used 50 stop words.

Title Bag of Words: Next, using the same vocabulary but without excluding stop words, we add word counts for the title of the article. We also count the number of words in the title that are entirely capitalized, generally a feature of hyperpartisan titles (Horne and Adali, 2017).

Sentiment Analyzer: We use two sentiment lexicons (Hu and Liu, 2004). The first contains 2000 words with positive sentiment, and the second contains 4000 words with negative sentiment. We count the occurrence of words from each list, hypothesizing that hyperpartisan articles will likely have many more words with polarized sentiment than non-hyperpartisan articles.

Complexity Features: Finally, we include features designed to capture the articles' complexity. This category includes features such as *Average Word Length*, *Type-Token-Ratio*, and *SMOG Readability Formula*. Each of these is designed to capture the complexity of a given text; *Average Word Length* gives us insights into the vocab choices and uses of ”advanced” words, *Type-Token-Ratio* measures the amount of ”novel” words in the text, the *SMOG Readability Formula* is based on the number of polysyllabic words per sentence (which is influenced both by vocabulary choice, and sentence length). Since prior work shows that hyper-partisan articles are often written at an easier reading level, with more repeating words, and simpler sentence structure, we expect that these complexity features will be useful in identifying hyperpartisan articles.

3.2 Feature Selection

The above feature space was very large compared to the number of available articles, so we implemented two different methods of feature selection: one using variance, and one using a χ^2 test. In each case, we perform statistics on the training set, attempting to describe which features are the most *distinguishing*. Given these statistics, we score each feature, and select a subset of the total feature set using either a threshold score or a target feature count. By experimenting on the smaller hand-labeled data set, we found that reducing to the best 3000 features maximized our performance for 10-fold cross validation. This modification was made after the evaluation, however; our results on the SemEval task represent the performance of our task without feature selection.

4 Results

Our final system achieved an accuracy of 0.653, which ranked 28th out of 42 submissions on the test set hand-labeled by article.

4.1 Feature Selection

As part of additional analysis, we examined the effectiveness of feature selection on the validation set. Table 1 shows that reducing the number of features to 3000 had a negligible effect on both accuracy and f-measure. Since the validation set is qualitatively different from the hand-labeled test set used in the official competition, these results are not directly comparable to our final system performance. In particular, we note that our system performs slightly better on the validation set than on the test set regardless of the number of features used, which may indicate that our classifier learned some characteristics of the source-labeled validation set that distinguished it from the hand-labeled test set.

Feature Selection	Accuracy	f1-measure
`all`	0.611	0.675
`3000`	0.5983	0.667

5 Discussion

Hyperpartisan news has been a concern since the rise of social media, and that concern has only grown since the 2016 election. Giving consumers of social media the knowledge of whether or not what they are reading is hyperpartisan could help to reduce the number of people fooled by fake or misleading facts, and it could help to reduce the partisan divide within the United States.

Feature Title	Category	χ^2	p-value
”trump”	Polarity	416	1.77e-92
A.R.I.	Complexity	377	3.67e-84
”*”	Title	208	2.95e-47
”class”	Title	179	9.45e-41
”american”	Title	170	7.41e-39
”most”	Title	143	5.04e-33
”political”	Title	137	1.08e-31
”israel”	Title	133	1.16e-30
”like”	Polarity	128.7	7.85e-30
”these”	Title	126	2.92e-29

Table 2: Highest ranked features from our hand labeled data-set.

Using our χ^2 feature selection system, we found the top 10 features over the hand-labeled article set, shown in Table 2. The size of the hand-labeled set is rather small, so the extremely small p-values are likely inflated by this.

The Automated Readability Index feature (a complexity feature measuring word length and sentence length) is the second highest performing, indicating that this way of capturing complexity is worthy of further study.

A number of BoW features on the title are also important. The selected words included fall under a few categories such as controversial topic (*trump*, *Israel*), generalization (*most*, *these*), and political terms (*political*, *class*). Some, like the presence of ”*” in title, seem like strange outliers that are likely a consequence of a combination of formatting artifacts and the small size of the hand-labeled dataset.

While an earlier, simpler version of our model achieved 10-fold cross-validation accuracy of .787 on the hand-labeled training set, the submission we submitted performed much more poorly on the final test set. We hypothesize that one source of this difference may have been in the tuning of our hyper-parameter related to feature selection. We tuned this parameter manually using results from 10-fold cross-validation on the hand labeled data-set. Because the hand labeled data was significantly smaller, it is possible that it took far fewer features to properly classify the space. Improved tuning of this parameter on a larger set could have given us better results. Nonetheless, our work demonstrates that BoW, complexity, and polarity features are all useful in identifying hyperpartisan news articles.

6 Namesake

Our system is named after D.X. Beaumont, a magazine editor and publisher on the short-lived TV Series *My Sister Eileen* that aired on CBS in 1960-61 (Wikipedia contributors, 2018). The series, based on autobiographical short stories published in The New Yorker by Ruth McKenney (Lippman, 2018). Ruth, who aspired to be a writer, worked for Beaumont (shown in Figure 1 as portrayed by Raymond Bailey). We imagine that the proliferation of hyperpartisan news in modern communication would have caused the orderly Ruth a great deal of frustration, and hope that our contribution to this task will benefit future writers and their publishers.

Figure 1: Darren McGavin, who portrayed D.X. Beaumont in the TV Series *My Sister Eileen*(NBC Television, 2017).

Acknowledgments

We would like to thank our stalwart grutor (a Harvey Mudd portmanteau of *grader* and *tutor*!), Jonah Rubin, for his help at all hours on our coursework during the semester that led to this system submission.

Abstract

This paper describes the system of NLP@UIT that participated in Task 4 of SemEval-2019. We developed a system that predicts whether an English news article follows a hyperpartisan argumentation. Paparazzo is the name of our system and is also the code name of our team in Task 4 of SemEval-2019. The Paparazzo system, in which we use *tri*-grams of words and *hepta*-grams of characters, officially ranks thirteen with an accuracy of 0.747. Another system of ours, which utilizes *tri*-grams of words, *tri*-grams of characters, *tri*-grams of part-of-speech, syntactic dependency sub-trees, and named-entity recognition tags, achieved an accuracy of 0.787 and is proposed after the deadline of Task 4.

1 Introduction

Fake news is a noteworthy term in recent years. The rise of users and rapid spread information on social networking have made on automatic controlling of fake news more difficult. Fake news articles are typically extremely one-sided (hyperpartisan), inflammatory, emotional, and often riddled with untruths (Potthast et al., 2018). The influence of misinformation varies depending on the style it is written in. For example, sarcasm in a sports news article will have less of an impact than news written in the hyper-partisan argumentation style, which can sway voter decision in an election.

Hyperpartisan detection in news articles is one of the ways to control fake news on the media and public. Kiesel et al. (2019) provided a new task, which they name "Hyperpartisan News Detection," to decide whether a news article text follows a hyperpartisan argumentation. We approach this task following traditional text classification by extracting style features. The bag-of-words model is the way of text representation and is applied to sentiment analysis effectively (Pang et al., 2002). Matsumoto et al. (2005) applied text mining techniques on dependency sub-trees as features for sentiment analysis at the document level. Our results show that n-grams of words and dependency sub-trees features from sentences of the document have certain impacts on the performance of the classifier. The details of the features in our systems and the results are described in Section 3 and Section 4.

2 Task Description

SemEval2019 Task 4 has only one task, in which participants are required to build the systems for hyperpartisan news detection. The task is to predict which category ("hyper-partisan" vs. "not hyper-partisan") an argumentation belongs to when given the news article in English (Kiesel et al., 2019). There are 645 articles in the for-ranking training set, and 628 articles in the for-ranking testing set (all of them are labeled through crowdsourcing on an article basis). Besides, the organizers of this task provided another dataset with the training/validation/testing set having 600,000/150,000/4,000 articles (all of them are labeled in accordance with the judgment of the publisher). The organizers use the *accuracy* as the main metric in the *for-ranking testing set* to evaluate the performance of the participants' systems. All submissions and results are validated by the organizers via the evaluation service TIRA (Potthast et al., 2019).

3 System Description

In this section, we describe the major stages we followed, as well as the prediction models we utilized in our detection system.

Input
Extracted sentences

Figure 1: Diagram of data preprocessing.

3.1 Data Preprocessing

Data preprocessing of the given input is the important phase for every task related to natural language processing. The input of SemEval-2019 Task 4 is an XML file, containing a title and many paragraphs in the body text. Paragraph segmentation is based on the HTML <p> tag because the <p> tag defines a paragraph. While many paragraphs are wrapped by the <p> tag, some are not. Observation of some inputs from the dataset shows that paragraphs that are not wrapped by any HTML tag may contain "noise," such as advertisements and the browser's error messages. On the other hand, texts displayed in HTML <p> tags can also contain "noise," such as notifications for redirecting a page (e.g., "Click here to..."). We did not handle the aforementioned noises in our experiment.

The next step after paragraph segmentation is sentence segmentation. During this process, we used spaCy tool (Honnibal and Montani, 2017) to extract sentences from titles, HTML <p> tags, and paragraphs not wrapped in any HTML tag of input (as we can see the diagram in Figure 1).

3.2 Features Extraction

3.2.1 N-grams of words

Before extracting n-grams of words, we break the sentences into words in three ways:

1. WS$_1$: The sentence is split by space/multi-space into tokens.
2. WS$_2$: The sentence is split by space/multi-space into tokens. After that, we discard tokens which are punctuations or English stop-words.
3. WS$_3$: The sentence is segmented into words. And then, we lemmatize words into lemmas. All is done by using the spaCy tool (Honnibal and Montani, 2017).

After splitting/segmenting the sentence into tokens/words, we put tokens/words are all in lowercase and implement extracting n-grams of them. The specific values of n for prediction models are mentioned in section 3.3.

3.2.2 N-grams of characters

Extracting n-grams of words is effective for text classification that is word-based representation, but this approach requires reliable tokenizers for breaking the sentences into words. Experiments on unsolicited e-mail messages (spam) and a variety of evaluation measures, Kanaris et al. (2007) show that n-grams of characters are more reliable to classify texts than n-grams of words. Potthast et al. (2018) show how a style analysis can distinguish hyperpartisan news from the mainstream, and they also use tri-grams of characters as features for the classifier in their experiments. As we described in section 3.1, unfortunately, the input of SemEval-2019 Task 4 contains a small number of strange n-grams of characters towards the tokenizers. Therefore, we decide to use n-grams of characters as the features in our system. We use the sentence with all of its tokens being rejoined after the segmentation in WS$_1$ (we described in section 3.2.1) with character space for extracting n-grams of characters. In our experiments, the value of n ranging from 2 to 7 and the specific values for prediction models are mentioned in section 3.3.

3.2.3 N-grams of part-of-speech

Argamon et al. (2003) found that n-grams of part-of-speech can efficiently capture syntactical information and gender-based style of the writer. Potthast et al. (2018) used tri-grams of part-of-speech to make a comparative style analysis of hyperpartisan (extremely one-sided) news and fake news. Although the efficacy of using n-grams of part-of-speech on fake news was not examined in their study, we decided to experiment by using n-grams of part-of-speech as features for hyper-partisan news detection. We used the spaCy tool (Honnibal and Montani, 2017) for part-of-speech tagging and extract tri-grams of part-of-speech as features.

3.2.4 Sub-trees of dependency tree

In our experiment, dependency parsing involves extracting from a dependency tree a dependency sub-tree, which is defined by Matsumoto et al. (2005) as "a tree obtained by removing zero or more nodes and branches from the original de-

Figure 2: Visualization of the dependency tree of the sentence within the bracket (“She’s the one, and PER_X, that caused the violence,” PER_Y said.). This sentence is taken from a news article of the training for-ranking training set which is mentioned in Section 2. The person’s name is replaced by PER_{uppercase letter} in this example (we did not do that in our experiment).

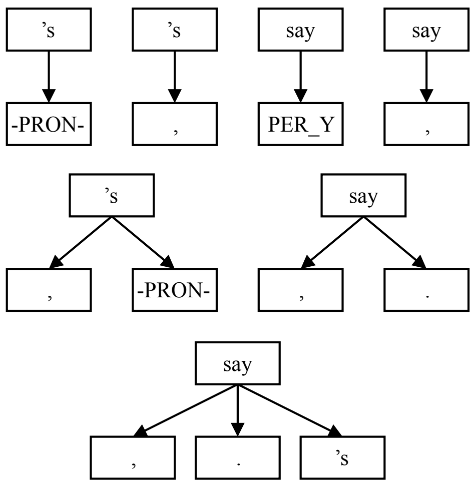

Figure 3: Visualization of seven sub-trees which are extracted from the dependency tree in Figure 2. There are four sub-trees with two nodes, two sub-trees with three nodes, one sub-tree with four nodes in the current figure. All words in this example are lemmatized.

pendency tree.” Figure 2 illustrates a dependency tree of a sentence parsed with spaCy tool (Honnibal and Montani, 2017), and its shortcoming that shows the double quotation mark on the left does not have any child node or parent node. This shortcoming, however, did not affect the extraction of all sub-trees of the dependency tree, but we resolved this issue by considering each group of sub-trees as one connected component, and the dependency tree as a graph that can contain more than one connected component. Figure 3, the number of nodes in a sub-tree can range from 2 to 4, and NetworkX tool (developed by Hagberg et al. (2008)) was used to extract all the sub-trees of the original dependency tree as one connected component for each node. All words at each node of sub-trees are lemmatized in our experiment. As we can see in Figure 3, some sub-trees can capture words which are not located close to each other.

3.2.5 Named-entity recognition tags

Characteristics of the input of SemEval-2019 Task 4 contains names of people, names of organizations. Therefore, we decided to use mentions of specific terms in named-entity recognition as features. In our experiments, a feature is represented by concatenating a mention and a named-entity recognition tag. We used the spaCy tool (Honnibal and Montani, 2017) for the named-entity recognition task.

3.3 Prediction Models

In this section, we describe the four models which we have summited to the organizers. In all models, we used linear SVM (SGDClassifier from Scikit-learn (Pedregosa et al., 2011)) as the classifier, and the loss function which is hinge loss with L2 regularization. In all models, we did not run validation experiments for turning regularization term α of all models. We used just the default value of $\alpha = 0.0001$ following SGDClassifier from Scikit-learn (Pedregosa et al., 2011). Most importantly, we concatenated different count vectors by way of extracting features described in section 3.2, to obtain the input representation of the model.

3.3.1 First model

This model uses *tri*-grams of words which are split from the text of the article (we did not segment the text into sentences) the way described in WS_1 in section 3.2.1). Besides, the first model uses *hepta*-grams of characters from the text of the article as features. We discarded the title when extracting the features for the first model, and we do not distinguish between texts with the HTML <p> tag wrapping and those without (as mentioned in section 3.1).

3.3.2 Second model

We extracted bi-grams of characters from the body text regardless of whether the text is wrapped by the HTML <p> tag or not, and for the title, we followed the way mentioned in WS_2 in section 3.2.1) to extract its bi-grams of words. Additionally, we extracted all mentions of named-entity recognition from all sentences of the article, and we distinguished between features from the title and those from the body text.

3.3.3 Third model

This model shares similar features with the second one, except for our extraction of the dependency sub-trees.

3.3.4 Fourth model

In this model, the title, the text with the HTML <p> wrapping, and those without are distinguished. All sentences are segmented to tokens in the same way described in WS_3 in section 3.2.1). We used tri-grams of words, tri-grams of characters, tri-grams of part-of-speech, syntactic dependency sub-trees, and named-entity recognition tags to extract the text before performing the TF-IDF transformation with Scikit-learn tool (developed by Pedregosa et al. (2011)) on the combined features with min_df at 0.05 and max_df at 0.95.

4 Results

	Accuracy	Precision	Recall	F1
First model[1]	0.747	0.754	0.732	0.743
Second model	0.685	0.687	0.678	0.683
Third model	0.707	0.666	0.831	0.739
Fourth model[2]	0.787	0.796	0.771	0.783

Table 1: Metric summary of fully trained models on the official test dataset.

We did not use the training dataset of 600,000 articles for training all the models in our experiments. The result (Table 1) shows a decrease in performance of the second and the third models when the n-grams of words were not used as features. The accuracy of the third model, however, increased by 2% compared with the second model when the extra dependency sub-trees were used as features. On the other hand, the fourth model achieved the highest accuracy, up to 0.787.

[1]The first model officially ranks thirteen in Sem-Eval 2019 Task 4.

[2]The fourth model is proposed after the deadline of Sem-Eval 2019 Task 4.

This accuracy level, however, is still lower than that achieved via deep learning techniques, such as the Convolutional neural network and pre-trained ELMo representations, employed by "Bertha von Suttner" team who were ranked first in SemEval-2019 Task 4.

5 Conclusion

Our major contribution to SemEval-2019 Task 4 is that using n-grams of words and dependency sub-trees as features for extracting has a positive impact on the performance of the classifier: In our experiment, we were able to achieve the accuracy of 0.787 with the proposed model that uses tri-grams of words, tri-grams of characters, tri-grams of part-of-speech, syntactic dependency sub-trees, and named-entity recognition tags. That model can also capture words which are not located close to each other through dependency sub-trees. The disadvantages of our models, however, are that extraction of dependency sub-trees is a time-consuming process, and the relations between sentences of the articles are not represented.

Orwellian-times at SemEval-2019 Task 4: A Stylistic and Content-based Classifier

Jürgen Knauth
Institute of Computer Science
University of Goettingen
jknauth@uni-goettingen.de

Abstract

While fake news detection received quite a bit of attention in recent years, hyperpartisan news detection is still an underresearched topic. This paper presents our work towards building a classification system for hyperpartisan news detection in the context of the SemEval2019 shared task 4. We experiment with two different approaches - a more stylistic one, and a more content related one - achieving average results.

1 Introduction

Recent years have seen a noticeable change in the political discourse: Political polarization has increased and political opinions have become more hyperpartisan (Doherty, 2017). This affects the media, especially news media and is therefore a topic of considerable interest for science and society.

We present an approach for the detection of high polarization and hyperpartisan news articles. Our approach addresses stylistic and content related features. The latter are implemented by identifying n-grams that are typical for either a hyperpartisan or a more balanced perspective.

1.1 The Task

The goal of the SemEval2019 Hyperpartisan News Detection Task (Kiesel et al., 2019) is to build a system capable of classifying arbitrary articles either as non-hyperpartisan or hyperpartisan.

1.2 The Dataset

For building a classification system the organizers of the task provided several data sets extracted from different American news sites:

a) a set of 600.000 articles for training (classification: by publisher's general orientation)

b) a set of 150.000 articles for validation (classification: by publisher's general orientation)

c) 645 training articles (classified individually by humans using a crowd sourcing approach)

d) validation set (classified by publisher, unknown size as this data set has been hidden during the task)

e) validation set (classified individually, unknown size as this data set has been hidden during the task)

All data - the articles themselves as well as the ground truth data - is provided in an proprietary but simple and well parsable XML format defined by the task owners. The individual data records includes a globally unique ID, the title, the source URL and publication time. Additionally the ground truth data for a) and b) contains information about a left-right bias of the publisher in general.

2 Related Work

Not so much research has been done in regard to hyperpartisan news detection. Other work is primarily addressing related fields such as ideology detection, fake news detection. For example (Hutto et al., 2015; Hamborg et al., 2018) addresses identification and quantification of media bias. (Iyyer et al., 2014) addresses political ideology detection using recursive neural networks. (Rashkin et al., 2017) is analyzing language in fake news for automated political fact-checking. One interesting work directly targeting hyperpartisan news is the work of (Potthast et al., 2018) identifing hyperpartisan news articles via style.

3 Methodology

3.1 PoS Tagging

As we hypothesize that not all parts-of-speech are equally important for distinguishing hyperpartisan and non-hyperpartisan articles, we lemmatized and pos-tagged the dataset.

Initially, we experimented with the TreeTagger (Schmid, 1994), however since this turned out not to be sufficiently robust for the noisy input data, which included encoding errors as well as portions of JavaScript code, we later adopted the Stanford CoreNLP tagger (Manning et al., 2014).

3.2 Feature Extraction

We used a total of 108 features for our experiments. The next sections discusses our features in detail.

3.2.1 Linguistic Complexity and Style Features

Basic complexity: We hypothesize that hyperpartisan texts are stylistically less complex than non-hyperpartisan texts (Potthast et al., 2018), hence we implemented a number of features measuring linguistic complexity. We measure the distribution characteristics of paragraph lengths, sentence lengths and word lengths. Individual features were derived from that data like minimum, maximum, variance, mean, et cetera.

Number of words in main part-of-speech categories: We collect the number of verbs, nouns, adjectives and adverbs in articles and derive distribution features from it. While not every part-of-speech category will have the same importance we rationalize that at least the distribution characteristics of nouns, adjectives and adverbs could be a style hint for hyperpartisan or non-hyperpartisan.

Simple form of lexical density: As "lexical density" we here consider the ratio of words being not part of the NLTK stop-words in comparison to the total number of words. The idea behind this feature is to detect articles with lower or higher information character and take some stylistic aspect into account.

Huffman compression ratio: Our huffman compression feature is used with similar intention. First: The general idea behind huffman compression (Huffman, 1952) is to build a dictionary of words ordered by frequency in a binary tree. This is done in such a way that in the end high frequency words can be encoded with a shorter bit code than low frequency words. The rationale in our approach here is to perform a compression of individual articles: The better this compression works the more an author of an article reuses his own words. The more difficult this compression is, the higher is the variety of words used by an author. For speed reasons we intentionally do not perform a full compression here but build a huffman compression tree and then estimate the size the indices would take in a full compression. We then put this information into relation to the total number of tokens of an article and use this as a feature.

Readability scores: A set of readability scores is used. Readability scores express the simplicity of a text in various different ways - at least to some extent - as well as give a rough judgement for the reading competence level of an audience required to understand the text. We implemented features based on four readability scores: ARI (Smith and Senter, 1967), Coleman-Liau (Coleman and Liau, 1975), Flesch-Kincaid (Kincaid et al., 1975) and Gunning-Fog (Gunning, 1952).

Vocabulary variety: The vocabulary variety classifier is calculating the ratio of uniquely used words in relation to the total number of words. This way this classifier assists in judging the complexity of the text in an article as well.

3.2.2 Arousal vs. Rationality

Distribution parameters of business words: We assume that news articles addressing business related topics are inherently not particularly hyperpartisan. Based on manual inspection of training data, we therefore created a list of 27 words, which we consider to be expressing business related topics, for example "sales", "growth", "CEO", "opportunity", "revenue", "Q1", "shareholder" and similar terms.

Distribution parameters of words of disgust: In a similar way to business words the corpus lemmas are judged whether they express some kind of disgust. For this purpose a hand picked vocabulary of 246 words had been created from publically available online dictionaries such as LEO (LEO), Wictionary (Wictionary) and similar that genuinely express some kind of disgust. Though this dictionary likely is not complete the assumption is, that it gives a general insight into whether a writer expresses disgust at least to some extend, e.g. "discord", "rupture", "distaste", "scandalous" or even words like "rotten". We intended here not to detect only archetypical words such as “awful” but also more uncommon words that might typically not be seen in news so frequently. The rationale behind this is that we noticed the phenomenon of hyperpartisan authors to attempt to use a more vivid and strong language with sometimes less common words.

Cardinal number ratio: Detecting cardinal numbers is another feature addressing very specific aspects of articles: The idea behind this feature is that more fact-based communication might more likely make use of numbers in order to express and proof their positions. While we can not check the truth of claims involving cardinal numbers we at least try to detect the quantity of such claims.

Pronouns before “need” and “must”: Two feature detectors address pronouns directly proceeding the words “need” or “must”. We noticed hyperpartisan articles where the authors directly address the reader and give advice how society should proceed. This is done in an inclusive way, so sequences like “we must (do sth)” or “we need (to do sth)” could be observed.

3.2.3 Content Features

To address content specifically we implemented features derived from the provided test data itself, though this way these features can cover only limited and existing content.

Attributively used adjectives: According to the theories behind framing in psychology, political influence can be produced by repeating specific kind of wordings (Wehling, 2016). We noticed that this technique seems to be used sometimes quite extensively by authors of more extreme positions in recent years as they have a quite unchanging perspective about topics, persons and events. For example in the manually classified data the term “jewish” is used to characterize a following noun about five times more often in hyperpartisan than non-hyperpartisan articles, “holistic” about 30 times and “immediate” only about a third of the times compared to non-hyperpartisan news. Based on this phenomenon a dictionary of adjectives which discriminate a following noun have been extracted from non-hyperpartisan and hyperpartisan pos-tagged training data in a separate processing process, resulting in 2720 adjectives for our use. Our feature is then measuring whether more non-hyperpartisan or hyperpartisan use of such adjectives can be observed in an article.

Lemma-bigram similarity scores: While our attributively-used-adjectives-feature focuses on the adjectives themselves and is therefore a single word feature, we additionally used lemma based bigram features. We extracted all bigrams in sentences for a window of four tokens from the manually tagged training data (and for experiments from the larger data set) and associated them with either non-hyperpartisan or hyperpartisan labels. For example the lemmas “obama” directly followed by “administration” appear significantly more often in hyperpartisan than non-hyperpartisan articles. It’s even more extreme with “obamacare” and “act”, sequences of “bad” and “happen” or “disastrous” and “war”: The latter having even no mentions at all in non-hyperpartisan articles. Interestingly some bigrams are less characteristic as one would expect: For example “illegal” and “immigration” is used quite frequently by both classes. Again other bigrams seem to be more typical for non-hyperpartisan news articles, e.g. “fake” and “story”.

For our implementation we determined the relation of how often either hyperpartisan and non-hyperpartisan bigrams appeared per paragraph:

$$f = (nH - nNH)/(nH + nNH) \qquad (1)$$

where *nH* and *nNH* refer to the number of hyperpartisan/non-hyperpartisan bigrams. This value will be positive or negative depending on the surplus of non-hyperpartisan vs. hyperpartisan bigrams encountered in unseen text. We do this for directly adjacent lemmas, for two lemmas skipping one token, two tokens and three tokens and calculate the four medians so that we end up with a set of feature values, each one expressing content similarity to our reference data.

3.3 Machine Learning

We built two different models by training a support vector machine with an rbf-kernel (libsvm). The first one is based only on the stylistic features and has been submitted for the first evaluation run of the task, the second one is based only on the content features which has been submitted for the second evaluation run of the task.

For training of the first model 100.000 articles have been selected by random with stratified sampling, arriving at 25.000 articles classified as hyperpartisan left, 25.000 hyperpartisan right and 50.000 non-hyperpartisan. Selecting a sub-

	Dataset	Acc	Prec	Rec	F1
M1	by-pub.	0.505	0.503	0.949	0.657
M2	by-pub.	0.537	0.530	0.658	0.587
M2	by-art.	0.671	0.654	0.729	0.689

Table 1: Results, Model 1 and Model 2 with validation dataset used, accuracy, precision, recall and F1 score.

set of the available articles was necessary as part-of-speech tagging with first the TreeTagger and then the CoreNLP tagger took quite some time to complete. As mentioned before we ran into some tagging problems because of errors in the corpus data and limited capabilities of the existing Python adapters for CoreNLP. Additionally we encountered some problems with larger amounts of data which surprisingly caused crashes in the C implementation of the SVM (NuSVC of sklearn) for unknown reasons. So in the end we limited ourselves to these 100.000 random articles to cope with these difficulties.

As we recognized during our work that the training data classified by-pubisher was - by nature - not so accurately labeled, we train our second model on the gold standard data with 645 manually labeled articles to avoid any noise for our features as much as possible. For this model we used only the content features.

4 Results and Conclusions

To train our models we used the provided training data "by-publisher" and "by-article" as described in the last section. Evaluation runs have then been performed on the validation data "by-publisher" and "by-article" (which were hidden during the duration of the shared task). The results can be seen in table 1.

Model 1 (which was trained on the 100.000 randomly picked articles focusing on style features) was tested against the validation data labeled by-publisher. Model 2 (which was trained on the 645 articles focusing on content features) was tested against the validation data labeled by-publisher and the validation data by-article in two separate runs. Our model 1 achieved better results than model 2 during our evaluation runs on the by-publisher data. It has been selected by the organizers for ranking in the leader board.

Validation showed that our first model exhibits a trend to judge articles too easily as being hyperpartisan. Though our second model exhibits a trend to more easily classify articles as hyperpartisan as well, this effect is not that strong.

Our second, content feature model did not perform that well on the test data labeled by-publisher than the first, the style-based model. Interestingly it performed better on evaluation data labeled by-article. As our training data of 645 articles for that model is small the second model likely suffers from overfitting.

5 Further Work

In this paper we have presented a binary classification system that assign labels "non-hyperpartisan" and "hyperpartisan" for articles. While we could achieve some results in that field we still think that more work is needed here.

Results of competing teams in the SemEval2019 shared task indicate that our current approach has not yet been explored to full extent in that regard: Better classification could be possible. We assume that additional effort should be taken in selecting more and better style and content features. Though stylistic approaches seem to be promising – comp. (Potthast et al., 2018) – we assume that future work should focus more on content and empathic perception of the content by the reader. For example sentiment could be taken into consideration as news articles tend to have different point of views on different topics. As there exists a variety of different sentiment tools of varying quality experiments need to be performed to explore possibilities of improving our models. Attempts in this regard have been undertaken by ourselves already but could not be completed for this shared task. Additionally it would be interesting to combine both approaches, something we were not able to explore sufficiently during this shared task.

Abstract

This paper describes the Rouletabille participation to the Hyperpartisan News Detection task. We propose the use of different text classification methods for this task. Preliminary experiments using a similar collection used in Potthast et al. (2018) show that neural-based classification methods reach state-of-the art results. Our final submission is composed of a unique run that ranks among all runs at 3/49 position for the by-publisher test dataset and 43/96 for the by-article test dataset in terms of Accuracy.

1 Introduction

Printed press have been in the last decades the main way to access to news in written format. This tendency is changing with the appearance of online channels but usually the main factors of the journalistic content generation are still there: events, journalists, and editors. One of the problems of the generation of this content is the influence of each factor in the veracity of the generated content. Two main factors may influence the final view of an article: writer's preferences and affiliation of the editor house.

Identifying partisan preferences in news, based only on text content, has been shown to be a challenging task (Potthast et al., 2018). This problem requires to identify if a news article was written in such a way that it includes an overrated appreciation of one of the participants in the news (a political party, a person, a company, etc.). Despite the fact that sharply polarized documents are not necessarily fake, it is an early problem to solve for the identification of fake content. A recent paper (Potthast et al., 2018) claims that stylometric features are a key factor to tackle this task.

In this paper, we present the description of our participation to the Hyperpartisan classification task at SemEval-2019 (Kiesel et al., 2019). This task was composed of two subtasks, the first consist to identify hyperpartisan bias in documents classified by its individual content (bias of the writer or by-article category) and the second by the editorial house that published the article (bias of the editorial house or by-publisher category) as depicted in Figure 1[1]. To address this problem, we experimented with well-known models based on deep learning (Honnibal and Montani, 2017; Kim, 2014). They achieve state-of-the-art results on a publicly available collection (Potthast et al., 2018), showing that neural models can effectively address the task of hyperpartisan detection without including stylometric features. Our final submission ranked in the top-3 for the by-publisher category, and 43/96 for the by-article category (or 21/42 in the official ranking).

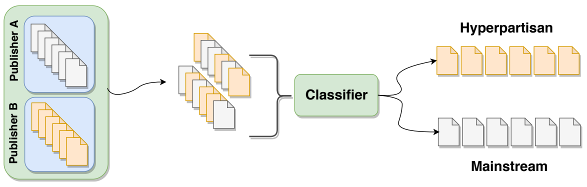

Figure 1: Publisher-based pipeline performed in training phase. During testing, different publishers were used and labels were unknown.

2 Classification Models

We have considered that the hyperpartisan classification task can be addressed as a binary classification task where only two classes ('hyperpartisan' and 'mainstream').

Three different models were considered for our participation. The first of them is based on a classical document-level representation and the

[1]More details of the dataset construction can be found in Kiesel et al. (2019)

other two are based on word-level representations through the use of word embedding. All of them can be seen as baselines and no specific adaptation to the dataset[2] was performed.[3]

2.1 TF-IDF + Adaboost

For this model we represented our documents using the classical TF-IDF representation. Finally, the Adaboost classifier (Freund and Schapire, 1997) is used under the default configuration. Note that this is a very basic baseline, as it does not use recent representation techniques such as word embeddings.

2.2 SpaCy Model

In this case, we used the SpaCy (Honnibal and Montani, 2017) library[4]. We used the text categorisation algorithm implemented in SpaCy which is based on the hierarchical attention network proposed in Yang et al. (2016). The main improvement to the original model is the use of hash-based embeddings. We only defined two hyper-parameters for the model: number of epochs and dropout rate. These parameters were set to 3 and 0.2, respectevelly.[5]

2.3 Convolutional Model

We also tested the neural classification model proposed by Kim (2014). This model uses convolutional neural networks that are finally reduced to a binary classification. This method is known as a highly competitive classification model for short documents. As SpaCy, this model is based on word embeddings representation. However, in this case we preferred to use the pre-calculated embeddings of GloVe (Pennington et al., 2014). Hyper-parameters were defined using the training data.

3 Experiments and Results

3.1 Experimental Setup

Experiments were performed using two collections, the ACL2018 collection (Potthast et al., 2018) and the SemEval19 collection (Potthast et al., 2019). The first collection is composed of 1627 articles including 801 hyperpartisan and 826 mainstream manually annotated documents. As this collection is not originally split in training-test sets, results are presented using cross-validation. The second collection was split in train, validation, and test sets for the by-publisher category, and in train and test for the by-article category as presented in Table 1. Results in this second collection are exclusively calculated using the TIRA evaluation system (Potthast et al., 2019).

	training	validation	test
by-article	645	-	628
by-publisher	600000	150000	4000

Table 1: Number of documents used for training, validation, and test used in the SemEval19 collection.

In order to determine the best configuration to our participation using the SemEval collection, we decided to perform experiments and fix hyperparameters using the ACL2018 collection.

3.2 Results in the ACL2018 Collection

Table 2 reported results of the 3 classification models presented in section 2 (lines labelled TF-IDF+Adaboost, SpaCy and CNN-Kim), as well as results of the approach presented in Potthast et al. (2018) (line labelled ACL18), on the ACL2018 collection.

We only used the first fold produced by the authors' code[6]. As our results are not directly comparable with the values reported in Potthast et al. (2018), we re-evaluated their approach on this single fold.

Values of the three F-measures were calculated with sklearn[7]. Note that in binary classification, micro F-measure values are equivalent to accuracy values.

Two state-of-the-art models (SpaCy and Kim (2014)) outperform the approach presented in Potthast et al. (2018), showing that stylometric features are probably not necessary for the task.

3.3 Results in the Semeval2019 Collection

Experiments on the official collection were performed through the use of TIRA (Potthast et al., 2019)[8]. As our previous experiments have not shown clear improvement with the convolutional model, we submitted our official runs using

[2]Different to the classical training of the involved classifiers.

[3]Further experiments were performed using network-based models but as results did not show improvement in an existing collection, we decided to not include these results.

	F-measure		
	macro	accuracy /micro	weighted
ACL18	0.7605	0.7509	0.7480
TF-IDF + Adaboost	0.7069	0.7130	0.7039
SpaCy (dp =0.2, epochs=3)	0.8087	0.8091	0.8081
CNN-Kim	**0.8273**	**0.8306**	**0.8290**

Table 2: Macro, micro and weighted F-measure for the ACL2018 collection.

	accuracy/micro	f1
top1	**0.7060**	0.6825
top2	0.6998	0.6587
our (rank 3/49)	0.6805	**0.7213**
top4	0.6640	0.7061

Table 3: Official results for the by-publisher test dataset.

SpaCy: it can be seen as an 'easy-to-implement' but strong baseline. The same model was trained on the by-publisher training set for both submissions (on the by-publisher and by-article dataset).

Tables 3 and 4 respectively present official results on the by-publisher[9] and the by-article datasets.

One can see that relative results (i.e. regarding the official ranking) are strongly better on the by-publisher dataset than on the by-article one. This can be easily explained by the fact that collections were differently annotated.

If we now compare accuracy scores of the SpaCy model between the ACL2018 collection and the SemEval2019 one, we can notice a decrease in performance (0.6640 vs 0.8091 on the by-publisher dataset for example), leading us to think that there exist some differences between the two collections. Both collections seem to be complementary for the evaluation of hyperpartisan detection.

Another important observation is that the SpaCy model performs remarkably well on the by-publisher set, although not specifically tuned for the hyperpartisan detection task. Indeed, we are ranked first on the F1 metric, and 3rd on the Accuracy one. Some other experiments are needed to get a fine-tuned model for the task, but this version can already be considered as a strong baseline for the by-publiser subtask.

	accuracy /micro	f1
top1	**0.8217**	0.8089
top2	0.8201	**0.8215**
top3	0.8089	0.8046
our (rank 43/96)	0.7245	0.6905

Table 4: Official results for the by-article test dataset.

4 Conclusion

Our experiments and participation to the Hyperpartisan task led us to conclude that:

- stylometric features seem not to be necessary to achieve state-of-the-art results for hyperpartisan detection in the ACL2018 collection. This deserves a set of extra experiments to better understand the real contribution of stylometric features when combined with strong representations/classifiers to validate the work of Potthast et al. (2018).
- a state-of-the-art classification model in its default configuration (SpaCy) can be considered as a strong baseline for next experiments. Indeed, SpaCy is top-ranked according to the F1 metric on the by-publisher dataset. One question is thus now if other top-ranked approaches are also from the text classification literature or dedicated ones.

Abstract

This paper describes our system for detecting hyperpartisan news articles, which was submitted for the shared task in SemEval 2019 on Hyperpartisan News Detection. We developed a Support Vector Machine (SVM) model that uses TF-IDF of tokens, Language Inquiry and Word Count (LIWC) features, and structural features such as number of paragraphs and hyperlink count in an article. The model was trained on 645 articles from two classes: mainstream and hyperpartisan. Our system was ranked seventeenth out of forty two participating teams in the binary classification task with an accuracy score of 0.742 on the blind test set (the accuracy of the top ranked system was 0.822). We provide a detailed description of our preprocessing steps, discussion of our experiments using different combinations of features, and analysis of our results and prediction errors.

1 Introduction

Fake news on various online media outlets misinform the public and threaten the integrity of journalism. This has serious effects on shaping public opinions on controversial topics such as climate change, and swaying voters in political elections. Yellow press existed long before the digital age but had limited reach when compared to mainstream press. However, with the introduction of social media, news that are extremely biased (hyperpartisan) tend to spread more quickly than the ones that are not (Vosoughi et al., 2018). Therefore, there is a need for automatic detection methods of hyperpartisan news. Computational methods for fighting fake news mainly focus on automatic fact-checking rather than looking at writing styles of news articles (Potthast et al., 2018). SemEval-2019 Hyperpartisan News Detection shared task aims to study the ability of a system to detect if a given article exhibits a hyperpartisan argumentation writing style to convince readers of a certain position. The shared task introduces a binary classification task of classifying an article into one of two possibilities: mainstream or hyperpartisan. The data for the shared task was introduced by (Kiesel et al., 2019) and consists of 645 of articles from mainstream, left-wing, and right-wing publishers. The articles from both left-wing and right-wing publishers were labeled as hyperpartisan.

The baseline system to detect hyperpartisan developed by (Potthast et al., 2018) uses Unmasking (Koppel et al., 2007) and was trained on 1,627 of articles. The articles are from nine publishers in the US: three mainstream (ABC News, CNN, and Politico), three left-wing (Addicting Info, Occupy Democrats, and The Other 98%), and three right-wing (Eagle Rising, Freedom Daily, and Right Wing News). Their model had a best accuracy of 75% by using stylistic features. However, their model is not directly comparable with ours since the dataset for the shared task is different.

In the following sections, we describe our system for identifying hyperpartisan news articles as part of our participation in the Hyperpartisan New Detection shared task in SemEval 2019 (Kiesel et al., 2019).

2 System Description

We trained a support vector machine model on a feature vector representing each article in our training dataset. To develop this model, we processed the dataset and analyzed different features and feature combinations.

2.1 Pre-processing

The training dataset contained 645 articles that include 238 (37%) hyperpartisan and 407 (63%) mainstream (Kiesel et al., 2018). The test dataset is 628 articles (314 from each class).

We clean the articles and titles from punctuation marks, stop words, none alphabetical characters, lemmatized and tokenized using the Natural Language Toolkit (NLTK) (Bird et al., 2009) . After that, those tokens are processed using the TF-IDF vectorizer in sci-kit-learn (Pedregosa et al., 2011) and stored as a vector.

2.2 Feature Extraction

The features we chose to extract from the articles, include the following:

1. *Words vector.* After pre-processing all the unigrams in the articles and the titles are stored in a TF-IDF vector.

2. *Linguistic Inquiry and Word Count (LIWC) features.* The words in every article and titles that are part of any dimension of the Linguistic Inquiry and Word Count (LIWC) dictionary. LIWC analyzes text by using a dictionary of the most common words and word stems. The dictionary is organized into different categories, some of which are affect words and function words. (Pennebaker et al., 2012) are counted and stored in a sixty-three dimensional TF-IDF vector.

3. *Punctuation.* The punctuation marks in the title and articles were grouped into six different categories and then counted and stored separately from the article and then stored in a six-dimensional TF-IDF vector. Because we were specifically interested in exclamation marks, question marks and quotations we let those three punctuation marks have their independent counts in the vector. The other three dimensions are colons and comma, dot, and parenthesis.

4. Article structure features:*Paragraphs, quotes, and external links* are counted and stored in a 3-dimensional vector.

5. *Emotion features.* The emotional content in the articles is captured using the NRC emotions lexicon (Mohammad and Turney, 2013). After counting the words in each emotion category, we store the counts in a ten-dimensional vector, where the elements represent anger, anticipation, disgust, fear, joy, negative, positive, sadness, surprise and trust.

After pre-processing and extraction, we experiment with different groupings of these features in our model to see which group of features is most effective for the given task. The next section discusses those feature combinations.

Features	Title				Article					F1
	W	L	P	E	W	L	P	E	S	
1	x	x	x	x						0.48
2					x	x	x	x		0.75
3					x	x	x	x	x	0.74
4	x	x	x	x	x	x	x	x	x	0.72
5	x				x					0.76
6		x	x	x		x	x	x	x	0.71
7					x	x	x		x	0.76
8	x	x		x	x	x		x		0.74
9		x				x				0.48
10			x				x			0.48
11				x				x		0.70
12	x				x	x	x		x	0.76

Table 1: Different feature combinations (W: Words vector, L: LIWC features, P: Punctuation Marks, E: Emotions and S: Articles Structure) and their weighted F1 score on the local validation set.

2.3 Feature Selection

Now that we have the extracted features we began grouping them and testing them in our model. We tested the different combinations of these features as shown in Table 1. In these experiments, the most effective combination of features was number 7 (the word tokens, LIWC, punctuation marks, and the article structure), number 5 (the word tokens of the article and title) and number 12 (all the features in 5 and 7). The other title features did not provide a good contribution to the model as we expected.

2.4 Model

The model[1] is constructed using a sci-kit-learn pipeline with two main steps. The first part is a dimensionality reduction using latent semantic indexing (Manning et al., 2008) using Truncated Singular value decomposition (SVD). The primary goal of using an SVD is to lower the rank of the feature matrix by merging the dimensions associated with terms that have a similar meaning. The second step is a linear support vector machine (SVM) model used in default settings, which takes as input the output of the

[1]https://github.com/amal994/hyperpartisan-detection-task

SVD. The SVM is useful in high dimensional spaces and when the number of features is higher than the number of articles in the dataset.

3 Results

In this section, we will review the results of our model and show its performance on a local validation set of size 129 articles (48 hyperpartisan, 81 not hyperpartisan) and the test set on TIRA (Potthast et al., 2019).

Measure	Validation Set	Test Set
accuracy	0.767	0.742
f1-score	0.767	0.709
precision	0.767	0.814
recall	0.767	0.627
true positives	26	197
true negatives	73	269
false positives	8	45
false negatives	22	117

Table 2: Main task classification results of the local validation and test datasets.

3.1 Main Task

For the main task, identifying hyperpartisan articles from a dataset of manually labeled articles, we created a local validation set, by partitioning the by-article dataset into a training and validation sets while keeping the split ratio equal in both. We do not report any results on the by-publisher datatset as we found class mismatch for some articles across the two datasets (i.e. some articles are labeled mainstream in the by-article and hyperpartisan in the by-publisher). Therefore, we decided to focus on the more accurately labeled dataset (the by-article), which is also the one used for share-task leaderboard ranking.

Model	Accuracy	
	validation set	test set
SVM	0.767	0.742
Ensemble	0.829	0.640
Ensemble-RNN	0.76*	0.694

Table 3: Classification results of various models. Ensemble-RNN model was tested using cross-validation so it is not directly comparable with the other two models in the validation scores.

In Table 2, we show the classification report of the SVM model after running on a local validation set and the official test set. When we tested the SVM model locally, it gave a high f1-score 0.767 which is the measure we relied on locally because the data was not balanced.
On the task leaderboard, tested on the test set in TIRA, the model ranked 17 among the 42 participating teams, with an accuracy of 0.742.

We also experimented with other machine learning models and compared them with our SVM model. We developed an ensemble model that consists of an SVM classifier, a Gradient Boosting Classifier and a Bagging Classifier with a decision tree as its base estimator. But that classifier only scored 0.64 accuracy on the test set, even though it scored 0.829 accuracy on the validation set. We also added an RNN classifier that uses ELMO embeddings (Peters et al., 2018) to the previously described ensemble model. That model increased the accuracy on the test set by a small value 0.694 but did not outperformed the SVM model.

3.2 Meta Learning

We also participated in the meta-learning sub-task, the task is to use all of the predictions from all of the participating teams classifiers as an input and come up with a meta classifier.

The dataset we were given is a list of predictions from all the participating classifiers and the gold labels for each article in this list.
The model we developed builds on the idea of a weighted majority algorithm but with changes to how the weights are being calculated. So instead of dividing by the total number of elements to calculate the weights, we have two separate weights, one for each class, and then we calculated those two weights for each classifier using equation 1 where H in the equation corresponds to the class (0 or 1), c is the classifier and y is the true label.

$$w(c, H) = \frac{\sum_i^n \mathbb{1}(y = H \wedge c(x) = H)}{\sum_i^n \mathbb{1}(y == H)} \quad (1)$$

This classifier had a validation accuracy of 0.899 and the baseline majority vote classifier 0.884. The model has only a slight advantage in its accuracy which is beneficial for the competition. Even though when used in real life the difference between the two accuracies is negligible.

4 Discussion

We can observe from the results in Table 1 that the TF-IDF features of articles and titles are the most useful for this task. They consistently have the highest accuracy score when combined with other features or when used alone as shown in feature set 5 in Table 1. This shows that it was hard for LIWC features by themselves to capture any linguistic patterns that correlate with hyperpartisan news. The superiority of TF-IDF could be due to trends related to a certain domain or publisher rather than to a general hyperpartisan trend. In order to examine the ability of other approaches to detect hyperpartisan news articles, we developed two other models. An Ensemble model of three models and an Ensemble-RNN model both described in Section 3.1. Both models scored almost as good as the SVM on the validation set (Ensemble-RNN model) or better than the SVM (Ensemble model). However, both scored significantly lower than the SVM model on the blind test set. The Ensemble-RNN model included a neural network which was trained on our small training set of 645 articles. Given the huge drop between validation and test scores, especially for the ensemble mode which dropped from 0.83 to 0.64, this indicates an overfitting on the training data. Although the deep learning models were not trained for more than five epochs to avoid overfitting, they were not able to learn beyond what was seen in the training data and were possibly memorizing the data. The complexity and subjectivity of the annotation task could have made it harder for the model to classify articles. We were also dealing with imbalance class sizes which made the model learn to predict one class better than the other. As for the meta-learning experiment, we followed a class-based weighted majority approach, where the classifiers that are better in classification of one class were given a higher weight for that class predictions and lower weight for their predictions in the other class. However, this approach only had a one-point improvement over the baseline. We analyzed the prediction errors of the SVM model to further understand what causes the model to make a wrong prediction.

4.1 Error Analysis

We looked more closely at four examples: one correct and one wrong prediction from each class. The first example is an article from Fox News about the 2016 US presidential elections [2]. This article was labeled as mainstream and was predicted correctly by our model. Although the article was predicted correctly by the classifier, it was not clear to us why this article was labeled as mainstream as it has a somewhat one-sided view to its story and thus could be labeled as hyperpartisan. This points out the uncertainty or noise in the annotation of some data points. The second mainstream article is from Yahoo! news and talks about Ivanka Trump [3]. It was wrongly classified as hyperpartisan by our model. This could be due to the fact that the content of the article is related to Trump, which appeared more in the hyperpartisan class in our dataset. The third article is labeled as hyperpartisan and predicted as such. It is an opinion piece from Online Athens about social justice [4]. It has phrases such as “so-called” and “Karl Marx would be so proud” which could’ve helped the model to use the learned TF-IDF features of the training data to make a correct prediction. The final article we looked at is from Real Clear Politics and talks about a joke made by Jimmy Kimmel [5]. This was wrongly classified as mainstream by the model which could be due to having structural features of mainstream articles (long article and no URLs). These four examples show that some of our lexical and structural features did not generalize well to the test set.

5 Conclusion

We presented an SVM model that detects hyperpartisan news articles with a 0.742 accuracy after it was trained on a total 645 articles from mainstream and hyperpartisan classes. This task was primarily challenging due to the complexity in labeling such articles, and differences in writing styles across domains, publishers and individuals. The small size of the training data along with the class imbalance also contributed to the complexity, which made it harder for the model to learn. We presented a summary of our experiments and analysis of our results and prediction errors.

Abstract

This paper describes our submission to task 4 in SemEval 2019, i.e., *hyperpartisan news detection*. Our model aims at detecting hyperpartisan news by incorporating the style-based features and the content-based features. We extract a broad number of feature sets and use as our learning algorithms the GBDT and the n-gram CNN model. Finally, we apply the weighted average for effective learning between the two models. Our model achieves an accuracy of 0.745 on the test set in subtask A.

1 Introduction

The proliferation of misleading information in the media has made it challenging to identify trustworthy news sources, thus increasing the need for fake news detection tools able to provide insight into the reliability of news contents. Since the spread of fake news is causing irreversible results, near-real-time fake news detection is crucial. However, knowledge-based and context-based approaches to fake news detection can only be applied after publication; they may not be fast enough (Potthast et al., 2017).

As a practical alternative, style-based approaches try to detect fake news by capturing the manipulators in the writing style of news content. This approach captures style signals that can indicate a decreased objectivity of news content and thus the potential to mislead consumers, such as hyperpartisan style. Hyperpartisan style represents extreme behavior in favor of a particular political party, which often correlates with a strong motivation to create fake news. Linguistic-based features can be applied to detect hyperpartisan articles (Potthast et al., 2017). Deep network models, such as convolution neural networks (CNN), applied to classify fake news detection (Wang, 2017). In this paper, we employ the stylometry-based approach and N-gram CNN model for detecting hyperpartisan news.

2 System Overview

For this task, we extract a broad number of features from the training data and then apply the classifier model to make predictions. Our system employs a gradient boosting decision tree (GBDT) model and N-gram CNN model. In subsequent sections, we describe data preprocessing, feature engineering and learning algorithms.

2.1 Data Preprocessing

Before applying the models, we need to do some transforming tasks of the article texts (i.e., *xml parsing, text tokenizing, stemming, lemmatization, and removing stopwords*) and extracting tasks of the internal and external links for each article. Apart from these tasks, we construct the bias domain dictionary from the *mediabiasfactcheck* site [1] to check the bias on the external linked domain in the article. For this ends, we crawled the top-level domain information from the sites corresponding to the five categories associated with hyperpartisan (e.g., *Left, Center, Least Biased, Right-center Bias, and Right Bias*) respectively.

2.2 Feature Engineering

Since hyperpartisan news is intentionally created for political gain rather than to report objective claims, they often contain opinionated and inflammatory language. Thus, it is reasonable to exploit linguistic features that capture different writing styles to detect hyperpartisan news. Linguistic features are extracted from the text content in terms of document organizations at a different level, such as characters, words, and sentences. Typical common linguisitic features are: *lexical*

[1] http://mediabiasfactcheck.com/

Type of Features	Feature Count
Count features	10
External link bias	3
Sentiment features	8
Readability features	14
Term features	44
Grammar transformation	45
Psycholinguistic features	54
POS tags	36
Word2vec features	301
TF-IDF	10,000

Table 1: Statistics of features.

features, including character-level and word-level features; *syntactic features*, including sentence-level features (i.e., *n-gram, POS tagging, etc.*).

We start by extracting several sets of linguistic features. These feature sets are designed to capture hyperpartisan article from the training datasets. Overall we selected 515 binary features and TF-IDF features. Table 1 provides extracted features on the training dataset.

Basic count features: Previous works on fake news detection (Rubin et al., 2016) as well as on opinion spam (Ott et al., 2011) suggest that the use of punctuation is useful to differentiate deceptive from truthful texts. We construct a basic count feature set including various punctuation characters and other features.

External link bias: We extract bias counts based on the bias domain dictionary for each external linked domain in the article (i.e.,*hyperpartisan links count, non-hyperpartisan links count, and unknown links count*). To determine biases of the external links, we exploit a biased domain dictionary crawling from the *mediabasisfactcheck* site, which consists of five categories for top-level domains(i.e., *left, right, left-center, center, right-center*). The external link bias is counted as the hyperpartisan when the externally linked site is belonging to *left* and *right* among these categories.

Sentiment features: Our system used the VADER sentiment analysis tools [2] to generate sentiment features on the title and body of articles. The VADER not only tells about the *Positivity* and *Negativity* score but also tells us about how positive or negative a sentiment is as shown in Figure 1.

Title
Liberals wailing about gun control, but what about abortion?
{'h_neg': 0.175, 'h_neu': 0.825, 'h_pos': 0.0, 'h_compound': -0.1779}

Body
In response to Joyce Newman's recent letter about a conversation about guns: According to the National Right to Life Organization, approximately 600,000 babies are murdered ....
{'b_neg': 0.2, 'b_neu': 0.79, 'b_pos': 0.01, 'b_compound': -0.9831}

Figure 1: An example of sentiment analysis.

Vocabulary richness and readability features: We also extract features indicating article understandability. These features include several vocabulary richness and readability scores, including the Brunet's Measure W, Hapax DisLegemena, Hapax Legomenon, Honores R Measure, Sichels Measure, Yules Characteristic K, Dale Chall Readability Formula, Flesch Reading Ease, Gunning Fog Index, Shannon Entropy, Simpson's Index etc[3]. Among this index, Simpson's index stems from the concept of biodiversity. We apply this index to measure the diversity of a text.

Simpson's Index $(D) = \sum(n/N)^2$
N = total number of words in a text
n = total number of unique tokens

Term features: Hyperpartisan news uses their language strategically despite the attempt to control what they are saying. This language occurs with certain verbal aspects and patterns of pronoun, conjunction, and negative emotional word usage. Based on this assumption, we extract term count features which count synonyms of several terms (e.g., to obtain the ORDER term Feature, we calculated the frequency of words such as *command, demand, instruction, prescription, order* in each article).

Grammar transformation: Analysis of the content-based approach is often not enough in predicting hyperpartisan news. Thus, we adopt language structure (syntax) to predict this task. We use spaCy tool [4] to transform news articles into a set of parse tree describing syntax structure.

Psycholinguistic features: For psycholinguistic features, we use the 2015 Linguistic Inquiry and Word Count (LIWC[5]) lexicon to extract the proportions of words that belong to the psycholinguistic categories. LIWC has two types of categories; the first kind captures the writing style

[3] https://en.wikipedia.org/wiki/Readability
[4] https://spacy.io
[5] http://liwc.wpengine.com/

of the author by considering features like the POS frequency or the length of the used words. The second category captures content information by counting the frequency of words related to some thematic categories such as affective processes(e.g., *positive emotion, negative emotion, anxiety, anger, sadness*), social processes (e.g., *family, friends, female references, male references*), etc. Regarding the use of this tool, we focus on the content information, and consequently, we decide to ignore the style categories.

Part-of-Speech (POS) tags: Syntactic features consist of function words and part-of-speech tags. Syntactic pattern varies significantly from one author to another. These features were extracted using more accurate and robust text analysis tools (i.e., part-of-speech taggers, and lemmatizers). In our system, we expand the possibilities of word-level analysis by extracting the utilities of features like POS frequency. For the extraction of syntactic features, we used NLTK POS tagger[1].

Word2Vec features : Recently, word representation model (e.g., *word2vec, GloVe*) based on neural networks which represents a word into a form of a real-valued vector have increased popularity (Mikolov et al., 2013). These approaches proved to be advantageous in many NLP tasks, such as Machine Translation, Question Answering, Document Classification, to name a few. We adopted a pre-trained 300-dimensional word vector [6] to create a vector representation of the article, with an average word2vec. Besides, we use the word2vec feature to extract the cosine similarity value between the news title and the text.

TF-IDF features: Finally, We extract unigrams, bigrams, and trigrams derived from the bag of words representation of each news article. To account for occasional differences in content length between train dataset and test dataset, these features are encoded as tf-idf values. We limit the number of features that the vectorizer will learn to 10,000 features.

2.3 Learning Algorithms

Based on the above multiple features, we explore several learning algorithms to build classification models. We adopt the average weighted value for effective learning between GBDT for the style-based and content-based features and the N-gram CNN model. (see Figure 2).

Layer	# of layers		hyperparameters
Embedding	1	l	5000
		d	300
Convoulution	3	m	[500,500,500]
		w	[3,4,5]
		w	max
Dense Layer	2	t	128
		o	2

l: max sequence length	d: embedding dimension
m: filter	w: kernel size
w: max-pooling	t: dense unit size
o: softmax	

Table 2: N-gram CNN model hyperparameters.

For deep learning model, we adopt N-gram CNN model proposed in (Shrestha et al., 2017). As shown in Figure 2 (right), the model receives a sequence of character n-gram as input. These N-gram are then processed by four layers: (1) an embedding layer, (2) a convolution layer, (3) a max-pooling layer, and (4) a softmax layer. We briefly sketch the processing procedure.

The network takes a sequence of character bigrams $x =< x_1, ..., x_l >$ as input, and outputs a multinomial over class labels as a prediction. The model first look up the embedding matrix to generate the embeddings sequence for x (i.e., the matrix C), and then pushes the embedding sequence through convolutional filters of three bigram-window sizes $w = 3, 4, 5$, each yielding m feature maps. We then apply the max-pooling to the feature maps of each filter, and concatenate the result vectors to obtain a single vector y, which then generate a prediction through the softmax layer.

Based on this model, we modified the network by adding a dense layer which helps detect hyperpartisan news features. After the experiment, the result shows that the character bigram CNN model outperforms the unigram CNN model. Table 2 summarizes the sizes of various parameters included in the N-gram CNN model. The official evaluation measure for subtasks A is *accuracy*.

Table 3

3 Experiments and Results

3.1 Datasets

The statistics of the datasets provided by SemEval 2019 task 4 (Kiesel et al., 2019) are shown Table

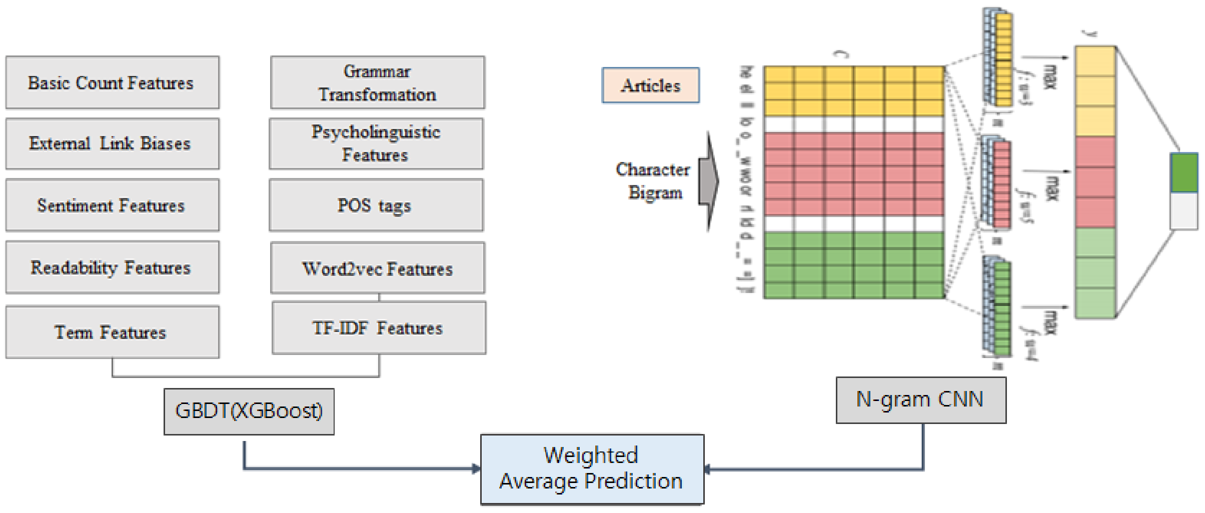

Figure 2: Hyperpartisan news detection model.

Subtask A	Hp(%)	NHp(%)
train (645)	238(36.9)	407(63.1)
Subtask B	Hp(%)	NHp(%)
train (600k)	300k(50%)	300k(50%)
valid (150k)	75k(50%)	75k(50%)

Table 3: Statistics of data sets in SemEval 2019 Task 4 Hp: hyperpartisan news; NHp: non-hyperpartisan news.

3.

3.2 Experiments on the Train Dataset

We conduct several experiments on each feature set to explore predictive separately. In these experiments, we use the GDBC (i.e., XGBoost) for the above feature set. For comparison with the N-gram model, we used the Char-level CNN model (Kim et al., 2016). The objective function was minimized through stochastic gradient descent over shuffled mini-batches with Adam(Kingma and Ba, 2014).

The performance is evaluated using 5-fold cross validation with accuracy and F-score. Table 4 lists the experimental results for each feature set on the training dataset. The prediction model through the incorporation of the entire feature showed higher accuracy than the prediction model for the individual feature.

3.3 Experiments on the Test Dataset

Our submission results to the subtask A on TIRA (Potthast et al., 2019)–the web service platform to facilitate software submissions into virtual machine– achieve an accuracy of **0.745** (precision: 0.853, recall: 0.592, F1: 0.6999). We ranked the 14th for subtask A in terms of accuracy. The prediction results of the test data are lower than the results of the training set, especially gains huge gap between precision and recall score.

Features (# of features)	Acc	F1
Count features (10)	0.6977	0.60
External link bias (3)	0.6512	0.60
Sentiment features (8)	0.6124	0.61
Readability features (14)	0.7442	0.74
Term features (44)	0.6512	0.65
Grammar transformation (45)	0.7829	0.78
Psycholinguistic features (54)	0.7984	0.79

TF-IDF (10,000)	0.7364	0.73
Char CNN (unigram)	0.7442	0.73
N-gram CNN (bigram)	0.7752	0.78
All Features (train dataset)	**0.8450**	**0.84**
All Features (test dataset)	**0.7450**	**0.70**

Table 4: Experimental results on the subtask A dataset.

4 Conclusion

Using a combination of the style-based approaches, the content-based approaches, and the N-gram CNN model, we construct the model for detecting hyperpartisan news. For this ends, we extract a broad number of linguistic features and employ GBDT model to make predictions. Finally, we adopted the weighted average value for effective learning between the two models.

Abstract

In this paper, we demonstrate the system built to solve the SemEval-2019 task 4: Hyperpartisan News Detection (Kiesel et al., 2019), the task of automatically determining whether an article is heavily biased towards one side of the political spectrum. Our system receives an article in its raw, textual form, analyzes it, and predicts with moderate accuracy whether the article is hyperpartisan. The learning model used was primarily trained on a manually prelabeled dataset containing news articles. The system relies on the previously constructed SVM model, available in the Python Scikit-Learn library. We ranked 6th in the competition of 42 teams with an accuracy of 79.1% (the winning team had 82.2%).

1 Introduction

The ability to quickly, precisely, and efficiently discern if a given article is hyperpartisan can prove to be beneficial in a multitude of different scenarios. Should we, for example, wish to evaluate if a certain news publisher delivers politically biased content, the best way to do so would be analyzing that very content. However, the sheer amount of articles modern news companies produce nowadays asks for an automated approach to the problem.

Spotting bias in text is both a well-known and challenging natural language problem. As bias can manifest itself in a covert or ambiguous manner, it is often hard even for an experienced reader to detect it. There was some research done on similar issues before (Doumit and Minai, 2011), but none specifically on the subject of hyperpartisan news.

The system described in this paper was built for Task 4 of the SemEval-2019 competition. The goal of the system, as set by the task, is to predict, as accurately as possible, whether a given article is hyperpartisan. While there were other criteria for evaluating the performance of the model (precision, recall, F1), we decided to optimize the program for the accuracy criterion, as the rankings were based solely on this measure. Accuracy, in this context, indicates the ratio of correctly predicted articles to the total number of articles. The final model reached an accuracy of 79.1%, which presents a decent score, considering the complexity of the problem and the available technology.

The system we built is based on the SVM model publicly available in Python's SciKit-Learn library (Pedregosa et al., 2011). Our model was trained on a handful of carefully chosen features derived from the given dataset and our understanding of the nature of bias. The dataset was split into a high-quality, manually labelled set of articles, and a large, but sub-par set of automatically labelled articles. By experimenting with the datasets, models, and features, we managed to create a system which ranked 6th in this competition.

2 Dataset Description

The dataset, which was provided by the task organizers, was divided into two separate clusters. The first and larger cluster consisted of one million news articles labelled solely by the political affiliation of the *publisher*. The second and much smaller cluster consisted of one thousand news articles labelled by people who read and evaluated them.

There was a substantial difference in labelling between these two datasets, so the quality and accuracy of the smaller dataset greatly overshadowed the abundance of articles in the larger dataset. Furthermore, the articles mostly came from large U.S. news publishers, such as: Fox News, CNN, Vox, etc. This predominance of prominent U.S. news networks and the substantial difference in quality largely impacted our feature design and, ultimately, our model selection.

The task itself was not divided into subtasks, but the submission on these two different datasets was regarded as a different subtask. The final test set, on which the main leaderboard is made, consisted solely of the articles from the smaller and more accurate dataset.

3 Model Description

Model selection and feature design were vastly influenced by the radical difference in quality between the two given datasets. As we mentioned, the larger, publisher-based dataset had a high number of mislabelled articles. For example, articles about diet tips, weather forecasts, or some other non-political news were often labelled as hyperpartisan news, solely on the fact that the publisher is classified as a generally biased news source. This mislabelling often caused our models to wrongly guess on what really indicates hyperpartisanism in news articles. Since the larger dataset often gave us relatively low accuracy, we decided to try a different approach.

Our first submitted model was trained only on the smaller and more accurate dataset. We decided to use SVC with GridSearch to maximize our accuracy on such a small dataset. Our best accuracy on the validation set, after cross-validation and with all features in place, was 77.9%. Furthermore, for our second submitted model, we decided to use a self-learning method to acquire more quality data from the larger dataset. Our first step was to train a logistic regression model on one-half of the smaller dataset, and, once trained, we tested that model on the larger dataset. All correctly classified articles were added to a new dataset. Once we extracted and combined all high-quality articles, we again used the SVC model. Our final accuracy on this model was also 77%.

4 Features

Our main tool used for processing news articles was word2vec[1] (Mikolov et al., 2013). Each word was converted into a vector, and all the word vectors generated from an article were then summed up. To prepare the dataset for word2vec, we used stemming and lemmatization tools from NLTK toolkit (Bird et al., 2009), and eliminated standard English stopwords. Also, in our earlier stages of development, we used chunking to get more meaningful information from the text.

[1]Additionaly, we experimented with GloVe (Pennington et al., 2014) and fastText (Bojanowski et al., 2016), but both models were outperformed by word2vec.

We ultimately ended up with a 300-dimensional vector for every article. This was the result of passing the preprocessed text into word2vec. Below, we elaborate on some other features we introduced to our model.

Publication date

Hyperpartisanism, or extreme bias, is a classification closely related to politics. As we were dealing predominatly with U.S. news outlets, we reasoned that news articles occurring around certain dates could demonstrate more hyperpartisanism. For example, months leading up to and following annual U.S. elections could be a mild indication of hyperpartisanism. Our first intuition was to only include months as a feature, since, in the U.S., certain election processes take place yearly. With further tests, we found that, if the year was also included, the accuracy improved by over 2%. That improvement could mean not only that elections produce more hyperpartisan news, but the type of the election, and maybe even the winner, could have an impact on news bias.

Website referencing

After inspecting a number of news articles in the dataset, we found that the majority of articles reference news sites whose objective political affiliation may be easily determined. Using that fact, we made a list of all known, extremely biased, U.S.-based news sources, and a list of objectively neutral news sources to counter the effect. By simply providing the number of extremely biased and neutral references, we improved the accuracy of our models by 2.3%. This could confirm that it is generally more common for news sources to reference other news sources with whom they share a similar political affiliation.

Sentiment analysis

Our initial assumption was that hyperpartisan articles tend to be more negative and aggressive than non-hyperpartisan articles. We used the sentiment intensity analyzer found in NLTK's sentiment library. The analyzer provides the scores for positivity, negativity, neutrality, and a compound score (i.e. aggregated score). We included these four as features in our model, which proved our theory correct and increased our accuracy results by 1.5%.

Model	Accuracy
Word2vec	0.58370
with added sentiment factor	0.58589
with added quotation counter	0.59874
with added date (month)	0.61360
with added date (month and year)	0.61782
with added NER counter	0.62556

Table 1: Validation results for our first SVC model on the by-publisher dataset, with particular features added one by one.

Model	Accuracy
Word2vec	0.75663
with added sentiment factor	0.76128
with added date (month and year)	0.76285
with added quotation counter	0.76904
with added trigger word counter	0.77981

Table 2: Validation results for our first SVC model on the by-article dataset, with particular features added one by one.

Trigger words
Analyzing the articles, we noticed that the writers of extremely biased news articles were prone to using *trigger words* more often than the writers of neutral news articles. With that in mind, we assembled a list of possible trigger words (containing mostly profanities). For each article, we took the count of *trigger words* in the text, and used it as input in the feature vector.

Named entity recognition
A named entity is a real-world object, such as a person, location, organization, product, etc., which can be denoted by a proper name. We decided to count, and use as another feature, the number politics-related named entities found in the articles. We assumed that the more named entities were found, the more biased an article would be. We used the software library spaCy[2] (Honnibal and Montani, 2017) and its named entity recognition tagger to extract mentions of various named entities, such as organizations, people, locations, dates, percentages, time, and money. We used the counts as inputs in the feature vector. Although counting most of the entity types dropped the total accuracy of the model, one type in particular was beneficial. It is a type called NORP and it denotes nationalities, religious groups, and political groups. Counting only the number of these named entities as a feature increased the model's accuracy slightly, by about 1%.

[2]https://spacy.io

5 Evaluation

First, we trained our model with the much larger but subpar *by-publisher* dataset, and then fine-tuned it using the much smaller but more precise *by-article* dataset.

5.1 Larger Dataset

Labels of the *by-publisher* dataset weren't as precise as the smaller dataset, which is why the accuracy results were lower, in the $58-62\%$ range. Table 1 showcases the results. We can see that adding a sentiment factor as a feature didn't change the overall accuracy for this dataset, but we should mention that it did increase the smaller dataset's accuracy much more. Adding the number of occurrences of biased publisher names quoted in the article increased the accuracy by about 1.3%. The largest increase in accuracy came with adding the date as a feature. Adding only the month as a feature increased the accuracy by 1.5%, but adding both month and year of article publication saw an additional increase of about 0.5%. Adding a counter of named entities (in particular: nationalities, religious groups, and political groups) increased the overall accuracy by just under 1%.

5.2 Smaller Dataset

Finally, the model with all of the features explained above was trained on the *by-article* dataset. While validating our results, the dataset was divided into five parts. 4⁄5 were used for training, and the remaining 1⁄5 was used for validation. The datasets were permutated, and, in the end, we took the average of the five permutations. We trained the model using 10 different classifiers. The validation results are shown in Table 3.

6 Conclusion

We described our system for hyperpartisan detection, developed for SemEval 2019 - Task 4. The essence of our system was SVC with GridSearch built on a variety of hand-crafted features. The task itself was a complex NLP problem, as hyperpartisanism detection in text often presents a problem even for an experienced human reader. Our main mission was to extract a few quality features that would help us tackle this convoluted problem. Future work includes experiments with different

Classifier	Accuracy

Abstract

This paper describes our submission[1] to the SemEval 2019 Hyperpartisan News Detection task. Our system aims for a linguistics-based document classification from a minimal set of interpretable features, while maintaining good performance. To this goal, we follow a feature-based approach and perform several experiments with different machine learning classifiers. On the main task, our model achieved an accuracy of 71.7%, which was improved after the task's end to 72.9%. We also participate in the meta-learning sub-task, for classifying documents with the binary classifications of all submitted systems as input, achieving an accuracy of 89.9%.

1 Introduction

Hyperpartisan news detection consists in identifying news that exhibit extreme bias towards a single side (Potthast et al., 2018). The shift, in news consumption behavior, from traditional outlets to social media platforms has been accompanied by a surge of fake and/or hyperpartisan news articles in recent years (Gottfried and Shearer, 2017), raising concerns in both researchers and the general public. As ideologically aligned humans prefer to believe in ideologically aligned news (Allcott and Gentzkow, 2017), these tend to be shared more often and, thus, spread at a fast and unchecked pace. Moreover, there is a large intersection of 'fake' and 'hyperpartisan' news, as 97% of fake news articles in BuzzFeed's Facebook fact-check dataset are also hyperpartisan (Silverman et al., 2016).

However, the detection/classification and consequent regulation of online content must be done with careful consideration, as any automatic system risks unintended censorship (Akdeniz, 2010). As such, we aim for a linguistically-guided model from a set of interpretable features, together with classifiers that facilitate inspection of what the model has learned, such as Random Forests (Ho, 1995), Support Vector Machines (Cortes and Vapnik, 1995) and Gradient Boosted Trees (Drucker and Cortes, 1996). Neural network models are left out for their typically less self-explanatory nature.

The SemEval 2019 Task 4 (Kiesel et al., 2019) challenged participants to build a system for hyperpartisan news detection. The provided dataset consists of 645 manually annotated articles (*by-article dataset*), as well as 750,000 articles automatically annotated publisher-wise (*by-publisher* dataset, split 80% for training and 20% for validation). Systems are ranked by accuracy on a set of unpublished test articles (from the *by-article* dataset), which has no publishers in common with the provided train dataset, preventing accuracy gains by profiling publishers. All experiments on this paper are performed on the *gold-standard* (*by-article*) corpus, as this was the official dataset.

The rest of the paper is organized as follows. Section 2 describes our pre-processing, feature selection, and the system's architecture. Section 3 analyzes our model's performance, evaluates each feature importance, and goes in-depth on some classification examples. Finally, Section 5 draws conclusions and sketches future work.

2 System Description

We propose a feature-based approach and experiment with several machine learning algorithms, namely support vector machines with linear ker-

[1] https://github.com/AndreFCruz/semeval2019-hyperpartisan-news

nels (SVM), random forests (RF), and gradient boosted trees (GBT). Our submission to the task was a RF classifier, as this was the best performing at the time. However, after the task's end we found a combination of hyperparameters that turned GBT into the best-performer. We detail all results in the following sub-sections.

All classifiers were implemented using *scikit-learn* (Pedregosa et al., 2011) for the *Python* programming language, and all were trained on the same dataset of *featurized* documents. In this section we describe the data pre-processing, our selection of features, as well as the classifiers' grid-searched hyperparameters.

2.1 Feature Selection

The statistical analysis of natural language has been widely used for stylometric purposes, in particular in order to define linguistic features to measure author style. These include, among others: document length, sentence and word length, use of punctuation, use of capital letters, and frequency of word n-grams; type-token ratio (Johnson, 1944); and frequency of word n-grams (see e.g. Stamatatos (2009) for a thorough survey of authorship attribution methods). Although these features have been successfully used in authorship attribution to establish the most likely writer of a target text among a range of possible writers (Sousa-Silva et al., 2010, 2011), research on how these features can be used to analyze group authorship – and subsequently identify an ideological slant – is less demonstrated. Therefore, we build upon previous research on Computer-Mediated Discourse Analysis (Herring, 2004) to test the use of these features to detect hyperpartisan news.

We compute a minimal set of style and complexity features, partially inspired by Horne and Adali (2017), as well as a bag of word n-grams. For tokenization we use the Python Natural Language Toolkit (Bird et al., 2009).

Our features are as follow: *num_sentences* (number of sentences in the document); *avg_sent_word_len* (average word-length of sentences); *avg_sent_char_len* (average character-length of sentences); *var_sent_char_len* (variance of character-length of sentences); *avg_word_len* (average character-length of words); *var_word_len* (variance of character-length of words); *punct_freq* (relative frequency of punctuation characters); *capital_freq* (relative frequency of capital letters); *types_atoms_ratio* (type-token ratio, a measure of vocabulary diversity and richness); and frequency of the k most frequent word n-grams.

Regarding word n-grams, we use $k = 50$ and $n \in [1, 2]$, as we empirically found these values to perform well while maintaining a small feature set. Moreover, we ignore n-grams whose document frequency is greater than 95%, as well as 1-grams from a set of known English stop-words (from *scikit-learn*'s stop-word list), whose frequency we assume to be too high to be distinctive. Text tokens and stop words are *stemmed* using the Porter stemming algorithm (Porter, 1980).

2.2 Hyperparameters

For RF, we use the following hyperparameter values: 100 estimators; minimum samples at leaf = 1; criterion = gini; minimum samples to split = 2.

For GBT, we use the following hyperparameter values: 50 estimators; minimum samples at leaf = 3; loss = exponential; learning rate = 0.3; minimum samples to split = 5; max depth = 8.

For SVM model, we use the following hyperparameter values: penalty parameter C = 0.9; penalty = l2; loss function = squared hinge.

These hyperparameter values are the result of extensive grid searching for each model, selecting the best performing models on 10-fold cross-validated results.

3 Results and Discussion

Table 1 shows the results of the models over 10-fold cross validation (top rows), and on the official test set (bottom rows). Besides our models, we show the performance of the provided baseline as well as the best performing submission to the task (last row). As results on the official test set were hidden during the duration of the task, we used cross-validated results to guide our decision-making in improving the models.

3.1 Feature Analysis

Making use of our choice of classifiers, we are able to interpret and analyze the most important features, as well as trace back the decision path for every document along each of the ensemble's estimators (RF and GBT).

Figures 1 and 2 show measures of feature importance for the RF and GBT models. Figure 1 shows the top features by *mean impurity decrease*

Dataset	*Model*	*Accuracy*	*Precision*	*Recall*	*F1*
10-fold CV on *by-article-training*	GBT	75.9	71.4	59.4	64.6
	RF	76.3	74.6	55.4	63.3
	SVM	72.7	71.3	45.5	55.1
by-article-test (official)	GBT	72.9	78.1	63.7	70.2
	RF	**71.7**	**80.6**	**57.0**	**66.8**
	Baseline	46.2	46.0	44.3	45.1
	Best Team	82.2	87.1	75.5	80.9

Table 1: Models performance: values in the top rows result from 10-fold cross-validation on the *by-article-training* set, and values in the bottom rows report evaluation on the official test set through TIRA (Potthast et al., 2019). RF refers to our task submission, while GBT is our best performing model, submitted after the task's closing.

on a feature's nodes, averaged across the ensemble's estimators/trees and weighted by the proportion of samples reaching those nodes (Breiman, 2001). Similarly, Figure 2 shows the top features by *relative accuracy decrease* (averaged across the ensemble's estimators) as the values of each feature are randomly permuted (Breiman, 2001).

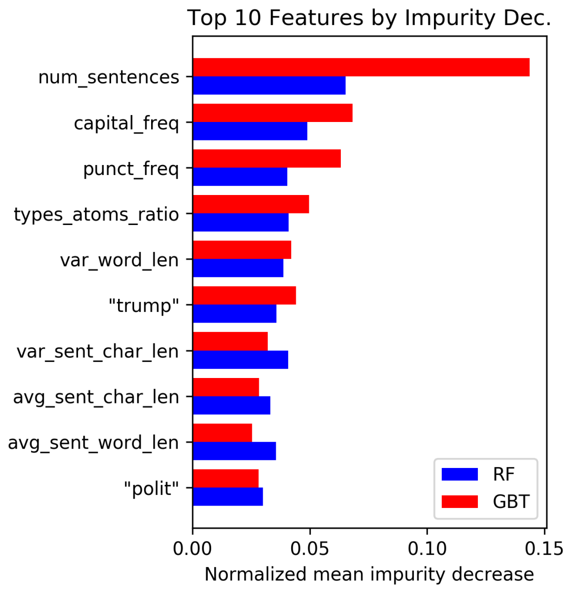

Figure 1: Top features by mean *impurity* decrease, sorted by average value among the two classifiers.

Interesting properties emerge from analyzing feature importance, notably that the *number of sentences* and the *frequency of capital letters* are the most important features on both measures. Moreover, the RF model tends to have a longer-tailed distribution of feature importances, while the GBT model tends to focus on a smaller subset of features for classification.

Interestingly, two 1-grams make it into the top-10 features by impurity decrease: 'trump' and 'polit'. Reliance on n-grams could present a larger problem, as these may refer to entities with a high variance of media attention. For instance, words like 'Hillary' or 'Obama' (which appear in the top-20 features) are probably not seen as often nowadays as they were back in 2016. As such, we are confident in the generalization capacity of the models, as the most discriminative features are mostly style and language-complexity features, which do not suffer from the previously stated biases of n-grams.

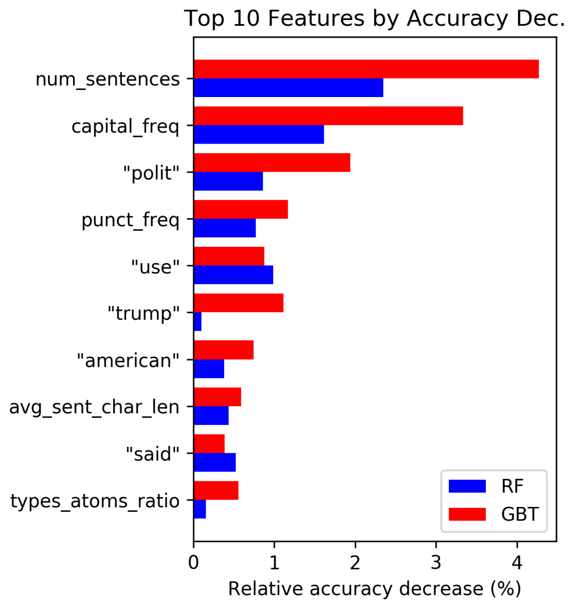

Figure 2: Top features by relative *accuracy* decrease, sorted by average value among the two classifiers.

3.2 Analysis of Predictions

In order to better understand our model's decision making, we analyze differences in distributions of document features for each predicted class, and compare them with the gold-standard values.

As seen in Table 2, articles predicted as hyperpartisan have a higher number of sentences, but each with lower length than mainstream articles, and with decreased vocabulary diversity (smaller type-token ratio). The frequency of the word 'trump' is also noticeably higher in hyperpartisan articles. There is a good alignment of *predicted* and *gold* articles, when projected onto this feature space.

Feature	Pred. Avg.		Gold Avg.	
	H	M	H	M
num_sentences	39.7	19.4	37.5	20.4
capital_freq	0.046	0.058	0.046	0.058
punct_freq	0.030	0.032	0.030	0.033
type_atoms_ratio	0.54	0.60	0.55	0.59
var_word_len	2.70^2	2.71^2	2.69^2	2.71^2
"trump"	6.13	2.54	5.86	2.64
var_sen_char_len	91.5^2	162^2	93.5^2	162^2
avg_sen_char_len	127	156	129	156
avg_sen_word_len	24.9	29.2	25.1	29.1
"polit"	1.37	0.35	1.34	0.35

Table 2: Average values for articles *predicted* (Pred.) hyperpartisan (H) or mainstream (M), and for their *ground-truth* (Gold), for top-10 features by impurity decrease.

4 Meta-learning Task

After the main task's end, organizers challenged participants to compete on a meta-learning task. This task's dataset consisted of the predictions made by each of the 42 submitted systems on the same test-set articles. Notably, a simple majority vote classifier (with the predictions of all 42 systems as input) achieved accuracy of 88.5%, substantially better than the best performing system's accuracy of 82.2%.

While a voting classifier performed considerably well, we intuitively postulated that the votes of the best-n classifiers (accuracy-wise) would perform better. Figure 3 shows the accuracy of n majority vote classifiers, from the top-*42* systems to the top-*1* system. The best performance is achieved using the top-*12* classifiers. However, in Figure 3, we can observe fluctuations in performance while removing the worst classifiers. This means that combining worst classifiers as we do in this task can yield performance improvements. We conclude that there is no discernible correlation between performance and smaller n. We leave as future work further investigation on what characteristics of the classifiers contribute to the fluctuations of the overall performance.

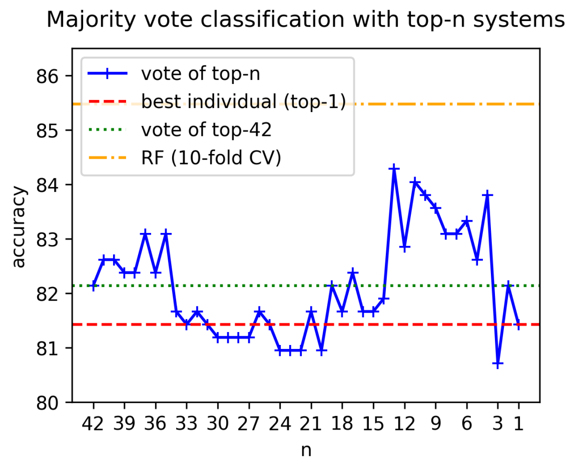

Figure 3: Performance of a majority vote classifier using the top-n best performing systems (by accuracy), on the provided *by-article-meta-training* dataset.

Our final submission for this sub-task consisted of a Random Forest model, whose features were the predictions of all 42 submitted systems, as well as an extra column with the average vote of all systems. See Table 3 for the final performance on the official *by-article-meta-test* dataset.

Model	*A*	*P*	*R*	*F1*
RF	89.9	89.5	90.4	90.0
Majority Vote (42)	88.5	89.2	87.5	88.3
Baseline	52.9	52.5	59.6	55.9

Table 3: Performance on the meta-learning task, evaluated on the *by-article-meta-test* dataset through TIRA.

5 Conclusions

We experimented with several models for hyperpartisan news detection, supplied with a small set of 9 linguistically-inspired features in addition to the 50 most frequent n-grams. Our official submission is a Random Forest model, which achieved an accuracy of 71.7%. On the meta-learning sub-task we achieved an accuracy of 89.9%.

For future work, we intend to further explore differences in writing style between hyperpartisan and mainstream articles, as well as ensembles of individually distinct classifiers, as it seems a promising path towards more accurate hyperpartisan news detection.

Team Harry Friberg at SemEval-2019 Task 4: Identifying Hyperpartisan News through Editorially Defined Metatopics

Nazanin Afsarmanesh, Jussi Karlgren, Peter Sumbler, Nina Viereckel
Gavagai
Stockholm , Sweden
{nazanin, jussi, peter, nina}@gavagai.io

Abstract

This report describes the starting point for a simple rule based hypothesis testing excercise on identifying hyperpartisan news items carried out by the Harry Friberg team from Gavagai. We used manually crafted *metatopics*, topics which often appear in hyperpartisan texts as rant conduits, together with tonality analysis to identify general characteristics of hyperpartisan news items. While the precision of the resulting effort is less than stellar— our contribution ranked 37th of the 42 successfully submitted experiments with overly high recall (95%) and low precision (54%)—we believe we have a model which allows us to continue exploring the underlying features of what the subgenre of hyperpartisan news items is characterised by.

1 Hyperpartisanism

Hyperpartisan news are news items that are strongly argumentative and one-sided. However, being biased is not enough to be characterised as being hyperpartisan, neither is it enough for a news item to use strong language. Confounders for this task includes items that use strong language without being partisan, items that are subjective but not ”hyper”, and items that report dispassionately on typically hyperpartisan topics.

We hypothesise that authors of hyperpartisan texts are in the process of performing a sub-genre of their own, intended not as much to convey the reader information about some state of the world but to mobilise sentiment and affect in the readership, and establishing a shared attitudinal space. Taking this point of departure, we assume that the linguistic items employed by the authors of hyperpartisan text are not only related to the topics under discussions, nor to argumentation, but also include some genre-specific features to explicitly signal hyperpartisanness. This report describes an experiment based on these starting points, performed on data from the 2019 SemEval task on Hyperpartisan News Detection. (Kiesel et al., 2019)

2 Gavagai Explorer

The Gavagai Explorer is a commercially available tool which provides an end-to-end solution for the analysis of unstructured text data (Espinoza et al., 2018). We have in these experiments made use of its components for topic clustering, sentiment analysis, and concept modelling.

2.1 Trigger Topics

The *topic clustering* is based on lexical cues, and can be used to detect what themes and topics are prevalent in some set of e.g. customer feedback messages. Here, we used the topic clustering to establish what sort of themes were frequent in the hyperpartisan training set.

We postulate that many *metatopics* turn out to become lightning rods for hyperpartisan argumentation, somewhat (but not entirely) unpredictably. A characteristic of some of the more extreme sample items was that a hyperpartisan rant will bring in additional only marginally related topics into an argumentation. We identified a small set of potential rant metatopics using the topic clustering mechanism in the Gavagai Explorer. A breakdown of these topics with some example terms can be found in Table 1.

2.2 Trigger Attitudes

The *concept modeling* tool allows an analyst to define measures based on lexical items. *Sentiments* are a special case, applied to the palette of human emotion. On entering some seed words, the user is presented with semantically similar terms acquired from a distributional model (Sahlgren et al., 2016). The user accepts terms which are relevant,

Topic	Example terms
American	across america, america first, god bless america, ...
Elites	elite, establishment, oligarchy, ...
Freedom of Speech	first amendment rights, freedom of speech, press freedom, ...
Islam	islamist, islamism, muslim, ...
Media	cable news, mainstream media, twitter, ...
People	people, these people, the people, ...
Political Movements	alt-right, bolshevik, marxist
Politicians	party leaders, political party, politician, ...
Populism	populism, populist, ...
Public Safety	felon, incriminating, predator, ...
Race	black lives matter, black people, white people, ...
Sexual Rights	reproductive rights, same sex marriage, transgender, ...
Support	support, supportive, supported, ...
Woman	woman, women, ...

Table 1: Trigger topics and some of terms that indicate them. The full list with all terms is available at https://www.gavagai.io/blog/2019/06/06/gavagai-identifying-hyperpartisan-news/ .

Concept	Example terms
Certainty	blatantly, undeniably, hands-down, ...
Cynical	bizarre, far-fetched, ludicrous, ...
Exasperation	and once again, for some reason, yet again, ...
Failure	catastrophe, complete failure, disaster, ...
Nonsense	arrogant, babble, claptrap, ...
Puffery	landmark, pioneering, visionary, ...
Weasel Words	recent study, widely acknowledged, been claimed, ...
Win and Lose	bruised, humiliated, vanquished, ...

Table 2: Trigger attitudes and some of terms that indicate them. The full list with all terms is available at https://www.gavagai.io/blog/2019/06/06/gavagai-identifying-hyperpartisan-news/ .

which are in turn used to provide more suggestions in the following iteration. Here, we used the concept modelling tool to define *trigger attitudes* such as those shown in Table 2.

We find that strongly expressed attitudes not necessarily mean that an article is hyperpartisan, but that the combination of a trigger topic together with negative sentiment appears to be indicative of hyperpartisanism. The sentiment analysis component identifies several types of polar language, and measures the intensity of expression in each item using both presence of polar terms and of amplifier terms such as ”extremely” and ”very”. In addition to standard polar sentiments we used the concept modeling tool to build a set of concepts tailored to observable presence in hyperpartisan texts (Karlgren et al., 2012).

2.3 Trigger Styles

Besides topical specificity we expect hyperpartisan texts to be couched in specific styles, as already established in previous studies (Potthast et al., 2018). We compared some stylistic features known to us to have discriminative power in other contexts, such as counts of exclamation marks, question marks, digits, capital letters, capitalised words, type token ratio, word length, sentence length etc. We found that the strongest single stylistic feature was the presence of many exclamation marks, in conjunction with trigger topics, while most other features on their own were less indicative. This is an indication that the authors of hyperpartisan texts appear to adhere to most stylistic conventions of the news genre.

3 Rule Based Fusion

We combined the above evidence in a rule based model, to achieve reasonably high explanatory power of results for downstream application. Through analysis of the training data, we distilled the results into the following pieces of reasoning, applied in the order given here:

1. Presence of many trigger topics (> 3) in an article, indicates it is hyperpartisan.

2. Presence of at least one trigger topic and a negative sentiment score for an article indicates it is hyperpartisan.

Figure 1: K W Gullers and Stieg Trenter, 1950s

3. A positive sentiment score combined with lack of trigger topics indicates a non-hyperpartisan article.

4. Presence of at least one trigger topic together with a high type token ratio *or* high ratio of questions in an article indicates it is hyperpartisan.

5. A high trigger attitude score (given in Table 2) indicates an article is hyperpartisan.

4 Results

The end results of our experiment on the by-article test set were decidedly underwhelming, with our contribution ranked 37th of 42 experiments. Our combined experimental pipeline yielded high recall (95%) and low precision (54%), meaning that it turned out to be overly sensitive to the features it was trained on. The rule set given above triggered for too many non-hyperpartisan items, with the last rule being the most permissive. We still believe that informed and hypothesis-driven analysis of content, rather than an end-to-end learning models, will result in a model of greater generality and greater explanatory power, but that the rule based combination should have been done using some learning scheme. While the precision of the resulting effort is less than stellar, we believe we have a model which allows us to continue exploring the underlying features of what the sub-genre of hyperpartisan news items is characterised by, and we also believe that the explicit representation of what features are in play will afford end users greater trust in the system's classification results.

5 Namesake

Harry Friberg was a fictional photojournalist and the protagonist of a series of crime novels by Stieg Trenter (1914-1967). The character first appeared in the novel *Farlig fåfänga*, 1944, and continued in a series of novels which have since become popular classics for their depiction of Stockholm in the 1950s. Harry Friberg was modeled on the internationally recognised photojournalist K W Gullers (1916—1998), a friend of the author.

Abstract

This paper describes our system for SemEval-2019 Task 4: Hyperpartisan News Detection (Kiesel et al., 2019). We use pretrained BERT (Devlin et al., 2018) architecture and investigate the effect of different fine tuning regimes on the final classification task. We show that additional pretraining on news domain improves the performance on the Hyperpartisan News Detection task. Our system[1] ranked 8th out of 42 teams with 78.3% accuracy on the held-out test dataset.

1 Introduction

With the rapid spread of the Internet and next-generation media development, people started to follow news through the Internet by abandoning de facto sources such as television and radio. Recent studies reveal that 43% of Americans report often getting news online (Shearer and Gottfried, 2017). In parallel with that, there also has been a massive improvement in the NLP research in news domain to keep the content true, fair and unbiased. SemEval-2019 Task 4: Hyperpartisan News Detection, is yet another attempt under this objective. Hyperpartisan is defined as being extremely biased in favor of a political party (Bastos and Mercea, 2017) and the aim of the shared task is to detect hyperpartisan argumentation in news text. Though it is an important task by itself, hyperpartisan argument detection is also considered as a very first step (or even replacement) of fake news detection, because it has been shown by (Potthast et al., 2018) that there is a high positive correlation between having a hyperpartisan argumentation and being fake for news items.

In this shared task, we seek to model this problem as a text classification task. In general, the task aims to label the text in the question with one or more classes or categories. The main question of text classification is how to mathematically represent the words/tokens such that they retain their original meaning in the context they appear. This question has been tried to be answered in many different ways so far. In earlier work, people mainly used the ”bag of words” approach in algorithms such as Naive Bayes, Decision Tree, and SVM. Then, (Mikolov et al., 2013) advanced the field further by introducing word embeddings, capturing a somewhat meaningful representation of words. However, recent studies (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2018) showed that contextual word embeddings perform quite better than traditional word embeddings in many different NLP tasks as a result of their superior capacity of meaning representation. Among those, BERT attracts researchers most because of (i) its transformer based architecture enabling faster training and (ii) state of the art results in many different tasks.

Though it is quite new, BERT has been tried in many different domains than the one proposed in Devlin et al. (2018). However, almost all of these studies have two things in common: they don't start training BERT from scratch and the target domain contains very limited data (Zhu et al., 2018; Yang et al., 2019; Alberti et al., 2019). In this study, on the other hand, we address (1) the performance of BERT by comparing its domain specific pre-trained and fine-tuned performances, and (2) in the setting where the target domain has extensively more data. In the following sections, we first summarize the BERT architecture, then give details of shared task data set, and then describe experimental setups we used to train BERT model. In the results section, we compare the performance of BERT under different settings and share our submission results for the shared task.

2 Method

Transformer[2] (Vaswani et al., 2017) originally came out as a machine translation architecture and it uses the idea of self attention mechanism (Parikh et al., 2016; Lin et al., 2017). It has an encoder-decoder design and both parts use the same novel multi-head attention mechanism. The encoder part takes an input sentence and derives a representation from it using this attention mechanism. Afterwards, the decoder generates the target sentence by performing multi-headed attention over the encoder stack.

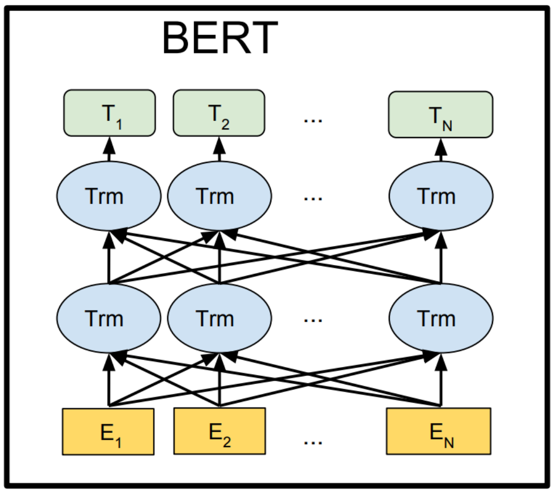

Figure 1: BERT Architecture (Devlin et al., 2018).

Figure 1 illustrates the architecture of the model. BERT learns bidirectional representations jointly on both left and right context of text making use of the encoder part of the Transformer. Devlin et al. (2018) introduced two unsupervised tasks to pretrain this architecture, Next Sentence Prediction and Masked Language Modeling. In Next Sentence Prediction task, the goal is to determine whether the sentence comes after the specified previous sentence or not. It takes two sentences as input, the latter being in its original form 50% of the time, while other times it can be any random sentence from the corpus. In Masked Language Modeling task, 15% of the words in the input sentences are masked and the model tries to predict these words. Training takes place with the combined loss of these two unsupervised tasks. Resulting representations can be further fine-tuned with a task specific layer on the top for a number of NLP tasks using appropriate supervised data.

[2]http://nlp.seas.harvard.edu/2018/04/03/attention.html

In this study, we use an open source PyTorch implementation[3] of BERT architecture. We make use of BERT-Base pretrained model provided by Devlin et al. (2018) in order to avoid pretraining from scratch. Similar to Devlin et al. (2018), we use the representation obtained from the last layer for the first token (i.e. ”[CLS]”) for the sentence representation and a softmax classifier on top of it for predicting hyperpartisanship.

3 Experiments

In this section, we first introduce data provided by the shared task and the data preprocessing step. Then, we give the details of our experiments and results with BERT under pretraining and fine-tuning settings.

3.1 Data

Task provides data that consist of 750.000 articles labelled portal-wise and 645 articles labelled manually, and they divide the former into 600.000 and 150.000 as train and development set. Portal-wise data is labelled as hyperpartisan or not, according to publishers known affinities provided by BuzzFeed journalists or MediaBiasFactCheck.com. In our experiments, we first shuffled and then split the portal-wise data into three: 705.000, 40.000, 5.000 articles for train, development and test respectively.

3.2 Preprocessing

For all our experiments we remove some unwanted text from the articles. We replaced HTML character reference for ampersand and numeric entity reference, and removed adjacent underscore characters which is possibly used as a replacement for classified information in data. We also removed lines, solely containing ”*” characters, used for separation of different news in the same article.

3.3 Input Representation

BERT restricts the input length to a maximum of 512 tokens. We select the first n tokens from the beginning of the article, because using the lead sentences of a news article has been found to be more effective for some NLP tasks (Wasson, 1998). We use the same tokenization method and embeddings as Devlin et al. (2018) to represent the words.

[3]https://github.com/huggingface/pytorch-pretrained-BERT

3.4 Fine-tuning Only

In order to show how BERT performs in news domain, our first attempt was to use the training data to only fine-tune the pretrained model for classification. We used BERT-Base which consists of 12 transformer blocks on top of each other applying 12 headed attention mechanism, hidden size of 768 and a total of 110 million parameters. We set 16 as our batch size and 2e-5 as our learning rate as recommended by Devlin et al. (2018) for fine-tuning on classification tasks.

Max Length	**Dev**		**Test**	
	Accuracy	*F1*	*Accuracy*	*F1*
128	84.99	84.91	84.40	84.36
256	88.91	88.89	**88.31**	88.31
512	**89.12**	89.09	88.15	88.14

Table 1: Classification results on our portal-wise data splits with fine-tuned BERT.

We performed experiments using 128, 256 and 512 as our maximum sequence lengths and found out that 256 gives us the best test results, as shown in Table 1. Although the results for experiments with maximum sequence lengths of 256 and 512 are relatively close to each other, we chose 256 for computational efficiency. From these results, we can argue that for news articles, the first 128 tokens do not carry enough information.

3.5 Pretraining + Fine-tuning

For the pretraining step, the data used by two unsupervised tasks need to be generated. For the Next Sentence Prediction task, originally, one would go over the articles sentence by sentence to generate pretraining data, but our data is not made of split sentences. To avoid using a tool for sentence splitting, as it would take too much time in large scale, for each document from the training data, we extract a chunk of text with a random length sampled from a uniform distribution defined as an interval between %15 and %85 of the maximum sequence length. The reason for this is to make the model more robust to non-sentential input and leave space for the second sentence. As the second sentence, 50% of the time, we select the chunk following the original one with a length that is complementing the first chunk's length up to maximum sequence length. Other times, when we need the next sentence to be random, we take a random chunk from other documents. We extract more than one sample from a single document, avoiding overlapping between chunks. For Masked LM task, we follow the same approach with Devlin et al. (2018).

Model	**Combined Loss**
BERT-Base	3.65
Our Version	**1.79**

Table 2: Results on the held-out dataset for pretraining tasks.

At the end of pretraining data generation process, we accumulated near 3.5 million samples, only running the process once on our train split, so without any duplication unlike Devlin et al. (2018) because of time restrictions. We also generated a small held-out dataset using our test split to use in evaluation. Starting from the pretrained model of BERT-Base instead of a cold start, we trained the model with a learning rate of 3e-5 and 256 as the maximum sequence length for 290k iterations. Table 2 presents the combined loss of two unsupervised tasks on the held-out data for original BERT-Base and further pretrained model with the generated data. Results show that pretraining BERT further with data from an unseen domain greatly increases its representational power.

Model	**Dev**		**Test**	
	Accuracy	*F1*	*Accuracy*	*F1*
Fine-Tuning Only	88.91	88.89	88.31	88.31
Pretraining +Fine-Tuning	**89.69**	89.67	**89.30**	89.29

Table 3: Comparison of fine-tuning only and pretraining + fine-tuning models.

After this step, we applied the same fine-tuning as previous section with the same parameters. Table 3 demonstrates that pretraining BERT with domain specific data using unsupervised tasks improves the performance of the model on the supervised classificiation task.

4 Shared Task Results

The evaluation of SemEval-2019 Task 4, Hyperpartisan News Detection task is done through the online platform of TIRA (**?**). It serves as a means of blind evaluation of the submitted model. Accuracy is used as the official evaluation metric and the deciding test set is an another manually labelled news articles set named "by-article-test-set" which was kept hidden from the participants.

Model	article-test				publisher-test			
	Accuracy	*Precision*	*Recall*	*F1*	*Accuracy*	*Precision*	*Recall*	*F1*
Fine-Tuning (publisher) + Fine-Tuning (article)	**78.3**	83.71	70.38	76.5	63.45	67.98	50.85	58.18
Pretraining (publisher) + Fine-Tuning (publisher) + Fine-Tuning (article)	73.4	66.81	92.99	77.76	64.15	60.64	80.6	69.21
Pretraining (publisher) +Fine-Tuning (publisher)	60.82	57.11	86.94	68.93	**67.25**	62.45	86.5	72.53

Table 4: Shared task results.

In our first attempt, we fine-tuned BERT with portal-wise train split using development set to get the best model. After this we further train it with 645 manually labeled data (i.e. ”by-article-train-set”), because it comes from the same sample as test data.

In our last attempt, we pretrained BERT with our portal-wise train split, and then fine-tune it as described before. Again, we further fine-tune our model with ”by-article-train-set” data. The results of our two attempts can be seen in Table 4. The third model in the table is to show the effect of the last fine-tuning step on ”by-article-train-set”.

Looking at the results of second and third models on ”by-article-test-set” shows us, although we fine-tune BERT with supervised data for the same classification task, fine-tuning on ”by-article-train-set” improves the results drastically. This may be rooted from the domain difference in between ”by-article-test-set” and portal-wise train data.

Although our experiments (Table 3) show us that pretraining BERT further with data from news domain has a positive effect on overall accuracy, we are not able to observe the similar effect on ”by-article-test-set”. The second model adapts to the publisher domain more than the first model does because of the extensive pretraining before fine-tuning. As the difference between publisher and article is highly notable from the findings before, overfitting to the publisher domain might end up hurting the generalization of the model. So, this would explain the unexpected drop of performance between the second model and the first model.

5 Conclusion

We presented a BERT baseline for the Hyperpartisan News Detection task. We demonstrated that pretraining BERT in an unseen domain improves the performance of the model on the domain specific supervised task. We also showed that the difference in news source affects the generalization. Our best performing system ranked 8th out of 42 teams with 78.3% accuracy on the held-out test dataset. From our findings, we believe that domain adaptation is important for the BERT architecture and we would like to investigate the effect of from scratch unsupervised pretraining on the supervised task as future work.

Acknowledgments

We would like to thank task organizers for their support. The study is funded by the European Research Council (ERC) Starting Grant 714868.

Howard Beale

Figure 2: Howard Beale delivering his ”I’m as mad as hell” speech.

Beale[4] is a news anchor who decides to commit suicide on live air. Instead, he gives his famous speech about modern American life and convinces American people to scream his words: ”I’m as mad as hell, and I’m not going to take this any more!”. But the media sees his breakdown as an opportunity for huge ratings. We believe that the speech is now more than ever relevant to our media. Choosing ”Howard Beale” as the team name is our scream from the windows of Academia.

Abstract

We describe the system submitted by the Jack Ryder team to SemEval-2019 Task 4 on Hyperpartisan News Detection. The task asked participants to predict whether a given article is hyperpartisan, i.e., extreme-left or extreme-right. We propose an approach based on BERT with fine-tuning, which was ranked 7th out 28 teams on the distantly supervised dataset, where all articles from a hyperpartisan/non-hyperpartisan news outlet are considered to be hyperpartisan/non-hyperpartisan. On a manually annotated test dataset, where human annotators double-checked the labels, we were ranked 29th out of 42 teams.

1 Introduction

SemEval-2019 Task 4 (Kiesel et al., 2019) asks to distinguish between articles that are extremely one-sided, i.e., extreme-left or extreme-right, and such that are not. The organizers provided two datasets:

1. **By article:** A small dataset of 645 manually annotated articles (*BA* in the following).
2. **By publisher:** A large dataset of 750,000 articles annotated using distant supervision, where an article is considered hyperpartisan if its source is labeled as such (*BP* in the following). The set is separated into 600,000 articles for training (*BP-train*) and 150,000 articles for validation (*BP-val*).

Furthermore, two test sets, one annotated by article (*BA-test*) and one annotated by publisher (*BP-test*), were hidden from the participants and they were used for getting the final scores for the competition. The task is a binary classification one, where each article is to be assigned one of two possible classes: *hyperpartisan* and *non-hyperpartisan*.

2 Related Work

Media bias was used as a feature for "fake news" detection (Horne et al., 2018a). It has also been the target of classification, e.g., Horne et al. (2018b) predicted whether an article is biased (*political* or *bias*) vs. unbiased. Similarly, Potthast et al. (2018) classified the bias in a target article as (*i*) left vs. right vs. mainstream, or as (*ii*) hyper-partisan vs. mainstream. Left-vs-right bias classification at the article level was also explored by Kulkarni et al. (2018), who modeled both text and URL structure. Some work targeted bias at the phrase or the sentence level (Iyyer et al., 2014), for political speeches (Sim et al., 2013) or legislative documents (Gerrish and Blei, 2011), or targeting users in Twitter (Preoţiuc-Pietro et al., 2017). More recent work has targeted the political bias of entire news outlets (Baly et al., 2018, 2019). Another line of related work focused on propaganda, which is a form of extreme bias (Rashkin et al., 2017; Barrón-Cedeño et al., 2019a,b). See also a recent position paper (Pitoura et al., 2018) and an overview paper on bias on the Web (Baeza-Yates, 2018). Overall, most of the above work focused on finding effective representations, e.g., in terms of features, rather than investigating the impact of sophisticated learning algorithms.

Recently, BERT, a pre-trained deep neural network (Devlin et al., 2019), based on the Transformer (Vaswani et al., 2017), has improved the state of the art for many natural language processing tasks. For example, it reached a score of 80.4 on the GLUE benchmark[1], 86.7% accuracy on MultiNLI, and F_1=93.2 on the SQuAD v1.1 question answering task. Currently, the top 11 systems in the SQuAD v2.0 use BERT.[2]

3 Method

We hypothesize that hyperpartisanship and extreme bias detection are related to sentiment analysis, which is one of the tasks in the GLUE benchmark. Given the recent success of BERT (Devlin et al., 2019) for sentiment analysis and other language processing tasks, we decided to experiment with it for hyperpartisan news detection.

In order to have a reference, we also experimented with Random Forests over TF.IDF representations. We used two BERT models: BERT without fine-tuning, and BERT with fine-tuning. We describe them in more detail below. In each case, we extracted features from the title and from the main text of the articles separately.

3.1 TF.IDF Features

In order to have a reference to compare our BERT-based approaches to, we also experimented with word-level TF.IDF features. First, we converted all text to lowercase and we stemmed it with the Porter stemmer. Then, we removed words with document frequency higher than 0.8. We then extracted two feature vectors by computing the term frequency and the inverse document frequency once on the title and separately on the body of the articles. We ended up with feature vectors of size 110,229 for the title and 1,798,179 for the content when TF.IDF vectors were computed on *BP-train* and *BA*, and 95,806 for the title and 1,507,789 for the content, when *BA* only was used.

We used the feature vectors in a Random Forest classifier with 100 estimators. Note that, differently from BERT, the TF.IDF representation is able to use information from the entire article.

3.2 Pre-trained BERT Features

Our second approach uses features extracted from Google's BERT, a model with pre-training language representations (Devlin et al., 2019). We fed to the model (*i*) the entire title and (*ii*) the first 256 tokens from the body of the article as two separate inputs, and then we obtained vector representations from the last layer of the BERT neural network. Note that we used the pre-trained BERT rather than training it with the data from the competition. Next, we concatenated the vectorial representations and we fed them to a two-layer feed-forward neural network with 32 neurons in the hidden layer. We used $\tanh$ as the activation function and a Gaussian noise with $\sigma = 0.2$.

3.3 Fine-tuned BERT Features

A natural extension of the approach in Section 3.2 is to fine-tune the BERT model on the datasets of the competition, i.e., on *BP+BA*. We performed fine-tuning on the same input used for computing the TF.IDF representations and we obtained two models, one from the titles only and one from the content of the articles only. As we did for the pre-trained model, we concatenated the internal vector representations from the last layer for both models and we passed them to the second neural network as in Section 3.2.

4 Experiments

We performed a number of experiments in order to select the best models to submit as official runs for the competition. The best model for the by-publisher dataset was selected on *BP-val* after training the models on *BP-train*. Since there was no validation set for the by-article dataset and *BA* was too small to be divided into training and validation sets, we trained our models on *BP* and we selected the best-performing one on *BA*. Table 1 shows the obtained accuracy values on *BP-val* (By-publisher) and *BA* (By-article) datasets. As we can observe, the performance of the TF.IDF model is behind those when using BERT, both with and without fine-tuning.

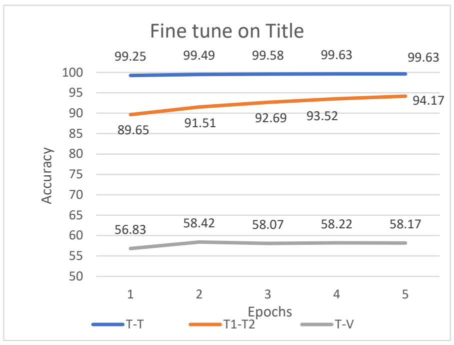
As a result, we opted for the two BERT models, trained on *BP+BA*, as our submissions for the competition. Table 2 shows the results on the hidden test sets.

Model	By publisher	By article
TF.IDF	56.13%	56.12%
BERT (no tuning)	61.20%	60.93%
BERT (fine-tuned)	61.70%	61.30%

Table 1: **Validation results:** Accuracy for our TF.IDF and BERT models on the by-publisher validation (*BP-val*) and on the by-article (*BA*) sets. The training was performed on *BP-train* and *BP*, respectively.

Model	By publisher	By article
BERT (no tuning)	63.25%	64.49%
BERT (fine-tuned)	64.60%	64.50%

Table 2: **Testing results:** Accuracy on the hidden test sets for the BERT models we submitted. Both models were trained on *BP+BA*.



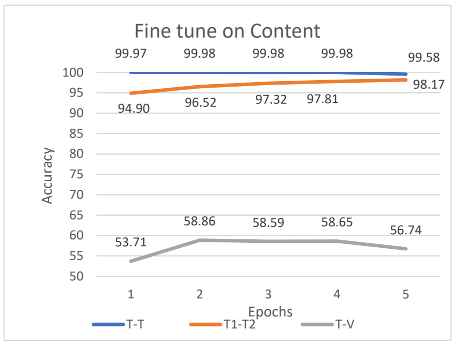


Figure 1: **Title as input:** Accuracy, at each epoch, for the fine-tuned BERT model. T-T stands for training and evaluating on *BP-train*, T1, T2 for training on the first half of *BP-train* and evaluating on the second half, T-V for training on *BP-train* and evaluating on *BP-val*.

Figure 2: **Content as input:** Accuracy, at each epoch, for the fine-tuned BERT model. T-T stands for training and evaluating on *BP-train*, T1, T2 for training on the first half of *BP-train* and evaluating on the second half, T-V for training on *BP-train* and evaluating on *BP-val*.

4.1 Result Analysis and Post-Submission Experiments

When developing the model for the submission, we focused on the datasets with by-publisher annotation. This is probably the reason why we performed much better on the by-publisher hidden test set, 7th out 28 teams, than on the hidden by-article test set, 29th out of 42 teams.

Another possible reason for the low results on the by-article hidden test set is overfitting on *BP*: our model might have learned to discriminate the publishers appearing in *BP* instead of the required labels *hyperpartisan* / *non-hyperpartisan*. Recalling that *BP-val* does not contain any articles from the publishers in *BP-train*, we conducted an experiment to see whether there was a correlation between the articles in the different partitions of the provided dataset. In particular, we created a recurrent model with a single layer of 1,024 GRUs, and we trained it on 80% of the data and we evaluated it on the remaining 20%. The model achieved 99.99% accuracy at predicting whether the article was from *BP-train* or from *BP-val*.

We further performed three additional experiments with the fine-tuned BERT model: (*i*) training and evaluating on *BP-train*, (*ii*) training on the first half of *BP-train* and evaluating on the second half of *BP-train*, and (*iii*) training on *BP-train* and evaluating on *BP-val*.

Figure 1 shows the accuracy for BERT at each epoch when using titles for the three configurations (*i*)–(*iii*) above: T is *BP-train*, T1 and T2 are the two halves of *BP-train*, and V is *BA*.

Figure 2 reports the performance for the same experiments when using the body text of the articles as input. While the accuracy for the curves T-T and T1-T2 is close to 100% or is monotonically increasing with respect to the number of training epochs, the curve T-V does not show the same behavior, suggesting that 58.42% is close to the best performance that can be achieved in this setting. The accuracy values, although not directly comparable, show that there is a huge gap between the performance on a dataset with the same set of publishers (T-T and T1-T2) vs. on a dataset where the news comes from a different set of publishers (T-V), thus supporting our hypothesis.

5 Conclusions and Future Work

We have described our participation in SemEval-2019 task 4 on hyperpartisan news detection. In particular, we explored using TF.IDF and BERT-derived representations, and we found the latter to be more informative. Thus, we submitted two BERT models as our official runs to the competition: one with and one without fine-tuning. Interestingly, fine-tuning the model did not yield any sizable improvements. Our analysis suggests that our BERT models might be learning the source of the article, rather than whether it represents a piece of hyperpartisan news.

In future work, we plan to experiment with the big cased BERT model and to combine it with stylistic features, which have been proven successful for the hyperpartisanship detection task.

Abstract

In this paper we describe our participation in the SemEval 2019 shared task on hyperpartisan news detection. We present the system that we submitted for final evaluation and the three approaches that we used: sentiment, bias-laden words and filtered n-gram features. Our submitted model is a Linear SVM that solely relies on the negative sentiment of a document. We achieved an accuracy of 0.621 and a f1 score of 0.694 in the competition, revealing the predictive power of negative sentiment for this task. There was no major improvement by adding or substituting the features of the other two approaches that we tried.

1 Introduction

With the growing role of social media in politics it becomes ever more important to safeguard the integrity of information people consume. News articles about important events in the world can affect political choices. It is therefore crucial to pinpoint what information people know to be trustworthy, factual and unbiased. One way to do this is by using a computational system that detects an author's or publisher's bias in a news article. In Potthast et al. (2018) we have seen that it is possible to build such a system by relying on the writing characteristics of a text.

To shed more light on potential linguistic computational methods for hyperpartisan news detection, we present our participation in the SemEval 2019 shared task on hyperpartisan news detection, of which the purpose is to identify whether a news article contains *hyperpartisan* (Kiesel et al., 2019) content. For our contribution, we set out to experiment with various types and levels of features, such as *a*) **sentiment** that could indicate an author's bias (Recasens et al., 2013), *b*) **bias-laden words** such as assertives, factives and hedges, and *c*) part-of-speech (from now on POS) **filtered n–grams**. In the end, we decided to submit a model that only uses the negative sentiment of an article as a feature. We obtained an accuracy of 0.621 and a f1 score of 0.694 on the by-article test set, which resulted to the 30th place in the competition. On the by-publisher test set, the systems accuracy was 0.589 and its f1 score 0.623 (20th place).

2 Related Work

One of the first studies on detecting linguistic bias in online texts were mainly focused on detecting biased language in Wikipedia articles. Despite the domain difference, this task is related to ours because Wikipedia is also a source of information which should contain unbiased language. Systems that were employed for this task used a combination of linguistic features, such as POS n-grams and binary features representing the usage of bias words, assertive verbs, factive verbs, hedges and sentiment features (Recasens et al., 2013; Hube and Fetahu, 2018). Most of these features were derived from existing lexicons. For sentiment features, both studies used a sentiment polarity lexicon from Liu et al. (2005).

A similar set of features was used in Hutto et al. (2015) to detect sentence based bias in news articles. Yet, they obtained sentiment features using the VADER sentiment analysis tool (Hutto and Gilbert, 2014). Because of their focus on sentence-based bias detection and the high relatedness of their study, it was interesting to investigate whether we could use the same features on document-level classification.

The studies that we discussed so far proved that it is possible to detect bias by using simple computationally derived linguistic features. On the other hand, we work with a much larger amount of documents which also come from a different genre.

Because of these aspects, it was fruitful to investigate how effective these features would be.

3 Data

We worked with the data provided by the organizers of the task. We show an overview of the data we used for the competition in Table 1. The sets named 'by-publisher' are automatically labeled using the publisher of the article, whereas the articles from the 'by-article' set were manually labeled through crowd-sourcing (Vincent and Mestre, 2019).

For the competition, we trained our models on the by-publisher training set. We used this data because of its size and the equal frequency distribution of the labels. We took the model with the highest accuracy on the by-publisher validation set for our final submission. After the evaluation period, we submitted several models that were trained on the by-article training data to find out whether we should have submitted a model that was trained on the by-article data.

name	**function**	**size**	**distribution**
by-publisher	training set	600,000	50-50
by-publisher	validation set	150,000	50-50
by-publisher	test set	4,000	50-50
by-article	training set	645	37% hyper. 63% mainstr.
by-article	test set for competition	638	50-50

Table 1: An overview of the data that we used for the shared task.

4 Final System

4.1 VADER Sentiment Analysis

The system we submitted for final evaluation is a simple SVM classifier with a linear kernel. It uses the LinearSVM[1] implementation from *scikit-learn* (Pedregosa et al., 2011) with default hyperparameter settings *C=1.0*, the *'squared hinge'* loss function and the *'l2'* penalization norm. The only features that the classifier uses to make a prediction is the intensity of the negative sentiment of each document which varies between 0 (neutral) and 1.0 (extremely negative). This score is computed by the freely available package **V**alence **A**ware **D**ictionary and s**E**ntiment **R**easoner[2] from NLTK(Loper and Bird, 2002). VADER was developed by Hutto and Gilbert (2014) and is a rule-based and lexical model for general sentiment analysis. Even though VADER is specifically developed to perform sentiment analysis in social media texts, the tool works reasonably well on determining the sentiment of news articles according to our observations.

4.2 Results

The system we submitted reached the 30th place with an accuracy of 0.621. The other scores are reported in Table 2. It also displays the performance of our model on the *by-publisher* development set and the *by-article* test set. We obtained a high recall on the official test set, which corresponds to the performance on the *by-article* test set. Nonetheless, since the evaluation script only tracked the *hyperpartisan=true* class and our model was apparently biased towards a hyperpartisan prediction, this metric is not informative because it implies that the mirrored *hyperpartisan=false* class has a much lower recall.

Furthermore, the scores in Table 2 show that our model neither performed well on the *by-article* (0.519 accuracy) nor the *by-publisher* (0.562 accuracy) development set. In particular, the accuracy on the *by-article* set is even lower than the accuracy of the baseline. Nonetheless, the model performed better on the official test set, since the accuracy and f1 score were substantially higher. We surmise that this is related to the inconsistent similarities of the data sets rather than the predictive power of the features.

	Accuracy	**Precision**	**Recall**	**F1**
official test set	0.621	0.582	0.860	0.694
by-publisher	0.562	0.559	0.585	0.572

Table 2: Evaluation metrics (of the true class) across different data sets of correctly detecting the hyperpartisan class.

5 Alternative Methods

Despite the low performance on the *by-publisher* development set, we submitted our final system because it had the highest accuracy on this development set (0.562 accuracy) and the competition evaluation was based on accuracy. In this section,

[1]https://scikit-learn.org/stable/modules/generated/sklearn.svm.LinearSVC.html

[2]https://www.nltk.org/_modules/nltk/sentiment/vader.html

Features	Set-up	Accuracy	Precision	Recall	F1 score
Tf-idf	Word uni-grams with default settings	0.5598	0.5412	0.7854	0.6408
	Word uni-grams with default settings + negative sentiment	0.5597	0.5411	0.7858	0.6409
Sentiment	positive score + negative score + compound	0.5247	0.5201	0.6373	0.5729
	compound score	0.4310	0.4389	0.4962	0.4658
	negative sentiment	0.5616	0.5589	0.5851	0.5717
	positive sentiment	0.4752	0.4779	0.5354	0.5050

Table 3: Performance of other models *trained* on the by-publisher training set on predicting hyperpartisan.

we outline the two other approaches with which we experimented: bias-laden words and filtered n-grams. We also present our attempts to improve the accuracy of our best model on the development set by combining features from the other two approaches. The performance of these models and other detrimental models on the development set are shown in Table 3.

5.1 Sentiment

VADER Sentiment In addition to the negative sentiment score, we also conducted experiments with systems that used several combinations of the negative, positive and compound score provided by VADER. However, none of the combinations outperformed the accuracy of the system that only took the negative sentiment into account. Moreover, as shown in Table 2, the compound score yielded the lowest performance. In our preliminary experiments, we also experimented with the neutral sentiment score but this led to low accuracy scores compared to the other scores. Besides, the evaluation procedure was based on predicting the hyperpartisan is true class, for which we can assume that its corresponding article is not neutral.
We tried to improve the score of the submitted model by using ordinal scales instead of interval variables, in which documents with a negative sentiment score exceeding 0.5 were labeled as having a ”high” negative sentiment and ”low” otherwise. This did not lead to improvement, which reveals that the raw sentiment score is a better predictor.

Other Sentiment Features We also developed systems that calculated the overall sentiment of a text by using the lexicons of positive and negative words from Liu et al. (2005). We experimented with two methods (1) by counting the amount of positive/negative words and (2) by using binary features where the value was True if it contained one of the words in the lexicons. This method was also used in Recasens et al. (2013). Nonetheless both methods did not even reach an accuracy of 30 percent.

5.2 Bias-Laden Words

Verbs We experimented with the same set of verbs as the mentioned previous studies: assertive verbs, factive verbs and hedges (Hooper, 1975). These words carry cues that may indicate bias. For instance, assertive verbs can be used to assert the truth of a proposition (i.e. *point out*, *claim*, *states*) and factive verbs can be used to presuppose the truth of their corresponding complement clause (i.e. *realize*, *revealed*, *indicated*). The usage of these verbs was encoded in the same way as we did for the lexical sentiment features. Yet, it was not possible to build accurate classifiers that used these features, since the accuracy fluctuated between 0.20 and 0.30. Also, we could not increase the performance of other systems by adding these features.

N-gram BOW We additionally tried to derive bias-laden words through BOW methods, as we surmised that the hyperpartisan texts contained more bias-laden words than legitimate news articles. Because of the size of the training set, we only experimented with uni-gram features (with tf-idf weighting). With this set-up, we obtained a similar accuracy score as when we used only the negative sentiment (see Table 2). Yet, we did not submit the uni-gram model for the competition because we surmised that the effectiveness of bag-of-word features would be more sensitive to the topic of the articles. As an effect, the generalizability on unseen data could be low.

5.3 POS-based N-gram Filtering

We experimented with POS-based features early on in an attempt to model *how* and *where* humans would perceive bias in a text on word-level. We found that adjectives, adverbs and (proper) nouns all somewhat contributed to the tone of a text. However, confidently identifying bias proved rather challenging in many cases. Nouns frequently provide thematic and topical information

Training data	System	Accuracy	Precision	Recall	F1 score
by-publisher	Submitted system: negative sentiment only	0.621	0.582	0.860	0.694
	Word uni-grams + negative sentiment	0.605	0.564	0.920	0.700
	POS filtering**	0.657	0.636	0.738	0.683
	Positive score + negative score + compound score	0.611	0.590	0.732	0.653
by-article	Character 3-to-5 grams	0.772	0.825	0.691	0.752
	Word uni-grams	0.755	0.803	0.675	0.734
	POS filtering	0.537	0.522	0.863	0.650

Table 4: Performance of models on the by-article test set submitted after the evaluation period. **only trained on 100k randomly obtained documents of the by-publisher set (with a balanced frequency distribution of labels).

about a text and adverbs and adjectives can indicate a level of subjectivity. Modals such as *would*, *could* and *must* could additionally carry assertiveness that could be related to bias (Recasens et al., 2013; Hube and Fetahu, 2018). We tried modelling this by extracting *n-grams* that followed certain patterns such as *a*) **nouns** in the middle of a trigram *b*) **particles** in the middle of a trigram *c*) **modal** verbs in the middle of a trigram *d*) **nouns** and their closest preceding adjectives/adverbs *e*) **adjectives/adverbs** and words after them. The n-grams essentially became a new, filtered representation of the *document* and would be weighted using tf-idf. We tested this intuition by splitting the training data. The results were quite promising as we (unofficially) achieved f1 scores of 75-85% using only 200,000 documents. However, results disappointingly floated between 53% and 58% when tested on the development data.

We concluded that the *n-grams* we extracted were not indicative enough to generalize well across different data sets, since they were essentially only a subset of the total body of possible *n-grams*.

6 Other Submissions

After the final submission deadline, we continued submitting models to investigate differences between the by-article and by-publisher training data sets. We also submitted models that solely relied on bag-of-words features, with which we experimented in early stages but discarded in our final submission because of the low performances on the by-publisher validation set.

The results of our submissions after the deadline (Table 4) reveal that bag-of-words and bag-of-characters are indeed useful when the model is trained on the by-article data. In particular, we could have obtained a high accuracy in the competition with a model trained on the by-article set, for instance by using character 3-to-5 grams (0.772 accuracy). Another observation is that the POS filtering model obtained a low accuracy on the test set, even when it was trained on the by-article data. Thus, this seems to indicate that bag-of-words are more effective than fine-grained POS filtering.

7 Conclusions

Detecting biased language is a difficult task because of the subjectivity of the task and the subtlety of linguistic context cues. *Bias* is a broad term which can be applied to many different areas and is not solely restricted to politics or economics. Per our own observations, it was difficult to exactly pinpoint the bias of a biased article.

We achieved promising results after our final submission with bag-of-words and bag-of-character n-grams. This indicates that a bag-of-words approach is able to identify token-based patterns in corpora that are related to bias. However, the reliability of a bag-of-words approach does depend on the lexical similarity between training and test data. We demonstrated this through our contradicting results on the provided validation and official test data.

Sentiment proved to be quite a strong feature that can already separate biased from unbiased articles, although more heuristics are needed. This could be combined with the title of the article which, much like sentiment, tells us something about the *entire* article. It could also be interesting to experiment with more general cues about *entire* texts rather than treating texts as only bags-of-words. This could help develop a system that scales better across different corpora and domains.

Abstract

This paper describes the approach of team Kit Kittredge to SemEval 2019 Task 4: Hyperpartisan News Detection. The goal was binary classification of news articles into the categories of "biased" or "unbiased". We had two software submissions: one a simple bag-of-words model, and the second an LSTM (Long Short Term Memory) neural network, which was trained on a subset of the original dataset selected by a voting system of other LSTMs. This method did not prove much more successful than the baseline, however, due to the models' tendency to learn publisher-specific traits instead of general bias.

1 Introduction

With the proliferation of online news agencies after the rise of the Internet, access to information about what is going on in the world has never been more widespread. How that information is presented, however, can have a large influence on what conclusions the reader draws from it. Being able to automatically identify hyperpartisanship (bias or adherence to one party or faction over others) in a news article would help individuals in their news consumption and potentially result in a better-informed population.

As suggested, the challenge approached in this paper is that of hyperpartisan news detection: a binary classification problem (biased or unbiased) with news articles as data. This task can be considered as related to stance detection and in general, sentiment analysis. The challenge was organized as Task 4 for SemEval 2019 (Potthast et al., 2018) (Kiesel et al., 2019). Final submissions were submitted through TIRA, with the test datasets hidden (Potthast et al., 2019).

First in this paper, Section 2 includes an introduction of the provided dataset and a description of preprocessing techniques used for our approach. Section 3 describes the first submitted software, a bag-of-words model. Section 4 continues with our second approach, an LSTM trained on a subset of the original dataset, and a description of how that subset was selected.

Section 5 presents our results on the test set and Section 6 delves into analysis, presenting potential reasons why the models did not perform very well.

2 Data

During the course of the task participants were granted access to different datasets with which to work.

A training dataset of 600,000 articles and a validation dataset of 150,000 articles were both released to participants. Both sets contain 50% unbiased and 50% biased articles, and of the latter, half are left-biased and the other half right-biased (in terms of their placement on the political spectrum). Importantly, these articles were all labeled with the overall bias of their publisher, which was obtained by MediaBiasFactCheck.com and BuzzFeed. The set of publishers whose articles appear in the training set has no overlap with the publishers of the validation set, and neither has any overlap with the publishers whose articles appear in the inaccessible test set.

We consider the labels of these datasets to be noisy: though publishers may have an overall bias, it is likely that most biased news agencies do not publish only biased articles, just as most unbiased news agencies may occasionally publish a biased piece.

Also relevant is a third released dataset referred to in this paper as the *byarticle* dataset. Unlike the other datasets, this one contains articles which were labeled individually through crowdsourcing. It is small, at 645 articles, and unbalanced, at 63% unbiased and 37% hyperpartisan.

2.1 Preprocessing

Certain preprocessing tasks were carried out on the entire dataset pre-training, and also applied to the test set during evaluation.

Some cleaning tasks required segmentation of texts into sentences or words using the Natural Language Toolkit (NLTK) (Bird et al., 2009).

Special characters, double spaces, more than three dots in a row, and any failures in character translation (for example, "gun control" becoming ?gun control?) were replaced or removed. Regular expressions were used for some of these tasks, as well as for removing `img` or `html` tags and URLs. Another list of phrases were summarily removed from each text: those which were likely byproducts of the articles' retrieval from their websites. These included "Continue Reading Below...", "Image Source:", "Opens a New Window", and so on.

As will be discussed, a recurring problem encountered by our models was the tendency to learn publisher-specific traits and not hyperpartisanship itself. To combat this we included methods to remove potential publisher-specific text, especially names and emails of the authors of the articles, in our preprocessing step.

3 Software 1: Bag-Of-Words

Our first approach was a bag-of-words baseline for initial exploration of the dataset and comparison with the more complex second approach.

3.1 Tokenization / Lemmatization

Texts were tokenized into words, and the words reduced to their lemmas, using spaCy (Honnibal and Johnson, 2015).

3.2 Vectorization

First we created a vocabulary of the most common 4000 words in the overall corpus (all datasets), excluding stopwords from a list compiled by scikit-learn (Pedregosa et al., 2011).

We also excluded from the vocabulary words from an exceptions list, in an attempt to reduce the problem of overfitting to the article publishers. This exceptions list was formed by counting all words in the training and validation datasets, and gathering those words which appeared five times more often (relative to the size of the corpus) in one set than in the other. Some of these terms were location-specific (*abq*, *lobos*, *nmsu* — likely a publisher based in New Mexico) and others hinted at coverage of a certain topic (*samsung*, *boeing*, *verizon* — possibly a publisher which wrote often about the stock market). The intent behind this was to help avoid the model picking up, for example, that the presence of terms surrounding New Mexico automatically meant a certain label.

With a final vocabulary, each text was then converted to a vector of length 4000, wherein each dimension is the count of the corresponding vocabulary word in that text.

3.3 Model

Using scikit-learn, the training and validation datasets were vectorized according to the previously described specifications and then fit to a logistic regression model. This was then submitted to TIRA.

4 Software 2: LSTM

Long Short Term Memory networks (or LSTMs) are a form of Recurrent Neural Networks (or RNNs) which is capable of learning long-term dependencies. Given the nature of the problem and the data — a text being a sequence of words, the relationship between them as important as the words themselves — we chose to develop a model with this architecture.

4.1 Word Embeddings

To transform the article texts into vectors able to be processed by the neural network, we chose to train our own skip-gram word embeddings on the total given corpus (training, validation and byarticle datasets). Embeddings of 50 dimensions (chosen mostly arbitrarily, but in part due to computational limits) were trained using the Python package gensim, for 10 epochs, including words in the vocabulary which appeared in the corpus over five times (Řehůřek and Sojka, 2010). The total vocabulary size was 457,197 words.

4.2 Vectorization

Texts were first transformed into arrays of the shape (100, 50), wherein 100 was the cutoff or maximum text length and 50 was the dimensionality of the word embeddings. Texts shorter than 100 words were padded with zero-vectors to keep the shape consistent to feed into the network.

Model	Test Dataset	Accuracy	Precision	Recall	F1
Bag-of-Words	byarticle	57.8	54.7	90.8	68.3
LSTM	byarticle	58.3	55.8	79.2	65.5
Bag-of-Words	bypublisher	61.2	57.8	83.4	68.2
LSTM	bypublisher	65.2	64.7	67.1	65.9

Table 1: Results on the test datasets.

4.3 Architecture

The model consists of a single LSTM layer with 50 units, followed by a dropout wrapper with a keep probability of 0.75 to help prevent overfitting. Next is a standard feedforward neural network output layer. AdamOptimizer was used with a 0.001 learning rate as well as softmax cross-entropy loss for optimization.

All LSTM models were trained using Tensorflow for approximately 2 epochs (Abadi et al., 2015).

4.4 Voting System

Knowing that the biggest obstacle faced so far was the tendency of models trained on the datasets to overfit to the publishers and not bias itself, we chose to pare down the dataset for the final submission. In theory the ideal dataset, in which there is no noise from the publisher-based labels, is contained within the original dataset. To find that subset — or at least to get closer — we implemented a voting system.

Three LSTMs of the previously described architecture were trained: one each on the training, validation and byarticle datasets. We then collected predictions from each LSTM, on each article in each dataset. The articles which all three LSTM models correctly labeled were pulled into a new dataset labeled *agree*. This dataset, in total size 162,046 articles with 37% biased and 63% unbiased labels, was what we trained our final model on.

4.5 Retrained LSTM

Once the new datasets were compiled from the voting system based on the originals, a new LSTM with the same architecture was trained on the combined data. This model was submitted to TIRA as our second software.

5 Results

Both approaches were scored on the hidden test datasets using TIRA. One of the two test datasets was labeled individually by article, referred to in this paper as the *byarticle-test* dataset, including 638 articles with no publisher overlap with any of the given corpora. The other, like the training and validation sets, was labeled overall by publisher, here referred to as the *bypublisher-test* dataset, with a total of 4000 articles, also including no publisher overlap with other datasets.

Results can be seen in Table 1. The LSTM tended to outperform the Bag-of-Words model in accuracy, but had lower f1 scores. All results showed higher recall than precision — and except for the case of the LSTM with the bypublisher-test set, markedly higher. By accuracy, the best result was the LSTM on the bypublisher-test set.

6 Discussion

In the published leaderboard, most teams had higher scores on the test dataset which was labeled by article rather than the one labeled by publisher; overall, the highest accuracy was over 10% higher on the byarticle-test set than on the bypublisher-test one. Our approaches, on the other hand, both performed better on the bypublisher-test dataset. This could be in part because we did not spend too much time optimizing over the small byarticle dataset which was released to us — trying additional techniques to maximize performance over this set could be a task for future work.

Why our results are better on the bypublisher-test sets is an interesting question. Our efforts in both approaches were focused on enabling the models into generalizing about bias, instead of on recognizing only which articles belong to which publishers. Better performance on the bypublisher-test run than on the byarticle-test run suggests that our efforts may have paid off, but in the sense that we are better able to identify biased publishers instead of biased articles. That is, the question that the first models were answering was, "Does this article belong to X set of publishers, or Y set of publishers?" We attempted to instead answer the question, "Is this article biased?" But higher accuracy on the bypublisher-test dataset indicates that we might instead answer the question, "Does this article belong to a biased *publisher*?"

6.1 Precision/Recall

Across all models recall was consistently higher than precision. Our approaches therefore were correctly picking out hyperpartisan articles, but also misclassifying unbiased articles as biased. There are a variety of reasons why this could happen: quotes by partisan speakers could affect a rating of an unbiased article which discusses it, or certain topics could be more often reported in a partisan manner so that unbiased articles around them are rare and misclassified. A closer examination of the test dataset results would be needed for a more concrete discussion.

6.2 Software 1 Exceptions List

The exceptions list was created with the intent of removing words from the vocabulary which were extremely lopsided in their use between publishers (as in, some publishers, or just one in particular, were much more likely to use the term than others). While initial results looked promising, it is possible that the method was not robust enough, and some unigram indicators of a certain publisher still ended up in the final model.

6.3 Software 2 Dataset: Voting System

The idea behind the voting system was to pare down the original dataset, reducing noise and therefore focusing on the data points where bias was most salient — and could as such be picked up by models trained on different publishers. Theoretically these articles would all have characteristics common to biased articles of all publishers. When put together, then, the hope was that a model trained on this subset of the dataset would learn those common characteristics and not just the publisher-specific ones.

There are many things that could have gone wrong with this system, however. Our cutoff for the news article length may have been too short, for example. Secondly, Since the three models used for voting did not have very high accuracy on each other's datasets in the first place, the level of noise may not have been reduced at all. Furthermore, the original training dataset was four times as large as the validation dataset, and the byarticle dataset was far smaller than either. Their subsets after the voting system was applied were equally unbalanced. When combined and used for training the final LSTM, it could have been unbalanced enough that the model learned mostly from the data from the original dataset, and the features from those publishers.

7 Conclusion

In approaching Task 4 (Hyperpartisan News Detection) in SemEval 2019, we developed two models for submission: a Bag-of-Words logistic regression model and an LSTM neural network trained on a subset of the original training and validation sets. While neither model reached high accuracy rates on the test datasets, their methods still provoke some discussion on how to better avoid fitting to the publishers and not bias itself.

8 Namesake

Margaret Mildred "Kit" Kittredge is a character from the American Girl doll and book series. She was born in Ohio in the 1920s and wanted to become a reporter when she grew up. In her room in the attic, she would write her news articles on a typewriter to share with her family.

Abstract

This paper reports an experiment carried out to investigate the relevance of several syntactic, stylistic and pragmatic features on the task of distinguishing between mainstream and partisan news articles. The results of the evaluation of different feature sets and the extent to which various feature categories could affect the performance metrics are discussed and compared. Among different combinations of features and classifiers, Random Forest classifier using vector representations of the headline and the text of the report, with the inclusion of 8 readability scores and few stylistic features yielded best result, ranking our team at the 9^{th} place at the SemEval 2019 Hyperpartisan News Detection challenge.

1 Introduction

Current influential technological megatrends, such as, smart phones and social networking often come with some unwanted side effects - prolific spread of false, biased and misleading information, for instance. In the past few years, the potential threats and consequences of disseminating fake news has reinforced the discussion on the responsibility of social media and governments to tackle the issue, sooner rather than later. Enabling users to report on and be informed of untruthful, deceitful and fraudulent content and sources is expected to become a type of guiding principle for those involved in publishing and disseminating content online.

There is a blurred line between deceptive writing and hyperpartisan reporting, producing extremely biased articles in favor of one political party, cause or individual, while preserving the format and appearance of professional articles. Adherence to the ethics and rules of objective reporting is frequently debatable when it comes to political analysis in media articles. While certain truthful facts are present, they are carefully entangled in a narrative package with biased views, populistic messages and divisive topics, using language that polarizes and flares emotions. Rather than labeling and grading news articles on the truth continuum, researchers usually opt for identification of the phenomenological and contextual features of distinguishing hyperpartisanship in online news articles.

People use diverse set of cues extrapolated from published text and external knowledge and sources, when verifying the veracity of information imparted by others. A large body of evidence documents the impact of deception has on language choices people make. A notable body of work exists revealing insights into the language of deceit in interrogation context (Porter and Yuille, 1996), court hearings (Coulthard et al., 2016), or personal relationships (Miller et al., 1986). Empirical studies still remain the primary manner in which manifestation of deceptive human behavior online is studied. Analysis of political language (Rashkin et al., 2017), partisan media (Gervais, 2014), and news publishing (Rubin et al., 2015) were also guided broadly by the questions pertaining to detecting deception in written language.

In what follows, we highlight the primary findings of our empirical research in identifying tangible verbal indicators as they relate to our central commitment of detecting deception in text. In this paper we examine the impact of grammar and psycho-linguistic word categories, syntactic word connotations and text complexity metrics on the task of distinguishing hyperpartisanship in real news articles.

2 Related Work

Given how prolific fake content has become, the phenomenon has challenged the interdisciplinary research community and has been the focus of notable research studies, especially in the field of natural language processing (NLP) and social network analysis.

While it is beyond the scope of this paper to exhaust a review on the topic, of particular relevance to the authors of this paper are the works in monitoring and detecting what is considered untruthful and deceitful content. The differences in the type of conveyed text and the underlying context are likely to afford contrasting models of deception i.e., combination of linguistic features and selection of classification algorithm they rely upon.

It is interesting to note that rather simple linguistic analysis could be successful on a number of NLP tasks relating to detection of deceptive text, such as fake news, opinions, trolling, hate and abusive language, including hyperpartisan reporting. This indicates that it is not semantics, but rather syntactic and pragmatics of the language style of the author that give clues of the underlying cognitive states relating to deception.

Low-level linguistic features such us word counts and frequencies (Horne and Adali, 2017), language modeling (Conroy et al., 2015; Potthast et al., 2018; Pérez-Rosas et al., 2018), part-of-speech tags (POS) (Lim et al., 2018; Conroy et al., 2015), Probabilistic Context Free Grammar (Feng et al., 2012), readability scores (Potthast et al., 2018), and their combinations have proved to be successful with varying performance and generalization power, especially for testing on cross-domain datasets. The research study most closely related to ours, proposes a model for hyperpartisan classification that yielded accuracy of 0.75 (Potthast et al., 2018), which will be used as a baseline accuracy against which our model will be compared.

The use of deep learning architectures (Wang, 2017) have complemented the list of traditional machine learning algorithms (ML), such as SVM (Yang et al., 2017; Lim et al., 2018), logistic regression, discriminant analysis, decision trees (Potthast et al., 2018) and neural networks (Vuković et al., 2009), used in the field of deceptive detection. An unavoidable discussion on the trade-offs between generality and specificity of the models has never ceased to flavor the interpretation of results and point out directions for future improvements.

3 Dataset

Two datasets of news articles were available for the SemEval 2019 Task 4: ”Hyperpartisan news detection” (Kiesel et al., 2019), one labeled *”by-article”* by professional journalists, and the other labeled *”by-publisher”*.

Our empirical study was focused on the former one, whose training dataset consists of 645 articles. The testing dataset, which is not publicly released, are made available via TIRA (Potthast et al., 2019), and it contains 628 *by-article* articles. It is balanced and consists of articles from previously unseen publishers in the training sets. For evaluation purposes, we randomly choose 80% of the *by-article* data for training, and the remaining 20% for validation.

4 Our Methodology

In this paper, we further enhance the feature set explored by related research, and explore few features that appeared to be promising to capture syntactic and pragmatic aspect of hyperpartisan reporting.

Word vector representations: Though previous research studies on this topic use language modelling i.e., frequencies of n-grams in an article to unmask the style of hyperpartisan reporting, our view is that it is distributed word vector representations might augment the model in capturing the style of deceptive and biased political reporting.

Word2Vec has been emphasized as providing better performance, generalizability and transfer of knowledge on a number of related NLP problems. In consequence, word2vec, pre-trained on part of the Google News dataset consisting of cca 100 billion words (Mikolov et al., 2013) was utilized in our model.

Indication of hyperpartisan language and style could be found in various parts of a journal article - article headline and individual sentences could be indicative of biased and partisan language. Transmission of context, set by a sentence that is entailed in the consecutive sentences in a document, is the core idea underlying the proposed word vector representations on two different levels, one on a sentence level and another on a document/article level. Consequently, three word embeddings representing the headline, the sentences and the entire document text were concatenated creating the final word2vec vector.

For the word and sentence tokenization we use the Natural Language Toolkit (NLTK)[1].

Readability scores: Readability scores measure the ease of comprehension of a particular style of writing based on metrics such as, word and sentence length and various weighting factors and ratios, making them closely related to the quantitative aspect of text complexity. In accordance with successful practices reported in previous research in text deception detection (Pérez-Rosas et al., 2018; Yang et al., 2017), we use eight such scores[2], namely Flesch Reading Ease (Flesch, 1948), Flesch Kincaid Grade Level (Kincaid et al., 1975), Coleman Liau Index (Coleman and Liau, 1975), Gunning Fog Index (Gunning, 1952), SMOG Index (Harry and Laughlin, 1969), ARI Index (Senter and Smith, 1967), LIX Index (Björnsson, 1968) and Dale-Chall Score (Chall and Dale, 1995).

General stylistic measures: We also employ elementary measures - number of characters, total words, different words, sentences, syllables, polysyllable words, difficult words (as defined by (Dale and Chall, 1948)), and words longer than 4, 6, 10 and 13 characters.

Psycho-linguistic features: Motivated by previous studies in the field of deceptive text analysis, including fake news examination (Cunha et al., 2018), exploring fraudulent hotel reviews (Fast et al., 2016), characterizing and detecting hateful Twitter users (Ribeiro et al., 2018), we explore the effect of all 194 types of features from the Empath (Fast et al., 2016) lexicon on the task of hyperpartisan news detection.

Part-of-speech tagging: The frequencies of part-of-speech (POS) categories of the words in text, in particular frequencies of nouns, proper singular nouns, personal and possesive pronouns, wh-pronouns, determiners, wh-determiners, cardinal digits, particles, interjections, adjectives, verbs in base form, past tense, gerund, past participle, 3rd and non-3rd person singular present, were added to our model.

Augmented stylistic feature set: Instead of eliminating stop-words, we take the number of their occurrences as a feature. We use the corpus made available by NLTK. Frequencies of interrogative (how, when, what, why) and all-caps words, negations (not, never, no) and punctuation marks are as stylistic features. The stylistic features were normalized by article length.

Bag-of-words of hyperlinks: The links in each article are abbreviated to their base URL form, using Python's Urllib[3], and further transformed into a bag-of-words (BoW) representation. Both internal (anchor links) and external links in respect to the articles, are taken into account for the BoW representation.

5 Results and Discussion

The relationship between various predictive models and evaluation metrics has always been a topic of interest in machine learning and NLP, and this section describes the performance of the feature sets we have experimented with. It is important to note that since the features we test can take values from different ranges, we perform min-max normalization on all of them to bring them in the $[0, 1]$ interval.

We have experimented with various classifiers, such as Logistic Regression, Multilayer Perceptron and Extra Trees, although the most successful one was Random Forest (RF) classifier with 100 trees, which is in line with the findings of the baseline model (Potthast et al., 2018). We use the Python implementation of the classifiers from the Scikit-learn library. [4]

While aiming for achieving high accuracy, avoiding overfitting was also an objective to ensure the model is robust enough to handle previously unseen data. The evaluation results obtained by the models on *by-article* validation and test datasets are presented in Table 1. A short description of the evaluated models follows:

- **Model 1** - A model that incorporates three concatenated word representation vectors, eight readability scores and the general stylistic features
- **Model 2** - The set of features of Model 1 augmented with psycho-linguistic features
- **Model 3** - Frequencies of the POS tags and additional stylistic features were added to the set of features included in Model 2
- **Model 4** - An extension of Model 1 feature set that included hyperlink features

4	0.763	0.851	0.637	0.729	0.837	0.903	0.609	0.727
5	0.710	0.784	0.580	0.667	0.806	0.784	0.630	0.699

Table 1: Performance comparison of models trained on the *by-article* dataset.

- **Model 5** - Principal Component Analysis (PCA) was used to reduce dimensionality of Model 3 to 50 features

The model i.e., feature set that exhibits the best performance is Model 1, that outperforms the other models on the validation as well as on the *by-article* test dataset, but also outperforms the baseline accuracy results presented in (Potthast et al., 2018) by 2.5%.

The attempts to improve the performance on the same dataset by augmenting the set of features with new ones were dissatisfactory and did not lead to any performance advantage. Augmenting the feature set with psycho-linguistic features or POS tags in Model 2 and Model 3 respectively, failed to gain any performance advantage compared to Model 1 Model 4 yielded the worst results. Reducing the dimensionality of the feature space of Model 3 to a 50-dimensional one by using PCA in Model 5, led to even greater degradation of performance metrics. When testing the predicting power of the hyperlink features independently from all other features, the results were significantly better than chance.

The weakness of the models can be explained by the difficulty in defining general heuristics with which to detect biased and deceptive reports. Much of this research represents an effort to understand the clues which give insight into the underlying conditions pertaining to such reporting in news articles. Close inspection of data and comparative analysis with the models participating on the same SemEval task could better support the interpretation of our results. In addition, not having information on the cases that were misclassified by our models, makes it difficult to speculate and offer solutions for proper treatment and improvement of the limitations of our model.

6 Conclusion

In this paper, we report on an experiment that examines the predictive effect of the different feature sets on automatic detection of hyperpartisan articles. Results implicate that the features examined in this research, to varying degree, capture the syntactic and pragmatic aspects of hyperpartisan style, and generalize well to a set of previously unseen articles by unseen publishers. The findings provide evidence of strong modeling capability of word vector embeddings combined with text complexity metrics of the reports and psycholinguistic features, demonstrating that the model accuracy rivals the performance of other teams participating in the SemEval 2019 hyperpartisan challenge, positioning our team at the 9^{th} place on the task's leaderboard.

Abstract

In this paper, we present an approach for classifying news articles as *biased* (i.e., *hyperpartisan*) or *unbiased*, based on a convolutional neural network. We experiment with various embedding methods (pretrained and trained on the training dataset) and variations of the convolutional neural network architecture and compare the results. When evaluating our best performing approach on the actual test data set of the SemEval 2019 Task 4, we obtained relatively low precision and accuracy values, while gaining the highest recall rate among all 42 participating teams.

1 Introduction

Hyperpartisan news detection describes the task of given a news article text, decide whether it follows a hyperpartisan argumentation, i.e., whether it exhibits blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person (Kiesel et al., 2019). In recent years, hyperpartisan news detection, which we consider synonymous to news bias detection, has attracted the interest of researchers and various approaches for news bias detection have been developed (Recasens et al., 2013; Baumer et al., 2015; Baly et al., 2018). However, the definition of *bias* and the task set-up of identifying biased news articles differs from authors to authors. For instance, authors might consider the bias in terms of the writing style, while others might consider it in relation to fact selection (Hamborg et al., 2018). In this paper, we use the definition and data set of SemEval 2019 Task 4 (Kiesel et al., 2019), which deliberately uses the generic definition outlined at the beginning. Note that news bias detection differs from related tasks such as opinion finding (Ounis et al., 2006; Macdonald et al., 2007), sentiment analysis, fake news detection (Potthast et al., 2018), claim assessment (Popat et al., 2016), argumentation mining on news articles (Palau and Moens, 2009), and personality detection based on texts (Mairesse et al., 2007).

From a technical perspective, in recent years deep learning techniques have outperformed traditional methods concerning various NLP tasks. This also applies to news article classification tasks (Ounis et al., 2006; Macdonald et al., 2007). Indeed, in the SemEval Twitter sentiment analysis competition in 2015, 2016, and 2017 (Rosenthal et al., 2015; Nakov et al., 2016; Rosenthal et al., 2017), among the most popular (and apparently effective) deep learning techniques were convolutional neural networks (CNNs). Thus, we decided to build a hyperpartisan news classifier based on a CNN. Next to our basic model, we also develop and evaluate variations of our model.

2 Approach

In the following, we outline our approach for news bias detection.[1]

2.1 Preprocessing

Given a set of news articles as input, we preprocessed them along the following steps:

Text Cleaning. We replaced the new lines by spaces, expanded contractions, and removed stop words, HTML tags, and special characters from the articles' content.

Texts to Sequences. The articles' content was tokenized and a word dictionary (size: 1,207,438) was generated.

Sequence Padding. We applied a padding with

a fixed sequence length l. We set $l = 5000$. Thus, around 0.04% of the sequences were truncated.

2.2 Basic Model Architecture

Our basic architecture is shown in the Figure 1. We use a CNN architecture that is based on Kim et al.'s approach for sentence classification (Kim, 2014). His proposed architecture has been widely applied for various tasks in the past. The CNN consists of two subsequent one-dimensional convolutional neural networks layers, appended by MaxPooling layers, and a dense neural networks layer processing the output of the second CNN layer. The model is completed by a final output layer that uses the sigmoid activation function to return a binary output (i.e., the classification into *biased* or *non-biased*).

In the following, we describe the architecture in more detail:

Input layer. Considering article's words were embedded into d-dimensional vectors, the final matrix used as input to the model can be written as $I = l \times d$ where l is the chosen sequence length (i.e., the length of the articles). Recall that $l = 5000$ in our setting.

First convolutional layer. The first transformation this embedded input goes through is a convolutional layer with f 1-dimensional filters of length k. Thus, the layer weights can be considered a matrix of shape $Wc \in R^{f \times k}$.

We chose as filter size $f = 64$, while using a filter length of $k = 4$. In our context, having 1-dimensional filters means that for each word in an article, its three adjacent words are considered as the context of the word. The output of the convolutional layer then is $C = conv(I, Wc)$ where $conv$ is the convolutional operation applied to input I using the weights matrix Wc. This operation includes applying the *ReLu* activation function to complete weights calculations. Also, a dropout function is used to prevent overfitting. We used a dropout rate of 0.2, which means 20% of the weights, chosen randomly, during each training epoch are set to 0.

First max pooling layer. The above output C is then considered the input to a 1-dimensional Max Pooling layer. The purpose of the layer is to try extracting only the most important features of the convolution outputs. This is done by keeping only the max value from a pool size p. As we chose $p = 4$, the output of this layer can be written as $M = max\_pool(C, p)$. This operation reduces the number of weights by four times.

Second convolutional layer and max pooling layer. The output M of the max pooling layer is the input of the second convolutional layer, and the whole process described above is applied to this input, to get a final output M_2.

Fully connected layer. Given the two-dimensional matrix of weights from the last step, the next layer in the network is a fully connected one with a size of 256 hidden neurons. But in or-

Table 1: Distribution of biased and unbiased articles ("a." for articles) in the training and validation data set.

	Training	Test
Total # samples	588837	147210
# samples w/ $l > 2500$	0.62%	0.58%
# samples w/ $l > 5000$	0.04%	0.03%
# of biased articles	290513	72629
# non-biased articles	298324	74581
% biased articles	49.34	49.34
% of non-biased articles	50.66	50.66

der for the convolutional output to serve as an input to this layer, it needs to be reduced in dimensionality. The way we chose to do that was using the flatten method, which keeps all of the values but flatten them in a long vector. A *ReLU* activation function and a dropout layer with a rate of 0.5 were used here.

Output layer. The last layer is a fully connected layer with one neuron. The sigmoid activation function is used to provide a binary output.

2.3 Architecture Variations

We developed and evaluated the following architecture variations:

1. The first variation only keeps the most important features by using the *GlobalMaxPooling* method. Keeping only the max values has shown good results when used with convolutional layers (Scherer et al., 2010).

2. The second variation uses the *flatten* method, which also transforms the convolutional filters weights to a one-dimensional vector, but does that by keeping all of the values (text features) from the convolutional filters and concatenates them in the resulting vector. Obviously, the length of the output from this method will be greater, usually much greater, than the previous method.

3 Evaluation

3.1 Data Set

Note that the actual SemEval 2019 Task 4 test data set is hidden and only used for submission. Thus, we used the training and validation data set of the SemEval 2019 Task 4 data set for training and testing our models before the SemEval submissions. Note also that, the biased news articles in the training and test data set always originate from sources other than the non-biased news articles. Biased news articles originated mainly from `foxbusiness.com`, `counterpunch.org`, `motherjones.com`, `truthdig.com`, and `dailywire.com`, while unbiased news articles originated mainly from `abqjournal.com` and `apnews.com`. The SemEval 2019 Task 4 is, thus, to some degree artificial, as, in reality, the source of a given article could be used as a feature for the classification.

Due to this correlation between the article's bias and its publisher, to have a generic model as much as possible it was important to have articles from the same publisher present in both sets. We decided to merge the training and validation data set, to shuffle the data randomly, and to split it into a training, validation, and testing data set by 60:20:20. Table 1 shows basic statistics about the used training data set and test data set.

Table 2: Hyperparameters.

Parameter	Value
CNN filter size for CNN	64
CNN kernel size for CNN	4
MaxPooling1D pool size	4
Dropout rate	0.2
Dense layer units	256
Layers Activation function	ReLu
Optimizer	Adam
Learning Rate	Adaptive (0.001→0.00001)
Loss function	Binary crossentropy
Batch Size	32

3.2 Evaluation Settings

We developed our models using Keras v2.1.2 with a Tensorflow v1.0.0 backend. Training the model was performed on a machine with 64GB memory and a GeForce GTX 1080 Ti GPU.

We implemented and evaluated our basic model using several word-based embedding methods, where an embedding vector is generated for each unique word on the text corpus. These embeddings can be categorized into two main categories: (1) pretrained word vectors and (2) custom word vectors (here, trained on the articles' content).

We fine-tuned the hyperparameters of our basic model using the dedicated validation data set. In the end, we used the parameters as shown in Table 2. Note that these optimal hyperparameters showed to be the best-performing ones on both Google's prebuilt word2vec and the custom word2vec which we had trained on our training data.

Table 3: Evaluation results on the custom validation split using various embedding methods.

Embedding	# Dim.	Accuracy	Precision	Recall	F1
Google's word2vec (general)	300	0.9255	0.9295	0.9197	0.9246
Stanford's GloVe (general)	100	0.9198	0.9161	0.9216	0.9188
Facebook's fastText (general)	300	0.9277	0.9378	0.9021	0.9196
Custom word2vec	100	0.9234	0.9246	0.9197	0.9222
Custom fastText	100	0.9114	0.9309	0.8860	0.9079
Custom news word2vec	100	0.9123	0.9142	0.9073	0.9108

Table 4: Results for the adapted CNN architecture.

Architecture	Accuracy
Model using GlobalMaxPooling	0.9225
Model using Flatten	0.9255

3.3 Evaluation Results

3.3.1 Evaluating the Basic Architecture

Table 3 presents the evaluation results for all used embedding methods. The embedding models gave similar results, with some slight differences in the model accuracies for some of them. Thus, we decided to go with one of the better performing models for the final SemEval test runs (see Sec. 3.3.3).

Although the fastText word embeddings are said to perform as well as word2vec embeddings while being trained much faster (Grave et al., 2017) and although the domain-specific pre-trained word2vec embeddings are said to perform better than the general pre-trained word2vec embeddings (Kim, 2014), the general pre-trained word2vec embeddings lead to the best results in our evaluation. A reason for that could be that the words used in the news articles are more spread in terms of the domains to which they belong. Thus, the word vectors trained by Google on 100 billion words of Google News performed even better than a specific word2vec model trained on millions of news articles.

3.3.2 Evaluating the Architecture Variations

We trained the extended models with the same hyperparameters as our basic model and used Google's word2vec as word embedding method based on our results from Sec. 3.3.1. The evaluation results are shown in Table 4.

Even though the training times for the flatten method were much longer due to the huge difference in terms of the number of trainable parameters, we obtained slightly better results than the GlobalMaxPooling method. Thus, the model chosen for the SemEval submission was the model employing the flattening method.

3.3.3 Evaluating on SemEval's Test Data Set

Applying our basic model – using our second architecture variation, Google's word2vec embedding model, the hyperparameters shown in Table 2 and the model itself trained using our mixed, "artificial" data sets – on the official SemEval test data set via official approach submissions, we obtained accuracy of 0.602, a precision of 0.560, a recall of 0.955, and a F1 score of 0.706. It becomes apparent that the precision value is considerably low, while the recall rate is the highest achieved rate among all submitted systems. Based on our investigations so far, we believe that one reason for the low accuracy on the evaluation data set is the labeling of the used data sets: while the train and test data set's labels depend solely on the article's publisher, the labels of the evaluation data set were hand-labeled on a single article basis.

4 Conclusion

In this paper, we presented a convolutional neural network architecture for determining whether a given news articles is *biased* (i.e., *hyperpartisan*) or not. In our experiments, we found that a convolutional neural network containing the flatten function and using Google's word2vec embeddings performs best. In the official SemEval 2019 Task 4 test runs, we obtained comparably low precision and accuracy values, while gaining the highest recall rate among all 42 participating teams. For the future, besides evaluating a deeper CNN, we plan to develop two further approaches. The first one will be based on LSTMs. The second model will be a hybrid model, consisting of a CNN layer, which is supposed to learn the text features, appended by an LSTM layer for learning sequence patterns of those features. Furthermore, we plan to work on a non-deep learning approach which assigns controversy scores to news articles and, in this way, determines the bias of the articles.

Abstract

This paper describes the team peter-parker's participation in Hyperpartisan News Detection task (SemEval-2019 Task 4), which requires to classify whether a given news article is bias or not. We decided to use JAVA to do the article parser and the BERT model to do the bias analysis and prediction. Furthermore, we will show experiment results with analysis.

1 Introduction

As the Hyperpartisan News Detection is getting more and more popular in NLP area in recent years, our team decided to focus on such kind of topic and choose task 4 in 2019 SemEval competition, which requires to decide whether a given news article is showing an unreasoning or blind allegiance to some specific groups or persons(Kiesel et al., 2019). For the task, it also requires the competitor's model to classify the news article in one of the two classes, bias or not. In previous SemEval competition, the classification tasks were mostly regarded as sentiment analysis on Twitter, news or scientific paper and so on. For SemEval 2019, the task focus on bias detection, which gives great help for people in daily life to acquire the news and articles in a more objective way.

So far, the machine learning approaches to do the bias detection were mostly using the RNN(Iyyer et al., 2014) or the Word Vectors(Anil Patankar and Bose, 2017), which can get the accuracy for more than 70%.

To reach a greater performance, we decided to adopt a state-of-the-art language model, BERT (Devlin et al., 2018), which set new records on many NLP tasks recently, into our political bias task analysis.

For dealing with the given large dataset, JAVA was used as a parser tool to help us make those training articles more readable.

2 Model Description

Our task is to predict whether an article or news is bias or not, which is entirely a binary classification task. Recently, Google released an essay about BERT and its code. They also provided the performance of BERT model on different tasks in the essay. One of them is similar to our task, which is called SST-2. It is a binary classification task, which is The Stanford Sentiment Treebank, a binary single-sentence classification task consisting of sentences extracted from movie reviews with human annotations of their sentiment. According to the result (about 95% accuracy), BERT perform pretty well on SST-2 task.

We chose to use BERT to do the task since it had better result on binary classification. We will introduce the BERT model and its detailed implementation in this section. In the following part, we will introduce the model architecture, input representation, pre-training procedure, and fine-tuning procedure.

2.1 Model Architecture

The architecture of BERT is a multi-layer bidirectional Transformer encoder. In this model, it indicates the number of layers as L, the hidden size as H, and the number of self-attention heads as A. It set the feed-forward/filter size to be 4H. It also provides two model sizes.

- BERT-Base: L=12, H=768, A=12, Total Parameters=110M
- BERT-Large: L=24, H=1024, A=16, Total Parameters=340M

2.2 Input Representation

No matter the input in one token sequence is a single text sentence or a pair of text sentences, BERT input representation is capable of representing them. To construct the input representation of a given token, we merged the corresponding token, segment and position embeddings.

2.3 Google pre-trained BERT

Instead of using traditional left-to-right or right-to-left language models, Google pre-train BERT using two new unsupervised prediction tasks which are Masked LM and Next Sentence Prediction.

2.4 Fine-tuning Procedure

It is easy to do BERT fine-tuning for sequence-level classification tasks. By construction corresponds to the special [CLS] word embedding, we take the final hidden state (i.e., the output of the Transformer) for the first token in the input for the interest of obtaining a fixed-dimensional pooled representation of the input sequence. We denote this vector as C $\in R^H$. Additionally, the only new parameters added during fine-tuning are for a classification layer W $\in R^{K*H}$. (K is the number of classifier labels). The label probabilities P$\in R^K$ are computed using a standard softmax, P = softmax(CW^T). All the parameters of BERT and W are fine-tuned cooperatively to maximize the log-probability of the correct label. Some modification must be done slightly on the above procedure in a particular task manner for span-level and token-level prediction tasks.

3 Experiments

3.1 Parse on the Datasets

A good training data cannot be made without data cleaning. There were 600,000 training data (by publisher) and 150,000 validation data (by publisher) and 645 training data (by article). For such a huge dataset, we first split data into 75 separated files, each contained 10,000 news articles so that they were easy to be opened by text editors.

After doing this, we used JAVA to do data parsing and cleaning and BERT model to do bias analysis and prediction. In the articles, some of the characters are escaped as HTML such as that " & " became &amp. It was really easy to unescape them with Java, which involved only one line of method invocation: StringEscapeUtils.unescapeHtml4().

There were some unknown Unicode characters in the articles, so it is good to be removed. Unfortunately, when applying some regular expressions to the articles to remove those characters, some of the articles in other languages would be gone, for example, Chinese, since it was hard to find all the occurring unknown characters in all news articles and we had to use a simple method which was blindly removing all the words, not in the range of \x00 to \x7F in Unicode. So, all the unknown characters could not be removed in order for retaining meaningful words in other languages.

Another problem was that most of the articles contained too many urls and a number of html tags because these articles are parsed from the internet. These might affect the performance and accuracy, so we used a set of regular expressions to catch and remove all the urls and html tags in different forms. Finally, another regular expression was applied to remove the duplicate punctuation such as a line of only periods to divide the articles.

3.2 Models and Training

After cleaning the data, we used BERT to train it with two procedures, which are pre-training and fine-tuning procedures.

3.2.1 Pre-training Procedure

According to Google, BERT needs plenty of time and resources to finish the pre-training procedure. Google used 4 Cloud TPUs in Pod configuration (16 TPU chips total) to train BERT-Base model. Considering the limited time and resource, we decided to download the pre-training model from Google instead of training it by ourselves. For the reason that the data consisted of different languages and Google only released the base model for multilingual data, we could only choose this, which is shown below:

- BERT-Base, Multilingual Cased: 104languages, L=12, H=768, A=12, Total Parameters=110M

3.2.2 Fine-tuning procedure

3.2.2.1 Modify processor

BERT needs an explicit input to train or predict, and it contains the processor to process the input of the model. For our task, we created a new processor for the dataset.

For a model that needs to perform a complete process of training, cross-validation, and testing, our custom processor needed to inherits the DataProcessor, overloads the get_labels function to gain label and also overloads the get_train_examples function, get_dev_examples function and get_test_examples function to get the individual input. These are invoked in the main function flags.do_train, flags.do_eval, and flags.do_predict phases, respectively. The contents of the three functions are much the same, except that you specify the address of the file to be read into.

Modifying get_train_examples function, the function needed to return a list which is made up by InputExample class. The InputExample class only contained the initialization functions. The initialization function only needed the variable guid, which was used to distinguish each example and it could be defined as train-%d'%(i) way. text_a is one string, text_b is another string. Text_a and text_b are two strings and they were merged with [CLS] and [SEP] to become [CLS]text_a[SEP]text_b[SEP]. This merged string was then given to the model. The last parameter, label, was also a string, and it should be guaranteed to appear in the list returned by the get_labels function.

Functions get_dev_examples and get_test_examples were modified using the same method above.

3.3 Results

The prediction procedure was done with the TIRA(Potthast et al., 2019) machine provided by the organizer.

Prediction on Training Set

We split the training set to get the validation set and the test set. The first experiment contained 10000 training articles, 2000 validation articles, 2000 test articles. Also, the proportion of the five categories was equal in the three sets mention above. All the articles are received from them in order from the given training set. Figure 1 shows the result of our first experiments.

Prediction on Test Set

In the second experiment, we directly used the aforementioned model to predict the given test set (byarticle) since the result was so good in the first experiment. But the accuracy was dropped down to 0.6077. The results is shown on the figure 2.

Prediction on Final Test Set

The accuracy we obtained in the second experiment was so bad and we thought that it was due to a lack of training data. So, we anticipated that more training data would help. Next, we trained all the data and predicted the test set pan19-hyperpartisan-news-detectionby-article-test-dataset-2018-12-07. The result was even worse in this final experiment, which is shown in the figure 3. The accuracy dropped to the lowest point, 0.5031. It was just like random guessing.

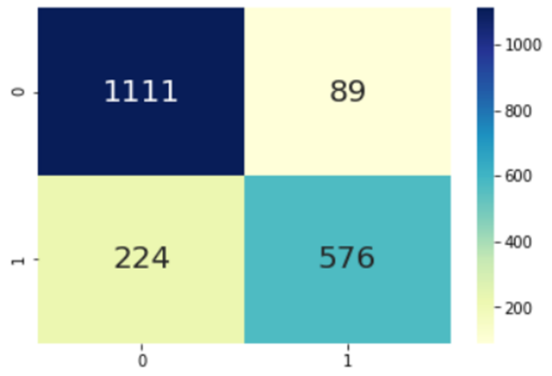

Figure 1: First experiment accuracy:0.9125, 0 is not bias,1 is bias.

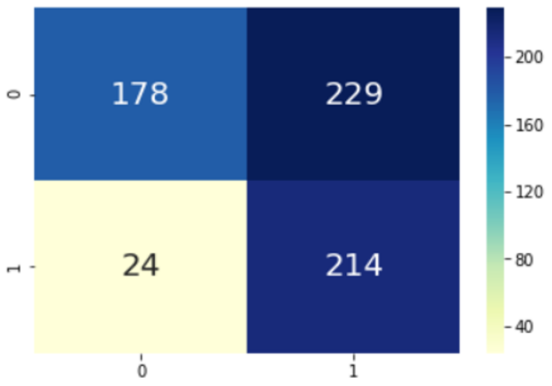

Figure 2: Second experiment accuracy:0.6077, 0 is not bias,1 is bias.

3.4 Error Analysis

We guess the reason why we get two different accuracies in two kinds of articles (by publisher, by article), is that the source of these two articles are different. Data by publisher is decided by the press and publisher, and the other is decided by manual selection. We only trained the data by publisher, so, it seems that it will not perform well on the type of data by article.

4 Conclusion

It was a great experience to use BERT to do the hyperpartisan news detection task although the result was not quite promising compared with the

one that Google has achieved. There are many works we can improve in this task, for example, we may do text summarization before training the data since every article is very long. All in all, more effort still need to be spent in the future time.

Abstract

We describe our submission to SemEval-2019 Task 4 on Hyperpartisan News Detection. We rely on a variety of engineered features originally used to detect propaganda. This is based on the assumption that biased messages are propagandistic and promote a particular political cause or viewpoint. In particular, we trained a logistic regression model with features ranging from simple bag of words to vocabulary richness and text readability. Our system achieved 72.9% accuracy on the manually annotated testset, and 60.8% on the test data that was obtained with distant supervision. Additional experiments showed that significant performance gains can be achieved with better feature pre-processing.[1]

1 Introduction

The rise of social media has enabled people to easily share information with a large audience without regulations or quality control. This has allowed malicious users to spread disinformation and misinformation (a.k.a. "fake news") at an unprecedented rate. Fake news is typically charactterized as being hyperpartisan (one-sided), emotional and riddled with lies (Potthast et al., 2018). The SemEval-2019 Task 4 on Hyperpartisan News Detection (Kiesel et al., 2019) focused on the challenge of automatically identifying whether a text is hyperpartisan or not.

While hyperpartisanship is defined as "exhibiting one or more of blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person", we model this task as a binary document classification problem. Scholars have argued that all biased messages can be considered propagandistic, regardless of whether the bias was intentional or not (Ellul, 1965, p. XV).

[1]Our system is available at https://github.com/AbdulSaleh/QCRI-MIT-SemEval2019-Task4

Thus, we approached the task departing from an existing model for propaganda identification (Barrón-Cedeño et al., 2019). Our hypothesis is that propaganda is inherent in hyperpartisanship and that the two problems are two sides of the same coin, and thus solving one of them would help solve the other. Our system consists of a logistic regression model that is trained with a variety of engineered features that range from word and character TF.IDF n-grams and lexicon-based features to more sophisticated features that represent different aspects of the article's text such vocabulary richness and language complexity.

Our official submission achieved an accuracy of 72.9% (while the winning system achieved 82.2%). This was achieved using word and character n-grams. Moreover, post-submission experiments have shown that further performance improvements can be achieved by carefully preprocessing the engineered features.

2 Related Work

The analysis of bias and disinformation has attracted significant attention, especially after the 2016 US presidential election (Brill, 2001; Finberg et al., 2002; Castillo et al., 2011; Baly et al., 2018a; Kulkarni et al., 2018; Mihaylov et al., 2018; Baly et al., 2019). Most approaches have focused on predicting credibility, bias or stance.

Stance detection was considered as an intermediate step for detecting fake claims, where the veracity of a claim is checked by aggregating the stances of the retrieved relevant articles (Baly et al., 2018b; Nakov et al., 2019). Several stance detection models have been proposed including deep convolutional neural networks (Baird et al., 2017), multi-layer perceptrons (Hanselowski et al., 2018), and end-to-end memory networks (Mohtarami et al., 2018).

The stylometric analysis model of Koppel et al. (2007) was used by Potthast et al. (2018) to address hyperpartisanship. They used articles from nine news sources whose factuality has been manually verified by professional journalists. Writing style and complexity were also considered by Horne and Adal (2017) to differentiate real news from fake news and satire. They used features such as the number of occurrences of different part-of-speech tags, swearing and slang words, stop words, punctuation, and negation as stylistic markers. They also used a number of readability measures. Rashkin et al. (2017) focused on a multi-class setting (real news vs. satire vs. hoax vs. propaganda) and relied on word n-grams.

Similarly to Potthast et al. (2018), we believe that there is an inherent style in propaganda, regardless of the source publishing it. Many stylistic features were proposed for authorship identification, i.e., the task of predicting whether a piece of text has been written by a particular author. One of the most successful representations for such a task are character-level n-grams (Stamatatos, 2009), and they turn out to represent some of our most important stylistic features.

More details about research on fact-checking and the spread of fake news online can be found in recent surveys (Lazer et al., 2018; Vosoughi et al., 2018; Thorne and Vlachos, 2018).

3 System Description

We developed our system for detecting hyperpartisanship in news articles by training a logistic regression classifier using features such as character and word n-grams, lexicon-based indicators, and readability and vocabulary richness measures. Below, we describe these features in detail.

Character 3-grams. Stamatatos (2009) argued that, for tasks where the topic is irrelevant, character-level representations are more sensitive than token-level ones. We hypothesize that this applies to hyperpartisan news detection, since articles on both sides of the political spectrum may be discussing the same topics. Stamatatos (2009) found that "the most frequent character n-grams are the most important features for stylistic purposes". These features capture different style markers, such as prefixes, suffixes and punctuation marks. Following the analysis in Barrón-Cedeño et al. (2019), we include TF.IDF-weighted character 3-grams in our feature set.

Word n-grams Bag-of-words (BoW) features are widely used for text classification. We extracted the k most frequent $[1, 2]$-grams, and we represented them using their TF.IDF scores. We ignored n-grams that appeared in more than 90% of the documents, most of which contained stopwords and were irrelevant with respect to hyperpartisanship. Furthermore, we incorporated Naive Bayes by weighing the n-grams based on their importance for classification, as proposed by Wang and Manning (2012). We define $\boldsymbol{x}_i \in \mathbb{R}^{|V|}$ as a row vector in the TF.IDF feature matrix, representing the i^{th} training sample with a target label $y_i \in \{0, 1\}$, where V is the vocabulary size. We also define vectors $\boldsymbol{p} = \alpha + \sum_{i:y_i=1} \boldsymbol{x}_i$ and $\boldsymbol{q} = \alpha + \sum_{i:y_i=0} \boldsymbol{x}_i$, and we set the smoothing parameter α to 1. Finally, we calculate the vector:

$$\boldsymbol{r} = \log\left(\frac{\boldsymbol{p}/\parallel \boldsymbol{p} \parallel}{\boldsymbol{q}/\parallel \boldsymbol{q} \parallel}\right) \tag{1}$$

which is used to scale the TF.IDF features to create the NB-TF.IDF features as follows:

$$\boldsymbol{x}_i' = \boldsymbol{r} \circ \boldsymbol{x}_i, \quad \forall i \tag{2}$$

Bias Analysis We analyze the bias in the language used in the documents by (*i*) creating bias lexicons that contain *left* and *right* bias cues, and (*ii*) using these lexicons to compute two scores for each document, indicating the intensity of bias towards each ideology. To generate the list of cues that signal biased language, we use Semantic Orientation (SO) (Turney, 2002) to identify the words that are strongly associated with each of the left and right documents in the training dataset. Those SO values can be either positive or negative, indicating association with right or left biases, respectively. Then, we select words whose absolute SO value is $\geq$ 0.4 to create two bias lexicons: BL_{left} and BL_{right}. Finally, we use these lexicons to compute two bias scores per document according to Equation (3), where for each document D_j, the frequency of cues in the lexicon BL_i that are present in D_j is normalized by the total number of words in D_j:

$$bias_i(D_j) = \frac{\displaystyle\sum_{cue \in BL_i} count(cue, D_j)}{\displaystyle\sum_{w_k \in D_j} count(w_k, D_j)} \tag{3}$$

Lexicon-based Features. Rashkin et al. (2017) studied the occurrence of specific types of words in different kinds of articles, and showed that words from certain lexicons (e.g., negation and swear words) appear more frequently in propaganda, satire, and hoax articles than in trustworthy articles. We capture this by extracting features that reflect the frequency of words from particular lexicons. We use 18 lexicons from Wiktionary, Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2001), Wilson's subjectives (Wilson et al., 2005), Hyland's hedges (Hyland, 2015), and Hooper's assertives (Hooper, 1975). For each lexicon, we count the total number of words in the article that appear in the lexicon. This resulted in 18 features, one for each lexicon.

Vocabulary Richness Potthast et al. (2018) showed that hyperpartisan outlets tend to use a writing style that is different from mainstream outlets. Different topic-independent features have been proposed to characterize the vocabulary richness, style and complexity of a text. For this task, we used the following vocabulary richness features: (*i*) type–token ratio (*TTR*), or the ratio of types to tokens in the text, (*ii*) *Hapax Legomena*, or the number of word types appearing only once in the text, (*iii*) *Hapax Dislegomena*, or the number of types appearing twice in the text, (*iv*) *Honore's R*, which is calculated as a combination of types, tokens, and hapax legomena (Honore, 1979):

$$\text{Honore's R} = \frac{100 \times \log(|\text{tokens}|)}{1 - |\text{Legomena}|/|\text{types}|} \tag{4}$$

We further used (*v*) *Yule's characteristic K*, which is defined as the chance of a word occurring in a text, estimated as following a Poisson distribution (Yule, 1944):

$$\text{Yule's K} = 10^4 \cdot \frac{\sum_i i^2|\text{types}_i| - |\text{tokens}|}{|\text{tokens}|^2}, \tag{5}$$

where tokens refer to all words in a text (including repetitions), types refer to distinct words, i are the tokens' frequency ranks (1 being the least frequent), and types$_i$ are the number of tokens with the i^{th} frequency.

Readability We also used the following readability features, which were originally designed to estimate the level of text complexity: (*i*) *Flesch–Kincaid grade level* represents the US grade level necessary to understand a text (Kincaid et al., 1975), (*ii*) *Flesch reading ease* is a score for measuring how difficult a text is to read (Kincaid et al., 1975), and (*iii*) *Gunning fog index* estimates the years of formal education necessary to understand a text (Gunning, 1968).

4 Experiments and Results

4.1 Dataset

We trained our models on the Hyperpartisan News Dataset from SemEval-2019 Task 4 (Kiesel et al., 2019), which is split by the task organizers into

(*i*) *Labeled by-Publisher*, with 750K articles labeled via distant supervision, i.e., using labels for their publisher.[2] The labels are evenly distributed between "hyperpartisan" and "not-hyperpartisan." This set is further split into 600K articles for training and 150K for validation.

(*ii*) *Labeled by-Article:* This set contains 645 articles labeled using crowd-sourcing (37% are hyperpartisan and 63% are not). Only articles with a consensus among the annotators were included.

4.2 Experimental Settings

We trained a logistic regression (LR) model with a Stochastic Average Gradient solver (Schmidt et al., 2017) due to the large size of the dataset. In order to reduce overfitting, we used $\mathbb{L}_2$ regularization (with $C = 1$ as the regularization parameter). Moreover, feature normalization was needed since the different features represent different aspects of the text, and thus have very different scales. We tried to normalize each feature set by subtracting the mean and then scaling it to unit variance. However, we found that multiplying the features by constant scaling factors resulted in better performance. The scaling factor for each family of features was a hyperparameter that we tuned on the validation dataset.

We trained the classifier using the 600K training examples annotated *by-Publisher*, then we used the remaining 150K examples for evaluation. We fine-tuned the hyperparameters on the 645 *by-Article* examples.

[2]The publisher's labels are identified by BuzzFeed journalists or by the Media Bias/Fact Check project

	Features	Labeled by-**Article**				Labeled by-**Publisher**			
		Accuracy	Prec.	Rec.	F1	Accuracy	Prec.	Rec.	F1
1	BoW (TF.IDF)	67.8	53.8	89.1	67.1	56.7	55.1	72.5	62.6
2	BoW (NB-TF.IDF)	69.6	56.1	80.7	66.2	57.1	56.4	61.9	59.0
3	↳+ Char trigrams	74.0	62.5	73.5	67.6	54.8	54.3	60.8	57.4
4	↳+ Bias	75.2	67.7	62.6	65.1	54.5	55.0	50.4	52.6
5	↳+ Lexical	75.2	67.0	64.7	65.8	52.3	52.3	51.5	51.9
6	↳+ Vocab. Richness	75.8	67.1	67.6	67.4	50.9	50.8	52.5	51.7
7	↳+ Readability	76.0	66.4	70.6	68.4	51.6	51.5	53.9	52.7

Table 1: An incremental analysis showing the performance of different feature combinations, evaluated on the validation datasets labeled by *article* and by *publisher*.

The hyper-parameters include the number of most frequent word n-grams k, $k \in [50, 200, 700]^{\times 10^3}$, and the scaling parameters of the features, except for the n-grams. Eventually, we set $k = 200,000$, and we used the most-frequent word $[1, 2]$-grams. Moreover, we assessed the different feature sets, described in Section 3 by incrementally adding each set, one at a time, to the mix of all features.

4.3 Results

Table 1 illustrates the results obtained on both the *by-Article* set (which we used to fine-tune the model's hyper-parameters) and the *by-Publisher* set (which we used for evaluation). Our results suggest that scaling the TF.IDF values through Naive Bayes is better than using raw TF.IDF scores. Hence, this is what we used in subsequent experiments. We can also see that adding each group of features introduces a consistent improvement in accuracy on the *by-Article* data. However, we observed an opposite behaviour on the *by-Publisher* data. We believe this is due to the significant amount of noisy labels introduced by the distant supervision labeling strategy. Therefore, we based our decisions on the results obtained on the *by-Article* data since its labels are more accurate.

The normalization strategy, i.e., scaling the features using calibrated scaling parameters, yielded significant performance improvements. Unfortunately, we could not perform this by the competition deadline, and thus we submitted the system that was available at that time, which was based on the BoW (NB-TF.IDF) and character 3-gram features, as shown in row 3 in Table 1. Our system achieved 72.9% accuracy on the test *by-Article* data, ranking 20th/42, and 60.8% accuracy on the test *by-Publisher* data, ranking 15th/42.

5 Conclusion

We presented our submission to SemEval-2019 Task 4 on Hyperpartisan News Detection. We trained a logistic regression model with a feature set that included word and character n-grams, weighted using TF.IDF, after scaling using Naive Bayes. Our system achieved accuracy of 72.9% and 60.8% on the test datasets that were labeled *by-Article* and *by-Publisher*, respectively.

We further experimented with additional features that represent different aspects of the article's text such as its vocabulary richness, the kind of language it uses according to different lexicons, and its level of complexity. Initial experiments showed that these features hurt the model.

However, with proper pre-processing and scaling, we were able to achieve significant performance gains of up to 2% absolute in terms of accuracy. Unfortunately, we only obtained these results after the competition's deadline, and thus they were not considered as part of our submission. Yet, we have described them in order to facilitate further research.

Acknowledgments

This research is part of the Tanbih project,[3] which aims to limit the effect of "fake news", propaganda and media bias by making users aware of what they are reading. The project is developed in collaboration between the Qatar Computing Research Institute (QCRI), HBKU and the MIT Computer Science and Artificial Intelligence Laboratory (CSAIL).

Abstract

This paper describes our system for the SemEval 2019 Task 4 on hyperpartisan news detection. We build on an existing deep learning approach for sentence classification based on a Convolutional Neural Network. Modifying the original model with additional layers to increase its expressiveness and finally building an ensemble of multiple versions of the model, we obtain an accuracy of $67.52\,\%$ and an F1 score of $73.78\,\%$ on the main test dataset. We also report on additional experiments incorporating handcrafted features into the CNN and using it as a feature extractor for a linear SVM.

1 Introduction

The goal of SemEval 2019 Task 4 is to determine whether a news article blindly follows a political argumentation or not, which is referred to as "hyperpartisan news" (Kiesel et al., 2019). Instead of predicting the exact political orientation, it focuses on whether an article is hyperpartisan in any way. This is a very topical issue since news are easily able to reach millions of people over the internet, and in recent years have been excessively used to influence the population, for example regarding elections. Specifically, one sided media coverage influences a lot of readers without their knowledge, demonstrating the necessity of automated detection of hyperpartisan news.

Approach In this work, we make use of deep learning models to address this task. We decided to adapt the sentence CNN proposed by Kim (2014), as it has been shown to be a strong baseline for text classification tasks. Since the model was originally designed for the classification of sentences, we had to make some modifications in order to deal with the longer texts provided in this task. While the very shallow model originally proposed by Kim (2014) is enough to adequately represent sentences, we found that it is not expressive enough to model entire news articles. Thus, we added a second convolutional layer and a batch normalization layer (Ioffe and Szegedy, 2015) to the model. Additionally, we specified a maximum length for articles, after which they are cut off. These modifications will be described in more detail in Section 3. We also experiment with including some hand-crafted features into the model in an attempt to improve the performance. Finally, we build an ensemble of multiple models to obtain our final results.

2 Feature Extraction

In order to train our models, we need to represent the input texts in some machine readable form. The data provided in the task contains multiple kinds of information that we use in different parts of our system, namely the CNN model and the hand-crafted features extracted to provide additional information.

2.1 CNN Model

On the one hand, our main CNN model is based purely on the text of the articles and requires little pre-processing. For this part, we built a specialized parser[1] to remove HTML tags and split the texts into tokens, which are then directly used as input to the CNN. We chose to allow some special characters like punctuation marks to support the model identifying different sentences. Contractions like *they're* or *he's* are split to obtain separate tokens which can then be mapped to existing ones.

An article is then represented as a sequence of one-hot vectors, where each dimension corresponds to a word in the vocabulary. This sequence is concatenated to form a matrix $M \in \mathbb{N}^{l \times v}$, where l is the length of the article and v is the vocabulary size.

[1] `https://github.com/o8Gravemind8o/nlp_tokenizer`

Word Embeddings As is common for NLP tasks, we use embedding vectors to represent the semantic meaning of tokens. Since the provided datasets are rather large and previous work has shown that domain specific word embeddings can greatly improve classifier performance compared to general embeddings (Hettinger et al., 2018), we train our embeddings on these datasets. More specifically, we use Word2Vec (Mikolov et al., 2013) as well as FastText (Bojanowski et al., 2017) to retrieve different embeddings and see how they perform in different approaches.

Dealing with Variable Article Length Due to CNNs not being able to process input of arbitrary length, we decided to represent articles with a fixed length of 2000 tokens. Articles that exceed this length are cut off at 2000 tokens. This saves a lot of training time and affects less than 3 % of the articles. In the same way, we pad articles shorter than 2000 tokens with zeros to achieve a consistent input size.

2.2 Hand-Crafted Features

On the other hand, we employ hand-crafted features partially based on the metadata that is contained in the HTML. We do this to enable our classifiers to use information that may not be contained in the raw text and also possibly recover information that is lost by the length limit we impose on the articles. For this purpose, we choose several kinds of information from the articles, inspired by Potthast et al. (2018). First, we count (a) every token in the article and (b) tokens which are placed between quotation marks. Furthermore, we use the corresponding HTML tag to count paragraphs and calculate the average number of tokens per paragraph. Finally, we use the overall number of hyperlinks as well as the number of internal and external links. These values are concatenated to form a feature vector that can be used as input to an SVM or as additional input to the CNN.

3 Model Architectures

In this section, we describe the architectures we evaluated in our experiments, starting with the base CNN model from Kim (2014) and extending this model step by step. We also describe an experiment to use the CNN model as a feature extractor for an SVM.

Base Model: Sentence CNN We use the sentence CNN from Kim (2014) as a starting point for our model, illustrated in Figure 1. Articles are fed into the CNN represented by the matrix described in Section 2.1. The first layer of the network then converts the one-hot representation to an embedding representation. To obtain a vector representation of the words, we use two different approaches described in Kim (2014), CNN-Rand and CNN-Static. With CNN-Rand, word vectors are initialized randomly and learned during training. CNN-Static uses the embeddings described in Section 2.1 and does not change them during training. The CNN extracts features from the articles through a convolution layer followed by max-over-time pooling. Classification of an article is obtained by flattening the max-pool feature map and passing the features through a fully connected layer.

First Extension: Article CNN As the base model discards all but one feature from the convolution activation map of each filter by using max-over-time pooling, a lot of features are lost. In the model's original task, which is sentence classification, this is not much of an issue. However, our experiments show that for the classification of articles (which are much longer than one sentence), we need to keep more information.

Therefore, we modify the sentence CNN and use this as a second model, which we call *Article CNN*. We add a second convolutional layer after the first one to learn features that cover a larger range in the article. Furthermore, we add a batch normalization layer after the first and after the second convolutional layer to speed up the training process (Ioffe and Szegedy, 2015).

Second Extension: Article CNN with Hand-Crafted Features In an attempt to incorporate additional information into our model, we provided the model with some handcrafted features described in Section 2.2. To make use of handcrafted features, we append them to the flattened output of the pooling layer of the Article CNN. Since we found that the model can not learn from the combination of CNN and hand-crafted features with only one dense layer at the end, a second dense layer is inserted before the first one. We refer to the resulting third model as *Article CNN HC*.

Model Variant: CNN as a Feature Extractor In an additional experiment, we use the CNN as a feature extractor for an SVM. To this end, we first

train the Article CNN regularly. We then convert an article to a feature representation by feeding it into the trained CNN and extracting the representation before the first dense layer. This vector is concatenated with the hand-crafted features described in Section 2.2 and used to train a linear Support Vector Machine (SVM) as an alternative to the neural classifier of the CNN.

4 Evaluation

After defining our models, we now shortly describe the datasets (for a more detailed description, see Kiesel et al. (2019)) before presenting the results of training and evaluation.

4.1 Data

For training and validation, the task provides 750 000 news articles, which are equally distributed into the two classes hyperpartisan and not hyperpartisan. 600 000 of these were used for training, the remaining 150 000 for validation. These articles have not been labeled individually, but according to their publisher, making them a form of weakly labelled data. The official evaluation was then performed on two concealed datasets, one with articles manually labeled by humans and one again labeled by publisher. The evaluation data contains 628 articles labeled individually and 4000 by publisher, with both being equally distributed into the two classes.

4.2 Metrics

We determine the performance of our models by measuring accuracy (Acc) and F1 score (F1). As accuracy is the official evaluation metric of SemEval Task 4, we optimize for this metric.

4.3 Training and Results

We chose to optimize the hyperparameters of our models by random search (Bergstra and Bengio, 2012). The hyperparameters with the best accuracy values of each architecture are shown in Table 1. All configurations use the CNN-static variant. Models were trained for a maximum of 5 epochs with a batch size of 256. We employed early stopping when the validation accuracy did not improve for 8 consecutive batches.

Results on the Validation Dataset First, we report the results obtained by our models on the validation dataset. All results on this dataset are shown in Table 2. The best configuration of the Sentence CNN achieves a maximum accuracy of 62.13 % and an F1 score of 70.47 %.

Our first extension, the Article CNN, increases the accuracy by 1.68 percentage points and F1 score by 6.09 percentage points. We attribute this to the increased model capacity, which enables the model to represent articles more adequately. With the max-pooling layer after the first convolution layer, the whole article is reduced to one value per convolution filter, which covers a maximum of 11 words (filter size is 11). The second convolution layer contains information of several outputs of the first layer, hence learning higher level features. As a result of that, less information about the article is lost by max-pooling.

Our second modification, the Article CNN HC, however, decreases the model's performance, as does using an SVM as a classifier instead of the

	Convolution 1		Convolution 2		Dense Layer		Miscellaneous	
Model	Filter Size	Filters	Filter Size	Filters	Dropout keep	Units	Activation	Embeddings
Sentence CNN	5	168	—	—	0.9	168	tanh	Word2Vec
Article CNN	9,10,11	306	7	199	0.837	4179	ReLU	FastText
Article CNN HC	7	405	9	210	0.079, 0.274	1890+7, 123	ReLU	Word2Vec

Table 1: Best hyperparameters obtained via random search. Article CNN HC has two dense layers, hence two numbers for dropout and units. We evaluated multiple filter sizes for Article CNN only, due to time constraints.

Model	F1	Acc
Sentence CNN	70.47	62.13
Article CNN	**76.56**	63.81
Article CNN HC	63.02	60.30
Article CNN + SVM	62.07	58.18
SVM HC	66.91	52.83
Ensemble 3	68.69	64.94
Ensemble 5	68.98	**66.01**

Table 2: Best results achieved on the validation dataset.

	Article		Publisher	
Model	F1	Acc	F1	Acc
Article CNN	70.26	64.81	67.81	**66.78**
Ensemble 3	72.05	65.29	**70.09**	66.08
Ensemble 5	**73.78**	**67.52**	69.85	66.28

Table 3: Results on the hidden test datasets.

final fully-connected part of the CNN (Article CNN + SVM). We also trained an SVM purely on the hand-crafted features for comparison (SVM HC), leading to a lower accuracy but higher F1 score than both variants of Article CNN HC.

Finally, we used an ensemble of multiple models for prediction. To this end, we used either 3 or 5 of our best individual models and combined their predictions by majority vote. Because of the non-deterministic nature of training (shuffling of the input data and random initialization of the network) (Reimers and Gurevych, 2017), multiple versions of the same model with similar accuracy may rely on different features and make different mistakes. Thus, a combined prediction by the best models can improve overall accuracy. This is confirmed by the results of Ensemble 3 and 5 presented in Table 2, leading us to submit these ensembles as our final systems. Our best model, Ensemble 5, combines 5 individual Article CNNs.

Results on the Test Dataset For the final evaluation, participants were able to submit two models for evaluation on the non-public test sets. We submitted our two ensemble models comprised of multiple instances of the Article CNN. Additionally we were able to evaluate our single best Article CNN on both test sets, giving us the evaluation results but not appearing on the scoreboard. Results on the test dataset are shown in Table 3. As on the validation dataset, the ensembles outperform the Article CNN in prediction accuracy on the main test set. Our best performing model, the Ensemble 5, reaches an accuracy of 67.52 % on the by-article test set and 66.28 % on the by-publisher test set. This corresponds to rank 25 of 42 on the Main Leaderboard (by-article) and rank 4 out of 28 on the by-publisher Leaderboard.[2]

5 Conclusion

In this paper, we have described our approach for SemEval Task 4 to detect hyperpartisanship in news articles. We trained a CNN for sentence classification and improved its performance by adding a second convolution layer and batch normalization. Moreover, we combined this model with handcrafted features. However, this did not lead to an improvement of classification performance, nor did the use of an SVM as an alternative classifier. Finally, an increase of accuracy was achieved by combining our best models for ensemble prediction. Through this approach, we obtained an accuracy of 67.52 % and F1 score of 73.78 % on the by-article test dataset as well as 66.28 % accuracy and 69.85 % F1 score on the by-publisher data set. For future research, possible modifications to our Article CNN that may bring further improvement are using more channels for the input or different filter sizes for max pooling. Apart from that, using Transformer models (Vaswani et al., 2017) could be rewarding, as they have become the standard for many tasks in Natural Language Processing.

[2]We would like to note that, by F1 score, we would rank 14 out of 42 in the Main Leaderboard (by-article).

Abstract

This paper describes our system submitted to SemEval-2019 Task 4: Hyperpartisan News Detection. We focus on removing the inherent noise in the hyperpartisanship dataset from both data-level and model-level by leveraging semi-supervised pseudo-labels and the state-of-the-art BERT model. Our model achieves 75.8% accuracy in the final by-article dataset without ensemble learning.

1 Introduction

With the ever-growing usage of internet, the problem of fake news that spreads in a destructive speed has attracted many attention. Fake news is a kind of news that is typically inflammatory, extremely one-sided (hyper-partisan) or untruthful to mislead the public into having distorted belief.

Previous works attempted to solve fake news problem from various aspects, ranging from knowledge-based (Wu et al., 2014; Shi and Weninger, 2016; Lee et al., 2018) to style-based (Wang, 2017; Potthast et al., 2018). There are some publicly available fake news datasets, however, often too small in size to be suitable for neural approaches (Horne and Adali, 2017; Pérez-Rosas et al., 2017). Recently, the organizers of SemEval2019 Task 4 (Kiesel et al., 2019) have released large-scale dataset to address fake news detection as a hyper-partisan news detection problem. The task is to determine whether a given article is hyper-partisan (extremely right-wing or left-wing) or not (mainstream). Such task will allow for pre-screening of semi-automatic fake news detection, and more importantly, bring us one step closer to solving fully automated fake news detection.

Initially, we focused on learning and utilizing useful features such as topic and sentiment information. Considering the purpose of hyper-partisan news, we believed that the stance on politically sensitive topics would be crucial in determining hyperpartisanship. However, experiments showed that the dataset contains some inherent noise that acted as a big barrier to learning a good classifier: 1) *noisy text* inputs from an article that contain domain-specific (i.e. political) words, slangs and spelling mistakes which are likely to be out of vocabulary (OOV). 2) *noisy labels* that mainly resulted from using publisher-level information for labeling articles (i.e. all articles from left/right-wing publishers are labeled as "hyper-partisan". For more detail, refer to Section 2).

Nevertheless, human-labeled large-scale dataset creation is a very expensive and time-consuming task, thus, it is crucial to find a better way to utilize this weakly-labeled dataset. Therefore, we experimented with reducing noise to help models learn better. In our work, we apply a semi-supervised pseudo-labeling to de-noise the dataset (Figure 1) and leverage the state-of-the-art pre-trained BERT (Devlin et al., 2018) to obtain a better representation of the noisy input.

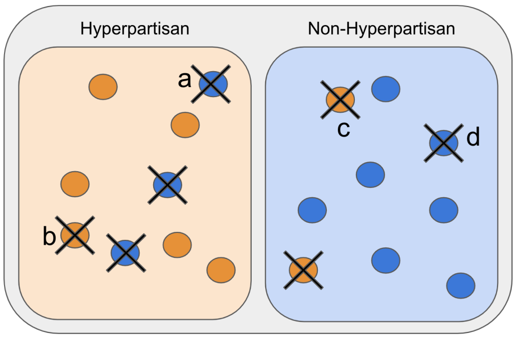

Figure 1: Illustration of filtering. Sample *a* and *c* are removed as pseudo-label ≠ by-publisher label. Sample *b* and *d* are removed as their prediction confidence was below threshold.

[*] These two authors contributed equally.

2 Data Analysis

Label Items	Train Set %	Val Set %
right	25%	25%
right-center	7.1%	8.8%
left	25%	25%
left-center	11.7%	15.7%
least bias	**31.2%**	**25.5%**
all	100%	100%
hyperpartisan	50%	50%
mainstream	50%	50%

Table 1: Data statistic of hyperpartisan and political orientation on by-publisher dataset.

We use a publicly available dataset "SemEval 2019 Task 4 - Hyperpartisan News Detection" [1] that are labeled in two different ways - publisher level and article level.

- Publisher-level (by-publisher): A total of 750K articles are labeled based on the political orientation of the publisher, without considering the content. It has an equal ratio (375K/375K) between hyperpartisan and non-hyperpartisan. Among the hyperpartisan samples, there's an equal ratio (187.5K/187.5K) between right and left political orientation.

- Article-level (by-article): A total of 645 articles labeled on article-level by checking the actual content. The data contains only articles for which a consensus among the crowd-sourcing workers existed. Of these, 238 (37%) are hyperpartisan and 407 (63%) are not.

2.1 Discussion on the Inherent Noise

By using human judgment, we discovered that some article samples did not always have the correct labels. Since the political orientation of the publisher was used as a sole criterion for the labels, such labeling noise is not surprising. It cannot be guaranteed that all articles from a hyper-partisan publisher are hyper-partisan. Another possible reason for such noise could be from not having enough non-hyper-partisan publishers (i.e. The percentage of "least bias" label items in Table 1 is not 50%), thus, treating news from "right-center" and "left-center" publishers also as non-hyper-partisan.

[1]https://zenodo.org/record/1489920#.XAAoMJMzYWq

3 Methodology

In this section, we describe how we did de-noising in our system in Figure 2. Our system consists of two steps: 1) Obtaining de-noised by-publisher dataset by leveraging clean by-article dataset. 2) Leveraging the de-noised by-publisher dataset and pre-trained BERT to train our final model. Note that our code is publicly available for reproducibility [2].

3.1 Step 1: Filter Noise by Leveraging Pseudo-labeling

To deal with the noise in the labels, we utilize pseudo-label for filtering out noisy labels from data-level (Figure 1). Pseudo-labeling is one of the semi-supervised learning methods, which approximates the labels of unlabeled data by using a model (M) trained on the labeled dataset. Originally, pseudo-labeling directly takes the prediction from the model M as the label. This could result in the final model trained on both human-labeled and pseudo-labeled to be bounded by the accuracy of the model M.

To avoid this problem: 1) We use the original by-publisher label as the constraint. We filter out data points that have a mismatch in the by-publisher label and pseudo-label to obtain cleaner by-publisher. 2) To be robust to the errors made by the model M, we set some thresholds to only use pseudo-labels with relatively high confidence. We only consider prediction scores that is bigger/smaller by $margin = 0.2$ than the mid-value (0.5). By doing so, we can filter out noisy labels with the guarantee that the noise level would be at worst kept the same; the size of our de-noised dataset is approximately 32K for both labels, which is 8.5% of original data. Note that in our system, the model M is a binary classifier trained on top of fine-tuned BERT (refer to step 2) using clean by-article dataset.

3.2 Step 2: Obtain Better Input Representation using BERT

The article texts are noisy with a lot of political words, slangs, and even spelling mistakes, many of which are out of vocabulary (OOV) and harmful to the sentence-level and article-level representation learning. We leverage state-of-the-art pre-trained language representation model BERT to

[2]https://github.com/zliucr/hyperpartisan-news-detection

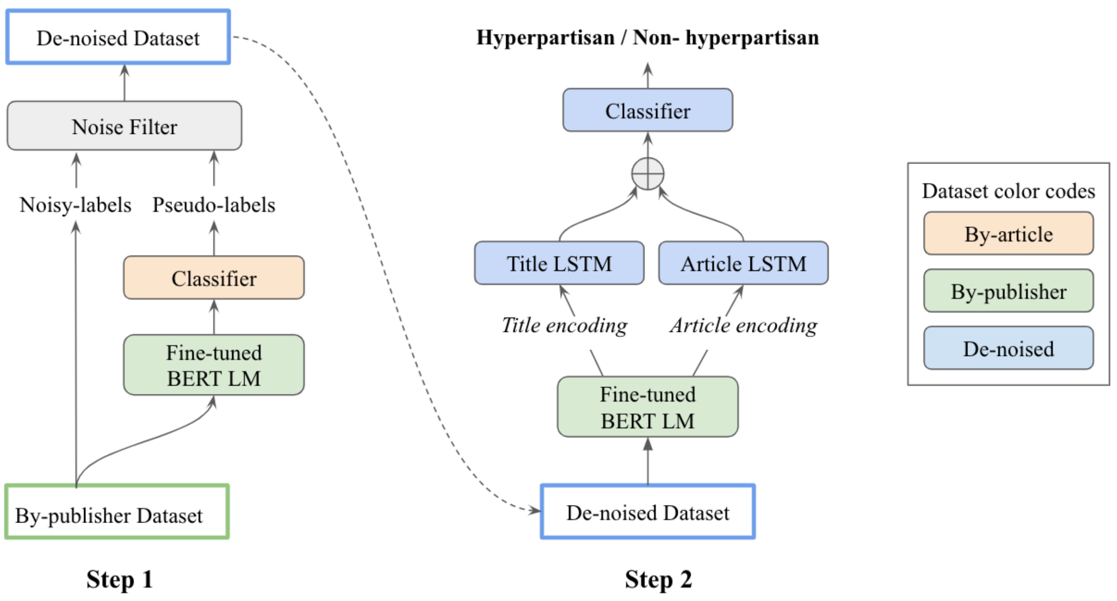

Figure 2: Architecture of the proposed system. Colors represent the dataset used to train the corresponding model.

eliminate OOV problem, since it uses byte-pairs vocabulary, and for a better input representation.

Since the pre-trained BERT model is trained on BooksCorpus and Wikipedia which are not directly relevant to news, we fine-tune the BERT, as in original paper, using our by-publisher news dataset to learn a better representation for our data domain. We build our proposed model by adding title LSTM and article LSTM on top of the fine-tuned BERT model to extract features that are concatenated and fed into the final binary classifier. We train our final classifier using the filtered dataset from Step 1.

4 Experiments and Analysis

4.1 Experimental Setup

We use BERT$_{BASE}$ model from (Devlin et al., 2018) which has 12 layers (i.e., Transformer blocks) with a hidden size of 768 and 12 self-attention heads. In step 1, the parameters of BERT model were fixed after fine-tuned on by-publisher datset, then we trained classifier on by-article dataset by using 16 batch size. We used 10-fold cross-validation to choose the parameters of the classifier, since the size of by-article dataset is small. In step 2, we used 16 batch size to train our LSTM for article model with a hidden size of 300 and LSTM for title model with a hidden size of 100. The classifiers in step 1 and 2 both consist of two linear layers with ReLU and batch normalization in between.

For the evaluation metric, we mainly considered accuracy and F1 score as the main indicator of performance. For analysis purpose, we also report precision and recall. In the competition, there were two types of test sets (i.e. by-publisher test set and by-article test set). However, all of the reported results are obtained from the by-article test set for fair and correct comparison.

4.2 Results

We ran the experiment on 3 baseline models for comparison and simple ablation study of our approach, and the results are presented in Table 2.

- **2 LSTM + Attention + Fine-tuned Classifier** ($LSTM_{ft}$)
  A baseline model consisting of 2 LSTM models (one for the title, and another for the article) with attention layers and a multi-layer perceptron (MLP) as a classifier on the top. It was trained on by-publisher dataset directly, then fine-tuned using the by-article dataset.

- **Pre-trained BERT+Classifier** ($BERT_{pt}$)
  This model uses the original pre-trained BERT model to encode both article and title, which get fed into multilayer perceptron (MLP) to predict the hyper-partisanship of the given article. The parameters of the BERT model was fixed when training the MLP classifier on the by-article data.

Models	Accuracy	Precision	Recall	F1
$LSTM_{ft}$	0.6258	0.5838	**0.8758**	0.7006
$BERT_{pt}$	0.5669	**0.8621**	0.1592	0.2688
$BERT_{ft}$	0.6592	0.8378	0.3949	0.5368
$BERT_{ft}$ + De-noise	**0.758**	0.744	0.7866	**0.7647**

Table 2: Results of our model and other baseline models on the final by-article test set.

- **Fine-tuned BERT+Classifier** ($BERT_{ft}$)
  For this model, everything is kept the same as $BERT_{pt}$ except for the fact that pre-trained BERT was fine-tuned using by-publisher dataset.

Firstly, we can observe that simply using pre-trained BERT ($BERT_{pt}$) to represent input cannot out perform LSTM model entirely trained on hyperpartisan dataset. However, by fine-tuning BERT using our dataset ($BERT_{ft}$), we gain improvement in performance by approximately 10% in accuracy, outperforming $LSTM_{ft}$ by $\approx 3\%$. Hence, we can infer that by injecting some domain-specific data into the original BERT, we can obtain an improved text representation for solving our task. Note that the model sizes for Pre-trained BERT + Classifier and Fine-tuned BERT + Classifier are the same.

Secondly, by training the same fine-tuned BERT model on the de-noised dataset mentioned in Section 3.1, we observed a big improvement in accuracy, F1 and recall by $\approx 10\%$, $\approx 23\%$ and $\approx 40\%$ respectively. This clearly illustrates the power of de-noising the dataset using pseudo-labels as auxiliary reference label. We also would like to emphasize that we did not use any ensemble learning or tricks, which normally gives extra $1-2\%$ gain in the final performance. Our system ranked 11 out of 43 teams that participated.

Lastly, we would mention that our $LSTM_{ft}$ model is a strong baseline because it was able to achieve a high score in the by-publisher test set by obtaining 0.663 and 0.694 for accuracy and F1 respectively (rank 5/28).

4.3 Interesting Analysis

Although our current system does not make direct use of topic information, we present an interesting result obtained while experimenting with topic modeling for hyper-partisanship detection. We used Latent Dirichlet allocation (LDA) for topic modeling, and the results empirically showed interesting relationships between topics and hyper-partisanship. Sensitive topics such as war and political parties tend to have more hyperpartisan news than neutral-topics such as school and sports games. We believe that leveraging such information would be helpful in future works.

5 Related Works

In this part, we briefly review the prior work in language representation as well as the semi-supervised learning method we used.

5.1 Language Representation

(Kiros et al., 2015) tried to learn sentence embedding by reconstructing the surrounding sentences of an encoded passage. (Peters et al., 2018) proposed to extract context-sensitive features from a language model. (Devlin et al., 2018) jointly conditioned on both left and right context and obtained state-of-the-art results on eleven natural language processing tasks.

5.2 Semi-supervised Learning

(Triguero et al., 2015) provided a survey of self-labeled methods for semi-supervised classification. (Zhu and Goldberg, 2009) showed self-labeled techniques are typically divided into self-training and co-training. (Lin et al., 2018) proposed semi-supervised learning to leverage a small amount of user-comment data to train a model and then expand the dataset by that trained model.

6 Conclusion

To conclude, we successfully removed noise from data-level and model-level by utilizing pseudo-labels and state-of-the-art BERT. Compared to other baselines, our de-noised model managed to outperform all, and achieve rank 11 from 42 teams. Since the cost of manual labeling fake news data is expensive, our approach to obtain cleaner and larger dataset by leveraging smaller but clean dataset is meaningful.

Abstract

This paper describes our system submitted to the formal run of SemEval-2019 Task 4: Hyperpartisan news detection. Our system is based on a linear classifier using several features, i.e., 1) embedding features based on the pre-trained BERT embeddings, 2) article length features, and 3) embedding features of informative phrases extracted from the by-publisher dataset. Our system achieved 80.9% accuracy on the test set for the formal run and got the 3rd place out of 42 teams.

1 Introduction

Hyperpartisan news detection (Kiesel et al., 2019; Potthast et al., 2018) is a binary classification task, in which given a news article text, systems have to decide whether or not it follows a hyperpartisan argumentation, i.e., "whether it exhibits blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person" (2019). As resources for building such a system, the by-publisher and by-article datasets are provided by the organizer. The by-publisher dataset is a collection of news articles labeled with the overall bias of the publisher as provided by BuzzFeed journalists or MediaBiasFactCheck.com. The by-article dataset is a collection labeled through crowdsourcing on an article basis. This data contains only the articles whose labels are agreed by all the crowd-workers. The performance measure is accuracy on a balanced set of articles.

Our system is based on a linear classifier using several types of features mainly consisting of 1) embedding features based on the pre-trained BERT embeddings (Devlin et al., 2018) and 2) article length features and 3) embedding features of informative phrases extracted from by-publisher dataset. Our system achieved 80.9% accuracy on the test set for the formal run and got 3rd place out of 42 teams in the formal run.

2 System Description

This section first presents an overview of our system and then elaborate on the feature set.

2.1 Overview of Our System

Our system is based on a linear classifier that models the conditional probability distribution over the two labels (positive or negative) given features. Let $\mathbf{f}$ be a feature vector. $\mathbf{W}$ denotes a trainable weight matrix, and $\mathbf{b}$ is a trainable bias vector, where $\mathbf{f} \in \mathbb{R}^D$, $\mathbf{W} \in \mathbb{R}^{D\times 2}$ and $\mathbf{b} \in \mathbb{R}^2$, respectively. Then, we compute the conditional probability as follows:

$$\mathbf{y} = \mathtt{softmax}(\mathbf{W}^\top \mathbf{f} + \mathbf{b}). \tag{1}$$

where, $\mathtt{softmax}(\cdot)$ represent the softmax function that receives an N-dimensional vector $\mathbf{x}$ and returns another N dimensional vector, namely:

$$\mathtt{softmax}(\mathbf{x}) = \frac{\exp(\mathbf{x})}{\sum_i \exp(x_i)}, \tag{2}$$

and $\mathbf{x} = (x_1, \ldots, x_N)^\top$. After the softmax computation, we obtain the two-dimensional vector $\mathbf{y} \in \mathbb{R}^2$. We assume that the first dimension of this vector represents the probability of the positive label, and the second one represents that of the negative label.

To boost the performance, we concatenate three types of features, $\mathbf{f}_1$, $\mathbf{f}_2$, and $\mathbf{f}_3$, into the single feature vector $\mathbf{f}$, where $\mathbf{f}_1 \in \mathbb{R}^{D_1}$, $\mathbf{f}_2 \in \mathbb{R}^{D_2}$ and $\mathbf{f}_3 \in \mathbb{R}^{D_3}$ and $D = D_1 + D_2 + D_3$.

As $\mathbf{f}_1$, $\mathbf{f}_2$ and $\mathbf{f}_3$, we design the following features.

- $\mathbf{f}_1$: BERT feature (Section 2.2)

- $\mathbf{f}_2$: Article length feature (Section 2.3)
- $\mathbf{f}_3$: Informative phrase feature (Section 2.4)

For training our classifiers, we used only the `by-article` dataset but not the `by-publisher` dataset. This is because the labels of the `by-publisher` dataset turned out rather noisy. In our preliminary experiments, we found that the performance drops when training the classifiers on the `by-publisher` dataset.

Furthermore, we apply the following three techniques.

1. **Word dropout**: We adopted word dropout (Iyyer et al., 2015) for regularization. The dropout rate was set to 0.3.
2. **Over sampling**: As mentioned above, the gold label distribution of the training set is unbalanced while that of the test set is balanced. We deal with this imbalance problem by sampling 169 (407 − 238) extra examples from hyperpartisan data.
3. **Ensemble**: We trained 100 models with different random seeds. In addition, we trained models for 40, 50, 60 and 70 epochs for each seed. Consequently, we finally average the output of these 400 models.

2.2 BERT Feature

Our system uses BERT (Devlin et al., 2018). As a strategy for applying BERT to downstream tasks, Devlin et al. (2018) recommends a fine-tuning approach, which fine-tunes the parameters of BERT on a target task. In contrast, we adopt a feature-based approach, which uses the hidden states of the pre-trained BERT in a task-specific model as input representation. A main advantage of this approach is computational efficiency. We do not have to update any parameters of BERT. Once we calculate a fixed feature vector for an article, we can reuse it across all the models for ensemble.

In our system, we used BERT to compute a feature vector $\mathbf{f}_1$ for an input article. Specifically, we first fed an article to the pre-trained BERT model as input and extracted the representations of all the words from the top four hidden layers. Then, to summarize these representations into a single feature vector $\mathbf{f}_1$, we tried the following three methods.

1. **Average**: Averaging the representations of all the words in an article.
2. **BiLSTM**: Using the representations as input to BiLSTM. This is the same method as the best performing one reported by Devlin et al. (2018).
3. **CNN**: Using the representations as input to CNN in the same way as Kim (2014).

As we describe in Section 3.2, we finally adopted the averaged BERT vectors as $\mathbf{f}_1$.

2.3 Article Length Feature

As $\mathbf{f}_2$, we design a feature vector representing the length of an input article. In our preliminary experiments, we found a length bias in hyperpartisan articles and non-hyperpartisan articles. Thus a vector representing the length bias is expected to be useful for discriminating these two types of articles.

Specifically, we define a one hot feature vector $\mathbf{f}_2$ representing distribution of the lengths of articles (the number of words in an article). To represent the length of an article as a vector, we make use of histogram bins. Consider the 100-ranged histogram bins. The first bin represents the length 1 to 100, and the second one represents the length 101 to 200. If the length of an article is 255, the value of the third bin (201 to 300) takes 1. In the same way, the third element of the length vector takes 1 and the others 0, i.e., $\mathbf{f}_2 = [0, 0, 1, 0, 0, \cdots]$. In our system, we set the dimension of the vector as $D_2 = 11$, whose last (11-th) element corresponds to the length longer than 1000.

2.4 Informative Phrase Feature

In the development set, we found some phrases informative and useful for discriminating whether or not a given article is hyperpartisan. We extracted such informative phrases and mapped them to a feature vector $\mathbf{f}_3$. In this section, we first explain the procedure of extracting informative phrases, and then we describe how to map them to a feature vector.

2.4.1 Phrase Set Creation

To create an informative phrase set, we exploit the `by-publisher` articles. Basically, we take advantage of chi-squared statistics of N-grams ($N = 1, 2, 3$).

Creation of S_h First, we calculate each chi-squared value χ_{x_i} of N-gram x_i appearing in the by-publisher articles as follows:

$$\chi_{x_i} = \frac{(O - E)^2}{E}. \quad (3)$$

O and E are defined as follows:

$$O = f_{\text{false}}(x_i), \quad (4)$$

$$E = \frac{T_{\text{false}} \times f_{\text{true}}(x_i)}{T_{\text{true}}}, \quad (5)$$

where $f_{\text{true}}(\cdot)$ and $f_{\text{false}}(\cdot)$ are functions that calculate the frequency of x_i in hyperpartisan articles and non-hyperpartisan articles, respectively. T_{true} and T_{false} are the summation of the frequency of all N-grams in hyperpartisan articles and non-hyperpartisan articles, respectively.

Then, based on the chi-squared values χ_{x_i}, we sort and select top-M N-grams. We can obtain a typical N-gram set (hereinafter, referred to as S_h) that is informative for judging whether an article is hyperpartisan or not.[1] In our system, we use $M = 200,000$.

S_h can mostly catch the characteristics of hyperpartisan articles. However, S_h may include some N-grams that are typical of a certain publisher. This is because the by-publisher dataset is labeled by the overall bias of the publisher as provided by BuzzFeed journalists or MediaBiasFactCheck.com.

Creation of S_p To remedy this problem, we create another phrase set S_p consisting of N-grams that are typical of a publisher, and exclude them from S_h.

Here we consider a certain publisher p_l. First, we calculate each chi-squared value of N-gram x_i in the same way as Eq 3,4,5 for S_h, but here we consider $true$ and $false$ as appearing in articles of publisher p_l and articles of other publishers, respectively, instead of appearing in hyperpartisan articles and non-hyperpartisan articles. Then, we pick up only N-gram x_i where $f_{\text{true}}(x_i)$ is less than $f_{\text{false}}(x_i)$ and sort all of them by the chi-squared values. This is because we aim to exclude only N-grams that are typical of a certain publisher.

Next, we try four types of ways to create S_{p_l} from sorted χ_x value statistics. Here j denotes the index of the N-gram list sorted by χ_x values, i.e., χ_{x_1} is the highest value in all calculated χ_x values.

[1] Actually, we cut off N-gram x if $f_{\text{true}}(x)$ is more than 100,000 for S_h.

1. **Top-T_o**: The first setting is to select top-T_o N-grams. Concretely, S_{p_l} is defined as follows:
$$S_{p_l} = \{x_j | j \leq T_o\}. \quad (6)$$
2. **χ-based**: The second setting is to select N-grams based on χ values. Concretely, S_{p_l} is defined as follows:
$$S_{p_l} = \{x_j | \chi_{x_j} > T_c\}. \quad (7)$$
3. **f_{true}-based**: The third setting is to select N-grams based on $f_{\text{true}}(x_j)$ values. Concretely, S_{p_l} is defined as follows:
$$S_{p_l} = \{x_j | f_{\text{true}}(x_j) > T_f, j \leq T_m\}. \quad (8)$$
4. **f_{true}-f_{false} ratio-based**: The fourth setting is to select N-grams based on ratios between f_{true} and f_{false}. Concretely, S_{p_l} is defined as follows:
$$S_{p_l} = \left\{ x_j \,\middle|\, \frac{f_{\text{true}}(x_j)}{f_{\text{false}}(x_j)} > T_r, j \leq T_m \right\}. \quad (9)$$

T_o, T_c, T_f, T_r and T_m are hyper-parameters[2].

Next, we obtain S_p defined as follows:

$$S_p = \bigcup_l S_{p_l}. \quad (10)$$

At last, we obtain an filtered N-gram set S defined as follows:

$$S = S_h \setminus S_p. \quad (11)$$

2.4.2 Phrase Embedding

We map each of the obtained N-gram phrase set S to a feature vector $\mathbf{f}_3$. We exploited GloVe vectors (Pennington et al., 2014) instead of one-hot vectors in order to facilitate generalization.

First, we enumerate N-grams included in an article and compute each N-gram vector. Each vector is the average of GloVe vectors of included words. For example, the vector for the phrase "news article" is computed as follows:

$$\frac{\texttt{GloVe}(\text{news}) + \texttt{GloVe}(\text{article})}{2}.$$

Here, $\texttt{GloVe}(w)$ denotes the GloVe (glove.840B[3]) vector of the word w. Then, we compute $\mathbf{f}_3$ as the average of all N-gram vectors included in the article.

[2] In our experiments, we fix T_m to 200,000.

[3] https://nlp.stanford.edu/projects/glove/

Method	Accuracy
Average	0.760
BiLSTM	0.712
CNN	0.758

Table 1: Accuracy of hyperpartisan classification for each operation on BERT vectors.

3 Experiments

3.1 Settings

We trained linear classifiers on the `by-article` dataset (not on the `by-publisher` dataset). In order to estimate the performance in the test set with each setting, we conducted 5-fold cross validation on `by-article` dataset. For optimization of the classifiers, we use Adam with learning rate of 0.001, $\beta_1 = 0.9$, $\beta_2 = 0.999$. We set the minibatch size to 32. Note that we did not take ensemble approach in the experiments we report in Section 3.2 and Section 3.3 for efficiency.

3.2 Operation on BERT Vectors

We conducted experiments on each of the three methods for BERT vectors (`BERT-Base, Uncased`[4]) mentioned in Section 2.2. In this experiment, we only used $\mathbf{f}_1$ as a feature vector $\mathbf{f}$, i.e., without using $\mathbf{f}_2$ and $\mathbf{f}_3$.

Table 1 shows the performance in each setting. The averaging method was the best performance this time. We therefore decided to adopt average BERT vectors as $\mathbf{f}_1$ for the evaluation of the formal run. In addition, we also used averaged BERT vectors as $\mathbf{f_1}$ in the following experiments.

3.3 Method to Create N-gram Set

As mentioned in Section 2.4, we examined which method is the best to create an informative N-gram set S (and $\mathbf{f}_3$ derived from them). In this experiment, we also used $\mathbf{f}_1$ and $\mathbf{f}_2$ with $\mathbf{f}_3$ as a feature.

Table 2 shows the performance in each setting. The performance was the best when we adopted Top-T_o ($T_o = 100$) for S_p creation. We therefore used $\mathbf{f}_3$ created in this setting.

3.4 Ablation

To verify the contribution of each three types of features, we conducted feature ablation experiments. In addition, we investigated to what extent ensemble approach improve the performance. In this experiments, we use only 10 (not 100) different random seeds for ensemble due to time constraints.

[4]https://github.com/google-research/bert

Method	Accuracy
Top-T_o ($T_o = 100$)	0.777
Top-T_o ($T_o = 1000$)	0.771
χ-based ($T_c = 20000$)	0.752
f_{true}-based ($T_f = 50$)	0.754
f_{true}-based ($T_f = 150$)	0.764
f_{true}-f_{false} ratio-based ($T_r = 0.5$)	0.754
f_{true}-f_{false} ratio-based ($T_r = 0.8$)	0.771
f_{true}-f_{false} ratio-based ($T_r = 1.0$)	0.756

Table 2: Accuracy of hyperpartisan classification for each method to create N-gram set.

Features	Ensemble	Accuracy
$\mathbf{f_1}, \mathbf{f_2}, \mathbf{f_3}$	true	0.788
$\mathbf{f_1}, \mathbf{f_2}, \mathbf{f_3}$	false	0.777
$\mathbf{f_1}, \mathbf{f_2}$	false	0.769
$\mathbf{f_1}$	false	0.760

Table 3: Result of ablation.

Table 3 shows the performance in each setting. We found that $\mathbf{f_2}$ and $\mathbf{f_3}$ improved the accuracy by about 0.01, respectively. Additionally, by using the ensemble method, the accuracy increased by about 0.01.

4 Conclusion

We described our system submitted to the formal run of SemEval-2019 Task 4: Hyperpartisan news detection. We trained a linear classifier using several features mainly consisting of 1) BERT embedding features, 2) article length features indicating the distribution of lengths of articles and 3) embedding features derived from filtered N-grams that are typically found in hyperpartisan articles. Our system achieved 80.9% accuracy on the test set for the formal run and got 3rd place out of 42 teams.

Tintin at SemEval-2019 Task 4: Detecting Hyperpartisan News Article with only Simple Tokens

Yves Bestgen
Centre for English Corpus Linguistics
Université catholique de Louvain
Place Cardinal Mercier, 10 1348 Louvain-la-Neuve, Belgium
yves.bestgen@uclouvain.be

Abstract

Tintin, the system proposed by the CECL for the Hyperpartisan News Detection task of SemEval 2019, is exclusively based on the tokens that make up the documents and a standard supervised learning procedure. It obtained very contrasting results: poor on the main task, but much more effective at distinguishing documents published by hyperpartisan media outlets from unbiased ones, as it ranked first. An analysis of the most important features highlighted the positive aspects, but also some potential limitations of the approach.

1 Introduction

This report presents the participation of Tintin (Centre for English Corpus Linguistics) in Task 4 of SemEval 2019 entitled Hyperpartisan News Detection. This task is defined as follows by the organizers[1]: "Given a news article text, decide whether it follows a hyperpartisan argumentation, i.e., whether it exhibits blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person."

This question is related to the detection of fake news, a hot topic in our internet and social media world (Pérez-Rosas et al., 2017). There are, however, essential differences between these two tasks. An article can be hyperpartisan without mentioning any fake content. Another difference is that it is a news article (or even a claim) that is fake whereas a news article but also a media outlet (or publisher) can be considered as hyperpartisan. The challenge organizers took these two possibilities (i.e. an article or a publisher can be hyperpartisan) into account by offering two test sets. The main test set, the labels-by-article one, contained documents that had been assessed as hyperpartisan or not by human judges, while the documents in the secondary test set, the labels-by-publisher one, had been categorized according to whether their publishers were considered to be hyperpartisan or not by organizations that disseminate this type of evaluation. In both these test sets, participants had to decide whether a document expresses a hyperpartisan point-of-view or not.

If the main task is particularly interesting, the secondary task is also relevant because it is about achieving through an automatic procedure what a series of organizations manually perform in a way that is sometimes called into question as to its impartiality and quality (Wilner, 2018). However, in this context, the task would preferably be evaluated, not at the document level, but at the publisher level by providing several documents from a publisher and asking whether the publisher is biased or not. Nevertheless, it can be assumed that many systems developed for categorizing publishers will start by evaluating each document separately and thus getting good performance in the current secondary task is at least a first step.

To take up these tasks, the question is how to determine automatically whether a document is hyperpartisan or not. This question has not attracted much attention in the literature, but, very recently, Potthast et al. (2018) proposed to use stylometric features such as characters, stop words and POS-tag n-grams, and readability measures. They compared the effectiveness of this approach to several baselines including a classical bag-of-words feature approach[2] (Burfoot and Baldwin, 2009). Their stylistic approach obtained an accuracy of 0.75 in 3-fold cross-validation in which publishers present in the validation fold were unseen during the learning phase. The bag-of-words feature

[1]https://pan.webis.de/semeval19/semeval19-web

[2]More specifically, Potthast et al. (2018) used the frequency, normalized by the document length, of the tokens of at least two characters that occurred in at least 2.5% of the documents in the collection.

approach obtained an accuracy of 0.71, which is not much lower. These results were obtained on a small size corpus (due to the cost of the manual fact-checking needed for the fake-news part of the study) containing only nine different publishers. It is therefore not evident that this corpus was large enough to evaluate the degree of generalizability of the bag-of-words approach, especially since Potthast et al. (2018, p. 233) emphasizes that using bag-of-words features potentially related to the topic of the documents renders the resulting classifier not generalizable. In contrast, the datasets prepared for the present challenge are significantly larger since the latest versions available contain more than 750,000 documents and more than 240 different media outlets.

Therefore, it seemed interesting to evaluate the effectiveness of a bag-of-words approach for the labels-by-publisher task, the one used by Potthast et al. (2018). This is the purpose of this study. Another reason why I chose to focus on the labels-by-publisher task is that I was unclear about what could be learned on the basis of the labels-by-publisher sets for the labels-by-article test set. If one can think that some publishers almost always distribute hyperpartisan articles, it seems doubtful that this is the case for all of them.

The next sections of this paper describe the datasets, the developed system, and the obtained results as well as an analysis of the most important features.

2 Data

As explained in Kiesel et al. (2019), several datasets of very different sizes were available for this challenge. The learning labels-by-publisher set contained 600,000 documents form 158 media outlets in its final version. The corresponding validation set contained 150,000 documents from 83 media outlets, and the test set consisted of 4,000 documents. The first labels-by-article set provided to the participants contained 645 documents and was intended for fine-tuning systems developed on the labels-by-publisher sets. The test set contained 628 documents.

Some of these datasets could be downloaded while those used to perform the final test were hidden on a TIRA server (Potthast et al., 2019). An important feature of these data is that no publisher in a dataset is present in any other dataset. This has the effect of penalizing (usefully) any system that learns to categorize on the basis of the publishers since generalization to unseen media outlets should be problematic.

3 System

3.1 The Bag-of-Words Feature Approach

The developed system, which implements the bag-of-words approach, is very classical. It includes steps for preprocessing the data, reading the documents, creating a dictionary of tokens (only unigram tokens as bigrams did not appear to improve performance), and producing the file for the supervised learning procedure. It was written in C, with an initial data cleaning step in Perl, and was thus very easy to install on a TIRA server. In this section, only a few implementation details are mentioned.

During preprocessing, a series of character sequences like *;amp;amp;amp;*, *&amp;#160;* and *&amp;amp;lt;* were regularized. When reading a document (both the title and the text), strings were split by separating the following characters when they were at the beginning or end of the strings and they were outputted separately: ’ * ” ? . ; : / ! ,) (} { [ ] -. Alphabetic characters were lowercased. A binary feature weighting scheme was used.

3.2 Supervised Learning Procedure

During the development and test phases of the challenge, the models were build using two solvers available in the LIBLINEAR package (Fan et al., 2008), the L2-regularized L2-loss support vector classification (-s 1) and the L2-regularized logistic regression (-s 7), which resulted in equivalent performance. The regularization parameter C was optimized on the labels-by-publisher validation set using a grid search.

4 Analyses and Results

4.1 Official Results

On the main task of the challenge, the Tintin system obtained an accuracy of 0.656, ranking 27th out of 42 teams, very far from the best teams who scored 0.82.

Twenty-nine teams submitted a system for the labels-by-publisher task. Tintin ranked first, with an accuracy of 0.706. This level of performance is identical to that obtained by Potthast et al. (2018) bag-of-words model in their experiments on a significantly smaller dataset.

In general, the performances of the different teams on the second task were much lower than on the main task. Tintin, on the other hand, achieved a better score on the second task. It is not the only system in this case since, of the 28 teams that participated in the two tasks, three others also scored better in the second task and one team only participated in this task. Reading the papers describing these systems will make it possible to know if these teams have also chosen to favor the secondary task. It is also noteworthy that the difference between the two best teams is much greater in the secondary task (0.706 vs. 0.681) than in the main task (0.822 vs. 0.820).

4.2 Analysis of the Most Important Features

In order to get an idea of the kind of features underlying the system's efficiency in the secondary task, the 200 features (and thus tokens) that received the highest weights (in absolute value) in the logistic regression model[3] were examined.

Table 1 shows the ten features that received the highest weights as well as a series of features selected because of their interest to understand how the system works. Positive weights indicate that the feature predicts the hyperpartisan category, while negative weights are attributed to features that are typical of the non-biased category. The table gives in addition to the token and the weight, the number of publishers (#Pub) and the number of documents (#Doc) in which that token appears for each of the two categories to be predicted. The maximum percentage of documents a publisher represents in each category is also provided (Max%). The percentage for the category that this feature predicts is boldfaced.

As expected, some of the most important features are typical of a single publisher like *globalpost*, which is present in 750 times more non-biased than hyperpartisan documents, but 99.76% of the non-biased documents come from the same publisher (*pri.org*). Other tokens are not so strongly associated with a single publisher. In the 8th position, the token *h/t*, a way of acknowledging a source, is present in 53 hyperpartisan media outlets and 63% of the documents of this category in which it occurs are not found in the publisher that contains the most (*dailywire.com*). *Jan* is an even more obvious example of features that are not tied to a single publisher.

There are also in these particularly important features some tokens that might not be seen as unexpected such as *leftists(s)*, *shit*, *beast*, *right-wing*, *hell...* Other features, such as *fla*, *beacon*, *alternet* or *via*, are not related to a single publisher, but their usefulness for categorizing unseen media outlets is no less debatable. For instance, *via* can be used in many different contexts such as *via twitter*, *transmitted to humans via fleas*, *linking Damascus to Latakia and Aleppo via Homs*. It is therefore widespread. However, its usefulness in categorizing *unseen* media outlets is not necessarily obvious since some part of its weight results from its occurrence in all of the 976 documents from *thenewcivilrightsmov* as each of these documents offers to *subscribe to the New Civil Rights Movement via email*.

These observations lead to wonder whether the system does not show a strong variability of efficiency according to the unseen publishers to predict, working well for some, but badly for others. It was not possible to evaluate this conjecture by analyzing the system accuracy for the different publishers in the test set since it is not publicly available. However, an indirect argument in its favor is provided by the meta-learning analyses done by the task's organizers that suggest that some publishers are much easier to predict than others. For these analyses, each set was randomly split into two samples (2668 vs. 1332 for the labels-by-publisher test set) and submitted to a majority voting procedure. As this procedure is unsupervised, the expected value of the difference in accuracy between the two samples is 0. This was not the case for the labels-by-publisher task since it was larger than 0.23, an extremely significant difference (Chi-square test). The most obvious explanation is to consider that the need to put each publisher in only one sample leads to a non-random distribution in which the publishers of one sample are much easier to predict.

5 Conclusion

The Tintin system, developed for the Hyperpartisan News Detection task, is extremely simple since it is exclusively based on the document tokens. If its performance on the main task was poor, it ranked first when it was used to discriminate documents published by hyperpartisan media outlets from unbiased ones. An analysis of the

Table 1: Some of the 200 most useful features for predicting hyperpartisanship.

Figure 1: Main entrance of the Musée Hergé[4].

most important features for predicting hyperpartisanship emphasizes the presence of tokens specific to certain publishers, but also of tokens that could have some degree of generalizability.

In future work, it might be interesting to use other weighting functions than the binary one such as the bi-normal separation feature scaling (Forman, 2008) that has been shown to be particularly effective for satire detection (Burfoot and Baldwin, 2009) or BM25 which has proved useful in the VarDial challenge (Bestgen, 2017). Such development, however, would only be justified if the system is stable, that is to say, if it achieves good performance for many publishers not seen during learning. Designing a weighting function that would favor the hyperpartisan distinction while simultaneously reducing the impact of the media outlets could perhaps improve this stability.

6 Namesake: Tintin

I chose this fictitious reporter as my namesake for this task because the Musée Hergé, an unusual looking building in front of which a huge fresco represents this cartoon character, is located a few tens of meters from my office in Louvain-la-Neuve. *Tintin* is also a French interjection that means *nothing* or *No way!*

Abstract

In this paper, we describe our attempt to learn bias from news articles. From our experiments, it seems that although there is a correlation between publisher bias and article bias, it is challenging to learn bias directly from the publisher labels. On the other hand, using few manually-labeled samples can increase the accuracy metric from around 60% to near 80%. Our system is computationally inexpensive and uses several standard document representations in NLP to train an SVM or LR classifier. The system ranked 4th in the SemEval-2019 task. The code is released for reproducibility[1].

1 Introduction

Bias is the inclination or prejudice for or against one person or group. News articles that contain extreme bias fail to provide fair and multi-faceted views for readers and can create polarization within the society (Bernhardt et al., 2008). A system that can detect bias in news articles is thus relevant, especially in a time where an increasing number of people consume news from online sources that might not be trustful.

The SemEval-2019 task aims to detect hyperpartisan news given the text of the news article, where hyperpartisan news is defined to be an article that overtly favors a side or view. The details of the task can be found in Kiesel et al. (2019). We are provided with a dataset of two parts. The first part is labeled by the publishers (e.g. if a publisher is decided to be a hyperpartisan source, all its articles are labeled as hyperpartisan), and split into a training and validation set with no overlapping publishers (which we will refer to as training-1 and validation-1). The second part is crowd-sourced and labeled per article (which we will call training-2).

[1]`https://github.com/chialun-yeh/SemEval2019`

Due to the large number of labeled samples, we decide to use a supervised classification approach, where features are extracted from the text and used to train a classifier. Bag-of-words (BoW), TFIDF weighting, and n-grams have been shown to be strong baselines (Hu and Liu, 2004; Wang and Manning, 2012). Other features such as Part-Of-Speech (POS), counts of sentiment and bias words have also been studied (Liu, 2012; Mukherjee and Weikum, 2015). In a similar setting, Potthast et al. (2018) uses features such as n-gram of characters, readability scores, dictionary, and the ratio of quoted words to separate hyperpartisan news from the mainstream. They trained a random forest classifier and achieved an accuracy of 75%.

Kulkarni et al. (2018) build a neural network to predict the political ideology of news articles to be either left, right or center. They combine information from the headlines, the links within an article, and the content. They use a CNN (Kim, 2014) for the headlines, a Node2Vec (Grover and Leskovec, 2016) to model the links and a hierarchical attention network (HAN) (Yang et al., 2016) to extract features from the content. They compare the model with several baselines, including a BoW LR model, a fully-connected feedforward network, and networks with only the individual components. Their proposed model performs the best. However, their system is trained and evaluated on only data with publisher labels. They randomly split them into training and testing sets, with overlapping publishers.

The main contribution of the paper is two-fold. First, we analyze the problem of using the dataset labeled by publishers, concluding that it is difficult due to the noisy labels. Second, we train SVM classifiers with different representations: TFDIF, doc2vec and GloVe pre-trained vectors. The 300-dimensional GloVe vectors obtain the best cross-validation accuracy as well as the performance metrics on the official test data.

This paper is organized as follows. In section 2, we describe the data pre-processing. In section 3, we present the two systems that we devise and explain how one motivates the other. In section 4, we present the performance of the final system. We outline our main conclusions and future work in section 5.

2 Pre-processing

Since the articles are collected from online news platforms, they contain texts that are irrelevant to the news itself. We use the following three steps to clean the data:
(a) Remove online usage including links, hashtags, @-tag, and advertisements.
(b) Remove parentheses, brackets, and curly brackets that contain additional information because the usage is often specific to publishers.
(c) Remove paragraphs that might reveal publisher information. Some publishers use headers and footers of specific patterns in their articles. We try to remove them by discarding the first and last paragraphs from the article if the article has more than two paragraphs, assuming that these two paragraphs have higher probabilities of being headers and footers. This is by no means optimal since the first paragraph often contains important content if it is not a header. Some publishers also inserted short text such as "read more here" between paragraphs. To remove these irrelevant texts that can reveal publisher pattern, we remove any paragraph with less than ten words. Any article with less than ten words after the cleaning is discarded.

We consider (a) and (b) as basic data cleaning and apply them on all data. On the other hand, (c) is a more aggressive cleaning that is done only on training-1. This is because we have a comparatively large training set where we can afford filtering out information and even entire articles.

3 System Description

3.1 System 1

In the first method, we use training-1 to train our models, validation-1 to choose hyperparameters, and training-2 to test the models. As mentioned earlier, training-1 is labeled by publishers. While a biased publisher publishes more biased articles on average, it is unlikely that all of its articles are biased. Therefore, the labels are noisy, e.g., some labels are flipped. It is, however, difficult to identify the articles that have the wrong labels without manual inspection. We assume that the publisher labels are correlated with true bias labels, thus providing information to learn bias. To have an idea of to what extent this assumption holds, we investigate training-2. We select publishers of whom at least five articles are included in the dataset and whose media bias can be retrieved from Media-Bias/FactCheck[2]. This results in a total of 24 publishers. The publisher bias ratings on the website can be roughly mapped to 7 categories, extreme-left, left, left-center, center, right-center, right, and extreme-right. In Table 1, we list these publishers along with the percentage of the articles that are rated as hyperpartisan by crowd workers. The number of articles per publisher range from 5 to 24. Figure 1 shows the percentage of hyperpartisan articles in each category. We see that left-center and center publishers indeed have considerably less percentage of hyperpartisan articles. However, right-center publishers are almost as biased as right publishers. The observation can be due to the small sample size (the high percentage is caused mainly by the publisher RealClearPolitics). In general, there is a correlation between the publisher and true hyperpartisanship.

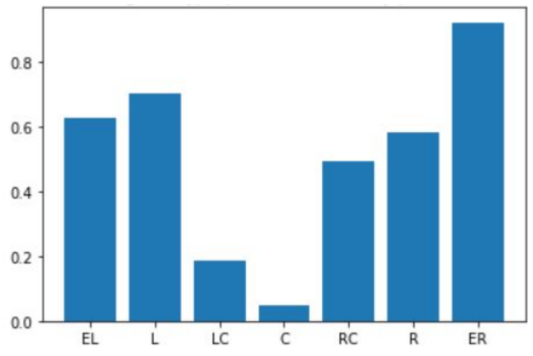

Figure 1: Percentage of hyperpartisan articles in the 7 bias categories: extreme-left (EL), left (L), left-center (LC), center (C), right-center (RC), right (R), and extreme-right (ER).

We use BoW and n-grams (n=1,2) as features, with different weighting schemes, including raw counts, binary, and TFIDF. For BoW and n-grams, the feature dimension is 50K and 500K respectively. We train two classifiers on each representation. The accuracy of the classifiers on validation-1 is listed in Table 2. We include experiments where training-1 is not cleaned with pre-

[2]https://mediabiasfactcheck.com/

processing step (c) to make sure that the step helps the task.

From the result, we observe that adding bigrams doesn't improve accuracy. We use the best model (BoW and an SVM classifier) to predict the articles in training-2. The accuracy is 56%, which is lower than the majority baseline of 63%.

Although we clean the dataset in an effort to prevent the classifier from overfitting on the publisher, it seems that the classifier cannot generalize to unseen publishers, and fails to capture bias. We also experiment with training a CNN (Kim, 2014) with the headlines, and a HAN (Yang et al., 2016) with the content. However, the two models again fail to generalize to new publishers. The observation makes us believe that the publisher labels are too noisy to be used directly to learn true bias. Another possible explanation could be that the publishers have too distinct writing styles so that the classifier focuses much on those features when learning.

3.2 System 2

Due to the observation in system 1, we decide to treat training-1 and validation-1 as unlabeled samples that can be used to train a feature extractor in an unsupervised setting. We then train the classifier using training-2. We use the first part of the data by the following two extractors.

1. TFIDF: The data is used to build vocabulary and record the inverse document frequency. All terms that occur in more than 90% of the documents are discarded, and we kept the most frequent 50K terms.

2. Doc2Vec: The data is used to train a PV-DM model proposed by Le and Mikolov (2014). We discard all terms that occur in less than 10 documents or are shorter than two characters. We train the model for 20 epochs using the implementation of gensim (Řehůřek and Sojka, 2010). When inferencing new documents, the word vectors are fixed and the model is trained for 100 epochs.

In addition, we experiment with using pre-trained word embeddings since the meaning of each word should not differ significantly in different corpora. We use vectors trained with GloVe algorithm (Pennington et al., 2014) on Wikipedia and Gigaword 5 [3]. The vectors are chosen because they are trained on Wikipedia and newswire text, which provides general knowledge and news domain specific usage. We take the vectors of each word in the document and average all the vectors. Stop words are removed, and if the document has more than 1000 words, we average over the first 1000 words (we find this to work better in our case empirically).

We also experiment with a set of features including normalized count of 5 POS tags, 6 readability scores, 8 normalized sentiment and bias word counts according to MPQA and bias lexicons (Wilson et al., 2005; Recasens et al., 2013), number of quotes, words, capitalized words, stop words, and sentences, and average length of words and sentences. This result in a total of 27 features which we call Feat.

For supervised training, we split training-2 into two sets. The first half, with 322 samples, is used to train and choose hyperparameters in a 10-fold cross validation setting. The second half, with 323 samples, is used for testing. We train LR and SVM on the features. Both linear SVM and SVM with rbf kernels are experimented with. We also have some initial experiments of single layer and two-layer neural networks of different hidden layer sizes but the small sample size makes them difficult to generalize.

4 Results

We first train LR and SVM with different GloVe vector dimensions. Table 3 shows the accuracy on the test set. SVM with rbf kernel works consistently better. The best vector dimension is 300.

We then compare different features, including TFIDF, Doc2Vec, GloVe, and the effect of adding Feat. Table 4 shows the accuracy on the test set. It shows that SVM performs better than LR, and only in the case of TFIDF does a linear SVM outperforms kernel SVM. It also shows that the pre-trained GloVe vectors achieve better performance than the vectors that are trained on our data. The ability to generalize might result from the larger corpus that is used to train the vectors. Adding simple lexical and sentiment features hurts the performance.

The three representations are furthered evaluated on another test set (the official test set of the

task) that is labeled by crowd workers. Since the additional feature set does not improve the performance, it is not further evaluated. In Table 5, the accuracy, precision, recall, and F1-score on the held-out test set are shown. Our classifiers tend to have a higher false negative rate. This can be due to the imbalance in the training data. Further experiments would be required to see whether re-sampling to have a balanced training set can improve that.

5 Conclusion and Future Work

In this paper, we present the system we use to compete in the SemEval-2019 hyperpartisan news detection task. The final model we use is a kernel SVM trained with pre-trained GloVe vectors. It turns out that a simple method which requires the least training time performs the best in this case.

Both system 1 and system 2 have interesting future work to be done. For system 1, it is interesting to correct the labels or filter the articles in order to obtain a cleaner data to learn from. For system 2, we plan to use contextual embeddings (Peters et al., 2018) or pre-trained language models (Radford, 2018; Devlin et al., 2018) to extract representations that are then fed into downstream classifiers. The high performances of the models made them interesting to compare with.

Abstract

We present our deep learning models submitted to the SemEval-2019 Task 4 competition focused at Hyperpartisan News Detection. We acquire best results with a Bi-LSTM network equipped with a self-attention mechanism. Among 33 participating teams, our submitted system ranks top 7 (65.3% accuracy) on the *labels-by-publisher* sub-task and top 24 out of 44 teams (68.3% accuracy) on the *labels-by-article* sub-task (65.3% accuracy). We also report a model that scores higher than the 8th ranking system (78.5% accuracy) on the *labels-by-article* sub-task.

1 Introduction

Spread of *fake news* (e.g., Allcott and Gentzkow (2017); Horne and Adali (2017)) (or 'low-quality' information (Qiu et al., 2017), among other terms) can have destructive economic impacts (Sandoval, 2008), result in dangerous real world consequences (Akpan, 2016), or possibly undermine the very democratic bases of modern societies (Qiu et al., 2017; Allcott and Gentzkow, 2017). Several approaches have been employed for detecting fake stories online, including detecting the sources that are highly polarized (or *hyperpartisan*)] (Potthast et al., 2017). Detecting whether a source is extremely biased for or against a given party can be an effective step toward identifying fake news.

Most research on news orientation prediction employed machine learning methods based on feature engineering. For example, Pla and Hurtado (2014) use features such as text n-grams, part-of-speech tags, hashtags, etc. with an SVM classifier to tackle political tendency identification in twitter. Potthast et al. (2017) investigate the writing style of hyperpartisan and mainstream news using a random forest classifier (Koppel et al., 2007). Further, Preoţiuc-Pietro et al. (2017) use a linear regression algorithm to categorize Twitter users into a fine-grained political group. The authors were able to show a relationship between language use and political orientation.

Nevertheless, previous works have not considered the utility of deep learning methods for hyperpartisanship detection. Our goal is to bridge this gap by investigating the extent to which deep learning can fare on the task. More precisely, we employ several neural network architectures for hyperpartisans news detection, including long short-term memory networks (LSTM), convolutional neural networks (CNN), bi-directional long short term memory networks (Bi-LSTM), convolutional LSTM (CLSTM), recurrent convolutional neural network (RCNN), and attention-based LSTMs and Bi-LSTMs.

We make the following contributions: (1) we investigate the utility of several deep learning models for classifying hyperpartisan news, (2) we test model performance under a range of training set conditions to identify the impact of training data size on the task, and (3) we probe our models with an attention mechanism coupled with a simple visualization method to discover meaningful contributions of various lexical features to the learning task. The rest of the paper is organized as follows: data are described in Section 2, Section 3 describes our methods, followed by experiments in Section 4. Next, we explain the results in detail and our submission to SemEval-2019 Task4 in Section 4. We present attention-based visualizations in Section 5, and conclude in Section 6.

2 Data

Hyperpartisan news detection is the SemEval-2019 task 4 (Kiesel et al., 2019). The task is set up as binary classification where data released by organizers are labeled with the tagset

	Labels-by-Publisher				Labels-by-Article		
	Train	**Dev**	**Test**	**Total**	**Train**	**Test**	**Total**
Hyperpartisan	383,151	66,849	50,000	500,000	214	24	238
Non- Hyperpartisan	416,849	33,151	50,000	500,000	366	41	407
Total	800,000	100,000	100,000	1,000,000	580	65	645

Table 1: Distribution of labels over our data splits.

{*hyperpartisan, not-hyperpartisan*}. The dataset has two parts, pertaining how labeling is performed. For **Part 1: labels-by-publisher**, labels are propagated from the publisher level to the article level. Part 1 was released by organizers twice. First 1M articles (less clean) were released, but then 750K (cleaner, de-duplicated) articles were released. We use all the 750K articles but we also add 250K from the first release, ensuring there are no duplicates in the articles and we also perform some cleaning of these additional 250K articles (e.g., removing error symbols). We ensure we have the balanced classes {hyperpartisan, not-hyperpartisan}, with 500K articles per class. For experiments, we split Part 1 into 80% train, 10% development (dev), and 10% test.

The labeling method for Part 1 assumes all articles by the same publisher will reflect the publisher's same polarized category. This assumption is not always applicable, since some articles may not be opinion-based. For this reason, organizers also released another dataset, **Part 2: labels-by-article**, where each individual article is assigned a label by a human. Part 2 is smaller, with only 645 articles (238 hyperpartisan and 407 non-hyperpartisan). Since Part 2 is smaller, we split it into 90% train and 10% test. Since we do not have a dev set for Part 2, we perform all our Hyperparameter tuning on the Part 1 dev set exclusively. Table 1 shows the statistics of our data.

3 Methods

3.1 Pre-processing

We lowercase all the 1M articles, tokenize them into word sequences, and remove stop words using *NLTK* [1]. For determining parameters like maximum sequence length and vocabulary size, we analyze the 1M articles, and find the number of total tokens to be 313,257,392 and the average length of an article to be 392 tokens (with a standard deviation of 436 tokens), and the number of types (i.e., unique tokens) to be 773,543. We thus set the maximal length of sequence in our models to be 392, and choose an arbitrary (yet reasonable) vocabulary size of 40,000 words.

[1]https://www.nltk.org/

3.2 Architectures

Deep learning has boosted performance on several NLP tasks. For this work, we experiment with a number of methods that have successfully been applied to text classification. Primarily, we employ a range of variations and combinations of recurrent neural networks (RNN) and convolutional neural networks (CNN). RNNs are good summarizers of sequential information such as language, yet suffer from gradient issues when sequences are very long. Long-Short Term Memory networks (LSTM) (Hochreiter and Schmidhuber, 1997) have been proposed to solve this issue, and so we employ them. Bidirectional LSTM (Bi-LSTM) where information is summarized from both left to right and vice versa and combined to form a single representation has also worked well on many tasks such as named entity recognition (Limsopatham and Collier, 2016), but also text classification (Abdul-Mageed and Ungar, 2017; Elaraby and Abdul-Mageed, 2018). As such, we also investigate Bi-LSTMs on the task. Attention mechanism has also been proposed to improve machine translation (Bahdanau et al., 2014), but was also applied successfully to various other tasks such as speech recognition, image captioning generation, and text classification (Xu et al., 2015; Chorowski et al., 2015; Baziotis et al., 2018; Rajendran et al., 2019). We employ a simple attention mechanism (Zhou et al., 2016b) to the output vector of the (Bi-)LSTM layer. Although CNNs have initially been proposed for image tasks, they have also been shown to work well for texts (e.g., (Kim, 2014)) and so we employ a CNN. In addition, neural network architectures that combine different neural network architectures have shown their advantage in text classification (e.g., sentiment analysis). For example, improvements on text classification accuracy were observed applying a model built on a combination of Bi-LSTM and two-dimensional CNN (2DCNN) compared to separate RNN and CNN models (Zhou et al., 2016a). Moreover, a combination of CNN and LSTM (CLSTM) outperform both CNN and LSTM on sentiment classification and question classification tasks (Zhou et al., 2015). The experiments of Lai et al. (2015) demonstrate that recurrent convolutional neural networks (RCNNs) outperforms CNN and RNN on text classification. For these reasons, we also experiment with RCNN and CLSM.

3.3 Hyper-Parameter Optimization

For all our models, we use the top 40K words from Part 1 training set (*labels-by-publisher*) as our vocabulary. We initialize the embedding layers with Google News Word2Vec model. [2] For all networks, we use a single hidden layer. We use dropout (Srivastava et al., 2014) for regularization.

Models	**Hidden No.**	**Drop out**	**Kernel size**	**Kernel No**
LSTM	300	0.1	N/A	N/A
Bi-LSTM	200	0.0	N/A	N/A
LSTM+Attn	500	0.0	N/A	N/A
Bi-LSTM+Attn	500	0.0	N/A	N/A
CNN	N/A	0.1	[4,5,6]	200
RCNN	200	0.3	N/A	N/A
CLSTM	200	0.3	[2,3,4]	70

Table 2: Our best Hyper-parameters.

For the best Hyper-parameters for each network, we use the Part 1 dev set to identify the number of units (between 100 and 600) in each network's hidden layer and the dropout rate (choosing values between 0 and 1, with 0.1 increments). For the CNNs (and their variations), we use 3 kernels with different sizes (with groups like 2,3,4) and identify the best number of kernel filters (between 30 to 300). All Hyper-parameters are identified using the Part 1 dev set. Table 2 presents the detailed optimal Hyper-parameters for all our models. [3]

[2]`https://github.com/mmihaltz/word2vec-GoogleNews-vectors`

[3]For all our networks, we identify our best learning rate as 0.001. For this reason, we do not provide learning rate in Table 2.

4 Experiments & Results

We run two main sets of experiments, which we will refer to as EXP-A and EXP-B. For EXP-A, we train on the labels-by-publisher (Part 1) train set, tune on dev, and test on test. All related results are reported in Table 3. As Table 3 shows, our best macro F_1 as well as accuracy is acquired with Bi-LSTM with attention (Bi-LSTM+ATTN). For EXP-B, we use Part 1 and Part 2 datasets in tandem, where we train on each train set independently and (1) test on its test data, but also (2) test on the other set's test data. We also (3) fine-tune the models pre-trained on the bigger dataset (Part 1) on the smaller dataset (Part 2), to test the transferrability of knowledge from these bigger models. Related results (only in accuracy, for space) are in Table 4. Again, the best accuracy is obtained with Bi-LSTM with attention.

SemEval-2019 Task 4 Submissions: We submitted our Bi-LSMT+Attention model from EXP A to the *labels-by-publisher leaderboard* in TIRA (Potthast et al., 2019), and it ranked top 7 out of the 33 teams, scoring at *accuracy=0.6525* on the competition test set. [4] From EXP-B, we submitted our model based on Bi-LSMT+Attention that was trained on Part 2 train exclusively dataset (by-ATC in Table 4) to the *labels-by-article leaderboard*. It ranked top 24th out of 44 teams (*accuracy=0.6831*). Post-competition, we submitted our EXP-B model that is pre-trained on the by-publisher data and fine-tuned on the by-article data (by-PSH+by-ATC in Table 4) to the *labels-by-article leaderboard*. It ranked top 8th, with *78.50% accuracy*. This might be due to the ability of this specific model to transfer knowledge from the big (*by-publisher*) training set to the smaller (*by-article*) data (i.e., better generalization).

5 Attention Visualization

For better interpretation, we present a visualization of words of our best model from EXP-B (by-PSH+by-ATC in Table 4) attends to across the two classes, as shown in Figure 1. The color intensity in the Figure corresponds to the weight given to each word by the self-attention mechanism and signifies the importance of the word for final prediction. As shown in Figure 1 (a), some heavily polarized terms such as 'moron', 'racism', 'shit',

[4]The competition test set is different from our own test set, which we created by splitting the data we received.

Models	Test Accuracy	Precision		Recall		F_1	
		Hyper	Non-hyper	Hyper	Non -hyper	Hyper	Non-hyper

	by-ATC	0.5504	**0.8615**	**0.8153**

Table 4: Results with Part 1 and Part 2 datasets (EXP-B). Last column "by-PSH +by-ATC" is the setting of our models pre-trained on Part 1 and fine-tuned on Part 2. +A= added attention.

'scream', and 'assert' are associated with the hyperpartisan class. It is clear from the content of the article from which the example is drawn that it is a highly opinionated article. In Figure 1 (b), items such as 'heterosexual marriage', 'gay', 'July', and 'said' carry more weight than other items. These items are not as much opinionated as those in 1 (a), and some of them (e.g., 'July' and 'said') are more of factual and reporting devices than mere carriers of ad hominem attacks. These features show that some of the model attentions are meaningful.

6 Conclusion

In this paper, we described our system of hyperpartisan news detection to the 4th SemEval-2019 shared task. Our best models are based on a Bi-LSTM with self-attention. To understand our models, we also visualize their attention weights and find meaningful patterns therein.

Abstract

In this paper, we present our submission for SemEval-2019 Task 4: Hyperpartisan News Detection. Hyperpartisan news articles are sharply polarized and extremely biased (one-sided). It shows blind beliefs, opinions and unreasonable adherence to a party, idea, faction or a person. Through this task, we aim to develop an automated system that can be used to detect hyperpartisan news and serve as a prescreening technique for fake news detection. The proposed system jointly uses a rich set of handcrafted textual and semantic features. Our system achieved 2nd rank on the primary metric (82.0% accuracy) and 1st rank on the secondary metric (82.1% F1-score), among all participating teams. Comparison with the best performing system on the leaderboard[1] shows that our system is behind by only 0.2% absolute difference in accuracy.

1 Introduction

Today in the age of digitization, a smartphone has become an indispensable tool for information sharing and consumption. It is much more convenient for users to read news through online articles and social media platforms. These platforms provide them quick and easy access to information almost everywhere. However, it is highly possible that the shared information is unverified and may bias the reader's opinions. This issue is exacerbated by the fact that most of the people find it difficult to distinguish between what's real and objective, what's fake and what's partisan.

Although these online news articles are expected to be written well-balanced without any prejudices, the authors/media houses may at times spill their standpoints and beliefs. Instead of providing a holistic view to the readers, the author tries to convey a picture with which he agrees and thus making the audience biased towards a party or a faction. When these news articles are extremely polarized towards one side of the argument, they are referred to as "Hyperpartisan News Articles".

This extreme polarization can leave users vulnerable to detrimental arguments and cloud their judgment to make objective decisions. These hyperpartisan articles may also carry some common elements of fake news. They are typically used to spread propaganda and manipulate readers. It targets human psychology by creating confirmation bias and echo chambers and therefore impairing their ability to dispel the hyperpartisan articles in favor of neutral articles.

SemEval-2019 Task 4 aims to solve this issue of hyperpartisanship. The objective of this task is to detect if a given news article has hyperpartisan arguments (extremely one-sided). In this paper, we have described our system that automates the process of identifying and annotating news articles as hyperpartisan or not.

2 Related Work

The problem of fake news and hyperpartisan has been discussed earlier by Potthast et al. (2017). They followed a style based approach to tackle the problem and have also suggested that writing style of left-wing and right-wing news are quite similar. Apart from this, there hasn't been much work in hyperpartisan news detection. Our approach is inspired by some recent work in the domain of sentiment analysis (Pontiki et al., 2016) and bias detection (Patankar et al., 2018; Recasens et al., 2013; Patankar and Bose, 2017; Baly et al., 2018). Jian and Wilson (2018) have explored linguistic signals embedded in news articles. They have used these linguistic clues to detect the spread of misinformation via social media. Iyyer et al. (2014) have

[1] https://pan.webis.de/semeval19/semeval19-web/leaderboard.html

studied the impact of words in identifying people's ideology and have proposed RNN to capture semantic features of a sentence.

3 System Description

Our hyperpartisan news detection system consists of three phases: 1) preprocessing, 2) generating article representation, and 3) training a classifier. An overview of our system is shown in Figure 1.

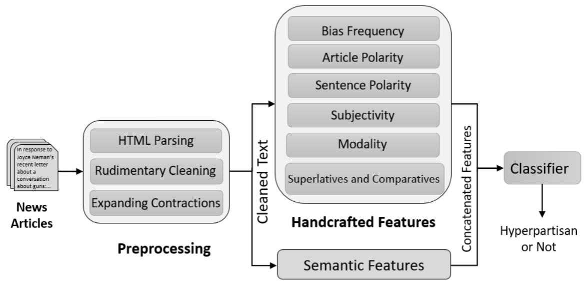

Figure 1: System Pipeline.

3.1 Preprocessing

The original dataset consisted of news articles along with HTML tags. Hyperpartisan news detection cleaner[2] was used to convert original text to plain text by removing tags. In the next step, further rudimentary cleaning of articles was done. We have also expanded contractions in the dataset like 'shan't' was converted to "shall not", 'don't' to "do not" etc.

3.2 Article Representation

Hyperpartisan news articles are extremely one sided and exhibits blind beliefs as compared to a neutral news articles. We have observed that writers of such articles generally, manifest usage of harsh tone and inflammatory language, they even exaggerate and convey opinions to stress their ideology. Hyperpartisan news articles tend to use superlatives and comparatives frequently to dramatize or exaggerate situations.

Polarity at an article level can capture emotions and sentiments of the article, it may also capture contextual polarity. Polarity at sentence level helps to identify bias localized to a sentence which might not be perceptible at an article level. It helps to shift the focus on bias-heavy sentences. By combining polarity at both levels, we can capture the tone, overpraise and sentiment in an article. Subjectivity, modality and bias lexicons help to discover the attitude, prejudice and beliefs expressed by the author. Building from these insights, we created a set of handcrafted textual features (HF), which are based on writing style, linguistics, and lexicons.

The problem with handcrafted features is that they don't capture the semantic relationship among the sentences. To solve this problem, we incorporated semantic features (SF) that can capture long-range dependencies of sentences and bring out the semantics of the article. The drawback of semantic features obtained via word based embeddings like Glove, is that it ignores word sequencing. In our approach, we have also explored features generated via distributed document representation (Universal Sentence Encoder or Doc2Vec) that are agnostic to word orderings and captures the semantics of an article.

Consider a set of N news articles $A = \{a_1...a_N\}$. Each article a_i has a set of $S = \{s_1...s_m\}$ sentences and a set of $W = \{w_1...w_l\}$ words, where l is the length of the article. We jointly used HF and SF to obtain article representation ($ArtRep$), where $\oplus$ is concatenation operator:

$$ArtRep = HF \oplus SF \tag{1}$$

Handcrafted features used in our system is described in Section 4 and semantic features are discussed in Section 5.

4 Handcrafted Features

Bias Score: For identifying bias words in an article, bias lexicon built from NPOV corpus of Wikipedia articles (Recasens et al., 2013) was used. Wikipedia advocates Neutral Point of View policy (NPOV), articles falling under NPOV dispute category were used to build this corpus. Bias score is the frequency of article words that occur in bias lexicon.

Article Level Polarity: Polarity of an article ($APol$) was extracted using MPQA Subjectivity lexicon (Wilson et al., 2005) ($SLex$), which lists around 8000 words with their prior polarity and their subjectivity type. Let a set of prior positive polarity words in an article be $PLex_i$ and negative polarity words be $NLex_i$. We computed positive ($APol_i^+$) and negative polarity score ($APol_i^-$) of

[2]https://github.com/webis-de/semeval19-hyperpartisan-news-detection-article-cleaner

an article a_i, where $\mathbb{1}$ is an indicator function:

$$APol_i^+ = \frac{1}{l}\sum_{j=1}^{l} \mathbb{1}(w_j \in (PLex_i \cap SLex)) \quad (2)$$

$$APol_i^- = \frac{1}{l}\sum_{j=1}^{l} \mathbb{1}(w_j \in (NLex_i \cap SLex)) \quad (3)$$

Sentence Level Polarity: Polarity was further fine-grained to generate features for sentences of a news article using Pattern toolkit for English [3]. A sentence s_j was given as an input to the toolkit and a polarity score α_j in the range of [-1.0, 1.0] was obtained. Positive ($PolScore_i^+$), negative ($PolScore_i^-$) and neutral polarity score ($PolScore_i^{Neu}$) of an article a_i was computed with $|0.1|$ as a threshold as it gave the best results for our system:

$$PolScore_i^+ = \sum_{j=1}^{m} \mathbb{1}(\alpha_j > 0.1) \quad (4)$$

$$PolScore_i^- = \sum_{j=1}^{m} \mathbb{1}(\alpha_j < -0.1) \quad (5)$$

$$PolScore_i^{Neu} = \sum_{j=1}^{m} \mathbb{1}(-0.1 \leq \alpha_j \leq 0.1) \quad (6)$$

Subjectivity and Modality: Subjectivity score is computed using Sentiment module of Pattern toolkit for English[3]. Toolkit gives a score based on adjectives and their context in the range of [0.0, 1.0]. Modality is a measure of the degree of certainty. It was computed using Modality module of Pattern toolkit for English[3].

Superlatives and Comparatives : Intensifying lexicons like adjectives and adverbs in superlative and comparative degree were used. We ran POS tagger from NLTK (Bird and Loper, 2004) on the article text to identify Subjective and Comparative adjectives and adverbs and their corresponding frequencies in the text were used as a feature.

5 Semantic Features

5.1 Glove

Glove (Pennington et al., 2014) provides distributional vector representations of words in the semantic space. We have used 300-dimensional Glove embeddings trained on Common Crawl data of 2.2 million words and 840 billion tokens. An article was tokenized into sentences and further into words to obtain it's article representation. Each of these words was vectorized using Glove pre-trained embeddings. Article representation was generated by averaging (Wieting et al., 2015) these 300-dimensional word embeddings.

[3]https://www.clips.uantwerpen.be/pages/pattern-en

Dataset	Articles
Hyperpartisan	238
Non-Hyperpartisan	407

Table 1: ByArticle Dataset statistics.

5.2 Doc2Vec

Doc2Vec (D2V) (Le and Mikolov, 2014) is an unsupervised algorithm to learn distributed representation of multi-word sequences in semantic space. We have used Python implementation of Doc2Vec provided by gensim to learn embeddings for the news articles. For our experiments, we have used 512-dimensional embeddings generated from D2V on article text.

5.3 Universal Sentence Encoder

Universal Sentence Encoder (USE) (Cer et al., 2018) is a pretrained model to generate embeddings for sentences, phrases and much larger multi-word sequences. It has shown good performance on diverse NLP tasks for e.g., phrase level opinion extraction and sentiment classification. USE takes English text as an input and generates 512-dimensional embedding. In our best system, we have used these 512-dimensional article embeddings, generated on feeding article text to USE.

6 Experiments

6.1 Dataset

We have used *ByArticle* dataset provided in the task, which is labeled through crowdsourcing. Dataset consists of 645 news articles and a label to denote if it is hyperpartisan or not, details of the dataset are provided briefly in Table 1. More information on the dataset can be found in (Kiesel et al., 2019).

Model	Acc.	Prec.	Recall	F1
Baseline	46.18	46.03	44.27	45.13
1st ranked system	**82.17**	**87.13**	75.48	80.90
SM	58.76	58.51	60.19	59.34
SC	65.76	70.37	54.46	61.40
B	68.63	73.31	58.60	65.13
SP	68.63	72.24	60.51	65.86
AP	65.13	64.90	65.92	65.40
HF	70.22	72.76	64.65	68.47
D2V+HF	73.41	69.60	83.12	75.76
Glove+HF	78.34	82.01	72.61	77.03
USE+HF	82.01	81.50	**82.80**	**82.15**

Table 2: SemEval-2019 Task 4 Performance comparison on hidden test data (SM: Subjectivity and Modality, SC: Superlatives and Comparatives, B: Bias Score, AP: Article Level Polarity, SP: Sentence Level Polarity, HF: set of all Handcrafted Features). All results reported in the table are in percentage and rounded to 2 decimal places.

6.2 Results and Analysis

Handcrafted features were concatenated with semantic features, to generate a rich article representation which was fed to the classifier as an input. A L2-regularized logistic regression (Pedregosa et al., 2011) classifier was trained with 10-fold cross-validation. Since the training dataset is unbalanced, we have used class weighted logistic regression by weighing classes inversely proportional to their frequency.

For evaluation, a balanced hidden test data (*ByArticle*) was provided by the organizers through TIRA (Potthast et al., 2019). We have used accuracy for performance evaluation, which was a primary performance measure in the task. Apart from this, we have also reported precision, recall, and F1-score on the dataset.

Table 2 shows the performance of our various approaches against the baseline results (Task 4 semeval-pan-2019-baseline on TIRA[4]). From the results, we can observe that our best performing system has outperformed the baseline by a huge margin, recording an absolute jump of 35.83% accuracy. We can also see that our system is as good as the best system (bertha-von-suttner[4]) submitted for the task, which has 82.17% accuracy, showing that we were behind by only 0.16%.

In order to assess the importance of each handcrafted feature, we performed experiments by using individual features and their combination (HF). In fact, Table 2 highlights that all the features jointly perform well with 70.22% accuracy. We found that bias lexicon and polarity based features are the most informative ones.

In an attempt to further improve our model's performance, we experimented by combining semantic features with handcrafted features as described in Section 3.2. Our results have also shown that handcrafted features alone aren't sufficient and better performance can be achieved by combining them with semantic features. USE+HF has beaten all our other models and showed an absolute improvement of 11.79% accuracy over the HF model. It also attained 1st rank on the leaderboard (based on F1-score) and 2nd overall rank (based on Accuracy).

The poor performance of D2V+HF can be attributed to the training of D2V as typically D2V requires large data for training. Results have also shown that USE+HF performed better than Glove+HF, and thus validating our earlier claim of limitations of word-based embeddings.

7 Conclusion and Future Work

In this paper, we proposed a novel approach to detect hyperpartisan arguments in a news article. Our system ranked 2nd in SemEval-2019 Task 4. Our approach leverages rich semantic and handcrafted textual features. In the paper, we have also studied the importance of capturing semantic relationship among sentences of an article. Our system employed linguistic and lexical features to detect polarity, sentiments and blind beliefs exhibited in an article. Experiments with various model configurations demonstrated the effectiveness of our approach.

Detecting hyperpartisan in news articles should also, involve incorporation of world knowledge, as statements as an individual may not be extremely biased but when seen from a global perspective, they turn out to be hyperpartisan. As a future work, we would like to exploit the use of external knowledge. We would also like to investigate the role of credibility of news sources (Baly et al., 2018; Popat et al., 2018) in detecting hyperpartisan news articles.

Abstract

The viral spread of false, unverified and misleading information on the Internet has attracted a heightened attention of an interdisciplinary research community on the phenomenon. This paper contributes to the research efforts of automatically determining the veracity of rumourous tweets and classifying their replies according to stance. Our research objective was to investigate the interplay between a number of phenomenological and contextual features of rumours, in particular, we explore the extent to which network structural characteristics, metadata and user profiles could complement the linguistic analysis of the written content for the task at hand. The current findings strongly demonstrate that supplementary sources of information play significant role in classifying the veracity and the stance of Twitter interactions deemed to be rumourous.

1 Introduction

Social networks continue to contribute to the way people connect, stay informed and contribute above and beyond what concerns their lives. However, these platforms currently play a crucial role in viral spreading of false information, and no doubt will become even more instrumental in the future. Consequently, it will be increasingly important to devise systems and establish practices of automatically identifying, filtering and labeling false information in order to help people make sense of information dispersed through social channels.

The damaging consequences of malicious intents to misinform, confuse and provoke through social media platforms remain persistently high in the discussions of researchers and practitioners. Perhaps even more so than the benefits of information dissemination. While the veracity of some false information can be determined unambiguously from external sources, it is a major challenge to verify the truthfulness of rumourous postings. Indeed, predictive analysis remains the primary manner in which social platforms could face the challenge of identifying rumours and taking appropriate actions. Over the past several years, research has emerged and at the same time, many challenges remain.

Decoding elusive social phenomenon such as spreading rumours is challenging not only due to their complexity, but also due to the diversity of the underlying causes and heterogeneity in their manifestations. Rumours represent intertwined threads of sensemaking Bordia and Difonzo (2004) that are initiated and spread by people trying to explain, solve and remove uncertainty relating to events and persons that attract public interest Peterson and Gist (1951). We argue that solutions that address these multi-dimensional issues cannot solely rely on natural language processing (NLP). Combining natural language processing with social analytics extends beyond the traditional realms of either technology to a variety of emerging applications, including rumour analysis.

The analysis of rumours can take on different meanings depending on the application domain - this research focuses on identifying the veracity of a rumourous tweet (Task B) and the stance of its replies i.e., classifying responses to a rumourous post as supporting, denying, querying or commenting (SDQC) the claim (Task A), both part of the RumourEval 2019 Gorrell et al. (2019). While this work was developed on the foundations laid out by previous research in the field Derczynski et al. (2017), it is among the rare solutions that explore complementary types of information that could augment the linguistic analysis when analyzing rumourous tweets. After a brief discussion of relevant research that is closely related to our objective, we highlight the primary findings of our research.

2 Related work

Our research follows the line of work of the research groups that have contributed to the discourse on the rumour analysis with several experimental studies. A review of past SemEval related tasks points out that much of the research of the problem of examining the veracity and support for rumours focused more on language analysis and less on utilizing the external information made available by the Twitter dataset. The findings that extend across several studies is how rather simplistic NLP techniques and analysis are capable of obtaining satisfactory results when classifying the support of rumourous posting. The similarities and differences between the work presented in this paper and previous research is discussed.

A model for automatic identification of rumourous tweets and classification of their responses into two denying and supporting classes, presented in Qazvinian et al. (2011), is based on linguistic features, such as, unigrams, bigrams, POS tags, URLs, and hashtags. While, we built upon the experiences of this research, especially in the approach of replacing a multi-class classification problem with a hierarchical pipeline of binary classifiers, our approach differs in a number of aspects. In particular, we further enhance the representation of rumourous posts with a number of features, from word embeddings, sentiment and stylistic features to structural properties of interaction threads. In addition, we argue that a suitable preprocessing of tweets is essential for successive NLP steps, which is in contrast to their decision not to perform any preprocessing of the text.

The research study by Lukasik et al. (2015) extends on the work of Qazvinian et al. (2011), especially by incorporating preprocessing steps, bag-of-words (BoW) and word clustering. The approach presented in this paper follows some of these ideas, although it differs in the scope and the way features are operationalized. For instance, TF-IDF n-gram counts and clusters of Word2Vec embeddings were used in our model.

Based on the premise that psychological and sociological information could play a key role in determining the truthfulness of rumours and inspired by the research of Mihaylova et al. (2018) on fact checking of questions posted on online forums, we have further explored the effect of various metadata and information from users profiles on the performance of the task.

3 Methods

3.1 Dataset

The dataset used for evaluating the model proposed in this research was made available by Zubiaga et al. (2016b). The rumourous tweets and their corresponding interactions threads were harnessed in 2016, verified and labeled by journalists and sociologists using crowdsourcing platforms Zubiaga et al. (2016a). The dataset contains rumourous tweets written in English, associated with nine events, five being news stories and four concerning specific events. Out of a total of 4560 tweets, 297 represent rumourous posts annotated for veracity, while the rest are responses to the original rumour, annotated according to their stance i.e., supporting, denying, querying or commenting the initial claim.

3.2 Preprocessing

Tokenization, part-of-speech tagging, lemmatization, and substitutions were used as preprocessing techniques; the set and order of preprocessing steps varies between features. In addition, a number of context-appropriate corrections of language variations of English e-dialect were performed:

- Characters are converted to lower-case letters; for sentiment feature extraction the original letter case was preserved;
- URLs, numerical sequences, email addresses were replaced with special tokens (e.g., *URL*, *NUM*, *EMAIL*). Special tokens, *QUOTE* and *USER*, were used whenever the original rumour tweet was quoted or a user is mentioned in a response tweet;
- For each hashtag, the # sign is replaced with a special token *HASHTAG*, while the text of the hashtag was kept for further analysis;
- Emojis are identified and each was represented as a different token;
- Consecutive repetitions of a character in a word were contracted to 2 instances of the character;

- All special characters were removed, with the exception of `\s\n\r.,?!:-+` that were treated as separate tokens

3.3 Feature Extraction

Automatic extraction of information related to language, discourse and context is a difficult task. Among different combinations of features, the model that yielded the best result is described. Linguistic analysis for extraction of seven types of features was performed on the preprocessed text of each tweet. In addition, we have analyzed the content of user profiles, including profiles of the initiators of rumours and those replying to initial posts. Our assumption was that while tweet analysis captures indicators pertaining to a particular rumour thread, the language analysis of a user profile could provide insights into personality, attitudes and online behavior of a user.

Language style features - In examining previous research on rumour analysis, we found that stylistic features are frequently presented as simple statistical features which had an effect on the performance of the task. We have considered the following: number of words and sentences, average number of words per sentence, ratio of word vs. non-word tokens, percentage of present dictionary words, mean and variance of word length, and percentage of unique words. The same set of stylistic features were calculated for the content of each tweet as well the text content found in the profile of the user who has posted the tweet.

Language model n-grams - Unigrams, bigrams and trigrams were extracted from the tweets and users profiles, keeping only 1/8, 1/16 and 1/20 of the most frequent unique unigrams, bigrams and trigrams respectively. Six vocabularies were created; three n-gram vocabularies for the tweets and three vocabularies of n-grams found in user profiles. Term frequency-inverse document frequency (TF-IDF) values were calculated and utilized as the final language model features.

POS tags - In accordance with the well-established practice to complement the language model n-grams with their part-of-speech tags, TF-IDF values were calculated for two POS tag vocabularies, one relating to tweets, the other to self-descriptions left by users in their profiles.

Word2Vec embeddings - Stop-words were removed and lemmatization was performed on the tweets as well as user profile text. Two Word2Vec models were trained on the SemEval 2019 dataset, one was trained on the sentences of the tweets, the other on the content of user profiles. The dimensionality of the vectors was set to 500. A context window of size 5 was used, while words with frequencies above 0.001 were subsampled. The two vocabularies of embedding vectors were clustered using the K-Means algorithm; the parameter K was set automatically to ensure that each word cluster will contain an average of 10 items. At last, for each token list, a Bag-of-Centroids feature vector was calculated by counting the word clusters the tokens belong to.

Sentiment features - Consistent with related studies, which suggest the predictive power of affective words on the task relating to detecting deception in online text, we perform a polarity sentiment analysis on the tweets, calculating three polarity scores, positive, negative and neutral for each sentence. The NLTK, Vader Sentiment Intensity Analyzer, was used because of its reported robustness to the style of online e-language (e.g., capitalization, punctuation, slang) Hutto and Gilbert (2014). A sentiment feature vector for each tweet was generated from the mean and variance for each polarity score.

Network structure - Social network communication exchanges (e.g., tree-structured threads of tweets) are naturally represented as graphs (DAG) - nodes represent rumour posts and their responses, while directed edges of the graph associate responses (e.g., reply, comments) with the target of their response. Based on the premise that variations in the structural properties of the underlying rumour threads could play an important role in identifying and classifying the veracity of rumours tweets and their responses, the following network characteristics were used: DFS and BFS priority, degree centrality, betweenness centrality, closeness centrality, HITS hub score and PageRank.

Twitter metadata - Several Twitter metadata were retrieved and included in our model. The following list of information were considered to be relevant and were added as separate features: the number of characters in a tweet, the number of favorites and retweets and the number of days since initial posting. For each user, the information whether the user account is verified, the number of user's followers, the number of statuses, the number of friends, the number of favorites, number of times listed and how long the user has had a Twitter account were also included. Some additional information on the graphical design choices a user made were also considered. For example, whether there is a background image or a default image was used and the colors selected for the text, border, sidebar, background and hyperlinks.

Similarity measure - Transmission of context shared by the initial rumour tweet and its responses was postulated to be important for the task of classifying the support of the responses (task A). Consequently, it was decided to calculate the differences between the feature vectors of each response tweet and the rumour tweet it replies to.

3.4 Feature Selection

The feature extraction process resulted in a set of approximately 14000 features for each tweet, in addition to the ones resulting from textual analysis of the user profile. Appropriate feature selection is essential for achieving good performance and avoiding overfitting by removing uninformative, redundant or noisy information. First, the features were normalized to the interval [-1, 1] using generalized Min-Max normalization. Then, a Random Forest classifier was used as a basis for calculating the information gain of each feature. The features with an above-average information gain score were selected, reducing the number of features by a factor of 10. It was decided not to eliminate any correlated features as the number of samples is quite low and any detected correlation might be due to statistical falsehood.

3.5 Model training

At the outset of our explorations in order to circumvent the difficulties imposed by a multi-class classification problem, presented as task A, a hierarchical one-vs-rest approach was adopted. To this end, a binary classifier was used to classify each response tweet into two classes, comment or non-comment; the next step classifies each non-comment tweet as a query or a non-query type. In the end, each non-query response was classified as being in support or denial of the original rumourous post.

Balancing of the datasets was a necessary step during the training of the models for task A, as the distribution of the original four SDQC classes was not uniform. The balancing process was performed by repeated random sampling. Thirty candidate datasets with uniform class distribution were formed by random sampling the more prevalent class and the best candidate was chosen using 3-fold cross validation with a Naive Bayes classifier.

The models used for Task A and B are ensembles of six different classifiers, including: Naive-Bayes, K-Nearest-Neighbours, Logistic Regression, Support Vector Machine, Neural Network and Random Forest. The ensemble classifier for task A was operationalized as majority voting, while for task B, probability-weighted voting was used (probability weights correspond to the confidence level of the veracity scores).

In order to train and evaluate the ensemble, each dataset was split into a training and a validation set using 3-fold cross-validation with stratified sampling. This process was repeated 10 times and the final evaluation scores were calculated by averaging the scores from each iteration. For some training runs, the parameters of the classifiers had been optimized by 3-fold cross validation using grid search. However, no notable improvements in evaluation results were witnessed.

The system[1] was implemented using Python 3.6, with the ScikitLearn, NLTK, gensim and NetworkX packages Pedregosa et al. (2011); Bird et al. (2009); Řehůřek and Sojka (2010); Hagberg et al. (2008).

4 Discussion of results

The performance results obtained by the model that included all categories of features, discussed in the previous section, when tested on our validation set are presented in Table 1. The same model was used to create our final submission for SemEval Task 7. It is worth noting that the best results were obtained for identifying queries in task A, obtaining an accuracy of 0.784, demonstrating that the model accuracy rivals the performance of domain experts. We would like to highlight the consideration that no external sources were used for determining the veracity of a rumour posting, including the resources deemed as appropriate by the task organizers, which might explain the lower performances on the second task B.

Although the aforementioned results provide compelling evidence suggesting that fusing linguistic analysis, metadata, user profiles and rumour thread structure can lead to satisfactory results for classifying the stance of a response to a

Model	Accuracy	Precision	Recall	F1	ROC AUC	Log loss
Task A - Comment	0.767632	0.773194	0.767632	0.766449	0.767632	/
Task A - Query	0.784186	0.790382	0.784186	0.783002	0.784190	/
Task A - Support/Deny	0.682915	0.687301	0.682915	0.681009	0.682702	/
Task B - Veracity	0.681707	0.693103	0.681707	0.677606	0.681707	0.600458

Table 1: Evaluation metrics on a randomly-created validation set

rumourous tweet, we have conducted two ablation studies, to find evidence of the performance gains that could be contributed to each category of features on both tasks.

The present study suggests that text analysis of rumourous tweets is the most important, yet not the sole constituent element when detecting the veracity of rumourous tweet and distinguishing the stance of the social response. While we are not in position to ascribe sound theoretical reason to all effects, we present the trends that appeared interesting and highlight the sensitivity of the performance results towards a particular category of features.

Table 2 displays the F1 results of ablation study when training the models for task A, removing one category of features at a time. The results affirm that capturing the metadata relating to the users profile and structural properties of the tree-like threads of tweet exchange complement the linguistic features and improve the predictive accuracy, especially for distinguishing between query, support and denial stance in rumour replies.

The ablation analysis strongly demonstrates that Twitter metadata has the most dramatic effect on distinguishing **comments** from all other rumour responses - removal of this category results in lowering the F1 values by 0.17. It appears that user's historical and behavioral metadata add to the prediction performance complementing the relevant n-grams in the content of the tweet and user profile. Some of the most relevant indicators in the rumourous comment include: end of sentence punctuation, hashtags, user mentioned in the tweet, pronouns and words such as: *reported*, *happening*, as well as n-grams extracted from the user profile, such as: *blog*, *I am*, *concerned citizen*, *culture*, *enthusiast*, *living*, etc.

Language model and word vectors representation of the content of tweets and user profiles were indicated as better predictors when identifying replies in the form of **queries**, resulting in 0.12 decrease in F1 values, if removed from the model. Some of the most relevant features were not surprisingly related to detecting question forms: *why*, *where*, *question mark at the end of a sentence*, *who was*, *what is*, *confirm*, *need*, and a number of word2vec clusters. In addition, language style, sentiment and Twitter interaction threads have also ranked in the top 10% of the most relevant features.

Sentiment and structural features have a more notable effect on discriminating between **supportive and denying responses**. We could hypothesize that the affective content of a tweet is a crucial indicator when distinguishing positive (confirmative) vs. negative (opposing) opinion toward the source tweet with rumourous claim. The top 10% of the best predictive indicators were the sentiment words, and n-grams, such as: *not*, *believe*, *know*, *oh*, *ugh*, *such*, *yeah*, *understand*, socially offensive words etc.

Table 3 shows the cross-entropy loss yielded by the models after each ablation step trained for predicting the **veracity** of a rumour (task B). The findings highlight the ability of language indicators to model the truthfulness or deception of a claim. The features with most predictive power were language model and word vector clusters, especially numbers and URLs in the tweet text, and words obtained from the user profile, such as: *delivering you*, *insightful analysis*, *breaking news*, *contact*, *facebook*, *latest*, *tweets*, *we*, *views*, EMAIL, *online news*, *around the world*, *channel*, *bbc*, *bbcsport*, *cnn*, etc.

The current findings demonstrate surprisingly low accuracies, (F1 = 0.21645 for Task A, F1 = 0.3326 for Task B) when evaluated on the testing dataset, although in line with the results of previous tasks on the same dataset Derczynski et al. (2017). Collecting larger quantities of Twitter data and optimization techniques could improve the consistency of the results obtained on the training and validation sets. Importance of close inspection of data, and comparative analysis with other research on the same task could better support the

interpretation of the results. We defer such discussion and directions for future research, until a detailed analysis of misclassified cases is done and proper treatment and improvements of such scenarios could be speculated.

5 Conclusion

The present research explores a hybrid approach to the problem of analyzing the veracity of rumours and the support for rumours on social media platforms. Following the results of previous research in this field, different combinations of features were examined, while also leveraging a variety of tangible indicators not accounted for in related research. The recurrent challenges in fully elucidating the language ambiguities of complex phenomena such as rumour spreading led us in a direction of including distal contextual indicators. In particular, the models were augmented with language indicators extrapolated from the content of user profiles, Twitter metadata, and thread structural characteristics of rumourous tweets. Their relevance and predictive effects have been confirmed with the results, providing exciting directions for further research on the problem.

Abstract

Researchers have been paying increasing attention to rumour evaluation due to the rapid spread of unsubstantiated rumours on social media platforms, including SemEval 2019 task 7. However, labelled data for learning rumour veracity is scarce, and labels in rumour stance data are highly disproportionate, making it challenging for a model to perform supervised-learning adequately. We propose an inference chain-based system, which fully utilizes conversation structure-based knowledge in the limited data and expand the training data in minority categories to alleviate class imbalance. Our approach obtains 12.6% improvement upon the baseline system for subtask A, ranks 1st among 21 systems in subtask A, and ranks 4th among 12 systems in subtask B.

1 Introduction

With the universality of the Internet, social media has become the main channel for acquiring and exchanging information. However, the free flow of information has given rise to the prevalence of rumours, among which fake ones are harmful since they are generally convincing and hard to distinguish. To address this problem, we need automatic rumour veracity classification on social media. A large amount of rumour stance instances on social media have been employed to assist the model in making better predictions regards the rumour's veracity.

Rumour stance classification and rumour veracity classification are two subtasks of SemEval 2017 Task 8 (Derczynski et al., 2017) and SemEval 2019 Task 7 (Gorrell et al., 2018). Subtask A predicts the stance of a post replying to a rumourous post, in terms of supporting, denying, querying and commenting the rumour. Subtask B anticipates the veracity of a rumour as true or false given the rumourous post and a set of additional resources.

Apart from variations in models, research in this area mainly focuses on the special characteristics of data coming from social media: conversation structure, rich intrinsic features, skewed distribution toward the *comment* class in rumour stance data and scarcity of available data for rumour veracity classification. While most pioneering works treated rumour evaluation as a single-tweet task, attempts to utilize the conversation structure included pairing source and replies together to make up input (Singh et al., 2017), and adopting the full conversation thread as input in the time sequence (Kochkina et al., 2017). With the realization of rich features hidden in tweet contexts, Qazvinian et al. (2011) was one of the first who extracted them and combined them with model input. The feature sets were augmented during the following work. In trying to acquire more comprehensive information, not only features of the tweet for prediction were taken into consideration, but also features from its conversation context (Enayet and El-Beltagy, 2017). To address the class imbalance problem, Wang et al. (2017) transformed subtask A into a two-step classification task: they first classified comments and non-comments, and then categorized non-comments into the other three classes. Finally, in order to make up for the absence of abundant accessible training data in the rumour veracity classification task, external resources usage such as Wikipedia dumps and news articles was encouraged in both RumourEval contests.

In our work, we find that simply taking the whole conversation as input is inadequate. We have to recognize the role each part assumes in the conversation thread and mark them accordingly in the input. Instead of filtering features solely based on the system performance, we prefer to run a feature selection before adding to the system and choose those that can bring a high deviation degree between data categories. Following the feature extraction work of Enayet and El-Beltagy (2017), we consider introducing more features from the conversation context to further assist model judgment. We alleviate class imbalance in stance classification by expanding training data in the under-represented classes with pre-screened external data from similar datasets. At last, we approach the data insufficiency issue by setting an average length limit and cutting the overlength ones to enlarge training data.

We propose an inference chain-based system for this paper. A conversation thread starts with a source tweet, and follows by replies, in which each one responds to an earlier one in time sequence. When we infer the stance of one tweet, the source or earlier replies in the same thread can give abundant additional hints. Therefore, we take each conversation thread as an inference chain and concentrate on utilizing it to solve the data issues discussed earlier.

Our approach for both tasks is fine-tuned on Generative Pre-trained Transformer (OpenAI GPT) (Radford et al., 2018), a model that has performed well in 9 NLP tasks. Our work primarily focuses on subtask A rumour stance classification, in which we expand training data from similar datasets, extract features and join separate parts to form input according to their roles in inference chain. For subtask B rumour veracity classification, we apply similar feature extraction and input concatenation process, except for replacing the data expansion step with data slicing. With the above implementation, our model outperforms all other systems in subtask A and places 4th in subtask B in SemEval 2019.

2 System Description

We propose a system that focuses on inference chain-based knowledge enhancement. The operations involved are displayed in Figure 1. We first perform data preprocessing on the raw dataset (Section 2.1) to fetch tweet content and facilitate the subsequent feature extraction step. Then we implement two data extension mechanisms on the training data: to relieve class imbalance toward one category in subtask A, we expand training data with external datasets (Section 2.2); to alleviate data sparsity and try to avoid under-fitting

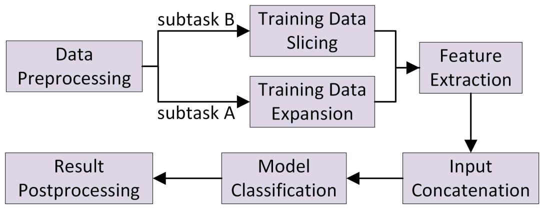

Figure 1: The operational flowchart for our system.

on the training set in subtask B, we set a length limit for each part of the input and split data instances accordingly (Section 2.3) to enlarge the amount of data. In trying to better utilize inference chain-based features, we extract word-level and tweet-level features and filter them for each subtask (Section 2.4). Finally, we concatenate each part in the inference chain with its features together (Section 2.5) and feed them in the model. After model classification, we adjust some of the results(Section 2.6) according to the organizers' requirements.

An illustration of our system is shown in Figure 2. How our base model GPT performs on the two classification tasks is depicted in the upper left corner. The right side presents how we organize our input for subtask A and B. In the lower left corner, we give an example of an inference chain (conversation thread) in the training data. To help understand, we define each part of it for the rest of this passage. For subtask A, we divide an inference chain into four parts: *source tweet*, *other tweets*, *parent tweet* and *target tweet*. For subtask B, an inference chain constitutes of a *source tweet* and a *thread content*. To better clarify, a *thread content* is defined as a whole inference chain excluding the source tweet, and we also define a whole inference chain excluding the target tweet as a *conversation context*. As depicted in the upper left corner, the goal is to predict the stance of a target tweet toward a rumour for subtask A, and the veracity of a rumour(usually contained in the source tweet) for subtask B.

2.1 Data Preprocessing

After extracting the tweet content out of the original data, we first perform word tokenization with Stanford CoreNLP[1], Spacy[2] and NLTK tools[3], among which the result of Stanford CoreNLP

user0: DETAILS: The hostage site is Lindt Chocolat Cafe near #Sydney Harbor http://t.co/1ZlzKDjvSf http://t.co/7u8EFUwCey

user1: @user0 Evacuate the city, asap! We do not know if he acts on his own yet he threatens he has devices all over Sydney.

user0: @user1 well...you're just a silly paranoid fuck now aren't you

user1: @user2 @user0 I hate terrorism and I am worried about the people of our western civilisation.

user2: @user1 @user0 western countries have killed more innocent children than hitler assmunch. But you prob don't consider that terror??

Figure 2: An overview of our system. The upper left corner is a diagram of how our base model GPT performs on the two classification tasks. The upper right corner is how we organize our input for subtask A and B. The lower left corner is a data example which helps explain "inference chain", "source tweet", "other tweets", "parent tweet", "target tweet", "thread content" and "conversation context" in the input. The lower right corner is the features we combined in the input.

proves to be the best. Then we fix some tokenization inaccuracies in the result. Blanks, emoticons and uncommon punctuations are removed to reduce the amount of Out of Vocabulary (OOV). Besides, we transform all user mentions into "@" and all URLs into "urlurlurl" in order to increase the repetition rate of these features and allow the model to learn them better. Finally, we convert all letters into their lower case for the same purpose.

Training Set			
Class	**Origin**	**Extended**	**Sum**
support	925(18%)	797	1722(23%)
deny	378(7%)	696	1074(14%)
query	395(8%)	912	1307(17%)
comment	3519(67%)	0	3519(46%)

Table 1: Distribution of tweets between classes before and after data expansion in the training set for subtask A.

2.2 Traning Data Expansion

We find that the data distribution in the training set is skewed toward *comment* in subtask A, which explains why it is hard for the model to reach high precision and recall scores in the other three classes. Thus we expand the training data with datasets on similar tasks with labels corresponding to the three minority classes in seeking for better class balance and more sufficient training.

For *support* and *deny*, we take each claim as both the target tweet and its conversation context in stance classification datasets SemEval 2016 task 6 dataset (Mohammad et al., 2016), Emergent (Ferreira and Vlachos, 2016), and twitter sentiment analysis dataset sentiment140 (Go et al., 2009). For *query*, we use passages as the conversation context, unanswerable questions as the target tweet in reading comprehension datasets SQuAD 2.0 (Rajpurkar et al., 2018) and CoQA (Reddy et al., 2018).

The acquirement of extended data takes two steps. We first calculate the sentence similarity of each data piece in external datasets with all sentences in the original dataset in terms of Levenshtein Distance, and only keep instances whose minimal distances with the original dataset are below 0.7. Then we test them in a model trained with the original dataset. If the model prediction is identical to the label we expect, we append this instance in our training set for subtask A. The data distribution before and after data expansion is shown in Table 1.

2.3 Traning Data Slicing

The training set for subtask B only has 327 pieces. Since the organizers define subtask B as a binary classification task, which classifies instances into two categories: *true* and *false*, and takes pieces whose confidence scores below 0.5 as *unverified*, the *unverified* class in the training set is entirely useless, which takes up 98 pieces. Discard of this class only makes the data scarcity problem worse and may lead to under-fitting on the training set.

We try to extend the training set from a different angle. We look at the distribution of sequence length and set a length restriction for each conversation context to 70 tokens and each target tweet to 28 tokens. For those that exceed the limit in the training set, we truncate each piece to the edge to create multiple instances and thus enlarge the training set. For the development set and test set, the length restrictions are also set, but only the first truncated piece for each instance is taken as input. Although data slicing may hurt long-distance dependency, the experiment result shows that this method performs better than the original.

2.4 Feature Extraction

Inspired by the features extracted by Kochkina et al. (2017) and Bahuleyan and Vechtomova (2017), we collect 56 word-level features and 16 tweet-level features. For word-level features, we calculate their distribution percentage on the four categories in subtask A and the three categories in subtask B in the training and development set, and only apply those that mark a clear distinction between the classes for each subtask. For the numerical tweet-level features, we cluster each one into several groups according to their values and determine a common value for the whole group. Where to add the features is illustrated on the right side in Figure 2.

After selection, the word-level features we apply to subtask A and B are as below:

Subtask A: Whether the tweet content has question marks, hashtags, URLs, “RT”(refers to retweet), positive words, negative words, swear-words, query words, forbidding verbs, accusing verbs, complaining verbs, warning verbs, permitting verbs, praising verbs, etc.

Subtask B: Whether the tweet content has exclamation marks, positive words, negative words, query words, false synonyms, false antonyms, declaring verbs, confirming verbs, arguing verbs, etc.

The tweet-level features we add for subtask A are as below:

Features for both Twitter and Reddit: Tweet favourite count, tweet depth in the thread and whether the user has user description.

Twitter-specific features: User-related features include whether the user is verified, user-related URLs, whether the user uses the default profile, user followers count, user friends count, user listed groups count, and user statuses count. Tweet-related features include tweet retweet count.

Reddit-specific features: Whether the tweet has self-text, tweet kind, whether the tweet is archived, whether the tweet is edited, whether the user is a submitter.

We’ve tried to add the above tweet-level features to input for subtask B, but unfortunately observe no performance improvement in our experiment, so the official submission for subtask B involves no tweet-level features.

As indicated in Enayet and El-Beltagy (2017), whether the users of the source and parent tweet are verified are useful in performance improvement for subtask A. So we speculate that word-level features and other tweet-level features may also be necessary hints for model prediction. We find that the model always creates mispredictions because the stance of the target tweet toward the rumour is indirect. Since many tweets express direct stances toward their parent tweets, we can infer their stances toward the rumour with the help of their parent. In addition, the model often mistakes the stance of target tweet toward source tweet as its stance toward the rumour. But in cases where the source tweet expresses *deny* towards the rumour, the two stances above are not consistent. Therefore, parent tweet and source tweet assume significant roles in an inference chain and we need to acquire more knowledge from them to improve the prediction accuracy of the target tweet. So we apply all filtered word-level and tweet-level features for the source, the parent and the target to the input for subtask A.

2.5 Input Concatenation

As described above, the model is likely to make correct predictions when it learns information from earlier tweets in the inference chain. We plan to concatenate the contexts in the inference chain with the target tweet to make up for input. The input concatenation method is depicted in the upper right corner of Figure 2. We concatenate *source tweet* with *thread content* to form an input structure for subtask B. We apply two methods in subtask A. At first we concatenate the *conversation context* and the *target tweet* with the same structure as subtask B. However, this method often results in the model's confusion between the stance of the target tweet toward the source and the parent. Thus, we decide to mark the position of the source and the parent in the conversation thread with delimiters and connect them with the rest of the conversation (other tweets) together. Each part is marked by delimiters and features are inserted behind them in the input.

2.6 Model

We employ OpenAI GPT that has been pretrained on BooksCorpus (Zhu et al., 2015) as our base model for task-specific fine-tuning. We've tried different activation functions, optimizers and hyperparameters but observe no performance improvement. So we use the default model configuration for the official submission. GPT requires its input length to be less than 512 tokens. For inputs that exceed this limit, we choose to cut off the "other tweets" sequence to fit this restriction.

Result Postprocessing As required by the organizers, we transform the labels of all blank instances into *comment* for subtask A, and take pieces whose confidence levels are below 0.5 as *unverified* in subtask B in the model prediction results.

3 Evaluation

We conduct experiments on data expansion, input format adjustment and word & tweet-level feature adding for subtask A, and perform data slicing and feature adding for subtask B. The dataset we used for this task is obtained from Zubiaga et al. (2016). We primarily focus on achieving a higher macro f1 score for both subtasks. We also display the comparison of the results on the test set between our official system and the baseline systems provided by the organizer.

3.1 Experiment Results

The following are the steps we conduct experiments toward creating the system for official submission.

Subtask A Our experiments conduct on the development set for subtask A is shown in Table 2. With the first input format (A), we achieve an initial result of 53.48%. Combining word-level, tweet-level features (B), and processing data expansion (C) brings an increase of 0.99% and 1.61% respectively. After converting to the second input format (D), we've seen a rise of 2.03% compared to A. Training data expansion (E) is also implemented on this input, but a decrease of 0.86% is observed. We suspect that after enhancing the percentage of the source and parent tweet in new input, data dissimilarity brought by the external dataset is aggravated. However, this inferior position is reversed by employing features. Word-level features (F) alone bring a 2.04% growth. Though tweet-level features alone haven't led in any extra increase, adding them together with word-level features (G) produces a result above 56%. Our final result for subtask A is ensembled on three runs (F1, F2, G) that achieve the best performance on the development set.

Subtask A		
	Systems	**MacroF**
A.	GPT(1st input)	0.5348
B.	GPT(1st input)+WF+TF	0.5447
C.	GPT(1st input)+DE	0.5509
D.	GPT(2nd input)	0.5551
E.	GPT(2nd input)+DE	0.5465
F1.	GPT(2nd input)+DE+WF	**0.5644**
F2.	(another run)	**0.5669**
G.	GPT(2nd input)+DE+WF+TF	**0.5631**

Table 2: Ablation results on the development set for subtask A. MacroF means macro f1 score. 1st input consists of conversation context and target tweet, while a 2nd input constitutes of source tweet, other tweets, parent tweet and target tweet. WF and TF refer to word-level and tweet-level features respectively. DE represents data expansion.

Subtask B Our experiments conducted on the development set for subtask B is shown in Table 3. Word features bring an increase of 3.71%. Tweet features prove to be disruptive and lead to a drop of up to 11.6%. So we discard this type of feature in subtask B entirely. The result we've submitted for subtask B is ensembled on two runs (B) that get the highest values on the development set.

Final Result Our final result on the test set and the comparison with the baseline systems are shown in Table 4. BranchLSTM and NileTMRG are two baselines implemented by the organizers.

Subtask B		
	Systems	**MacroF**
A.	GPT+DS	0.4701
B.	GPT+DS+WF	**0.5072**
C.	GPT+DS+WF+TF	0.4143

Table 3: Ablation results on the development set for subtask B. DS refers to training data slicing. WF and TF are the same meaning as Table 2.

Our system is 12.6% higher than the baseline system in macro f1 for subtask A, but 8.3% and 5.6% lower in macro f1 for subtask B compared with BranchLSTM and NileTMRG respectively. Our system ranks first in subtask A and fourth in subtask B.

Official Submission			
	Subtask A	Subtask B	
System	**MacroF**	**MacroF**	**RMSE**
BranchLSTM	0.493	**0.336**	0.781
NileTMRG		0.309	**0.769**
Our System	**0.6187**	0.2525	0.8179

Table 4: Official submission results on the test set for our system and the organizers' baselines.

3.2 Error Analysis

We perform error analysis for the results on the test set. Classification reports for both subtasks are provided in Table 5. The problem for subtask A lies in that the model often confused the *comment* class with the other three classes. The possible reason can be the relatively larger proportion of *comment* data. None of the classes performs well in prediction for subtask B, though results are better for the *true* class comparing with the other two classes. Precision, recall and macro f1 scores go extremely low for the *unverified* class. A reasonable explanation may be the *unverified* class is not directly acquired from the model but comes from the other two classes.

3.3 Comparison with ESIM

Since rumour evaluation can be seen as a task that given a target tweet and its background conversation, infer the target label of this tweet, they can be treated as a subtask of natural language inference, so we employ ESIM (Chen et al., 2016) in this task.

The results are shown in Table 6. The input format is the same as subtask B in GPT. We also try to apply features and change word embeddings in ESIM. But no results reach the result in GPT with an equivalent configuration. So the base model we employ for the system is GPT instead of ESIM.

Subtask A				
	prec.	**rec.**	**f1**	**distribution**
support	0.89	0.93	0.91	1476
deny	0.45	0.51	0.48	101
query	0.62	0.59	0.60	93
comment	0.66	0.38	0.48	157
Subtask B				
	prec.	**rec.**	**f1**	**distribution**
true	0.46	0.47	0.47	40
false	0.22	0.13	0.16	31
unverified	0.09	0.20	0.13	10

C.	ESIM(google news)+WF+TF	0.466
Subtask B		
	Systems	**MacroF**
A.	ESIM(glove)	0.473

Table 6: ESIM results on the development set for both subtasks.

4 Conclusions

We introduce a framework with a strong focus on inference chain-based knowledge enhancement for determining rumour stance and veracity in SemEval 2019 task 7. In order to address the problems of class imbalance, training data scarcity, model's insufficient learning of features and tree-structured conversations, we employ data expansion, data slicing, feature extraction, and input concatenation mechanisms in our system respectively. Our system takes first place in subtask A and fourth place in subtask B.

In future, we would like to introduce synonyms, tweet similarity and sentiment features in our model to further facilitate the recognition of relations between tweets. We will also utilize the prediction results from stance classification, expand training data with external datasets and introduce additional knowledge base such as Wikipedia to assist the model prediction in rumour veracity classification.

Abstract

This paper describes our system submitted to SemEval 2019 Task 7: RumourEval 2019: Determining Rumour Veracity and Support for Rumours, Subtask A (Gorrell et al., 2019). The challenge focused on classifying whether posts from Twitter and Reddit *support, deny, query,* or *comment* a hidden rumour, truthfulness of which is the topic of an underlying discussion thread. We formulate the problem as a stance classification, determining the rumour stance of a post with respect to the previous thread post and the source thread post. The recent BERT architecture was employed to build an end-to-end system which has reached the F1 score of 61.67 % on the provided test data. Without any hand-crafted feature, the system finished at the 2nd place in the competition, only 0.2 % behind the winner.

1 Introduction

Fighting false rumours at the internet is a tedious task. Sometimes, even understanding what an actual rumour is about may prove challenging. And only then one can actually judge its veracity with an appropriate evidence. The works of Ferreira and Vlachos (2016) and Enayet and El-Beltagy (2017) focused on predictions of rumour veracity in thread discussions. These works indicated that the veracity is correlated with discussion participants' stances towards the rumour. Following this, the SubTask A SemEval-2019 Task 7 consisted in classifying whether the stance of each post in a given Twitter or Reddit thread *supports*, *denies*, *queries* or *comments* a hidden rumour.

Potential applications of such a function are wide, ranging from an analysis of popular events (political discussions, academy awards, etc.) to quickly disproving fake news during disasters.

Stance classification (SC), in its traditional form, is concerned with determining the attitude of a source text towards a target text (Mohammad et al., 2016). It has been studied thoroughly for discussion threads (Walker et al., 2012; Hasan and Ng, 2013; Chuang and Hsieh, 2015). However, the objective of SubTask A SemEval-2019 Task 7 is to determine the stance to a hidden rumour which is not explicitly given (it can be often inferred from the source post of the discussion – the root of the tree-shaped discussion thread – as demonstrated in Figure 1). The competitors were asked to classify the stance of the source post itself too.

.@AP I demand you retract the lie that
people in #Ferguson were shouting "kill the police",
local reporting has refuted your ugly racism

Figure 1: An example of discussion's source post denying the actual rumour which is present in the source post – annotated with red cursive

The provided dataset was collected from Twitter and Reddit tree-shaped discussions. Stance labels were obtained via crowdsourcing. The discussions deal with 9 recently popular topics – Sydney siege, Germanwings crash etc.

The approach followed in our work builds on recent advances in language representation models. We fine-tune a pre-trained end-to-end BERT (Bidirectional Encoder Representations from Transformers) model (Devlin et al., 2018), while using discussion's source post, target's previous post and the target post itself as inputs to determine the rumour stance of the target post. Our implementation is available online.[1]

2 Related Work

Previous SemEval competitions: In recent years, there were two SemEval competitions targeting the stance classification. The first one focused on the setting in which the actual rumour was provided (Mohammad et al., 2016). Organizers of

[1]www.github.com/MFajcik/RumourEval2019

SemEval-2016 Task 6 prepared a benchmarking system based on SVM using hand-made features and word embeddings from their previous system for sentiment analysis (Mohammad et al., 2013), outperforming all the challenge participants.

The second competition was the previous RumourEval won by a system based on word vectors, handcrafted features[2] and an LSTM (Hochreiter and Schmidhuber, 1997) summarizing information of the discussion's branches (Kochkina et al., 2017). Other submissions were either based on similar handcrafted features (Singh et al., 2017; Wang et al., 2017; Enayet and El-Beltagy, 2017), features based on sets of words for determining language cues such as Belief or Denial (Bahuleyan and Vechtomova, 2017), post-processing via rule-based heuristics after the feature-based classification (Srivastava et al., 2017), Convolutional Neural Networks (CNNs) with rules (Lozano et al., 2017), or CNNs that jointly learnt word embeddings (Chen et al., 2017).

End-to-end approaches: Augenstein et al. (2016) encode the target text by means of a bidirectional LSTM (BiLSTM), conditioned on the source text. The paper empirically shows that the conditioning on the source text really matters. Du et al. (2017) propose target augmented embeddings – embeddings concatenated with an average of source text embeddings – and apply them to compute an attention based on the weighted sum of target embeddings, previously transformed via a BiLSTM. Mohtarami et al. (2018) propose an architecture that encodes the source and the target text via an LSTM and a CNN separately and then uses a memory network together with a similarity matrix to capture the similarity between the source and the target text, and infers a fixed-size vector suitable for the stance prediction.

3 BUT-FIT's System Description

3.1 Pre-processing

We replace URLs and mentions with special tokens $\$URL\$$ and $\$mention\$$ using tweet-processor[3]. We use spaCy[4] to split each post into sentences and add the $[EOS]$ token to indicate termination of each sentence. We employ the tokenizer that comes with the Hugging Face PyTorch re-implementation of BERT[5]. The tokenizer lowercases the input and applies the WordPiece encoding (Wu et al., 2016) to split input words into most frequent n-grams present in the pre-training corpus, effectively representing text at the subword level while keeping a 30,000-token vocabulary only.

	S	D	Q	C	Total
train	925	378	395	3519	5217
in %	18	7	8	67	
dev	102	82	120	1181	1485
in %	7	6	8	80	
test	157	101	93	1476	1827
in %	9	6	5	81	

Table 1: Distribution of examples across classes in the training/development/test data set. The examples belong to 327/38/81 training/development/test tree-structured discussions.

3.2 Model

Following the recent trend in transfer learning from language models (LM), we employ the pre-trained BERT model. The model is first trained on the concatenation of BooksCorpus (800M words) (Zhu et al., 2015) and English Wikipedia (2,500M words) using the multi-task objective consisting of LM and machine comprehension (MC) sub-objectives. The LM objective aims at predicting the identity of 15% randomly masked tokens present in the input[6]. Given two sentences from the corpus, the MC objective is to classify whether the second sentence follows the first sentence in the corpus. The sentence is replaced randomly in half of the cases. During pre-training, the input consists of two documents, each represented by a sequence of tokens divided by the special $[SEP]$ token and preceded by the $[CLS]$ token used by the MC objective, i. e., $[CLS]document_1[SEP]document_2[SEP]$. Input tokens are represented by jointly learned token embeddings E_t, segment embeddings E_s, capturing whether the word belongs into $document_1$ or $document_2$, and positional embeddings E_p.

[2]The features included: a flag indicating whether a tweet is a source tweet of a conversation, the length of the tweet, an indicator of the presence of URLs and images, punctuation, the cosine distance to the source tweet and all other tweets in the conversation, the count of negation and swear words, and an average of word vectors corresponding to the tweet.

Figure 2: An architecture of BUT-FIT's system. The text segment containing $document_1$ is green, the segment containing $document_2$ (the target post) is blue. The input representation is obtained by summing input embedding matrices $E = E_t + E_s + E_p \in \mathbb{R}^{L\times d}$, L being the input length and d the input dimensionality. The input is passed N times via the transformer encoder. Finally, the $[CLS]$ token-level output is fed through two dense layers yielding the class prediction.

Our system follows the assumption that the stance of discussion's post depends only on itself, on the source thread post and on the previous thread post. Since the original input is composed of two documents, we experimented with various ways of encoding the input (see Section 5), ending up with just a concatenation of the source and the previous post as $document_1$ (left empty in case of the source post being the target post) and the target post as $document_2$. The discriminative fine-tuning of BERT is done using the $[CLS]$ token level output and passing it through two dense layers yielding posterior probabilities as depicted in Figure 2. A weighted cross-entropy loss is used to ensure a flat prior over the classes.

3.3 Ensembling

Before submission, we trained 100 models differing just by their learning rates. We experimented with 4 different fusion mechanisms in order to increase the F1 measure and compensate for overfitting:

The `TOP−N` fusion chooses 1 model randomly and adds it to the ensemble. Then, it randomly shuffles the rest of the models and tries to add them into the ensemble one at the time, while iteratively calculating ensemble's F1 by averaging the output probabilities, effectively approximating the Bayesian model averaging. If a model increases the total F1 score, the model is permanently added to the ensemble. The process is repeated until no further model improving the ensemble's F1 score can be found. This procedure resulted in a set of 17 best models.

The `EXC−N` fusion chooses all models into the ensemble and then iteratively drops one model at the time, starting from that which dropping results in the largest increase of the ensemble's F1. The process stops when dropping any other model cannot increase the F1 score. Using this approach, we ended up using 94 models.

The `TOP−N`$_s$ is analogous to the `TOP−N` fusion, but we average pre-softmax scores instead of output class probabilities.

The `OPT−F1` fusion aims at learning weights summing up to 1 for the weighted average of output probabilities from models selected via the procedure used in the `TOP−N` strategy. The weights are estimated using modified Powell's method from the SciPy package to maximize the F1 score on the development dataset.

4 Experimental Setup

We implemented our models in PyTorch, taking advantage of the Hugging Face re-implementation (see Footnote 5), with the *"BERT-large-uncased"* setting, pre-trained using 24 transformer layers, having the hidden unit size of $d = 1024$, 16 attention heads, and $335M$ parameters. When building the ensemble, we picked learning rates from the interval $[1e{-}6, 2e{-}6]$. Each epoch iterates over the dataset in an ordered manner, starting by the shortest sequence. We truncate sequences at maximum length $l = 200$ with a heuristic – firstly we truncate the $document_1$ to length $l/2$, if that is not enough, then we truncate the $document_2$ to

	#Θ	Acc_{test}	macro F1_{dev}	macro F1_{test}	F1_S	F1_Q	F1_D	F1_C

Table 2: Overview of the results. The values for each single model were obtained by averaging results of 11 models. We report the mean and the standard deviation in these cases. #Θ denotes the number of parameters. Columns F1_S to F1_C report individual F1 scores for each class. All ensemble models have the F1 score optimized on the development dataset. BiLSTM+SelfAtt contains 4.2M parameters, without pre-trained BERT embeddings. $\text{BERT}_{big-nosrc}$ and $\text{BERT}_{big-noprev}$ denote system instantiations with an empty source and an empty target post, respectively. Note that the accuracy is biased towards different training data priors as shown in Table 1. SemEval submissions are denoted by *.

the same size. We keep the batch size of 32 examples and keep other hyperparameters the same as in the BERT paper. We use the same Adam optimizer with the L2 weight decay of 0.01 and no warmup. We trained the model on the GeForce RTX 2080 Ti GPU.

5 Results and Discussion

We compare the developed system to three baselines. The first one is the branch-LSTM baseline provided by the task organizers[7] – inspired by the winning system of RumourEval 2017. The second baseline (FeaturesNN) is our reimplementation of the first baseline in PyTorch without the LSTM – posts are classified by means of a 2-layer network (ReLU/Softmax), using only the features defined in Footnote 2. In the third case (BiLSTM+SelfAtt), we use the same input representation as in our submitted model but replace the BERT by an 1-layer BiLSTM network followed by a self-attention and a softmax layer, inspired by Lin et al. (2017).

The results are shown in Table 2. BERT models had to cope with a high variance during the training. This might be caused by the problem difficulty, the relatively small number of training examples, or the complexity of the models. To deal with the problem, we decided to discard all models with F1 scores of less than 55 on the development dataset and we averaged the output class probability distributions when ensembling. Our initial experiments used sequences up to the length of 512, but we found no difference when truncating them down to 200.

What features were not helpful: We tried adding a number of other features, including those indicating positive, neutral, or negative sentiment, and all the features used by the FeaturesNN baseline. We also tried adding jointly learned POS, NER, and dependency tag embeddings, as well as the third segment embeddings[8]. We also experimented with an explicit $[SEP]$ token to separate the source and the previous post in the BERT input. However, none of the mentioned changes led to a statistically significant improvement.

6 Conclusions and Future Directions

The system presented in this paper achieved the macro F1 score of 61.67, improving the baseline by 12.37%, while using only the source post of discussion, the previous post and the target post to classify the target post's stance to a rumour.

A detailed analysis of the provided data shows that the employed information sources are not sufficient to correctly classify some examples. Our future work will focus on extending the system by a relevance scoring component. To preserve the context, it will evaluate all posts in a given discussion thread and pick up the most relevant ones according to defined criteria.

[7] http://tinyurl.com/y4p5ygn7

[8] We tried adding the learned representations to the input the same way the segment/positional embeddings are added.

A Supplemental Material

A.1 Dataset Insights

The dataset contains a whole tree structure and metadata for each discussion from Twitter and Reddit. The nature of the data differs across the sources (for example, the Reddit subset includes upvotes).

When analysing the data, we spotted several anomalies:

- 12 data points do not contain any text. According to the task organizers, they were deleted by users at the time of data download and been left in the data not to break the conversational structure.

- The query stance of some examples taken from subreddit DebunkThis[9] is dependent on the domain knowledge. The class of some examples is ambiguous; they should be probably labelled by multiple classes.

A.1.1 Domain knowledge dependency

Examples from subreddit DebunkThis have all the same format ”Debunk this: [statement]”, e.g. *”Debunk this: Nicotine isn't really bad for you, and it's the other substances that makes tobacco so harmful.”*. All these examples are labelled as queries.

[9]https://www.reddit.com/r/DebunkThis/

A.1.2 Class ambiguity

The source/previous post *”This is crazy! #CapeTown #capestorm #weatherforecast https://t.co/3bcKOKrCJB”* and the target post *”@RyGuySA Oh my gosh! Is that not a tornado?! Cause wow, It almost looks like one!”*, labelled as a comment in the dataset, might be seen as a query as well.

A.2 Additional Introspection

Figures 3, 4, 5, and 6 demonstrate attention matrices A, derived from the multi-head attention defined as:

$$A = \frac{QK^\top}{\sqrt{d_k}}, \qquad (1)$$

where $Q, K \in \mathbb{R}^{L \times d_k}$ are the matrices containing query/value vectors and d_k is the key/value dimension. The insights are selected from the heads at the first layer of the transformer encoder.

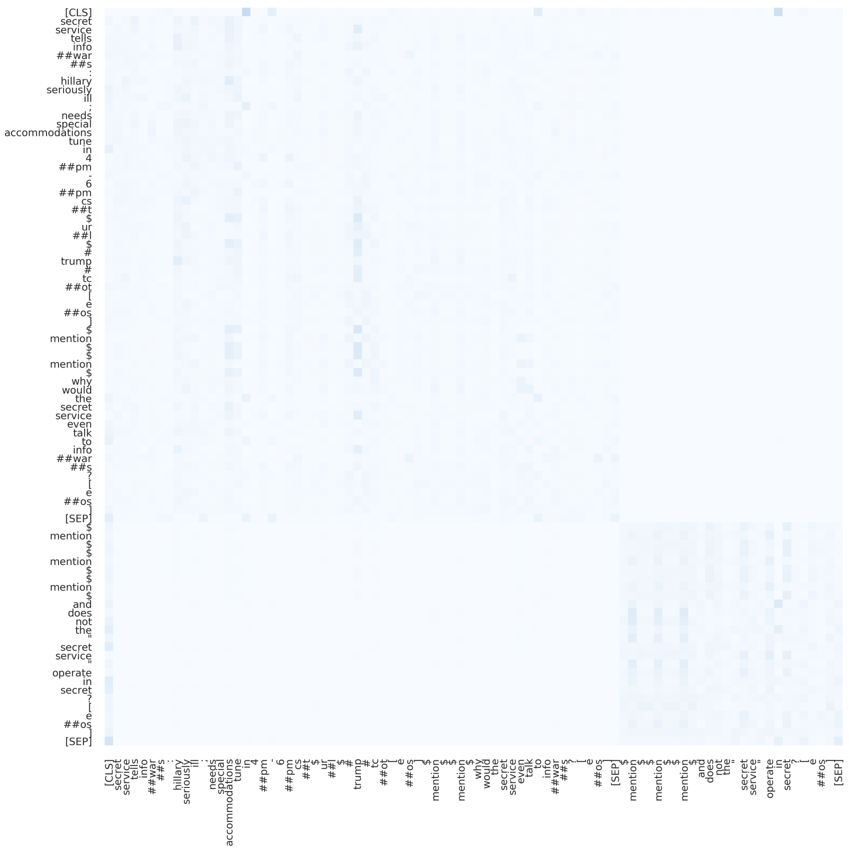

Figure 3: Intra-segment attention – the attention is made only between the subword units from the same segment.

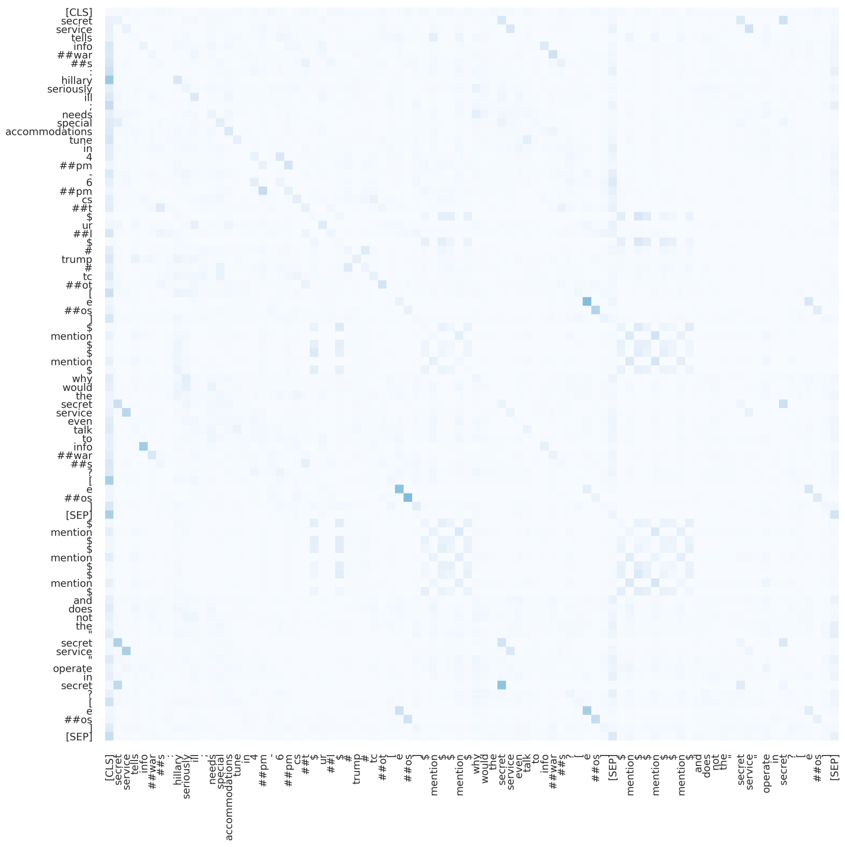

Figure 4: Attention matrix capturing the subword similarity.

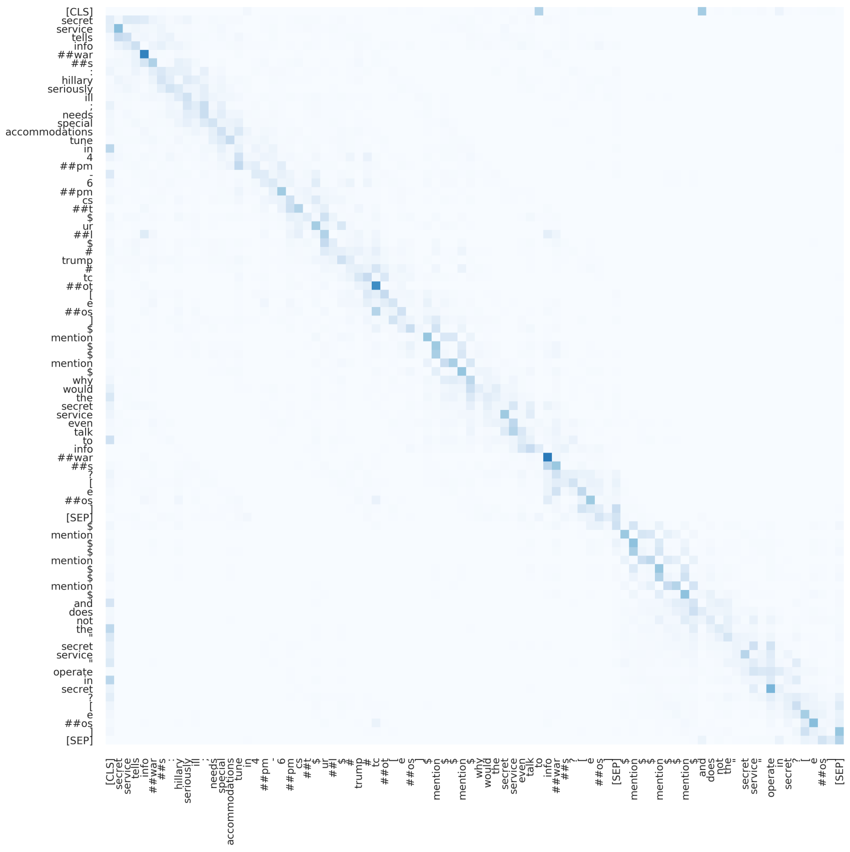

Figure 5: ’Soft’ local context aggregation.

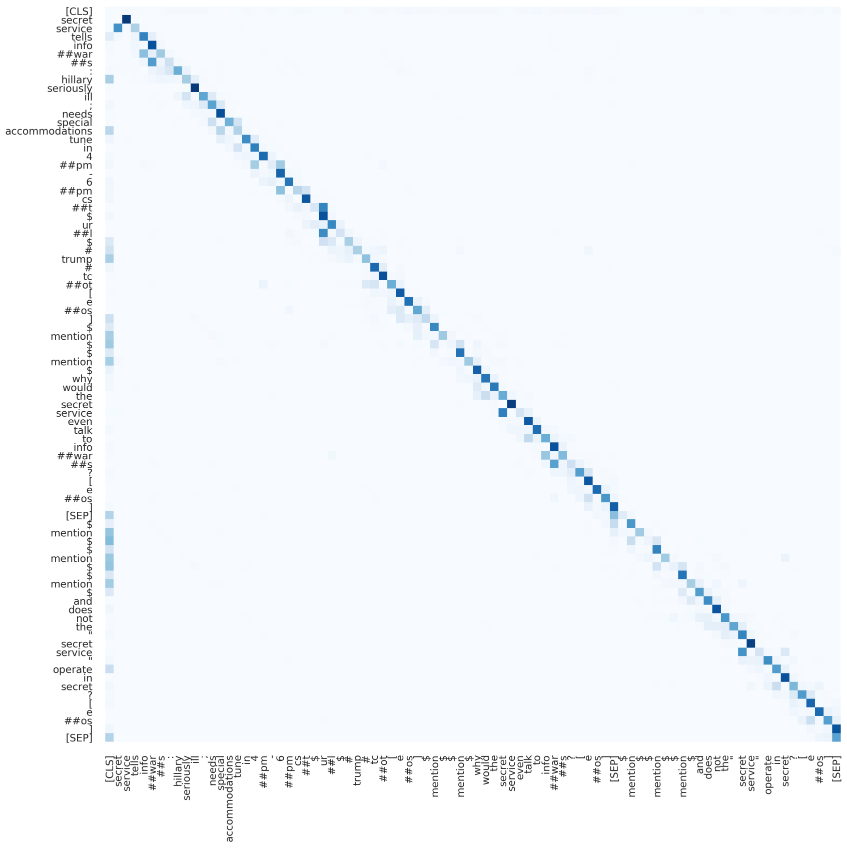

Figure 6: ’Hard’ local context aggregation – the signal is mostly sent further to another transformer encoder layer.

CLEARumor at SemEval-2019 Task 7: ConvoLving ELMo Against Rumors

Abstract

This paper describes our submission to SemEval-2019 Task 7: RumourEval: Determining Rumor Veracity and Support for Rumors. We participated in both subtasks. The goal of subtask A is to classify the type of interaction between a rumorous social media post and a reply post as support, query, deny, or comment. The goal of subtask B is to predict the veracity of a given rumor. For subtask A, we implement a CNN-based neural architecture using ELMo embeddings of post text combined with auxiliary features and achieve a F_1-score of 44.6%. For subtask B, we employ a MLP neural network leveraging our estimates for subtask A and achieve a F_1-score of 30.1% (second place in the competition). We provide results and analysis of our system performance and present ablation experiments.

1 Introduction

Online social media has changed the way of communicating and disseminating media content and opinions, but also paved the way for spreading false or unverified rumors.

RumourEval 2019 (Gorrell et al., 2019) provides a dataset of labelled threads from Twitter and Reddit where each source post mentions a rumor. Subtask A (SDQC) consists of deciding for each post in a thread whether it is in a *support*, *deny*, *query*, or *comment* relation to the rumor. The goal of subtask B (Verification) it to classify the veracity of the rumor as *true*, *false*, or *unverified*. Figure 1 clarifies our terminology and the tasks.

Automated rumor classification is a challenging task as there is no definite evidence (e.g., authorized confirmation). In its absence, stance analysis is a useful approach. Systems that employ neural network architectures showed promising results in RumourEval 2017 (Derczynski et al., 2017), with

A *thread* is the set containing a source post and all its reply posts.

the LSTM-based sequential model of Kochkina et al. (2017) performing best.

In this paper, we describe our approach CLEARumor (ConvoLving ELMo Against Rumors) for solving both subtasks and provide empirical results and ablation experiments of our architecture. We make our PyTorch-based implementation and trained models publicly available[1].

2 System Description

After preprocessing the post text (Section 2.1) and embedding it with ELMo (Section 2.2), our architecture for subtask A (Section 2.3) passes the embedded text through a convolutional neural network (CNN) block, adds auxiliary features, and

[*]The first two authors contributed equally.

[1]https://github.com/Institute-Web-Science-and-Technologies/CLEARumor

uses a multilayer perceptron (MLP) block for estimating class membership. These estimates are combined with further auxiliary features and fed into an MLP block for the classification for subtask B (Section 2.4).

2.1 Preprocessing

For preprocessing, we rely mostly on Erika Varis Doggett's tokenizer for Twitter and Reddit[2], with which we strip away all user handles (e.g., "@FutbolLife"), remove the number sign in front of hash tags (e.g., "#Ebola" becomes "Ebola"), remove URLs, and limit repetitions of the same character to at most three times (e.g., "heeeeey" becomes "heeey"). We further decided to lowercase all text, which resulted in improved performance over mixed case in initial experiments. Last, all posts are truncated after 32 tokens[3].

2.2 ELMo Embeddings

The task of word embedding is to represent each word in a given sentence by a vector, which among other things allows for encoding words at the input layer in a neural network architecture. Traditional embedding methods such as word2vec (Mikolov et al., 2013) or GloVe (Pennington et al., 2014) work independently of context and always map the same word to the same vector.

In contrast, ELMo (Peters et al., 2018) is a recent embedding approach based on bidirectional LSTM networks that considers the context a word occurs in and is thereby able to address certain linguistic peculiarities, e.g., that the same word can have different meanings depending on its context. Further, ELMo incorporates subword units and is thereby able to represent words not seen during training successfully, an important benefit for the social media domain, where users frequently misspell existing words or introduce new ones. Formally, given a sequence of words $w_1 w_2 \ldots w_n$ ELMo represents the k-th word w_k as

$$\mathbf{ELMo}_k^{\text{task}} = \gamma^{\text{task}} \sum_{j=0}^{L} s_j^{\text{task}} \mathbf{h}_{k,j}, \qquad (1)$$

where L gives the number of internal layers that were used to train ELMo, $\mathbf{h}_{k,j}$ is the contextual

[2]https://github.com/erikavaris/tokenizer

[3]Only 10 out of the total 6634 Twitter posts are longer than this, while a few Reddit posts are up to 1,000 tokens long which would result in very impractical batch sizes.

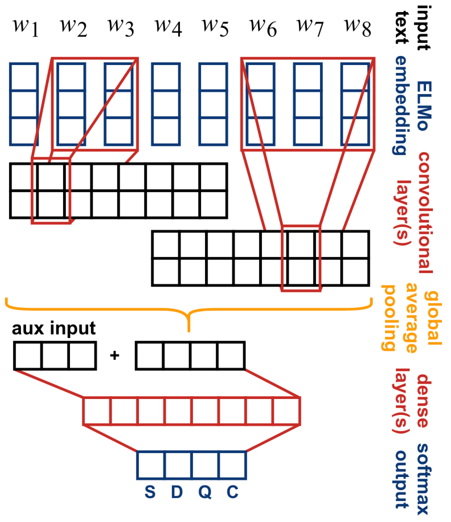

Figure 2: CLEARumor architecture for subtask A.

vector representation of layer j for word k, and γ^{task} and the s_j^{task} are scalars that can be tuned specifically for the task at hand.

We report results for the pretrained model `elmo_2x4096_512_2048cnn_2xhighway_5.5B`[4] for which $L = 2$ and which outputs 1024-dimensional embedding vectors (but didn't notice drastic improvements over the much smaller models). ELMo allows us to fine-tune γ^{task}, s_j^{task}, and even the $\mathbf{h}_{k,j}$ by backpropagating gradients to them, but we decided against this, because the RumourEval dataset is very small (cf. Table 1) adjusting these weights can quickly lead to overfitting, and keeping the weights constants allows us to precompute and store all ELMo embeddings once before the training process which results in a major boost in performance.

2.3 Subtask A

Our architecture for subtask A is visualized in Fig. 2. First, the tokenized text of the post that is to be classified as either support, deny, query, or comment is represented with an ELMo embedding. Next, the embedded text is fed into L_{conv}-many convolutional layers. Here, a single convolutional layers consists of multiple 1D-convolution operations with a set of different kernel sizes S, each mapping onto C convolutional channels, which are then concatenated along the channel axis. Each convolution operation is batch normalized (Ioffe and Szegedy, 2015) after a ReLU activation. To maintain an equal sequence length, sequences are padded with zero vectors. The result-

[4]https://allennlp.org/elmo

ing sequence representation is transformed into a single $|S| \cdot C$-dimensional vector via global average pooling. This sequence vector is concatenated with a vector of auxiliary features that encodes meta information about the post under classification (detailed in the next paragraph). Following is a stack of L_{dense}-many dense layers, for which dropout-regularization (Srivastava et al., 2014) is performed after ReLU activation. Finally, a single linear layer that is softmax-activated yields the four estimates of class membership. Parameters are optimized using Adam (Kingma and Ba, 2015) and a cross-entropy loss.

We use the following auxiliary features: (1) a two-dimensional Boolean vector encoding whether the post is from Twitter or Reddit; (2) a five-dimensional real-valued vector encoding meta-information for the post author: whether the user is verified or not, the number of followers they have, the number of accounts they follow themselves, and a ratio of the latter two numbers[5]; (3) the cosine similarity of the averaged ELMo embeddings of the post under classification to those of the thread's source post (defined to be 1 for source posts); and (4) a three-dimensional Boolean vector encoding whether the post is a source post, a direct reply, or a nested reply.

As hyperparameters, we employ a learning rate of 10^{-3}, a batch size of 512, and train for 100 epochs. In our loss function, we weigh the estimates of support, deny, and query equally but that of comment at only a fifth of the strength because of the imbalance of the dataset. We add L2-regularization with a weight of 10^{-2}. In our reported results we use $L_{\text{conv}} = 1$ convolutional layer, with kernel sizes $S = \{2, 3\}$ each mapping into $C = 64$ channels, after which follow $L_{\text{dense}} = 3$ dense layers with 128 hidden units each and a dropout of 0.5.

2.4 Subtask B

For subtask B we build a single feature vector that we feed into a MLP classifier. We reuse all the auxiliary features from subtask A except the last two, because all posts under classification in subtask B are source posts. We further add the following features: (1) a two-dimensional Boolean vector encoding whether media (an image or a URL) is attached to the post, (2) the upvote-to-downvote ratio of the post for Reddit (manually set to 0.5 for Twitter), (3) a two-dimensional real-valued vector encoding which fraction of the thread's posts are direct replies and which fraction are nested replies, (4) the averaged support, deny, and query probability estimates from subtask A averaged over all posts in the thread. Similarly to subtask A, this feature vector is fed into a stack of L_{dense}-many dense layers with dropout-regularization (Srivastava et al., 2014) after ReLU activation, after which a single softmax-activated linear layer yields estimates for the three classes true, false, or unverified.

Our model was trained with a learning rate of 10^{-3} and a batch size of 128 for 5000 epochs. In our loss calculation, we weigh the unverified class at 0.3 of the strength of the other two, and add a L2-regularization weight of 10^{-2}. We used $L_{\text{dense}} = 2$ dense layers with 512 hidden units each and a dropout of 0.25.

3 Evaluation

The dataset of RumourEval 2019 is summarized in Table 1. Our results for subtask A and B are

Subtask A		**S**	**D**	**Q**	**C**	**Σ**

Table 3: Evaluation results for subtask B. We report F$_1$ (multiplied by 100) and RMSE (root mean squared error) scores for the development (Dev), the test (Test) datasets and for 10-fold cross validation (CV). CLEAR$_{\text{Subtask-B}}$ is our subtask B architecture using the subtask A estimates from CLEAR$^{\text{aux}}_{\text{CNN+MLP}}$. CLEAR$_{\text{NileTMRG}}$ uses the same estimates but computes task B results using the NileTMRG system (Enayet and El-Beltagy, 2017).

detailed in Table 2 and Table 3, respectively.

The reported results differ from our official submission, because we continued to tune hyperparameters afterwards. We report results as trained on the training dataset and then evaluated on the development and test datasets, as provided by the RumourEval organizers. Because neural network experiments are naturally nondeterministic (Reimers and Gurevych, 2018) and we did indeed notice huge variances when retraining models, we report the mean and standard deviation over 10 runs for each experiment. Additionally, we report scores from a 10-fold cross validation over the whole dataset. Simple cross-validation would be inappropriate in our setting, because for example a split could result in the case where the same rumors occur in both the training and the test dataset which would allow a model to just memorize which posts are rumorous. We ensure that this does not happen in our case, by keeping all posts belonging to the same rumor[6] in the same cross validation fold. Note that scores on the organizer split and the cross validation are not directly comparable as different fractions of the whole dataset are used for training (~60-70% for the organizer split and ~90% for 10-fold cross validation).

4 Conclusion

We have presented CLEARumor, our architecture for the RumourEval 2019 shared tasks. In future we aim to generalize our approach, e.g., we currently use domain-specific features for characterizing the post author popularity, such as number of followers for Twitter, which are not available for all social media platforms. Besides investigating how well our approach translates to other languages, we are interested in studying the results for other pretrained word representation approaches, e.g., BERT (Devlin et al., 2018).

[6]For Twitter posts, the dataset contains rumor-topic labels for each thread, so we ensure that each topic only occurs in one fold. For Reddit posts, no labelling is available, so we can only ensure that all posts of a thread occur in the same fold.

Abstract

The paper presents Columbia team's participation in the SemEval 2019 Shared Task 7: RumourEval 2019. Detecting rumour on social networks has been a focus of research in recent years. Previous work suffered from data sparsity, which potentially limited the application of more sophisticated neural architecture to this task. We mitigate this problem by proposing a multi-task learning approach together with language model fine-tuning. Our attention-based model allows different tasks to leverage different level of information. Our system ranked 6th overall with an F1-score of 36.25 on stance classification and F1 of 22.44 on rumour verification.

1 Introduction

The ubiquity of social media is allowing unverified news and rumours to spread easily. Efforts have been made to explore automated methods for rumour detection and verification (Derczynski et al., 2017; Zubiaga et al., 2016, 2018), and has shown promising potential to tackle this issue at scale.

RumourEval 2019 Shared Task 7 tackles the problem of predicting the veracity of rumours and stance of replies. It consists of two subtasks: task A (SDQC), in which stance (support, deny, querying, comment) of responses to a rumourous statement are predicted, and task B (verification), in which the statement's veracity is to be predicted. Size of training data provided for Task A is 5,217 and for Task B is 327.

In this paper, we proposed several methods to alleviate data sparsity and unleash the power of sophisticated neural models:

1. *Jointly learning to perform rumour verification and stance detection.* Training a neural network on limited amount of data for a single task is hard, especially in a sentence classification task. This is because of the weak supervision signal caused by the information asymmetry between the source text and the target labels. With supervision signal from multiple tasks, a neural network can exploit information in the training data more thoroughly.

2. *Using self-attention.* To predict the stance of a post, we want to selectively pay attention to some other posts that are relevant to this post. We use a QKV-style attention (Query, Key, Value) (Vaswani et al., 2017) to summarize the post context into a single vector (where in practice one attention head is usually enough). In addition, we use representations at different levels for different tasks.

3. *Using language model fine-tuning for stance classification.* We use the Universal Language Model Fine-tuning (ULMFiT) (Ruder and Howard, 2018) to improve our stance classifier. We begin with a generic language model trained on the Wikitext 103 dataset (Merity et al., 2016). This dataset consists of a large collection of pre-processed English Wikipedia articles. This enables the language model to properly model the general properties of language. Next, we fine-tune this language model on task specific data: RumourEval2019 dataset. Finally, a classification layer is added and the model is initialized with parameters from the fined-tuned language model.

Our system, which relies on these three key factors, are now publicly available.[2]

* Equal contribution.

2 Related Work

Rumour Detection. Recently there has been a growing interest on developing methods for the task of rumour detection (Zubiaga et al., 2018), including a shared task in 2017 (Derczynski et al., 2017), which established a strong baseline for stance classification — task A(Kochkina et al., 2017), while (Enayet and El-Beltagy, 2017) established the same for veracity — task B. Dungs et al. (2018) discuss how stance information can facilitate veracity classification, while (Zubiaga et al., 2017) explore the use of contextual information for rumour detection. These results show that stance information and context information are important for rumour verification.

Multi-task Learning. Text classification tasks invariably suffer from the weak supervision signal due to loss of information in projecting text to task labels. There has been a growing number of works that explore multi-task learning for text classification (Zhang et al., 2017; Xiao et al., 2018). For the task of rumour detection specifically, there were attempts in jointly train for stance classification and rumour verification (Kochkina et al., 2018). Our muti-task approach uses a different, more advanced sentence embedding approach and uses the same LSTM for both tasks but with hidden states from different levels, which can be considered as different level representations of sentences. Empirically we found that higher levels of representation performs better for stance classification, while lower levels are better for veracity classification.

Transfer Learning with pre-trained Language Models. To alleviate the problem of data scarcity, researchers have proposed various approaches for pre-training language models on large-scale monolingual corpora, such as ELMo, ULMFiT, BERT, GPT, and have shown their effectiveness on several NLP tasks (Peters et al., 2018; Ruder and Howard, 2018; Devlin et al., 2018; Radford, 2018). In our work we use ULMFiT (Ruder and Howard, 2018) for stance classification.

3 System Description

We propose two system configurations:

1. *System1:* A joint-learning for task A and task B without using language model fine-tuning.
2. *System2:* Language model fine-tuning for task A.

3.1 System1: Joint Training for Stance Classification and Rumour Verification

We formulate the joint learning of Task A and B as follows: Given a branch of conversation $\mathbf{X}$ containing n posts

$$\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_n),$$

where each post $\mathbf{x}_k$ is a sequence of m_k words:

$$\mathbf{x}_k = (x_{k,1}, x_{k,2}, \cdots, x_{k,m_k}).$$

The goal is to build two neural probabilistic models $p(\mathbf{y}_{\text{stance}}|\mathbf{X}; \theta, \phi_{\text{stance}})$ and $p(y_{\text{veracity}}|\mathbf{X}; \theta, \phi_{\text{veracity}})$, where θ is the shared parameters, ϕs are parameters unique to each task, $\mathbf{y}_{\text{stance}} = (y_1, y_2, \cdots, y_n)$ are stance labels, and y_{veracity} is the veracity label.

To estimate θ and ϕs, we perform maximum likelihood estimation (MLE) over the training dataset $\mathcal{D} = \{(\mathbf{X}_d, \mathbf{y}_d)\}_{d=1}^{N}$, with optimization objectives being negative log-likelihoods:

$$\begin{aligned}
\mathcal{J}_{\text{stance}} &= -\sum_d \log p(\mathbf{y}_{\text{stance}}|\mathbf{X}; \theta, \phi_{\text{stance}}) \\
&= -\sum_d \sum_i \log p(y_i)_{\text{stance}}|\mathbf{X}; \theta, \phi_{\text{stance}}) \\
\mathcal{J}_{\text{veracity}} &= -\sum_d \log p(y_{\text{veracity}}|\mathbf{X}; \theta, \phi_{\text{veracity}})
\end{aligned}$$

Rumour verification and stance classification are highly-related tasks that can potentially provide useful information for each other. Therefore we integrate the two tasks for joint training, allowing more accurate estimation of the shared part of parameters θ.

To find an appropriate balance between the supervision signals from the two tasks, we introduce a tunable hyper-parameter λ. We then rewrite our objective function as follows:

$$\mathcal{J} = \lambda \cdot \mathcal{J}_{\text{stance}} + (1 - \lambda) \cdot \mathcal{J}_{\text{veracity}}$$

We designed an effective neural network to model $p(\mathbf{y}_{\text{stance}}|\mathbf{X}; \theta, \phi_{\text{stance}})$ and $p(y_{\text{veracity}}|\mathbf{X}; \theta, \phi_{\text{veracity}})$, which provides latent structures to capture subtleties of conversations. This model architecture is described below.

Neural Network Architecture

Inspired by the idea of BranchLSTM (Kochkina et al., 2017), we propose a model based on a single branch from the conversation tree. Our model is different from BranchLSTM (Kochkina et al., 2017) in the following ways:

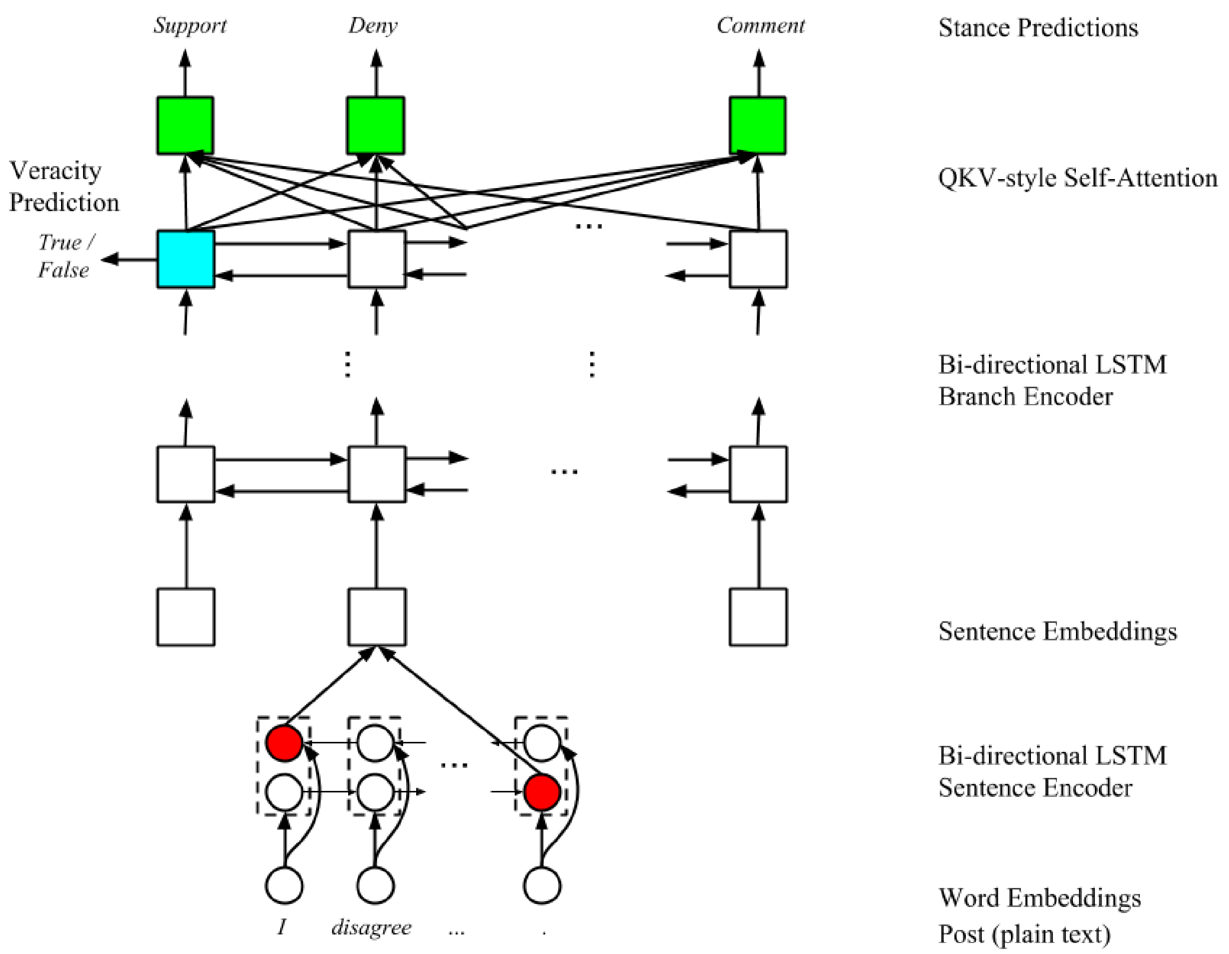

Figure 1: Model Architecture.

1. The sentence vector representation (sentence embedding) is generated with a bi-directional LSTM, as compared to simply taking the average of word vectors in BranchLSTM. This allows sentence embeddings to selectively encode important words and capture long-distance dependency in the sentence.

2. We apply a Transformer-style attention (Vaswani et al., 2017) on top of branch-level LSTM. This enables the most important information to flow in when trying to decide the stance of a post.

3. Rumour verification is incorporated as a task being jointly learnt together with stance classification, yet exploiting information at a different level from stance classification. In practice, hidden states at different levels of LSTM is being used for different tasks.

Figure 1 shows our overall model architecture, which we describe in more detail below.

Word Embeddings. The word embedding space is adjustable in our model. We initialize the word embedding matrix with pre-trained GloVe embeddings (Pennington et al., 2014). While we fix most word embedding vectors, we also keep some of the most frequent word embeddings trainable, allowing the word embedding space to adjust itself.

Sentence Embeddings. We consider each post as a sentence and we encode it with a bi-directional LSTM. We then take the last hidden state of the forward LSTM and first hidden state of the backward LSTM and concatenate them. The resulting vector can be considered as a dynamically generated sentence embedding.

Stacked Branch Encoder. To capture the interaction between posts in a branch of conversation, we use a stacked Bi-LSTM to encode the sentence embeddings obtained from previous steps. This results in a higher level representation of each post, which is fully aware of the conversation context. The higher the level in the LSTM stack, the more the representation is aware of context.

Attention. To predict the stance of a post, we want to selectively pay attention to some other posts that are relevant to this post. We use a QKV-style of attention (Vaswani et al., 2017) to summarize the post context into a single vector (where in practice one attention head is usually enough).

Stance Classifier. We first send the highest-level representation of posts to a QKV-style self-attention, which produces an attention-weighted context vector for each post in a branch. We then concatenate each post's representation with its corresponding context vector, and feed it through an MLP followed by a softmax for stance classification. During our experiment, we found that one attention head is good enough and is better than using multi-head attention.

Veracity Classifier. We take the representation of the original post (which is the first post in each conversation) from some intermediate layer, and feed it through an MLP followed by a softmax for veracity classification. This design corresponds to the intuition that when judging the authenticity of a post, the model should focus more on the post itself and less on how people judge it.

All hyperparameters can be found in our code with default settings.

3.2 System2: LM fine-tuning for Stance Classification

We also tried improving our stance classifier by using the Universal Language Model Fine-tuning (ULMFiT). After training a generic language model trained on Wikitext 103 dataset, we fine-tuned the LM on RumourEval2019 dataset.

Pre-processing was inspired by BranchLSTM system (Kochkina et al., 2017). Tweets along a particular branch were concatenated starting from the source tweet till the target node and considered as one training instance. The SDQC label of the last node concatenated was considered to be the label of the training instance. Here, replies are being referred to as nodes. For instance, source + reply 1 + reply 2, label of reply 2 was one training instance.

Finally, we used a BiLSTM max pooling network which was presented in (Conneau et al., 2017) and is shown in Figure 3. This model was initialized with parameters from the fined tuned language model. In this architecture, the representation generated by the BiLSTM was max pooled, i.e. the maximum value over each dimension was selected to form a fixed-size vector and was followed by softmax for stance classification.

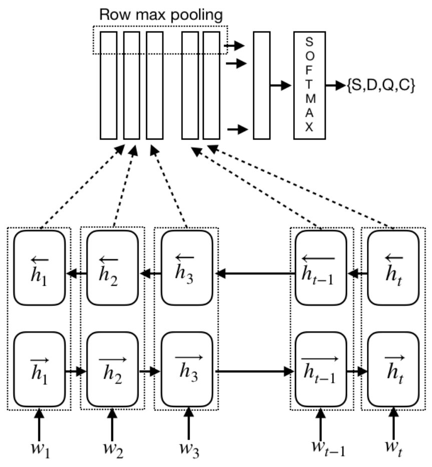

Figure 2: Max pooling in System2

4 Results and Analysis

For System1, we achieved an F1-score of 22.44 on task B and an F1-score of 34.04 on task A. For System2, we achieved F1-score of 36.25 on task A (System2 is only applied to task A). Performance of System1 on task A is slightly lower than the performance of System2, because we only treat task A as an auxiliary task for task B and did not apply ULMFiT to task A. Our final submission consisted of using System 2 for task A and System1 for task B. Our final submission ranked 6th in the final leaderboard.

	Verif	RMSE	SDQC
System 1	0.2244	0.8623	0.3404
System 2			0.3625
Final Submission	0.2244	0.8623	0.3625

Table 1: Performance of two systems on test set.

Unbalanced Class Labels. The model in System1 suffers heavily from an unbalanced class problem. From Table 2, we can see that the model is not giving any predictions of D (Deny) and Q (Query), which is why even though it has high accuracy (83%+), its F1 is lower than that of System2.

	S	D	Q	C
System 1	81	0	0	1746
System 2	62	16	84	1665

Table 2: Predicted class frequencies of SDQC classification on test data.

This problem is mitigated a little bit in System2, as we witnessed a few examples of D and Q predictions. This could potentially be because of the general knowledge gained by pre-training on large-scale Wikipedia text. Even then, D and Q classes are rare in the model predictions.

Instability in Training. System1 shows a perturbing training loss after it decrease to a certain level. After a certain point, the F1 score and accuracy on development set begins decreasing. One explanation is that the size of training data is too small and noise in the data negatively impacts the model.

5 Conclusion

In this work, we present the Columbia Team's system submission for the RumourEval 2019 shared task. We tackle the issue of data sparsity by multi-task learning which fully utilizes the training data. In addition, we also apply pre-training techniques such as ULMFiT which was effective in improving results on task A.

GWU NLP at SemEval-2019 Task 7: Hybrid Pipeline for Rumour Veracity and Stance Classification on Social Media

Sardar Hamidian and Mona Diab
Department of Computer Science
The George Washington University
Washington DC, USA
{sardar, mtdiab} @gwu.edu

Abstract

Social media plays a crucial role as the main resource news for information seekers online. However, the unmoderated feature of social media platforms lead to the emergence and spread of untrustworthy contents which harm individuals or even societies. Most of the current automated approaches for automatically determining the veracity of a rumor are not generalizable for novel emerging topics. This paper describes our hybrid system comprising rules and a machine learning model which makes use of replied tweets to identify the veracity of the source tweet. The proposed system in this paper achieved 0.435 F-Macro in stance classification, and 0.262 F-macro and 0.801 RMSE in rumor verification tasks in Task7 of SemEval 2019.

1 Introduction

The number of users who rely on social media to seek daily news and information rises daily, but not all information online is trustworthy. The unmoderated feature of social media makes the emergence and diffusion of misinformation even more intense. Consequently, the propagation of misinformation online could harm an individual or even a society. Most of the current approaches on verifying credibility perform well for the unfold topics which are already verified by a trustworthy resource (Qazvinian et al., 2011; Hamidian and Diab, 2015). However, the performance suffers when it comes to real life application for dealing with the emerging rumors which are priorly unknown. Identifying the emerging rumor and veracity of the rumor by relying on previous observations is a challenging task as the new emerging rumor could be entirely new regarding the event, propagation pattern, and also the provenance. Despite these challenges, many researchers have been studying the generalizable metrics that could be aggregated from the source, replied posts, or network information (Vosoughi et al., 2018b; Kochkina et al., 2018; Grinberg et al., 2019). Our first mission in this paper is to automatically determine the veracity of rumors as part of the SemEval task. SemEval is an ongoing shared task for evaluations of computational sentiment analysis systems. Task 7 (RumourEval19) (Gorrell et al., 2019) is one of the twelve tasks, consisting of two subtasks. Task A is about stance orientation of people as supporting, denying, querying or commenting (SDQC) in a rumor discourse and Task B is about the verification of a given rumor. We propose a hybrid model with rules and a neural network machine learning scheme for both tasks. For task A we rely on the text content of the post, and its parent. In Task B not only do we aggregate contextual information of the source of the rumor but also using the veracity orientation of the others in the same conversation. We devise some rules to improve the performance of the model on query, deny, and support cases which are relatively essential classes in the verification tasks. Integrating the rule-based component we could reach a better performance in both tasks in comparison with a model which only relied on a machine learning approach.

2 Related work

There are several studies about the behavior of misinformation on social media, how it is distinguished and how social media users react to it. Most of these studies use data from Twitter since it has an infrastructure which allows researchers to access network information and meta information of all the users through Twitter APIs. In this section, we mainly focus on machine learning approaches in the study of rumor credibility and stance on Twitter.

One of the earliest work and the most relevant work to this task is that reported in Qazvinian et al. (2011), which addresses rumor detection (rumor/Not-rumor/undetermined) and opinion classification (deny/support/question/neutral) on Twitter using content-based as well as microblog-specific meme features. According to this work, content-based features performed better than meta information and network features for rumor identification and opinion classification tasks. In another study (Castillo et al., 2013), leveraged both information cascade and content features of the tweets by applying a supervised mechanism to identify credible and newsworthy content. According to Castillo's work "confirmed truth," or the rumors which are verified as true, are less likely to be questioned than false rumors regarding their validity. In mor recent study, (Vosoughi, 2015) proposes his two-step rumor detection and verification model on the Boston Marathon bombing tweets. The Hierarchical-clustering model is applied for rumor detection, and after the feature engineering process, which contains linguistic, user identity, and pragmatic features, the Hidden Markov model is applied to find the veracity of each rumor. Vosoughi (2015) also analyses the sentiment classification of tweets using the contextual Information, which shows how tweets in different spatial, temporal, and authorial contexts have, on average, different sentiments. In his recent work (Vosoughi et al., 2018a) he analyzed the spread of false and true news on Twitter on a large dataset. According to his research, fake news is more likely to diffuse deeper and longer in the information network than sound news. Moreover, his research suggests that false news are more novel and likely to be shared in comparison to the true news. Vosoughi et al. (2018a) also studied the false and true stories from an emotional perspective. According to his work, false stories inspired fear, disgust, and surprise in replies, while true stories inspired anticipation, sadness, joy, and trust.

3 Dataset

The dataset provided for this task contains Twitter and Reddit conversation threads associated with rumors about nine different topics on Twitter and thirty different topics on Reddit. The Ottawa shootings, Charlie Hebdo, the Ferguson unrest, Germanwings crash, and Putin missing are some of the rumors in this dataset. The overall size of the data including the development and evaluation set is 65 rumors on Reddit and 37 rumors with 381 conversations on Twitter. Table 1 illustrates all the information of underlying replies and source rumor in both social media platforms.

	Reddit		**Twitter**	
	#Src	*#Rep*	*#Src*	*#Rep*
Training	30	667	297	4222
Development	10	426	28	1021
Evaluation	25	736	56	1010
Total	65	1829	381	6253

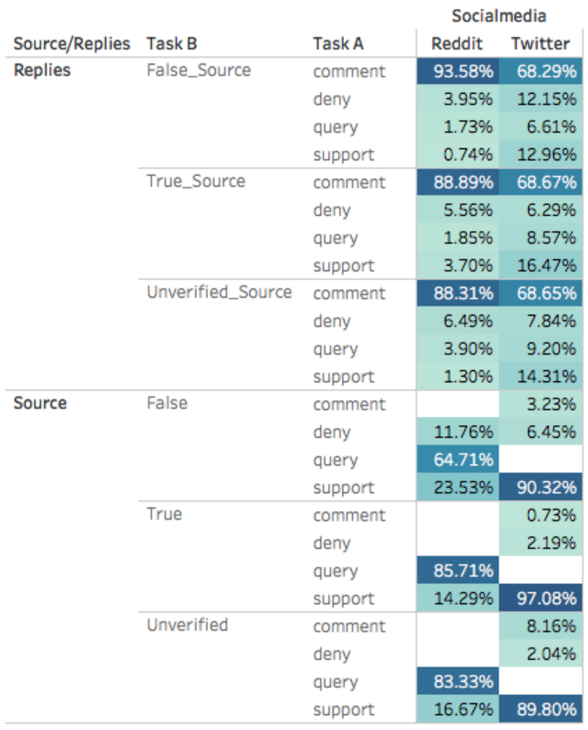
Table 1: Number of source (Src) conversations and replies (Rep) on Reddit and Twitter in the training, development and Evaluation sets.

3.1 Data insight

Figure 1 shows the distribution of the tags for both tasks across different platforms. According to the table, the stance orientation of the rumor conversations varies between Twitter and Reddit. In general, Reddit users leave more comments than Twitter users and this is regardless of the rumor veracity. In false rumors Twitter conversations are more oriented toward denial than Reddit's conversations; however, Twitter users support and deny false rumors to relatively the same extent. Twitter users are more supportive and ask more questions in regards to true rumors than the Reddit users, but they both deny true rumors to almost the same amount.
Interestingly, in both platforms, people question unverified rumors more than true and false rumors. For the source of conversation, Reddit and Twitter are significantly different. Regardless of the veracity, the source in Reddit conversations is more skewed to the query than the other stance tags, while Twitter is more toward the support. Despite some common characteristics Reddit and Twitter users behave differently when it comes to rumors. Reddit users do not deny the TRUE or UNVERIFIED rumors and question more when the rumor is false, yet Twitter users support more without any inquiries. It is worth noting that the conclusions mentioned in this section could only be valid for the data provided and in other conditions the same correlations might not be present.

4 System Description

For both tasks, we mainly rely on the content to determine the stance and verification of the



Source/Replies	Task B	Task A	Socialmedia Reddit	Twitter
Replies	False_Source	comment	93.58%	68.29%
		deny	3.95%	12.15%
		query	1.73%	6.61%
		support	0.74%	12.96%
	True_Source	comment	88.89%	68.67%
		deny	5.56%	6.29%
		query	1.85%	8.57%
		support	3.70%	16.47%
	Unverified_Source	comment	88.31%	68.65%
		deny	6.49%	7.84%
		query	3.90%	9.20%
		support	1.30%	14.31%
Source	False	comment		3.23%
		deny	11.76%	6.45%
		query	64.71%	
		support	23.53%	90.32%
	True	comment		0.73%
		deny		2.19%
		query	85.71%	
		support	14.29%	97.08%
	Unverified	comment		8.16%
		deny		2.04%
		query	83.33%	
		support	16.67%	89.80%

Figure 1: The distribution percentage of stance and verification tags on Twitter and Reddit dataset. "TaskB_Source" (exp. False_Source) indicate the verification tag of the source of conversation.

sources in the conversation. Our primary analysis in the insight section showed that there is a significant correlation between the two tasks. For the unverified rumors, the stance orientation is more toward queries rather than concluding support or denial; on the other hand, for true rumors, people are more likely to support or comment on the conversation than question or deny. Therefore, stance is key information to determine the veracity of the source rumor in the conversation. Task A is a four-way classification experiment in which we propose a hybrid model including a neural network-based (NN) model to encode the contextual representation of the post and its parent and then a rule-based model which is mainly designed to improve the performance on the minority classes including "support," "deny," and also "query." Task-B is a three-way classification task (True, False, and Unverified) in which we rely on both source and conversation content. We expand the veracity tags for the source of the conversation to the underlying posts and create a new set of veracity tags including Source_True, Source_False, and Source_Unverified (Six-way classification). We first apply a sequential neural network-based approach to identify the veracity tag of the source and also replied posts. From the sources with a low confidence value a voting mechanism is applied among all the posts in associated conversation, i.e. if the majority of the tweets in the conversation classified as Parent_true then the source of the conversation will be labeled as True.

4.1 Neural Network Approach

Given the success of recurrent neural networks (RNN) on language problems, we build a standard Bi-LSTM network for both tasks as illustrated in Figure 2. We also investigated the effectiveness of multitask learning in this experiment by sharing the information of two tasks in the same pipeline, but it does not lead to noticeable improvement in the performance.

Figure 2: Illustration of the hybrid network comprising the rule-based and Bi-LSTM-Softmax network on Task A and Task B.

4.1.1 Input Representations

Recent studies on NLP applications are reported to have good performance applying the pre-trained word embedding (Socher et al., 2013). We adopted two widely-used methods including the character embedding and pre-trained word vectors, i.e., GloVe (Pennington et al., 2014). We use a Bi-LSTM network to encode the morphology and word embeddings from characters. Intuitively the concatenated fixed size vectors $W_{Character}$ capture word morphology. $Word_{Character}$ is concatenated with a pre-trained word embedding from GloVe $W_{pre-trained-Glove}$ to get the final word representation. For Contextual Encoding, once the word embedding is created we use another Bi-LSTM layer to encode the contextual meaning from the sequence of word vectors $W_1, W_2, ..., W_t$

	Task A						Task B				
	Accuracy	Macro-F	Support	Query	Deny	Comment	Accuracy	Macro-F	True	False	Unverified
Dev	0.802	0.487	0.420	0.586	0.058	0.885	0.315	0.187	0.418	0.0	0.142
Test	0.796	**0.435**	0.446	0.408	0.0	0.886	0.382	**0.262**	0.525	0.0	0.260

Table 2: Accuracy and F score (macro-averaged) results on the development and test sets of Task A and B.

and consequently obtain a vector representation of a sentence from the final hidden state of the LSTM layer. The input representation would capture the word level syntax, semantics and contextual information. For Twitter data, we only rely on the tweet content for both source and replies, but for the Reddit rumor we use the "title" and "selftext" and only "body" for the replies.

4.2 Rule-based components

The first analysis of the data showed that stance knowledge could significantly help the determination of the source rumor in the conversation. However, due to imbalanced data, identifying the minority classes including deny, query, and support is challenging. We devise a new set of rules to improve the performance of Task A. Using the confidence values of the NN model we only selected the cases with low confidence for the rule-based experiments. We relied on simple rules for each stance class. For Query, a new set of rules was designed to identify the query cases using question marks and syntactic information of the sentence. For Deny, we calculated the cosine similarity of the source and response in addition to sentiment differences of the source and replied post. For the support cases, we mainly relied on the URL and picture existence in the content. The domain of the URL checked for being a fact-checking or news source. We also checked the existence of the picture in the post and consider that as one of the conditions for the supporting tweets.

5 Experimental Setup

The shared task dataset is split into training, development and test sets by the SemEval-2019 task organizers. We conducted and tuned the optimal set of hyperparameters by testing the performance on the development set and the output of the final model on the test set evaluated by the organizers. The statistics of the dataset are shown in Table 1.

5.1 Preprocessing

We applied various degrees of preprocessing on the content, we first removed the very short, deleted, and also the removed cases (Those that are labeled [deleted] or [removed] by the task organizers) from the dataset. We replaced the URLs from news sources with the token NURL and all the fact-checking URLs with FURLs. For compound words and hashtags, we used a simple heuristic. If the hashtag or a word contained an uppercase character in the middle of the word, then we split it before the uppercase letter. For instance, #PutinMissing are separating into two words Putin Missing.

5.2 Training

For all of the pipelines, the network is trained with backpropagation using Adam (Kingma and Ba, 2014), Root Mean Square Propagation (RmsProp), and Stochastic Gradient Descent (SGD) optimization algorithms. The parameters get updated in every training epoch. The character and Glove pre-trained embedding size [100, 200, 300] are examined with batch size 20 with 100 epochs. The training is stopped after no improvements in five consecutive epochs to ensure the convergence of the models. The highest performance on the development set was achieved under the following parameters: hidden size of Bi-LSTM (100); optimization (RMSprop); initial learning rate (0.003); L2 ($Lambda = 0.1$); character and word embedding size (300, 100); dropout size (0.3).

6 Result and Evaluation

In this section, we discuss the experimental results in both tasks. Table 2 shows overall and per category results for Task A and B. The proposed model achieved 0.435 F-Macro in stance classification, and 0.262 F-macro and 0.801 RMSE in rumor verification tasks. In overall evaluation, we ranked as the third group in Task B and tenth in Task A out of twenty-five teams.

7 Conclusion

Identifying rumor veracity is an important and challenging task. Our first mission in this paper is to automatically determine the veracity of rumors as part of the SemEval task. We proposed a hybrid model comprising the rules and NN machine learning approach to identify the stance in the rumor conversation and the veracity of the source in Twitter and Reddit datasets. The proposed system achieved the third best performance for RumourEval, Task7 of Semeval 2019.

Abstract

This paper describes the participation of the SINAI-DL team at RumourEval (Task 7 in SemEval 2019, subtask A: SDQC). SDQC addresses the challenge of rumour stance classification as an indirect way of identifying potential rumours. Given a tweet with several replies, our system classifies each reply into either supporting, denying, questioning or commenting on the underlying rumours. We have applied data augmentation, temporal expressions labeling and transfer learning with a four-layer neural classifier. We achieve an accuracy of 0.715 with the official run over reply tweets.

1 Introduction

Fake news has been identified as "news stories that have no factual basis but are presented as news" (Allcott and Gentzkow, 2017). On a conceptual level, we can define hoaxes or rumours as false information spread across social media with the intention to be picked up by traditional news websites (Rubin et al., 2015). Rumours have been around for millennia, as attested by the ancient (and modern) Greek word 'pheme', which means rumour or inaccurate information.

We have participated in RumourEval (SemEval 2019 Task 7, Subtask A), named *SDQC: Determining support for rumours*, with the complementary objective of tracking how other sources orient to the accuracy of the rumourous story by looking at the replies to the tweet that presented the rumourous statement (Gorrell et al., 2019).

These replies are extracted from Twitter and Reddit, but we have only processed the tweet replies, obtaining a good score in terms of accuracy.

The rest of the paper is organized as follows. Section 2 is a brief overview of the task. Data analysis is shown in section 3. Section 4 describes the neural network architecture. The experiments and results are analyzed in section 5. Finally, conclusions and proposals for further experimentation are provided in section 6.

2 Related Work

The previous edition of RumorEval was organized as part of the SemEval 2017 workshop. Thirteen systems were presented in that edition. Most of the systems presented face this task as a tweet classification task with four categories. Some participants use neural networks such as LSTM (Kochkina et al., 2017) and CNN (Chen et al., 2017; García Lozano et al., 2017), or SVM machine learning algorithm (Wang et al., 2017; Singh et al., 2017), using as main feature word embeddings. Most systems add lexical, syntactic and semantic features to word embeddings.

3 Data analysis

The data provided by the organization consist of a set of tweets and replies. Replies can be originated from two different sources: Reddit or Twitter. We have only worked with Twitter replies because features of Reddit replies and tweets are different, especially in regards to the length. In Table 1 we present the datasets distribution.

Dataset	Tweets	Replies	Tweets replies
train_EN	327	5,217	4,244
dev_EN	38	1,485	1,025
test_EN	56	1,746	1,010

Table 1: Datasets distribution (only tweets).

The objective of task A is to determine whether each reply supports, denies, queries or comments the rumour. The classification of tweet replies in each of the four categories established is shown in Table 2. We can conclude that although the labels show a realistic situation in terms of user comments, the classes are very unbalanced.

Category	train_EN	dev_EN	test_EN
Comment	2,897	779	771
Deny	335	70	92
Query	358	107	56
Support	634	69	91

Table 2: Tweets replies distribution.

In order to decide which window size to use in our system, we generated a cumulative histogram according to the different lengths of the tweets replies. Our objective was to select a size that could cover a high rate of tweets replies. In Table 3 we summarize the quantiles at 80 % and 90 % for the different datasets. Based on the values we decided to select a window size with 30 words because approximately 90 % of training and development tweet replies have a length of 30 words or less.

Data	Quantile 0.8	Quantile 0.9
train_EN	25	29
dev_EN	28	30

Table 3: Length of tweet replies covering 80 % and 90 % of cases.

4 System overview

Nowadays, deep neural architectures are populating the scientific playground in many scenarios: image recognition, speech recognition (Graves et al., 2013) and synthesis (Ze et al., 2013), and, of course, text classification (Zhang et al., 2015). But these supervised learning algorithms demand certain requirements that sometimes are difficult to meet. One of the most difficult to overcome in some cases is the need for a large and varied learning data set. When there is a lack of data, two main strategies can be followed: *transfer learning* and *data augmentation*.

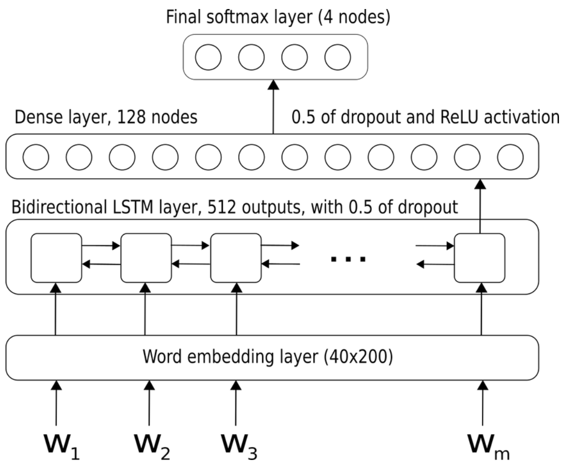
4.1 Model description

We have implemented the proposed neural network using the Keras[1] library for Python, running on TensorFlow over an NVIDIA Titan X card. Each model took approximately 15 minutes to get trained and few seconds to classify development or test sets. The architecture of our neural network follows a sequence of layers as follows:

[1]http://keras.io

1. **First layer**: An embedding layer that is loaded with pre-trained weights, and converts each word into a 200-dimensional vector of real values.
2. **Second layer**: A bi-directional LSTM recurrent network with 512 activations and a dropout value of 0.5.
3. **Third layer**: A dense network with 128 activations and the *ReLU* function as activation function. A dropout of 0.5 is also applied after this network.
4. **Fourth layer**: last classification layer, with 4 activations on the final softmax function.

Figure 1 shows the neural network model with the four layers.



Final softmax layer (4 nodes)
Dense layer, 128 nodes
0.5 of dropout and ReLU activation
Bidirectional LSTM layer, 512 outputs, with 0.5 of dropout
...
Word embedding layer (40x200)
w_1
w_2
w_3
w_m

Figure 1: Neural network model.

The model has been trained with the hyperparameters values specified in Table 4 (ce means cross-entropy).

Parameter	value
Batch size	512
Loss function	categorical ce
Optimization algorithm	Adam
Sequence length	30 terms
No. Epochs	50

Table 4: Hyperparameters

The texts have been preprocessed as follows:

1. Lower case is applied.
2. Hashtags are split into several tokens according to a camel case approach. For example, "*#MeToo*" is converted into the terms "*<BOH>me too <EOH>*".

3. Mentions are replaced by the token <*MENTION*>

4. Unknown terms (those not found in the embedding dictionary) are replaced by the token <*UNK*>.

5. A final token <*EOT*> is added at the end of the tweet.

We have taken an already trained word embedding matrix for the first layer, allowing the weights of the these learned model to get retrained during the learning process. We have used the weights from the GloVe Twitter model provided by the Stanford NLP Group, which is built over 2 billion tweets (27B tokens, 1.2M vocab, uncased, 200-dimensional vectors, 1.42 GB download).

4.2 Data augmentation

There are two important reasons for proposing data augmentation. On the one hand, deep neural models require a significant amount of training data to extract relevant features. On the other hand, as we can see in the section 3 there is a strong class imbalance between the samples (in dev and train datasets more than 75 % of the tweets are labeled as *comments*).

For each tweet, our system expands the information using paraphrasing. To express the same message with different words, we applied the online tool RewriterTools[2]. For instance, the paraphrase of the tweet *"EU's hailed migrant plan 'a road to Hell' Czech Republic refuses involvement"* is *"EU's hailed migrant layout 'a avenue to Hell' Czech Republic refuses involvement"*.

4.3 Temporal expressions

As human beings, we tend to organize the flux in structured units known as events. Events take place at certain times, which are expressed in the text in the form of temporal expressions. However, these expressions are not always explicit dates that a computer is able to understand. For this reason, we decided to add a module that is capable of processing temporal information at the level of events and temporal expressions and annotate and resolve this information, so that it can be used in the detection of a rumor.

TimeML (Saurí et al., 2006) is the most standardized schema to annotate temporal information. They defined the event as "something that can be said to obtain or hold true, to happen or to occur". This annotation schema annotates not only events and temporal expressions, but also temporal relations, known as links (Pustejovsky et al., 2003). Example below shows a sentence annotated with TimeML temporal expressions (`TIMEX3`), events (`EVENT`), and the links between them (`TLINK`).

```
John <EVENT eid='e1'>came</EVENT> on <TIMEX3 tid='t1'>Monday</TIMEX3>
<TLINK eventInstanceID='e1'
relatedToTime='t1'
relType='IS_INCLUDED' />
```

In our approach, the Temporal Information Extraction and Processing was performed by TIPSem system (Temporal Information Processing using Semantics) (Llorens et al., 2013, 2012)[3]. TIPSem is able to automatically annotate all the temporal information according to TimeML standard annotation scheme (Saurí et al., 2006). In this first approach of the system, only the tags regarding temporal expressions and events have been considered and we will explore using the links as further work.

5 Experiments and results

We performed an evaluation of the proposed neural network on the development set, but training a model on two different official training sets: the official ones and those augmented by paraphrasing the given tweets. The results were discouraging when paraphrased tweets are added to the training set, as Table 5 shows. After checking the tweets generated by the paraphrasing tool, we noticed that the quality was low, with non-sense texts in some cases and few structural variations from the original tweet. Thus, we believe that the network was not even less robust, but worse as a non-realistic model was learned.

The detection of temporal expressions and the inclusion of the generated tags into the model didn't report any improvement either. We believe that the related embeddings (randomly initialized) needed a far larger set to fit in the transferred learned embedding model for GloVe vectors.

Thus, our submission relies only on official training data which was, as we know, not enough data to ensure a good learning process. Anyhow, our system performed in 9th position out from 21 in

[2]https://www.rewritertools.com/paraphrasing-tool

[3]`http://gplsi.dlsi.ua.es/demos/TIMEE/`

train data	accuracy on dev data
official	0.690499
official + paraphrased	0.675808
official with temporal tags	0.684622

Table 5: Development experiments

subtask A, with an SDQC value of 0.3927 (F1-score).

Table 6 shows the results obtained with the official run over test set (only with the tweet replies).

truth label	accuracy	total	correct
all labels	**0.7148**	**1,066**	**762**
support	0.0219	91	2
deny	0.1413	92	13
query	0.4285	56	24
comment	0.9377	771	723

Table 6: Test experiments: official run

In the first analysis of results we can verify that the neural network system, on the base case, has worked correctly (almost perfect) for the *comment* class that have a sufficient number of examples of train and dev, and much worse for those with very few examples (classes support, deny and query).

We have to finish a more exhaustive analysis of these results, especially of the mislabelled samples. For instance, in the analysis of the truth label *support*, our system tags the most of the cases with the *comment* label. In this case, we can conclude that the *comment* label has been overtrained because of the greater number of examples (high bias).

6 Conclusions and future work

Our proposal explores how transferred embeddings and data augmentation may help in a text classification task like RumourEval. By augmenting official training data with paraphrasing, no improvement is noticed on classifying development data, due to the poor quality of the paraphrasing tool. So, we plan to explore other augmentation strategies, like a forward-backward translation. Neither temporal expression detection has been found useful in this task, at least with the model proposed. We have found also that the models trained exhibits high variance. That means that we are overfitting the model on training data, so despite the use of the dropout technique, early stopping, fewer parameters or more training data could help to produce a more robust model. Attention mechanism in the neural network could also help (Wang et al., 2016), along with a pre-training of the LSTM with a large corpus of tweets for a language model (predicting next word) and then transfer those weights and retrain them for this specific task.

Finally, we intend to incorporate a module that takes into account the reputation of the user who makes comments, based on non-textual parameters, such as the relationship between the user of the original tweet and the user of the reply tweet, number of followers, knowledge of the subject, etc. We will use that information to work in the second task, predicting the veracity of the original tweet.

Abstract

In the present paper we describe the UPV-28-UNITO system's submission to the RumorEval 2019 shared task. The approach we applied for addressing both the subtasks of the contest exploits both classical machine learning algorithms and word embeddings, and it is based on diverse groups of features: stylistic, lexical, emotional, sentiment, meta-structural and Twitter-based. A novel set of features that take advantage of the syntactic information in texts is moreover introduced in the paper.

1 Introduction

The problem of rumor detection lately is attracting considerable attention, also considering the very fast diffusion of information that features social media platforms. In particular rumors are facilitated by large users' communities, where also expert journalists are unable to keep up with the huge volume of online generated information and to decide whether a news is a hoax (Procter et al., 2013; Webb et al., 2016; Zubiaga et al., 2018).

Rumour stance classification is the task that intends to classify the type of contribution to the rumours expressed by different posts of a same thread (Qazvinian et al., 2011) according to a set of given categories: supporting, denying, querying or simply commenting on the rumour. For instance, referring to Twitter, once a tweet that introduces a rumour is detected (the "source tweet"), all the tweets having a reply relationship with it, (i.e. being part of the same thread), are collected to be classified.

Our participation to this task is mainly focused on the investigation of linguistic features of social media language that can be used as cues for detecting rumors[1].

2 Related work

The RumorEval 2019 shared task involves two tasks: Task A (rumour stance classification) and Task B (verification).

Stance Detection (SD) consists in automatically determining whether the author of a text is in favour, against, or neutral towards a given target, i.e. statement, event, person or organization, and it is generally indicated as TARGET-SPECIFIC STANCE CLASSIFICATION (Mohammad et al., 2016).

Another type of stance classification, more general-purpose, is the OPEN STANCE CLASSIFICATION task, usually indicated with the acronym SDQC, by referring to the four categories exploited for indicating the attitude of a message with respect to the rumour: Support (S), Deny (D), Query (Q) and Comment (C) (Aker et al., 2017). Target-specific stance classification is especially suitable for analyses about a specific product or political actor, being the target given as already extracted, e.g. from conversational cues. On this regard several shared tasks have been organized in recent years: see for instance SemEval-2016 Task 6 (Mohammad et al., 2017) considering six commonly known targets in the United States, and StanceCat at IberEval-2017 on stance and gender detection in tweets on the matter of the Independence of Catalonia (Taulé et al., 2017). On the other hand, the open stance classification, (i.e. the task addressd in this paper), is more suitable in

[1]Source code is available on GitHub: https://github.com/bilalghanem/UPV-28-UNITO

classifying emerging news or novel contexts, such as working with online media or streaming news analysis.

Provided that attitudes around a claim can act as proxies for its veracity, and not only of its controversiality, it is reasonable to consider the application of SDQC techniques for accomplishing rumour analysis tasks. A first shared task, concerning SDQC applied to rumor detection, has been organized at SemEval-2017, i.e RumorEval 2017 (Derczynski et al., 2017). Furthermore, several research works have analyzed the open issue of the impact of rumors in social media (Resnick et al., 2014; Zubiaga et al., 2015, 2018), for instance exploiting linguistic features (Ghanem et al., 2018). Such a kind of approaches may be also found in works which deal with the problems of Fake News Detection (Ciampaglia et al., 2015; Hanselowski et al., 2018).

Furthermore, a rumor is defined as a "circulating story of questionable veracity, which is apparently credible but hard to verify, and produces sufficient scepticism and/or anxiety so as to motivate finding out the actual truth" (Zubiaga et al., 2015).

Concerning veracity identification, increasingly advanced systems and annotation schemas have been developed to support the analysis of rumour veracity and misinformation in text (Qazvinian et al., 2011; Kumar and Geethakumari, 2014; Zhang et al., 2015).

3 Description of the task

The RumorEval task is articulated in the following sub-tasks: **Task A** (open stance classification – SDQC) is a multi-class classification for determining whether a message is a "support", a "deny", a "query" or a "comment" wrt the original post; **Task B** (verification) is a binary classification for predicting the veracity of a given rumour into "true" or "false" and according to a confidence value in the range of 0-1.

3.1 Training and Test Data

The RumourEval 2019 corpus contains a total of 8,529 English posts, namely 6,702 from Twitter and 1,827 from Reddit.

The portion of data from Twitter has been built by combining the RumorEval 2017 training and development datasets (Derczynski et al., 2017), and includes **5,568** tweets: 325 source tweets (grouped into eight overall topics such as Charlie Hebdo attack, Ottawa shooting, Germanwings crash...), and 5,243 discussion tweets collected in their threads.
The dataset from Reddit, which has been instead newly released this year, is composed by **1,134** posts: 40 source posts and 1,094 collected in their threads.

	Training	Test
Twitter	5,568	1,066
Reddit	1,134	761
Total	6,702	1,827

Table 1: Training and test data distribution.

All data have been split in training and test set with a proportion of approximately $80\% - 20\%$ (see Table 1).

4 UPV-28-UNITO Submission

The approach and the features selection we applied is the same for both tasks and is based on a set of manual features described in Section 4.1. We built moreover another set of features (i.e. second-level features) extracted by using the manual features together with features based on word embeddings (see Section 4.2 for a detailed description). For modeling the features distribution with respect to each thread, we used for task B the same features as in task A. Then, in both tasks, we fed the features to a classical machine learning classifier.

4.1 Manual Features

For enhancing the selection of features, we investigated the impact of diverse groups of them: emotional, sentiment, lexical, stylistic, meta-structural and Twitter-based. Furthermore, we introduced a novel set of syntax-based features.

Emotional Features - We exploited several emotional resources in order to build features for our system. Three lexica: (a) **EmoSenticNet**, a lexicon that assigns six WordNet Affect emotion labels to SenticNet concepts (Poria et al., 2013); (b) the **NRC Emotion Lexicon**, a list of English words and their associations with eight basic emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive) (Mohammad and Turney, 2010);

and (c) **SentiSense**, an easily scalable concept-based affective lexicon for Sentiment Analysis (De Albornoz et al., 2012). We also exploited two tools: (d) **Empath**, a tool that can generate and validate new lexical categories on demand from a small set of seed terms (Fast et al., 2016); and (e) **LIWC** a text analysis dictionary that counts words in psychologically meaningful categories (Pennebaker et al., 2001).

Sentiment Features - Our sentiment features were modeled exploiting sentiment resources such as: (a) **SentiStrength**, a sentiment strength detection program which uses a lexical approach that exploits a list of sentiment-related terms (Thelwall et al., 2010); (b) **AFINN**, a list of English words rated for valence with an integer between minus five (negative) and plus five (positive) (Nielsen, 2011); (c) **SentiWordNet**, a lexical resource in which each WordNet synset is associated to three numerical scores, describing how objective, positive, and negative the terms contained in the synset are (Esuli and Sebastiani, 2007); (d) **EffectWordNet**, a lexicon about how opinions are expressed towards events, which have positive or negative effects on entities (+/-effect events) (Choi and Wiebe, 2014); (e) **SenticNet**, a publicly available resource for opinion mining built exploiting Semantic Web techniques (Cambria et al., 2014); and (f) the **Hu&Liu** opinion lexicon[2].

Lexical Features - Various lexical features already explored in similar Sentiment Analysis tasks were employed: (a) the presence of **Bad Sexual Words**, a list extracted from the work of Frenda et al. (2018); (b) the presence of **Cue Words** related to the following categories: *belief, denial, doubt, fake, knowledge, negation, question, report* (Bahuleyan and Vechtomova, 2017); the categories *an, asm, asf, qas, cds* of the multilingual hate lexicon with words to hurt **HurtLex** (Bassignana et al., 2018); (d) the presence of **Linguistic Words** related to the categories of *assertives, bias, fatives, implicatives, hedges, linguistic words, report verbs*; (e) the presence of specific categories present in **LIWC**: *sexual, certain, cause, swear, negate, ipron, they, she, he, you, we, I.* (Pennebaker et al., 2001).

Stylistic Features - We employed canonical stylistic features, already thoroughly explored in Sentiment Analysis tasks and already proven useful in multiple domains: (a) the count of **question marks**; (b) the count of **exclamation marks**; (c) **length** of a sentence; (d) the **uppercase ratio**; (e) the count of consecutive **characters** and **letters**[3] (f) and the presence of **URLs**.

In addition to the above-listed, common features exploited in Sentiment Analysis tasks, in this work we introduce two novel sets of features: (1) **Problem-specific features** (considering the fact that the dataset is composed by Twitter data and Reddit data) and (2) **Syntactical features**.

Meta-structural features - Since training and test data are from Twitter and Reddit both, we explored meta-structural features suitable for data coming from both platforms: (a) the **count of favourites/likes**, in which we have two different value distribution (Twitter vs. Reddit), so we normalized them in a range 0-100; (b) the **creation time** of a post, encoded in seconds; (c) the **count of replies**; and (d) the **level**, i.e. the degree of "nestedness" of the post in the thread.

Twitter-only Features - Because of the duplicitous nature of the RumorEval 2019 dataset (Twitter and Reddit), some of the several features, already thoroughly used in Sentiment Analysis tasks and based on Twitter metadata, could not be used in this task[4]. As follows: (a) the presence of **hashtags**; (b) the presence of **mentions**; (c) the count of **retweets**. And also some user-based features: (d) whether the user is **verified** or not; (f) the count of **followers**; (g) the count of **listed** (i.e. the number of public lists of which this user is a member of); (h) the count of **statuses**; (i) the count of **friends** (i.e. the number of users that one account is following); (l) the count of **favourites**.

Syntactic Features - In our system some feature has been also modeled by referring to syntactic information involved in texts (Saif et al., 2016). After having parsed[5] the dataset in the *Universal De-*

[2]http://www.cs.uic.edu/liub/FBS

[3]We considered 2 or more consecutive characters, and 3 or more consecutive letters.

[4]For the instances from Reddit, that did not have a representation of one of the following features, the empty values has been filled with a weighted average of the values obtained by other similar instances.

[5]The parsing system we applied is UDPipe, available at: https://pypi.org/project/ufal.udpipe/

pendency[6] format, thus obtaining a set of syntactic "dependency relations" (*deprel*), we were able to exploit: (a) the **ratio of negation** dependencies compared to all the other relations; (b) the Bag of Relations (BoR_all) considering all the *deprels* attached to **all the tokens**; (c) the Bag of Relations (BoR_list) considering all the *deprels* attached to the tokens belonging to a selected **list of words** (from the lists already made explicit in the paragraph "Lexical Features" in Section 4.1); and finally (d) Bag of Relations (BoR_verbs) considering all the *deprels* attached to all the **verbs**, thus fully exploiting morpho-synctactic knowledge.

4.2 Second-level Features

For the second-level features, we employed (a) the cosine similarity of one instance wrt its parents and (b) information of the tree structure of a thread, exploiting its "nesting" and depth from the source tweet.

Similarity with Parents - In this feature, we used the cosine similarity to measure the similarity between each post with its parents. The parents of a reply are the (A) direct upper-level post and (B) the source post in the thread (see Figure 1).

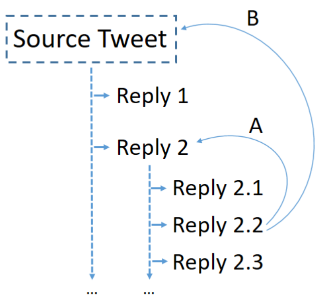

Figure 1: An example for reply 2.2 parents.

We extracted the cosine similarity in A and B by using the manual features' final vector and words embeddings average vectors of the posts; the words embeddings average vector for a post is extracted by averaging the embeddings of the post's words[7].

[6]The *de facto* standard for the representation of syntactical knowledge in the NLP community: https://universaldependencies.org/

[7]We used the pre-trained Google News word embeddings in our system: https://code.google.com/archive/p/word2vec/

SDQC Depth-based Clusters - We built level-based stance clusters from the posts. For each stance class (SDQC), we extracted all the belonging posts that correspond to one of the four classes and we computed the average value of the feature vectors (as one unique cluster). Since we have four main stances, this process ended with four main clusters. For the feature extraction, we measured the cosine similarity for each post wrt these four clusters. As done in the previous feature described above, we built these clusters by using both the manual features' vectors and word embeddings' vectors of the posts, so each stance cluster is represented in two ways. In these four main clusters, we didn't consider the nesting of the posts in the thread.

Also, we obtained the same clusters but instead of averaging all the posts that correspond to a stance, we considered the nesting of the posts in the thread. We split the nesting of the threads into five groups: posts with depth one, two, three, four, five or larger. For each of these levels, we extracted four SDQC clusters (depth-based). For instance, if a post occurs in depth two, we measured the cosine similarity between this post and 1) the four main SDQC clusters[8], 2) the four depth-based SDQC clusters two.

Concerning task B, we modeled the distribution of the features used for task A. For each thread we did the following:

1. We counted how many posts in the thread correspond to each of the stances.
2. We extracted the averaged features' vectors for each stance's posts in the thread.
3. We extracted the standard deviation for each stance's posts in the thread.

5 Experiments

We tested different machine learning classifiers in each task performing 10-fold cross-validation. The results showed that the Logistic Regression (LR) produces the highest scores. For tuning the classifier, we used the Grid Search method. The parameters of the LR are: $C = 61.5$, $penalty = L2$, and since the dataset is not balanced, we used different weights for the classes as COMMENT =

[8]Four features using the manual features, and another four using the words embeddings.

0.10, DENY = 0.35, SUPPORT = 0.20 and QUERY = 0.35. We conducted an ablation test on the features employed in task A in order to investigate their importance in the classification process. Table 2 presents the ablation test results as well as the system performance using 10-fold cross-validation.

SET	FEATURE	M-F1
A	All features	54.9
B	A - Emotional features	54.5
C	A - Sentiment features	54.7
D	A - Lexical features	53.6
E	A - Syntactic features	54.7
F	A - Stylistic features	50.1
G	A - Meta-structural features	54.5
H	A - Twitter-only features	54.9
I	A - Cosine similarity with parents	55.3
I.1	I using only manual features	54.9
I.2	I using only words embeddings	54.9
J	A - SDQC depth-based clusters	47.7
J.1	J using only manual features	53.3
J.2	J using only words embeddings	51.1
K	A-(C+E+I)	55.6
L	A-(B+C+E+G)	55.7
M	A-(B+C+E+G+I.2)	55.9

Table 2: Ablation test.

Provided that the organizers allowed two submissions for the final evaluation, on both tasks we used all the features (set A) in the first submission and set M for the second submission. In Table 3 we present the final scores achieved on both tasks.

	MACRO-F1	RMSE
Task A	48.95	–
Task B	19.96	82.64

Table 3: Final results.

6 Error Analysis

A manual error analysis allow us to see which categories and posts turned out to be the most difficult to be dealt with our system. We found out that SUPPORT was misclassified 114 times, DENY 92 times, QUERY 44 times, and COMMENT 57 times. Therefore, SUPPORT seems to be the hardest category to be correctly classified.
Table 4 reports the detailed confusion matrix of predicted vs. gold labels and shows that the most of errors are related to the category SUPPORT (in the gold dataset) and COMMENT (in our runs), while any error involves the more contrasting classes (e.g. SUPPORT and DENY). By better investigating the gold test set, it should be moreover observed that several semantically empty messages of the test set have been marked using some class, while our system marks them as COMMENT, i.e. selecting the more frequent class when a clear indication of the content is lacking.

		PREDICTED			
		S	D	Q	C
GOLD	S	–	0	13	101
	D	1	–	6	85
	Q	5	1	–	38
	C	5	17	35	–

Table 4: Confusion matrix of errors.

7 Conclusion

In this paper we presented an overview of the UPV-28-UNITO participation for *SemEval 2019 Task 7 - Determining Rumour Veracity and Support for Rumours*.

We submitted two different runs in the detection of rumor stance classification (Task A) and veracity classification (Task B) in English messages retrieved from Twitter and Reddit both. Our approach was based on emotional, sentiment, lexical, stylistic, meta-structural and Twitter-based features. Furthermore, we introduced two novel sets of features, i.e. *syntactical* and *depth-based* features, which proved to be successful for the task of rumor stance classification, where our system ranked as 5th (out of 26) and, according to the RMSE score, we ranked 6th in Task B for veracity classification. Since the two latter groups of features produced an interesting contribution to the score for Task A, but they were fairly neutral in Task B, we will follow this trail and try to inquire more on these aspects in our future work.

Abstract

Since the resources of Community Question Answering are abundant and information sharing becomes universal, it will be increasingly difficult to find factual information for questioners in massive messages. SemEval 2019 task 8 is focusing on these issues. We participate in the task and use Generative Pretrained Transformer (OpenAI GPT) as our system. Our innovations are data extension, feature extraction, and input transformation. For contextual knowledge enhancement, we extend the training set of subtask A, use several features to improve the results of our system and adapt the input formats to be more suitable for this task. We demonstrate the effectiveness of our approaches, which achieves 81.95% of subtask A and 61.08% of subtask B in accuracy on the SemEval 2019 task 8.

1 Introduction

With the development of Community Question Answering (cQA) forums, massive information is being shared. However, not all information is factual, which makes finding an appropriate answer to satisfy the information needs of questioners more difficult. Previous work which concentrated on these problems (Nakov et al., 2017) reranked the questions based on their relevance with the original question. Šaina et al. (2017) treated the similarity ranking task as a binary classification problem. We study these issues in SemEval-2019 Task 8 (Mihaylova et al., 2019) by using the contextual Knowledge-enhanced GPT (Radford et al., 2018), which use Transformer (Vaswani et al., 2017) as model architecture. The contextual knowledge enhancement includes data extension, feature extraction, and input transformation.

The task includes two subtasks and they are both three classification problems. In subtask A, we need to find out whether a question seeks a factual answer, an opinion or just want to socialize with others. We classify the answers for questions that look for factual information in subtask A into three classes in subtask B: true, false or nonfactual. In this paper, we study both subtasks and use a similar system to solve them.

Several challenges exist when doing this task. The size of datasets for both subtasks is small. The data contains a number of complex long text, which makes extracting key information more difficult. The input format of GPT changes with different objectives of tasks, so it requires some modifications to fit specific tasks.

We apply three points to solve these problems. We extend the training set of subtask A from two other datasets: DailyDialog (Li et al., 2017) and SQuAD2.0 (Rajpurkar et al., 2018). We use two methods to guarantee the quality of expanded datasets. Firstly we use the Levenshtein Distance to screen similar data, and then we use the prediction of the model to further screen the results of the previous step. Goyal (2017) and Xie et al. (2017) used various features. Le et al. (2017) used keywords to solve the previous similar problem. We follow their work in feature extraction. Working on subtask A, we also use characteristic words as features to improve the system. Input transformation for classification task is $Start + Text + Extract$, including randomly initialized start and end tokens. We concatenate the text and features token sequences with a delimiter token.

The remainder of this paper is organized as follows. Section 2 contains a description of our system. The experiments and analysis of the results are introduced in section 3. We describe the conclusions in section 4.

2 System Description

As Figure 1 shows, our system is composed of the following components: data extension, feature extraction, input transformation, and model.

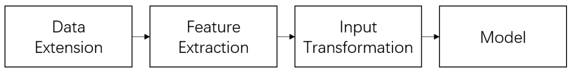

Figure 1: Flowchart of the system

Since the data provided by the task organizers are insufficient, our model does not get a high accuracy on such a small amount of data. We apply the data extension(Section 2.1) to address this problem. The extended datasets are DailyDialog and SQuAD2.0. We use two Levenshtein Distance and model prediction to ensure the expanded data similar enough to original data.

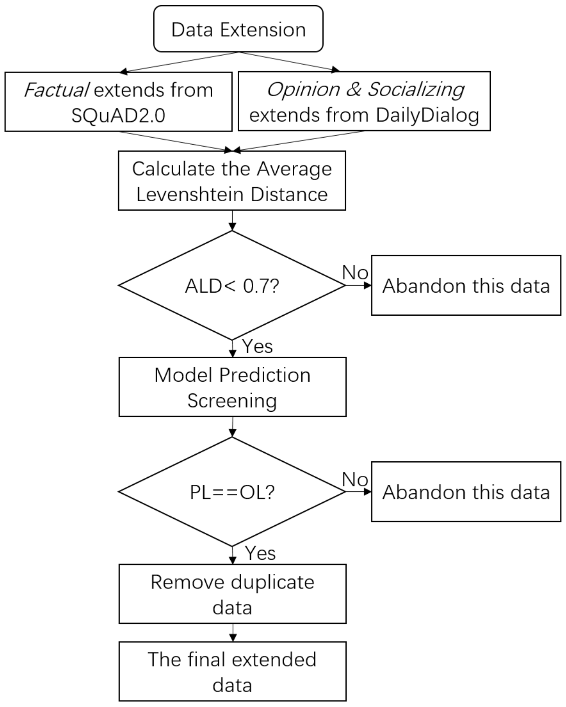
Since the data is composed of long text with complex information, it is difficult for our model to extract key information. We use feature extraction(Section 2.2) to solve this problem, which is able to bring high discrimination between data categories. We add two kinds of features to the input: original features directly extracted from the training data and observed features is summarized by us. After feature extraction, the key information gets enhanced and our model has easier access to significant information of data.

Different types of tasks correspond to different input transformation of GPT. We change the input transformation(Section 2.3) to fit different tasks. If a task is about classification, the input format is supposed to be $Start + Text + Extract$. We need to adjust the input of our model to adapt to the specific task, also need to add features in the data. We use special character $Delim$ to connect different features and the main text, then we use the connected formats as our input.

2.1 Data Extension

This section briefly introduces the datasets of subtask A, subtask B, DailyDialog and SQuAD2.0. Then we introduce data extension from DailyDialog and SQuAD2.0. Figure 2 shows the total process of extending data for subtask A. We use two approaches to ensure the data that we expanded from other datasets similar enough with original data. The two approaches are Levenshtein Distance screening and model prediction screening.

Data Overview The datasets we used for subtask A and subtask B are provided by the task organizers. We extend the training set of subtask A from two other datasets: DailyDialog and SQuAD2.0.



Data Extension
Factual extends from SQuAD2.0
Opinion & Socializing extends from DailyDialog
Calculate the Average Levenshtein Distance
ALD< 0.7?
No
Abandon this data
Yes
Model Prediction Screening
PL==OL?
No
Abandon this data
Yes
Remove duplicate data
The final extended data

Figure 2: Flowchart of data extension. ALD represents average Levenshtein distance. PL stands for perdicted label and OL stands for original label. Since *Opinion* and *Socializing* are both extended in Daily Dialog, so we remove duplication in the alternative extended datasets of *Opinion*.

- In subtask A, there are 1118 threads in the original dataset. Each thread consists of RelQBody, RelQSubjcet, RelQCategory, RelQDate, RelQId, RelQUser Id and RelQUsername. RelQBody is a complete question description but its text is too long. RelQSubject is short but lacks feature information. RelQCategory is mentioned to show the question's category and it is useful in classifying the questions. Our emphasis is subtask A, which is working on deciding the questions' classification label *Factual*, *Opinion* and *Socializing*. Specifically, the size of each class is 311, 563 and 244. The *Opinion* class accounts for more than half of the total data.

- The dataset of Subtask B is similar to subtask A. There are 495 answers in the original dataset. One question corresponds to one or several answers. The purpose of subtask B is to divide the answers into three categories: *True*, *False* and *Nonfactual*.

- DailyDialog is a multi-turn dialog dataset, which includes questions and answers, and the data size is 11318. The topic of DailyDialog is about daily life, so we consider that we expand *Opinion* and *Socializing* label data from it.

- SQuAD2.0 is a reading comprehension dataset, which intends to answer a question according to the context. Absolutely, questions in this dataset all ask for factual information since the answers can be found from the context. We decided to extend the *Factual* label data from the questions of this dataset.

Levenshtein Distance Screening Levenshtein distance is also known as Editing distance, which refers to the smallest number of editing operations required to change one string into another. The editing operation consists of three choices: replacing one character with another, inserting one character, and deleting one character. When comparing the two sentences, they will be more similar if the Levenshtein distance is smaller.

Levenshtein distance is used to calculate the similarity between two sentences. Since the length of sentences in the dataset is uncertain, the Levenshtein distance is an integer of indeterminate size. We divide the Levenshtein distance by a larger length of two sentences. Ultimately, what we get is not an unlimited integer, but a decimal between 0 and 1. In this paper, it is called average Levenshtein distance, as shown in Equation(1), where ALD(s1,s2) represents the average Levenshtein distance of sentence 1 and sentence 2.

$$ALD(s1, s2) = \frac{LevenshteinDistance}{max(len(s1), len(s2))} \quad (1)$$

We regard the question data of the cQA(community QA) forum as the original data and divide it into three categories according to the different labels of the questions. When traversing instance in *Opinion* and *Socializing*, the ALD between the original data and the question of DailyDialog data is calculated. When traversing the data of *Factual*, the ALD between the original data and the question of SQuAD 2.0 data is calculated.

We set a threshold of **0.7**. At this threshold, we are able to get more data which is guaranteed to be sufficiently similar. After calculating the ALD, if the value is less than the threshold, it means the two sentences are sufficiently similar. Then we use this data as alternative extended data. Finally, we get three alternative extended datasets with their original label. Since *Opinion* and *Socializing* are both extended from DailyDialog, it will be some plication in the two extended datasets. The original *Socializing* data is less than *Opinion*, so we remove duplication in the extended datasets of *Opinion* in order to get roughly the same amount of data. It means if a data appears in the alternative extended datasets of *Socializing*, then remove this data in the alternative extended datasets of *Opinion*.

Model Prediction Screening The question dataset of the cQA forum is used as the training set to train the GPT model, and the candidate extended dataset is used as the test set to predict. If the predicted label is consistent with the original label of the test set, then this data is considered to be correct prediction data. As one of the extended datasets, if the predicted label is inconsistent with the original label, which means that it is wrong, it is considered that this data is not helpful to the model, so we discard this data.

	original	extended	sum
factual	311	434	745
opinion	563	308	871
socializing	244	598	842

Table 1: Class distribution of subtask A

After screening by Levenshtein distance and model prediction, we finally get 434, 308 and 598 for *Factual*, *Opinion* and *Socializing* to expand. After expansion, the number of three classified data is 745, 871 and 842, respectively. Table 1 shows the total data category distribution of the subtask A.

2.2 Feature Extraction

We introduce two kinds of features and explain how we apply these features to the GPT model in detail.

Features Acquisition Subtask A includes two kinds of features. One we call *Original Features* is given directly in the dataset. The other we call *Observed Features* is obtained from the data observation. For subtask B, we just use the features

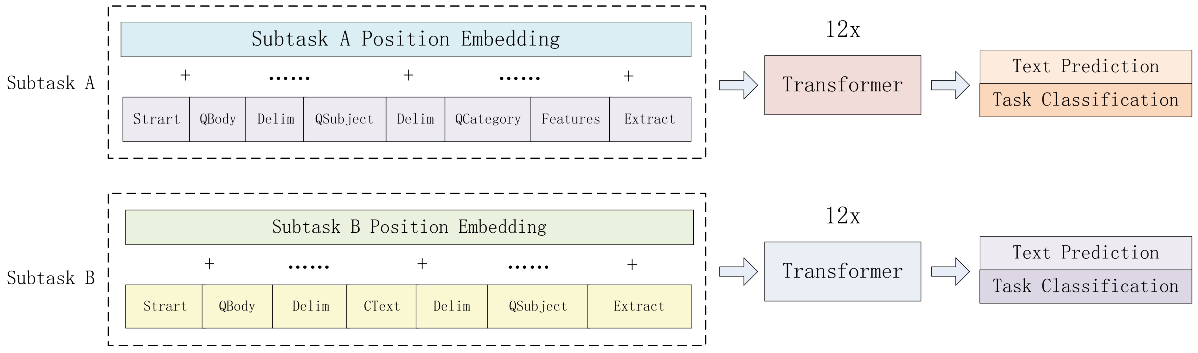


Figure 3: Input formats of subtasks. The input formats consist of text embedding and position embedding. Subtasks A and B input to the model separately. In the model, it is a 12-layer decoder-only transformer with masked self-attention heads. Text prediction and task classification are both the fine-tuning objective of the GPT model.(Radford et al., 2018)

extracted directly in the dataset. We present two kinds of features as follows.

Original Features In the dataset of subtask A, each thread consists of RelQBody, RelQSubjcet, RelQCategory, RelQDate, RelQId, RelQUser Id and RelQUsername. The main text is RelQbody, and we consider other information as features. Through our screening, it is a suitable method to regard RelQSubject and RelQCategory as original features. For extended data, they are no original features.

For subtask B, we choose RelQbody and RelQ-Subject as the original features.

Observed Features The second kind of feature is obtained from data observation in subtask A. In *Factual* data, there are a lot of questions about Visas for couples, working, pets and animals, opportunities, etc. In *Opinion* data, questions that ask for advice are more common. In *Socializing* data, the questions are more colloquial, so it may include a word like *qler*. We chose the observed characteristic words as features. There are several examples for each class:

- *Factual*: *visit, license, husband, wife, embassy, sponsor*
- *Opinion*: *advice, school, suggestion, advise*
- *Socializing*: *ql, qler, weekend, love, going, today*

2.3 Model

Input Transformation Input sequence contains three special characters $Start$, $Extract$ and $Delim$, representing the start, end, and delimiter token respectively. We treat subtask A and B as question classification tasks. Their input formats are as follows.

- Subtask A: The most useful information in the data is the complete problem description RelQBody. We choose it as the main text and RelQSubject and RelQCategory as the original features. We employ the main text and two original features as the input. The observed features are also added to the input. The final input representation is $Start + RelQBody + Delim + RelQSubject + Delim + RelQCategory + Features + Extract$.
- Subtask B: We use RelCText as the main text, and use RelQBody and RelQSubject as original features. These features constitute the model input. We do not employ observed features in subtask B. So the final input format is $Start + RelQBody + Delim + RelCText + Delim + RelQSubject + Extract$

Model Description GPT is a language model, pre-trained on BooksCorpus (Zhu et al., 2015). There are 12-layer *Transformer* blocks. When optimizing, the training loss is the sum of text prediction loss and classification loss. Different tasks correspond to different input formats when using the GPT model for fine-tuning. Subtasks A and B input separately to the model. Figure 3 shows the input formats in detail.

3 Experiments

We present the experiments we conduct on our system and make a detailed analysis. We compare the performance between GPT and other models in subtask B. Follow Radford et al. (2018), we use the default model configuration for our model.

3.1 Results

We evaluate the systems on the development set and use accuracy as the main evaluation criteria. We use the organizer's score on the practice leaderboard of CodaLab as the baseline. Table 2 shows our performances on subtask A in detail. Original F and Observed F represent original features and observed features respectively. DE means Data Extension which we mentioned in section 2.1. Our best system achieves 81.59% in the development set.

	Acc	F1	AvgRec
GPT	0.7768	0.6392	0.6392
Above+Original F	0.7964	0.6738	0.6721
Above+Observed F	0.7992	0.6795	0.6771
Above+DE	**0.8159**	0.6959	0.6859

Table 2: Development result of subtask A. Acc means accuracy. Above means that a new change is added to the system which mentioned in previous row.

Table 3 shows our performances on subtask B. **F** represent features in the original dataset. We get 69.05% in the development set.

	Acc	F1	AvgRec	MAP
GPT	0.6369	0.4207	0.4312	0.7889
GPT+F	**0.6905**	0.4848	0.4789	0.7500

Table 3: Development result of subtask B. Acc means accuracy.

Using our best system we evaluate in the test set. As Table 4 shows, the score of our official submission is 81.95% in subtask A, which ranks sixth in all participants. The baseline of the test set is 45.0% in accuracy which lower than all the participants' score. In subtask B, we achieve 61.08% in the test set, which ranks seventh in all participants. The baseline of subtask B is 83.0%.

	Subtask A	Subtask B
Baseline	0.450	**0.830**
Our System	**0.8195**	0.6108

Table 4: Official submissions results on the test set for our system and the organizers's baselines. The metric is accuracy.

3.2 Analysis

Subtask A Adding original features proves to be useful to GPT, which increases by 2% than single GPT in accuracy. Observed features are not as useful as original features are. They only improve the result slightly. Data extension is also helpful, which improves the score by 1.67%.

Subtask B Original features are helpful for GPT and increase accuracy by 5.36%. It is a great improvement. The possible explanation might be that original features provide key information to the classification task in subtask B. However, their performance on the test set is not satisfactory, which only achieves 61.08%.

We implement the ESIM model (Chen et al., 2016) in subtask B, which applies bidirectional Long Short Term Memory (Hochreiter and Schmidhuber, 1997) and an alignment mechanism, achieving 63.69% in accuracy of the development set. Furthermore, we concatenate glove embeddings with contextual embeddings produced by ELMo (Peters et al., 2018) as features, improving accuracy of the development set by 2% in subtask B. Both results in subtask B are less than the best result of GPT, which is 69.05%. So we use GPT as our official system in subtask B.

4 Conclusions

We use the GPT model to participate in SemEval 2019 task 8. The goal of this task is question classification and answer classification. We demonstrate that large gains on fact checking can be realized by data extension, feature extraction, and input formats transformation. Our official submission achieves accuracy 81.95% of subtask A and 61.08% of subtask B, which ranks us 6th and 7th in the competition. What's more, features and data expansion are both helpful to the system.

For future work, we think data extension may be useful in subtask B since it performs well in subtask A. Furthermore, we would like to use external information in this task.

Abstract

Community Question Answering (cQA) is one of the popular Natural Language Processing (NLP) problems being targeted by researchers across the globe. Couple of the unanswered questions in the domain of cQA are 'can we label the questions/answers as factual or not?' and 'Is the given answer by the user to a particular factual question is correct and if it is correct, can we measure the correctness and factuality of the given answer?'. We have participated in SemEval-2019 Task 8 which deals with these questions. In this paper, we present the features used, approaches followed for feature engineering, models experimented with and finally the results. Our primary submission with accuracy (official metric for SemEval Task 8) of 0.65 in Subtask B (Answer Classification) and 0.63 in Subtask A (Question Classification) stood at 6^{th} and 16^{th} places respectively.

1 Introduction

Community Question Answering (cQA) forums such as Quora, StackOverflow, Yahoo! Answers, Qatar Living etc., now-a-days are fast and effective means of getting answers for any question. But the answers may or may not be correct and factual always. The focus of cQA research, for the last few couple of years, is revolving around determining the model which predicts the best answer for the question, given a question and a number of answers (might be hundreds or even thousands in number).

cQA is one of the popular problems being constantly in focus of SemEval organizers since 2015. The subtasks that were targeted earlier include (i) classifying the answer to a particular question as good or potentially good or bad in 2015[1], (ii) three reranking subtasks i.e., Question-Comment Similarity, Question-Question Similarity and Question-External Comment Similarity in 2016[2] and (iii) Question Similarity (QS) to detect duplicate questions and Relevance Classification (RC) in 2017[3]. Contrary to earlier tasks of SemEval focusing mainly on classification and similarity of questions and/or answers and/or comments, SemEval-2019 targets the factuality of the questions (whether the question is factual or not) and the factuality of the answers (whether the answers provided to the factual questions are factual or not). The tasks become more challenging as data have noisy (like *!!!*), and unstructured (like *Oh..*) words.

SemEval-2019 Task 8 features the following two subtasks:

Subtask A (Question Classification) - determine whether a question asks for a factual information, an opinion/advice or is just socializing. Example from the "Qatar Living" forum given in competition page[4] for this subtask is as follows:
Q: I have heard its not possible to extend visit visa more than 6 months? Can U please answer me.. Thankzzz...
answer 1: Maximum period is 9 Months....
answer 2: 6 months maximum
answer 3: This has been answered in QL so many times. Please do search for information regarding this. BTW answer is 6 months.
This subtask aims at building models to detect true factual information in cQA forums.

Subtask B (Answer Classification) - determine whether an answer to a factual question is true, false, or does not constitute a proper answer.
This subtask aims at building models that classify the answers into the following three categories, given a factual question: ***a)*** *Fac-*

tual - True ***b)*** *Factual - False and* ***c)*** *Non-Factual.* The examples for each of them are as follows:

- **Factual - True:**
  Q: I wanted to know if there were any specific shots and vaccinations I should get before coming over [to Doha].
  A: Yes there are; though it varies depending on which country you come from. In the UK; the doctor has a list of all countries and the vaccinations needed for each.
- **Factual - False:**
  Q: Can I bring my pitbulls to Qatar?
  A: Yes you can bring it but be careful this kind of dog is very dangerous.
- **Non-Factual:**
  Q: Which is suggested - buy a new car or an used one?
  A: Its better to buy a new one.

We participated in both the subtasks of SemEval-2019 Task 8. For detailed description of the task, different approaches used by other participants and results obtained by all the participants, please refer the task description paper (Mihaylova et al., 2019).

The rest of the paper is organized as follows: Section 2 describes the related work. Section 3 describes the data used for this SemEval task. Sections 4 and 5 elucidate the system architecture (feature extraction and model building) and experimentation details (along with the results) respectively. Section 6 concludes the paper with focus on future research on this task.

2 Related Work

Some of the earlier works on cQA include the use of classification models - Support Vector Machines(SVMs) (Šaina et al., 2017; Nandi et al., 2017; Xie et al., 2017; Mihaylova et al., 2016; Wang and Poupart, 2016; Balchev et al., 2016) for Similarity tasks; Convolutional Neural Networks (CNNs) for Similarity tasks (Šaina et al., 2017; Mohtarami et al., 2016) and for answer selection (Zhang et al., 2017); Long-Short Term Memory (LSTM) model for answer selection (Zhang et al., 2017; Feng et al., 2017; Mohtarami et al., 2016); Random Forests (Wang and Poupart, 2016); LDA topic language model to match the questions at both the term level and topic level (Zhang et al., 2014); translation based retrieval models (Jeon et al., 2005; Zhou et al., 2011); XgBoost (Feng et al., 2017) and Feedforward Neural Network (NN) (Wang and Poupart, 2016).

All of the above related works on cQA used the features such as Bag of Words (BoW) (Franco-Salvador et al., 2016), Bag of vectors (BoV) (Mohtarami et al., 2016), Lexical features (for example, Cosine Similarity, Word Overlap, Noun Overlap, N-gram Overlap, Longest Common Substring/Subsequence, Keyword and Named Entity features etc.) (Franco-Salvador et al., 2016; Mohtarami et al., 2016; Nandi et al., 2017); Semantic features (for eg, Distributed representations of text, Knowledge Graphs, Distributed word alignments, Word Cluster Similarity, etc.) (Franco-Salvador et al., 2016); Word Embedding Features (like Word2vec[5] (Mikolov et al., 2013), GloVe[6](Pennington et al., 2014) etc.) (Wang and Poupart, 2016; Mohtarami et al., 2016; Nandi et al., 2017); Metadata-based features (like user information, answer length, question length, question marks in answer, question to comment length etc.) (Mohtarami et al., 2016; Mihaylova et al., 2016; Xie et al., 2017).

Another related task to cQA is Fact Checking in Community Forums (Mihaylova et al., 2018). This work doesn't involve classification of questions/answers based on factuality but it determines the veracity of the answer given a particular question. This work is related to our task in a way that the data being used in our task is annotated and released to the research community by Tsvetomila Mihaylova and her team.

The fact that this research problem is relatively new, the strengths of the scalable gradient tree boosting algorithm, XGBoost (Chen and Guestrin, 2016) and distributed sentence encoder, Skip-Thought vectors (Kiros et al., 2015) are not explored yet. We tried to apply and combine these two effective methods for finding factual nature of the questions and answers.

3 Data Description

The data for both Question Classification - Subtask A and Answer Classification - Subtask B, is organized into train, dev and test sets. The number of samples in each of these datasets is shown in the Table 1.

[5]https://code.google.com/archive/p/word2vec/
[6]http://nlp.stanford.edu/projects/glove/

Subtask	Datasets		
	Train	Dev	Test
A	1118	239	935
B	495	112	310

Table 1: Dataset Description

The data, in Question Classification, has both subject and body for each question. Similarly, for Answer Classification, the data has question subject, question body and an answer (as a comment text). The data of both the subtasks also have other information related to meta-data like user information, date and time of the question and answer post. The detailed description of data can be seen in task description paper (Mihaylova et al., 2019).

4 System Description

4.1 Feature Extraction

4.1.1 Data pre-processing

We have applied some basic preprocessing tasks like removing URLs, converting text to lowercase along with removing stopwords.

4.1.2 Extract Skip-Thought vectors

We choose Skip-Thought Vectors as word embeddings for this task mainly because these are highly generic sentence representations unlike GloVe or Word2Vec which averages word embeddings of each individual word to calculate the word embedding for a complete sentence.

In subtask A, we have retrieved Skip-Thought vectors for question body and question subject. In subtask B, we extracted Skip-Thought vectors for question body, question subject and answer comment. For both the subtasks, we have used the code[7] written by the Skip-Thought vectors' authors.

4.2 Model Building

Once we have extracted Skip-Thought vectors, we used these vectors to train different models - AdaBoost Classifier (only in case of Subtask B), DecisionTree Classifier, RandomForest Classifier, ExtraTrees Classifier, XGBoost Classifier and Multi-layer Neural Network with dropout layers in between, Adam optimizer and softmax activation in the final layer. The hyper-parameters of all the models is determined by applying Grid-Search with 10-fold cross-validation. The hyper-parameters are shown in the Table 2.

Classifier	Hyper-parameters
Decision Tree	min_samples_split = 2

Random Forest	n_estimators = 25
	min_samples_leaf = 1
	min_samples_split = 2

Extra Trees	n_estimators = 20
	max_features = 37

XGBoost	learning_rate = 0.1
	n_estimators = 100
	max_depth = 5
	objective = 'multi:softprob'

Adaboost	n_estimators = 45
	learning_rate = 1.0

Table 2: Hyper-parameters used for models

5 Evaluation and Results

5.1 Subtask A (Question Classification)

For this subtask, we extract Skip-Thought vectors as described in section 4.1.2. Once we get these two vectors, we generated four different combinations of vectors - (i) question body only, (ii) question subject only, (iii) concatenation vector of both question body and question subject and (iv) average vector of both question body and question subject. We trained all the models mentioned in the section 4.2 with each one of these vectors. The evaluation scores for these models on test data are shown in the Table 3.

5.2 Subtask B (Answer Classification)

For this subtask, we extract Skip-Thought vectors as described in section 4.1.2. Once we get these three vectors, we generated two different combinations of vectors - (i) concatenation vector of question body, question subject & answer and (ii) average vector of question body, question subject & answer. We trained all the models mentioned in the section 4.2 using each one of these embedding vectors. The evaluation scores for these models (except MAP scores) on test data are shown in the Table 4.

In both the tables 3 and 4, the column **Vector** represents Skip-Thought vector combination type (whether it is body only (in case of Subtask A) or subject only (in case of Subtask A) or

concatenation of vectors of body, subject and answer/comment or average of vectors of body, subject and answer/comment). On dev data set, XGBoost Classifier with concatenated Skip-Thought vectors generated best scores for both subtasks. Hence, these are part of final submissions.

However, the rows which are marked in bold (in both subtasks) produced best accuracy score with Multi-layer Neural Network Classifier beating the best score of our CodaLab final submission. The Multi-layer Neural Network is designed to have an input layer, 2 hidden layers and an output layer with "relu" activations at input and hidden layers and "sigmoid" activation at output layer. All the layers are trained with 50 neurons except the output layer which has one neural node. This model counters overfitting problem by introduction of intermittent Dropout layers.

Another interesting observation that we found is the models, surprisingly, performed better when URLs are kept in the text compared to when URLs were removed.

6 Conclusion

The earlier works on cQA didn't use Skip-Thought vectors, to the best of our knowledge. Hence, we used these vectors for both subtasks. We also have tried unique combinations of Skip-Thought vectors of question body, question subject and comments/answers (only in case of Subtask B) - either concatenation or average of vectors with different models. Out of all the models, concatenated Skip-Thought vectors with XGBoost Classifier generated best result out of all the combinations; as a result of which we stood 6^{th} in Subtask B and 16^{th} in Subtask A. However, post-evaluation submission which used concatenated Skip-Thought vectors with Neural Network classifier produced better accuracy score of 0.6752 compared to 0.6537 (which is official best result for Task B) and 0.6884 compared to 0.6299 (which is official best result for Task A). However, in future we would like to extend our work with other word embeddings like Word2vec, GloVe and BERT (Devlin et al., 2018) features and compare the results with current work using Skip-Thought vectors.

Abstract

Community Question Answering forums are very popular nowadays, as they represent effective means for communities to share information around particular topics. But the information shared on these forums is often not correct or misleading. This paper presents the ColumbiaNLP submission for the SemEval-2019 Task 8: Fact-Checking in Community Question Answering Forums. We show how fine-tuning a language model on a large unannotated corpus of old threads from Qatar Living forum helps us to classify question types (factual, opinion, socializing) and to judge the factuality of answers on the shared task labeled data from the same forum. Our system finished 4th and 2nd on Subtask A (question type classification) and B (answer factuality prediction), respectively, based on the official metric of accuracy.

1 Introduction

Community Question Answering (cQA) forums such as StackOverflow, Yahoo! Answers, and Quora are very popular nowadays, as they represent effective means for communities to share information and to collectively satisfy their information needs. Questions asked on these sites can be of different types, and the answers can often be false, misleading or irrelevant.

SemEval-2019 Task 8 is structured around two subtasks. Subtask A is a question classification task, where the questions types are:

- **Factual**: The question is asking for factual information, which can be answered by checking various information sources, and it is not ambiguous (e.g., "What is Ooredoo customer service number?").
- **Opinion**: The question asks for an opinion or an advice, not for a fact. (e.g., "Can anyone recommend a good Vet in Doha?"")
- **Socializing**: Not a real question, but intended for socializing or for chatting. This can also mean expressing an opinion or sharing some information, without really asking anything of general interest (e.g., "What was your first car?")

Subtask B is an answer classification task: are the answers to *factual questions* factual or not, and if they are factual are they true or false:

- **Factual - TRUE**: The answer is True and can be proven with an external resource. (Q: "I wanted to know if there were any specific shots and vaccinations I should get before coming over [to Doha]."; A: "Yes there are; though it varies depending on which country you come from. In the UK; the doctor has a list of all countries and the vaccinations needed for each.").
- **Factual - FALSE**: The answer gives a factual response, but it is False, it is partially false or the responder is unsure about (Q:"Can I bring my pitbulls to Qatar?"; A: "Yes you can bring it but be careful this kind of dog is very dangerous.").
- **Non-Factual**: When the answer does not provide factual information to the question; it can be an opinion or an advice that cannot be verified (e.g., "It's better to buy a new one.").

2 Related Work

Yu and Hatzivassiloglou (2003) separated opinions from fact, at both the document and sentence level.

(Mihaylova et al., 2018) were the first to propose a novel multi-faceted model for fact checking of answers on community question answering forums. Their proposed model captures information

Table 3: External unannoted questions and answers.

from the answer content (what is said and how), from the author profile (who says it), from the rest of the community forum (where it is said), and from external authoritative sources of information (external support). (Nakov et al., 2017) proposed models for credibility assessment in community question answering forums. However, credibility is different from veracity as it is a subjective perception about whether a statement is credible, rather than verifying whether it is true/false as a matter of fact.

Recently there has been a lot of attention on building models for fact checking. (Thorne et al., 2018) introduce a new publicly available dataset for fact extraction and verification (FEVER Shared Task). The dataset consists of 185,445 claims generated by altering sentences extracted from Wikipedia, and the task is to classify claims as SUPPORTED, REFUTED or NOTENOUGHINFO. However, the verification of the claims is limited to a particular database (namely Wikipedia) unlike Subtask B. Also, the claims are inherently less noisy as compared to answers in Community Question Answering forums.

Pre-trained language models have been recently used to achieve state-of-the-art results on a wide range of NLP tasks (e.g., sequence labeling and sentence classification). Some of the recent works that have employed pre-trained language models include (Howard and Ruder, 2018), (Peters et al., 2018), (Yang et al., 2018), and (Radford et al., 2018). In this paper, we show the effectiveness of the Universal Language Model Fine-tunig (ULMFiT) method (Howard and Ruder, 2018) for both question classification and answer fact checking.

3 Data

One of key challenges for both Subtask A and B is the limited amount of annotated data. This poses a challenge to apply state-of-the-art neural discrimination models without using additional data.

3.1 Labeled Data

Subtask A has a total of 1,118 questions divided into three types. Table 1 show the class distribution. Subtask B has a total of 495 answers divided into three types. Table 2 shows the class distribution.

3.2 Unlabeled Data

The task allows the use of external unnannoted data of 189,941 threads from Qatar Living Forum. Each of these threads have questions and answers just as our training data but without any labels. These threads may contain enough information to estimate the factuality of the answers in Subtask B as well as linguistic patterns in the questions asked for Subtask A. We refer to the resulting collection of comments as the **QL** dataset.

4 Model and Analysis

As the QL data is from the same distribution as our shared task data (Quatar Living), we need a method of incorporating this dataset into our models for both subtasks. We use a language model fine-tuning approach, which requires only unlabeled data similar to the task of interest.

The Universal Language Model Fine-Tuning method (ULMFiT) (Howard and Ruder, 2018) consists of the following stages: a) General-domain LM pre-training b) Task-specific LM fine-tuning and c) Task-specific classifier fine-tuning. In stage (a), the language model is trained on Wikitext-103 (Merity et al., 2017) consisting of 28,595 pre-processed Wikipedia articles and 103 million words capturing general properties of language. Stage (b) fine-tunes the LM on task-specific data, as no matter how diverse the general-domain data used for pre-training is, the data of the target task will likely come from a different distribution. In stage (c), a classifier is trained on the target task, fine-tuning the pre-trained LM but with an additional layer for class prediction. The models use a stacked Long Short Term Memory (LSTM) network to represent each sentence. For stages (a) and (b), the output of the LSTM is used to make a prediction of the next token and the parameters from stage (a) are used to initialize stage

65	**81**

Table 4: Accuracy on the test splits while doing cross validation on training data for Subtask A

(b). For stage (c), the model is initialized with the same LSTM but with a new classifier layer given the output of the LSTM.

This process is illustrated in Figure 1. We refer the reader to Howard and Ruder (2018) for further details. In our work, we maintain stages (a) and (c) but modify stage (b) so that we fine-tune the language model on the unlabelled data rather than the task-specific data. The goal of ULMFiT is to allow training on small datasets of only a few hundred examples, but our experiments will show that fine-tuning the language model on the QL data improves over only task-specific LM fine-tuning.

4.1 Subtask A

For Subtask A we fine-tune a language model on the 189,941 questions from the QL dataset. Our initial experiments show that fine-tuning the LM on the QL dataset give large performance gains over fine-tuning on task specific data as demonstrated in Table 4.

Lets take the following question:

> *Ramadan Working Hours? For companies who are operating 5 days a week; what are your timings? Ours is 8:00am to 3:00pm.?*

This is a **Factual** question, but the task-specific LM fine-tuning labels it as **Socializing**, while fine-tuning on QL data allows the model to correctly classify it as **Factual**. To understand why this happens, we delve deeper into the unlabeled data set where we find multiple similar questions based on TF-IDF similarity, demonstrating that the LM Fine-Tuning on QL data learns representations of questions based on discriminatory phrases.

- ***Ramadan Working Hours?*** *Eid holidays announced*
- ***Ramadan Working Hours?*** *good morning; Did anybody knows what is the right time* ***timing*** *or* ***working hours*** *during* ***Ramadan****? Thanks and advance.*
- ***Ramadan Working Hours?*** *Ministry of Civil Service Affairs and Housing has issued a circular in this regard defining the restricted* ***working hours****. Can somebody help me to find the English translation of that. Thank you*
- *help pls! can somebody tell me the* ***Ramadan Working Hours?*** *of ministry of Foreign Affairs???*

On the official test data, the ULMFiT approach where the target task classifier is fine-tuned on the LM fine-tuned on questions from QL data gives us an accuracy of **83** placing us 4th on the leaderboard.

4.2 Subtask B

For Subtask B we followed a similar approach of LM fine-tuning. We obtained representations of answers by fine-tuning a LM on 1,894,456 answers from the QL dataset. Next, we obtained

ANSWER	AVG COSINE SIMILARITY
Medical Check is for everyone mate	0.81
The test is done for everyone; but is restricted to the above categories u mentioned.	0.44
Regardless what your job is...everybody gets tested for hepatitis B/C cheers Never say never	0.76
As I told u hepatitis B/C are checked for everyone applying for residence permit.If the result is positive u go back where u came from. And I know all of the above because my husband is a consultant pathologist. cheers	0.72

Table 5: Average Cosine Similarity scores of contextual representations of each answer to every other answer in the thread

representations by fine-tuning a LM on 1,894,456 question-answer pairs, in order to capture whether an answer is actually suited for the question asked or something irrelevant. An answer which is relevant to the question asked can then be easily discerned from an irrelevant one by a discriminative classifier.

Our model did not take into account external evidence from search engines as done by (Mihaylova et al., 2018), so we had to rely on intra-forum evidence for factuality features. Our hypothesis is that for factual questions, the answers which are factually true are similar to each other, while answers which are false or irrelevant are different from other answers. We incorporated this behaviour in our model: for every answer we computed the cosine similarity between the contextual representation of the answer obtained from last layer of the LSTM used to train the language model for answers. For each answer, we averaged the cosine similarity between that answer and the other answers in the same thread.

For example, take the question:

> *Hi all; are hepatitis B and C checked for in the medical test for non-medical professionals? Basically;I have been getting conflicting information on this. Some say that Hep B and C are tested for everyone applying for residence permit. Others say that only medical professionals; primary school teachers and food handlers are tested for Hep B and C. Please discuss!*

From Table 5 we see that the answer with the lowest cosine similarity (0.44) is the answer which is factually false, compared to the other answers which are factually true and have a higher cosine similarity.

We use these answer representations, question-answer pair representations and the average cosine similarity as features to train an XGB classifier to obtain our final results. For threads with only 1 answer we took the cosine similarity as 0.5.

FEATURES	ACCUARCY
LM on answers	61
LM on Q-A pairs	64
LM on answers and Q-A pairs	72
LM on answers and Q-A pairs + Avg Cosine Similarity	**79**

Table 6: Ablation scores for Subtask B on the final test set for Task 8.

Table 6 shows us the ablation scores for each approach. The best accuracy obtained is a combination of all the approaches together. We obtain an accuracy of **79** placing us 2nd on the leaderboard. The absence of true labels for both the dev and the test set prevents us from conducting an error analysis.

5 Implementation

The language model is fine tuned for 15 epochs as done in the ULMFIT original paper for both Subtasks. For classifier fine-tuning we use the same hyper-parameters as (Howard and Ruder, 2018) except the learning rate which is set to .0001 . We train our classifier for 5 epochs on both sub-tasks. Each model was run 10 times to account for variance and the results reported for both the tasks are the average of 10 runs. We did not use any special pre-processing technique and use the same approach as done in the ULMFIT paper, i.e clean up extra spaces, tab characters, new line characters and other characters and replace them with standard ones. We also use Spacy library to tokenize the data. The implementation can be found here [1]

6 Conclusion

We show that fine-tuning a language model on a large unsupervised corpus from the same community forum helps us achieve better accuracy for question classification. Most community

[1]https://github.com/fastai/fastai/blob/master/courses/dl2/imdb.ipynb

question-answering forums have such unlabeled data, which can be used in the absence of large labeled training data .

For answer classification we show how we can leverage information from previously answered questions on the thread through language model fine tuning. Our experiments also show that modeling an answer individually is not the best idea for fact-verification and results are improved when considering the context of the question.

Determining factuality of answers definitely requires modeling world knowledge or external evidence. The questions asked are often very noisy and require reformulation. As a future step we would want to incorporate external evidence from the internet in the factual answer classification problem.

Abstract

In the following, we describe our system developed for the Semeval2019 Task 8. We fine-tuned a BERT checkpoint on the qatar living forum dump and used this checkpoint to train a number of models. Our hand-in for subtask A consists of a fine-tuned classifier from this BERT checkpoint. For subtask B, we first have a classifier deciding whether a comment is factual or non-factual. If it is factual, we retrieve intra-forum evidence and using this evidence, have a classifier deciding the comment's veracity. We trained this classifier on ratings which we crawled from qatarliving.com.

1 Introduction

This paper contains our system description for the SemEval2019 task 8 about Fact Checking in Community Forums. The task 8 is divided into two subtasks: In subtask A, the goal is to determine whether a question asks for a factual answer, an opinion or is just posed to socialize. In subtask B, if we have a question asking for a factual answer, we classify the answers to such a question into three categories, namely the answer is either true, false or non-factual, i.e. it does not answer the question in a factual way.

For subtask A, we trained a BERT classifier on the training set and optimized hyper-parameters on the development set. For subtask B, we decided to tackle the challenge with two binary classifiers: Firstly, we decide whether a comment is factual or not. If our classifier decides that a comment is factual, we retrieve intra-forum evidence to determine the comment's veracity using a textual entailment approach. Given the small training set for subtask B, we decided to leverage openly available information on qatarliving.com to create a medium-sized training set. We found that comments on qatarliving.com are sometimes associated with ratings[1] (ranging from 1 to 5) and discovered that high ratings often correspond to replies answering the question in a true way. If a comment has recieved a low rating, we inferred that the comment was most likely not helpful to answer the question and therefore we decided to treat it as a false reply.

2 Related Work

Automated Fact Checking is recently mostly perceived as a number of tasks which can be pipelined together. In the FEVER shared task, most participating systems would first find evidence and then train textual entailment models (Thorne et al., 2018). Related work for Fact Checking in community forums considers a multi-faceted approach incorporating firstly what is said, how it is said and by whom and secondly external evidence from either the web or from the forum itself (Mihaylova et al., 2018). An SVM is trained on top of these features to decide the veracity of a comment.

In our system, we took a similar approach by first retrieving possible evidence, secondly filtering such evidence (through another classifier) and eventually train a system which decides the veracity of a comment based on whether the comment is entailed by the found evidence or not.

3 System Description

Recent progress in natural language understanding shows that pre-training transformer decoders on language modelling tasks leads to remarkable transferable knowledge which boosts performance on a wide range of NLP tasks (Radford et al., 2018). The most recent development then is the

[1]We learnt after the deadline of the shared task that these ratings were automatically generated: https://www.qatarliving.com/forum/technology-internet/posts/searching-information-qatar-living-has-just-grown-faster

Deep Bidirectional Transformers (BERT) which is jointly pre-trained on a masked language modelling task (therefore bidirectional) and on a next-sentence prediction task pushing already impressive results even further (Devlin et al., 2018). All our classifiers in our hand-in are fine-tuned BERT models.

3.1 Domain Adaptation

We firstly fine-tuned a BERT checkpoint (pre-trained on uncased English data only) on the unannotated dataset from Qatar Living with 189,941 questions and 1,894,456 comments (Nakov et al., 2016). Fine-tuning a BERT checkpoint on a new domain consists of further training it jointly on the masked language modelling task and the next-sentence prediction task. For this dataset, it is not always trivial to decide what a sentence is and we use whole comments later on anyways, so we replaced the next-sentence prediction task by a next-comment prediction task, that is our model has to guess whether two comments are appearing consecutively in a thread or not.

Given the peculiarities of the BERT tokenizer, we cleaned the dataset through the following steps:

- we lowercased all characters
- we replaced a character which appears more than three times consecutively to only appear three times ("!!!!!!!!!" then becomes "!!!")
- we removed user specific quotes
- we removed comments containing a type/token ratio[2]of less than 0.15 (because we noticed that they are mostly spam)
- we replaced urls with a special token "url", phone numbers with a special token "tel" and email addresses with a special token "email"

In Table 1, we show the masked language modelling accuracy (MLM) and next-comment prediction accuracy (NC) for the uncleaned and the cleaned version, both fine-tuned for 100k steps. We also show results for training a task-specific model for subtask A (accuracy on the development set) with the stand-alone BERT model, a fine-tuned model on the raw data and a fine-tuned model on the cleaned data.

[2]https://en.wikipedia.org/wiki/Lexical_density

System	MLM	NC	task A
not fine-tuned	-	-	0.80
fine-tuned raw data	0.68	1	0.79
fine-tuned cleaned data	0.57	0.89	**0.84**

Table 1: Effect of cleaning the dataset

We capped characters to only appear maximum three times consecutively. If they appear more often, they would form a subword anyways and we think it is too easy for the model to guess such subwords in longer sequences (consider the sequence "!!!!<MASKED>!!!!!"). Users in the forum can add specific quotes which are appended to their posts, e.g. one user chose the ending *life's too short so make the most of it; you only live but once...* which appears 3865 times in the data. We refer to this as "user specific quotes" and removed them as we believe the model would overfit on such quotes during fine-tuning and would not learn useful knowledge about the domain while doing so. Lastly, we believe that there is not much value to be gained in learning urls, phone numbers and emails, and they often get splitted into a long series of subword units (the vocabulary is managed through byte-pair encoding). We think, these reasons combined make the model learn such patterns very well (resulting in a higher accuracy for the BERT tasks for the model trained on the raw data), but it does not gain much transferable knowledge by doing so, resulting in a lower accuracy for subtask A.

3.2 Subtask A

For subtask A, we trained a task-specific BERT classifier from the fine-tuned BERT checkpoint explained above. Fine-tuning such a classifier consists of learning embeddings for a special classification token, let the model compute self-attention over its 12 layers and finally gather the hidden representation of the classification token (the first token in the sequence usually). This hidden representation is fed into one hidden layer and lastly one classification layer. The input to the model is the concatenation of the question's subject and its body and we regularize the model by applying a dropout of 0.1 on the classification layer. We grid-searched over the proposed hyper-parameter range in the BERT paper (that is initial learning rate, batch-size and number of fine-tuning epochs) (Devlin et al., 2018).

In Table 2, we report the accuracy on the development set for a number of experiments with different features. RelQBody (the opening post by the thread creator) is the question's body, RelQSubject the question's subject (the title of a thread) and RelQ_Category its category (the name of the sub-board it has been posted in). We concatenated the different features with whitespaces in between.

Feature	acc
RelQBody	0.82
RelQSubject + RelQBody	**0.84**
RelQ_Category + RelQSubject + RelQBody	0.83

Table 2: Accuracy for different features for subtask A

Using only the question's body results in slightly worse results than the concatenated subject and body. We also tried to add the category, that is the name of the sub-forum a question has be posted in. The rationale here is that one subboard on qatarliving is called "Socialising" and we thought it might give the model a cue that questions there are more prone to be of the class socializing. However, we get slightly worse results by including it. Our final hand-in eventually consists of an ensemble of 5 models (the voting strategy is majority voting) which are trained on the concatenation of the subject and the body of a question.

Our system ranked fifth with an accuracy of 82% on the test set.

3.3 Subtask B: Overview

As we described earlier, we decided to tackle subtask B as a series of different tasks and for each, we trained different models:

1. decide whether a comment is factual or non-factual
2. retrieve related threads (based on the question of a thread)
3. filter for relevant comments in related threads
4. train a textual entailment[3] system, that is whether the evidence entails a claim or not

For the first step, we have fine-tuned a BERT checkpoint on the SQuAD question answering corpus (Rajpurkar et al., 2016). If a comment contains the answer to a question, we consider it as factual and have to check its veracity in a further step. If the answer to a question can not be found in the comment, we label it as non-factual. If the answer can be found in a comment, i.e. we have a factual comment, we continue with steps 2-4.

For the second step, we search for intra-forum evidence in the qatar living forum dump (Nakov et al., 2016). We concatenate the subject and body of each thread. We lowercase all the tokens, remove all characters except the letters a-z and use the snowball stemmer (Porter, 2001) for stemming the tokens. Afterwards, we search for the most similar threads using TF-IDF[4] and keep the five most similar threads.

We also manually evaluated whether gigablast[5] and the duckduckgo API[6] would yield useful evidence, but after having checked 15 sampled questions from the development set manually, we decided to not pursue this any further. First of all, if we just use the question's subject concatenated with its body as the query for the search engine, it would not be precise and most such queries would not return relevant web pages. One has to summarize this large text of the question automatically into a query suitable for a web search engine. We manually created search-engine searchable queries for the 15 sampled questions and found that only two of such queries returned relevant results. This may be because there is less information available on the internet for queries regarding living in Qatar except for the forum qatarliving.com itself. Hence, we decided to let go of the idea of using publicly available web search engines with automatically summarized questions for this task.

For the third step, we trained a BERT model on the concatenation of the SemEval2016 task 3 subtask A and subtask C data to filter the intra-forum evidence. The input to the model is the original question (the one we want to fact-check comments for) and the found replies in the most similar threads. The output is whether a comment answers that question in a relevant way (yes or no). For the test set for task B, we found 642 comments via the TF-IDF search engine and after filtering the comments, we are left with 162 comments as evidence (24% of these 642 comments).

For the fourth and last step, we also used a BERT model. This model should predict the veracity of a comment given the retrieved evidence in step two and three. However, given the small

[3]https://en.wikipedia.org/wiki/Textual_entailment

[4]https://radimrehurek.com/gensim/

[5]https://www.gigablast.com/

[6]https://duckduckgo.com/api

size of the training set for subtask B (135 false and 166 true comments), we did not manage to find a suitable hyper-parameter configuration which would yield a model with decent performance on the development set.

3.4 Subtask B: Textual Entailment Model

While looking at the forum online, we noticed that some comments in the forum are associated with ratings (Figure 1). Such ratings can range from 1 to 5 and we found that comments with a rating of 5 tend to answer questions in a true way and comments with a rating of 2 or 3 tend to have not been that helpful (we did not find any comments with a rating of 1).

Hence, we have crawled the threads from the forum dump (Nakov et al., 2016) online so that we get the corresponding ratings. We found that the url of a thread is a combination of the sub-forum a thread has been posted in and its subject (with whitespaces replaced with a ”+” and some stop-words removed) and reverse engineered the name of the urls. We ignored the threads for which we couldn’t find the corresponding web page automatically. After having crawled the website for one night (with short pauses after each call to the website), we ended up with 19’000 comments with a rating of 5 and 13’000 comments with a rating of 2 or 3, resulting in a corpus with 32’000 examples. With this corpus, we trained a textual entailment system which predicts whether a comment is associated with a rating of 2-3 or 5 (we left out comments with a rating of 4 and comments without a rating).

We then retrieved intra-forum evidence as described above for all these 32’000 comments and trained our BERT checkpoint (which was pre-trained on the forum dump) on that corpus and obtain ”question-comment-evidence” triplets. Let us assume the question is *”Where can I get Potassium Nitrate?”*, the comment is *”Try Metco industrial area. 465 1234”* and we retrieve two evidence texts *”potassium nitrate are not allowed to buy here in qatar. you have to ask a permission from the police department or to the civil defense...”* and *”not sure if same as what you want; but i got potassium before from pharmacies...”*. We then form two triplets (one for each evidence text) and let the model predict an output for each.

Since the different retrieved evidence for each claim is independent, we thought that it would be a bad idea to just concatenate all the evidence and use that as input to our classifier. We therefore decided to aggregate the outputs of each triple using the logsumexp function (Eq. 1) which is a smooth version of the max function and allows the model to back-propagate dense gradients (Verga et al., 2018). We think this lets the model also figure out on its own which evidence it should look out for.

$$scores(i) = log \sum exp(A_{ij}) \quad (1)$$

A is a matrix with two columns (bad rating or good rating) in which we stack the predictions for each ”question-comment-evidence” triplet. That is, each row in that matrix is the prediction for a comment with a rating given one evidence comment found in the forum. In comparison to the normal max function (which back-propagates sparse gradients), we learn from each comment-evidence pair and not only from the one with the highest scores.

We trained that model with a batch-size of 8 answers and for each answer, we retrieve 4 evidence comments (resulting in 32 triplets). During test time, we retrieve up to 8 evidence comments, predict results for each triplet and aggregate the predictions for each triplet using the logsumexp function to yield a final classification. In Table 3, we show the results of our two classifiers on the training set of subtask B (because we did not use that set for training at all).

class	pr	rc	F1
non-factual	0.43	0.53	0.47
factual	0.63	0.53	0.58
factual false	0.36	0.52	0.42
factual true	0.71	0.56	0.62

Table 3: Results on training set of subtask B

The first two rows show the results of our BERT model trained on the SQuAD corpus. The factual class contains the examples which are true or false. After having performed a manual error analysis for the factual and non-factual class, we conclude that we disagree with some of the annotations in the training corpus. The last two rows show the performance of our classifier trained on ratings on the training set. For the true answers, it performs better than for the false answers (which might be due to a slight imbalance of training examples in our compiled corpus).

Rating: 5/5

Qatarisun before you come all the way shouting and trying to be a smart look up for what he was asking :) not a single visa his asking for a Multiple entry Visit Visa if you only know what is it :)

and yes its only for British valid for 5 years.

theres multiple entry visa.

business visit visa

tourist visa

envestor visa

working visa

and on arrival visa which is for 33 countries

and many more kind of visas but he was asking for multiple entry visa you dumb qatarisun

Figure 1: Comment with an associated Rating

3.5 Subtask B: Contrastive Runs

We only handed in contrastive runs for subtask B. The difference to our original hand-in is solely the classifier deciding whether a comment is factual or non-factual. In our first contrastive run, we used the BERT model pre-trained on the concatenation of the SemEval2016 task 3 subtask A and C data (the same we use to filter evidence). For our second run, we used a ranking model to get a similarity score between a question and a comment based on the ratings. We minimized the following

$$\text{loss} = \sum_i max(0, \delta - cos(q_i, comment_{5i}) + cos(q_i, comment_{0i}))$$

where i is a data point from the web-crawled corpus, $comment_{5i}$ is the vector obtained by the model for a comment with rating 5, $comment_{0i}$ is the obtained vector by the model for a comment without a rating, q_i is the model obtained vector for the corresponding question, δ(=0.1) is the allowed margin between a positive similarity and a negative similarity which is chosen as a hyperparameter. All vectors are obtained by max pooling the hidden states of an encoder BI-LSTM on the input text (question/comment). Our assumption is that the comment with rating 5 will be a factual answer in most of the cases (noisily labelled). Furthermore, we fine-tuned this model for the answer classification task on the training dataset for the labels 'non-factual' and 'true/false'. In table 4, we report the results for our different runs on the test set.

We also submitted an all non-factual baseline on the test set and it scored 83% accuracy. We think this biased test set hence does not reflect the model's ability to fact check comments. We reckon that in further work on this dataset, one should therefore not focus on accuracy but on a different metric.

run	**acc** (%)	F1	AvgRec	MAP
main	**0.72**	0.4	0.44	0.27
1. Contrastive run	**0.81**	0.48	0.53	0.21
2. Contrastive run	**0.48**	0.21	0.31	0.29
non-factual baseline	**0.83**	0.28	0.33	0.29

Table 4: Results of different runs for subtask B on test-set

4 Conclusion

We described our hand-in for the semeval2019 task 8. For subtask A, we fine-tuned a BERT checkpoint pretrained on a cleaned qatar living forum dump. For subtask B, we decided to use two classifiers. One classifier decides whether a comment is factual or non-factual. If it is factual, a second classifier makes a prediction about the comment's veracity. Given the small size of the training dataset, we crawled qatarliving.com to generate a medium sized, weakly supervised training corpus based on ratings in the forum. To train our model, we searched for intra-forum evidence for every comment and fine-tuned a BERT classifier for each question-comment-evidence triplet. Since the retrieved evidence is independent of each other, we did not concatenate all the evidence for a question but aggregated results for each triplet using the logsumexp function. We decided to use this function for aggregation because it allows the model to send back dense gradients and learn from all the comment-evidence pairs and not only the evidence with the highest score.

Abstract

This report describes the methods employed by the Democritus University of Thrace (DUTH) team for participating in SemEval-2019 Task 8: Fact Checking in Community Question Answering Forums. Our team dealt only with Subtask A: Question Classification. Our approach was based on shallow natural language processing (NLP) preprocessing techniques to reduce noise in data, feature selection methods, and supervised machine learning algorithms such as NearestCentroid, Perceptron, and LinearSVC. To determine the essential features, we were aided by exploratory data analysis and visualizations. In order to improve classification accuracy, we developed a customized list of stopwords, retaining some opinion- and fact-denoting common function words which would have been removed by standard stoplisting. Furthermore, we examined the usefulness of part-of-speech (POS) categories for the task; by trying to remove nouns and adjectives, we found some evidence that verbs are a valuable POS category for the opinion-oriented question class.

1 Introduction

The significance of Community Question Answering (CQA) forums has risen in the past years. Such forums represent a modern need for information that comes with the abundance of online sources and the needs of millions of people for answers. Popular forums like StackOverflow, Yahoo! Answers, and Answers.com provide platforms for general or specific questions in a wide range of topics by users' and also a community-based model for user interaction.

The large numbers of questions and answers located in these forums generate many opportunities for information retrieval and data mining applications, such as query-intent detection, opinion mining, fake news classification, etc. (Tsur et al., 2016; Jo et al., 2018; Sethi, 2017). More advanced applications do not only aim at analyzing opinions but—by categorizing the feelings of the Q&As—they may be able to detect inappropriate content such as hate speech and act accordingly (Karadzhov et al., 2017; Baly et al., 2018).

The SemEval Task 8, Fact Checking in Community Forums, aims to determine whether the answers that are provided for a question in a forum are true or false. While answers to fact-oriented questions can be deemed true or false, opinion-oriented and socializing questions evoke answers for which a true/false categorization does not make much sense. As a result, determining the question type is a necessary first step. Consequently, the subtask A of SemEval Task 8 has the goal of classifying questions in three categories: opinion, factual, or socializing.

The rest of this report is structured as follows. Section 2 reviews some previous studies for CQA classification. Section 3 describes our system, while Section 4 presents experiments and results. Conclusions are summarized in Section 5.

2 Related Work

In recent years, plenty of research work examined the problem of classifying texts of CQA forums. Some related work which we found useful or inspiring are mentioned below.

Mihaylova et al. (2018) proposed a novel approach based on multi-faceted modeling of facts, which integrates knowledge from several complementary sources, such as the answer content (what is said and how), the author profile (who says it), the remainder of the community forum (where it is said), and external authoritative sources of information (external support).

Another study which provided us with helpful information about the importance of feature selection on the development of a question classifier was by Huang et al. (2008). They demonstrated the importance of using the wh-word (what, which, when) in question classification. Such words are commonly disregarded and used in stopwords lists. Our approach is also trying to use features such as imperative verbs that indicate an opinion.

The SemEval-2015 Task 3, Answer Selection in Community Question Answering, targeted to classify comments in a thread as relevant, potentially useful, or bad, concerning the thread question (Nakov et al., 2015). This task encouraged solutions for the question classification problem that involved semantic or complex linguistic information.

Finally, (Mihaylova et al., 2016; Baldwin et al., 2016; Franco-Salvador et al., 2016) participated in subtasks A, B, and C at SemEval-2016 Task 3 that involved tasks for Question-Comment Similarity, Question-Question Similarity, and Question-External Comment Similarity. They proposed classification models and provided results that highlighted the importance of lexical and semantic features.

The aforementioned studies help to identify 'gaps' in this research topic and ways to attempt new and different approaches for question classification.

3 System Description

In this section, we give the details of our question classification model, applied pre-processing techniques, as well as some statistics and visualizations for the dataset of the task.

3.1 Dataset

The organizers provided the dataset in an XML format. The given training set consisted of 1,118 questions for Subtask A that were selected from the Qatar Living forum.

We used Python's Element Tree library to parse and isolate specific content from the XML. The interesting tags to select were RelQBody (the question) and RELQ_FACT_LABEL (labeled question by organizers).

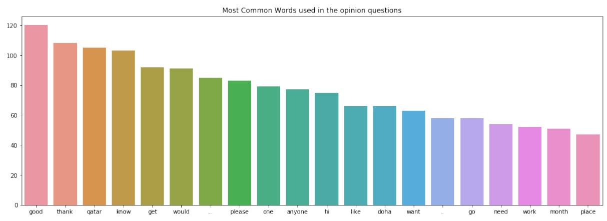
Before pre-processing, an exploratory data analysis gives us the opportunity to better understand the dataset. Because we will develop a multipurpose model that classifies not only the opinion but fact and socializing questions, it is helpful to understand in depth the character of the questions.

A way to understand the contents of the forum is to examine Table 1 where almost 50% of the questions are opinion oriented. Also, Figure 1 presents the most common words in opinion questions.

Label	**Number of Questions**
Opinion	563
Factual	311
Socializing	244

Table 1: Question types in the dataset

Figure 1: Most common words in opinion questions



3.2 Pre-processing

To reduce the noise of the text, based on the results of Symeonidis et al. (2018), we applied the following pre-processing:

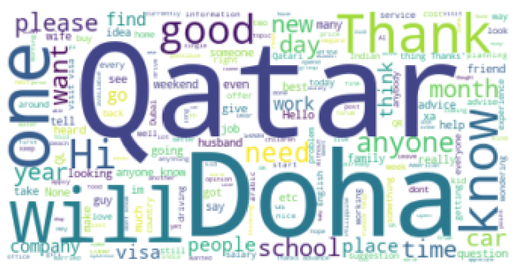
- Remove Numbers
- Remove Punctuation
- Remove Symbols
- Lowercase
- Replace all URL addresses, normalizing them to 'URL'

Figure 2 shows the most frequent words on the dataset as a wordcloud.

The final steps of pre-processing are tokenization and stemming. A basic process in NLP is to identify tokens or those basic units which need not be decomposed in subsequent processing.

The entity word is one kind of token for NLP (Webster and Kit, 1992). Stemming is a process of reducing words to their stems or roots to reduce the vocabulary size and manage the case of data sparseness (Lin and He, 2009). For example, conjugated verbs such as 'goes', 'going', and 'gone' are stemmed to the term 'go'.

Figure 2: Wordcloud of frequent words



We used Python's SpaCy[1] library to tokenize the text and convert it to lemmas. This function also removes symbols (or punctuation) such as '[','...','-'.

Stopwords are frequent words that appear in the text, but they can have an impact on retrieval efficacy. The removal of stopwords also modifies the document length and subsequently affects the weighting process and efficiency during processing of the collection (Kwok, 1998).

For our task, we found out that the most commonly-used stopword lists contain words that can be helpful. For example, the word 'believe' is included in most stopword lists. While it is a ubiquitous word, it may also indicate an opinion; therefore, it can be useful for our purpose. In order to tackle this problem, we made a custom stopword list that only removes pronouns such as 'i','he','she', etc. NLTK's[2] list of English stopwords used as guideline and contained 127 words.

Although there is an abundance of stopwords lists that contain even more words we used a small one on purpose. We wanted to eliminate words from our dataset that would not bear any significance in our task. The next step, based on the vocabulary of the dataset, was to manually find words that could help us identify whether the question is opinion oriented, factual, or socializing. We excluded, from the NLTK's stopword list, words such as 'believe', 'think', 'mean', 'consider', and others. Our final revised stopword list consists of 50 words.

4 Experiments

This section summarizes our experiments in the context of SemEval 2019 Task 8 Subtask A. Beyond our officially submitted runs, we present some additional experiments that although they did not perform very well, there seems to be a promising room for improvement in the future.

[1]https://spacy.io

[2]https://www.nltk.org/

4.1 Machine Learning Methods

For the training of our classifiers, we used Python's Scikit-Learn library (Pedregosa et al., 2011). We split the dataset into 749 training questions and 369 testing questions, i.e. a typical 2/3–1/3 split (ratio 2:1). After the split, the questions in the training set were shuffled for training. With the class `sklearn.pipeline`, we performed a sequence of different transformations and parameters.

Vectorizer: We compared three common vectorizers such as CountVectorizer, HashingVectorizer, and TfidfVectorizer. Finally, our selection was the TfidfVectorizer since it yielded the best results when it comes to accuracy. The TfidfVectorizer converts a collection of raw documents to a matrix of tf-idf weighted features.

Classifiers: We experimented with various classifiers, and decided to use the following three since they yielded the best accuracy results.

- **NearestCentroid**: Each class is represented by its centroid, with test samples classified to the class with the nearest centroid.
- **Perceptron**: It is a simple and efficient algorithm to fit linear models, and suitable for very large numbers of features.
- **LinearSVC**: An SVM algorithm which tries to find a set of hyperplanes that separate space into areas representing the classes. The hyperplanes are chosen in a way to maximize the distance from the nearest data point of each class.

4.2 Results

The official run that we submitted for the competition proved to be the most successful. In the following tables, we present the produced test results by using the three different classifiers, the TfidfVectorizer, and the custom stopword list. The results are shown in Tables 2, 3, and 4. We can observe that the most accurate classifier overall is the NearestCentroid.

We experimented further based on the hypothesis that opinion classification can be more effective by using only verbs. Until recently, most

LinearSVC	accuracy	recall	f1-score
Factual	0.60	0.40	0.48
Opinion	0.62	0.82	0.70
Socializing	0.75	0.53	0.62
Total	0.64	0.64	0.62

Table 2: Test results with LinearSVC

NearestCentroid	accuracy	recall	f1-score
Factual	0.63	0.49	0.55
Opinion	0.71	0.76	0.73
Socializing	0.70	0.77	0.73
Total	0.68	0.69	0.68

Table 3: Test results with NearestCentroid

classification techniques have considered adjectives, adverbs, and nouns as features. The usefulness of part-of-speech categories in text classification was investigated as early as in (Arampatzis et al., 2000), where it was found that a traditional keyword-based indexing set can be reduced to retain only its nouns and adjectives without hurting effectiveness, even slightly improving it. Nevertheless, the aforementioned work was on topic classification; later, Karamibekr and Ghorbani (2012) showed that verbs are vital in classifying opinion terms, particularly in social domains.

We conducted two experiments by removing either nouns or adjectives from our dataset to help our classifiers adjust mostly on verbs. We can observe, in Tables 5 and 6, that classifiers achieved a better accuracy score when it comes to opinion as opposed to fact and socializing questions. Nevertheless, by removing either nouns or adjectives, there is an overall drop in effectiveness in all classes. Thus, there is evidence that verbs are a useful part-of-speech category for opinion classification, but they are not sufficient by themselves.

Our official submission to the competition ranked our team to the 16th place from 22 teams.

Perceptron	accuracy	recall	f1-score
Factual	0.54	0.36	0.43
Opinion	0.62	0.79	0.70
Socializing	0.64	0.49	0.56
Total	0.60	0.61	0.59

Opinion	0.66	0.65	0.66
Socializing	0.53	0.69	0.60
Total	0.59	0.59	0.59

Table 6: Test results without Adjectives

The results of our model are shown in Table 7.

Accuracy	F1	AverageRecall
0.71	0.56	0.60

Table 7: Official Results - Use of NearestCentroid

5 Conclusions

We presented a supervised learning model for classifying questions from online Q&A forums in three categories: factual, opinion, and socializing. We used standard pre-processing techniques, and made a custom stopword list to tackle the specific task at hand. Using standard classification methods, we achieved satisfactory and promising results. We also tried to use verb-oriented feature sets for classification which although they provided mixed results it seems that they can be improved.

Abstract

Online Community Question Answering Forums (cQA) have gained massive popularity within recent years. The rise in users for such forums have led to the increase in the need for automated evaluation for question comprehension and fact evaluation of the answers provided by various participants in the forum. Our team, **Fermi**, participated in sub-task A of Task 8 at SemEval 2019 - which tackles the first problem in the pipeline of factual evaluation in cQA forums, i.e., deciding whether a posed question asks for a factual information, an opinion/advice or is just socializing. This information is highly useful in segregating factual questions from non-factual ones which highly helps in organizing the questions into useful categories and trims down the problem space for the next task in the pipeline for fact evaluation among the available answers. Our system uses the embeddings obtained from Universal Sentence Encoder combined with XGBoost for the classification sub-task A. We also evaluate other combinations of embeddings and off-the-shelf machine learning algorithms to demonstrate the efficacy of the various representations and their combinations. Our results across the evaluation *test* set gave an accuracy of 84% and received the **first** position in the final standings judged by the organizers.

1 Introduction

The massive rise in popularity of Community Question Answering (cQA) forums like StackOverflow, Quora, Yahoo! Answers and Google Groups have led to an effective means of information dissemination for topic-centered communities to share and engage in knowledge consumption needs. After a considerable time, information becoming obsolete is a major problem which results in change of many of the facts that were previously true. Another problem is that most of the forums lack exhaustive moderation and control – which results in high-latency quality checks and eventually results in the sharing of non-factual information. Various factors are responsible for this – primarily being ignorance or misunderstanding and sometimes, maliciousness of the responder to the questions (Mihaylova et al., 2018).

In the pipeline of detection of whether the given responses to a question are indeed factual, the necessary first step is to discern what category the question asked in the cQA forum falls into. As an example, *"What is Domino's customer service number?"* is a factual question as it asks for a fact rather than an opinion or discourse. In contrast, consider the question *"Can someone recommend a good pediatrician in Mumbai?"* asks for an opinion rather than a particular factual information as opinions on the matter of a good pediatrician may be subjective and depend on various other factors the conclusion of which is not universally true.

We tackle the problem proposed by organizers (Mihaylova et al., 2019) in sub-task A as a multi-class classification problem, i.e., categorizing questions in cQA forums into one of the following three categories:

1. Factual: The question is asking for factual information, which can be answered by checking various information sources, and it is not ambiguous. *(e.g., "What is the currency used in Taiwan?")*

2. Opinion: The question asks for an opinion or an advice, not for a fact. *(e.g., "Can somebody recommend good restaurants around the SF Bay Area?")*

3. Socializing: Not a real question, but intended for socializing or for chatting. This can also mean expressing an opinion or sharing some information, without really asking anything of general interest. *(e.g., "What was your first bike?")*

Our submission involves the use of pre-trained models for generating sentence embeddings from existing trained models and then employing the use of off-the-shelf machine learning algorithms for the multi-class prediction problem. The approach is described in Section 3 where we describe our methodology in detail.

2 Related Work

For classification tasks like question similarity across community QA forums, machine learning classification algorithms like Support Vector Machines (SVMs) have been used (Šaina et al., 2017; Nandi et al., 2017; Xie et al., 2017; Mihaylova et al., 2016; Wang and Poupart, 2016; Balchev et al., 2016). Recently, advances in deep neural network architectures have also led to the use of Convolutional Neural Networks (CNNs) (Šaina et al., 2017; Mohtarami et al., 2016) which perform reasonably well for selection of the correct answer amongst cQA formus. Algorithms and methods for answer selection also include works by (Zhang et al., 2017) which use a Long-Short Term Memory (LSTM) model for answer selection. Similarly, LSTMs for answer selection are also used by (Feng et al., 2017; Mohtarami et al., 2016). Other works in the space include use of Random Forests (Wang and Poupart, 2016); topic models to match the questions at both the term level and topic level (Zhang et al., 2014). There have also been works on translation based retrieval models (Jeon et al., 2005; Zhou et al., 2011); XgBoost (Feng et al., 2017) and Feedforward Neural Networks (NN) (Wang and Poupart, 2016).

All of the above related works on cQA used the features such as Bag of Words (BoW) (Franco-Salvador et al., 2016); Bag of vectors (BoV) (Mohtarami et al., 2016); Lexical features (for example, Cosine Similarity, Word Overlap, Noun Overlap, N-gram Overlap, Longest Common Substring/Subsequence, Keyword and Named Entity features etc.) (Franco-Salvador et al., 2016; Mohtarami et al., 2016; Nandi et al., 2017); Semantic features (for example, Distributed representations of text, Knowledge Graphs, Distributed word alignments, Word Cluster Similarity, etc.) (Franco-Salvador et al., 2016); Word Embedding Features (like Word2vec, GloVe etc.) (Wang and Poupart, 2016; Mohtarami et al., 2016; Nandi et al., 2017); and Metadata-based features (Mohtarami et al., 2016; Mihaylova et al., 2016; Xie et al., 2017).

In this work, we seek to evaluate pre-trained sentence embeddings and how they perform across comprehension of questions in the community QA tasks. We now describe the methodology and data in the following section.

3 Methodology and Data

The data supplied by organizers is used for the task at hand. Specifically, for sub-task A, the *subject* and *body* for each question is provided by the task organizers. The data consists of 1118 training instances along with 239 and 935 question instances in the development and testing sets respectively.

3.1 Word Embeddings

Word embeddings have been widely used in modern Natural Language Processing applications as they provide vector representation of words. They capture the semantic properties of words and the linguistic relationship between them. These word embeddings have improved the performance of many downstream tasks across many domains like text classification, machine comprehension etc. (Camacho-Collados and Pilehvar, 2018). Multiple ways of generating word embeddings exist, such as Neural Probabilistic Language Model (Bengio et al., 2003), Word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and more recently ELMo (Peters et al., 2018).

These word embeddings rely on the distributional linguistic hypothesis. They differ in the way they capture the meaning of the words or the way they are trained. Each word embedding captures a different set of semantic attributes which may or may not be captured by other word embeddings. In general, it is difficult to predict the relative performance of these word embeddings on downstream tasks. The choice of which word embeddings should be used for a given downstream task depends on experimentation and evaluation.

3.2 Sentence Embeddings

While word embeddings can produce representations for words which can capture the linguistic properties and the semantics of the words, the idea of representing sentences as vectors is an important and open research problem (Conneau et al., 2017).

Finding a universal representation of a sentence which works with a variety of downstream tasks is the major goal of many sentence embedding techniques. A common approach of obtaining a sentence representation using word embeddings is by the simple and naïve way of using the simple arithmetic mean of all the embeddings of the words present in the sentence. Smooth inverse frequency, which uses weighted averages and modifies it using Singular Value Decomposition (SVD), has been a strong contender as a baseline over traditional averaging technique (Arora et al., 2016). Other sentence embedding techniques include p-means (Rücklé et al., 2018), InferSent (Conneau et al., 2017), SkipThought (Kiros et al., 2015), Universal Encoder (Cer et al., 2018).

We formulate sub-task A of Task 8 in SemEval 2019 as a text multi-classification task. In this paper, we evaluate various pre-trained sentence embeddings for identifying each of the categories of factual, socializing and opinion among the questions in community QA forums. We train multiple models using different machine learning algorithms to evaluate the efficacy of each of the pre-trained sentence embeddings for the sub-task. In the following, we discuss various popular sentence embedding methods in brief.

- InferSent (Conneau et al., 2017) is a set of embeddings proposed by Facebook. InferSent embeddings have been trained using the popular language inference corpus. Given two sentences the model is trained to infer whether they are a contradiction, a neutral pairing, or an entailment. The output is an embedding of 4096 dimensions.

- Concatenated Power Mean Word Embedding (Rücklé et al., 2018) generalizes the concept of average word embeddings to power mean word embeddings. The concatenation of different types of power mean word embeddings considerably closes the gap to state-of-the-art methods mono-lingually and substantially outperforms many complex techniques cross-lingually.

- Lexical Vectors (Salle and Villavicencio, 2018) is another word embedding similar to fastText with slightly modified objective. FastText (Bojanowski et al., 2016) is another word embedding model which incorporates character n-grams into the skipgram model of Word2Vec and considers the sub-word information.

- The Universal Sentence Encoder (Cer et al., 2018) encodes text into high dimensional vectors. The model is trained and optimized for greater-than-word length text, such as sentences, phrases or short paragraphs. It is trained on a variety of data sources and a variety of tasks with the aim of dynamically accommodating a wide variety of natural language understanding tasks. The input is variable length English text and the output is a 512 dimensional vector.

- Deep Contextualized Word Representations (ELMo) (Peters et al., 2018) use language models to get the embeddings for individual words. The entire sentence or paragraph is taken into consideration while calculating these embedding representations. ELMo uses a pre-trained bi-directional LSTM language model. For the input supplied, the ELMo architecture extracts the hidden state of each layer. A weighted sum is computed of the hidden states to obtain an embedding for each sentence.

Using each of the sentence embeddings we have mentioned above, we seek to evaluate how each of them performs when the vector representations of the body of questions in the cQA forums are supplied for classification with various off-the-shelf machine learning algorithms. For each of the evaluation tasks, we perform experiments using each of the sentence embeddings mentioned above and show our classification performance on the *dev* set given by the task organizers.

Model	**F-1**	**Acc**
Universal Encoder + XGB	**0.72**	**0.84**

Table 1: Results showing Macro-F1 score and accuracy for Sub-task A, using Universal Encoder Sentence embeddings and training the model with XGBoost.

4 Results

The official ranking metric is Accuracy. We have included the F-1 score here as well for comparison. Table 1 provides the results on the system runs for the evaluation phase as judged by the organizers on the CodaLab platform. Our system ranked *first* among the participants in the evaluation phase. We observe that Universal Sentence

Model	**RF**		**SVM-RBF**		**XGBoost**	
	Acc.	F-1	Acc.	F-1	Acc.	F-1
Universal Sentence Encoder	68.66	72.32	67.38	68.25	73.73	73.56
InferSent	53.91	50.89	61.56	63.45	60.82	59.32
Concat-p mean	56.22	49.01	65.64	69.54	60.36	60.01
Lexical Vectors	62.80	62.11	72.42	71.55	71.30	68.30

Table 2: *Dev* Set Accuracy and Macro-F-1 scores (in percentage) for **Sub-Task A** of Task 8

Encoder representations with the XGBoost classifier gives the best results on the test set.

As a way to elicit different performances for our experiments, we also provide our results from the system runs on the development set provided by the organizers. These results are shown in Table 2.

5 Conclusions and Future Work

We see from the results that our system is able to discern the type of questions asked in community QA forums with high performance metrics. This shows that using pre-trained embeddings with a simple machine learning classification algorithm often helps in greater understanding of the text at hand – in this case, the questions in community question-answering forums.

In future work, we also seek to evaluate different transfer learning approaches which utilize pre-trained language models (LMs) across different base language corpora and see how varying these base corpora for pre-training the language model results in the performance change while finetuning for question comprehension in cQA forums.

Abstract

We describe our system for SemEval-2019, Task 8 on "Fact-Checking in Community Question Answering Forums (cQA)". cQA forums are very prevalent nowadays, as they provide an effective means for communities to share knowledge. Unfortunately, this shared information is not always factual and fact-verified. In this task, we aim to identify factual questions posted on cQA and verify the veracity of answers to these questions. Our approach relies on data augmentation and aggregates cues from several dimensions such as semantics, linguistics, syntax, writing style and evidence obtained from trusted external sources. In subtask A, our submission is ranked 3rd, with an accuracy of 83.14%. Our current best solution stands 1st on the leaderboard with 88% accuracy. In subtask B, our present solution is ranked 2nd, with 58.33% MAP score.

1 Introduction

With the rising popularity of online community question answering (cQA) systems such as Quora, StackOverflow, and Qatar Living forum (QLF), the amount of information shared over these platforms is also increasing rapidly with time. These forums provide effective information sharing mechanism to their users who can seek answers to their queries as well as post answers to the questions. However, the information shared on such platforms may not always be factual and correct. The responders may misunderstand the question being asked or merely ignore certain specific details. At times, the information shared may even be false or ambiguous in the desired context. This is aggravated by lack of moderation and systematic control on cQA forums. The Semeval-2019 Task 8[1] on "Fact Checking in Community Question Answering Forums" aims to solve this real-life problem.

The above task tries to explore the veracity of an answers to a question posted on QLF. While the precedent tasks such as SemEval (Nakov et al., 2015, 2016, 2017), address the issue of ranking answers according to their relevance to a question, the task-at-hand is the first one to consider the correctness of answers. This task is formulated as a two-stage problem. The first stage aims to identify the user posts asking for factual information. The answers to the identified factual questions are then fact-verified in the second stage. Both the subtasks are designed as 3-class supervised classification problems.

More specifically, the first stage or subtask A addresses the problem of determining whether the posted question asks for factual information, an opinion/advice or is just meant for socializing. For example, *"what is Ooredoo customer service number?"* asks for factual information, whereas *"What was your first car?"* is socializing and *"which is the best bank around?"* is seeking guidance/opinion. Each data sample in subtask A is a question posted by a user consisting of a subject, body and meta information (user ID, username, and the category of question, e.g., "Education," "Visa and Permits", "Welcome to Qatar" etc.).

The second stage or subtask B focuses on determining whether an answer to a factual question is true, false or does not constitute a proper answer, in which case, it is labeled as non-factual. For example, to the question *"Can I bring my pitbulls to Qatar?"*, Answer A1: *"Yes, you can bring it but be careful this kind of dog is very dangerous"* is factual-false[2], Answer A2: *"No, you cannot as they are banned"* is factual-true[2] and Answer A3: *"There goes another job opportunity for the sake*

*Equal Contribution
[1]http://alt.qcri.org/semeval2019/index.php?id=tasks

[2]can be verified at http://canvethospital.com/pet-relocation/

of two lovely animals. ” is non-factual. The data is organized as a question-answer tuple: question posted by a user and an answer (body, username and answer ID) posted by the same or another user. It has been ensured that all the questions in this task are factual questions.

Our approach to solving this task is based on extracting rich-feature representation from the input and training a classifier to make predictions. The feature representation integrates knowledge from various complementary sources, such as the question/answer content, the content of other answers in the thread, evidence from trustworthy external sources of information, and the relevance of an answer to the question. For subtask A, we rely on question content (semantic, linguistic and syntactic cues), whereas the evidence from external sources and answer relevancy to the question are essential aspects for subtask B. For both the subtasks, we also leverage a data augmentation approach which facilitates the generalization ability of learned classifier on unseen test data as well as ameliorates the class imbalance issues present in the training data.

The rest of the paper is organized as follows: Section 2 gives an overview of our system. Section 3-5 describe the details of our approach. Section 6 demonstrates the experimental results. We conclude in Section 7.

2 System Overview

Our proposed system primarily relies on following key components (i) data augmentation (DA) (ii) pre-processing of question/answer content and (iii) feature extraction from multi-faceted sources.

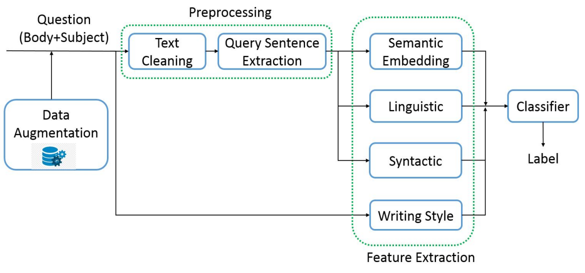

Figure 1: System Overview for Subtask A

As depicted in Figure 1, following DA and preprocessing of the question, our system for subtask A extracts semantic (what is said), linguistic (how it is said), syntactic (how it is structured) and writing style based features (how it is depicted) from the processed question. These extracted features are then combined to train a classifier for label prediction.

Subtask B also leverages DA and preprocessing as its first key steps. However, apart from features extracted for subtask A (as mentioned above), it also utilizes external evidence and forum-level features (Figure 2). The external evidence is collected from trusted sources using a search-engine. The forum-level features capture the relevancy of an answer to the question and its similarity to other answers in the same thread.

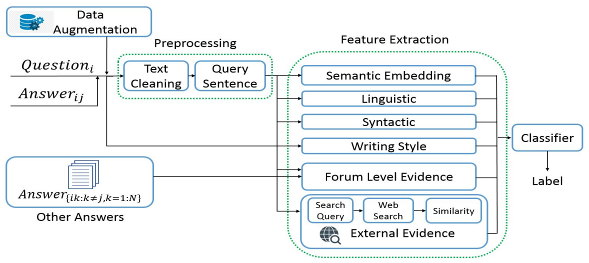

Figure 2: System Overview for Subtask B

3 Data Augmentation (DA)

Data augmentation (DA) is one of the main components of our proposed system that resulted in significant performance gains. For both the subtasks, the training data is imbalanced. This motivated us to look for ways to balance the distribution of data samples across classes and at the same time incorporate adversarial examples which are plausible in the real scenario but are not present in the training data. We next discuss the DA details for both the subtasks in the following subsections.

3.1 Subtask A

In the training data for subtask A, the number of samples from the “opinion” class (563) is observed to be twice as many samples from “factual” (311) or “socializing” class (244). In order to balance the class distribution, we sought to oversample both of the non-majority classes based on the domain knowledge.

For the “Factual” class, we leveraged the questions asked in subtask B. In subtask B, by its formulation, one is supposed to verify the veracity of answers to “factual questions.” Thus, we used the training, development and test set of subtask B to augment training data for subtask A (“factual” class instances). This way, we extracted a total of 91 distinct factual questions. For the “socializing” class, we utilized the QL-unannotated-data[3] to se-

[3]additional resource by (Mihaylova et al., 2018)

Class	Question Body
Factual	**Can someone please tell me where can i find Garlic Oil in Qatar?** i heard it is good for hairfall. dont know if its true or not but really want to try it. So help me guys!
Opinion	**Is it right to resign from your job at this time of global crisis?** the reason is i'm not doing anything in the office. I feel useless; but I'm hesistant to resign because of the condition today even that I'm on husband sponsor.
Socializing	**Is this a beginning of a mutual friendship between Christianity and Islam in Qatar?** I hope they're going to sell some Bibles in Villagio coz I can't find somebody sellin' it around here.

Table 1: Example for query-sentence selection. The highlighted text is considered as the query-sentence.

lect samples from categories ("Funnies," "Good News Everyone," "Party on my mind," "Recipes," "Press Releases") that are assured to contain only socializing content. In these categories, the users are just trying to make conversation or share anecdotes. As the number of such samples is considerably large, we sample 320 samples (using reservoir sampling (Vitter, 1985)) to balance the distribution across classes in the original training data.

3.2 Subtask B

For subtask B, we consider an adversarial setting closely related to the problem at hand. As mentioned before, each data sample in this subtask is a question-answer tuple, and the answer can be either "true", "false" or "non-factual." A related task was demonstrated in Semeval 2016 task 3 "Answer Selection in cQA" (Nakov et al., 2016) where the objective was to re-rank the answers based on their relevancy to the question. In this task, the replies such as follow-up question from other user, clarifications, and acknowledgment from the user himself were categorized as "Bad" answers. Although, in the task-at-hand, the organizers have omitted such answers, in the real-life scenario they will also be present and should be categorized as "non-factual" in our current problem setting.

Thus, to include such samples, we extract factual questions from the training data of subtask A. For each of these questions, we select "bad answers" from the data provided in the SemEval 2016 task. The chosen question-answer pair is then annotated as "non-factual" and added to the training data of subtask B.

4 Preprocessing

Before feature extraction, we pre-process the input question/answer using several key steps. We expand the contractions and terms commonly used on social media platforms such as 'i'm: 'i am,' 'i'd: i would,' 'pls: please,' 'nt: not,' 'thru: through' etc. Furthermore, we use several markers such as URLs, images, emoticons, and punctuation marks in the question/answer to extract writing style and syntactic features (described in Section 5.3). For semantic and linguistic features, we strip these markers.

4.1 Query Sentence Extraction

Based on the empirical evidence, we could infer that the body of each question posed by the user contains several sentences. However, among all these sentences, only one or two convey the query he/she really wants to ask. Also, the user may post his question in the question subject itself. Thus, we extract these "query-sentences" from the question body and subject and use them to extract linguistic, semantic features. An example of the query-sentence and original question posted by the user for each of the three classes corresponding to subtask A is depicted in Table 1.

In order to extract query-sentence, we parse each sentence in the question using Stanford CoreNLP constituency parser (Manning et al., 2014). A sentence is considered a query-sentence if its parse-tree has *SBARQ/SQ* constituent phrases. We also use some common heuristics such as, whether the sentence ends with a question-mark or starts with common "wh" words (what, why, how etc).

5 Modeling Content : Feature Extraction

We use rich feature representation to model the information conveyed in question/answer. In the subsequent subsections, we describe the details of each of these features.

5.1 Semantic Sentence Embedding

Following the pre-processing step, we compute semantic sentence embedding for query-sentence by using two approaches. The first approach utilizes universal sentence encoder (USE) (Cer et al., 2018). It has been known to perform well with minimal amounts of supervised training data for a downstream task, which is precisely our setting for both the subtasks. The second approach appropriates pre-trained word embeddings (glove) (Pennington et al., 2014), averaged over each word in a sentence to compute sentence-level embedding.

5.2 Linguistic Features

Often, forum users exhibit linguistic cues in writing questions and answers. For example, they may use subjectively loaded words such as 'awesome,' 'worst' etc. while asking for an opinion rather than factual information. While answering on the forum, they may exhibit the degree of confidence in the truthfulness of what they say by using words like "most likely", "probably", "think" etc. We therefore use linguistic markers such as hedges (Hyland, 2018), weasels(Vincze, 2013), factives (Hooper, 1974), assertives (Hooper, 1974), implicatives (Karttunen, 1971), mood[4], modality[4], subjectivity[4], sentiment[4] and polarity of subjective words (Riloff and Wiebe, 2003) based on respective lexicons to compute a feature vector. (For details, refer to (Mihaylova et al., 2018))

5.3 Writing Style Features

We extract writing style features from the question/answer which capture the format of a user-post. A socializing question is more likely to be written informally as compared to factual/opinion query. A non-factual answer which is not much informative may also carry distinctive cues. To capture these aspects, we count the number of punctuations, emoticons, NON-ASCII characters and check the presence of URL, image, ALL CAPS, consecutive character repetition ($\geq$ 3 times). Table 2 depicts how the number of samples exhibiting a particular writing style feature vary across the three classes in subtask A. A similar trend is present for factual (true/false) versus non-factual answers in subtask B.

Feature	Opinion	Factual	Socializing
All Caps	8	1	4
URL	2	0	173
Image	0	0	3
Repetition	9	3	130

Table 2: Writing Style Based Feature Distribution across Classes for Subtask A

5.4 Syntactic Features

We also examine syntactic features such as part-of-speech (POS) and category of question encoded as bag-of-words features. Further, we consider the expected answer type for a question (QType) and named-entity-type (NET) in an answer.

QType suggests the kind of information the question is seeking such as "description", "entity", "human", "location", "number", "yes/no" and "others" (extracted using work in (Madabushi and Lee, 2016)). Such features help segregate the socializing class in subtask A. For subtask B; we exploit the relation between what type of information the user wants to ask (QType) and what type of information is provided in the answer (NET). To capture this, we extract the type of all named-entity mentions in the answer. We consider "person", "organization", "location" and "quantity" as possible NE tags extracted using spacy[5].

5.5 External Evidence

In subtask B, the verification of an answer requires external evidence to conclude about its veracity. We extract external evidence by formulating a search-query from the question and answer followed by a web search [6] of this search-query. For each of the obtained search results, we compute its similarity with the question and answer respectively. These similarity scores are then used as features to a classifier.

Search-Query Formulation In order to search the web for relevant evidence, we formulate a search-query based on the question and answer. We extract query-sentence from the question posted by a user and append "Qatar" if neither 'Doha' nor 'Qatar' is present in it.

Further, to incorporate relevant information from the answer into this search-query, we find the answer sentence that has the highest similarity with the query-sentence. From this top-ranked sentence, we extract up to 7 keywords based on named entities, noun-chunks[5] and unigrams sorted by tf-idf scores, where named entities and noun-chunks are given high priority. Query-sentence combined with keywords from the answer is used as search-query.

Search Results We collect search results (snippets) from reputed sources (e.g., news, government websites, official sites of companies) (Mihaylova et al., 2018) for search-query formulated as above. Since the search-query may not always be perfect, we also obtain search results by drop-

Question	Answer	Evidence	Source	Class
how cold is doha during winter?	**8-10 degree** i guess	Over the course of the year, the temperature typically varies from **57 F (14 C) to 107 F (42C)** and is rarely below 51F or above 112F	Weatherspark	False
any private beaches in Qatar?	While Going to Shammal after 40 KM from Doha you will find **Al Ghariyah**	Qatar is a peninsula....This is a list of beaches in Qatar. Contents.**Al Ghariyah beach** is located 80 km north of Doha.	Wikipedia	True

Table 3: Example of external evidence collected in Subtask B

ping a few keywords from the search-query. From all the obtained search results, we select snippets that are most relevant to the question and the answer. Table 3 illustrates the external evidence retrieved for two question-answer pairs.

Similarity based Features For each question-answer pair, we compute their similarity with external search results obtained above. We use three similarity metrics: containment of unigrams, bigrams and trigrams (Lyon et al., 2001), cosine similarity of USE embedding and cosine similarity of tf-idf representation. For each metric, we compute the similarity of the snippet with: question, answer, query-sentence + top-answer sentence and all of them together. We then take the average and maximum over similarity scores for all the search results.

5.6 Forum-Level Features

These features capture the relevance of an answer with respect to a question as well as to other answers. An answer which contains information similar to that specified in other answers is more likely to be relevant and trustworthy. Thus, we consider the similarity of the answer with the question as well as its similarity with other answers in that thread. Here, also we consider all three similarity metrics mentioned before.

6 Experiments and Evaluation

6.1 Setting and Evaluation Metrics

We now utilize all features as portrayed in Figure 1 for subtask A and Figure 2 for subtask B. We train two separate SVM classifiers (Burges, 1998) on respective features for 3-class classification for both the subtasks. We use 10-fold cross validation for hyper-parameter tuning of SVM based on which, we choose "linear" kernel with C=0.5 (regularization parameter) for all the demonstrated experiments. All the results are reported on the test data with accuracy, recall, and F1 measure as evaluation metrics.

Additionally, we calculate Mean Average Precision (MAP) for subtask B, where the 'True' instances are considered relevant examples (in the context of Information Retrieval). MAP measures the capability of the system to predict 'True' instances with higher confidence.

6.2 Results for Subtask A

Table 4 shows the performance of the proposed system (PS). From the results, we can observe that our PS (excluding syntactic features) achieves an impressive performance with accuracy of 84.12% and 72.17% F1. Our submission (with all the features in PS + (POS and QType)) achieved similar performance and ranked 3rd on the leaderboard (83% acc., 71% F1) with only a marginal difference with respect to the first (84% acc., 72% F1) and second-ranked (83% acc., 72% F1) systems. To push our system's performance even further, we experimented in the post-evaluation phase and achieved 88.10% accuracy and 77.37% F1, highest on the post-evaluation leaderboard [7]. This current best solution leverages QType features, extensive data augmentation using bagging technique and excludes writing style features.

In order to appraise the importance of each feature, we conducted an ablation study by analyzing individual features and their combinations. It can be followed from the results that the semantic embedding contributes most to the performance of the system. However, embeddings derived using USE perform better than glove embeddings. This difference is possibly due to the failure of glove-based embedding in capturing word-order and long-range dependencies.

The second most important contributor is the data augmentation approach which resulted in notable accuracy gains (3.71% improvement). As expected, it allows the system to generalize better and ameliorates the issue of class imbalance. Following it is the query-sentence extraction approach with $\sim$1% accuracy enhancement. The

Table 4: Experimental Results. Subtask A (Left) and Subtask B(Right)
PS: Proposed System, WS: Writing Style, Ling: Linguistic, Qsent: Query Sentence, DA: Data Augmentation, Sem: Semantic Embedding, Cat: Category, Ext: External Evidence, Forum: Forum level evidence, NE: Named Entity from answer

performance is in line with the expectations as query-sentences are sufficient in capturing the essence of user question. QType and linguistic cues help improve the performance further.

However, we notice that the performance improves by excluding the writing style features. The possible reason for this observation can be the absence of such features in the test data. In the training and development data-sets, the presence/absence of these features was a distinguishing factor among classes (see Table 2) which made them worth considering.

6.3 Results for Subtask B

Table 4 shows the performance of PS with the ablation study. Our PS (also our best[7]) achieves an accuracy of 77.85% with 58.33 MAP (highest among all the participating systems). From the ablation study, we observe that although removal of external evidence results in slight accuracy gains (0.86%), it causes a drastic reduction in MAP score (33.33 points). This signifies the importance of external evidence as these features enable the system to make better predictions for the true/false classes.

We also conducted a majority baseline experiment where all the samples are labeled as "non-factual." This experiment resulted in the best performance on the leaderboard with 83% accuracy and very poor MAP. This illustrates that the test data has a majority of non-factual instances. Thus, measuring the performance of any system solely on accuracy for this problem is not fair.

As it can be inferred from the ablation study, among all the features, reputed source based search-results selection (contributing 4.95% acc. gain) and forum-level features (contributing 2.37% acc. gain) are the most important. Reputed source selection helps in relying on only trusted sources for external evidence selection and hence make better predictions for true/false classes. Forum level features help in distinguishing among non-factual versus true/false samples.

Further, data augmentation in subtask B results in significant performance gains of 10.11% accuracy. It helps the system learn about the characteristics of "bad answers" which are not present in the training data and hence enables the system to generalize better on the test data. For this subtask as well, semantic embedding plays a vital role in capturing the essence of the question-answer pair, contributing 3.87% gain in accuracy.

7 Conclusion

In this work, we have described our system for Semeval-2019 Task 8 on Fact-checking in cQA Forums. Our system leverages data augmentation and integrates knowledge from various aspects, such as the semantics, linguistics, syntax and writing style along with complementary information from trustworthy external sources and QLF.

Our submission was ranked third in Subtask A with marginal performance differences compared to the best-ranked systems. Our current best solution is ranked first on the leaderboard with 88% accuracy[7]. In subtask B, our current best solution is ranked 2nd, with 58.33% MAP score, highest among all participating systems[7].

However, none of the participating systems could beat the majority baseline for subtask B in terms of accuracy, which signifies that we are still far from solving this task to its entirety with a decent performance. Thus, there remains a lot of potential in this research direction.

Abstract

The article describes our submission to SemEval 2019 Task 8 on Fact-Checking in Community Forums. The systems under discussion participated in Subtask A: decide whether a question asks for factual information, opinion/advice or is just socializing. Our primary submission was ranked as the second one among all participants in the official evaluation phase. The article presents our primary solution: Deeply Regularized Residual Neural Network (DRR NN) with Universal Sentence Encoder embeddings. This is followed by a description of two contrastive solutions based on ensemble methods.

1 Introduction

Community question answering forums are good platforms for knowledge sharing; hence, they are widely used sources of information. The growing popularity of such knowledge exchange leads to a growing need to automate the process of verifying the post quality. The first step, often overlooked, is to categorize each question and establish what kind of information the user seeks.

Question classification has been mainly used to support question answering systems. Two main method types have been proposed in the literature: (1) rule-based approaches with linguistic features (Tomuro, 2004; Huang et al., 2008; Silva et al., 2011), and (2) machine learning approaches (Zhang and Lee, 2003; Metzler and Croft, 2005). These methods are rather simple, due to the fact that question classification is often just a preprocessing step in a larger task. However, we can observe some recent advances in this area, such as ULMFiT (Howard and Ruder, 2018), which achieves state-of-the-art performance on the TREC dataset (Voorhees and Tice, 1999).

The present article describes our systems submitted to the SemEval 2019 competition Task 8 subtask A on question classification. The competition data set consisted of QatarLiving forum questions classified as FACTUAL, OPINION or SOCIALIZING. The training data contained only 1,118 questions. Moreover, according to our evaluation, human-level accuracy on this data set was about 0.75, which was relatively low. Therefore, we approached the task as a challenging classification problem.

The article is structured as follows. Section 2 presents our experiments with preprocessing methods. Section 3 describes our official submission, where we propose an architecture utilizing several regularization methods to address the problem of the small data set. For comparative purposes, section 4 presents two ensemble models as contrastive examples. Section 5 provides the results achieved by the models. Lastly, section 6 concludes the discussion.

2 Data Preprocessing

We tested a few simple text preprocessing setups. Unfortunately, none of them helped the models achieve improved results. Hence, they are here presented as negative results, and for reference.

First, all emojis were removed from the text, and all URLs were replaced with the string 'url link'. Next, all dates and hours were replaced with 'date' and 'hour', respectively. Ordinal numbers – i.e. 1^{st}, 2^{nd}, 5^{th} etc. – were replaced with 'nth', while the remaining numbers were substituted wtih 'num'. All of these sequences were found using regular expressions. Furthermore, if most of the letters were uppercase, the whole text was lowercased.

Second, some of the forum-specific jargon was replaced with more generally used terms. This was achieved by an internally prepared dictionary that translated 'qar' into 'Qatar currency', 'qling' into ‘browsing Qatar forum’, ‘ql’ into ‘Qatar forum’, ‘villagio’ to ‘Qatar shopping center’, etc. Additionally, it helped us to correct common spelling errors, such as ‘doha’ for ‘Doha’ and ‘qatar’ for ‘Qatar’. Finally, spelling correction was performed by a custom character-based CNN language model. This way, we hoped to obtain a better representation of texts when embedded into vectors.

However, the experiments showed that none of these methods brought significant improvement in classification accuracy. It seemed that noise removal, combined with text normalization, deprived the data of significant features and information which carried crucial meaning for preparing text embeddings. Therefore, we finally did not perform any preprocessing and worked on raw question subjects and body text.

3 Primary Submission

3.1 Features

The feature space for the models was created by combining three different sources of information:

1. *Universal Sentence Encoder* – The concatenated post subject and body text were embedded with the Universal Sentence Encoder (USE) (Cer et al., 2018) to create a 512-dimensional vector representation.

2. *fastText embeddings* – The concatenated post subject and body text were tokenized with the Spacy library and embedded on the word level with 300-dimensional fastText vectors. Then, the vectors were averaged on the sequence dimension.

3. *Category statistics* – For each QL post category, the ratio of the FACTUAL, OPINION and SOCIALIZING labels was calculated. The three numbers were normalized, forming a 3-dimensional vector.

The three subfeature vectors were concatenated to produce an 815-dimensional vector for each question.

3.2 Model Architecture

We proposed the Deeply Regularized Residual Neutral Network architecture, shown in Figure 1.

The model took as its input the 815-dimensional vector of floats (concatenated USE embeddings,

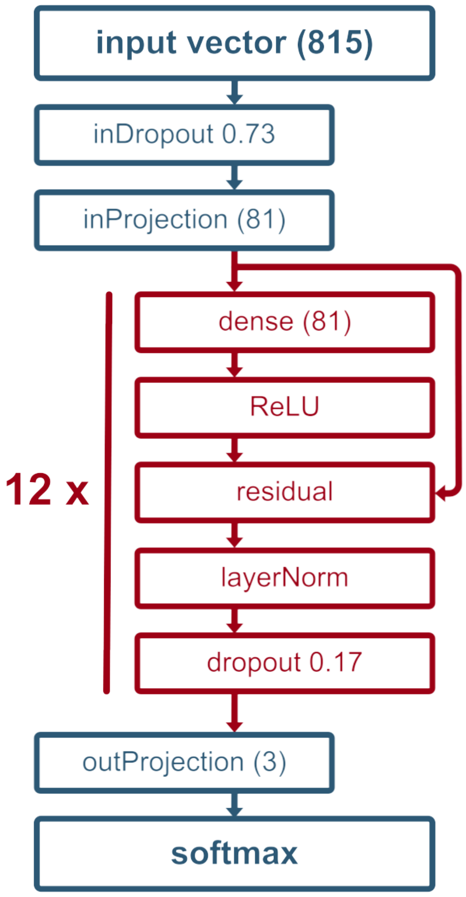

Figure 1: The architecture of DRR NN (primary submission).

fastText embeddings averaged, and category statistics). During the training, a large dropout of 0.73 was applied to the input vector.

The core of the model was a deep subnetwork built of 12 stacked blocks. Each block contained an 81-dimensional dense layer followed by ReLU activation, residual connection, layer normalization and 0.17 dropout. Finally the output of the last block was projected with a dense layer into a 3-dim logits vector.

The model was trained with the Adam optimizer, at a 6e-3 learning rate, and with 500-epoch linear warmup. We used softmax cross entropy loss with 0.14 of L2 penalty regularization.

All model hyperparameters were optimized with a randomized search algorithm and 5-fold cross-validation over the training data set. The final model size was 148K learnable variables.

3.3 Model Training

The main idea behind the advanced training procedure was to split the training data into a bigger learning part and a smaller validation part. The loss was minimized on the learning part until the accuracy on the validation part began to increase.

Generally, model performance depends on many factors, such as training efficiency, model architecture, optimization algorithms, etc. At the same time, it is affected by sample distribution between learning and validation parts.

In order to aggregate more knowledge from the training data, we used 5-fold cross-validation splits. We prepared 4 such splits using different random seeds. This procedure gave us a total of 20 different pairs of learning/validation sets.

We set the maximum number of epochs to 700. The model was validated after each training epoch and saved until its classification accuracy improved. Usually, the accuracy was improving for about 300-600 epochs. For the final prediction, we used the argmax of the summarized softmax of 20 models:

$$\arg\max \sum_{k=1}^{20} \mathrm{softmax}(logits_k).$$

4 Contrastive Submissions

For the contrastive submissions, our overall idea was to utilize multiple models that were as varied as possible, and combine their outputs.

In the first step, we used the following systems to obtain label probabilities for each question:

- *ELMO* (Peters et al., 2018) – a deep, contextualized word representation to obtain sentence representation, followed by a neural network of two dense layers. We arrived at the following architecture and hyper-parameters during the optimization: a dense layer of 48 neurons (dropout 0.5), followed by a second dense layer of 10 neurons (dropout 0.5). When tested on the training data in cross-validation, this solution alone achieved a micro-accuracy of 0.72.

- *BERT* (Devlin et al., 2018) – a deep, bidirectional transformer model with sequence classification layers on the top. The BERT language model was pre-trained, so only the sequence classifier was initialized and trained on the SemEval data. We used the PyTorch implementation of the case-insensitive 'base' version[1] with the optimal number of epochs (10) determined on the development set. When tested on the training data in cross-validation, this solution alone achieved a micro-accuracy of 0.717.

- *Bag-of-words* – a machine learning solution based on character n-gram vectorization with TF-IDF weighting and a linear kernel SVM classifier. We used the implementation from the scikit-learn package (Pedregosa et al., 2011). When tested on the training data in cross-validation, this solution alone achieved a micro-accuracy of 0.699.

In the second step, we prepared two different ensemble models combining the probability outputs from *ELMO*, *BERT*, *Machine Learning* and *DRR NN*.

The first contrastive submission (**Contrastive-1**) used the SVM classifier with linear kernel. The second contrastive submission (**Contrastive-2**) was designed as a bagging classifier of 10 estimators, each a voting ensemble of logistic regression, random forest and SVM with linear kernel.

5 Results

Table 1 contains the results of the evaluation on the official test set. The primary submission and both contrastive submissions were presented during the official phase of the contest. After the official competition, we tested additional solutions. Surprisingly, we achieved the best results with the SVM classifier (RBF kernel) on the USE embedding (**Post-evaluation**).

Model	**Accuracy**	**F1**	**AvgRec**
DRR NN (Primary)	0.83	0.72	0.76
Contrastive-1	0.83	0.72	0.76
Contrastive-2	0.81	0.69	0.73
Post-evaluation	0.87	0.77	0.78

Table 1: Official results of our submissions on the test set.

6 Conclusions

According to the experiments, and as reflected in the results on the test set, the best performing system was DRR NN based on the Universal Sentence Encoder. We attributed its good performance

[1] https://github.com/huggingface/pytorch-pretrained-BERT

on the small data set to the deep regularization and the advanced training procedure. However, the SVM classifier performed even better, probably thanks to its overfitting resistance (Xu et al., 2009).

Additionally, we tested several approaches, including the usual high performers, such as BERT or ELMO, and the ensemble systems. None of them was able to outperform our primary submission. We attribute such behaviour to data over-fitting and lack of ability to extract higher-level dependencies from the provided samples.

Some influence on the results could have been exerted by the significantly differing distributions of post categories among the train, dev and test sets. For example, while more than 30% of all questions from the test set belonged to the 'Visas and permits' category, only 8% from the train set and 5% from the dev set fall into the same category.

Linear SVM with the USE embeddings reached an accuracy of 0.84 on the dev set and 0.86 on the test set. Surprisingly, with a different set of parameters, we achieved 0.87 accuracy on the test set, and only 0.81 accuracy on the dev set.

Abstract

The SemEval 2019 Task 8 on Fact-Checking in community question answering forums aimed to classify questions into categories and verify the correctness of answers given on the QatarLiving public forum. The task was divided into two subtasks: the first classifying the question, the second the answers. The TueFact system described in this paper used different approaches for the two subtasks. Subtask A makes use of word vectors based on a bag-of-word-ngram model using up to trigrams. Predictions are done using multi-class logistic regression. The official SemEval result lists an accuracy of 0.60. Subtask B uses vectorized character n-grams up to trigrams instead. Predictions are done using a LSTM model and achieved an accuracy of 0.53 on the final SemEval Task 8 evaluation set. In a comparison of contextual inputs to subtask B, it was determined that more contextual data improved results, but only up to a point.

1 Introduction

The SemEval 2019 Task 8 on Fact-Checking gave us the opportunity to develop a system that evaluates the factual content of questions and answers in the field of community question answering forums. This popular niche on the internet provides helpful information for specific interests, such as information on life in Qatar or elsewhere in the world, coding help on Stack Overflow, or answers to a wide range of questions on Quora, Reddit/r/Ask or Yahoo! Answers. Often other resources are not at hand or misleading, and it proves difficult to find what one is looking for amid non-relevant questions, let alone be sure the answers found are correct. A system that can, with some degree of accuracy, pick out the factual questions and then predict the correctness of the given answers, is a means to ensure quality in community question answering forums. There may also be many further applications in information retrieval – ordering search results based on estimated factuality in a web query or even identifying truthful answers in automatic question answering systems.

The task was divided into two subtasks. While Subtask A required a classification of the questions into three distinct categories "Factual", "Socializing", and "Opinion", Subtask B took the subset of the "Factual" questions to classify them according to either "True", "False" or "NonFactual" in terms of the actual answer. Similar tasks were already part of SemEval 2015 (Nakov et al., 2015) and SemEval 2016 (Nakov et al., 2016).

The Tuefact system follows this division, even going as far as using different pre-processing to accommodate for the different needs. While the question classification is done with a bag of word approach using word trigrams, the answer classification uses character trigrams. The models used to make predictions are logistic regression for Subtask A and a long short-term memory model (LSTM) (Hochreiter and Schmidhuber, 1997) for Subtask B.

The following section describes the data provided for the tasks. The next two sections describe the two components of our language independent system in detail together with a brief discussion of failed approaches and changes that lead to improvements. In the last two sections we discuss further work to be done on the TueFact system and our conclusion about the current version of it.

2 The data

The pre-annotated data from the QatarLiving forum was provided in XML format. It was split into two files: one for the question classification, the other for the answer classification.

The data for Subtask A comprised a total of

168 questions. Each question contained a subject line, i.e. a summary of the question, the detailed question, and all answers given to the question. The meta information contained amongst others the date, user name, and id. The questions were annotated into the three categories “Factual”, “Opinion”, and “Socializing”. 33 of the questions were labeled as “Factual”, 73 as “Opinion”, and 62 as “Socializing”. The longest question was 98 words long, the shortest only 5, the average length of questions was 41.1 words.

The data provided for Subtask B contained a total of 95 questions labeled “Factual”. The meta information was the same. Of the 356 given answers 128 were labeled as “True”, 102 as “False”, and 126 as “NonFactual”. The longest answer was 195 words long, the shortest consisted of only one word, the average length of answers was 31.5 words.

For further information about the data please refer to the task description paper from Mihaylova et. al (2019). No special data pre-processing steps were used in preparation for either subtask – no noticeable performance gains were observed when stripping accents, punctuation symbols, or lowercasing.

3 Question classification

The goal of this subtask was to classify the questions posted on the QatarLiving forum,[1] a community question answering forum, as either: 1. “Factual”, meaning that it asks about something specific, and can receive a correct or incorrect answer, 2. “Opinion”, in which the answers cannot be right or wrong, as it does not ask for objective facts but the personal input of the answering people, and 3. “Socializing”, where the goal of posting the question was not seeking information at all, but rather looking for online communication.

[1]https://www.qatarliving.com/forum

3.1 Approach

We approached this task as a multi-class learning problem, instead of first dividing the questions into “Factual” and “NonFactual”, and then further dividing the “NonFactual” questions into “Opinion” and “Socializing”. As baseline model we decided to use multi-class logistic regression based on character bigrams, and only the subject line of the questions as input. Our reasoning for the use of this baseline model was to see how such a basic model would perform, and where we could take it from there. It achieved an accuracy of just over 50% on our development set, a randomly split quarter from the data set provided.

The current model uses a multi-class logistic regression model with a limited-memory Broyden-Fletcher-Goldfarb-Shanno (BFGS) algorithm (Saputro and Widyaningsih, 2017) solver to predict the labels. The labels were encoded using the scikit-learn library (Pedregosa et al., 2011) and the questions vectorized from word uni-, bi- and trigrams. We used raw counts for all word-grams, and did not add weighting. We further decided not to use a language dictionary as external feature, in order to maintain language independence.

3.2 Results

For means of evaluating our models, and as the data set was small, we have randomly split the training data and used one quarter of it as a development set. The development set was then not only used to evaluate our model in terms of accurcay, but also to compare the predicted to the actual labels. Our system was best at correctly predicting “Opinion” in an average of 10 cases compared to an average of four misclassified cases with no clear tendency of misclassifying it as either “Factual” or “Socializing”. False predictions were equally often made in the classification of the labels “Socializing” and “Factual”, which suggests further improvement possibilities.

Best training results on the development set were achieved at an accuracy of 0.714. The official SemEval result lists an accuracy of 0.60.

	No CC	Limited CC	Subject + IDs Only	Full CC
Accuracy	61.5	67.12	79.94	79.92

Table 1: Averaged 5-fold cross-validated accuracy on the development set for the character-based embeddings variation.

4 Answer classification

In this subtask, answers to the questions from the first task were to be classified into "Factual" and "Non-Factual", and "Factual" items further classified into "True" or "False". Unlike in the first task, there is no distinction made between types of non-factual comments (e.g. socializing or opinion).

4.1 Approach

Our approach to this task was to treat the problem as a multiple-class learning problem with three categories: "Non-Factual", "True" and "False". Variations of the model which split it into two sequential learning problems – fact or non-fact, then true or false – showed no significant difference.

The basic task B model consists of a LSTM network architecture (Hochreiter and Schmidhuber, 1997) with an embedding layer, two hidden layers of 100 nodes followed by a softmax activation layer to permit multiple classification. Embeddings were trained using the top 400 uni-, bi- and tri-gram features by frequency in the data. In training, we used categorical cross-entropy as a loss function. In all model variations, we trained for 200 epochs with a batch size of 128 and used L2 weight regularization with a factor of 0.012.

4.2 Variations and results

We examined three main variations of input to the model for answer classification: no comment chain (CC), limited comment chain, subject and comment identifier only and full comment-chain (see table 1). In no CC, we included only the comment itself being classified. In limited CC, we included the comment and all previous comments in the chain. In the subject plus comment identifier variation, we included the question subject heading, the comment text and commenter identifier. In the full CC variation we included the subject heading and the entirety of all comments in the chain. In tables 1 and 2, we abbreviate the same way.

Next, we experimented with word-level versus character-level embeddings (see table 2). In the end, unfortunately, our best results for task B on the evaluation set (also with the subject and identifiers only variation) were less encouraging at 53 percent.

5 Future work

Due to time constraints, several improvements to the models for both tasks weren't completed in time for the final evaluation. For the question classification task, we aimed to experiment with word- or character-embeddings instead of only a bag-of-n-grams approach in order to enable work on a multi-channel convolutional neural network model, which is also being pursued further. In some NLP tasks, CNNs have been shown to outperform not only traditional machine learning models but recurrent neural networks as well, and this may also be the case here (Wu et al., 2016).

For the answer classification task, work is underway on a model variation which tags comments based on the proportion of their content that can be found on multiple websites from a web query consisting of the question subject line.

6 Conclusions and analysis

For Subtask A, we considered two approaches: simple logistic regression, and a convolutional neural network approach. The initial success of the logistic regression approach on the development data suggests a 'simplicity first' strategy is sensible in this case, but its mediocre performance on the evaluation data indicates it is not especially robust.

In Subtask B, we examined only a single approach using a LSTM trained with embeddings, but with a number of variations. Variations including more of the comment chain as input were more successful than using single-comment answers as input, however we found little difference between including the entire comment chain and including only the subject question and comment identifiers. We suspect this is due to the fact that all answers include each other at least once in the full-chain variation, so it provides less to distinguish the answers from one another. Further, all vari-

	No CC/WB	Limited CC/WB	Full CC/WB
Accuracy	59.87	66.97	79.14

Table 2: Averaged 5-fold cross-validated accuracy on the development set for the word-based embeddings variation.

ations using character-based embeddings slightly outperformed model variations employing word-based embeddings (1 to 5 percent). This isn't entirely unexpected – solely character embedding based models performed very well in the SemEval 2018 Irony Detection task (Van Hee et al., 2018) as well, which bore similarities. One hypothesis for this result is that with small input sizes (such as tweets or forum posts) word-based embeddings may distinguish fewer distinctions, but it may also simply be that there is no significant performance difference. In which case, character- embeddings should be preferred as they do not require a maintenance of a large dictionary.

Overall, the TueFact system is an acceptable baseline and a solid starting point for further work in the direction of fact checking in community question answering forums. But perhaps of greatest interest are our comparative results under different input. The significance of input choice on performance is highlighted: our results show that while inclusion of more context can certainly be useful, the intuition that more data will always improve performance in this task should not be taken as a given.

Abstract

The objective of the task, Fact-Checking in Community Forums , is to determine whether an answer to a factual question is true, false, or whether it even constitutes a proper answer. In this paper, we propose a system that uses a long short-term memory with attention mechanism (LSTM-Attention) model to complete the task. The LSTM-Attention model uses two LSTM(Long Short-Term Memory) to extract the features of the question and answer pair. Then, each of the features is sequentially composed using the Attention mechanism, concatenating the two vectors into one. Finally, the concatenated vector is used as input for the MLP (Multi-Layer Perceptron) and the MLP's output layer uses the softmax function to classify the provided answers into three categories. This model is capable of extracting the features of the question and answer pair well. The results show that the proposed system outperforms the baseline algorithm.

1 Introduction

Many questions pertaining to various fields are posted to QA forums by users every day, where they collect answers. However, the answers do not always address the question asked. Indeed, in some cases, the answer has nothing to do with the question. There are several reasons why this is the case. For example, the responder could have misunderstood the question and so provided a wrong answer. Most QA forums have little control over the quality of the answers posted. Moreover, in our dynamic world, the true answer was true in the past, but it may be false now . Figure 1 presents an example from the Qatar Living forum. In this case, all three answers could be considered to be good since they formally answer the question. Nevertheless, a1 contains false information, whereas a2 and a3 are correct, as can be established from the official government website.

q**:** I have heard its not possible to extend visit visa more than 6 months? Can U please answer me.. Thankzzz...

a_1**:** Maximum period is 9 Months....

a_2**:** 6 months maximum

a_3**:** This has been anwered in QL so many times. Please do search for information regarding this. BTW answer is 6 months.

Figure 1: An example from the Qatar Living forum

In this study, we aim to solve the problem of detecting true factual information in online forums. Given a question requesting factual information, the goal is to classify the provided answers into the following categories.

(i) Factual - True: The answer is true and can be proved by cross referencing with an external resource.

(ii) Factual - False: The answer gives a factual response, but it is either false, partially false, or the responder is uncertain about their response.

(iii) Non-Factual: The answer does not provide factual information relevant to the question; it is either an opinion or an advice that cannot be verified.

To the best of our knowledge, various approaches have been proposed for the purposes of fact-checking in community forums (Mihaylova et al., 2018), such as long short-term memory (Gers et al., 2000) .

In this paper, we provide an LSTM-Attention model for fact-checking in community question answering forums. In our approach, we use pretrained word vectors for word embedding. The LSTM layer is used to extract features from the question and answer sentences. Finally, these features are used by the Attention Mechanism (Vaswani et al., 2017) with a focus on extracting useful information from the features that are significantly relevant to the current output.

The remainder of this paper is organized as fol-

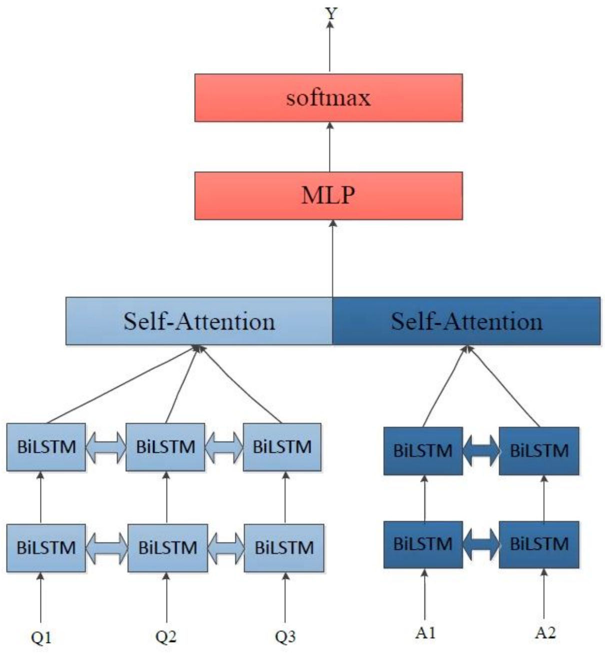

Figure 2: LSTM-Attention Model

lows. In section 2, we described the LSTM, Attention model, and their combination. Section 3 summarizes the comparative results of the proposed model against the baseline algorithm. Section 4 concludes the paper.

2 LSTM-Attention Model for Fact-Checking

Figure 2 shows the architecture of our model. First, a sentence is transformed into a feature matrix. The feature matrix is then passed into the LSTM to extract salient features.

A simple tokenizer is used to transform each sentence into an array of tokens, which constitute the input to the model. This is then mapped into a feature matrix or sentence matrix by an embedding layer. The n-gram features are extracted when the feature matrix passes through the LSTM, and the output of the LSTM is passed into the Self-Attention layer. This layer composes the useful features to output the final regression results by means of a linear decoder.

2.1 Embedding Layer

Vectors encoded using the one-hot method have large dimensions and are sparse. Suppose we encounter a 2,000-word dictionary in natural language processing (NLP). When the one-hot method is used for coding, each word will be represented by a vector containing 2,000 integers. If the dictionary is larger, this method will be very inefficient.

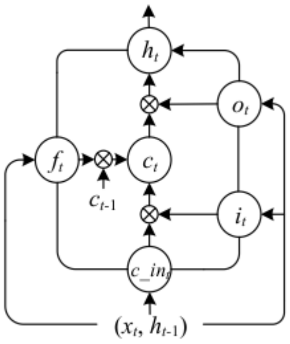

Figure 3: LSTM

The one-hot-vector method has many defects when used for word encoding. One is that it has too much redundancy; the other is that the dimension of the vector is too high. The vector will have as many dimensions as there are words, which will increase the computational complexity. Word-embedding Mikolov et al. (2013) transforms an original high-dimensional redundant vector into a low-latitude vector with strong information content. No matter how many words there are, the converted vector generally has only 256 dimensions to 1024 dimensions.

The embedding layer is the first layer of the model. Each sentence is regarded as a sequence of word tokens $t_1, t_2...t_n$, where n is the length of the token vector.

2.2 Long Short-Term Memory

In theory, RNN Tsoi and Back (1994) should be able to handle such long-term dependency. We can pick and choose the parameters carefully to solve the most elementary form of this type of problem (Le et al., 2015). However, in practice, RNN is not able to learn this knowledge successfully. Therefore, the LSTM was designed to solve the problem of long-term dependency. In practice, the LSTM excels at dealing with long-term dependency information rather than the ability to acquire it at great cost. RNN has a chain of repeating neural network modules. In standard RNN, the repeating module has a very simple structure. LSTM has the same structure, but the structure of repeating modules is more complex. This is different from that of the single neural network layer. Figure 3 shows the detailed structure of an LSTM. The LSTM cal-

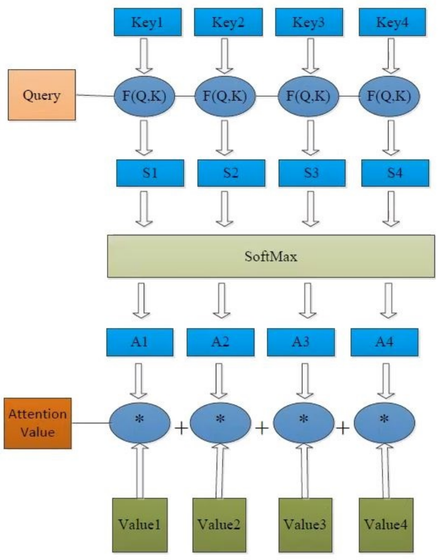

Figure 4: Attention

culates hidden states H_t and outputs C_t using the following equations.

• Gates:

$$\begin{aligned} i_t &= \sigma\left(W_{xi}x_t + W_{xi}h_{t-1} + b_i\right) \\ f_t &= \sigma\left(W_{xf}x_t + W_{hf}h_{t-1} + b_f\right) \\ o_t &= \sigma\left(W_{xo}x_t + W_{xo}h_{t-1} + b_o\right) \end{aligned} \quad (1)$$

• Input transformation:

$$c\_in_t = tanh\left(W_{xi}x_t + W_{xi}h_{t-1} + b_{in}\right) \quad (2)$$

• State update:

$$\begin{aligned} c_t &= f_t \otimes c_{t-1} + i_t \otimes c\_in_t \\ h_t &= o_t \otimes tanh\left(c_t\right) \end{aligned} \quad (3)$$

Here, x_t is the input vector; c_t is the cell state vector; W and b are layer parameters; f_t , i_t , and o_t are gate vectors; and σ is the sigmoid function. Note that $\otimes$ denotes the Hadamard product. Bidirectional LSTM comprises a forward LSTM and a reverse LSTM. It captures context feature information very well as compared to LSTM. Therefore, bidirectional LSTM usually performs better than LSTM and we use it to process the sequences. Among the many hidden layers of deep neural networks, the earlier layers learn simple low-level features, and later layers combine simple features to predict more complex things. Therefore, we use several hidden layers to make predictions more accurate.

2.3 Attention Mechanism

The concept of the Attention mechanism came from the human visual attention mechanism (Butterworth and Cochran, 1980). When people perceive things visually, they usually do not observe the scene end-to-end. Instead, they tend to observe specific parts according to their needs. When people find that a scene has something they want to observe in a certain part, they will learn to pay attention to that part in the future when similar scenes appear. With RNN or LSTM, the information accumulation of several time steps is needed to connect long-distance interdependent features. However, the longer the distance is, the less likely it is to be captured effectively. In the Attention calculation process, the connection between any two words in a sentence is directly established through one calculation step. Thus, the distance between long-distance dependent features is greatly shortened, which is conducive to the effective use of these features. Obviously, it is easier to capture the long-distance interdependent features in sentences after the introduction of Attention. In figure 4, self attention can be described as mapping a query and a set of key-value pairs to an output. The calculation of Attention is mainly divided into three steps. The first step calculates the similarity between query and each key to get the weight. The second step uses a softmax function (Jean et al., 2015) to normalize these weights. Finally, the weight and the corresponding key value are weighted and summed to get the final Attention. Currently, in NLP research, the key and value are always the same, that is, key=value. In this part, we use self-attention, which is denoted as key=value=query (Firat et al., 2016).

$$\begin{aligned} &Attention(Q, K) = \\ &\sum_{n=1}^{n} Similarity(Q, K_i) * V_i \end{aligned} \quad (4)$$

2.4 MLP Layer

This layer is a fully connected layer that multiplies the results of the previous layer with a weight matrix and adds a bias vector. The ReLU (Jarrett et al., 2009) activation function is also applied in this layer. The final result vectors are finally input to the output layer.

2.5 Output Layer

This layer outputs the final classification result. It is a fully connected layer that uses softmax as an activation function.

3 Experiments and Evaluation

3.1 Data Preprocessing

The organizers of the competition provided the training data that included one question and a number of answers. Each of answer was to be classified into the categories: (Factual - TRUE, Factual - FALSE, Non-Factual). We extracted the questions and corresponding answers, and then concatenated them into the form of a question-answer pair. As all of the data was provided by the "Qatar Living" forum, the content primarily contained English text, and all non-english characters were ignored. We converted all letters into lower case to accommodate the known tokens in word2vec pretrained word vectors. We counted the sentence length of questions and answers. Most of them were no more than 80 words. Therefore, we set the length of the sentence to 80 words. The word2vec pretrained data was used to initialize the weight of the embedding layer. word2vec is a popular unsupervised machine learning algorithm to acquire word embedding vectors. We used 100-dimension word vectors to initialize the weight of the embedding layer.

3.2 Implementation

We used Keras with TensorFlow backend. The hyper-parameters were tuned in train and dev sets using the scikit-learn grid search function that can iterate through all possible parameter combinations to identify the one that provides the best performance. The optimal parameters found are as follows. The LSTM layer count is 2, and the dimension of the LSTM hidden layer (d) is 200. The dropout rate is 0.3. The training has a batch size of 128 and runs for 30 epochs. The results also revealed that the model using pre-trained word2vec vectors and an Adam optimizer achieved the best performance.

3.3 Evaluation Metrics

The system was scored based on Accuracy, macro-F1, and AvgRec where the "Factual - True" instances were considered to be positive, and the remaining instances to be negative.

3.4 Results and Discussion

To prove the advantages of our system architecture, we ran a 6-fold cross validation on different sets of layers. On training data, the trial data experiment results shown in Table 1:

Model	**F_1-score**
CNN	0.483
LSTM	0.498
BiLSTM	0.514
BiLSTM-Attention	**0.548**

Table 1: The trial data experiment results.

Our system achieved 0.548 accuracy on Subtask B. The evaluation results revealed that our proposed system showed considerable improvement over the average baseline, which we attribute to our LSTM with Attention architecture. Our system can effectively extract features from question and answer. Using this, prediction can be made on whether the answers are actually factual and whether the fact is true or not.

4 Conclusion

In this paper, we described our submission to the SemEval 2019 Workshop Task 8, which involved Fact-Checking in Community Forums. The proposed LSTM-Attention model combines LSTM and Attention. LSTM extracts local information within both the answer and question. The Attention Mechanism resolves the issue of poor learning effect on the long input sequence. The official results reveal that our system output performed all baseline algorithms and ranked 9th on Subtask B. In future work, we will query a search engine to fetch relevant documents from the Internet to achieve an improved classification system.

Abstract

This paper describes the participation of DBMS-KU team in the SemEval 2019 Task 9, that is, suggestion mining from online reviews and forums. To deal with this task, we explore several machine learning approaches, i.e., Random Forest (RF), Logistic Regression (LR), Multinomial Naive Bayes (MNB), Linear Support Vector Classification (LSVC), Sublinear Support Vector Classification (SSVC), Convolutional Neural Network (CNN), and Variable Length Chromosome Genetic Algorithm-Naive Bayes (VLCGA-NB). Our system obtains reasonable results of F1-Score 0.47 and 0.37 on the evaluation data in Subtask A and Subtask B, respectively. In particular, our obtained results outperform the baseline in Subtask A. Interestingly, the results seem to show that our system could perform well in classifying Non-suggestion class.

1 Introduction

Nowadays, a huge number of texts are posted in online reviews or discussion forums. Such media can be a valuable source for obtaining a suggestion about products or services (Negi and Buitelaar, 2015; Negi et al., 2016). The obtained suggestion is not only useful for readers but also important information for stakeholders (Negi et al., 2016). Indeed, such advice can be used to improving the quality of products or giving helpful recommendations (Brun and Hagege, 2013). However, identifying a suggestion from a lot of reviews or comments needs extra effort and time. Moreover, such online texts are mostly in unstructured form (Negi et al., 2018; Negi and Buitelaar, 2017). Thus, automatically mining the suggestion from given texts is challenging and significant (Negi et al., 2016).

Suggestion mining is relatively a new research interest in text classification tasks (Negi and Buitelaar, 2015). Several studies have initiated to mining suggestions from online texts (Negi et al., 2018; Negi and Buitelaar, 2017; Negi et al., 2016; Negi, 2016; Negi and Buitelaar, 2015; Brun and Hagege, 2013; Ramanand et al., 2010; Dong et al., 2013; Wicaksono and Myaeng, 2012, 2013). Particularly, (Negi and Buitelaar, 2015; Brun and Hagege, 2013; Ramanand et al., 2010) have tried to identify suggestions from customer reviews. Meanwhile, (Negi, 2016; Dong et al., 2013; Wicaksono and Myaeng, 2012, 2013) have mined such advice by using Twitter or discussion forums dataset. Then, (Negi et al., 2018; Negi and Buitelaar, 2017) have utilized WikiHow and open domain corpora for their work. However, they concluded that it is not easy to identify suggestion texts automatically. In other words, it still has room to improving the classification result in the suggestion mining task. The task of suggestion mining from online reviews and forums, namely, Task 9 (Negi et al., 2019), is opened in the International Workshop on Semantic Evaluation 2019 (SemEval-2019).

This paper delineates the participation of DBMS-KU team in both Subtask A and Subtask B of Task 9 of SemEval-2019 (Negi et al., 2019). To address these two Subtasks, we utilize several approaches, namely, Random Forest (RF), Logistic Regression (LR), Multinomial Naive Bayes (MNB), Linear Support Vector Classification (LSVC), Sublinear Support Vector Classification (SSVC), Convolutional Neural Network (CNN), and Variable Length Chromosome Genetic Algorithm Naive Bayes (VLCGA-NB). The obtained results of our experiments are encouraging and show a promising improvement in identifying Suggestion and Non-suggestion.

The rest of this paper is organized as follows. Section 2 explains the problem definition, problem formulation, and dataset. Section 3 presents the tools and libraries used in this work. Section 4 describes our employed methods. Section 5 repre-

Proceedings of the 13th International Workshop on Semantic Evaluation (SemEval-2019), pages 1185–1191

sents our experiments that consist of data preprocessing, parameter, and evaluation measurement. Section 6 discusses our obtained results. Finally, we conclude this work in Section 7.

2 Problem Definition

Suggestion mining is a binary classification problem. Particularly, suggestion mining is a task that labels sentences as Suggestion or Non-suggestion. However, suggestion sentences can have very broad meaning. Thus, the domain and scope of the suggestion text classification should be described. The Task 9 of SemEval-2019 consists of Subtask A and Subtask B that are classifying a suggestion in intra-domain and cross-domain, respectively (Negi et al., 2019).

2.1 Problem Formulation

Suggestion text classification consists of assigning $suggestion, nonsuggestion$ to $(s_i, l_j) \in SxL$, where S is sentences and $L = [l_1, ..., l_n]$ is a set of *n* predefined labels. Each sentence is classified as Suggestion or Non-suggestion class.

2.2 Datasets

Dataset used in Task 9 of SemEval-2019 is divided into training, trial, and evaluation parts (Negi et al., 2019). The dataset consists of three columns: id, sentence, and label (see Table 1). The provided dataset is imbalanced in which, overall, Non-suggestion class is larger than Suggestion one.

3 Tools and Libraries

The common classification methods, such as Support Vector Machine, Random Forest Classifier, Linear Regression, and Naive Bayes application are facilitated by the most outstanding library for machine learning, namely, SciKit-Learn (Pedregosa et al., 2011). Correspond to its name, NLTK (Bird et al., 2009) is used as the toolkit for Natural Language Processing (NLP) operations such as tokenization, stemming, metrics, corpus, and classification. Pandas (McKinney, 2010) is chosen as the tools for collection and format the data because of its ease of use. The Keras library (Chollet et al., 2015) that runs on top of Tensorflow (Abadi et al., 2015) is also utilized for building high-level neural networks, i.e., for building the Convolutional Neural Network in this work. Furthermore, we utilize Seaborn[1] and Matplotlib library (Hunter, 2007) as confusion matrix visualization.

4 Classification Methods

This section details the classification methods used in our experiments on Suggestion classification.

4.1 Baseline

Baseline method provided by organizer utilizes the suggestion keyword, pattern string, and Part-Of-Speech (POS) Tagger matching. The list of suggestion keywords utilized in the baseline is "suggest", "recommend", "hopefully", "go for", "request", "it would be nice", "adding", "should come with", "should be able", "could come with", "i need", "we need", "needs", "would like to", "would love to", "allow", and "add". The baseline method also utilizes the wishes identification pattern string from (Goldberg et al., 2009). The POS tag of each word in the sentences is also done to collect Modal and Verb POS tag only. The classification is done by checking all words in the sentence. If the sentence contains one of the three matches, then the sentence is classified as a Suggestion class.

4.2 Common Classification Methods

Common classification methods, such as Support Vector Machine (SVM), Random Forest Classifier (RF), Linear Regression (LR), and Naive Bayes (NB) are employed in this research. Two types of SVM are utilized, that is, Linear Support Vector Machine Classifier (LSVC) and Sublinear Support Vector Machine Classifier (SSVC). The implementation of the common classification methods is available at (Fatyanosa, 2019c).

4.3 Variable Length Chromosome Genetic Algorithm-Naive Bayes

Variable Length Chromosome Genetic Algorithm - Naive Bayes (VLCGA-NB) is utilized for features selection. We follow the model and parameter from (Fatyanosa et al., 2018). The first step of VLCGA-NB is selecting initial features from keywords that appear in the Suggestion sentences but do not appear in the Non-suggestion ones in the training data. Within the randomly determined maximum chromosome size, these keywords are

9735	These page templates should be updated to use the medium-sized semibold font by default for the title text.	1
...	...	...

then randomly selected as genes in Genetic Algorithm (GA). Therefore, each chromosome within population will have different length with different genes. All populations resulting from the initialization then evolve through generation by passing the crossover, mutation, and selection operator. A number of children produced by crossover and mutation operator are based on Crossover Rate (CR) and Mutation Rate (MR). Two types of crossover are utilized in this research, viz., Union Crossover and Intersection Crossover. The mutation is done by changing the genes with another feature which is not contained in the chromosome. The gene which will be mutated within chromosome is selected by comparing the generated random value with the MR. If the random value is higher than MR, then the gene will be mutated. The purpose of the crossover operator is to help the algorithm to explore the search space, while the purpose of mutation operator is to exploit certain area in the search space. With these operators, there will be diversity within the population that can help to avoid early convergence. By ranking the fitness value using elitist selection, the next population for the next generation is selected from the prior population and the produced children. Only the chromosome with the highest ranking within the number of population will be selected. All these operators are then iterated until the maximum number of generations. The best chromosome produced in the last generation is then used as the Suggestion keywords in the baseline code provided by the organizer. GA, which is a well-known evolutionary algorithm, is one of the powerful stochastic and heuristic algorithms. The use of GA is legion as it can provide search space exploration through crossover operator and exploitation through mutation operator. Thus, GA is possible to search in a very wide search space and allow it to produce nearly optimal results. This ability becomes the motivation for feature selection using GA. However, the drawback of the GA is that it is not guaranteed to produce the global optimal, but instead satisfactory results. Moreover, GA requires parameter tuning to find the appropriate parameter based on the dataset and needs a longer runtime. Despite its drawback, we expect that GA can produce a limited number of Suggestion features which has a major contribution to the Suggestion classification in this work. The implementation of the VLCGA-NB is available at (Fatyanosa, 2019b).

4.4 CNN

For our purpose in this work, we follow the Keras model's architecture from (Chollet, 2017) as shown in Figure 1. This architecture tends to obtain high accuracy when applied on the Newsgroup dataset. The text classification using CNN is done in four steps. First, all sentences are converted into word index order. Only 20,000 frequently words with the upper limit length of 1000 words will be considered. Next, 100-dimensional Global Vectors for Word Representation (GloVe) embeddings are utilized as the embedding matrix. Then, this matrix is loaded into Embedding layer of Keras. Finally, the Softmax function is used in the final layer of CNN. The implementation of the CNN is available at (Fatyanosa, 2019a). Although there are several pre-trained word vectors, GloVe and word2vec are considered as the most popular vectors (Lee et al., 2016). Based on (Pennington et al., 2014), their GloVe vector has outperformed other word representations in terms of word comparison, correlation, and named entity recognition. We thus use the GloVe vector as our pre-trained word embedding in this work.

5 Experiments

We conducted the experiments with the seven classification methods in this section. We employed the datasets from both Subtasks for evaluating the

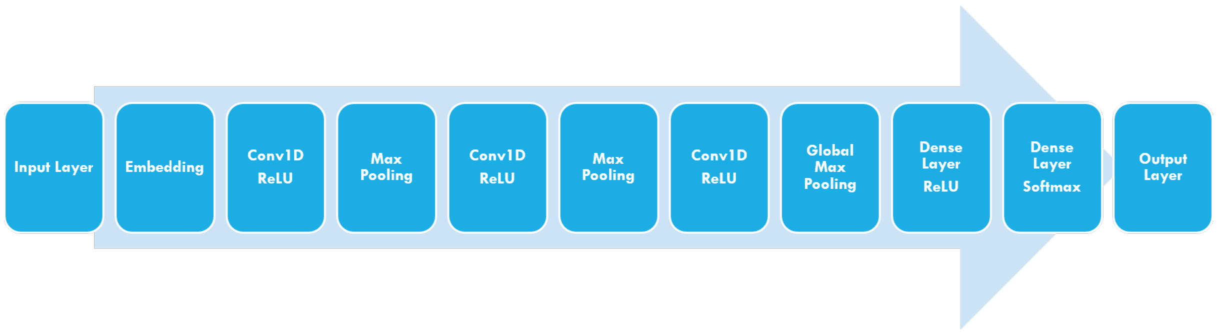

Figure 1: CNN Architecture from (Chollet, 2017)

performance of those classification methods. We compared the performance of seven classification methods against the baseline provided by the organizer.

5.1 Data Preprocessing

We performed a sequence of preprocessing steps to address noise in the data. For RF, MNB, LSVM, and LR, all features were converted into numerical feature vectors using the Term Frequency-Inverse Document Frequency (tf-idf) from *SciKit-Learn* with parameter *sublinear_tf=True, min_df=5, norm='l2', encoding='latin-1', ngram_range=(1, 2), stop_words='english'*. The obtained number of features was 3166. While the parameters of SSVM were *sublinear_tf=True, analyzer='word', tokenizer=tokenize, lowercase=True, ngram_range=(1, 1), stop_words=en_stopwords, norm='l2', min_df=3*. The obtained number of features was 3844.

The series of VLGCA-NB preprocessing was different from other classification methods because it did not need the vector form of words. All words were converted to lowercase. Number, stop words, punctuation, non-English words, non-alphabetic characters, and words smaller than two characters were removed, lemmatization was performed, and all contractions were replaced by their real words or phrases. The number of features was decreased to 493 after the preprocessing step.

5.2 Parameters

To apply CNN to the classification, we used fixed parameters with $maximumEpoch = 10$ and $batchSize = 100$. We also employed fixed parameters for VLCGA-NB with $Populationsize = 100$, $Generationsize = 50$, $Crossoverrate = 0.7$, and $Mutationrate = 0.3$.

RF, CNN, and VLCGA-NB are stochastic algorithms which mean the results will differ for each run. Therefore, those algorithms were run five times. The best result among the five attempts was selected for comparison with other algorithms.

5.3 Evaluation Measurement

Classifier performance evaluation using accuracy is often considered as a suited measurement. However, the datasets from both subtasks were imbalanced. Majority class is often reckoned by the classifier, thus, higher accuracy will be achieved for it. Therefore, in this research, we used Precision, Recall, and F1-Score as the main evaluation measures. Accuracy measurement (Equation (1)) was still used in the fitness function of VLCGA-NB. F1-Score (Equation (4)) computation relied on Precision (Equation (2)) and Recall (Equation (3)) measurements. As the Suggestion results were more concerned, the evaluation of this competition was the Suggestion results' F1-Score.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F1\text{-}Score = 2x\frac{Precision x Recall}{Precision + Recall} \quad (4)$$

$where:$
$TP =$ True Positive
$TN =$ True Negative
$FP =$ False Positive
$FN =$ False Negative

Evaluation measurement for VLCGA-NB was done in every generation using Fitness Function based on the result of Naive Bayes classification.

The Fitness value was found by addition of accuracy, F1-Score of Suggestion and F1-Score of Non-suggestion, which were defined as follows:

$$\begin{aligned} Fitness = Accuracy + F1\text{-}Score_{suggestion} \\ + F1\text{-}Score_{non-suggestion} \end{aligned} \quad (5)$$

6 Results and Discussion

In this section, we evaluated the classification performance of the seven classification methods with the baseline for both Subtasks. The methods performance was evaluated on Precision, Recall, and F1-Score metrics, except for the VLCGA-NB, we still used accuracy in the fitness function.

A typical observation from the confusion matrix produced in this research was that the number of correct classification was higher than the number of misclassified for the Non-suggestion class, except for baseline of Subtask A. This result was unvaried across all methods, with a little difference of the whole classification count. Though Subtask A aimed to classify Suggestion in the same domain, the number of correct classification of Suggestion class was lower than the number of misclassified for most of the classification methods. In particular, baseline and SSVC obtained better results than other utilized methods. Furthermore, as Subtask B aimed to classify Suggestion in the different domain, eventually it was hard for all classification methods to obtain even fair results. All of them failed to obtain a higher number of correct classification of the Suggestion class.

Table 2 shows the precision, recall, and F1-Score comparisons for each class in Subtask A. We noted that the obtained result of all classification methods outperformed that of the baseline for the Non-suggestion class. MNB yielded the best results with 0.95.

In terms of F1-Score of the Suggestion class, refer to Table 2, we noted that RF, SSVC, and VLCGA-NB obtained a competitive result outperforming baseline for Suggestion class. The highest F1-Score was obtained by SSVC at 0.47. RF and VLCGA-NB produced F1-Score at 0.29 and 0.31, respectively. Overall, note that MNB and SSVC obtained the best F1-Score for Non-suggestion and Suggestion classes, respectively.

Table 3 shows the experimental results for the dataset in Subtask B. We noted that the F1-Score of Non-suggestion yielded a good result with the higher F1-Score obtained by RF classifier. However, the F1-Score of Suggestion class produced poor finding, except for the baseline. F1-Score of Suggestion class using the baseline achieved surprisingly well considering their simplicity, which yielded 0.73. A possible reason for this finding might be that the manually selected keywords and patterns based on which usually used to suggest something would make use of the common Suggestion sentence that a machine might not be able to discover. A possible problem with the baseline approach was probably that the keywords and patterns for Suggestion class might be also used for Non-suggestion class. Therefore, it might be difficult for baseline to define which keywords and patterns actually used in Suggestion sentences. This could be proven from the F1-Score results for the Non-suggestion class in Subtask A which yielded the lowest result of 0.59.

Regarding the number of features selected by VLCGA-NB, the features were decreased from 493 to 372. Refer to our defined expectation in 4.3, VLCGA-NB was able to produce a limited number of features which has major contribution to the Suggestion classification. This could be proven from its F1-Score results which yielded higher value compared to the baseline in Subtask A.

7 Conclusion

This paper has described our approach for participating in both Subtask A and Subtask B of Task 9 of SemEval-2019, that is, suggestion mining from online reviews and forum (Negi et al., 2019). Our approach explored and compared various classification methods, namely, Random Forest, Logistic Regression, Multinomial NB, Linear SVC, Sublinear SVC, CNN, and VLCGA-NB. Since the datasets provided by the organizer were imbalanced data, it was more important to correctly classify a sentence as a Suggestion class. Thus, the F1-Score of the Suggestion class was more considered. Compared to the baseline, all algorithms performed better classification for the Non-suggestion class in both Subtask A and Subtask B. In contrast, they performed worse classification than the baseline for the Suggestion class in both Subtask A and Subtask B. This poor performance was except for the RF, SSVC, and VLCGA-NB that could outperform the baseline for classifying the Suggestion class in Subtask A. Based on our results, we observed that besides the imbalanced data, the implicit meaning problem related to the

CNN	0.58	0.51	0.96	0.05	0.73	0.1
VLCGA-NB	0.6	0.69	0.96	0.11	0.74	0.19

Suggestion class was also the challenge of the suggestion mining. The feature selection corresponds with the Suggestion class will be our future intention. In addition, it might be valuable to inspect further the use of our approach to other text classification tasks such as deceptive opinions (Siagian and Aritsugi, 2017, 2018) and fake news identifications.

DS at SemEval-2019 Task 9: From Suggestion Mining with neural networks to adversarial cross-domain classification

Tobias Cabanski
t.cabanski@posteo.de

Abstract

Suggestion Mining is the task of classifying sentences into suggestions or non-suggestions. SemEval-2019 Task 9 sets the task to mine suggestions from online texts. For each of the two subtasks, the classification has to be applied on a different domain. Subtask A addresses the domain of posts in suggestion online forums and comes with a set of training examples, that is used for supervised training. A combination of LSTM and CNN networks is constructed to create a model which uses BERT word embeddings as input features. For subtask B, the domain of hotel reviews is regarded. In contrast to subtask A, no labeled data for supervised training is provided, so that additional unlabeled data is taken to apply a cross-domain classification. This is done by using adversarial training of the three model parts label classifier, domain classifier and the shared feature representation. For subtask A, the developed model archives a F1-score of 0.7273, which is in the top ten of the leader board. The F1-score for subtask B is 0.8187 and is ranked in the top five of the submissions for that task.

1 Introduction

For getting feedback from costumers or users, an organization often uses forums and social media channels. Also ratings of products on rating platforms can be an useful feedback to make a product better. The feedback from a customer can be in the form of a suggestion which appears in a rating text or is directly asked from the customer. The task of suggestion mining can be defined as the extraction of sentences that contain suggestions from unstructured text (Negi et al., 2018). SemEval-2019 Task 9 Subtask A provides the challenge to do suggestion mining on data from an online suggestion forum. For that subtask, a train and validation set is provided so that it is possible to apply supervised training. For subtask B, suggestions in hotel reviews should be identified. An additional difficulty for that subtask is that no labeled data is given except a small validation set, which is not allowed to be used for supervised training. For both tasks, silver standard datasets are allowed to use, which means that data that is likely to belong to a certain class can be taken as long as it is not manually labeled. A more detailed task description can be found in (Negi et al., 2019).

2 Data

The dataset for subtask A provides an overall count of 8500 examples, where 6415 examples are labeled as non-suggestion and 2085 as suggestion. Also a trial dataset is provided that contains 592 examples, divided in 296 examples for each class. Every example contains only one sentence, which could be part of a whole post in the forum where it was extracted.

The domain of software suggestion forum posts in general provides more balanced data than other domains, for example hotel reviews. Also the domain contains very specific vocabulary which is frequently used in software development, so that it can be difficult to use a trained model of this domain for other domains (Negi et al., 2018).

For subtask B, only a validation dataset is provided. The set contains an overall count of 808 examples with 404 examples for each class. As mentioned in the introduction, it is not allowed to use the validation data for supervised learning for this subtask. The data is only allowed to be used for model evaluation and error analysis and also for automatic hyperparameter tuning. The presented solution in this paper uses the validation data for early stopping at a fixed count of train steps after the best score is reached. The model state at the best score is then returned and used for the prediction of the test data.

For both subtasks, additional data is allowed that is not manually labeled. In this work, the hotel review dataset, which is presented in (Wachsmuth et al., 2014), is used to apply cross-domain classification for subtask B. The dataset comes with nearly 200k examples of hotel reviews without labels.

3 Related Work

The task of text classification improved a lot during the last years. In the past, machine learning techniques like support vector machines were used to assign a class to a text. In (Joachims, 1998), a text classification with support vector machines is presented. For that, a document vector is extracted for the whole text and used as the feature vector for the classification.

Since such methods can provide a good base line today, the increasing popularity of neural network approaches provides new methods that can classify texts more exactly. Especially the introduction of word embeddings in (Mikolov et al., 2013) was a big step forward in the field of text processing and opened new opportunities for many natural language processing tasks. Also for the task of text classification, word embeddings are useful features and can lead to good results. Since the release of these word embeddings, many other word embedding approaches have been introduced. A very recent one is shown in (Devlin et al., 2018) and is called BERT: Bidirectional Encoder Representations from Transformers. These embeddings are the result of the training process of transformer, which is described in (Vaswani et al., 2017) and delivers a state-of-the-art method for different natural language generation tasks, especially for translation.

To use the word embeddings as features for text classification, a commonly used approach is Long-short term memory (LSTM), which is described in (Hochreiter and Schmidhuber, 1997). The advantage of using LSTM cells over support vector machines as classifier is the processing of features in time steps. By passing a single word embedding into a single time step of the LSTM, every feature is processed separately. Since the features are processed one after the other, also the order of the features has influence on the classification process. In addition to that, LSTM cells have a state that enables them to save information for many previous time steps. For text classification, this can be useful when there are connections between words in a text that are far apart.

Another method to process word embeddings are convolutional neural networks (CNN), which are introduced in (LeCun and Bengio, 1998). With the ability to extract features of two-dimensional input data by defining a sliding window of variables, the method is often used for image processing. But also good results for text classification are reported, for example in (Kim, 2014). The results show that even a simple CNN with one layer performs very well and a tuning of hyperparameters brings an improvement of the performance.

For subtask B, the focus gets in the direction of methods for cross-domain classification. By the introduction of Generative Adversarial Nets (GAN) in (Goodfellow et al., 2014), a new way for training neural networks was provided that leads to new opportunities for different task, especially image generation. In (Chen and Cardie, 2018) is shown that this training technique could also be used for cross-domain classification of texts of different domains. As the main four components, a shared feature extractor, a domain feature extractor, a text classifier and a domain discriminator are introduced. The main goal of that system is to learn a domain invariant feature representation by training the shared feature extractor with the discriminator and the text classifier. The discriminator learns to separate the domains and the training goal for the shared feature extractor is to increase the loss of the discriminator. The extracted features become invariant for the domains, so that the text classifier results improve for the domain where no labels are given.

4 Models

In this section, the models for subtask A and B are presented. The overall idea of the model for subtask A is using an ensemble of LSTM and CNN networks. As input features, pre-trained BERT embeddings for the texts are used.

For subtask B, the idea is to extend the model from subtask A with a domain discriminator and shared features. Since that adds a lot of parameters to the model, the text classifier has a simpler structure than in subtask A and uses only CNNs for classification. The full TensorFlow implementation of the models can be found at GitHub.[1]

[1]https://github.com/tocab/semeval2019Task9

4.1 BERT embeddings

For both subtasks, BERT embeddings are used to create a representation of the text. The TensorFlow implementation, which is openly available and comes with pre-trained multi-language embeddings, is taken for that.[2] The model for creating the embeddings is the small uncased model, which has been trained on lower cased wikipedia texts. It has a total count of twelve layers and a layer size of 768 in each hidden layer. The whole model has a 110 million parameters in total.

To extract the embeddings out of the model, the text gets tokenized and mapped into a sequence of integers by using the vocabulary of the pre-trained model. This representation is then given into the network, where it passes the different transformer layers. The embeddings are delivered by the hidden layers of the model. In this project, the output from the last four layers before the output layer is taken as the representation of a word, so that every word is represented by a vector of the shape $(4, 768)$.

4.2 Subtask A

For subtask A, a text classification ensemble of LSTM and CNN is built. To bring all sentences to the same length, a maximum sequence length of 40 is defined. With that sequence length, for around 95% of all train data sentences all words are taken as input. Only for the remaining 5% which have more than 40 words, the texts are cut to the maximum sequence length. If a text is shorter than 40 words, it is filled with zeros. Using the batch size of 64, the input shape for a batch for the training process is $(64, 40, 768)$ for every of the four extracted input features from BERT.

One problem of the data is the imbalance of the classes. When taking random batches out of the whole dataset, it is likely that the count of one class is always higher than of the other. The algorithm learns to predict the class with the higher example count with a higher probability. To avoid that, the technique of oversampling is applied to the training process. The data is separated into two sets, each for every of the two classes and then fed into the network alternately. When all examples of the class with the lower count were used as training input, the set gets repeated so that these examples occur more often as training input.

[2]https://github.com/google-research/bert

The model structure for subtask A can be divided into the three following main parts:

- Processing of single words with dense layers.
- Processing of the whole text with LSTM cells.
- Processing of sliding windows through the text with CNN.

For the processing of the dense layer and the LSTM, separated graphs are created for each of the input features from BERT. As mentioned before, four embeddings for a word are gathered, each of a different hidden layer of the transformer. Thus four graphs of dense layers and LSTM layers are created, each for processing a different embedding type of the input text.

The first step is a transformation of every single input word with a dense layer. This approach is applied to focus on single signal words that can occur in the text. For example, the occurrence of the word *recommend* could be a hint for a suggestion, without regarding other words. The outputs of the single word processings are concatenated and forwarded to a dense layer to reduce the dimension.

The LSTM is represented by two cells to realize a bidirectional approach. The output of the two cells is concatenated and followed by a `GlobalMaxPool`-Layer, which takes the maximum of the output's timestep axis to bring it into a one-dimensional representation. To do a further feature transformation, a dense layer is applied to the output. The result is concatenated to the output of the previous described single word approach.

Unlike the single word processing dense layer and the LSTM, the CNN approach processes all four BERT features for the words in the same network. When using CNNs for image processing, the colors of an image are arranged as additional channels that the CNN can process. For feeding the CNN with all BERT features for the words, they are shaped similarly to an image and can be seen as the channels of the word. By using that approach, the words are given with four channels into the CNN. The output of the CNN is then processed by a dense layer. The CNN approach can be seen as an bag of words approach, which takes the words within a sliding window until the end of text is reached. The amount of words is fixed, the approach is build for each of 2-5 words.

At the end of the processing, the dense- and LSTM-features and the CNN-features are concatenated and given to the classification layer, which is composed of two dense layers. For more robust predictions, three graphs are build to get three predictions, the final result is formed by the mean. For training the model, the cross-entropy-loss is used. The model gets optimized with `AdamOptimizer`. On every training step, the model is validated with the provided validation dataset, and the model weights on the best F1-score are taken to predict the test examples.

4.3 Subtask B

For subtask B, a similar model as in (Chen and Cardie, 2018) is built to do cross-domain classification. The model in this work is composed of three major parts:

- **Label classifier**: Model that predicts if an example is a suggestion.
- **Domain classifier**: Model for the prediction of the domain of an example.
- **Shared features**: Model that applies a transformation on the input features.

The training of the model can be split into two phases: The pre-training phase of the supervised label classifier and the adversarial training of the domain classifier and the shared features.

In the pre-training phase, the model uses supervised training like for subtask A. In this phase, the label classifier and the shared features are trained to get the best score on the suggestion data of the domain of online suggestion forums. The shared features get the word embeddings as input and apply a CNN on each BERT embedding. The size of the CNNs is the same as the length of the embedding, so that the projected word features are of the same shape as the input features.

In the next step, the projected features are classified with the label classifier. Unlike to subtask A, only the CNN part is used for the classification because of the amount of additional parameters of the shared features and the domain classifier. The CNN works like in subtask A and processes the four BERT features as single channels. In this task, a sliding window of the word counts from 2-6 words is taken. The optimization is applied with `AdamOptimizer` and stops when the best score is reached on the validation data of subtask A.

#suggestions	2085	296	87	133
#non-suggestions	6415	296	746	700

Table 1: Count of the examples for the different datasets and the prediction on the test set for subtask A.

In phase two, the domain classifier starts with the training and learns to choose the right domain for the examples. To do that, also examples of the unlabeled hotel review dataset are given into the net. The domain classifier has the same structure as the text classifier and uses CNNs to find the right label for an example.

After one train step of the domain classifier, the shared features are retrained in an adversarial way to maximize the loss of the domain classifier. To realize this, the parameters are trained with the switched labels for the hotel review examples which are marked as suggestions for this training step.

After the training step of the domain classifier and the shared features, the validation examples of subtask B are used to predict a score. To do that, the examples are predicted with the text classifier, which uses the updated shared features to make a prediction if the example is a suggestion. Early stopping is used to find the best model with the validation data, so the model stops at the maximum F1-score for the validation set for subtask B.

5 Results

In this section, the results for subtask A and B are discussed. Also the test data, which has been provided to the participants after the evaluation phase, is used for the analysis.

5.1 Subtask A

For subtask A, the best model reached a F1-score of 0.7273 for the test data. This model archived a validation F1-score of 0.875 which is a noticeable difference to the test data score. To find the difference in the datasets, the example counts are compared in Table 1. It can be seen that there are differences in the ratio of the data. While the train data contains about 25% of examples for suggestions, for the test data there are only about 15%. Since oversampling is used to tackle the problem of class imbalance, this difference of train and test

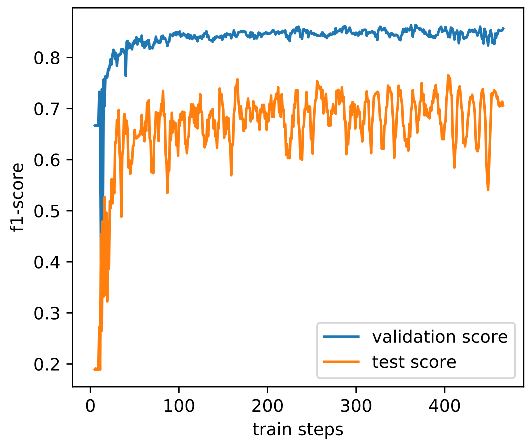

Figure 1: Comparison of the F1-scores for validation and test set during training for subtask A.

data should not have much influence on the result. Also the counts of predicted classes for the test set can be seen in the table, which show a similar amount like the test classes, but has some more predictions for the class of suggestions.

Another factor for the gap between validation and test score could be explained by very different examples in the two sets. In addition to that, the validation set may be better represented by the train set. That could lead to bad results for the test data when stopping at a good F1-score for the validation data. For analyzing this, another train run is started and the curve for the F1-score for the validation set and the test set plotted. The outcome can be seen in Figure 1.

It can be seen that the test F1-score is constantly lower than the validation score. Also there are much variations in the test score, even in a late train phase. Overall it can be determined that the train data describes the validation data better than the test data with the given model for subtask A.

5.2 Subtask B

The model for subtask B reached a final F1-score on the test data of 0.8187. In comparison to subtask A, it can be seen that the final score on the test data is higher, although no labeled data is given for that task except the validation data. The reason for this could be the use of the external hotel review dataset that inputs many new examples into the model. The overall count of examples for hotel reviews is much higher than the labeled data in subtask A, so that the higher score can be explained with the presence of more data.

	val	**test**	**pred**
#examples	808	824	824
#suggestions	404	348	402
#non-suggestions	404	476	422

Table 2: Subtask B dataset and prediction counts.

Also the validation score of 0.884 doesn't differ to the test score as much as in subtask A. This also shows that the use of external data improves the overall result of the model. The validation data for subtask B was used to apply early stopping and saving the weights at the best validation F1-score. Like for subtask A, the class counts for the different datasets are shown in Table 2. It can be seen that the distribution of the classes in the test and validation set is more equal than in subtask A, what could be a reason why the model archived better results. To verify this, another training run is started to compare the test and validation F1-score over the training epochs. The results can be seen in Figure 2. The validation data score for subtask A and B and the test score for subtask B is plotted for every training step. Since the training is separated into two phases, the left graph shows the scores for the pre-training phase and the right graph for the adversarial training.

In the pre-training phase of the model, the score of the validation data of subtask A improves as expected since supervised training is performed. Also it can be seen that the subtask B data score shows a high variance over the epochs, but decreases slightly. Over all epochs, the test and validation score of subtask B is nearly the same what could be a hint that the difference between the datasets is very small. This is confirmed in phase two of the training, where the validation and test score increase in the first epochs. Although the validation score reaches a higher peak for the F1-score, the peak of the test score is found in around the same region of train steps. The validation score for subtask A decreases in the adversarial train phase, what could be caused by a overfitting to the hotel review domain. Also the validation score of subtask B decreases after about 50 epochs. The reason for that could be that the amount of non-suggestions in very high in the hotel reviews data, so that the model unlearns to distinguish between the two classes.

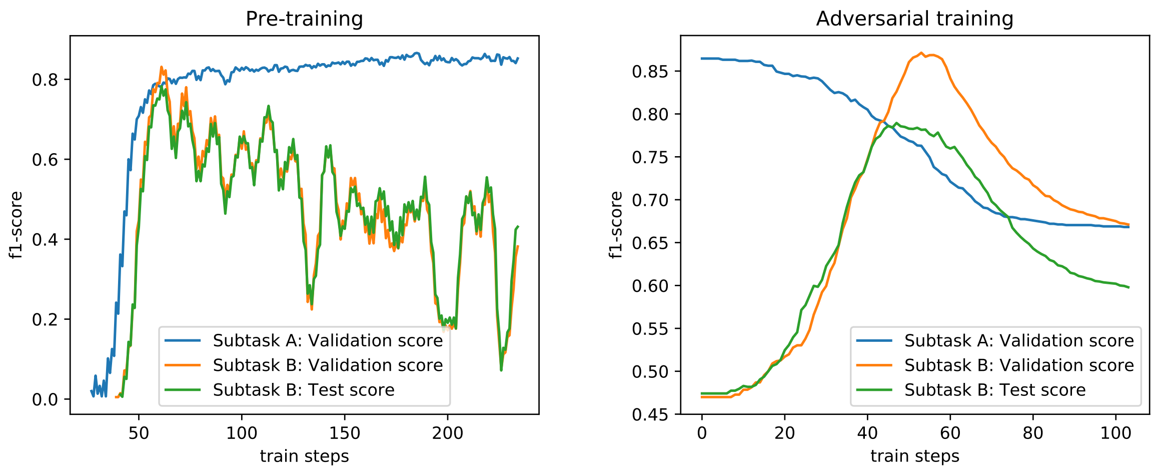

Figure 2: Two training phases for subtask B: First the pre-training with the subtask A data, then the adversarial training with the hotel review dataset.

6 Conclusion and Future Work

In this work, for each subtask of SemEval-2019 Task 9 a solution is presented. For subtask A, a supervised model is built on the neural network techniques CNN and LSTM. As input features, BERT word embeddings are taken, which are pre-trained on huge datasets. One problem in subtask A is the class imbalance of the data, which is tackled with oversampling. Another problem that occurred during the evaluation of the training phase is the difference of examples in the validation and the test set, what could be one of the reasons why the validation score is much higher than the test score. In future works, it can be tried to extend the labeled data with additional unlabeled data to tackle the problem of class imbalance and too few examples. Since extending the data works for subtask B, it could also work for subtask A and the domain of suggestion forum posts.

Subtask B sets the task to classify sentence as suggestion or non-suggestion for the domain of hotel reviews. Unlike to subtask A, only a small validation set is given as labeled data which is not allowed to be used for supervised training. To solve the problem of not having labeled data, the technique of cross-domain classification has been used. This is done by building a neural network model, which is trained in an adversarial way. Like in subtask A, a classification model for the suggestions is given. In addition to that, a shared feature representation and a domain classifier are added. The domain classifier is trained to assign the right domain label to a sentence. The shared feature representation is trained adversarial to the domain classifier, so that it learns to generate a global representation for both domains. For that, an unlabeled external dataset is taken which contains examples for the domain of hotel reviews.

The results for subtask B show that the adversarial training can improve the F1-score for the domain with no labeled data. This happens with the cost of lowering the score for the labeled data, on which the model was pre-trained. Also the score for the hotel review data falls down after the peak is reached. This makes it necessary to have at least a small dataset which contains labeled data for subtask B to measure the score during the training and stop when best score has been reached. For future work, it could be tried to develop a better shared features method where a good feature representation for both domains is formed. That would give a classifier that could be used to predict sentences of both domains. Another improvement could be archived by developing a model where the curve for the unlabeled data doesn't fall down that sharply in the late train phase. This could lead to a method were no labeled data is needed to stop the training at a good point.

aysu.e.can@gmail.com

Ethem F. Can
SAS Inst.
ethfcan@gmail.com

Abstract

Social media has an increasing amount of information that both customers and companies can benefit from. These social media posts can include Tweets or be in the form of vocalization of complements and complaints (e.g., reviews) of a product or service. Researchers have been actively mining this invaluable information source to automatically generate insights. Mining sentiments of customer reviews is an example that has gained momentum due to its potential to gather information that customers are not happy about. Instead of reading millions of reviews, companies prefer sentiment analysis to obtain feedback and to improve their products or services.

In this work, we aim to identify information that companies can act on, or other customers can utilize for making their own experience better. This is different from identifying if reviews of a product or service is negative, positive, or neutral. To that end, we classify sentences of a given review as **suggestion** or **not suggestion** so that readers of the reviews do not have to go through thousands of reviews but instead can focus on actionable items and applicable suggestions. To identify suggestions within reviews, we employ a hybrid approach that utilizes a recurrent neural network (RNN) along with rule-based features to build a domain-independent suggestion mining model. In this way, a model trained on electronics reviews is used to extract suggestions from hotel reviews.

1 Introduction

With the growth of social media usage, the interest in text mining approaches has increased. One task that has gained momentum recently is sentiment analysis where the goal is to determine opinions/emotions from a text input, generally a product or service review. Different approaches have been proposed for sentiment analysis task such as multilingual models to be used with limited data (Can et al., 2018) and sentiment lexicons (Banea et al., 2008). Twitter posts also has been one source of reviews to be mined in terms of sentiment (Pak and Paroubek, 2010; Ezen-Can and Can, 2018; Tellez et al., 2017).

The task of suggestion mining is similar to sentiment analysis in that the input is the same (e.g., customer reviews). However, the output of a sentiment analysis model and a suggestion mining model is different. While sentiment classifiers focus on grouping reviews as positive or negative, suggestion mining models identify the reviews that have suggestions/actionable items/advice to other people/service providers.

In this paper, we present a suggestion mining model that takes product/service reviews and classifies each sentence in a given review as suggestion or not suggestion. To that end, we employ a hybrid LSTM model that utilizes both the textual reviews and features extracted from a rule-based approach.

2 Related Work

For the suggestion mining task, there is not a large body of work in the NLP community. (Brun and Hagege, 2013) use a corpus of reviews of printers made by different manufacturers. Their approach relies on linguistic information such as thesaurus, parser and patterns. (Goldberg et al., 2009) address the task of suggestion mining as a 'wish detection' task and use templates to detect wishes on product reviews and political discussion posts. (Dong et al., 2013) focus on Tweets and classify them as containing suggestion or not by using factorization machines. (Wicaksono and Myaeng, 2013) employed Hidden Markov models with three different sets of features: syntactic, contextual, and sentence informativeness features.

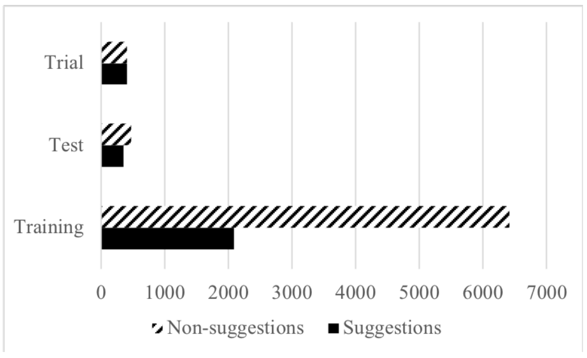

Figure 1: Distribution of classes in the training, trial and test sets.

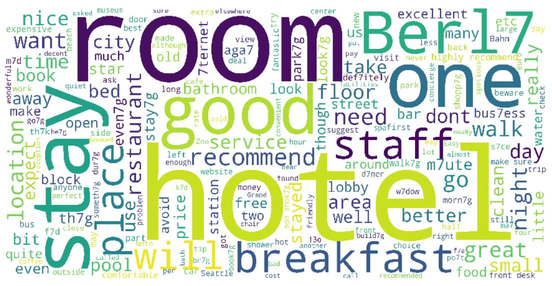

Figure 2: Word cloud of the reviews in the test set.

Recently, (Negi and Buitelaar, 2017) collected a new corpus for suggestion mining (not available at the time of this writing).

Our approach is different from the existing prior work in that we use a hybrid approach where a deep learning model is used in addition to a rule-based technique. The features extracted by rule-based approach are utilized as information sources to an LSTM network where the customer reviews are also fed into as textual input. In this way, we intend to use as many information sources as possible to improve results of a suggestion mining classifier.

3 Corpus

The corpus provided by the Semeval 2019 Suggestion Mining Challenge (Negi et al., 2019) was highly imbalanced as can be seen in Figure 1. There was a total of 8500 reviews, only 2085 of which were suggestions. The test set consisted of 824 observations.

Due to the nature of the challenge, the training set and the test set were from different domains. While the training set contained software/application reviews, test set was collected from hotel reviews. An excerpt from the training set can be seen in Table 1. The word clouds for these two datasets (Figures 2 and 3) show the difference in the most frequently used words.

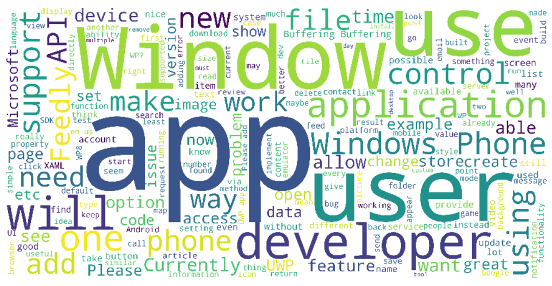

Figure 3: Word cloud of the reviews in the training set.

Review	Class
"I would like to be able to enable WP alerts be forwarded to XBox One when I am near it or manually configured for it."	Suggestion
"When you apply new policies on already existing, especially if it is related to name, all the existing credibility and market is lost."	Non-suggestion
"I find myself having to manually tab out get figures, enter them in."	Non-suggestion
"Possible solution: Route class implements IRoutePath."	Non-suggestion
"Street names color stays black and not being centered."	Non-suggestion

Table 1: Excerpt from the training set.

4 Methodology

In this section, we explain the model architecture used for the task of suggestion mining and the features utilized by the model.

4.1 Features

For suggestion mining, we used two sets of features: rule-based and model-generated from word embeddings. In this section, we describe each of these features.

4.1.1 Rule-Based Features

The rule-based features are extracted from the heuristics used in the baseline system for this challenge. Below are explanations of each of these rule-based feature.

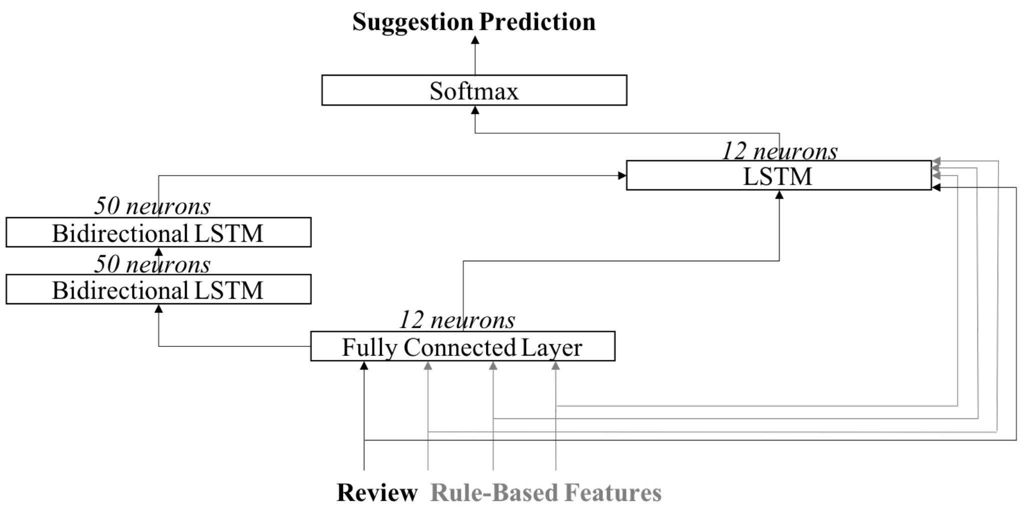

Figure 4: RNN architecture incorporating two different sources of information.

- *Rule-Based Feature 1:* the first rule-based feature is using a pattern matching algorithm based on regular expressions. This heuristic focuses on finding keywords and patterns within the input text such as '.*would \s like.*if.*' and '.*i \s wish.*'. Existence of at least one of these patterns in the review triggers a value of 1 for this feature, 0 otherwise. There are 13 patterns for this heuristic.

- *Rule-Based Feature 2:* the second rule-based feature utilizes keywords without any patterns such as 'suggest', and 'recommend'. Once one of the keywords in the list is present in the given review, the rule flags a 1 value indicating that the review contains a suggestion. There are 17 keywords in total.

- *Rule-Based Feature 3:* the third rule-based feature relies on part of speech tags. There are two part of speech tags that this heuristic is looking for (i.e., MD and VB) to be present in the tagged review to come to the conclusion that the given review is a suggestion.

4.1.2 Word Embeddings

Recurrent neural networks requires a mechanism to convert textual input to numerical vectors to be able to perform computations. To this end, we used pre-trained word embeddings where each word in the embedding table has a vector of size 100. In this study Glove embeddings is used which was trained on Wikipedia 2014 and Gigaword 5 corpora (Pennington et al., 2014).

4.2 RNN Architecture

As part of the RNN architecture, we used a fully-connected layer that takes the rule-based features and the review as the inputs. Then two bidirectional LSTM layers follow for modeling the textual input. Before the softmax layer, an LSTM layer takes the advantage of both learned representations form bidirectional layers and the rule-based features. Figure 4 depicts the architecture of the RNN model.

In the bidirectional layers, we used a dropout of 0.2 and MSRA initialization (He et al., 2015) in all layers. The training set is shuffled randomly before the first epoch. During training, ADAM optimizer (Kingma and Ba, 2014) with gradient clipping is used.

4.3 Ensemble

To fuse the different approaches utilized during the modeling phase, we used an ensemble technique. This technique take the outputs of both the rule-based features and the RNN model. If one of the rule-based features classify the review as a suggestion, the ensemble concludes that the review is a suggestion. If rule-based features classify the review as a non-suggestion and RNN classifies as a suggestion, the overall ensemble labels the observation as a suggestion. Otherwise, a non-suggestion tag is used. It is important to note that, RNN is also incorporating the rule-based features in the model. As can be seen in Figure 4, two main sources of information are fed into the model.

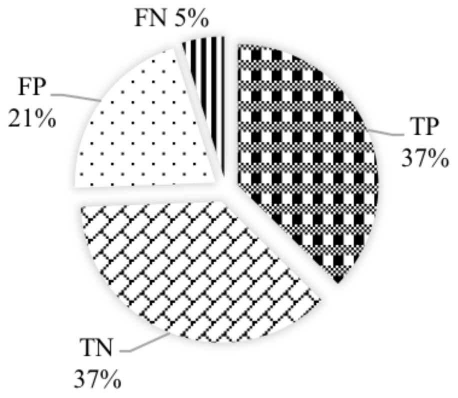

Figure 5: Pie chart showing false / true positives / negatives in the final predictions on the test set.

"and I was woken by the early morning firing up of the local bus service (a courtyard-facing room is essential unless you have industrial strength earplugs.)..."
"Don't eat breakfast in the restaurant, too costly."
"Look around the same area for another hotel."
"Avoid these rooms - it is very clear why they do not have a photograph of them on their web site."

Table 2: Samples from true positives.

5 Results

In this section, we report the results for the test set as well as discussion on the results.

5.1 Experimental Results

For the trial dataset, where the domain was hotel reviews and the majority baseline was 50%, the hybrid approach achieved F1 measure of 77.70%. It is important to note that, trial dataset has not been used to tune or validate the model. With the test dataset, the model obtained 74.49% F1 score where the majority baseline was 57.77%.

5.2 Discussion

Figure 5 shows the ratios of true/false positives and true/false negatives. From our investigation, we found out that the hybrid approach was useful in generalization of the model where the reviews did not have any keywords or patterns defined in the rules. Since RNN used generic pre-trained word embeddings (not specifically trained on either of the domains of the training set or the test set), generalization is expected for RNN. Some examples of such test observations can be seen in Table 2.

"Only one almost useless pillow per person though (think no thicker than a cracker) and no availability of additional bed linen as most other hotels would normally provide."
"Leaving your bedroom window open is not an option as my heavily bitten body will testify!"
"No shampoo provided in the room, Shower Gel dispensers don't work well."
"Put your towel on the wet floor or you will definitely slip."

Table 3: Samples from false positives.

An interesting finding in the results is about false positives. The trend observed in the false positives is that, the reviews that were helping other customers and giving hints *to the customers* rather than *to the service providers* were considered as suggestions by the model. Table 3 shows examples of those reviews where the ground truth considered these reviews as non-suggestions. However, they are suggestions to the receiving end of the service. This finding shows the difficulty of classifying this dataset because suggestions to customers and service providers can both be considered as suggestions (although not labeled as such in the ground truth).

6 Conclusion

Suggestion mining is a crucial task for mining social media data so that companies can focus on services that need improvement. Most of the times, obtaining labeled data in several different domains is not easy. Therefore, in this paper, we focused on domain-independent suggestion mining models where the training set and test set have reviews for different domains. To make our model robust, we utilized a hybrid approach that incorporates both rule-based features and relationships extracted by LSTM from raw text input. Instead of having to decide between rule-based approaches and deep learning, we fused the information sources in two ways. First by using external features in RNN and second by ensembling the result of RNN with rule-based features. By incorporating multiple information sources, we showed that the suggestion mining accuracies outperformed the baseline.

Abstract

We present the INRIA approach to the suggestion mining task at SemEval 2019. The task consists of two subtasks: suggestion mining under single-domain (Subtask A) and cross-domain (Subtask B) settings. We used the Support Vector Machines algorithm trained on handcrafted features, function words, sentiment features, digits, and verbs for Subtask A, and handcrafted features for Subtask B. Our best run archived a F1-score of 51.18% on Subtask A, and ranked in the top ten of the submissions for Subtask B with 73.30% F1-score.

1 Introduction

Suggestion mining can be viewed as a task of extracting suggestions from unstructured text samples (Ramanand et al., 2010; Negi and Buitelaar, 2015). The task goes beyond the sentiment polarity detection and is useful for a variety of purposes, e.g., organizations can improve their products basing on the suggestions from online sources without the need of manually analyzing large amounts of unstructured data (Dong et al., 2013).

In this first edition of the suggestion mining SemEval task (Negi et al., 2019), two settings of the task are addressed: single-domain (or domain-specific) suggestion mining, where the training, development, and test sets belong to the same domain (in the context of this shared task, suggestion forum for Windows platform developers), and cross-domain setting, where training and development/test sets belong to different domains (training on developer suggestion forums and testing on hotel reviews). In the both domains, only explicit expressions of suggestions are considered: lexical cues of a suggestion are explicitly mentioned in the text (Negi et al., 2018).

We approach the task from a machine-learning perspective as a binary classification of given sentences into suggestion and non-suggestion classes. We propose a straightforward approach that can be applied when the availability of training/evaluation data and external linguistic resources is scarce, and evaluate it in the context of this shared task. We were particularly interested in evaluating our approach under cross-domain conditions (Subtask B), since this setting is more common in a real-word scenario of the task.

Further, we briefly describe the datasets used in the competition and focus on the configuration of our system.

2 Data

The training dataset provided by the organizers, as well as the development and test sets for Subtask A consist of explicit suggestion and non-suggestion sentences extracted from the feedback posts on the Universal Windows Platform[1], while the development and test sets for Subtask B are on a different domain: a subset of the sentiment analysis dataset of hotel reviews from the TripAdvisor website (Wachsmuth et al., 2014).

The training, development (dev.), and test datasets statistics in terms of the total number (no.) of sentences, the number of suggestion sentences, and the percentage (%) of suggestion sentences is provided in Table 1. A more detailed description of the datasets used in the shared task can be found in (Negi et al., 2019).

Dataset	Total no. of sentences	No. of suggestions	% of suggestions
Training	8,500	2,085	24.53%
Dev. (Subtask A)	592	296	50.00%
Dev. (Subtask B)	808	404	50.00%
Test (Subtask A)	833	87	10.44%
Test (Subtask B)	824	348	42.23%

Table 1: Suggestion mining datasets statistics.

[1]https://www.uservoice.com

As one can see from Table 1, the distribution of the suggestion and non-suggestion classes is balanced in the development sets, but imbalanced in the training and test data, which is closer to the usual distribution of the suggestion sentences in online reviews and forums (Asher et al., 2009; Negi and Buitelaar, 2015; Negi et al., 2018).

3 Methodology

In this section, we describe the features we used and the experimental setup of our best run.

3.1 Features

Handcrafted features Following previous studies on suggestion mining (Ramanand et al., 2010; Brun and Hagège, 2013; Negi and Buitelaar, 2015), we manually selected a list of representative keywords and patterns of a suggestion from the training and development data. It has been shown that suggestion expressions often contain modal verbs (Ramanand et al., 2010), e.g., *should*, *would*, which are included in our list. We also consider some verbs in their infinitive form, e.g., *suggest*, *recommend*, as well as other lexical cues such as comparative adjectives, e.g., *better*, *worse*. For Subtask A, we used a set of 57 handcrafted keywords and 77 keywords were used for Subtask B. Some of the keywords used for Subtask B did not contribute to the results obtained on the subtask A development data, and therefore were discarded. The number of such heuristic keywords in each sentence was used as a feature for the machine-learning algorithm.

Function words Function words are considered one of the most important stylometric features (Kestemont, 2014). We hypothesize that the distribution of function words is different for suggestion and non-suggestion sentences. The function word feature set consists of 318 English function words from the scikit-learn package (Pedregosa et al., 2011). Each function word was considered as a separate feature for Subtask A.

Sentiment features As mentioned in (Brun and Hagège, 2013; Negi et al., 2018), suggestions are usually expressed when a person is not entirely satisfied with the product. To capture this, we used the sentiment information from the NRC Word-Emotion Association Lexicon (Mohammad and Turney, 2013) focusing on words with negative polarity. The number of negative sentiment words in each sentence was used as a feature for Subtask A.

Digits We used the number of digits in a sentence as a feature for Subtask A. This feature is used to evaluate wether the language used in suggestion expressions is more "concrete" (as opposed to abstract) and digits usage can be one of such indicators. Other types of named and numeric entities we examined did not improve our results.

Verbs Following the work by Negi and Buitelaar (2015), we used the number of verbs in a sentence as a feature for Subtask A. The parts-of-speech (POS) tags were obtained using the TreeTagger software package (Schmid, 1995).

When used for Subtask B, function words, sentiment features, digits, and verbs did not improve the performance of our system.

3.2 Experimental setup

Classifier We used the scikit-learn (Pedregosa et al., 2011) implementation of the Support Vector Machines (SVM) algorithm, which is considered among the best-performing algorithms for text classification tasks in general, including when cross-domain conditions and binary classification are concerned (Markov et al., 2017), and for the suggestion mining task in particular (Negi and Buitelaar, 2015; Negi et al., 2016). We set the class_weight parameter to 'balanced' and the penalty parameter (C) to 0.01 for Subtask A and to 0.0001 for Subtask B, tuning the parameters according to the results on the development data.

Weighting scheme We used term frequency (tf) weighting scheme, i.e., the number of times a term occurs in a sentence.

Evaluation For the evaluation of our system, we conducted experiments on the development sets for Subtasks A and B measuring the results in terms of precision, recall, and F1-score for the positive class (the official metric). For training our system, we used only the data provided by the organizers: when evaluating on the development data, we trained our system on the training datasets, while when evaluating on the test data, we merged the training and Subtask A development sets.[2]

[2]Participants were prohibited from using additional hand-labeled training data of the same domain for Subtask B.

4 Results and discussion

First, we present the results in terms of precision (%), recall (%), and on F1-score for the positive class (%) obtained on the Subtask A development data. The contribution of each feature type incorporated in our system is shown through an ablation study in Table 2. The number of features (No.) is also provided.[3] The handcrafted features and function words are the most indicative features in our system (when used in isolation they achieve a F1-score of 72.76% and 69.77%, respectively), while other types of features slightly improve the performance of our system.

Features	Precision	Recall	F1-score	No.
All features	77.93	78.72	78.32	275
– handcrafted	75.00	66.89	70.71	274
Drop:	**2.93**	**11.83**	**7.61**	
– function words	71.72	71.96	71.84	4
Drop:	**6.21**	**6.76**	**6.48**	
– sentiment features	77.29	77.03	77.16	274
Drop:	**0.64**	**1.69**	**1.16**	
– digits	77.52	78.04	77.78	274
Drop:	**0.41**	**0.68**	**0.54**	
– verbs	77.67	78.72	78.19	274
Drop:	**0.26**	**0.00**	**0.13**	

Table 2: Ablation study of the feature types used for Subtask A.

The results in terms of precision, recall, and F1-score on the development sets for Subtasks A and B, as well as the official results obtained on the test sets are provided in Table 3. The results for the rule-based baseline approach proposed by the organizers are also presented.

Subtask A	**Precision**	**Recall**	**F1-score**
Baseline dev.	58.72	93.24	72.06
Our dev.	77.93	78.72	78.32
Baseline test	15.66	91.95	26.76
Our test	38.92	74.71	51.18
Subtask B	**Precision**	**Recall**	**F1-score**
Baseline dev.	72.85	81.68	77.01
Our dev.	85.42	82.67	84.03
Baseline test	68.86	78.16	73.22
Our test	73.62	72.99	73.30

Table 3: Results for the INRIA and the baseline approaches on the development (dev.) and test sets for Subtasks A and B.

[3]Note that we use function words as features (274 features), while the number of occurrences of the handcrafted keywords, sentiment features, digits, and verbs is considered as a feature (4 features in total).

Though the F1-score achieved by our system is higher than the one achieved by the official baselines in all cases, there is a considerable drop on the test sets: 27.14% F1-score drop for Subtask A and 10.73% for Subtask B. For Subtask A, the drop is mainly caused by the low precision achieved on the test set (precision of 77.93% on the development set and 38.92% on the test set).

After the evaluation period, in order to examine whether the drop in precision and the large number of false positives provided by our system on the Subtask A test set is partly related to the different distribution of classes in the development and test data – 50% and 10.44% of suggestions, respectively (see Table 1) –, we balanced the classes in the training and test sets to be in phase with each other and evaluated the impact of classes distribution on the results achieved by our system:

- *Test-like distribution*: we randomly removed positive examples from the training data so that the distribution of classes in the training set is the same as in the test set (10.44% of positive examples instead of 26.19% in the merged training and Subtask A development data).

- *Train-like distribution*: we removed negative examples from the test data so that the distribution of positive classes in the test set is the same as in the training data (26.19% instead of 10.44%).

The results for these two experiments are shown in Tables 4 and 5.[4]

Setting	Precision	Recall	F1-score
Original distribution	38.92	74.71	51.18
Test-like distribution	41.96	75.86	54.03
Gain:	**3.04**	**1.15**	**2.85**

Table 4: Results for the original and test-like distributions of positive classes.

Setting	Precision	Recall	F1-score
Original distribution	38.92	74.71	51.18
Train-like distribution	64.87	74.71	69.07
Gain:	**25.95**	**0.00**	**17.89**

Table 5: Results for the original and train-like distributions of positive classes.

[4]The result for the test-/train-like distributions was calculated as average over three experiments removing three different sets of positive/negative examples.

As one can see from Tables 4 and 5, balancing the distribution of positive classes, so that it is the same in the training and the evaluation data, enhances the performance of our system (by around 3% in the test-like setting and around 18% in the train-like setting) mainly due to the increase in precision, which indicates that the distribution of calsses should be taken into account when developing a robust suggestion mining system.

5 Conclusions

We presented the description of the best submission of the INRIA team to the suggestion mining shared task at SemEval 2019. Our approach is based on the Support Vector Machines algorithm trained on handcrafted features, function words, sentiment features, digits, and verbs for Subtask A (single-domain setting). For Subtask B (cross-domain setting), only handcrafted features are used. Our best run showed 51.18% F1-score for Subtask A and 73.30% for Subtask B. The results obtained on the test sets are lower than on the development data. Additional experiments revealed that the drop in F1-score is partly related to the different distribution of classes in the training data and in the development set used to evaluate and tune our system. In future work, we plan to improve our list of handcrafted features to make our system robust to variations in the distribution of classes and across different suggestion mining domains.

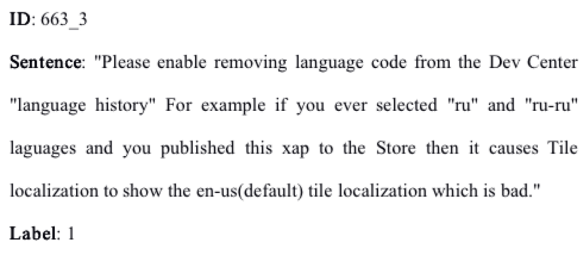
Abstract

In this paper, we describe a suggestion mining system that participated in SemEval 2019 Task 9, SubTask A - Suggestion Mining from Online Reviews and Forums. Given some suggestions from online reviews and forums that can be classified into suggestion and non-suggestion classes. In this task, we combine the attention mechanism with the LSTM model, which is the final system we submitted. The final submission achieves 14th place in Task 9, SubTask A with the accuracy of 0.6776. After the challenge, we train a series of neural network models such as convolutional neural network(CNN), TextCNN, long short-term memory(LSTM) and C-LSTM. Finally, we make an ensemble on the predictions of these models and get a better result.

1 Introduction

Suggestion mining can be defined as the extraction of suggestions from unstructured text, where the term “suggestions” refers to the expressions of tips, advice, recommendations etc(Negi et al., 2019). These suggestions largely express positive and negative sentiments towards a given entity, but also tend to contain suggestions for improving the entity. Suggestion mining remains a relatively young area compared to Sentiment Analysis, especially in the context of recent advancements in neural network based approaches for learning feature representations. In this task, suggestion mining that classified sentences into suggestion and non-suggestion classes was defined by the organizer.

In this paper, we mainly use an attention-based LSTM model(Hochreiter and Schmidhuber, 1997) for this task. The word-embedding used for all models in this task is Word2Vec. Then, the word vectors are fed into the long short-term memory (LSTM) layer. Finally, an attention mechanism(Luong et al., 2015) is added into the neural networks, and the prediction results are output via the softmax activation. What’s more, we try a number of other models (such as the TextCNN(Kim, 2014), the C-LSTM(Zhou et al., 2015) and the attention-based Bi-LSTM(Lai et al., 2015)) for comparative experiments. Furthermore we combine all of the above models to get results by soft voting.



ID: 663_3

Sentence: "Please enable removing language code from the Dev Center "language history" For example if you ever selected "ru" and "ru-ru" laguages and you published this xap to the Store then it causes Tile localization to show the en-us(default) tile localization which is bad."

Label: 1

Figure 1: An example from the SemEval 2019 Task 9 dataset

The rest of our paper is structured as follows. Section 2 introduces models. Section 3 describes data preparation. Experiments and evaluation are described in Section 4. The conclusions are drawn in Section 5.

2 Model

For this task, we use 6 models for experiments. Among these models, the attention-based LSTM models can get the best results. This model combines the attention mechanism with the LSTM. The attention mechanism is a good solution to the information vanish problem in long sequence input situations. When dealing with machine comprehension problems, the LSTM and the attention mechanism are more effective than they are used individually.

For this task, we have 4 chances to submit our result in the final submission. We use different methods that are the attention-based LSTM, C-LSTM and ensemble different models.

In this task, we not only select some single models but also use the ensemble model architecture(Sarle, 1996). The ensemble model(Kuncoro et al., 2016) architecture, shown in figure 1, is an ensemble of many single models(We call them sub models)(Dietterich, 2000). Because each sub model is independent of each other, their weights are not shared and just use the same word embedding when training each sub model. The process of the whole ensemble model is carried out model by model. First, each model is run independently, and then the result file is saved. After running all the independent models, the result files are taken out and the final result is determined by the soft vote(Rokach, 2010).

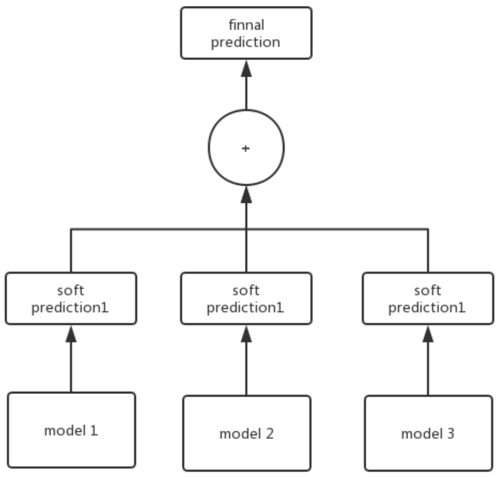


Figure 2: The architecture of the models ensemble

2.1 CNN and TextCNN

The convolutional neural network was originally used to process image data. In recent years, the application of convolutional neural networks has gradually penetrated into many different fields, such as speech recognition and natural language processing. The convolutional neural network consists of three parts. The first part is the input layer. The second part consists of *n* cyclic layers and collection layers. The third part consists of a fully connected multi-layer perceptual classifier. The difference between a cyclic neural network and a common neural network is that the convolutional neural network consists of a feature extractor with a convolutional layer and a sub-sampling layer. In the convolutional layer, one neuron is only connected to several adjacent neurons.

TextCNN is a model that uses multiple convolutional neural networks to output in tandem (Kim, 2014). In the model, the convolution window of each convolutional neural network is different in size. The convolution results obtained by convolution windows of different sizes are combined and output.

In our task, we also use the basic convolutional neural network and TextCNN to conduct experiments(Zhang and Wallace, 2015). For this task, we find that TextCNN can get a better result than a single convolutional neural network. So, we will be more inclined to choose a TextCNN model instead of a single CNN model for our task.

2.2 LSTM

Traditional recursive neural networks are ineffective when dealing with very long sentences. The LSTM (Hochreiter and Schmidhuber, 1997) model is developed to solve the gradient vanishing or exploding problems in the RNN. Currently, the LSTM is mainly used in natural language processing such as speech recognition and machine translation. Compared with the traditional RNN, an LSTM unit is added to the traditional model for judging the usefulness of information. Each unit mainly contains three gates (the forget gate, the input gate, and the output gate) and a memory cell. The system will judge the usefulness of the information after the input information is fed into an LSTM(Liu et al., 2016). Only the information that matches the rules of the algorithm will be saved, and the other information will be discarded by the forget gate.

2.3 Bi-LSTM

Single direction LSTM(Lai et al., 2015) suffers a weakness of not using the contextual information from the future tokens. Bidirectional LSTM (Bi-LSTM) exploits both the previous and future context by processing the sequence on two directions and generates two independent sequences of LSTM(Kim et al., 2016) output vectors(Liu et al., 2016). One processes the input sequence in the forward direction, while the other processes the input in the backward direction.

In this task, we also use the Bi-LSTM to get a better result(Huang et al., 2015). We select the model that can be compared with other models as comparative experiments.

2.4 C-LSTM

It has been successfully demonstrated that neural network models can achieve good results in tasks such as sentence and document classification. Convolutional neural networks (CNN) and recurrent neural networks (RNN) are two mainstream methods for this classification task (Zhou et al., 2015). At the same time, these two methods can also be used for our tasks, which use a completely different approach to understanding natural language. In this model, we combine the advantages of both CNN and RNN models and call it C-LSTM for sentence representation and text classification. C-LSTM uses CNN to extract a series of higher-level phrase representations and feeds them to the Long-Term Short-Term Memory Recurrent Neural Network (LSTM) for sentence representation(Stollenga et al., 2015). C-LSTM captures local features of phrases as well as global and temporal sentence semantics. Then, we predict the results based on the labels of the sentences (Zhou et al., 2015).

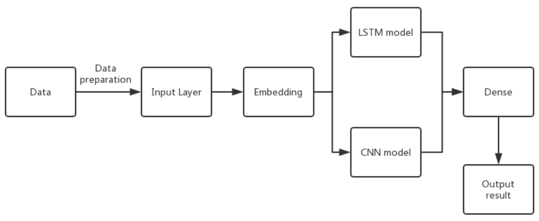

Figure 3: C-LSTM model for our task

In our experiments, the C-LSTM model is compared with a single CNN model, TextCNN, and a single LSTM, Bi-LSTM model. The results show that the C-LSTM model can achieve a better result in this task.

2.5 Attention-based LSTM model

The LSTM model can alleviate the problem of gradient vanishing, but this problem persists in long range reading comprehension contexts. The attention mechanism(Bahdanau et al., 2014) breaks the constraint on fix-length vector as the context vector, and enables the model to focus on those more helpful to outputs. After LSTM layer, we use the attention mechanism on the output vectors produced by previous layer. It is proven effective to improve the performance of our model.

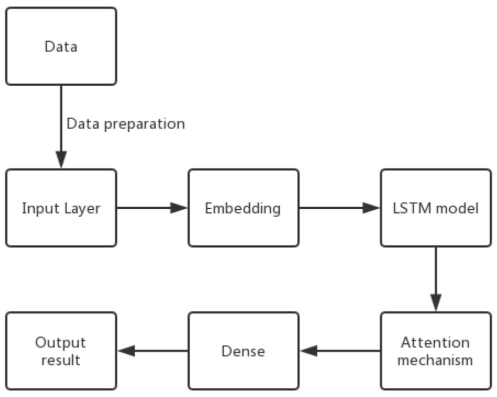

Figure 4: An attention-based LSTM model for our task

In the attention-based LSTM model, all sentences and labels are converted to word vectors by the word embedding layer. These word vectors will be fed to the LSTM layer. Subsequently, the word vector is represented as a hidden vector. Next, the attention mechanism assigns weights to each hidden vector, and the mechanism produces attention weight vectors and weighted hidden representations. Note that the weight vector is mainly obtained by calculating the similarity. An attention weight vector is generated by calculating a sentence vector matrix and a label vector matrix. The attention weight vector is then fed to the softmax layer.

The attention mechanism allows the model to retain some important hidden information when the sentence is long. In our mission, the information of sentences and tags is kept for a relatively long time. Using the standard LSTM may result in the loss of hidden information. To solve this possible problem, we have facilitated the attention-based LSTM model.

In our task, the attention mechanism(Yang et al., 2016) can get better results. We think that the attention mechanism(Vaswani et al., 2017) can improve the efficiency of task. So, we combine the attention mechanism with the LSTM model. This model can get the best results among the single models, which is the final system we submitted.

3 Data Preparation

The organizers provided training, trial, and test sets, containing 8500, 592 and 833 sentences respectively(Negi et al., 2019). Each sentence corresponds to one label, 0 or 1. Although official data is regular, we need to do a further normalization. We want to make it possible to read these sentences easily. First of all, we have completely restored the abbreviated words. For example "i'm not asking microsoft to gives permission like android so any app can take my data" will become "i am not asking microsoft to gives permission like android so any app can take my data". In this sentence "i'm" is an abbreviation. So, we found these abbreviations and restored it by creating a list.

examples	normalization
i'm	i am
doesn't	dose not
can't	can not
i'll	i will
i've	i have
...	...
i'd	i would
it's	it is

Table 1: normalization patterns

Then we noticed that it is also very important to remove some unnecessary characters, such as "!","?" etc. What's more, we find that the link to the web-page is useless for this task. So we remove all urls.

For data pre-processing, we wrote the code to realize the functions and we can improve the efficiency of our final experimental results through these data pre-processing methods.

4 Experiments and evaluation

After data pre-processing, we start the main part of the experiment. The preprocessed data is feed into our prepared model for experimentation. At the same time, we do experiments on different models to compare the test results. In the experiments, we also find that the same model will get different results under different parameter adjustments. For example, we use the C-LSTM model for experiments, and our experimental results range from 0.67 to 0.78 with different parameters in the trial data. Therefore, reasonable adjustment of parameters during the experiment is also a factor in obtaining a good experimental result.

We run each individual model 5 times and use the average as the final result of this model. In all of models, dropout parameters are changed from 0.2 to 0.6, What's more, in the LSTM model, we also select the recurrent dropout (Srivastava et al., 2014) that are set between 0.2 and 0.45. And we set epoch = 10 and batch size = 64.

In this task, we mainly select 6 models and ensemble all of these models. In the table 3 we post the F1-score and recall of the model.

Model	Recall	F1-score
CNN	0.78	0.5523
TextCNN	0.80	0.5908
LSTM	0.81	0.6104
C-LSTM	0.83	0.6222
Attention-BiLSTM	0.85	0.6610
Attention-LSTM	0.84	0.6776
ensemble models	0.82	0.6806

Table 2: Recall and F1-score for each models on task test data

5 Conclusion

In this task, we accomplish this task by integrating LSTM and attention mechanism. After competition, we try various structurally different models and an ensemble of all the models. The performance of a single model is slightly worse than the ensemble model. And there are certain differences between the different parameter results of the same model. Our results are still not as satisfying as the top teams on the leaderboard.

However, in this task, we have some problems which we can't solve. For example, we can not successfully solve the problem of data imbalance. We can not consider the problem of model optimization too much and we don't try more ways of ensemble model.

In the future, we will continue to adjust the model, improve the hardware configuration of the computer, collect more external data, and conduct more experiments to get better results. Furthermore, we will try again to solve the problem of data imbalance. We will continue to do model optimization and we will try more ways of ensemble model.

Abstract

In this paper we present our approach and the system description for Sub Task A of SemEval 2019 Task 9: Suggestion Mining from Online Reviews and Forums. Given a sentence, the task asks to predict whether the sentence consists of a suggestion or not. Our model is based on Universal Language Model Fine-tuning for Text Classification. We apply various pre-processing techniques before training the language and the classification model. We further provide detailed analysis of the results obtained using the trained model. Our team ranked 10th out of 34 participants, achieving an F1 score of 0.7011. We publicly share our implementation[1].

1 Introduction and Background

Suggestion mining can be defined as the process of identifying and extracting sentences from unstructured text that contain suggestion (Negi et al., 2018). Suggestions in the form of unstructured text could be found in various social media platforms, discussion forums, review websites and blogs. They are often expressed in the form of advice, tips, recommendations, warnings, things to do, and various other forms in an explicit as well as an implicit way.

Identifying and retrieving suggestions from text can be useful in an industrial setting for enhancing a product, summarizing opinions of the consumers, giving recommendations and as an aid in decision making process (Jijkoun et al., 2010). For normal users of online platforms it could help in seeking advice related to general topics of interest like travel, health, food, shopping, education, and many more. Given the abundance of textual information in the Internet about a variety of topics, suggestion mining is certainly an useful task interesting to researchers working in academia as well as industry.

Most of the previous efforts in the direction of understanding online opinions and reactions have been limited to developing methods for areas like sentiment analysis and opinion mining (Medhat et al., 2014; Baghel et al., 2018; Kapoor et al., 2018; Mahata et al., 2018a,b; Jangid et al., 2018; Meghawat et al., 2018; Shah and Zimmermann, 2017). Mining and understanding suggestions can open new areas to study consumer behavior and tapping nuggets of information that could be directly linked with the development and enhancement of products (Brun and Hagege, 2013; Dong et al., 2013; Ramanand et al., 2010), improve customer experiences (Negi and Buitelaar, 2015), and aid in understanding the linguistic nuances of giving advice (Wicaksono and Myaeng, 2013).

Suggestion mining is a relatively new domain and is challenged by problems such as *ambiguity in task formulation and manual annotation*, *understanding sentence level semantics*, *figurative expressions*, *handling long and complex sentences*, *context dependency*, and *highly imbalanced class distribution*, as already mentioned by (Negi et al., 2018). Similar problems are also observed in the dataset shared by the organizers for the SemEval task, as it is obtained from a real-world application comprising of suggestions embedded in unstructured textual content.

Problem Definition - The problem of suggestion mining as presented in the SemEval 2019 Task 9 (Negi et al., 2019), is posed as a binary classification problem and could be formally stated as:

[1]https://github.com/isarth/SemEval9_MIDAS

Given a labeled dataset D of sentences, the objective of the task is to learn a classification/prediction function that can predict a label l for a sentence s, where $l \in \{suggestion, nonsuggestion\}$.

Our Contributions - Some of the contributions that we make by participating in this task are:

• To our knowledge we are the first one to use Universal Language Model Fine-tuning for Text Classification (ULMFiT) (Howard and Ruder, 2018), for the task of suggestion mining and show the effectiveness of transfer learning.

• We perform an error analysis of the provided dataset for Sub Task A, as well as the predictions made by our trained model.

Next, we give a detailed description of our system and the experiments performed by us along with explaining our results.

2 Experiments

2.1 Dataset

The dataset used in all our experiments was provided by the organizers of the task and consists of sentences from a suggestion forum annotated by humans to be a *suggestion* or a *non-suggestion*. Suggestion forums are dedicated forums used for providing suggestions on a specific product, service, process or an entity of interest. The provided dataset is collected from uservoice.com[2], and consists of feedback posts on Universal Windows Platform. Only those sentences are present in the dataset that explicitly expresses suggestions, for example - *Do try the cupcakes from the bakery next door*, instead of those that contain implicit suggestions such as - *I loved the cup cakes from the bakery next door* (Negi et al., 2018).

Label	**Train**	**Trial**
Suggestion	2085	296
Non Suggestion	6415	296

Table 1: Dataset Distribution for Sub Task A - Task 9: Suggestion Mining from Online Reviews.

For Sub Task A, the organizers shared a training and a validation dataset whose label distribution (*suggestion* or a *non-suggestion*) is presented in Table 1. The unlabeled test data on which the performance of our model was evaluated was also from the same domain. As evident from Table 1, there is a significant imbalance in the distribution of training instances that are *suggestions* and *non-suggestions*, which mimics the distributions of these classes in the real-world datasets. Although the dataset was collected from a suggestion forum and is expected to have a high occurrence of suggestions, yet the imbalance is more prominent due to the avoidance of implicit suggestions.

2.2 Dataset Preparation

Before using the provided dataset for training a prediction model, we take steps to prepare it as an input to our machine learning models. We primarily use Ekphrasis[3] for implementing our preprocessing steps. Some of the steps that we take are presented in this section.

2.2.1 Tokenization

Tokenization is a fundamental pre-processing step and could be one of the important factors influencing the performance of a machine learning model that deals with text. As online suggestion forums include wide variation in vocabulary and expressions, the tokenization process could become a challenging task. Ekphrasis ships with custom tokenizers that understands expressions found in colloquial languages often used in forums and has the ability to handle hashtags, dates, times, emoticons, besides standard tokenization of English language sentences. We also had to tokenize certain misspellings and slangs (eg. "I'm", "r:are") after carefully inspecting the provided dataset.

2.2.2 Normalization

After tokenization, a range of transformations such as word-normalization, spell correction and segmentation are applied to the extracted tokens. During word-normalization, URLs, usernames, phone numbers, date, time, currencies and special type of tokens such as hashtags, emoticons, censored words etc. are recognized and replaced by masks (eg. <date>, <hashtag>, <url>). These steps results in a reduction in the vocabulary size without the loss of informative excerpts that has signals for expressing suggestions. This was validated manually by analyzing the text after applying the different processing steps. Table 2 shows an example text snippet and its form after the application of the pre-processing steps.

[2]https://www.uservoice.com/

[3]https://github.com/cbaziotis/ekphrasis

Text Snippet before Pre-processing	**Text Snippet after Pre-processing**
ie9mobile does not do this :(	ie mobile does not do this <emsad>
For example if you want a feed for every Tumblr feed containing the hashtags " "#retail #design " "; " "http://www.tumblr .com/tagged/retail+ design""; would be a feedly feed."	For example if you want a feed for every tumblr feed containing the hashtags <hashtag>retail <hashtag>design <url>would be a feedly feed

Table 2: Text snippet from the dataset before and after applying pre-processing steps.

2.2.3 Class Imbalance

As already pointed in Section 2.1, *class imbalance* is a prevalent challenge in this domain and is reflected in the provided dataset. We use oversampling technique in order to tackle this challenge. We duplicate the training instances labeled as *suggestions* and boost their number of occurrences exactly to double the amount present in the original dataset.

3 Model Architecture Training and Evaluation

We show the effectiveness of transfer learning for the task of suggestion mining by training Universal Language Model Fine-tuning for Text Classification (ULMFiT) (Howard and Ruder, 2018). One of the main advantages of training ULMFiT is that it works very well for a small dataset as provided in the Sub Task A and also avoids the process of training a classification model from scratch. This avoids overfitting. We use the fast.ai[4] implementation of this model.

The ULMFiT model has mainly two parts, the *language model* and the *classification model*. The language model is trained on a Wiki Text corpus to capture general features of the language in different layers. We fine tune the language model on the training, validation and the evaluation data. Also, we additionally scrap around two thousand reviews from the Universal Windows Platform for training our language model. After analysis of the performance we find optimal parameters to be:

- BPTT: 70, bs: 48.
- Embedding size: 400, hidden size: 1150, num of layers: 3

We also experiment with MultinomialNB, Logistic Regression, Support Vector Machines, LSTM. For LSTM we use fasttext word embeddings[5] having 300 dimensions trained on Wikipedia corpus, for representing words.

Table 3, shows the performances of all the models that we trained on the provided training dataset. We also obtained the test dataset from the organizers and evaluated our trained models on the same. The ULMFiT model achieved the best results with a F1-score of 0.861 on the training dataset and a F1-score of 0.701 on the test dataset. Table 4 shows the performance of the top 5 models for Sub Task A of SemEval 2019 Task 9. Our team ranked 10th out of 34 participants.

Model	**F1 (train)**	**F1 (test)**
Multinomial Naive Bayes (using Count Vectorizer)	0.641	0.517
Logistic Regression (using Count Vectorizer)	0.679	0.572
SVM (Linear Kernel) (using TfIdf Vectorizer)	0.695	0.576
LSTM (128 LSTM Units)	0.731	0.591
Provided Baseline	0.720	0.267
ULMFit*	0.861	0.701

Table 3: Performance of different models on the provided train and test dataset for Sub Task A.

Ranking	**Team Name**	**Performance (F1)**
1	OleNet	0.7812
2	ThisIsCompetition	0.7778
3	m_y	0.7761
4	yimmon	0.7629
5	NTUA-ISLab	0.7488
10	**MIDAS (our team)**	**0.7011***

Table 4: Best performing models for SemEval Task 9: Sub Task A.

4 Error Analysis

In this section, we analyse the performance of our best model (ULMFiT) on the training data as shown by the confusion matrix presented in Figure 1. We specially look at the predictions made by our model that falls into the categories of False Positive and False Negative, as that gives us insights into the instances which our model could not classify correctly. We also present some of the instances that we found to be wrongly labeled in the provided dataset.

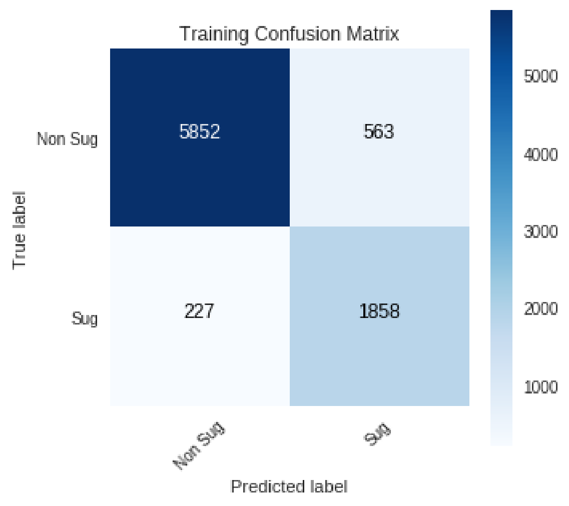

Figure 1: Confusion matrix training data

False Positives (Labeled or predicted wrongly as suggestion) Some examples that seems incorrectly labeled as suggestion in training data are given below:

- **Id 2602**: Current app extension only supports loading assets and scripts.
- **Id 3388**: One is TextCanvas for Display and Editing both Text and Inking.
- **Id 0-1747**: Unfortunately they only pull their feeds from google reader

Some examples that are incorrectly predicted by the model as suggestions are:

- **Id 1575**: That's why I'm suggesting a specialized textbox for numbers.
- **Id 1462**: If you have such limits publish them in the API docs.
- **Id 1360-2**: Adding this feature will help alot.

False Negatives (Labeled or predicted wrongly as Non Suggestion) Some examples that seems incorrectly labeled as non suggestion in the training data:

- **Id 0-1594**: Please consider adding this type of feature to feedly.
- **Id 3354**: Please support the passing of all selected files as command arguments.
- **Id 0-941**: Microsoft should provide a SDK for developers to intergate such feedback system in their Apps.

Some examples that are incorrectly predicted by the model as non-suggestions:

- **Id 0-757**: Create your own 3d library.
- **Id 834-15**: Please try again after a few minutes" in Firefox.
- **Id 4166**: I want my user to stay inside my app.

We also find that **77%** of the false positives have keywords (*want, please, add, support, would, could, should, need*), with **would** being highest i.e. around 30%.

5 Conclusion and Future Work

In this work we showed how transfer learning could be used for the task of classifying sentences extracted from unstructured text as suggestion and non-suggestions. Towards this end we train a ULMFiT model on the dataset (only Sub Task A) provided by the organizers of the SemEval 2019 Task 9 and rank 10th in the competition out of 34 participating teams.

In the future we would like to experiment and show the effectiveness of our trained model in Sub Task B where the training dataset remains the same, but the test dataset consists of suggestions from a different domain. It would be interesting to see how our model performs in predicting out-of-domain suggestions and show the ability of the ULMFiT model to fine-tune itself to a completely new domain with the already existing pre-trained model. Another interesting area would be to explore Multi Task Learning models and see how the domain of suggestion mining could get benefited by borrowing weights from models trained on other related tasks and similar tasks across different domains.

Abstract

In this paper, we present neural model architecture submitted to the SemEval-2019 Task 9 competition: "Suggestion Mining from Online Reviews and Forums". We participated in both subtasks for domain specific and also cross-domain suggestion mining. We proposed a recurrent neural network architecture that employs Bi-LSTM layers and also self-attention mechanism. Our architecture tries to encode words via word representations using ELMo and ensembles multiple models to achieve better results. We performed experiments with different setups of our proposed model involving weighting of prediction classes for loss function. Our best model achieved in official test evaluation score of 0.6816 for subtask A and 0.6850 for subtask B. In official results, we achieved 12th and 10th place in subtasks A and B, respectively.

1 Introduction

Review-based portals and online forums contain plethora of user-generated text. We can consider customer reviews and inputs from online forums as an important source of novel information. These texts often contain many different opinions, which are the subject of research in area of opinion mining.

On the other hand, there can be also different types of information within these texts, such as suggestions. Unlike opinions, suggestions can appear in different parts of text and also appear more sparsely. Suggestion mining, as defined in this task, can be realized as standard text classification. We perform classification to two classes, which are suggestion and non-suggestion.

As presented by organizers, suggestion mining has different challenges (Negi et al., 2019):

- Class imbalance - suggestions appear very sparsely in reviews and forums and most of the samples are negatively sampled,
- Figurative expressions - expression can be often found in social networks but it is not always in form of suggestion,
- Context dependency - some sentences can be viewed as a suggestion, if it appears in specific domain or surrounded by specific sentences,
- Long and complex sentences - suggestions can be expressed as only small part of original sentence, which can be much longer.

Unlike opinions, suggestions can be more likely extracted also by pattern matching. We can extract suggestions by different heuristic features and keywords, such as *suggest, recommend, advise* (Negi and Buitelaar, 2015). Some works deal with domain terminology, thesaurus, linguistic parser and extraction rules (Brun and Hagege, 2013). Linguistic rules were also used for identification and extraction in sentiment expression (Viswanathan et al., 2011).

We believe that different extracted information from customer reviews and online forums can offer a valuable input for both customers and owners of products or forums and this information can be also a subject for automatic opinion summarization (Pecar, 2018).

In this paper, we present a neural network architecture consisting of different types of layers, such as embedding, recurrent, transformer or self-attention layer. We continued in our previous work on multi-level pre-processing (Pecar et al., 2018). We performed experiments with different word representations, such as ELMo, BERT or GloVe. We report results of our experiments along with error analysis of our models.

2 Model

In this SemEval task, we experimented with multiple setups based on different types of neural layers on the top of an embedding layer. In Figure 1, we show general architecture of our proposed model. We also experimented with a transformer encoder, which is described in the paragraph on encoder layer below.

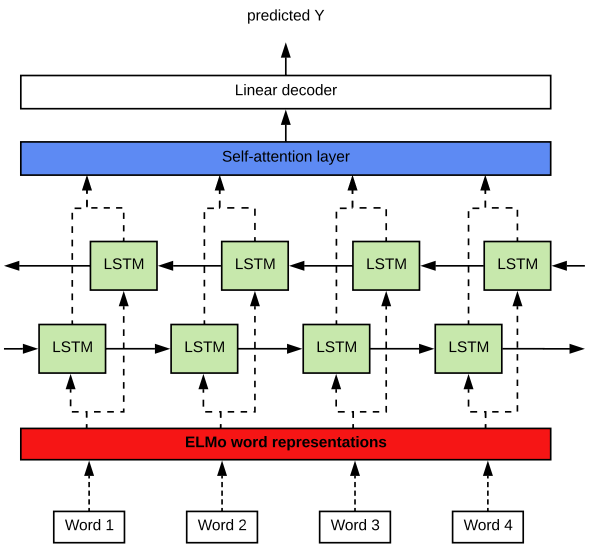

Figure 1: Proposed neural model architecture

Preprocessing We consider preprocessing of input samples as one of the most important phases in natural language processing. For user generated content, preprocessing is even more important due to noisy and ungrammatical text. We performed a study on the impact of preprocessing in our previous work (Pecar et al., 2018).

For this suggestion mining task, we used preprocessing in several stages, which were performed in order as follows:

1. text cleaning – removing all characters from not Latin alphabet, such as Cyrillic, Greek or Chinese characters,

2. character and word normalization – normalization of different use of characters and words, such as apostrophe, punctuation, date and time (e.g. ‘’ for apostrophe and ”“„ for quotation),

3. shorten phrase expanding – expanding all shorten phrases to their appropriate long form (e.g. *I'll* to *I will*),

4. expanding negations – expanding all negation forms, which appeared in short form to their appropriate long form (e.g. *aren't, won't* to *are not, will not*),

5. punctuation escaping – escaping all punctuation with spaces do separate those characters from words.

Word Representations To represent words from samples, we used deep contextualized word representations (Peters et al., 2018) also known as ELMo along with its available pre-trained model[1]. We also experimented with transformers model word representations known as BERT (Devlin et al., 2018) and its pre-trained model[2]. For language modeling in subtask B, we also experimented with GloVe embeddings (Pennington et al., 2014).

Encoder layer Word representations are fed into different encoder layers. Mostly, we used different setups of Bi-LSTM. We experimented with multiple stacked recurrent layers with different number of units within layers. In both cases (only one layer, multiple stacked layers) we used also self-attention mechanism to improve results and reduce over-fitting to the train dataset. We also tried to experiment with different attention layers and used transformer encoder (Vaswani et al., 2017) but due to very high requirements for memory, we were not able to run model with full size of this network and smaller networks produced significantly worse results.

Decoder Layer We used standard linear layer to decode output representation of recurrent layers with self-attention mechanism to class probabilities. In case of model ensemble, we needed to employ also another logarithmic softmax function for better interpretations of probabilities of samples for both classes.

Loss Function For a loss function, we experimented with the standard cross-entropy loss and the negative log likelihood loss in case a logarithmic softmax were used. We also experimented with weight setup for classes for loss contribution.

Model Ensemble Model ensemble can be considered as a useful technique to obtain better results than using only single model for predictions.

[1]https://allennlp.org/elmo
[2]https://github.com/google-research/bert

We experimented with different size of model ensemble and also two different types. In one model, we tried averaging model prediction probabilities and in second one, we used voting mechanism and predicted class with more votes.

Regularization To reduce possibilities of overfitting to train dataset, we used also dropout as a regularization technique. We used dropout on embedding layer output, on encoder output along with dropout between stacked RNN layers and also at the output of attention layer. We used different dropout probabilities in range from 0.2 to 0.6.

3 Evaluation

In this section, we briefly summarize basic information about used dataset. Later, we describe different setups of our model. Each team could submit in total 4 submission as an official results. For evaluation, binary F1 measure (F1 score over positive labels) was taken as an official results of submission.

3.1 Dataset

The dataset for suggestion mining task consists of feedback posts on Universal Windows Platform available on *uservoice.com*. The dataset contains only labels for two categories: the text is suggestion or it is not. The train dataset contains approximately 9 thousands of text samples. For validation, there were available approximately 600 samples for subtask A and 800 samples for subtask B. The size of test datasets were approximately 800 and 1000 samples for subtask A and B, respectively. More detailed information can be found in the main paper of the task (Negi et al., 2019).

3.2 Results

In Table 1, we provide basic information about setups of performed submission. For every setup, we used ELMo word representations as an embedding layer, different setups of dropout in each layer of neural network in the range from 0.3 to 0.6. Each LSTM layer has its hidden size set to 1024 units per layer. For some submissions, we also experimented with model ensemble. We took different number of models, which had the best performance on development (trial) set and used averaging predicted probabilities to get final prediction or voting mechanism and get label with more votes. In subtask A, we used 5 best trained models for voting model ensemble and 3 models for mean model ensemble. In subtask B, we used 3 best trained models for model ensemble.

In Table 1, we show also results of submitted all models in 3 measures, micro F1, macro F1 and binary F1 (F1 score over positive samples). As an official results, binary F1 measure was taken. From these results, we can observe that model ensemble can significantly help obtain better results for both subtasks.

3.3 Model ensemble results

In this section, we discuss results of each model from model ensemble in detail for both subtasks.

Table 2 shows results of each model used for model ensemble for subtask A. We can observe that the best model obtained binary F1 score 0.6609 and both types of model ensembles get better results up to 2 percents than each model separately. For mean model ensemble first 3 models were used and for voting ensemble all 5 models were used.

Table 3 shows results of each model used for model ensemble for subtask B. We can see that the best model obtained binary F1 score 0.6770 and both types of model obtained better results than each model separately. For both types of model ensemble all 3 models were used. Results for voting ensemble were not part of the official submissions.

3.4 Error analysis

We provide also error analysis of proposed model for both subtasks. We made 3 official submissions for subtask A and 2 for subtask B.

In Table 4, we show simple results from confusion matrix for subtask A and also for subtask B. For subtask A, we can observe that the main problem of our proposed models was high number of false positive labels and our models predicted presence of suggestion too often. In subtask B, there is more problematic prediction of non-suggestion labels, where number of false negative samples is much bigger. This problem can be caused also due to different distributions in training and test datasets. We also used for training dataset from a different domain, which even highlighted this problem. We used the same class weight modification for loss in subtask B as was used in subtask A.

task	submission	layers	model ensemble	micro F1	macro F1	binary F1
A	1	2 Bi-LSTM	Mean	0.9147	0.8162	0.6816
	2	2 Bi-LSTM	Voting	0.9116	0.8091	0.6696
	3	2 Bi-LSTM	None	0.9051	0.8029	0.6609
B	1	1 LSTM	Mean	0.7779	0.7567	0.6850
	2	1 LSTM	None	0.7463	0.7306	0.6656

Table 1: Official submission results in different measures

model	micro F1	macro F1	binary F1
1	0.9051	0.8029	0.6609
2	0.9050	0.8000	0.6550
3	0.9075	0.8021	0.6577
4	0.9099	0.8013	0.6543
5	0.9159	0.8061	0.6601
mean	0.9147	0.8162	0.6816
voting	0.9116	0.8091	0.6696

2	0.7730	0.7446	0.6593
3	0.7463	0.7306	0.6656
mean	0.7779	0.7567	0.6850
voting	0.7574	0.7803	0.6830

Table 3: Results of unsubmitted models in different measures for subtask B

3.5 Unsubmitted models

In this section, we present results of models, which were not used to make an official submission. We experimented with these models for subtask A and also subtask B. Results can be found in Table 5 and 6. Each model in this section is used without model ensemble and we can compare results with the best models themselves. In each table, best model indicates best submitted model without any model ensemble.

The only modification used for model 1 is replacing ELMo word representation with BERT. Obtained word representations from pre-trained BERT performed much worse than ELMo representation. This fact was also observed while evaluating on development (trial) dataset.

Model 2 had a more significant modification, where LSTM encoder was replaced with transformer network (Vaswani et al., 2017). Due to high memory requirements of this model we were not able to run full encoder of the original network and used only smaller part with 6 layers and 4 head attention layers.

task	submission	TP	FP	FN	TN
A	1	76	60	11	686
	2	75	62	12	684
	3	77	69	10	677
B	1	199	34	149	442
	2	208	69	140	407

Table 4: Error analysis for submissions

As we observed in error analysis of submitted results (see Table 4), one of the significant problems was predicting too many positive labels. For all submissions, we used re-balancing class weights for loss function based on distribution in train dataset (0.6625, 2.0384). In model 3, we changed class weights to be more balanced (1.0 and 2.0). In model 4, we used completely balanced weights (1.0 and 1.0) and in model 5, we tried to change class weights to prefer negative labels (2.0 and 1.0).

model	micro F1	macro F1	binary F1
best	0.9051	0.8029	0.6609
1	0.8415	0.7214	0.5384
2	0.9123	0.7952	0.6404
3	0.9314	0.8440	0.7272
4	0.9459	0.8577	0.7457
5	0.9495	0.8479	0.7236

Table 5: Results of unsubmitted models in different measures for subtask A

For subtask B, we also experimented with use of pre-trained weights from language model. We trained language model on dataset of hotel reviews – arguana (Wachsmuth et al., 2014). Unfortunately, without fine-tuning on in-domain dataset used for classification, this model did not obtained better results. We show results of this experiment as model 1 in Table 6. We suppose that further experiment would be needed with combination of class re-balancing for loss and also fixing pre-trained weights. Since our language model was trained with GloVe embeddings, we had to use GloVe also in training for this task. Models 2 and 3 show results with change of class weight for loss function to prefer positive labels (1.0, 4.0 and 1.0, 5.0).

model	**micro F1**	**macro F1**	**binary F1**
1	0.7208	0.6698	0.5401
2	0.7961	0.7844	0.7341
3	0.8264	0.8186	0.7810

Table 6: Results of unsubmitted models in different measures for subtask B

As we showed in this section, our further experiments along with error analysis showed also significant improvement in comparison to performed official submissions. We believe further work can provide even better results, especially in combination with model ensemble.

4 Conclusions

We proposed a neural model architecture for suggestion mining. For subtask A, we employed bidirectional LSTM encoder, which consisted from 2 stacked layers followed by self attention. For subtask B, better performance proved only one layer in one direction to reduce learning process and over-fitting to train domain. Our experiments showed that pre-trained ELMo word representations performed much better than pre-trained BERT. We also performed other experiments with different setups of our architecture, which were not submitted as official results. As we showed, model ensemble can significantly improve results compared when using only single models.

To obtain better results, we would need to employ transfer learning to a much bigger extent, especially for subtask B. We could also consider further experiments with re-balancing of class weights for loss function, as we predicted too many suggestions, especially for subtask A. Another possible experiments would employ transformer network, which we were not able to fully employ due to high resource requirements. Interesting would be also employing some pattern approaches, which proved as very successful for subtask B in baseline provided by organizers. Code for our submission can be found in GitHub repository[3].

Abstract

As online customer forums and product comparison sites increase their societal influence, users are actively expressing their opinions and posting their recommendations on their fellow customers online. However, systems capable of recognizing suggestions still lack in stability. Suggestion Mining, a novel and challenging field of Natural Language Processing, is increasingly gaining attention, aiming to track user advice on online forums. In this paper, a carefully designed methodology to identify customer-to-company and customer-to-customer suggestions is presented. The methodology implements a rule-based classifier using heuristic, lexical and syntactic patterns. The approach ranked at 5^{th} and 1^{st} position, achieving an f1-score of 0.749 and 0.858 for SemEval-2019/Suggestion Mining sub-tasks A and B, respectively. In addition, we were able to improve performance results by combining the rule-based classifier with a recurrent convolutional neural network, that exhibits an f1-score of 0.79 for subtask A.

1 Introduction

Nowadays, online platforms and e-commerce sites have become increasingly popular. In such online environments people are willingly sharing views, feelings and opinions about specific products and services by conveying written recommendations on several topics. The pool of advising items that float in contemporary e-commerce environments posts a critical task: how to identify, capture and extract useful information from them. Digging into these information pools of unstructured commenting dialogues about ideas and thoughts expressed by reviewers on the product, its features, components or functions can be seen as an Opinion Mining (OM) problem (Banitaan et al., 2010), with the relevant research gaining increasingly significant attention.

However, OM strategies attempt to extract the sentiment of users written passages, failing to correctly capture putative advice, especially in the presence of mixed emotions. For example, a suggestion in an online trip advising platform could contain the sentence *“If you sleep lightly, this would be a problem because of all the trams that go by - so ask for an interior room.”*. The passage conveys a negative sentiment which is impossible to grasp correctly. Confronted with this problem, computational methodologies that automatically identify and highlight clear-cut advice in written recommendations raises as a major need. Towards this end, Suggestion Mining (SM) strives to track suggestions and tips in passages. Suggestive sentences could be positive, negative or they may not contain any sentiment at all, a fact that makes their tracking quite puzzling (Negi and Buitelaar, 2015). In general, advice may be expressed by using either *explicit suggestions*, which propose direct and conventionalized forms of recommendations (Martínez Flor, 2005), or *implicit suggestions* where the precise recommendation is in a way veiled and should be inferred (Negi and Buitelaar, 2015).

The work reported in this paper copes mainly with explicitly expressed suggestions, ignoring indirect recommendations, such as *The best thing about the Westin, as everybody has already stated, is the location.* where, via the expressed positive response, the writer implies a recommendation about *Westin* hotel. In particular, we tackle the problem of detecting suggestive comments by carefully devising a number of heuristic features to represent various lexical and imperative patterns that are indicative of explicit advice. The basic contributions of the proposed SM approach are:

- Implementation of a robust and extended identifier of imperative, prompting and solicitation clauses in sentences that are mostly related with advice and suggestions.

- Extension and elaboration on existing dictionaries and respective lexical patterns that are indicative of advice and suggestions, focusing on reviews related to electronics and hotels.
- Composition of a fully equipped and highly accurate suggestion mining framework that compares and outperforms other related approaches.

2 Related Work

Even if SM is still in its youth, few related studies aim towards the extraction of suggestions. Goldberg et al. (2009) introduced a pattern-based approach to capture the desires of customers regarding company suggestions, utilizing a Support Vector Machines (SVM) classifier. A similar study, conducted by Ramanand et al. (2010), on extracting suggestions and purchase desires for product services is founded on a pattern-based approach and the devise of respective rules. The first study that focused on the extraction of exact suggestions from product reviews and utilized feature-based classification techniques is reported in (Brun and Hagege, 2013). The same line of research is followed in Negi and Buitelaar (2015) where, an SVM approach is employed to classify heuristically devised sequential features. In a follow-up work (Negi et al., 2016) it was demonstrated that the utilization of deep learning techniques, such as Convolutional Neural Network (CNN) and Long-Short-Term-Memory (LSTM) architectures, may improve prediction performance. In a similar setting, in Golchha et al. (2018) a hybrid deep learning framework is introduced, which is composed by both recurrent and convolutional network architectures, coupled with linguistic features. A different approach is proposed in Gottipati et al. (2018) that exploits suggestions on student feedback comments utilizing a decision tree classification approach.

3 Experimental Setup

3.1 Dataset

The SemEval-2019/SM task 9 (Negi et al., 2019), targets the handling of different suggestion forms. It provides a 9K training dataset with sentences related to customer suggestions that were extracted from the "Universal Windows Platform (available from `uservoice.com`).The provided dataset is imbalanced as only 26% of cases are classified as suggestions. The provided test dataset for subtask A was also imbalanced as it contains only 87 suggestive instances from a total of 833 sentences. Data for subtask B was extracted from TripAdvisor forum[1], and carries different aspects of advice between customers. The provided test set contains 824 sample instances, 348 of which indicate explicit suggestions.

3.2 Preprocessing: *To do or not to do?*

Suggestions often comprise phrases, expressions and lexical patterns to denote their suggestion content. Such patterns may contain several *stop-words* such as *be* or *should*. We claim that retaining stop-words is needed in order to identify special lexical patterns like for example, "be sure" or "would be nice", which are indicative of the suggestion mood and content of sentences. To this end, we keep the prepossessing step as simple as possible by just lowering uppercase letters and deleting repeated punctuation. We also apply `pyspellchecker`[2] to correct any misspelled words.

4 Method

Our approach to the SM task is founded on the careful identification of lexical patterns and the assignment of contextual importance weights to them. A respective rule-based classifier is then formed that computes the degree of a sentence's suggestion content according to the importance of the included patterns. The identified patterns for both subtasks A and B are acquired by utilizing a common dictionary of suggestion patterns and related corpora, as well as imperative featured patterns described in Section 4.1. In addition, the submitted classifier for subtask A was further improved by coupling it with a convolutional recurrent neural network (Section 5).

4.1 Detection of Imperative Forms

As a linguistic property the imperative mood is found to be deeply connected to suggestions in various studies Wicaksono and Myaeng (2012). Thorough observation and analysis of the linguistic characteristics related to both subtasks, led us

to extend the idea of an imperative mood detector for a task-independent and rule-based detection algorithm, able to identify the presence of prompting or solicitation clauses. The ensemble of these key features is accomplished by a mixture of rules that check both word and Part-of-Speech (POS) tag combinations, as POS tags usually avoid the sparse nature of word-based patterns. Our algorithmic approach unfolds in three steps:

- Each sentence undergoes basic preprocessing, including the replacement of each word with a tuple that contains the word and its POS tag, and enable the formation of mixed rules. In order to minimise POS errors that could lead to misclassification due to incorrect pattern recognition, a combination of the TextBlob library API[3] and the tagged Brown Corpus were utilized to assure correct word tagging.

- Each sentence is split into separate clauses that may independently indicate imperative mood, depending on their first word or verb phrase. Sentences are split at certain punctuation marks, special characters and the word 'please', as the latter provides almost absolute evidence of a following verb phrase.

- Each clause is then checked for the occurrence of certain POS tag patterns (see Figure 1), which are strong indicators of imperative mood.

4.2 Subtask A

The devised rule-based classifier assigns confidence scores to sentences on the basis of lexical-patterns organised in pre-specified categories and respective lists (detailed below). For subtask A we developed two lexical lists and one pattern-based list that vary according to their semantic content. The confidence score for each sentence is computed by a weighed additive formula that sums the hit-rates of all engaged features. A sentence is considered as suggestion if it exceeds a score of 0.15. The specific threshold is fixed after extensive experimentation on the given input dataset. Furthermore, we applied a 0.2 penalty for short phrase sentences that contain less than five words, as they

[3]https://textblob.readthedocs.io/

are considered to lack explicit suggestion content. In Table 2 we present performance results for each of these lists, as well as the prediction performance figures achieved by their combination (submitted results).

List $\mathbf{P_a^A}$. The first high rated list is composed by word features that are indicative and capture writers suggestive mood, e.g., *suggest , should , shouldn't, needs, idea, helpful, consider , allow, disallow*. Such words urge developers and supply companies to improve products and services by tracking words with directive, e.g., (*should, suggest*) or advisory content, e.g., (*idea, consider, helpful*). Sentences containing features from this list are considered as putative suggestions, assigned a 0.3 confidence score

List $\mathbf{P_b^A}$. The second list is composed by features that represent lexical patterns which, even if they do not contain individual words indicative of suggestive expressions, could be utilised when they emerge together in order to better grasp suggestive content and improve classifier's confidence. This list contains modal words, *would, could*, as well as their negations, *wouldn't, couldn't*. In addition, the list is enhanced with two developer related verbs, *create, include*. A sentence that contains both *could* and *create*, and which is rationally considered as suggestion, is: *"Read/write access to email sync settings could enable applications to create custom sync profiles (based on week-days time position etc)."*. Each hit from this list assigns a 0.1 weight to the sentence confidence score.

Patterns $\mathbf{P_c^A}$. Along with single word features we enhance our classifier with pattern-based features, elaborating on an earlier related work (Goldberg et al., 2009). To this end, we utilized several sequential lexical features as shown in Table 1. In addition, claiming that phrases like *will/would be* followed by words of positive polarity, e.g., *helpful, very very nice* are most of the times indicative of suggestions, we counted the total polarity of the three words following the phrase *will/would be*. When such patterns occur, the sentence's confidence score is increased by 0.25.

4.3 Subtask B

Following the same methodology as in subtask A we acquire a list of lexical features along with a list of weighted sequential lexical patterns. To develop lexical and n-gram patterns we extracted

Feature Set	Dev			Test		
	Prec	Rec	F1	Prec	Rec	F1
$P_a^A + P_b^A$	0.86	0.4	0.55	0.67	0.64	0.66
P_c^A	**0.87**	0.35	0.5	**0.7**	0.41	0.53
Imperative	0.83	0.23	0.36	0.67	0.21	0.32
Submitted-All	0.81	**0.71**	**0.76**	0.66	**0.86**	**0.74**

Table 2: Comparison between different lexical patterns on the development and test sets for subtask A.

Feature Set	Dev			Test		
	Prec	Rec	F1	Prec	Rec	F1
P_a^B	0.94	0.47	0.62	0.93	0.49	0.65
P_b^B	**0.98**	0.52	0.68	0.89	0.49	0.64
Imperative	0.97	0.38	0.54	**0.93**	0.36	0.52
Submitted-All	0.94	**0.78**	**0.86**	0.90	**0.82**	**0.86**

Table 3: Comparison between different lexical patterns on the development and test sets for subtask B.

the most frequent patterns from Wachsmuth et al. (2014), keeping those with the most advising content. For this subtask we consider a sentence as suggestive if it exceeds a 0.1 confidence score.

List $\mathbf{P_a^B}$. In contrast with subtask A, where suggestions appear between customers and companies, in subtask B most of the suggestions refer just to customers. Thus, we acquired a number of lexical features indicating a warning, an advice or a desire in order to capture suggestions in travel forums.

Caution words: *avoid, beware,don't, expect, remember*

Advice words: *tip, advise, advice, recommended, recommendation, suggest, suggestion, ask, bring, pick, consider, spend, expect, can*

Wish words: *please, can, hopefully, enjoying, want, wanting, prefer*

The occurrence of each of the above listed words in a sentence is assigned a weight of 0.25.

List $\mathbf{P_b^B}$. As in subtask A we used several sequential lexical patterns to identify and capture bi-grams and tri-grams with suggestive content. All lexical patterns of this list are summarized in the second column of Table 1.

5 Improving Predictions with Recurrent Convolutional Neural Networks - (R-CNN)

As simple and carefully devised lexical patterns are able to capture suggestive content in reviews and customer-to-customer conversations, we attempted to create an even more robust classifier

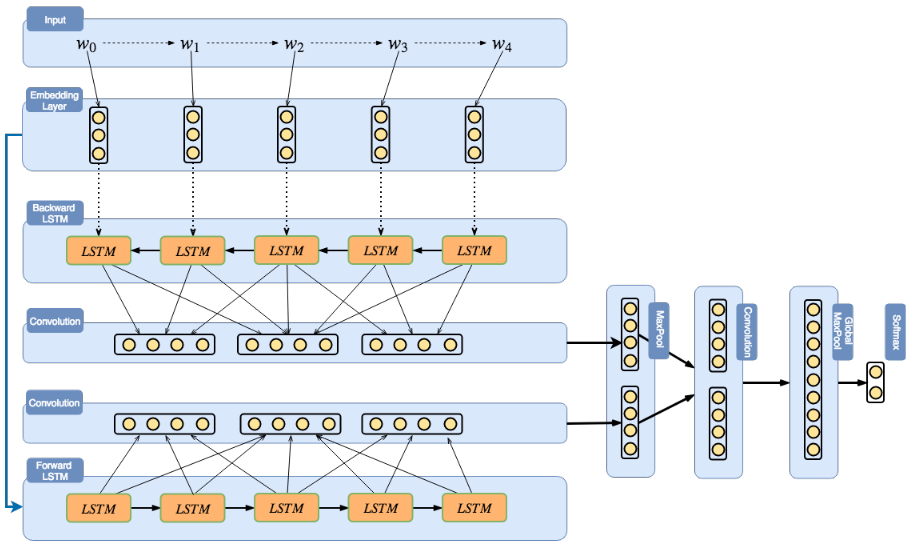

Figure 2: The recurrent convolutional neural network architecture (R-CNN).

on customer-to-companies suggestions. Thus, we coupled and enhanced our subtask A submitted classifier with a deep learning (DL) LSTM-CNN neural architecture.

5.1 Embedding Layer

DL is a very powerful classification approach, with the *Word Embeddings* machinery to be an important and necessary part for their training, especially for recurrent neural network (RNN) architectures (Mikolov et al., 2013). Word embeddings project each word to its semantic and highly dimensioned vector representation, and are induced by exhaustive training of huge corpora. In the present work we utilized 300-dimensional pre-trained Standford GloVe embeddings (Pennington et al., 2014).

5.2 Bidirectional LSTM

Due to the sequential nature of textual information neural architectures able to capture time-depended information are needed. This property is offered by RNN, and especially Long-short-term-memory (LSTM) architectures (Hochreiter and Schmidhuber, 1997). Forward LSTMs processes input information $\mathbf{x} = (x_0, x_1, ..., x_n)$ from first word x_0 to the last one x_n educing relative hidden states h_t for each time step t. However, a lot of sequential information may be hidden in long distant dependencies. Thus, to enhance forward LSTMs performance we utilized bidirectional LSTMs (Bi-LSTM) processing input from both directions, forward (from x_0 to x_n) and backward (from x_n to x_0). Thus, for a given time sample t, the hidden state h_t is defined as the concatenation of forward and backward hidden states:

$$h_t = \overrightarrow{h_t}||\overleftarrow{h_t}, \quad h_t \in R^{2*L} \tag{1}$$

where $\overrightarrow{h_t}$, $\overleftarrow{h_t}$ denotes forward and backward hidden states respectively, and $mathitL$ denotes the number of units in each LSTM cell.

5.3 Convolutional Layer

Convolutional layers are the basic component of Convolutional Neural Networks (CNN), containing m convolutional filters aiming to reduce frequency variations. The convolution layer maps input matrix $\mathbf{S} \in R^{l \times D}$ into $c \in R^{|s|+h-1}$ using convolutional filters $\mathbf{F}$ with length h, and calculating each component c_i by:

$$c_i = \sum_{k,j} (\mathbf{S}_{[i:i+h]})_{k,j} \cdot \mathbf{F_{k,j}} \tag{2}$$

Filters $\mathbf{F}$ slide over the input matrix, performing element wise product between a column slice of input s and filter matrix k, in order to produce each vector component c_i. Finally, vectors c_i aggregate over all filters, producing a feature map matrix $\mathbf{C} \in R^{m \times |s|+h-1}$, which is passed through a non-linear ReLu activation function.

5.4 Pooling Layer

To reduce the spatial size of the convolutional layer output we use a pooling layer. Pooling layers manage to tune and reduce the amount of network parameters preventing overfitting. In the current work, a MaxPooling layer is used over the convolutional layers, performing a maximum element selection of n non-overlapping intervals. Thus, MaxPooling layer results in $\mathbf{C_{pool}} \in R^{m \times \frac{|s|+h-1}{n}}$.

5.5 The Enhanced Classifier

The devised recurrent convolutional neural network (R-CNN) architecture is shown in Figure 2. Each Bi-LSTM layer, comprised by 164 units each, was fed with 300-dimensions embedding vectors. The output of Bi-LSTM is processed by two 1-d convolutional-pooling layers containing 128 ReLU activated filters of length 5. Each convolutional layer is followed by a max-pooling layer of size 5 to reduce networks parameters. For the final pooling layer we utilize a global pooling that maps all sequential patterns to a feature vector, followed by a *softmax* activated dense network. The classification result coming from the R-CNN network couples the rule-based classification (presented in Section 4.2) following a parallel fail-safe mode, that is: in the event that the softmax output exceeds a certain *confidence threshold limit* for a specific class label (as shown in Table 4), and the rule-based classification induces the opposite label, the finally assigned class label is the one induced by the R-CNN.

5.6 Training

The proposed rule-based and R-CNN coupled model was trained following a combination of train-and-trial one epoch mode. In addition, we applied several regularization techniques to prevent overfitting. In particular, we adopted Dropout (Srivastava et al., 2014; Gal and Ghahramani, 2016), empirically set to 0.3, in order to randomly deactivate 30% of recurrent neuron connections between LSTM units. Finally, to optimize network training performance we adopted Adam optimizer as proposed by Kingma and Ba (2014), using cross-entropy loss function.

6 Results

Our officially submitted results ranked in the 5^{th} and 1^{st} place for subtasks A and B, respectively (results are presented in Tables 2 and 3). Our rule-based approach that expand proposed lexical and pattern-based lexical features tend to perform significantly well for both suggestion domains, customer-to-company and customer-to-customer. As shown in Table 3, the proposed model achieves almost the same results on both development and test datasets, as well as stable precision and recall performances. The combination of lexical, sequential and imperative mood features attains 0.86 *f1-score* and robust performance over all metrics. Similar to subtask B, the submitted results for subtask A exhibit almost the same *f1-scores* on both development and test datasets, 0.76 and 0.74, respectively. However, and in contrast to subtask B, one may observe a slight unstable performance between precision and recall, as shown in Table 2. To this end, and in order to improve precision performance, we introduced the ensemble-like combination of R-CNN and rule-based classifiers (Section 5.5). As illustrated in Table 4, the combined classifier achieves increased precision figures by up to 8%, and manages to outperform related submitted systems, and attain state-of-the-art prediction scores.

Method	Test-Subtask A		
	Prec	Rec	F1
R-CNN	0.64	0.79	0.71
Submitted	0.66	**0.86**	0.74
Proposed-0.75	0.73	0.78	0.77
Proposed-0.80	0.73	0.84	0.78
Proposed-0.85	**0.74**	0.85	**0.79**

Table 4: Comparison between rule-based submitted results, R-CNN and their combination. The proposed method tested on several confidence thershold limits as defined in Section 5.5.

7 Conclusion & Future Work

The presented work, introduces and implements a pattern/rule-based classification methodology on two SM tasks that shows very good performance. In addition, we introduce and propose a combination of the pattern/rule-based classifier with a carefully devised R-CNN classifier that achieves highly accurate and state-of-the-art results. Due to the different hyperparameters and rule weight optimization needed for each dataset, our implementation is currently split into two content-specific classifiers. Therefore, a robust classifier detecting cross-domain suggestions, regardless of the input content, is an important goal to fulfill and we plan to work towards this target.

OleNet at SemEval-2019 Task 9: BERT based Multi-Perspective Models for Suggestion Mining

Jiaxiang Liu, Shuohuan Wang, and Yu Sun

Baidu Inc., Beijing, China,
{liujiaxiang, wangshuohuan, sunyu02}@baidu.com

Abstract

This paper describes our system participated in Task 9 of SemEval-2019: the task is focused on suggestion mining and it aims to classify given sentences into suggestion and non-suggestion classes in domain specific and cross domain training setting respectively. We propose a multi-perspective architecture for learning representations by using different classical models including Convolutional Neural Networks (CNN), Gated Recurrent Units (GRU), Feed Forward Attention (FFA), etc. To leverage the semantics distributed in large amount of unsupervised data, we also have adopted the pre-trained Bidirectional Encoder Representations from Transformers (BERT) model as an encoder to produce sentence and word representations. The proposed architecture is applied for both sub-tasks, and achieved f1-score of 0.7812 for subtask A, and 0.8579 for subtask B. We won the first and second place for the two tasks respectively in the final competition.

1 Introduction

Suggestion mining, which can be defined as the extraction of suggestions from unstructured text, where the term *suggestions* refers to the expressions of tips, advice, recommendations etc. (Negi et al., 2018). For example, *I would recommend doing the upgrade to be sure you have the best chance at trouble free operation.* and *Be sure to specify a room at the back of the hotel.* should be a suggestion for electronics and hotel separately. Collecting suggestions is an integral step of any decision making process. A suggestion mining system could extract exact suggestion sentences from a retrieved document, which would enable the user to collect suggestions from a much larger number of pages than they could manually read over a short span of time.

Suggestion mining remains a relatively young area. So far, it has usually been defined as a problem of classifying sentences of a given text into suggestion and non-suggestion classes. Mostly rule-based systems have so far been developed, and very few statistical classifiers have been proposed (Negi and Buitelaar, 2017) (Negi et al., 2016) (Negi and Buitelaar, 2015) (Brun and Hagège, 2013). A related field to suggestion mining is sentiment classification which given a sentence or a document, it should infer the sentiment polarity e.g. positive, negative, neutral. So, many classical sentiment classification systems can be used in suggestion mining like the widely used CNN-based models (Kim, 2014) or RNN-based models (Kawakami, 2008). However, there are still many challenges in this suggestion mining task. First of all, both of the subtasks suffers from severely lack of data. Second, one of the subtasks requires the model should have transferability without seeing any of the target domain data. To tackle those problems, knowledge transfer or transfer learning between domains would be desirable. In recent years, transfer learning techniques have been widely applied to solve domain adaptation problem, e.g. (Ganin et al., 2016). And in our system, considering the simplicity for training a model, we turn to taking use the power of large amount of unsupervised data for knowledge representations for both same domain and cross domain tasks.

Recently researches have shown that pre-training unsupervised language model can be very effective for learning universal language representations by leveraging large amounts of unlabeled data, e.g. the pre-trained Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018). It has shown that BERT can be fine-tuned to create state-of-the-art models for a range of NLU tasks, such as question answering

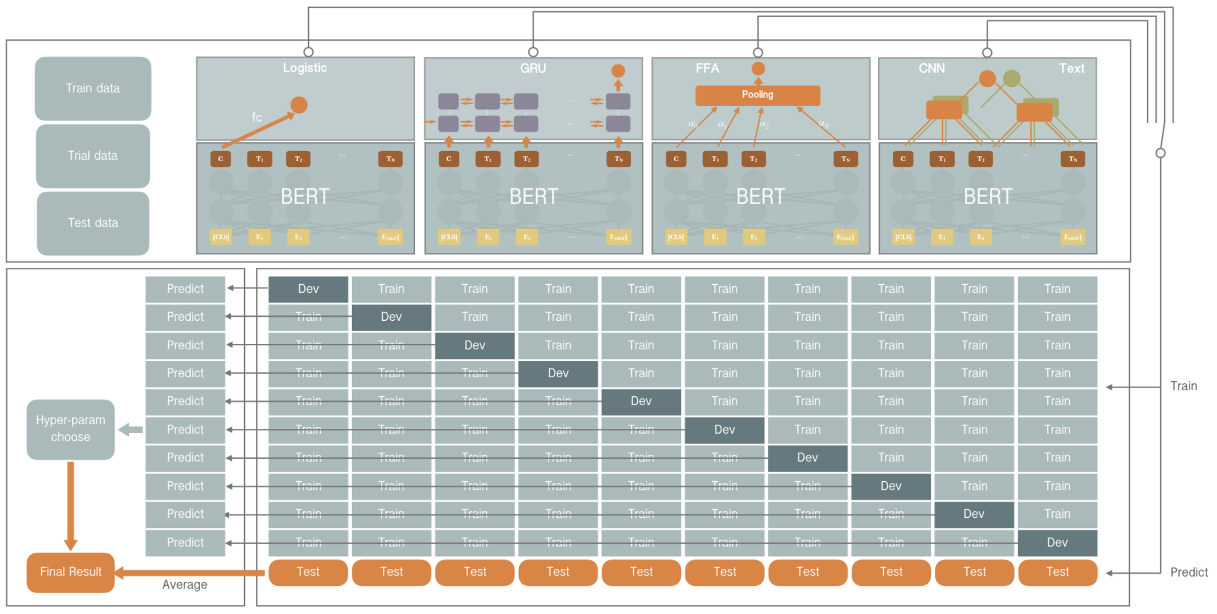

Figure 1: An overall framework and pipeline of our system for suggestion mining

and natural language inference. To further make use of the model in our task, various of different task specified layers are devised. The experiment on test datasets shows that with the devised task specified layers, a higher f1 scores can be got in both tasks, and moreover, benefiting from the large amount of unlabeled data, it is very easy to train cross domain models.

The paper is organized as follows: Section 2 describes the key models proposed for the SemEval 2019 Task 9 (Negi et al., 2019). Section 3 shows the experiment details including dataset preprocessing method, experiment configurations, threshold selection strategy and the alternatives we explored with respect to sublayers and their combination, and performances of different models. Finally, we conclude our analysis of the challenge, as well as some additional discussions of the future directions in Section 4.

2 System for Suggestion Mining

2.1 Multi-Perspective Architecture

As shown in Figure 1. our model architecture is constituted of two modules which includes a universal encoding module as either a sentence or a word encoder, and a task specified module used for suggestion classification. To fully explored the information generated by the encoder, we stack a serious of different task specified modules upon the encoder according to different perspective. Intuitively, we could use the sentence encoding directly to make a classification, to go further beyond that, as language is time-series information in essence, the time perspective based GRU cells can also be applied to model the sequence state to learn the structure for the suggestion mining task. Similarly, the spatial perspective based CNN can be used to mimic the n-gram model, as well. Moreover, we also introduce a convenient attention mechanism FFA (Raffel and Ellis, 2015) to automatically learns the combination of most important features. At last, we ensemble those models by a voting strategy as final prediction by this system. The different task specified modules will be described below.

2.2 Sentence Perspective Encoding

In the sentence encoder module, a special mark $[CLS]$ is added to the front of each sentence to help the encoder to encode all the input sentence. As a result, the output corresponds the first token is regarded as the sentence representation,

$$\begin{cases} c = E(w_t), & t = 0 \\ e_t = E(w_t), & t \in [1, T] \end{cases} \tag{1}$$

where E is the encoder module, which we user BERT in practice, c, e_t is sentence and word representation respectively, T is the total length of input sequences. We fed c into a logistic network to classify the suggestions.

2.3 Time Perspective Encoding

The Gated Recurrent Unit (GRU)(Cho et al., 2014) is famous for processing sequence data, e.g. sentences, with less parameters. In our task, we feed the e_t into GRU cells to get word representation from a time series perspective h_t,

$$\begin{aligned} z_t &= \sigma\big(e_t U^z + h_{t-1} W^z\big) \\ r_t &= \sigma\big(e_t U^r + h_{t-1} W^r\big) \\ \tilde{h}_t &= \tanh\big(e_t U^h + (r_t * h_{t-1}) W^h\big) \\ h_t &= (1 - z_t) * h_{t-1} + z_t * \tilde{h}_t \\ u &= \frac{1}{T} \sum (h_t) \\ v &= \max_{1 \le t \le T} (h_t) \\ c &= [u; v] \end{aligned} \tag{2}$$

where h_t is hidden state of GRU of time step t, u is a mean pooling vector of h_t, and v is a max pooling vector of h_t. In practice, not only the h_t is used to feed into the classification layer, but the concatenated vector c is also used to train a binary classification logistic layer.

2.4 Spatial Perspective Encoding

To model the spatial connections of adjacent words, we use Convolutional Neural Network (CNN) (Kim, 2014), which is easy to implement and very fast for train. In our system, two CNN layers are stacked upon BERT model and the batch normalization (Ioffe and Szegedy, 2015) is applied in each layer. Also, the ReLu (Nair and Hinton, 2010) function is chosen as activation function. And we use max pooling to fuse the output of convolutional layers.

2.5 Attention Perspective Encoding

A recently proposed method for easier modeling of long-term dependencies is *attention* (Bahdanau et al., 2014). Attention mechanism allows for a more direct dependence between the state of the model at different points in time. Intuitively, the model with less parameters is easier to train based on small dataset, therefore, we try to use a more straight and simplified attention model, *Feed Forward Attention* (FFA) (Raffel and Ellis, 2015), which would allow it to be used to produce a single vector v from an entire sequence, the process could be formulated as follows:

$$\begin{aligned} s_t &= f(e_t) \\ \alpha_t &= \frac{exp(s_t)}{\sum_{k=1}^{T} exp(s_k)} \\ l &= \sum_{t=1}^{T} \alpha_t e_t \end{aligned} \tag{3}$$

where, f is a function mapping e_t to a unnormalized scaler s_t indicating the importance of word w_t. The l is used to make a classification to decide which input sentence is a suggestion.

But what should be noticed here is that, subtask B, whose trial data and test data are all from hotel review domain and no training data from same domain as test data is provided, is substantially a transfer learning problem. It can only learn from windows forum corpus provided in subtask A. Therefore, squeeze more cross-domain features and drop the noise is critical for subtask B. So we also introduce the hard attention mechanism (Shankar et al., 2018) :

$$l' = \sum_{\alpha \in TopK(\vec{\alpha})} \alpha h_t \tag{4}$$

we select top k important words by the attention weights α. At last the vector l and l' are used to train a binary classification logistic layer for the subtasks.

2.6 Ensemble

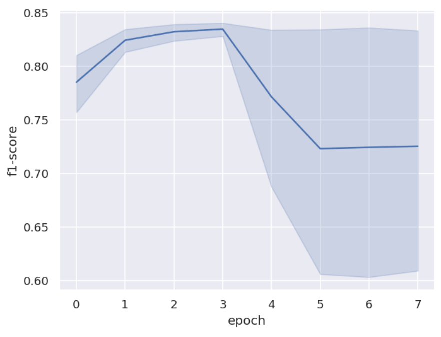
As shown in Figure 1., cross validation was adopted to ensure robustness for each model to the task 9 of SemEval-2019. In subtask A, after the 10 folds cross validation in training set has finished, the result for each fold is concatenated and used to select best classification threshold to decide a test sample from label 0 to 1. The model trained in each fold is also used to predict on test data, so the 10 test predictions is fused by mean pooling as a final prediction. Finally the simple voting method is used to fuse different model's result. In subtask B, we use the trial data as dev set to select best hyper parameters, so no cross validation is used.

3 Experiment

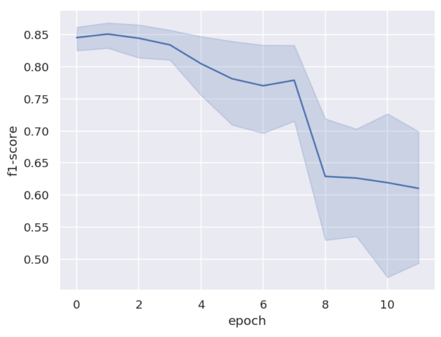
3.1 Dataset

The statistics of datasets provided by SemEval 2019 Task 9 are show in Table 1.

In both subtasks, no extra data are used for training models. As shown in Table 1, there are 8500



(a) Subtask A



(b) Subtask B

Figure 2: Mean f1 score for trial set of different models for every epoch. In subtask A, f1 score incrementally increase and fall after the 3rd epoch, while in subtask B, f1 score of initial epoch is always surprisingly high and decreases thereafter.

Subtask A	Suggestion(%)	Non-Suggestion (%)
train	2085 (0.24)	6415 (0.75)
trial	296 (0.50)	296 (0.50)
test	87 (0.10)	746 (0.89)
Subtask B	Suggestion(%)	Non-Suggestion(%)
trial	404 (0.49)	405 (0.50)
test	348 (0.42)	476 (0.57)

Table 1: Dataset statistics for subtask A and subtask B

train examples, 592 labeled trial examples and 833 unlabeled test examples in subtask A. Different from subtask A, there are only 808 labeled trial examples, and 824 unlabeled test examples in subtask B, no training data from same domain as test data is provided. So, we use all labeled data in subtask A as the training data to do a transfer learning task to help learn subtask B. In both subtasks, the trial sets are used to help select the best model.

3.2 Details

Data Preprocessing: We use the same data cleaning method as (Cho et al., 2014), which removed the special marks. The sample is forced to *unk* if the cleaned sentence is empty.

Data augmentation method was also used in subtask A. During the error analysis procedure, we found that the model has strong tendency to learn specific terms for the task, which means the model is overfitting training data. To tackle this problem, not only dropout method is used, but also we introduce a auxiliary model to identify the importance terms according feature scores, e.g. the feature weights in a linear model. In our experiment, we use linear-kernel SVM as the auxiliary model. Specifically, we first run a linear-kernel SVM on training set. To get best performance of SVM, grid search is used to choose best hyperparameters. When finished training SVM model, the coefficients of features in the model is collected. Then, according to the value of coefficient, the most J important word are selected as key features. Finally, we replicate training samples with random dropping those important words with drop rate α to force the model to not only rely on specific terms, but also learn sentence structure of this task. In our experiment, we take J as 100, and α 0.5.

In subtask B, besides cleaning data, we combine subtask A train set and subtask A trial set to form a bigger training set. But the drop important word strategy is not applied.

Threshold choosing: As suggestion mining is introduced as a binary classification problem, choosing appropriate threshold for the logit is vital to the performance. In subtask A, a 10-fold cross validation is executed and we obtain the best threshold by calculating f1-score between the concatenated 10 validation results and training set.

In subtask B, all the data of subtask A is used as training data, and the threshold is chosen by using the subtask B trial dataset.

Empirically, the representations from BERT is universal, so after task specified fine-tuning, the performance will increases as it is show in Figure 2a. But, for the subtask B, training dataset of subtask A have a different distribution from data of subtask B. However, we assume that they still share some underlying semantics. Therefore by

Models	CV f1-score	test score
BERT-Large-Logistic	0.8522 (±0.0213)	0.7697
BERT-Large-Conv	0.8520 (±0.0231)	0.7800
BERT-Large-FFA	0.8516 (±0.0307)	0.7722
BERT-Large-GRU	0.8503 (±0.0275)	0.7725
Ensemble	–	**0.7812**

Table 2: SubtaskA models performances. CV f1-score is used to record cross validation dev set scores, and the test score is generated by trained model predicting on released labeled test data.

Models	Subtask B Trial set score	Subtask B Test set score
BERT-Large	0.8695	0.8302
BERT-Large-Conv	0.9001	0.8425
BERT-Large-FFA	0.8795	0.8409
BERT-Large-GRU	0.8796	0.8486
Ensemble	–	**0.8579**

Table 3: Subtask B models performances. We use labeled data from subtask A as training set, subtask B trial data as dev set to select best hyper-parameters, and test score is generated by trained model predicting on released labeled test data

training with subtask A data, the model should also works in the subtask B.

As shown in Figure 2a we noticed that, in subtask A, there is an obvious increasing tendency of f1 score until the 3rd epoch indicating the model have found the optimal parameters for fine-tuning. And for subtask B, which is shown in Figure 2b, best performance is always achieved in very early steps of initial epoch when fine-tuning the model and decrease all the way down, which proves that the model are learning common features cross the two different domains, but as the training process proceeds, more and more features about subtask A are learned, which cause the performance of subtask B decrease.

Learning rate tricks: Considering that the number of training dataset is too small to train a complex model, different learning rate are applied for different layers. Specifically, we apply a small learning rate for pre trained BERT layers, and a larger learning rate for new task specified layer.

3.3 Results

In the early stage of this competition, we have tried many non-BERT models, e.g. CNN (Kim, 2014), Transformer Encoder (Vaswani et al., 2017), Capsule Networks (Gong et al., 2018). However, none of the results from those models are competitive with the models based on BERT . The scores are summarized in Table 2 and 3. The result have shown that with the ensemble strategy of different models, scores of both tasks increases.

It should be noted here that, for every model of subtask A, we run 5-10 times training process repeatedly with different random seeds to ensure we can get a reliable evaluation result. For the final submission, we use the voting strategy to fuse all predictions of each model, and the ensemble results is 0.7812 and 0.8579 for subtask A and B respectively.

4 Conclusion

In this paper, we have introduced an empirical multi-perspective framework for the suggestion mining task of SemEval-2019. We propose an ensemble architecture for learning representations by using different classical models including CNN, GRU, FFA Network, etc. According to the obtained promising performances on both subtasks, we found that the pre-trained model by a large amount of unlabeled is critical for most nlp tasks, even for domain adaptation tasks without a specific neural architecture. In the future, in order to make more use of the dataset from different domains, adversarial gradient or common domain feature learning methods can be adopted along with pre-trained models to reach a better performance.

Abstract

This paper describes the work on mining the suggestions from online reviews and forums. Opinion mining detects whether the comments are positive, negative or neutral, while suggestion mining explores the review content for the possible tips or advice. The system developed by SSN-SPARKS team in SemEval-2019 for task 9 (suggestion mining) uses a rule-based approach for feature selection, SMOTE technique for data augmentation and deep learning technique (Convolutional Neural Network) for classification. We have compared the results with Random Forest classifier (RF) and Multi-Layer Perceptron (MLP) model. Results show that the CNN model performs better than other models for both the subtasks.

1 Introduction

Sentiment analysis is a process of computationally identifying and categorizing the opinions from unstructured data. This can be used to identify a user's perspective of a product — positive, negative or neutral. Opinion mining is used to identify whether the product is a success in the market or not. Suggestion mining finds out ways to enhance the product to satisfy the customers.

Review texts are mainly used to identify the sentiments of the user. Besides sentiments, review texts also contain valuable information such as advice, recommendations, tips and suggestions on a variety of points of interest (Negi and Buitelaar, 2017a). These suggestions will help other customers make their choices, on the one hand, and the sellers improve their products, on the other hand.

Suggestion mining is relatively a young field of research compared to sentiment analysis. While mining for suggestions, the propositional aspects like mood, modality, sarcasm, and compound statements have to be considered. It is observed that, in some cases, grammatical properties of the sentence alone can be used to identify the label, while in other cases semantics play a significant role in label classification (Negi and Buitelaar, 2017b).

"Task 9 – Suggestion mining from online reviews and forums" has two subtasks (Negi et al., 2019). Subtask A is to classify a sentence into a suggestion or a non-suggestion. Subtask B is a cross-domain testing in which the model learned from a domain-specific dataset is used to classify dataset from a new domain. We have built classifiers using MultiLayer Perceptron (MLP), Random Forest (RF) and Convolutional Neural Network (CNN) models. However, due to the imbalance in the data, we have augmented it using Synthetic Minority Over-sampling TEchnique (SMOTE). We found that the CNN model performs better compared to RF and MLP classifiers for both the subtasks.

2 Related Work

Ramanand et al. (2010) discusses the rule-based method to find out the suggestions from the reviews. They have identified two kinds of 'wishes' viz the desire to improve the product and the desire to purchase the product. They have formulated the rules using modal verbs and certain sentence patterns. Viswanathan et al. (2011) develops an ontology-based knowledge representation for suggestion mining.

Customer-to-customer (CTC) suggestions are extracted by Negi and Buitelaar (2015) using keywords, POS tags, and imperative mood patterns. Customers feedback are analyzed using CNN and GRU network by Gupta et al. (2017). Long Short-Term Memory (LSTM) and CNN are used for sentence classification by Negi and Buitelaar (2017a).

A Linguistic-based approach is used to analyze customer experience feedback by Ordenes et al. (2014) and Brun and Hagege (2013). We have used MultiLayer Perceptron for performing task 1 and task 3 in SemEval 2018. Task 1 was to identify the affect in tweets (Angel Deborah et al., 2018) and task 3 was to identify the irony in English tweets (Rajalakshmi et al., 2018).

3 System Description

Suggestions are mined mainly for business people to improve the product or for fellow customers to detect advice (Negi et al., 2016). We have used a linguistic rule-based method for feature extraction. Data is augmented to balance the imbalance in the data. The extracted Bag of Words (BOW) features are used in MLP, RF and CNN classifier for suggestion mining.

3.1 Feature extraction

The dataset is preprocessed to remove the stop words and non-printable characters using the NLTK functions. The features from the unstructured text are extracted using parts-of-speech (POS) tag. Modal verbs (MD) and the base form of verbs (VB) are considered to be suggestion features. Since the dataset has an imbalance, we have fewer examples for the suggestion class. Hence we have added synonyms and certain keywords used in baseline to enhance the BOW feature set. Top 5 synonyms for a particular word is obtained using synsets function from wordnet and keywords such as 'suggest', 'recommend', 'add', 'extend', 'idea', 'enhance', 'helpful', and 'useful'are added to enhance the feature set.

3.2 Handling imbalanced data

Imbalance in data is a scenario where the number of observations of one class is significantly lower than those of other classes (Chawla, 2009). This problem is predominant in fraudulent transactions, rare disease identification, criminal detection and also in suggestion mining. The model developed on this dataset will be inaccurate and biased since the traditional machine learning algorithms do not consider the distribution of the classes.

Imbalance in data can be remedied using the following methods.

1. Data level resampling
   (a) Random undersampling
   (b) Random oversampling
   (c) Cluster based oversampling
   (d) Synthetic Minority Oversampling Technique (SMOTE)
   (e) Modified Synthetic Minority Oversampling technique (MSMOTE)
2. Algorithmic ensemble techniques
   (a) Bagging
   (b) Boosting: Ada boost, Gradient tree boosting, XG boost

Data augmentation can be done in data space or feature space. SMOTE algorithm is used to create augmented samples in feature space (Wong et al., 2016). A subset of minority data is used to generate similar instances, synthetically. Synthetic data are generated based on the k nearest neighbours. These synthetic data are added to the original dataset to balance it.

The procedure for balancing the minority class data (Chawla et al., 2002) is outlined in Algorithm 1. SMOTE algorithm is applied on the minority sample BOW feature vectors to generate the synthetic data.

```
Algorithm 1: SMOTE Algorithm
Input: Unbalanced dataset.
Output: Balanced dataset
begin
  1. Set the balancing ratio as auto to balance the given dataset equally.
  2. For each instance $i$ in the minority sample
     (a) Compute $k$ nearest neighbours.
     (b) For each instance $n$ in neighbour list
         i. $\mathrm{diff}_{i,n}$ = difference between $i$ and $n$.
         ii. $\mathrm{rand}$ = Generate a random number between 0 and 1.
         iii. synthetic_sample = $i + \mathrm{rand} * \mathrm{diff}_{i,n}$
         iv. Add the synthetic_sample to original dataset
end
```

3.3 Classifier algorithms

MultiLayer Perceptron, Random Forest and Convolutional Neural Network algorithms are used to build models. The augmented data is given to each of these classifiers and the models are built in Python programming environment. The results show that the CNN model performs better than MLP and RF.

3.3.1 MultiLayer Perceptron

MLP is a feedforward neural network mainly used for classification. It comprises an input layer, one or more hidden layers, and an output layer. The number of neurons in the input layer is decided by the number of features in the feature vector. The number of neurons in the output layer depends upon the number of classes. In our network, we have 5048 input neurons and 2 output neurons for suggestion/non-suggestion classification. We have used two hidden layers with 512 and 256 neurons respectively. Relu activation function is used for the input and hidden layers, while the softmax function is used for the output layer. Nadam gradient descent algorithm is used for optimization of the model.

3.3.2 Random Forest

Random forest classifier is an ensemble learning technique that uses decision tree as a basic learning algorithm. This is used to overcome the overfitting problem present in decision tree. Random forest creates a set of decision trees for randomly selected subsets of training data. It then aggregates the results of all these decision trees to make the final prediction. We have used 100 decision trees to build the random forest classifier and information gain as the measure of split criteria.

3.3.3 Convolutional Neural Network

Convolutional neural network is a deep learning technique that has already achieved remarkable results in computer vision. In text processing, deep learning techniques are used to learn the word vector representation through various neural models (Kim, 2014) and (Zhang and Wallace, 2015). We have used input embedding layer, convolutional one dimension layer with 32 filters, max-pooling layer with pool-size as 2, flatten layer, fully connected dense layer and output layer. We have added the dropout layer as 0.2 to regularize the network (Srivastava et al., 2014). The batch size of the model is set as 128 and the learning rate as 0.01. Softmax activation function is used in output layer and relu activation function is used in all other layers. Nadam algorithm is used for optimization.

3.4 Algorithm

The procedure for suggestion mining is outlined in Algorithm 2:

Algorithm 2: Suggestion Classification

```
Input: Augmented dataset.
Output: Suggestion/Non-Suggestion class labels
begin
  1. Preprocess the dataset
     (a) Separate labels and sentences.
     (b) Remove the stop words and non-ascii
         characters from the sentences using
         NLTK functions.
     (c) Perform tokenization and Parts-of-
         Speech tagging using functions of the
         NLTK toolkit.
  2. Feature selection
     (a) Identify the features using MD (Modal
         verbs) and basic form of verbs (VB).
     (b) Add the features and their synonyms
         into BoW.
     (c) Encode the features of sentences as a
         one-hot vector.
     (d) Represent the labels as a one-hot encod-
         ing of binary class in target vector.
  3. Balance the dataset using SMOTE technique.
  4. Build models (MLP, RF, CNN) with BoW
     feature vectors and target vectors.
  5. Predict the labels for the test dataset.
     (a) Preprocess the test dataset
     (b) Represent the sentences as one hot vec-
         tor with the help of BoW features of the
         training set.
     (c) Predict the labels of the test sentences by
         giving the BoW feature vector as input
         to the built model.
  6. Calculate the accuracy and F1 score.
end
```

4 Dataset

The dataset given for suggestion mining task is prepared by a study of suggestions which appeared in different domains (Negi et al., 2018). For subtask-A, suggestion forum dataset is used for training and testing. For subtask-B, suggestion forum dataset is used for training and hotel review dataset (Wachsmuth et al., 2014) is used for testing purposes. The suggestion forum training dataset has 2085 instances of suggestion class and 6415 instances of non-suggestion class. The trial test set for suggestion forum dataset has equal number of instances (296) for both classes. The trial test set for hotel review dataset has an equal number of instances (404) for both the classes.

5 Performance Evaluation

The performance of the system is measured using precision, recall and F1-score for suggestion examples alone, using formulas shown in Equations 1 to 3.

$$\text{Precision } (\text{P}_{sugg}) = \frac{\text{TP}}{\text{TP} + \text{FP}} \quad (1)$$

$$\text{Recall } (\text{R}_{sugg}) = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (2)$$

$$\text{F1 score}_{sugg} = 2 \times \frac{\text{P}_{sugg} \times \text{R}_{sugg}}{\text{P}_{sugg} + \text{R}_{sugg}} \quad (3)$$

where TP is True Positive, TN is True Negative, FP is False Positive and FN is False Negative.

The F1 score for subtask A and subtask B using various models are shown in Table 1 and 2 respectively. Results show that CNN performs slightly better than MLP and RF models. The performance of the CNN model depends on the dataset size. Hence on increasing the data, we can get better results in CNN.

F1-Score	**Value**
MLP	0.45
RF	0.4
CNN	**0.49**
Baseline	0.2676

Table 1: Performance for Subtask A

F1-Score	**Value**
MLP	0.154
CNN	**0.155**

Table 2: Performance for Subtask B

We also worked with original data as such (without balancing) and created models using MLP, RF, and CNN. The F1 score for those models are very low, as almost all the samples are classified to non-suggestion class. CNN model with hand-selected features converges in less time with the same accuracy when compared to the CNN model with pre-trained Word2Vec embeddings. We intend to further investigate the model behavior using the variations of SMOTE such as borderline SMOTE, ADASYN and MSMOTE. For subtask B, the results are very low, since we have used the model built for suggestion forum dataset to make the prediction on hotel reviews dataset. The performance can be increased by incorporating transfer learning.

6 Conclusion and Future Scope

Customers generally express their opinions about an item through online reviews, blogs, discussion forums, or social media platforms. These opinions not only contain positive or negative sentiments but also contain suggestions to improve the item or advice to other customers. We have used CNN for suggestion mining. Dataset is augmented using SMOTE technique to handle the imbalance. Rule-based approach is used for feature extraction.

The performance can be improved by extracting the features using lexicons and increasing the number of convolutional layers in CNN structure. We intend to work with variations of SMOTE algorithm for balancing data and compare the results. We would also like to investigate the performance of Recurrent Neural Network (RNN) for mining suggestions from unstructured data.

Abstract

This paper describes the suggestion miner system that participates in SemEval 2019 Task 9 - SubTask A - Suggestion Mining from Online Reviews and Forums. The system participated in the subtasks A. This paper discusses the results of our system in the development, evaluation and post evaluation. Each class in the dataset is represented as directed unweighted graphs. Then, the comparison is carried out with each class graph which results in a vector. This vector is used as features by a machine learning algorithm. The model is evaluated on, hold on strategy. The organizers randomly split (8500 instances) training set (provided to the participant in training their system) and testing set (833 instances). The test set is reserved to evaluate the performance of participants systems. During the evaluation, our system ranked 31 in the Coda Lab result of the subtask A (binary class problem). The binary class system achieves evaluation value 0.35.

1 Introduction

Suggestion mining or *identification of suggestions* within the text is a relatively new area which is gaining popularity among many private and public sector organizations, service providers and consumers/customers at large due to its number of uses. Suggestion mining, in general, refers to the extraction of tips, advise or recommendations from an unstructured text, which can lead to a number of use cases (Negi et al., 2018). Currently, suggestion mining is considered to be an intrinsic part of any decision-making process, used by different entities to get an insight into people's perspectives and improve their products or services (Negi et al., 2018), (Jijkoun et al., 2010). To get reviews and suggestions, organizations either ask them from users explicitly or extract them from online reviews, blogs, discussion forums, social media etc. This is because, these platforms are progressively gaining popularity (due to their expeditious advancements and ease of use) for obtaining public opinions towards events, brands, products, services, entities etc. Consider some examples which have been seen among many online reviews, giving useful suggestions to whom it may concern: "I would recommend doing the upgrade to be sure you have the best chance at trouble-free operation.", "Be sure to specify a room at the back of the hotel" (Negi et al., 2018), "Make sure you bring plenty of sun tan lotion-very expensive in the gift shop" (Negi and Buitelaar, 2015). We can clearly see that these reviews contain suggestions and recommendations for others to make use of a service or a product if they want to avail it at its best. Before the advent and realization of the importance and use of suggestion mining, opinion mining has been used by stakeholders to mine text with a perspective of summarizing opinions on the basis of sentiment polarities (Liu, 2012). Though identifying negative and positive sentiment distribution within a text is important from a lot of perspectives, however, identification of a suggestion oriented text would be more useful for stakeholders looking for improvements in their services or products, and also, for the services seeker and potential buyers of a product (Negi and Buitelaar, 2015). Thus, automatic identification and classification of suggestion oriented text from a large corpus of raw text is the need of the hour, as, is not feasible manually.

Some empirical analysis has been done previously for automatic suggestion mining, as, (Negi and Buitelaar, 2015) used Support Vector Machine (SVM) to identify suggestion oriented sentences within customer reviews. In another study ((Negi et al., 2016)) the authors used Neural Network architecture to classify suggestions from raw text. (Negi and Buitelaar, 2017) used Long Short Term

Figure 1: Graph Construction with vicinity size 2 illustrates how the vicinity size move toward the end of the tweet; in this example, the frame is the two following words and for each word some edges and nodes are added to the graph.

Memory (LSTM) model to classify sentences as suggestions or non-suggestions. The authors, in their study trained word embeddings on suggestions (taken from WikiHow ”Tips” section) and the resulting LSTM model, showed higher performance from the previous ones. The graph-based centrality measure is also used to classify short text analysis(Ishtiaq et al., 2019). Lubna et al. proposed word sense disambigousness technique to evaluate the adverb, adjectives, and verb combination (Zafar et al., 2017).

By analysing the current suggestion mining techniques and studies ((Negi et al., 2018), (Negi and Buitelaar, 2017)), it is realized that suggestion calcification task face many overlapping challenges as with other sentence classification problems. They include: annotations of data, comprehending sentence-level semantics, making sense of figurative and sarcastic expressions, long and complex sentences (covering multiple aspects and diverse domains), catering diverse domain sentences (rather than classifying domain specific ones), imbalanced class distributions (due to the imbalanced availability of suggestion oriented text within the raw text in certain domains) etc (Negi et al., 2018).

This paper describes our proposed model for the SemEval-2019 pilot challenge for suggestion mining's Sub-Task A, i.e classify a given text as a suggestion or non-suggestion text, using same domain training and testing data. As described in the challenge highlights, the data set will belong to a particular domain i.e. suggestion forum for windows platform developers, which needs to be classified as a suggestion or non-suggestion class. For this challenge, our proposed model is a hybrid one, inspired by two previous studies ((Giannakopoulos et al., 2008) and (Maas et al., 2011)), in combination with some additional features and word graph similarity score as used by Usman et al (Ahmed et al., 2018). The word graph model used in this research is adopted from Usman et al technique of Iron detection (Ahmed et al., 2018). The detailed description of our model is given under the proposed model section. Rest of the paper includes task overview, data set description, results and evaluation, followed by discussion and conclusion.

2 Task Overview

In SemEval-2019, task 9 contains two sub-tasks A and B, for suggestion mining from a given text. The text (dataset) for this challenge which needs to be classified against each subtask is taken from two domains, i.e. suggestion forums and hotel reviews (Negi et al., 2019).

In this paper, we are focusing on sub-task A, which is, detection of a suggestion or non-suggestion text, from, the text of suggestion forums (dedicated resources used to provide suggestions for improvements in any under-discussed entity). For this task, the training and validation data sets will belong to one domain, and the details of it are covered in the dataset overview section.

3 Proposed Model

Our proposed model is a hybrid approach, in which the given text is represented as a directed unweighted word graph at first (for both the

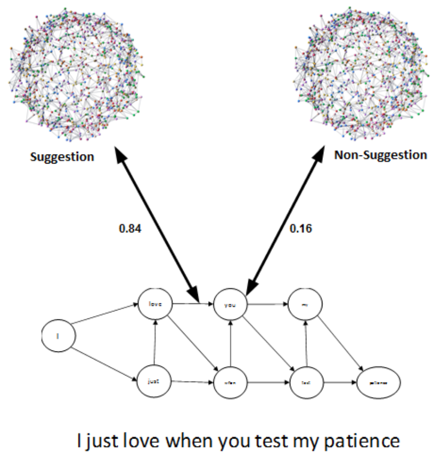

Figure 2: Graph Similarity Feature Extraction for one measure. The graph of a forum review used to compare with training data class graphs, in order to produce two numbers (depending upon the numbers of classes). These numbers will be used as a feature vector. The feature vector is provided to the trained model to predict the class of the new forum review.

classes). The edge between each word is created based on the vicinity window size, as explained in the subsection Graph construction. After graph construction, a comparison is carried out between each graph for construction of a feature vector, which is later used as an input for our machine learning algorithm. The graph is constructed based on a class assignment, which is later used to measure the similarity of a text with each class graph (suggestion or non-suggestion). For similarity measurement between the class graph and text graph, we used containment similarity, maximum common subgraph similarity and its variant compare graph in terms of similarity.

3.1 Dataset Overview

For the training, trial and evaluation dataset are provided by the organizer via Github: `https://github.com/Semeval2019Task9/Subtask-A`. The dataset for this task is annotated in two phases (Negi et al., 2019). In the first phase, crowd-sourced annotators are involved for performing the annotations, whereas in the second phase in-house expert annotators are used (Negi et al., 2019). The finalized datasets include only those sentences which explicitly express suggestions rather than those that only provide information which can be used to infer suggestions. The dataset is collected from a particular suggestion forum's reviews (uservoice.com) on universal windows platform (Negi et al., 2019). The number of sentences in the dataset is shown in Table 2.

Table 1: Feature Set

No.	Features
1	Containment Similarity UniGram
2	Containment Similarity BiGram

4	Maximum Common Subgraph Edge Similarity (MCSES)
5	Maximum Common Subgraph Directed Edge Similarity (MCSDS)
6	Number of Characters
7	Number of Words

Table 2: Dataset Statistics

Class	Train set	Trial Test set	Test set
Suggestions	2085	296	87
Non-suggestions	6415	296	746

3.2 Graph Construction

For the graph construction, we consider the given text (which needs to be classified as either suggestion or non-suggestions) as a set of words, based on their vicinity. Each word is considered as a labelled node in a graph, which is joined with a directed edge, depending on the window size. For our analysis, we used a vicinity size of 2, adopted by analysing our results during the tuning phase of our model. Figure 1 illustrates the complete graph construction process of a sentence, with vicinity size 2. We can clearly see how nodes and edges are added in the graph against each word. Further, in order to check text graph similarity with the class graph, our model makes use of the containment similarity (non-normalized value), maximum common subgraph similarity and its variant compare graph.

4 Feature Engineering

4.1 Containment Similarity

Containment similarity measure is used to measure two graphs similarity by calculating the common edges between them by the number of edges of the smaller graph (Aisopos et al., 2012). Equation 1 illustrates the mathematical expression of containment similarity measure, where GT (target graph) is the text word graph, Gs (source graph) is the word graph of suggestion class. e is the edge of a word graph and the size of the graph is the

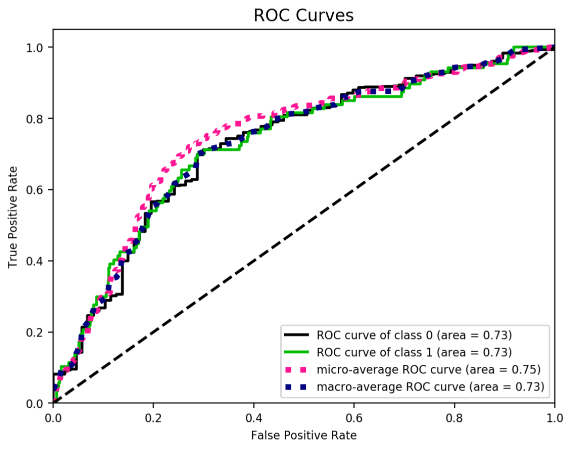

Figure 3: Precision Recall Curve of Binary Class problem

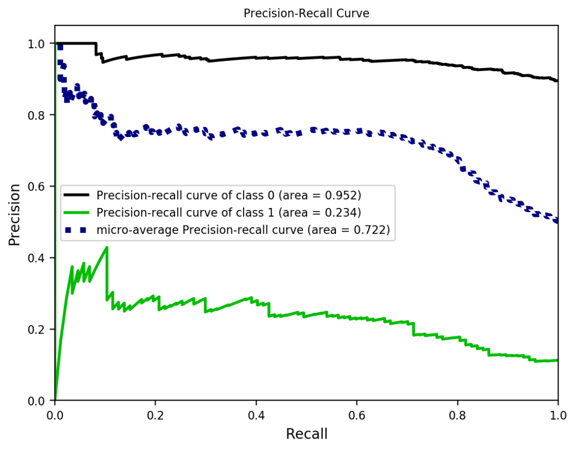

Figure 4: Precision Recall Curve of Multi Class problem

number of nodes or edges.

$$CS(G_T, G_S) = \frac{\sum_{e=G_T} \mu(e, G_S)}{min(|G_T|, |G_S|)} \quad (1)$$

4.2 Maximum Common Sub Graph

We used three variations of maximum common sub graph metric to find similarity between text graph and class graph. Equation 2 illustrates the node similarity calculation method, equation 3 illustrates the edge similarity of the two graphs where as equation 4 illustrates directed edge similarity.

$$MCSNS = \frac{MCSN(|G_T|, |G_S|)}{min(|G_T|, |G_S|)} \quad (2)$$

Maximum Common Sub graph Node Similarity (MCSNS) is the difference of target (GT) and source graph (GS).

$$MCSUES = \frac{MCSUE(|G_T|, |G_S|)}{min(|G_T|, |G_S|)} \quad (3)$$

Maximum Common Sub graph Edge Similarity (MCSUE) is the total number of edges contained in the MCS after taking the difference of target graph (GT) and source graph (GS), without considering the direction.

$$MCSDES = \frac{MCSDE(|G_T|, |G_S|)}{min(|G_T|, |G_S|)} \quad (4)$$

MAximum Common Sub graph Directed Edge Similarity (MCSDES) is the number of the edges contained in the MCS that have the same direction in the graphs. A full feature set is mentioned in Table 1.

4.3 Model Selection

To solve binary class suggestive review classification, we used Tree-based Pipeline Optimization Tool (TPOT), (Olson et al., 2016). The labelled data is given as an input to TPOT, which returns the hyper tuned model for the binary class classification problem. After close analysis it is observed that the data suffers from class imbalance problem. To handle this problem, we used SMOTE ((Cummins et al., 2017)) a Python toolbox. TPOT gives extreme gradient boosting classifier tune parameters i.e. *GradientBoostingClassifier(learning_rate=1.0, max_depth=7, max_features=0.35, min_samples_leaf=19, min_samples_split=10, n_estimators=100, subsample=1.0)* for binary classification.

5 Result Analysis and Conclusion

The model achieved rank in the Coda Lab challenge is 31, with an evaluation value of 0.34. After the release of Gold set, the model is tuned again using the same TPOT library, which is then trained and evaluated. The results are shown in the figure and .

This work describes our suggestion mining technique which is a hybrid of graph structuring and classification algorithm. Our technique uses graph similarity metrics to find similar graphs from the dataset, which later serves as an input (feature vector) to the classification algorithm. The technique generates word graphs against given reviews which are replicated throughout the dataset using graph similarity techniques. Though the results need improvement however they are convincing enough to show that use of word graphs with different vicinity window can be helpful in classifying suggestions related reviews within a domain. For further model improvements, use of different similarity metrics can be adopted as well as graph constructions using different vicinity window size can be tested.

Abstract

This paper presents our submissions to SemEval-2019 Task9, Suggestion Mining. Our system is one in a series of systems in which we compare an approach using expert-defined rules with a comparable one using machine learning. We target tasks with a syntactic or semantic component that might be better described by a human understanding the task than by a machine learner only able to count features. For Semeval-2019 Task 9, the expert rules clearly outperformed our machine learning model when training and testing on equally balanced testsets.

1 Introduction

In the field of natural language processing, approaches featuring machine learning (ML) nowadays predominate. These have been shown to be quite effective with a wide range of tasks, including text mining, authorship attribution, and text classification. They are particularly suited for dealing with large data volumes and are robust in the sense that they can handle quite 'noisy' data. Unlike expert-informed approaches where rules need to be hand-crafted and apply only under predefined conditions, ML approaches learn from training data and are able to extrapolate. Proponents of ML approaches tend to dismiss the enterprise of hand-crafting rules as difficult, error-prone, time-consuming, and generally ineffective as even an extensive set of complex rules is bound to be incomplete and difficult to maintain.

Over the past years we have conducted a number of studies directed at the extraction of actionable information from microblogs. These include a range of topic areas and domains, including the detection of threatening tweets (Oostdijk and van Halteren, 2013a,b), the identification of potentially contaminated food supplements in forum posts (Oostdijk et al., submitted), and topic/event detection in tweets about natural disasters (floods (Hürriyetoğlu et al., 2016), earthquakes (Hürriyetoğlu and Oostdijk, 2017; Oostdijk and Hürriyetoğlu, 2017)), about traffic flow (Oostdijk et al., 2016) and about outbreaks of the flu (Hürriyetoğlu et al., 2017). In each case we have been exploring the role of the human expert in an expert-informed pattern recognition approach and a comparable ML approach, seeking out the strengths and weaknesses of either and attempting to arrive at a superior hybrid approach.

Semeval-2019, Task 9, Suggestion Mining (Negi et al., 2019), appeared to be another task that would lend itself to human rule building. As suggestions may be phrased in many different ways, successfully recognising that an utterance contains a suggestion requires human understanding of the context. Also, the amount of available training data was quite limited so that bringing into play the human expert's knowledge of the forms that suggestions may take would be an advantage, even though the task was not too clearly defined.

As a counterpart to the human rules, we built a machine learning system. For easier comparison of the patterns suggested by the machine learner and by the human expert, the learning component was a rather simple odds-based technique which still proved competitive in VarDial2018 (van Halteren and Oostdijk, 2018). As features we used character and token n-grams as well as syntactic patterns. In addition, the machine learner was somewhat expert-informed, as it was provided with several word lists related to suggestions.

Below we first describe the rule systems built by the human expert (Section 2) and the machine learner (Section 3) in some more detail. Then we proceed to the quantitative evaluation (Section 4), followed by a qualitative analysis of the evaluation phase (Section 5). We conclude with a discussion of what we learned in this shared task (Section 6).

2 Recognition with expert rules

The expert-rule-based system we applied uses a dedicated (task-specific) lexicon and set of hand-crafted rules in order to generate search queries. The system only targets suggestions, i.e. we only specify rules for patterns that should identify suggestions. Furthermore, we chose to design and apply one and the same set of rules and lexicon for both evaluation sets.

The lexicon comprises 1256 entries. Most of the entries are single words. However, we also included some multi-word items such *in order to*, *for example*, *at least* and *be able to* as well as phrase-like items such *why not* and *how about*. The lexicon includes a few frequently observed spelling variants, for example *pls*, *plz*, *dont* and *kinda*. With each entry, part-of-speech-like information is provided (e.g. verb, adjective, adverb but also *please*, which is given its own class). Typical examples of some of the lexicon entries are:

awesome	ADJ	would	AUXwould
just	ADV	very	ADVintens
provide	Vimp	provide	Vinfin

The rule set consists of 138 finite state rules. They describe how lexical items can combine to form search queries made up of multi-word n-grams. To give some examples, `AUXwould - BE - ADVintens - ADJ` matches e.g. *would be very helpful* and *would be really awesome*; `AUXshould - ADV - Vinfin` matches e.g. *should directly see* and *should properly support*; and `PLEASE - Vimp` e.g. *please provide* and *pls fix*. Rules typically combine two to five elements (parts of speech; POS). Given that some lexical entries are multi-word items, the patterns actually describe strings up to a length of nine words (one of the strings matching the rule `AUXcould - ADV - BE - ADVintens - ADJ` is, for example, *could at the very least be even more robust*).

In previous tasks, pattern recognition using word n-grams has been proven to be very effective. Moreover, the specification of the rules and the lexicon is much easier and far less time-consuming than would be the case for an all-encompassing description, as human experts need not concern themselves with describing elements and details irrelevant to the task at hand. In this particular case, trying to recognize suggestions, we experienced the drawback of only having access to the raw text input, something that did not bother us as much with other tasks. What we found was that in order to be able to recognize the many suggestions that take the form of an imperative sentence, we somehow needed to be able to distinguish between an imperative verb form and an infinitive or present tense verb. Noting that imperative verbs tend to occur (near) sentence- or clause-initially, we tried to account for this in our rules. In some cases we could make use of the presence of a comma, semi-colon or colon, that would identify the (potential) beginning of a clause. In such cases the punctuation mark was included as an element in the rules describing imperative structures. In order to identify the beginning of a sentence, we decided to automatically insert markers in the input during the preprocessing phase. These markers would also indicate the type of sentence (interrogative `MRKques` vs declarative or imperative `MRKsint`). Here the distinction between interrogatives and other types of sentence helped in distinguishing between *do/don't/dont* as an operator (auxiliary verb) in a question and as an operator in an imperative sentence. `MRKsint - Vimp` matches e.g *Allow applications to define ...* and *Ask for a room in ...*; and `MRKsint - ADV - Vimp` matches e.g. *At least support ...* and *Just don't forget ...*

3 Recognition by machine learning

For the ML approach we tried to use quite a wide spread of feature types, namely (a) character n-grams, with n ranging from 3 to 9; (b) token unigrams; (c) token n-grams, with n ranging from 2 to 4 (in which the individual positions can be filled with the actual token, the POS tag, or the word group (see below)); (d) syntactic structure of the main clause; (e) syntactic rewrites of all constituents; (f) syntactic n-grams (i.e. selected subtrees from the complete parse tree, e.g. function and category of a mother and two daughters).

For the character n-grams and the tokens, we applied a minimal level of pre-processing. In the training data, we cleaned up misplaced quotes and commas in the provided .csv-files. In the (later) trial data and in the evaluation data, which came in an HTML-format, we also replaced SGML-entities by their character counterpart, e.g. `&quot;` was replaced by `"`.

The POS tags and syntactic structure were produced by the Stanford NLP system (Manning et al., 2014). The dependency parse labeling was then transformed to a constituency tree that conformed (as much as feasible) to our own view of English syntactic structure, being that developed in the TOSCA project (Aarts et al., 1998). All syntactic features were derived in either a fully lexicalized or fully unlexicalized version. Although we feel the syntactic features can be of considerable value, we consider this component a weak spot in the current system, as the parser regularly produces incorrect analyses. In the current task, this was especially the case for the training data.

In the lexicalized syntactic features, as well as in the token n-grams, a token slot could also be filled with a word group indicator. We found candidates for these lists by searching the 2006 Google n-gram collection (Brants and Franz, 2006) with some regular expressions, and then cleaned them up manually. There were four word groups. `GrpADJgood` contains 100 positive adjectives, e.g. *better* and *advisable*, being the first 100 manually approved from 1774 sorted matches with e.g. `^it (would|could|might|may) be (.*) (to|if)`. `GrpADVinten` covers 37 intensifying adverbs, e.g. *very* and *critically*, selected from 448 matches with e.g. `^(would|could|might|may) be (.*) ($adjgood) (to|if)`. `GrpVadvise` contains 723 verbs that indicate what is being suggested, e.g. *adopt* and *edit*, selected from 987 matches with e.g. `^(i|we) (suggest|advise|propose|request) you to (.*)`. And `GrpADVdescr` has 41 adverbs that can modify the advised action, e.g. *always* and *never*, selected from 212 matches with e.g. `^(suggest|advise|propose|request) that you (.*) ($vadvise)`. When used in a feature, each group indicator is concatenated with the POS tag. The introduction of the word groups appears to be effective: one of the strongest markers, found 82 times with suggestions and only twice with non-suggestions, is "It would be GrpADJgoodJJ".

Our choice of recognition system was influenced by the desire to compare to the human rules. After successful recognition, we wanted to be able to identify which features contributed to the success. For this experiment, we chose a very simple algorithm. We counted the occurrences of each feature in the training items marked as suggestions or as non-suggestions and compared the two counts to derive odds. For example, the character 8-gram `Please a` was found 60 times in suggestion items and once in non-suggestion items. Correcting for the different numbers of items in the two classes, and adding one to avoid division by zero, this led to odds of 45.89 in favour of suggestions. In order to avoid exaggerated counts because of repeated items, we only used the first occurrence of each item, leaving us with 1758 suggestions and 5339 non-suggestions. This removal was done even if the repeated items had different suggestion labels. For the actual recognition, we only used features that had odds higher than or equal to 3:1. In the prediction phase, the odds of all features present in an item were taken and their sum was compared to a threshold, which we chose by tuning on the trial data.

As with other tasks, we investigated hybridization of our two approaches. In this case, straightforward combination of the final choices seemed not very fruitful on the trial data. However, when we compared the suggestions for each individual feature type in the machine learning with those of the expert rules, we found especially syntactic n-grams were able to identify suggestions not found by the rules, which were limited to contiguous n-grams. We therefore built a combination that marked those items as suggestions that were recognized as such by the rules, plus those for which the recognition score by only the syntactic n-gram features was over the optimal threshold for the trial data. The relative quality of rules and machine learning on the trial data for Subtask B made us decide not to attempt combination there.

4 Quantitative evaluation

In this discussion, we do not want to compare to other systems in the shared task. For this we refer the reader to the task description paper (Negi et al., 2019), where it can be seen that more intricate machine learning systems, especially those using pre-trained language models, perform much better. We will rather examine how our internally comparable systems behave on the four item sets. In order to make the measurements compatible, we first have to make some adjustments. Both trial sets contained equal numbers of suggestions and non-suggestions, so that precision and recall were equally valuable. In the evaluation sets, there were more non-suggestions than suggestions, so that precision has more influence than recall. For comparison we needed to recalculate precision (and hence F_1; recall is unchanged) by

Approach	Meas	TrialA	EvalA	EvalBalA	TrialB	EvalB	EvalBalB

Table 2: F_1-score for each test set for each feature type, using model learned from training material for Subtask A, and oracle thresholds.

extrapolating the systems' behaviour to a balanced testset. E.g., the expert rules had 80 false accepts on a total of 146, so a precision of $66/146$ i.e. 0.4521. In a balanced dataset, 87 instead of 746 non-suggestions, not 80/746, but 9.3298/87 would be falsely accepted. Precision would be $66/(66 + 9.3298)$ i.e. 0.8761. We stress that we are not trying to make out results look more impressive, but merely want to make behaviour on trial and evaluation sets comparable.

Table 1 shows the evaluation results for our three systems and the organisers' baseline, with the adjusted scores shown in the columns marked EvalBal. Here, we can see that the enormous drops in quality between TrialA and EvalA were an illusion, caused by the difference in balance. Also, our three systems are now consistent in their order: expert rules outperform machine learning, but the (very eclectic) combination scores yet a bit better. In fact, we now see that all systems gain precision when going from TrialA to EvalA, but at the cost of recall. For the machine learner, this is not exclusively due to overtraining in threshold optimization, as we see below in the discussion of Table 2. A discussion of the results for the expert rules can be found in Section 5. The lower degree of change for the baseline can probably be explained by the rather general level of the rules there. Going from Subtask A to Subtask B, the machine learner suffers a substantial loss in quality, which is understandable as it is trained only on Subtask A data. Interestingly, there are almost no differences between TrialB and EvalB. For the expert rules, the situation is rather different. From TrialA to TrialB, we see a precision gain and recall loss, leading to a slight increase in F_1; but the move from TrialB to EvalB leads to a serious drop in both precision and recall.

In Table 2, we show the F_1-score for each individual feature type, as well as for the sum for comparison. On TrialA, the most useful individual feature types appear to be token bi- and trigrams and

Feature	TrainA	TrialA	EvalA	TrialB	EvalB
Total items	1758/ 5339	296/ 296	87/ 746	404/ 404	348/ 476
`CG8_##Allow#`	63/2	14/0	5/0	0/0	0/0
`T4_WWWG_It_would_be_GrpADJgoodJJ`	82/2	13/1	4/0	0/0	0/0
`CG7_re#shou`	31/1	8/0	0/1*	0/0	0/0
`CG8_Please#a`	60/1	6/0	2/0	0/0	0/0
`SRFC_S_V_VP_A_VBx_OD_NP_A_PP`	28/0	4/0	1/0	0/0	1/0
`SCFFCCL_S_CS_AJP(nice)_A_SBAR(if)`	20/1	4/0	1/0	1/0	0/1
`CG8_#Provide`	20/0	3/0	1/0	0/0	0/0
`SCFFCCL_ROOT_UTT_S(suggest)_NOFUpunc_.(.)`	14/0	3/0	1/0	4/0	5/0
`T3_WWW_#_I_'d`	24/0	4/1	0/3*	2/0	1/0
`SCFFCCL_VP_AVB_MD(should)_MVB_VBN(GrpVadvise)`	46/5	4/1	3/1	1/0	3/1*

Table 3: Ten high-odds features (excluding correlated ones), with effectiveness on all test sets. Each cell contains observation counts in suggestions/non-suggestions. Hash marks indicate spaces and out-of-sentence positions. The asterisk (*) means we disagree on one of the non-suggestions, but did use the provided labels.

character n-grams. The other feature types lag behind, but do help reach a higher score with the sum of all feature scores. Syntactic rewrites by themselves have a much lower F_1, but this is due to their low recall potential (precision 0.7267, recall 0.3682). When moving to EvalA, we see that character n-grams and token unigrams maintain their quality, indicating that the same kind of words are being used, but higher n-grams and syntax lose severely, which suggests that EvalA is more different from the training data than TrialA in how words are combined.

When we proceed to Subtask B, all feature types lose quality. As we moved to a different domain, and a different genre, this is not surprising. Machine learning depends on having training and test data that is as similar as possible. It is encouraging to see that the syntactic n-grams do manage to perform similarly to Subtask A. This means that machine learning at a more abstract level is able to move to another domain more easily.

If we examine which features are responsible for the recognition, we see that all play some role. There are, however, some more effective ones. We show ten of these in Table 3. Note that this is a manual selection, as simply taking the ten highest scoring ones would show only two basic patterns in various guises, e.g. *Please* as several character n-grams, as token unigram, in a token bigram, and as an adverbial in a syntactic n-gram. Some of the ten patterns need explanation: `CG7_re#shou` is part of the token bigram *there should*. `SRFC_S_V_VP_A_VBx_OD_NP_A_PP` means that a sentence is being rewritten as a verb phrase (i.e. a sequence of verb with possibly additional internal adverbials), followed by an adverbial realized by a non-finite verb, then a direct object realized by a noun phrase, and finally an adverbial realized by a prepositional phrase. If we search for examples, we find e.g. *Please allow the access to phone filesystem.*. It turns out that Stanford CoreNLP marks *Please* as a verb, placing *allow* as head of an "xcomp" clause, which confuses our analysis transformer and makes *allow* an adverbial. This is clearly wrong but, as it is done consistently, this pattern still provides a good marker. `SCFFCCL_VP_AVB_MD(should)_MVB_VBN(GrpVadvise)` indicates that within a verb phrase, we find both the modal *should* and a past participle of one of the verbs for something that is advisable. `SCFFCCL_S_CS_AJP(nice)_A_SBAR(if)` represents a sentence with a subject complement *nice* and an adverbial clause headed by *if*. And `SCFFCCL_ROOT_UTT_S(suggest)_NOFUpunc_.(.)` represents a sentence with a main verb with lemma *suggest*, combined with a period as punctuation, which nicely rules out questions with *suggest*. All these patterns have a good precision, but their recall is obviously limited. The first two manage to get about 5 percent on Subtask A, then we quickly drop to 2.5 and 1. In general, recall is similar for TrialA and EvalA. However, the strongest markers are absent altogether in Subtask B, where suggestions are apparently worded differently. Only the final two syntactic n-grams show a significant presence, which is in line with the discussion on feature types above.

5 Qualitative evaluation

Upon inspection of the results obtained on the evaluation set with the expert rules, we specifically looked at the false accepts and false rejects. Contrary to what we thought might happen, only very few cases were missed out on due to omissions in the lexicon.

With cases that we missed (i.e. where we failed to recognize a suggestion) we did not find any clear clues as to what could be added to the patterns already specified in our rules set. There were some cases involving imperatives that we missed due to the fact that the punctuation mark we relied upon appeared to be absent, while gleaning the sentence type (interrogative) from the input final punctuation mark failed in cases where the input consisted of two or more sentences.

As for false accepts, we found that several cases were wrongly taken to be suggestions on the basis of a matching imperative pattern. Here the earlier problem of being unable to distinguish imperative verb forms from infinitives and present tenses no longer presented itself. Instead, word forms that are ambiguous between noun and verb such as *map* and *phone* were mistakenly held to be imperative verbs. Other false accepts were cases where otherwise highly successful rules proved to be too limited in their scope. For example, the pattern `AUXwould - Vinfin` would match *would allow* but then the sentence actually continues with *but* so that what initially looks like a suggestion turns out to be an observation, e.g. *The control would allow for the use of the contact picker but allows for manual entry and deletion of contacts*. Similar cases involving *but* were found with other patterns. In the cases of single instances slight modifications of the rules might have avoided wrongfully identifying something as a suggestion but there is very little evidence to go by, so there is no telling how it would impact on a different dataset.

We also noticed that some patterns occurred (almost) exclusively in Subtask A or B. Building separate rule sets for the two tasks might hence have been beneficial. However, the whole point of the exercise in Task 9 was to see whether a rule set can be ported to a new, mostly unknown, domain.

6 Discussion

The task was more difficult than we had expected. When we set out, we thought we knew what a suggestion was. However, after confronting our first version of the expert pattern system with the training data, we needed to review our ideas. After careful error analysis, we adapted our system and came to achieve quite acceptable results on the trial data, yet there remained a gap between what we (intuitively, as experienced language users) would consider a suggestion and quite a number of other cases which were labelled as such. In our view, there is a fine line between a suggestion and a non-suggestion, and perhaps one needs more context than a single sentence in order to tell which it is. We speculate that this may well explain the drop in performance. This is in line with the fact that the datasets provided, i.e. the training, trial and evaluation data, were rather different in nature: the training data comprised many inputs that were made up of multiple sentences, while the trial data and certainly the evaluation data mostly comprised single sentence inputs. Another factor which may have been at play here (and again we can only speculate), is that the annotations provided were made by different groups of annotators. This would then also explain some of the inconsistencies in the labeling, where similar cases were labeled differently.

Moving to our system, the expert-informed rule approach used previously with other tasks once more showed its strengths. The word n-gram patterns used are simple yet quite robust and effective, targeting specifically those parts of the input that are deemed relevant for the task at hand, without requiring these to be linguistically complete or well-formed phrases or clauses. There are no a priori limitations as to the length of the word n-grams. Compiling a lexicon and a set of rules requires limited effort. More than before, however, with the present task we experienced the limitations of using only contiguous word n-grams. Moreover, having only access to the raw text, information about the syntactic structure of a sentence was lacking, which in specific cases is key to being able to successfully identify a suggestion. We were able to fill some of this gap by combining with the ML approach, but improvements were as yet meagre as the parser was not performing optimally. Still, we have good hopes for this form of expert-informed hybridization.

Abstract

This paper describes our system, Joint Encoders for Stable Suggestion Inference (**JESSI**), for the SemEval 2019 Task 9: Suggestion Mining from Online Reviews and Forums. JESSI is a combination of two sentence encoders: (a) one using multiple pre-trained word embeddings learned from log-bilinear regression (GloVe) and translation (CoVe) models, and (b) one on top of word encodings from a pre-trained deep bidirectional transformer (BERT). We include a domain adversarial training module when training for out-of-domain samples. Our experiments show that while BERT performs exceptionally well for in-domain samples, several runs of the model show that it is unstable for out-of-domain samples. The problem is mitigated tremendously by (1) combining BERT with a non-BERT encoder, and (2) using an RNN-based classifier on top of BERT. Our final models obtained second place with 77.78% F-Score on Subtask A (i.e. in-domain) and achieved an F-Score of 79.59% on Subtask B (i.e. out-of-domain), even without using any additional external data.

1 Introduction

Opinion mining (Pang and Lee, 2007) is a huge field that covers many NLP tasks ranging from sentiment analysis (Liu, 2012), aspect extraction (Mukherjee and Liu, 2012), and opinion summarization (Ku et al., 2006), among others. Despite the vast literature on opinion mining, the task on suggestion mining has given little attention. Suggestion mining (Brun and Hagège, 2013) is the task of collecting and categorizing suggestions about a certain product. This is important because while opinions indirectly give hints on how to improve a product (e.g. analyzing reviews), suggestions are direct improvement requests (e.g. tips, advice, recommendations) from people who have used the product.

To this end, Negi et al. (2019) organized a shared task specifically on suggestion mining called SemEval 2019 Task 9: Suggestion Mining from Online Reviews and Forums. The shared task is composed of two subtasks, Subtask A and B. In Subtask A, systems are tasked to predict whether a sentence of a certain domain (i.e. electronics) entails a suggestion or not given a training data of the same domain. In Subtask B, systems are tasked to do suggestion prediction of a sentence from another domain (i.e. hotels). Organizers observed four main challenges: (a) sparse occurrences of suggestions; (b) figurative expressions; (c) different domains; and (d) complex sentences. While previous attempts (Ramanand et al., 2010; Brun and Hagège, 2013; Negi and Buitelaar, 2015) made use of human-engineered features to solve this problem, the goal of the shared task is to leverage the advancements seen on neural networks, by providing a larger dataset to be used on data-intensive models to achieve better performance.

This paper describes our system **JESSI** (Joint Encoders for Stable Suggestion Inference). JESSI is built as a combination of two neural-based encoders using multiple pre-trained word embeddings, including BERT (Devlin et al., 2018), a pre-trained deep bidirectional transformer that is recently reported to perform exceptionally well across several tasks. The main intuition behind JESSI comes from our finding that although BERT gives exceptional performance gains when applied to in-domain samples, it becomes unstable when applied to out-of-domain samples, even when using a domain adversarial training (Ganin et al., 2016) module. This problem is mitigated using two tricks: (1) jointly training BERT with a CNN-based encoder, and (2) using an RNN-based encoder on top of BERT before feeding to the classifier.

JESSI is trained using only the datasets given on the shared task, without using any additional external data. Despite this, JESSI performs second on Subtask A with an F1 score of 77.78% among 33 other team submissions. It also performs well on Subtask B with an F1 score of 79.59%.

2 Related Work

Suggestion Mining The task of detecting suggestions in sentences is a relatively new task, first mentioned in Ramanand et al. (2010) and formally defined in Negi and Buitelaar (2015). Early systems used manually engineered patterns (Ramanand et al., 2010) and rules (Brun and Hagège, 2013), and linguistically motivated features (Negi and Buitelaar, 2015) trained on a supervised classifier (Negi et al., 2016). Automatic mining of suggestion has also been suggested (Dong et al., 2013). Despite the recent successes of neural-based models, only few attempts were done, by using neural network classifiers such as CNNs and LSTMs (Negi et al., 2016), by using part-of-speech embeddings to induce distant supervision (Negi and Buitelaar, 2017). Since neural networks are data hungry models, a large dataset is necessary to optimize the parameters. SemEval 2019 Task 9 (Negi et al., 2019) enables training of deeper neural models by providing a much larger training dataset.

Domain Adaptation In text classification, training and test data distributions can be different, and thus domain adaptation techniques are used. These include non-neural methods that map the semantics between domains by aligning the vocabulary (Basili et al., 2009; Pan et al., 2010) and generating labeled samples (Wan, 2009; Yu and Jiang, 2016). Neural methods include the use of stacked denoising autoencoders (Glorot et al., 2011), variational autoencoders (Saito et al., 2017; Ruder and Plank, 2018). Our model uses a domain adversarial training module (Ganin et al., 2016), an elegant way to effectively transfer knowledge between domains by training a separate domain classifier using an adversarial objective.

Language Model Pretraining Inspired from the computer vision field, where ImageNet (Deng et al., 2009) is used to pretrain models for other tasks (Huh et al., 2016), many recent attempts in the NLP community are successful on using language modeling as a pretraining step to extract

feature representations (Peters et al., 2018), and to fine-tune NLP models (Radford et al., 2018; Devlin et al., 2018). BERT (Devlin et al., 2018) is the most recent inclusion to these models, where it uses a deep bidirectional transformer trained on masked language modeling and next sentence prediction objectives. Devlin et al. (2018) reported that BERT shows significant increase in improvements on many NLP tasks, and subsequent studies have shown that BERT is also effective on harder tasks such as open-domain question answering (Yang et al., 2019), multiple relation extraction (Wang et al., 2019), and table question answering (Hwang et al., 2019), among others. In this paper, we also use BERT as an encoder, show its problem on out-of-domain samples, and mitigate the problem using multiple tricks.

3 Joint Encoders for Stable Suggestion Inference

We present our model **JESSI**, which stands for Joint Encoders for Stable Suggestion Inference, shown in Figure 1. Given a sentence $x = \{w_1, w_2, ..., w_n\}$, JESSI returns a binary suggestion label $y = \{0, 1\}$. JESSI consists of four important components: (1) A BERT-based encoder that leverages general knowledge acquired from a large pre-trained language model, (2) A CNN-based encoder that learns task-specific sentence representations, (3) an MLP classifier that predicts the label given the joint encodings, and (4) a domain adversarial training module that prevents the model to distinguish between the two domains.

BERT-based Encoder Fine-tuning a pre-trained BERT (Devlin et al., 2018) classifier then using the separately produced classification encoding [CLS] has shown to produce significant improvements. Differently, JESSI uses a pre-trained BERT as a word encoder, that is instead of using [CLS], we use the word encodings $e_1^{(b)}, e_2^{(b)}, ..., e_n^{(b)}$ produced by BERT. BERT is still fine-tuned during training.

We append a sentence encoder on top of BERT, that returns a sentence representation $s^{(b)}$, which is different per subtask. For Subtask A, we use a CNN encoder with max pooling (Kim, 2014) to create the sentence embedding. For Subtask B, we use a bidirectional simple recurrent units (Lei et al., 2018, BiSRU), a type of RNN that is highly parallelizable, as the sentence encoder.

CNN-based Encoder To make the final classifier more task-specific, we use a CNN-based encoder that is trained from scratch. Specifically, we employ a concatenation of both pre-trained GloVe (Pennington et al., 2014) and CoVe (McCann et al., 2017) word embeddings as input $w_i, 1 \leq i \leq n$. Then, we do convolution operations $\text{Conv}(w_i, h_j)$ using multiple filter sizes h_j to a window of h_j words. We use different paddings for different filter sizes such that the number of output for each convolution operation is n. Finally, we concatenate the outputs to obtain the word encodings, i.e. $e_i^{(c)} = \oplus_j(\text{Conv}(w_i, h_j))$, where $\oplus$ is the sequence concatenate operation.

We pool the word encodings using attention mechanism to create a sentence representation $s^{(c)}$. That is, we calculate attention weights using a latent variable v that measures the importance of the words $e_i^{(c)}$, i.e., $a_i = \text{softmax}(v^\top f(e_i^{(c)}))$, where $f(\cdot)$ is a nonlinear function. We then use a_i to weight-sum the words into one encoding, i.e., $s^{(c)} = \sum_i a_i e_i^{(c)}$.

Suggestion Classifier Finally, we use a multi-layer perceptron (MLP) as our classifier, using a concatenation of outputs from both the BERT- and CNN-based encoders, i.e., $p(y) = \text{MLP}_y([s^{(b)}; s^{(c)}])$. Training is done by minimizing the cross entropy loss, i.e., $\mathbb{L} = -\log p(y)$.

Domain Adversarial Training For Subtask B, the model needs to be able to classify out-of-domain samples. Using the model as is decreases performance significantly because of cross-domain differences. To this end, we use a domain adversarial training module (Ganin et al., 2016) to prevent the classifier on distinguishing differences between domains. Specifically, we create another MLP classifier that classifies the *domain* of the text using the concatenated sentence encoding with *reverse gradient function* $\text{GradRev}(\cdot)$, i.e., $p(d) = \text{MLP}_d(\text{GradRev}([s^{(b)}; s^{(c)}]))$. The reverse gradient function is a function that performs equivalently with the identity function when propagating forward, but reverses the sign of the gradient when propagating backward.

Through this, we eliminate the possible ability of the classifier to distinguish the domains of the text. We train the domain classifier using the available trial datasets for each domain. We also use a cross entropy loss as the objective of this classifier. Overall, the objective of JESSI is to minimize the following loss: $\mathbb{L} = -\log p(y) - \lambda \log p(d)$, where λ is set increasingly after each epoch, following Ganin et al. (2016).

4 Experimental Setup

Dataset and Preprocessing We use the dataset provided in the shared task: a training dataset from the electronics domain, and labeled trial and unlabeled test datasets from both the electronics and hotels domain. Table 1 summarizes the dataset statistics and shows the distribution differences between two domains. During training, we use the labeled training dataset to train the suggestions classifier, and trial datasets, without the suggestion labels, to train the domains classifier. For preprocessing, we lowercased and tokenized using the Stanford CoreNLP toolkit[1] (Manning et al., 2014).

Implementation We use the pre-trained BERT models[2] provided by the original authors to initialize the parameters of BERT. We use BERT-large

Table 1: Dataset Statistics

for Subtask A and BERT-base for Subtask B[3]. For our CNNs, we use three filters with sizes $\{3, 5, 7\}$, each with 200 dimensions. For the BiSRU, we use hidden states with 150 dimensions and stack with two layers. The MLP classifier contains two hidden layers with 300 dimensions.

We use dropout (Srivastava et al., 2014) on all nonlinear connections with a dropout rate of 0.5. We also use an l_2 constraint of 3. During training, we use mini-batch size of 32. Training is done via stochastic gradient descent over shuffled mini-batches with the Adadelta (Zeiler, 2012) update rule. We perform early stopping using the trial sets. Moreover, since the training set is relatively small, multiple runs lead to different results. To handle this, we perform an ensembling method as follows. We first run 10-fold validation over the training data, resulting into ten different models. We then pick the top three models with the highest performances, and pick the class with the most model predictions.

5 Experiments

In this section, we show our results and experiments. We denote JESSI-A as our model for Subtask A (i.e., BERT→CNN+CNN→ATT), and JESSI-B as our model for Subtask B (i.e., BERT→BISRU+CNN→ATT+DOMADV). The performance of the models is measured and compared using the F1-score.

Ablation Studies We present in Table 2 ablations on our models. Specifically, we compare JESSI-A with the same model, but without the CNN-based encoder, without the BERT-based encoder, and with the CNN sentence encoder of the BERT-based encoder replaced with the BiSRU variant. We also compare JESSI-B with the same model, but without the CNN-based encoder, without the BERT-based encoder, without the domain adversarial training module, and with the BiSRU sentence encoder of the BERT-based encoder replaced with the CNN variant. The ablation studies show several observations. First, jointly combining both BERT- and CNN-based encoders help improve the performance on both subtasks. Second, the more effective sentence encoder for the BERT-based encoder (i.e., CNN versus BiSRU) differs for each subtask; the CNN variant is better for Subtask A, while the BiSRU variant is better for Subtask B. Finally, the domain adversarial training module is very crucial in achieving a significant increase in performance.

[3]Due to memory limitations, we are limited to use the smaller BERT model for Subtask B. We expect an increase in performance when BERT-large is used.

Model	F-Score
JESSI-A	88.78
+ BERT→BISRU	86.01
– CNN→ATT	85.14
– BERT→CNN	83.89

(a) Subtask A

Model	F-Score
JESSI-B	87.31
– CNN→ATT	84.01
– BERT→BISRU	81.13
+ BERT→CNN	70.21
– DOMADV	47.48

(b) Subtask B

Table 2: Ablation results for both subtasks using the provided trial sets. The + denotes a *replacement* of the BERT-based encoder, while the – denotes a *removal* of a specific component.

Out-of-Domain Performance During our experiments, we noticed that BERT is unstable when predicting out-of-domain samples, even when using the domain adversarial training module. We show in Table 3 the summary statistics of the F-Scores of 10 runs of the following models: (a) vanilla BERT that uses the [CLS] classification encoding, (b-c) our BERT-based encoders BERT→CNN and BERT→BISRU that use BERT as a word encoder and use an additional CNN/BiSRU as a sentence encoder, (d) JESSI-B that uses BERT→BISRU and CNN→ATT as joint encoders, and (e) CNN→ATT that does not employ BERT in any way. The results show that while CNN→ATT performs similarly on different runs, BERT performs very unsta-

Model	min	max	mean	std
BERT	0.00	70.59	22.52	31.0
BERT→CNN	0.00	74.62	28.23	34.1
BERT→BiSRU	54.00	88.83	74.86	8.8
JESSI-B	69.28	89.21	82.41	5.6
CNN→Att	68.19	77.06	72.50	2.5

Table 3: Summary statistics of the F-Scores of 10 runs of different models on the trial set of Subtask B when doing a 10-fold validation over the available training data. All models include the domain adversarial training module (+DomAdv), which is omitted for brevity.

bly, achieving varying F-Scores as low as zero and as high as 70.59, with a standard deviation of 31. Appending a CNN-based sentence encoder (i.e., BERT→CNN) increases the performance, but worsens the stability of the model. Appending an RNN-based sentence encoder (i.e., BERT→BiSRU) both increases the performance and improves the model stability. Finally, combining a separate CNN-based encoder (i.e., JESSI-B) improves the performance and stability further.

Test Set Results Table 4 presents how JESSI compared to the top performing models during the competition proper. Overall, JESSI-A ranks second out of 33 official submissions with an F-Score of 77.78%. Although we were not able to submit JESSI-B during the submission phase, JESSI-B achieves an F-Score of 79.59% on the official test set. This performance is similar to the performance of the model that obtained sixth place in the competition. We emphasize that JESSI does not use any labeled and external data for Subtask B, and thus is just exposed to the hotels domain using the available *unlabeled* trial dataset, containing 808 data instances. We expect the model to perform better when additional data from the hotels domain.

Performance by Length We compare the performance of models on data with varying lengths to further investigate the increase in performance of JESSI over other models. More specifically, for each range of sentence length (e.g., from 10 to 20), we look at the accuracy of JESSI-A, BERT→BiSRU, and BERT→CNN on Subtask A, and the accuracy of JESSI-B, BERT→BiSRU, and BERT→CNN, all with domain adversarial training module, on Subtask B. Figure 2 shows the plots of the experiments on both subtasks. On both experiments, JESSI outperforms the other models

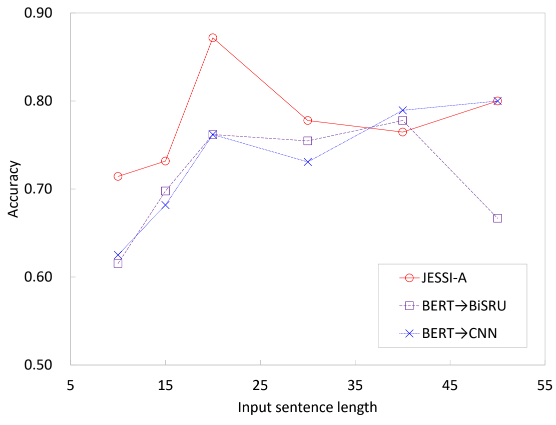
Rank	Model	F-Score
1	OleNet	78.12
2	JESSI-A	77.78
3	m_y	77.61

(a) Subtask A

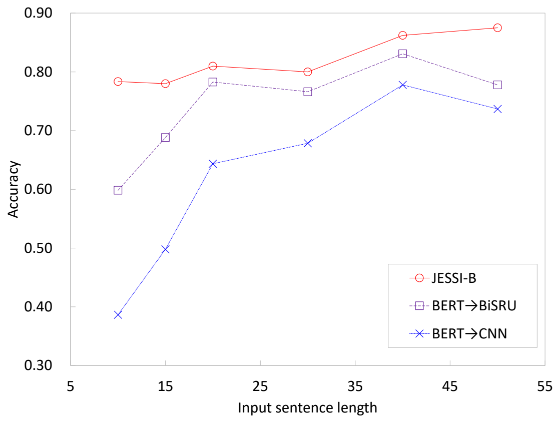
Rank	Model	F-Score
1	NTUA-ISLab	85.80
2	OleNet	85.79
3	NL-FIIT	83.13
*	JESSI-B	79.59
11	CNN→Att+DomAdv	64.86

(b) Subtask B

Table 4: F-Scores of JESSI and top three models for each subtask. Due to time constraints, we were not able to submit JESSI-B during the competition. For clarity, we also show our final official submission (CNN→Att+DomAdv).



(a) Subtask A



(b) Subtask B

Figure 2: Accuracy over various input sentence length on the test set.

when the sentence length is short, suggesting that the increase in performance of JESSI can be attributed to its performance in short sentences. This is more evident in Subtask B, where the difference of accuracy between JESSI and the next best model is approximately 20%. We can also see a consistent increase in performance of JESSI over other models on Subtask B, which shows the robustness of JESSI when predicting out-of-domain samples.

6 Conclusion

We presented JESSI (Joint Encoders for Stable Suggestion Inference), our system for the SemEval 2019 Task 9: Suggestion Mining from Online Reviews and Forums. JESSI builds upon jointly combined encoders, borrowing pre-trained knowledge from a language model BERT and a translation model CoVe. We found that BERT alone performs bad and unstably when tested on out-of-domain samples. We mitigate the problem by appending an RNN-based sentence encoder above BERT, and jointly combining a CNN-based encoder. Results from the shared task show that JESSI performs competitively among participating models, obtaining second place on Subtask A with an F-Score of 77.78%. It also performs well on Subtask B, with an F-Score of 79.59%, even without using any additional external data.

Abstract

We present a system for cross-domain suggestion mining, prepared for the SemEval-2019 Task 9: Suggestion Mining from Online Reviews and Forums (Subtask B). Our submitted solution for this text classification problem explores the idea of treating different suggestions' sources as one of the settings of Transfer Learning - Domain Adaptation. Our experiments show that without any labeled target domain examples during training time, we are capable of proposing a system, reaching up to 0.778 in terms of F_1 score on test dataset, based on Target Preserving Domain-Adversarial Neural Networks.

1 Introduction

Suggestion mining is an emerging task in a natural language processing (NLP) field. Definition of suggestion mining task differs in NLP's community. Close areas of study like opinion mining or sentiment analysis get a lot of attention not only from academic, but also industrial researchers. From a linguistic point of view, while these areas treat neutral polarity of a statement as an absence of opinion (Liu, 2009), suggestion does not have to be connected with positive or negative emotion and can be treated as complementary information (Negi and Buitelaar, 2015). Lack of sensitivity to statement's sentiment and various suggestions' realization strategies (Martínez Flor, 2005) make suggestion mining task interesting and challenging from a NLP's standpoint.

In this work, we present a system for cross-domain suggestion mining, ranked in the 7^{th} place in SemEval-2019 Task 9 Subtask B. The training data for this task was collected from feedback posts on Universal Windows Platform. On the other hand, the test dataset comes from the different domain of hotel reviews from the TripAdvisor website (Negi et al., 2019). In this work we will refer to those datasets' domain as *source domain* and *target domain* accordingly. For suggestion mining task in this context, we employ ensemble of Domain-Adversarial Neural Networks (DANN) where we use Structured Self-Attentive Sentence Embedding (Lin et al., 2017) as a feature extractor. Moreover, to achieve better adaptation towards target domain, we follow the approach of Gui et al. (2017) for the part-of-speech tagging and extend DANN with a Target Preserving component in a form of words decoder for target domain sentences. We train all of the parts of the described system using modified domain adversarial training procedure than the one proposed in (Ganin et al., 2016).

2 Data preparation

2.1 Dataset augmentation

Training dataset for Subtask B was built using only sentences from source domain. In order to train DANN we take advantage of an additional set of unlabeled sentences from the same domain as a test dataset. We use a subset of data from another corpora (Wachsmuth et al., 2014) consisting of hotel's reviews.

The selection of the subset is as follows, first we take benefit of a "weak" classifier in the form of the baseline, rules-based system provided by the organizers, to predict a class in the mentioned corpora. After that we choose the subset with the same distribution of classes (2085 *suggestions* and 6415 *no suggestions*) and remove too short statements to obtain a histogram of sentences' lengths close to the rest of datasets.

2.2 Preprocessing

We use Keras (Chollet et al., 2015) to perform preprocessing such as removing punctuation signs and lower-casing sentences. Considering that our

model is based on recurrent neural network, we also pad sentences or shorten them to have maximum count of 50 tokens. Finally, as the source domain has a lot of urls, we replace all of them with a single *"https"* token.

2.3 Word embeddings

Last step is mapping sentences to mathematically computable form. We leverage the existing language models, which are pre-trained on huge volumes of raw text. Following the recent research, showing superiority of the contextual word embeddings over theirs predecessors, we apply Embeddings from Language Models (ELMo) (Peters et al., 2018) provided by Tensorflow Hub (Abadi et al., 2015). However, we do not fine-tune them with our model.

3 Model description

3.1 Domain-Adversarial Neural Networks

Ganin et al. (2015; 2016) proposed a system for unsupervised Domain Adaptation problem, adaptable to any neural network architecture. It consists of three components: a feature extractor, a label predictor and a domain discriminator. Last one, thanks to gradient reversal layer (GRL), which reverses flow of a gradient with respect to hyperparameter λ, allows to force the feature extractor to learn domain-invariant representations. Fig. 1 presents high level overview of the proposed architecture.

DANN minimizes loss presented in Eq. 1, where y stands for suggestion classifier, d domain descriptor and f for feature extractor presented in the following Section. An upper index in loss $\mathcal{L}$ symbolizes examples' domain.

$$E(\theta_f,\theta_y,\theta_d) = \frac{1}{n}\sum_{s=1}^{n}\mathcal{L}_y^s(\theta_f,\theta_y) - \lambda(\frac{1}{n}\sum_{s=1}^{n}\mathcal{L}_d^s(\theta_f,\theta_d) + \frac{1}{n'}\sum_{t=n+1}^{N}\mathcal{L}_d^t(\theta_f,\theta_d)) \tag{1}$$

3.2 Structured Self-Attentive Sentence Embedding

We model sentences using Structured Self-Attentive Sentence Embedding (SSASE) as feature extractor. Taking ELMo word embeddings as an input, followed by Bidirectional LSTM (BiLSTM) layer, SSASE used extended self-attention represented as an attention matrix (A) regularized by a penalization term as in Eq. 2, where $||\bullet||_F$ is Frobenius norm of a matrix and I is an identity matrix. Impact of penalization is controlled by hyperparameter α.

$$P = \alpha||(AA^T - I)||_F^2 \tag{2}$$

The attention matrix is calculated as shown in Eq. 3, where H is BiLSTM concatenated output, W_1 and W_2 are matrices of weights.

$$A = softmax(W_2 tanh(W_1 H^T)) \tag{3}$$

3.3 Target Preserving component

To prevent erasing targets domain specific features, we extend DANN with a target domain words decoder (model further referred as TPDANN-SSASE). The decoder is formed by an LSTM layer followed by one fully-connected layer. It takes as input a matching timestep of SSASE's BiLSTM outputs and predicts the input word.

In terms of the objective function, decoder's loss was limited by hyperparameter $\gamma = 0.4$ as in Eq. 4, where θ_r stands for decoder's parameters and θ_f^* - parameters of feature extractor's BiLSTM.

$$E(\theta_f,\theta_y,\theta_d,\theta_r) = E(\theta_f,\theta_y,\theta_d) + \gamma\frac{1}{n'}\sum_{t=n+1}^{N}\mathcal{L}_r^t(\theta_f^*,\theta_r) \tag{4}$$

3.4 Training algorithm

We apply a modification of domain-adversarial training procedure (Ganin et al., 2016). We treat an architecture as two separate networks with shared parameters of a feature extractor and a domain descriptor (θ_d and θ_f). In each training step, taking regular DANN as an example, we first update parameters trained using source domain Eq. 5, 6, 7 and then with a target domain examples as shown in Eq. 8, 9, where θ' stands for temporal state of parameters between those two updates and η denotes learning rate. The proposed change in the learning algorithm has been beneficial in terms of exploration properties.

$$\theta'_f \longleftarrow \theta_f - \eta(\frac{\partial \mathcal{L}^s_y}{\partial \theta_f} - \lambda \frac{\partial \mathcal{L}^s_d}{\partial \theta_f}) \tag{5}$$

$$\theta_y \longleftarrow \theta_y - \eta \frac{\partial \mathcal{L}^s_y}{\partial \theta_y} \tag{6}$$

$$\theta'_d \longleftarrow \theta_d - \eta \frac{\partial \mathcal{L}^s_d}{\partial \theta_d} \tag{7}$$

$$\theta_d \longleftarrow \theta'_d - \eta \frac{\partial \mathcal{L}^t_d}{\partial \theta'_d} \tag{8}$$

$$\theta_f \longleftarrow \theta'_f - \eta(-\lambda \frac{\partial \mathcal{L}^t_d}{\partial \theta'_f}) \tag{9}$$

4 Evaluation

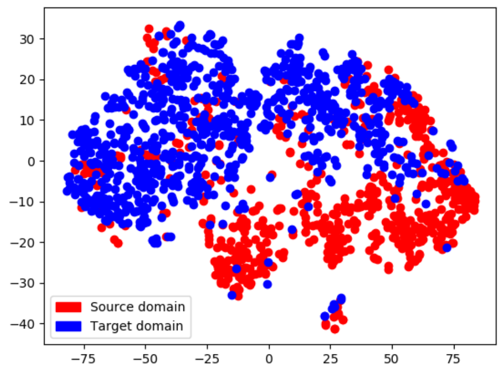
4.1 Results

The metric which was taken into account in SemEval-2019 Task 9 Subtask B was F_1 score. Table 1 presents results for tested architectures for validation and test datasets. Our baseline method is *fastText* (Joulin et al., 2017). It achieves higher score ($F_1 = 0.684$) on Subtask's A validation dataset (source domain) than on target domain, indicating that there is a shift between domains. We notice the same behaviour while testing SSASE model with only a label classifier. By adding domain adaptation components we manage to limit that problem. DANN-SSASE* is trained using default domain-adversarial training procedure (Ganin et al., 2016), while further models benefit from our proposed algorithm. We achieve final score, resulting in the 7^{th} place, by creating unweighted ensemble of three TPDANN-SSASE models.

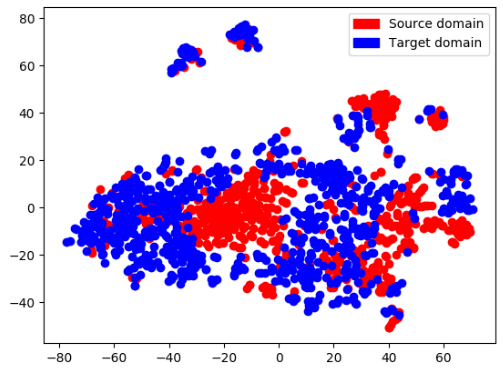
4.2 Hyperparameters

We use default ELMo embeddings with length of 1024. Each LSTM layer has 300 units (BiLSTM 600). Attention matrix dimensions are accordingly equal to 400 and 9 for W_1 and W_2. We set a penalization hyperparameter α to 0.45.

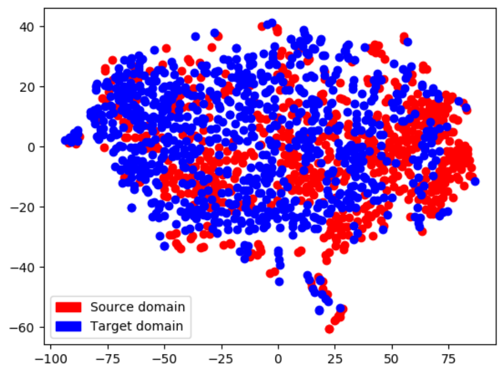
4.3 Domains shift



(a) SSASE



(b) DANN-SSASE



(c) TPDANN-SSASE

Figure 2: Domains shift reduction between models.

Method	Validation dataset	Test dataset
fastText	0.532	0.591
SSASE	0.517	0.467
DANN-SSASE*	0.616	0.558
DANN-SSASE	0.781	0.753
TPDANN-SSASE	0.831	0.764
TPDANN-SSASE ensemble	0.836	0.778

Table 1: F_1 score on target domain validation and test datasets.

Method	Source	Target
SSASE	8.26	8.78
DANN-SSASE	8.08	8.55
TPDANN-SSASE	7.24	7.56

Table 2: Mean count of the 10 nearest neighbours from the same domain. Desired score is equal to 5. To build kNN model, a representation of sentences was extracted from the last layer of a feature extractor and distance was measured using a Euclidean distance.

To measure a problem of domains shift and impact of domain adaptation components in our models we propose a metric based on number of nearest neighbours from the same domain. Assuming that there is no shift between domains, mean number of k nearest neighbours from particular domain over the whole dataset is equal to $\frac{k}{2}$. On the other hand to perfect overlap, it would be equal to k, as each sample could only have neighbours from the same domain.

We take the last layer of a feature extractor as the representations for which euclidean distance metric was employed to find nearest neighbours. Results presented in Tab. 2 indicate that models with better domain-invariant properties have better results in terms of suggestion mining task, TPDANN-SSASE achieves the closest values to $\frac{k}{2}$. In order to present how the domains overlap changed over models, we visualize them using T-SNE (van der Maaten and Hinton, 2008) (Fig. 2). The visualization confirms results presented in Tab. 2 - we observe the highest overlap for TPDANN-SSASE.

5 Conclusion

In this work, we introduced a new system for cross-domain suggestion mining based on the domain-adversarial neural networks. Domains shift reduction led to improvement of classification accuracy in target domain. Our proposed modification of adversarial training procedure allowed ensemble of TPDANN-SASSE models to reach F_1 value of 0.778.

Yimmon at SemEval-2019 Task 9: Suggestion Mining with Hybrid Augmented Approaches

Yimeng Zhuang
Samsung Research China - Beijing (SRC-B)
ym.zhuang@samsung.com

Abstract

Suggestion mining task aims to extract tips, advice, and recommendations from unstructured text. The task includes many challenges, such as class imbalance, figurative expressions, context dependency, and long and complex sentences. This paper gives a detailed system description of our submission in SemEval 2019 Task 9 Subtask A. We transfer Self-Attention Network (SAN), a successful model in machine reading comprehension field, into this task. Our model concentrates on modeling long-term dependency which is indispensable to parse long and complex sentences. Besides, we also adopt techniques, such as contextualized embedding, back-translation, and auxiliary loss, to augment the system. Our model achieves a performance of F1=76.3, and rank 4th among 34 participating systems. Further ablation study shows that the techniques used in our system are beneficial to the performance.

1 Introduction

Suggestion mining is a trending research domain that focuses on the extraction of extract tips, advice, and recommendations from unstructured text. To better recognize suggestions, instead of only matching feature words, one must have the ability to understand long and complex sentences.

SemEval-2019 Task 9 provides the suggestion mining task (Negi et al., 2019). The task can be recognized as a text classification task, given a sentence collected from user feedback, participating systems are required to give a binary output by marking it as suggestion or non-suggestion.

To address this problem, we focus on solving long-term dependency on long and complex sentences. Consequently, we transfer Self-Attention Network (SAN), a successful model in machine reading comprehension field, in which long-term dependency is crucial, into this task. Furthermore, we also utilize multiple techniques to improve the suggestion mining system.

2 System description

In this paper, we consider suggestion mining as a text classification task. Figure 1 gives an overview of our model. First, the input text is converted into word embeddings with linguistic features. Then, we use several stacked semantic encoders to generate the hidden representations for each token. On top of that, a softmax output layer estimates the probability of the text being a suggestion.

2.1 Input encoding

The input encoding layer is in charge of encoding each token of the input text to singular vectors. Tokenization is completed during preprocessing. In our work, we adopt WordPiece embedding (Wu et al., 2016) and feed it into a pretrained language model (LM) to generate contextualized embeddings. Compared to context independent word vectors, such as widely used GloVe (Pennington et al., 2014), SGNS (Mikolov et al., 2013), contextualized vectors show significant advantages in disambiguation and sentence modeling. Besides, well-pretrained language model also transfers external knowledge to this task, full use of transfer learning is the key to the advance in modern neural natural language processing. On the choice of the pretrained language model, we compared two publicly available models ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018), and we finally choose BERT for better performance. Due to the out-of-memory issues [1], we do not update the parameters of BERT during training, thus we only use it as a static feature extractor.

[1] https://github.com/google-research/bert#out-of-memory-issues

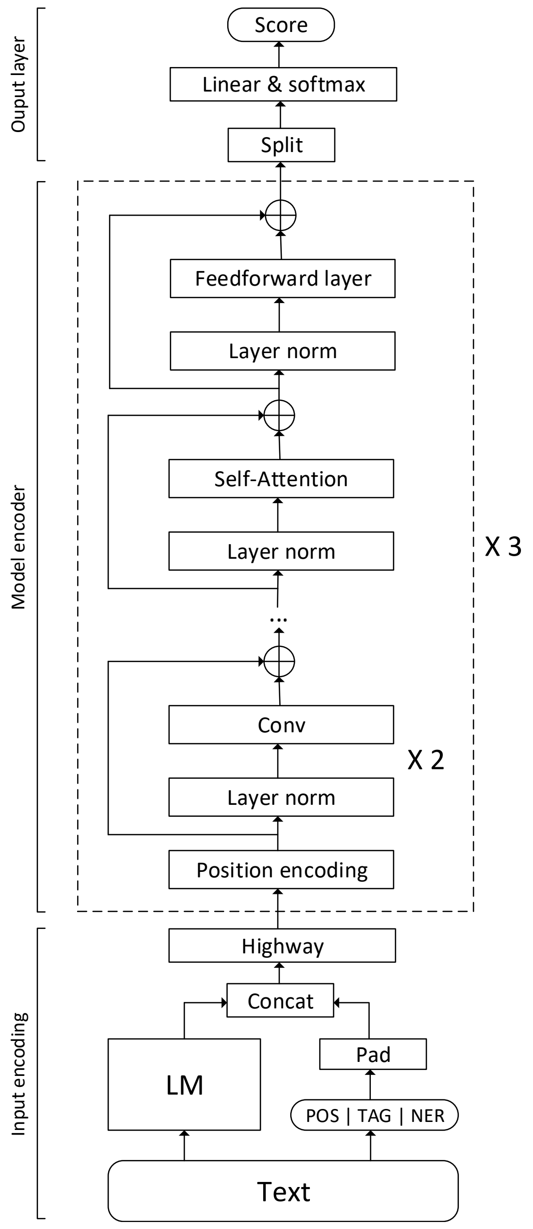

Figure 1: Overview of our system

Also, linguistic features are extracted to improve system performance further. In this work, we extract part-of-speech (POS) and named entities (NER) by spaCy [2]. Two kinds of part-of-speech granularity are used, primary POS and extended POS tag (TAG). In order to obtain linguistic feature sequences with the same length as the BERT outputs, we pad zero vectors at the start and end position of the linguistic feature sequences. Then, the contextualized vectors and linguistic feature vectors are concatenated. A two layers highway network (Srivastava et al., 2015) is also adopted on top of this representation. The vectors are projected to d dimensions immediately.

[2]https://spacy.io

2.2 Model encoder

The model encoder is the central part of our system, and it is in charge of modeling long-term dependency and extracting deep features. Because of the success of Self-Attention Network (SAN) (Shen et al., 2018) in various NLP tasks, we adopt a structure from QANet (Yu et al., 2018), which is a variant of Self-Attention Network, as our model encoder.

As is shown in the middle part of Figure 1, the model encoder is a combination of convolution, self-attention and feed-forward layer. This structure is repeated three times. The input vectors of this structure are firstly added by sinusoidal position embedding (Gehring et al., 2017) to encode a notion of the order in the sequence. The position embedding is calculated as follows:

$$\begin{aligned} PE_{i,2j} &= sin(i/10000^{2j/d}) \\ PE_{i,2j+1} &= cos(i/10000^{2j/d}) \end{aligned} \tag{1}$$

After that there are convolution blocks, following (Yu et al., 2018), depth-wise separable convolution layers are chosen for better generalization and memory efficiency. The model encoder is highly dependent on input layer normalization and residual connections, each block is in a uniform structure: *layer normalization / operation / residual connection*. In our system, we repeat convolution blocks two times for better and deeper local feature extraction.

In the self-attention layer, the scaled dot-product attention is computed:

$$A_i = softmax(\frac{QK^T}{\sqrt{d}}) \cdot V \tag{2}$$

Where Q, K, and V are query, key, and value respectively, they are the linear projection of each position in the input. As in (Vaswani et al., 2017), multi-head attention mechanism is adopted which integrates multiple scaled dot-product attentions.

$$A = [A_1; \cdots ; A_i; \cdots ; A_n] \cdot W^A \tag{3}$$

where A_i denotes the i-th head, $[\cdot]$ is concatenation operator, W^A is a trainable parameter.

At last, there is a fully connected block. In our method, it is a little different from the original work (Yu et al., 2018). We append a gate mechanism to refine tokens by their importance (Wang et al., 2017).

$$S = FFN^2(LayerNorm(H)) \odot G + H \quad (4)$$
$$G = G^*/max(G^*) \quad (5)$$
$$G^* = sigmoid(LayerNorm(H) \cdot W^G + b^G) \quad (6)$$

where we assume the input of this block is $H \in \mathbb{R}^{m\times d}$, m is the sequence length, FFN^2 denotes a 2-layer non-linear feed-forward network, $S \in \mathbb{R}^{m\times d}$ represents the output of this fully connected block. $G \in \mathbb{R}^{m\times 1}$ and $G^* \in \mathbb{R}^{m\times 1}$ are the output weight of the gate. $W^G \in \mathbb{R}^{m\times 1}$ and $b^G \in \mathbb{R}^1$ are trainable parameters. The maximum operation aims to select the maximum element in G^*, and the division operation normalizes these weights so that the maximum weight in G is always one.

2.3 Output layer

Given the output $S = [s_1, s_2, \cdots, s_m]$ of previous layers, this output layer converts these hidden representations into the final probability. Since we have adopted BERT in the input encoding layer, the first vector of the sequence is a special classification token [CLS], which can be used as the representation of the whole sentence. We split the matrix S and take the first vector $s_1 \in \mathbb{R}^d$. The probability of the input text being a suggestion text is estimated as follows.

$$p = softmax(W^p \cdot s_1 + b^p) \quad (7)$$

where $W^p \in \mathbb{R}^{2\times d}$ and $b^p \in \mathbb{R}^2$ are trainable parameters, $p \in \mathbb{R}^2$ denotes the output probabilities including "yes" probability p^1 and "no" probability p^0.

2.4 Loss

We treat this task as a text classification problem and use log-loss as the loss function.

$$\mathcal{L}_0 = \frac{1}{N}\sum_{i=1}^{N} y_i log(p_i^1) + (1-y_i)log(p_i^0) \quad (8)$$

where N is the number of examples, $y_i \in \{0,1\}$ represents the label of i-th example, p_i^1 and p_i^0 are the predictions.

Besides, in order to better recognize important tokens and filter trivial tokens out, we add an auxiliary loss to discourage large weights in G in Equation 4. Thus only those tokens that have contributions to the classification have non-zero weights in G.

$$\mathcal{L}_1 = \beta\frac{1}{N}\sum_{i=1}^{N} \|G_i\|_1 \quad (9)$$

where $\|\cdot\|_1$ denote 1-norm, β is a hyper-parameter, we use $\beta = 10^{-3}$ in this work. The final loss is the sum of $\mathcal{L}_0$ and $\mathcal{L}_1$.

2.5 Class imbalance

As is pointed out in (Negi et al., 2019), suggestions appear sparsely in online reviews and forums, and this makes class imbalance a critical problem. For simplicity, we do not take measures during training. In inference, we slightly adjust the predicted probability and divide it by a *priori*, which is the rate of positive examples in training data.

$$\begin{aligned} p &= softmax((W^p \cdot s_1 + b^p) \times 10) \\ p^{1*} &= p^1/priori \\ p^{0*} &= p^0/(1-priori) \end{aligned} \quad (10)$$

where p^{1*} and p^{0*} are the actual predictions for inference, the system outputs "yes" when p^{1*} is larger than p^{0*}. Other symbols are the same as in Equation 7.

2.6 Back-translation

Because the given training data set is not large, we also utilize a data augmentation technique to enrich the training data. The data augmentation technique we used is back-translation (Yu et al., 2018). Specifically, we first translate the given training data into Chinese by a neural machine translation system and then translate it back into English by another neural machine translation system. The two neural machine translation systems are trained on a subset of the WMT18 data sets [3]. Both original training data and the augmented data are applied to train our text classification system, but the augmented data is given a small weight (=0.2) when calculating the loss.

3 Experiments

3.1 Setup

SemEval 2019 Task 9 Subtask A [4] provides a suggestion mining data set collected from feedback

[3]http://statmt.org/wmt18
[4]https://competitions.codalab.org/competitions/19955

posts on Universal Windows Platform. The data set is split into an 8980-example training set, a 592-example validation set, and an 833-example test set. Since the organizer does not limit the usage of the validation set, we merge it into training data and train our model through the k-fold cross-validation method. Specifically, we split all training data into eight subsets, and guarantee the rate between the number of positive examples and the number of negative examples is about 1:3 in each subset. The preprocessing process is implemented as the description in section 2.1.

The kernel size of convolution layers is 7, and the hidden size d is 256, the number of heads is 8 in multi-head self-attention layers. Adam optimizer (Kingma and Ba, 2014) with learning rate 0.0008 is used for tuning the model parameters. The mini-batch size is 32. For regularization, the dropout rate is set to 0.1. The submission predictions are obtained by integrating eight runs through voting.

Approach	Test F1	
Baseline	26.8	
1st ranked system	78.1	
2nd ranked system	77.8	
3rd ranked system	77.6	
Our system	76.3	
5th ranked system	74.9	
Ablation - single model	F1	Δ
Our full system	73.3	-
- Contextualized embedding	67.6	-5.7
- Back-translation	71.4	-1.9
- Priori	72.5	-0.8
- Linguistic features	72.6	-0.7
- Auxiliary loss	72.7	-0.6

Table 1: Performance of the Top 5 systems on the leaderboard of subtask A, and our ablation experiments.

3.2 Results

Table 1 shows the main results on the test set. Compared with the rule baseline, participants improve their performance with substantial gains. Our system achieved F1=76.3 on the test set and ranked 4th among all 34 teams.

In order to evaluate the individual contribution of each feature, we run an ablation study. Contextualized embedding is most critical to the performance, and it concludes that transferring common sense by learning large corpus is vital for this task. Back-translation accounts for about 2% of the performance degradation, which clearly shows the effectiveness of data augmentation. Besides, linguistic features, auxiliary loss, and *priori* are also beneficial to the system.

Base		Large	
F1	F1	F1	F1
72.9	71.8	75.4	75.9
72.9	70.6	73.9	76.6
74.3	74.8	74.0	76.2
75.3	73.5	76.3	75.1
Ensemble			
#	F1	#	F1
2	72.9	8	74.5
4	74.7	12	75.5
16	76.3	Oracle	79.6

Table 2: Performance of every single model and ensemble models.

3.3 Ensemble models

Table 2 reports the effect of ensemble. To obtain the submission predictions, we trained eight models on the eight subsets mentioned in section 3.1. Four of these models are based on a 110M parameters base BERT model, and the other four are based on a 340M parameters large BERT model. The performance of every single model is reported. It is evident that different data partition causes quite a large performance variance. Thus, ensemble is necessary. The result shows that as the number of models increases the ensemble effect improves. Also, we experiment by searching the optimal model combination assuming the test label is known to show the performance limitation (the Oracle performance).

4 Conclusion

In this work, we adopt multiple techniques to improve a suggestion mining system. The core of our system is a variant of Self-Attention Network (SAN), which originates from the machine reading comprehension field. Based on this model, techniques, such as contextualized embedding, back-translation, linguistic features, and auxiliary loss, are investigated to improve the system performance further. Experimental results illustrate the effect of our system. Our model achieves a performance of F1=76.3, and rank 4th among 34 participating systems.

Abstract

In this paper we describe a deep-learning system that competed as SemEval 2019 Task 9-SubTask A: Suggestion Mining from Online Reviews and Forums. We use Word2Vec to learn the distributed representations from sentences. This system is composed of a Stacked Bidirectional Long-Short Memory Network (SBiLSTM) for enriching word representations before and after the sequence relationship with context. We perform an ensemble to improve the effectiveness of our model. Our official submission results achieve an F_1-score 0.5659.

1 Introduction

Suggestions in the Oxford Dictionary are defined as ideas or plans for consideration. Some of the listed synonyms of suggestions are proposal, proposition, recommendation, advice, hint, tip, clue. In general, other types of text and suggestions are easily distinguished by the definition of the suggestion (Negi and Buitelaar, 2015).

Suggestion mining can be defined as the extraction of suggestions from unstructured text, where the term 'suggestions' refers to the expressions of tips, advice, recommendations etc. We often see comments on products in product forums which are recommended or not recommended, and some users will consider whether to purchase the product based on these comments. Suggestion mining is also defined as automatic extraction of recommendations from a given text. These texts that express user suggestions can usually be found in social media platforms, blogs, or product online forums (Negi and Buitelaar, 2017; Negi et al., 2016).

Suggestion mining remains a relatively young area compared to Sentiment Analysis (Negi and Buitelaar, 2017), due to the lack of a large number of tagged datasets. SemEval 2019 Task 9-SubTask A is mainly a binary classification, identifying sentences which express suggestions in a given text. And we need to classify each sentence of given text, the categories being suggestions or non suggestions. This is similar to the polarity analysis of emotions, as positive or negative instances, respectively.

In the past, classification problems in natural language processing were solved by traditional methods, such as sentiment analysis (Nielsen, 2011; Go et al., 2009; Bollen et al., 2011; Mohammad et al., 2013; Kiritchenko et al., 2014) which were handled by classifiers such as Naive Bayes (McCallum et al., 1998)and SVMs (Gunn et al., 1998). However, deep neural networks achieve increasing performance compared to traditional methods, due to their ability to learn more abstract features from large amounts of data, producing state-of-the-art results in sentiment analysis.

The SubTask-A is part of SemEval 2019 Task9: Suggestion Mining from Online Reviews and Forums, and is concerned with classifying suggestions forum for Windows platform developers—suggestions or non suggestions. There are 34 teams who participated in the task(Negi et al., 2019).

In this paper we describe our system designed for this task. First, we model the sentence and establish the vector representation of the sentence through Word2Vec (Mikolov et al., 2013a), a Stacked Bidirectional Long-Short Memory Network(SBiLSTM) for enriching word representations with context. Finally, the sentence representation is projected into the label space through a Dense Layer.

The rest of the paper is organized as follows: Section 2 provides the details of the proposed model; Data Processing and analysis are discussed in section 3. Experiments and results are described in Section 4. Finally, we draw conclusions in Section 5.

2 System Description

2.1 Network Architecture

First we use the embedding layer to get a distributed representation of the words, then feed the results of the embedding layer to the first BiLSTM layer. Using the LSTM model (Hochreiter and Schmidhuber, 1997) can better capture long-distance dependencies and learn what information to remember and what information to forget by training the model. BiLSTM captures the semantic information of sentences from both forward and reverse directions. In order to get more fine-grained sentence information, we use 2-layer BiLSTM. The features obtained from the first BiLSTM are then put into the next BiLSTM (Graves and Schmidhuber, 2005; Graves et al., 2013). The final result is obtained by the softmax used as the activation function in the Dense layer. The model architecture is show in Figure 1.

2.2 Word Embedding

Word embedding is unarguably the most widely known technology in the recent history of NLP. It converts words into a distributed representation that can solve dimensional disaster problems (Bengio et al., 2003). And it projects words from high-dimensional space to a lower-dimensional vector space through hidden layers and performs semantic feature extraction (Kim, 2014). This technology has a wide range of applications in NLP. It is well-known that using pre-trained embedding helps, as well.

Word embeddings can better measure the similarity between words, and are also dense vector representation of words that capture semantic and syntactic information. So in this task we try to use the Word2Vec (Mikolov et al., 2013b) and Glove (Pennington et al., 2014) to get the vector representations of the words.

3 Data Processing and Analysis

There are two categories: suggestion and non-suggestion in the data set given in the shared task. And the organizer provides the third version data sets: a total of 8,500 sentences in training and 592 sentences in trial and 833 sentences in test.

3.1 Data Processing

We perform a series of specification processing on the text in the dataset.

- All characters are converted to lowercase.
- Contraction normalization, like replacing "don't" and "dont" with "do not", "cant" and "can't" with "can not" and so on.
- All hyperlinks are replaced by "url".

After the above processing, we find that some words in the text have not been segmented correctly. For example, the correct form of "supportedcultures" should be "supported cultures". There are many such words in the dataset, and if we don't deal with them, there will be a lot of unknown words in the vocabulary. In order to solve this problem, we use *Ekphrasis* (Baziotis et al., 2017), a tool geared towards text from social networks, such as Twitter or Facebook. *Ekphrasis* performs tokenization, word normalization, word segmentation (for splitting hashtags) and spell correction.

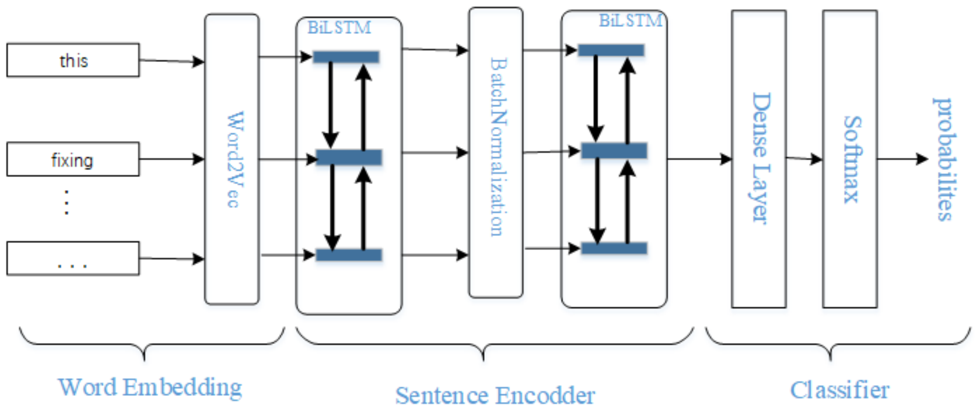

Figure 1: Our system architecture

3.2 Data Analysis

Sentence length: In order to determine the length of the training set sentence in the input model, after the data processing is finished, we analyze the length of each sentence. First, we find that the longest sentence is 495, the shortest is 0, and the sentence length is shown in Figure 2.

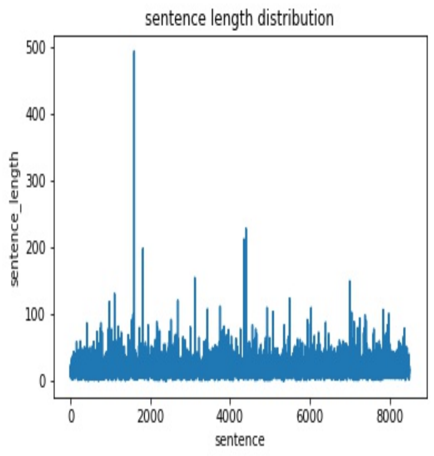

Figure 2: Training set sentence length distribution

If the sentence is too long, the calculation time will increase. If it is too short, the extra information will be lost. Therefore, according to the sentence length distribution map, the length of the sentence in the input model is finally determined to be 75.

Training set label: Table 1 shows the label distribution for the dataset.

	Train set	Trial set	Test set
Suggestions	2085	296	87
Non-suggestions	6415	296	746

Table 1: Number of sentences in each dataset.

It can be seen from Table 1 that the label of the training set is extremely unbalanced, and the ratio of suggestion and non-suggestion reaches 1 : 3. In order to balance the training set data, we process those sentences labeled with the suggestions. We use the shuffle data enhancement method, which re-range the word order inside the sentences. We performed two shuffle operations, and the last data in the suggestions and non-suggestions in the final dataset were 6255 and 6415, respectively.

4 Experiments and Results

We use Python based neural network library, Keras[1], for the implementation. We train and validate our models on the training and validation sets provided by the organizer. The official evaluation metric is based on macro average F_1-*score* measure. More details about the data and the evaluation metrics can be found in the task description paper (Negi et al., 2019).

SBiLSTM: For the Stacked BiLSTM, the first layer BiLSTM *units* = 256, and the second layer BiLSTM *units* = 180.

Optimization: Optimization is carried out with Adaptive Moment Estimation(Adam) (Kingma and Ba, 2014), using the default learning rate 0.001, and hyperparameters $\beta_1 = 0.9$, $\beta_2 = 0.999$.

Loss Function: Usually the multi-classification problem uses *categorical crossentropy* as the loss function. But our system uses *binary crossentropy* in this binary classification.

As shown in Table 2, the number of unknown words in the dataset in Word2Vec are less than those in Glove. To reduce the number of unknown words in the embedding, making the context semantics better learned by the model. We randomly assign the vectors of unknown words. And we experimented with the embedding of the words Word2Vec and Glove, and found that the results of Word2Vec performed better than Glove.

Embedding	Ukw	Evaluation set F1
Glove	394	0.5422
Word2Vec	231	**0.5482**

Table 2: Comparison between Word2Vec and Glove on DBiLSTM models.

We compare the two network structures of Stacked LSTM and Stacked BiLSTM. As can be seen from the results in Table 3, the performance of the Stacked BiLSTM is better than that of LSTM.

Model	Embedding	Evaluation set F1
LSTM	Word2Vec	0.5612
BiLSTM	Word2Vec	**0.5637**

Table 3: Comparison of LSTM and BiLSTM.

Finally, we train the single model with the dropouts of 0.55, 0.60, 0.65, respectively. Each

[1]http://keras.io/

single model produces a soft probability, then we use the sum of the probabilities as the final prediction. We find that the performance of ensemble model is better than a single model.

Dropout	Evaluation set F1
0.55	0.5307
0.60	0.5214
0.65	0.5422
Ensemble	**0.5659**

Table 4: The model adopts Word2Vec, data enhancements and Stacked BiLSTM architecture. Dropout is recurrent-dropout in the BiLSTM layer.

5 Conclusion and Future Work

In this paper, we have presented a Stacked BiLSTM(SBLSTM) model for predicting the suggestion mining classification. The word embedding Word2Vec is used in our system, an ensemble method can significantly enhance the overall performance.

In the future, we will try to use language models to obtain the representation of sentences, and explore other NLP models to make the experimental results better. At the same time, we will also try to use transfer learning technology.

Kunming, P.R. China
Contact: xjzhang@ynu.edu.cn

Abstract

Consumer opinions towards commercial entities are generally expressed through online reviews, blogs, and discussion forums. These opinions largely express positive and negative sentiments towards a given entity; however, they may also contain suggestions for improving the entity. In this task, we extract suggestions from a given unstructured text, in contrast to the traditional opinion mining systems. This type suggestion mining is more applicable and extends capabilities. In this paper, we propose the use of bidirectional encoder representation learned from transformers (BERT) to address the problem of domain specific suggestion mining in task A. In detail, BERT is also used to extract feature vectors and perform fine-tuning for the task . For Task B, we applied an ensemble model to combine the BiLSTM, CNN, and GRU models, which can perform cross domain suggestion mining. Officially released results show that our system performs better than the baseline algorithm does.

1 Introduction

Suggestion mining is used to extract advice from text such as that provided in online reviews, blogs, discussion forums, and social media platforms where consumers share their opinions towards commercial entities like brands, services, and products. Most of the traditional sentiment analysis methods are emotion classifications. Opinion mining can improve service and quality. Such systems have become an effective way for marketing, economics, politics, and advertising. The application of suggestion mining provides the motivation, for the SemEval 2019 Task 9 (Negi et al., 2019), which contains two subtasks that classify given sentences into suggestion and non-suggestion classes. Subtask A requires a system to achieve domain specific training, whereby the test dataset will belong to the same domain as the training and development datasets. This was part of a suggestion forum for windows platform developers. Subtask B applies the system to cross domain training, where training, development, and test datasets will belong to different domains. Training and development datasets will remain the same as Subtask A, while the test dataset will belong to the domain of hotel reviews.

There are many methods in sentiment analysis. In many reports on this subject, it has been implied that these models help improve classification. Successful models include convolutional neural networks (CNN), long short-term memory (LSTM), and bi-directional LSTM (BiLSTM). CNN can capture local n-gram features, while LSTM can maintain memory in the pipelines and solve the problem of long sequence dependence in neural networks.

In this paper, we propose a bidirectional encoder representation learned from transformers (BERT) model (Devlin et al., 2018) for Task A. It comprises two phases. The first phase is called pre-training and is similar to word embedding. The second phase is called fine-tuning and uses a pre-trained language model to complete specific NLP downstream tasks. We used a pre-trained model that was provided by Google AI team. It included weights for the pre-trained model and a vocab file that maps component words of sentences to indexes of words. It also included the JSON file, which specifies the model hyper-parameters. Fine-tuning was applied to sequence classification: the BERT directly takes the final hidden state of the first [CLS] token, adds a layer of weight, and then softmax predicts the label probability. The structure is shown in Figure 2.

For Task B, we apply the bert model to test data, the score is 0.343, it is very low. the reason is that the task B is cross-domain training, so we intro-

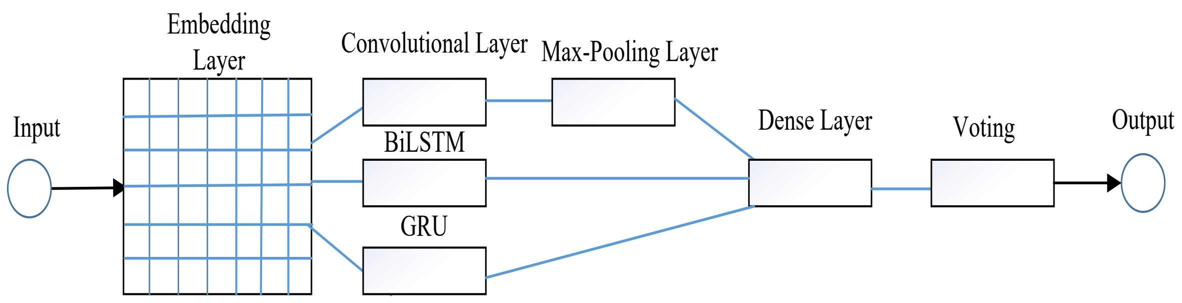

Figure 1: The CNN-BiLSTM-GRU architecture

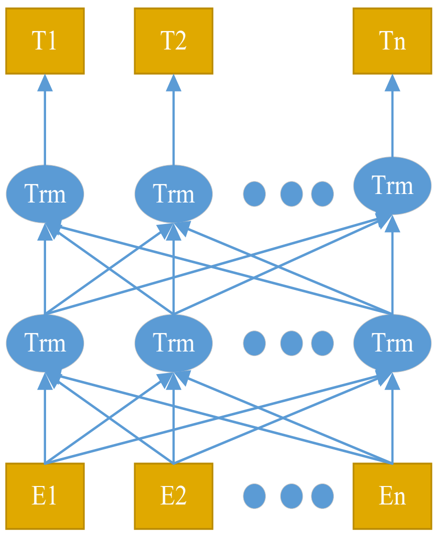

Figure 2: The architecture of BERT

duced an ensemble model that includes the CNN, BiLSTM, and GRU model. The structure is shown in Figure 1. We constructed the word vectors from 300-dimensional Glove vector. Then, a word vector matrix was loaded into the embedding layer. After this, the CNN applies the convolutional layer and max pooling layer to extract n-gram features, and passes through the dense layer to classify the sentence. BiLSTM can obtain the semantic information from the context. The forward and backward layers are connected to the output layer. GRU has a structure similar to that of LSTM, but is simpler. Finally, we combined CNN with BiLSTM and GRU using a soft-voting method, and output the results. The experimental results show that our model has good performance. According to the official review, we achieved sixth place among the 34 teams working on Task A.

The rest of the paper is organized as follows. In Section 2, we describe the BERT model. There, we also detail CNN, BiLSTM, and GRU and their combination. The comparative experimental results are presented in Section 3. Conclusions are drawn in Section 4.

2 The BERT and CNN-BiLSTM-GRU model

Figure 2 shows the BERT model. First, for each token, a representation is generated by its corresponding token embedding, segment embedding, and position embedding. Word-Piece was embeded (Wu et al., 2016) along with 30,000 token vocabularies. Finally, an output layer was used to fine-tune the parameters. Figure 1 shows the ensemble model used to combine the CNN, BiLSTM, and GRU models. First, all component words were transformed to a feature matrix by an embedding layer. Then a convolutional layer and a max pooling layer, were used for feature extraction. To avoid over-fitting, a dropout layer was used after both convolution and max-pooling layers. BiLSTM outputs predictive label sequence directly to input sentences. GRU is a variant of LSTM that has fewer parameters and is relatively easier to train. We embedded these models with the vote method and finally output the result.

2.1 Bidirectional Encoder Representations from Transformers (BERT)

Input characterization. For the task of sentence classification, BERT will add the [CLS] and [SEP] identifiers to the beginning and end of each input text; thus, the maximum sequence length can be described as follows.

$$max\_seq = S_t + 2 \qquad (1)$$

where *max_seq* denotes the maximum sequence length, and *St* is the set text length. We set the S_t=78, and *max_seq*=80. For every input sentence, BERT introduces masked language mode, and next sentence prediction. Input embedding is the sum of token embedding, segmentation embedding, and position embedding.

Transformer. The multi-layer transformer Vaswani et al. (2017) structure operates through the attention mechanism to convert the distance between two words at any position into the numeral 1. Owing to the transformer's overall architecture, the input sequence will first be converted into a word embedding vector, which can be used as the input of the multi-head self-attention module after adding the position coding vector. The output of the module can be used as the output of the encoder module after passing through a fully connected layer.

Output.The highest hidden layer of [CLS] is directly connected to the output layer of softmax as a sentence. The output result of BERT is label probability. The sum of the probabilities of all labels is 1, and the probability value of returning a label is the same as the order of setting labels in MrpcProcessor. This task sets the labels to 0 and 1. The probability of the first column returned in this experiment is 0, and the probability of the second column is 1.

2.2 CNN

Embedding Layer. The embedding layer is the first layer of model. Load Glove (Lee et al., 2016; Cun et al., 1990) with word embedding (Zahran et al., 2015) and is used for model initialization of online reviews. The embedded layer converts a positive integer (subscript) into a vector of fixed size N. N is defined as 80; any sentence exceeding this size is reduced to 80, and any sentence with a size less than 80 is padded to 80 by adding 0s.

Convolution Layer. The convolution layer is used to extract n-gram features from the embedding matrix. The calculation method of the convolution layer is as follows,

$$conv = \sigma(Mat \circ W + b) \qquad (2)$$

where σ is an activation function, *Mat* indicates an embedding matrix, W and b respectively denote convolution kernel and bias. Here, $\circ$ is a convolution operation. We use 3*3 convolution kernels. The activation function is ReLU (Nair and Hinton, 2010)

Max pooling layer. Pooling is selecting a part of the input matrix and is used to choose the best representative for the region. The max pooling layer selects the max feature.

Dropout Layer. To avoid over-fitting, we introduce the dropout layer (Hinton et al., 2012) after both a convolution layer and max pooling layer, which is to randomly throw away some weight of the current layer. It can reduce model complexity and enhance the generalization ability of the model.

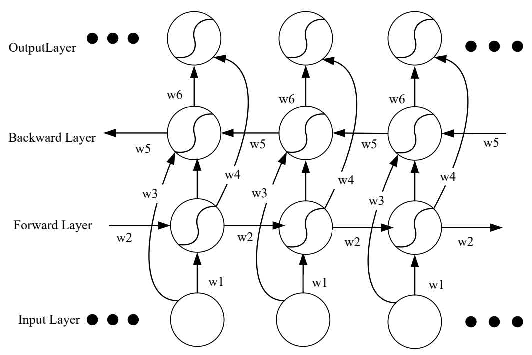

Figure 3: The architecture of BiLSTM

2.3 BILSTM and GRU

Bi-directional Long Short-Term Memory (BiLSTM) (Brueckner and Schuller, 2014; Li and Chang, 2015) is a variant of Recurrent Neural Network (RNN). Owing to its design characteristics, BiLSTM is ideal for modeling time-series data such as text data. Figure 3 shows the BiLSTM structure. BiLSTM is an abbreviation of LSTM Graves (2012); Greff et al. (2016); Graves (2012), which is a combination of forward LSTM and backward LSTM. Both are often used to model context information in natural language processing tasks.

Gated Recurrent Unit (GRU)(Cho et al., 2014) is a variant of LSTM, although the model is simpler than the standard LSTM model. It combines a forget gate and input gate into a single update gate. It also mixes cell state with hidden state.

$$\begin{aligned} z_t &= \sigma(W_z \cdot [h_{t-1}, x_t]) \\ r_t &= \sigma(W_r \cdot [h_{t-1}, x_t]) \\ \tilde{h}_t &= \tanh(W \cdot [r_t * h_{t-1}, x_t]) \\ h_t &= (1 - z_t) * h_{t-1} + z_t * \tilde{h}_t) \end{aligned} \qquad (3)$$

where h_t is hidden states, x_t is the input vector, σ is the sigmoid function, and r_t and z_t are the reset and update doors, respectively.

2.4 Ensemble

Each classifier is independently classified, and the integrated model can improve the correct rate. In this task, each base learner has a predicted value, and we used a soft-voting classifier as the final predicted value. The soft-voting classifier predicts the class label based on the sums of the predicted probabilities. The corresponding type with the highest probability is the final prediction result.

Model	Trial	Test
CNN	0.505	0.216
BiLSTM	0.498	0.180
CNN-BiLSTM	0.667	0.210
BERT	**0.851**	**0.735**

Table 1: The experiment results.

Parameters	BiLSTM/GRU	CNN
Neurons	60	120
Dropout rate	0.4	0.0
Weight	2	5
Activation	softmax	softmax
Init mode	LeCun	LeCun
Learning rate	0.001	0.2
Momentum	0.4	0.4

Table 2: The best-tuned parameters.

3 Experiments and Evaluation

In this section, we report the experiments were conducted to evaluate the proposed models on both sub-tasks. We also report the results of the official review. The details of the experiment are described as follows.

3.1 Data Preparation

Subtask A. Organizers provided training data from online forum comments that included three parts: id, sentence, and label. The given label is 0, indicating that the suggestion is not recommended. Here, 1 indicates a positive suggestion. This is equivalent to the suggestion mining used to discover sentences with suggestions. The positive and negative emotional statements of a given data set are unbalanced, and the negative emotions are three times more abundant than the positive emotions. According to this situation, we used oversampling to process the data; the positive emotional sentences were randomly copied from the training set in the same proportion as the negative emotional sentences. We extracted 0.2 ratio data as a validation set in the training set. In this experiment, we used the BERT-Base model which is pre-trained by Google AI team to process the text.

Subtask B. To address the problem of imbalance in data distribution, Task B uses the define loss function. In our model, we introduced a focal-loss function (Lin et al., 2017) that reduced the weight of many negative samples in training. This loss function is a dynamically scaled cross entropy loss function. As the correct classification increases, the scale factor in the function is reduced to zero. This scale factor can automatically reduce the impact of simple samples during training. Quickly focus your model on difficult samples. Data processing removes stop words, replaces URLs with <urls>, and removes characters except for alphanumeric characters and punctuation.

3.2 Implementation Details

Subtask A. In this experiment, TensorFlow (GPU backed) was used. We used the BERT-Base model to process the data. We introduced other three models (CNN, BiLSTM, and BiLSTM) as baseline algorithms. We combined commonly used parameters to tune-in the training. For the task, the batch size was 30, the learning-rate set was 2e-5, and the number of the training epoch was 10.

Subtask B. We used Scikit-Learn to perform a grid search (Pedregosa et al., 2013) to tune the hyper-parameters, by which we could find the best parameters to evaluate the system. The weight indicates the weight_constraint. The LeCun indicates LeCun uniform. The fine-tuned parameters are summarized in Table 2.

3.3 Evaluation Metrics

Classification performance of the submissions will be evaluated based on binary F_1-score for the positive class. Binary F_1-score will range from 1 to 0.

3.4 Results and Discussion

The trial and test data for the baseline model and the BERT model shows that our model has the best score in Table 1.

Subtask A. Our system achieved the F1 score of 0.7353 on Subtask A, and the baseline score was 0.2676. The results show that our proposed system is a significant improvement over the baseline. The main reason is that not only the BERT is a multi-layer bidirectional transformer encoder, but also the BERT-Base model is powerful pre-training model.

Subtask B. Our model score was 0.5035, while the baseline score was 0.7329. There is a need to do more for improvement. For cross-domain suggestion mining, it is necessary to increase the generalization ability of the training model to achieve use in multiple domains.

4 Conclusion

In this paper, we describe a task system that we submitted to SemEval-2019 for suggestion mining. For Subtask A, we use the BERT model. For Subtask B, we introduced CNN combined with BiLSTM and GRU. The experimental results show that the models we introduced achieved good performance in the final evaluation phase. In future research, we will attempt to generalize models with better capabilities to obtain more better results.

Abstract

This paper describes our submission for the SemEval-2019 Suggestion Mining task. A simple Convolutional Neural Network (CNN) classifier with contextual word representations from a pre-trained language model is used for sentence classification. The model is trained using tri-training, a semi-supervised bootstrapping mechanism for labelling unseen data. Tri-training proved to be an effective technique to accommodate domain shift for cross-domain suggestion mining (Subtask B) where there is no hand labelled training data. For in-domain evaluation (Subtask A), we use the same technique to augment the training set. Our system ranks thirteenth in Subtask A with an F_1-score of 68.07 and third in Subtask B with an F_1-score of 81.94.

1 Introduction

Task 9 of SemEval-2019 (Negi et al., 2019) focuses on mining sentences that contain suggestions in online discussions and reviews. Suggestion Mining is modelled as a sentence classification task with two Subtasks:

- Subtask A evaluates the classifier performance on a technical domain specific setting.
- Subtask B evaluates the domain adaptability of a model by doing cross-domain suggestion classification on hotel reviews.

We approached this task as an opportunity to test the effectiveness of transfer learning and semi-supervised learning techniques. In Subtask A, the high class imbalance and relatively smaller size of the training data made it an ideal setup for evaluating the efficacy of recent transfer learning techniques. Using pre-trained language models for contextual word representations has been shown to improve many Natural Language Processing (NLP) tasks (Peters et al., 2018; Ruder and Howard, 2018; Radford, 2018; Devlin et al., 2018). This transfer learning technique is also an effective method when less labelled data is available as shown in (Ruder and Howard, 2018). In this work, we use the BERT model (Devlin et al., 2018) for obtaining contextual representations. This results in enhanced scores even for simple baseline classifiers.

Subtask B requires the system to not use manually labelled data and hence it lends itself to a classic semi-supervised learning scenario. Many methods have been proposed for domain adaptation for NLP (Blitzer et al., 2007; Chen et al., 2011; Chen and Cardie, 2018; Zhou and Li, 2005; Blum and Mitchell, 1998). We use a label bootstrapping technique called tri-training (Zhou and Li, 2005) with which unlabelled samples are labelled iteratively with increasing confidence at each training iteration(explained in Section 2.4). Ruder and Plank (2018) shows the effectiveness of tri-training for baseline deep neural models in text classification under domain shift. They also propose a multi-task approach for tri-training, however we only adapt the classic tri-training procedure presented for suggestion mining task.

Detailed explanation of the submitted system and experiments are elicited in the following sections. Section 2 describes the components of the system. Following this, Section 3 details the experiments, results and ablation studies that were performed.

2 System Description

The models and the training procedures are built using AllenNLP library (Gardner et al., 2018). All the code to replicate our experiments are public and can be accessed from `https://github.com/sai-prasanna/suggestion-mining-semeval19`.

2.1 Data cleaning and pre-processing

Basic data pre-processing is done to normalize whitespace, remove noisy symbols and accents. Very short sentences with less than four words are disregarded from training.

2.2 Word Representations

We use GloVe word representations (Pennington et al., 2014) and compare the performance improvement that we obtain with pre-trained BERT representations (Devlin et al., 2018).

2.3 Suggestion Classification

Our baseline classifier is Deep Averaging Network (DAN) (Iyyer et al., 2015). DAN is a neural bag-of-words model that is considered as a strong baseline for text classification. In DAN, a sentence representation is obtained by averaging the word level representations and is fed to a series of rectified linear unit (ReLU) layers with a final softmax layer.

A simple Convolutional Neural Network (CNN) text classifier (Kim, 2014) is used for the final submission.

2.4 Training

We use the classic tri-training procedure for label bootstrapping as mentioned in (Ruder and Plank, 2018). Consider a labelled dataset L from the source domain S and an unlabelled dataset U from the target domain T. The objective of tri-training is to label U iteratively and augment it with L. Three CNN +BERT classifiers M_1, M_2, M_3 are trained separately using subsets of L namely l_1, l_2, l_3 respectively. These subsets are obtained from L using bootstrap sampling with replacement.

The above mentioned models are used to predict labels for the unlabelled set U. Predictions which are agreed by two models is considered as a new training example for the third model in the next iteration. For example, an unlabelled sentence $U_1 \in U$ is added as a labelled example to l_1, if and only if the label for U_1 is agreed upon by both M_2 and M_3. Same way, l_2 is updated with newly labelled data if those labels have been agreed by M_1 and M_3 and so on. This constitutes a single iteration of tri-training. The procedure that is used for the training of our models is mentioned in Algorithm 1.

In this way, the original training data gets added with three newly labelled subsets which are again used for the next training iteration. At the end of each iteration, validation F_1-score is calculated by using the predictions that are obtained through a majority vote. The procedure is continued until there is no improvement in the validation score.

Algorithm 1 Tri-training

```
 1: $L \leftarrow Labelled\ Data$ , $|L| = m$
 2: $U \leftarrow Unlabelled\ Data$ , $|U| = n$
 3: for $i \leftarrow 1, 2, 3$ do
 4:     $l_i \leftarrow BootstrapSamples(L)$
 5: end for
 6: repeat
 7:     for $i \leftarrow 1, 2, 3$ do
 8:         $M_i \leftarrow Train(l_i)$
 9:     end for
10:     for $i \leftarrow 1, 2, 3,$ do
11:         $l_i \leftarrow L$
12:         for $j \leftarrow 1, n$ do
13:             if $M_p(U_j) == M_q(U_j)$
14:                 $where\ p,\ q \neq i$ then
15:                 $l_i \leftarrow l_i + \{(U_j, M_p(U_j))\}$
16:             end if
17:         end for
18:     end for
19: until no improvement in validation metrics
```

3 Experiments and Results

This section details the various experiments that were performed using the above components for our submissions.

3.1 Data

The test set provided during the trial phase of the evaluation is used as the validation data for all our experiments. For those experiments that do not involve tri-training, we only use the provided labelled data from the technical domain for training.

In Subtask B, for those experiments that involve tri-training, L is the same as mentioned above. U here is obtained in two ways:

- Unlabelled data from final test set of Subtask B.
- Unlabelled data from Yelp hotel reviews (Blomo et al., 2013).

The results reported are mean and confidence intervals of Precision, Recall and F_1-score over five runs of the same experiments with different random seeds.

Subtask A - Technical Domain

Experiment	Validation			Test

Table 1: Performance metrics of different models on validation and test sets of both subtasks. Confidence intervals for the metrics are reported for five runs using different random seeds on t-distribution with 95% confidence. Upsampling is used in the training dataset unless otherwise specified. Single model from experiments with * was used for the final submission.

3.2 Input

For input representations, we use 300d GloVe vectors with dropout (Srivastava et al., 2014) of 0.2 for regularization. We also experiment with the pre-trained BERT base uncased model. The BERT model is not fine-tuned during our training. A dropout of 0.5 is applied for the 768d representations obtained from BERT.

3.3 Baseline Deep Averaging Net

Our neural baseline is Deep Averaging Net (DAN) (Section 2.3). When used with GloVe, the hidden sizes of DAN are 300, 150, 75, and 2 respectively. When BERT representations are used, the hidden sizes of the network are 768, 324, 162, and 2 respectively. We report an F_1-score of 60.82 when DAN is used with BERT in Subtask A and 70.49 in Subtask B. Both these scores are a significant improvements from those obtained with GloVe representations (Table 1).

We retain the same configuration of BERT embedding layer for other experiments also. Training is performed with Adam (Kingma and Ba, 2015) optimizer with a learning rate of $1e{-}3$ for all the models.

3.4 CNN Classifier

The CNN classifier is composed of four 1-D convolution layers with filter widths ranging from two to five. Each convolutional layer has 192 filters. The output from each layer is max-pooled over sequence (time) dimension. This results in four 192d vectors, which are concatenated to get a 768d output.

The max-pooled outputs are passed through four fully connected feed forward layers with hidden dimensions of 768, 324, 162, and 2 respectively. The intermediate layers use ReLu activation and the final layer is a softmax layer. We use dropout of 0.2 on all layers of the feed forward network except for the final layer.

Without tri-training, this model obtains an absolute improvement of $\approx 4\%$ F_1-score over DAN in Subtask A. However in Subtask B, it performs poorer than the baseline DAN model with an F_1-score of 64.31. This decrease in performance could be because of overfitting on the source domain due to the larger number of parameters in CNN compared to DAN.

3.5 Tri-training

The aim of doing tri-training is for domain adaptation by labelling unseen data from a newer domain. For Subtask B, the CNN + BERT model achieves an F_1-score of 82.19 when trained with the tri-training procedure mentioned in Algorithm 1. Tri-training is used to label the 824 unlabelled sentences from the test set of Subtask B and augmented with the original training data. This score is a huge improvement from the classifier model trained only on the given data which gets an F_1-score of 64.31.

We also do the same experiment using 5000 unlabelled sentences from Yelp hotel reviews dataset (Blomo et al., 2013). The model obtains a similar score of 81.98 which proves the importance of tri-training in domain adaptation.

For Subtask A, we get an improvement in the F_1-score using tri-training, however the increase is not as profound as we observe for Subtask B. We compare the statistical significance of the different models and experiments in Section 3.7.

3.6 Upsampling

We also wanted to find how the class balance in the dataset has affected our model performance. The class distribution of the datasets including the test set distribution that was obtained after the final evaluation phase are mentioned in Table 2.

Dataset	Suggestions (%)
Training	23
Subtask A validation	50
Subtask B validation	50
Subtask A Test	**10**
Subtask B Test	42

Table 2: Label distribution

The original training data has a class imbalance with only 23% of the sentences labelled as suggestions. We tried to balance the labels by naive upsampling, ie., adding duplicates of sentences that are labelled as suggestions. This allowed us to have a balanced training dataset for our experiments. This resulted in consistent gains over the original dataset during the trial evaluation phase.

However during the final submission, in Subtask A we found that the model's performance in the test set did not correlate well with that of the validation set as shown in Table 1. This could be because the percentage of positive labels in the test set is only 10% while the validation set has 50%.

Experiments without upsampling gives better performance in test set even though there is a decrease in the validation score. For Subtask B however, upsampling has actually increased the model performance. On hindsight, this could be because of similar distribution of class labels in both validation and test sets.

The submitted models received an F_1-score of 68.07 in Subtask A and 81.03 in Subtask B.

3.7 Statistical Significance Test

Reichart et al. (2018) suggests methods to measure whether two models have statistically significant differences in their predictions on a single dataset. We incorporate a non-parametric testing method for significance called the McNemar's test recommended by them for binary classification. Pairwise comparison of few of our models are reported in Table 3. The table contains the p-values for the null hypothesis. The null hypothesis is that two models do not have significant differences in their label predictions. In simpler words, a small p-value for an experiment pair denotes a significant difference in the prediction disagreement between two models. For example, from Table 3, DAN + GloVe and DAN + BERT models have a p-value less than 0.05 in both sub-tasks. This indicates that there is significant disagreement between the predictions of two models. Since DAN + BERT gets a better F_1-score and $p < 0.05$, we can confidently assert that improvement is not obtained by chance.

We use majority voting from five random seeds to get the final predictions on the test set for doing the paired significance testing.

4 Conclusion

We discussed our experiments for doing suggestion mining using tri-training. Tri-training combined with BERT representations proved to be an effective technique for doing semi-supervised learning especially in a cross-domain setting. Future work could explore more optimal ways of doing tri-training, evaluate the effect of contextual representations in tri-training convergence, and try more sophisticated architectures for classification that may include different attention mechanisms.

Subtask	Model A	Model B	p-value
A	DAN +glove	DAN +bert	≈ 0
A	DAN +bert	CNN +bert	0.046
A	CNN +bert	CNN +bert +tritrain$_{Test}$	**0.108**
B	DAN +glove	DAN +bert	$1.419e-05$
B	DAN +bert	CNN +bert	**0.4208**
B	CNN +bert	CNN +bert +tritrain$_{Test}$	$3.251e-08$
B	CNN +bert +tritrain$_{Test}$	CNN +bert +tritrain$_{Yelp}$	**0.5862**

Table 3: Pairwise comparison of various models using the McNemar's Test. $p \leq 0.05$ indicates a significant disagreement between the model predictions.

Abstract

This paper describes our system that competed at SemEval 2019 Task 9 - SubTask A: ”Suggestion Mining from Online Reviews and Forums”. Our system fuses the convolutional neural network and the latest BERT model to conduct suggestion mining. In our system, the input of convolutional neural network is the embedding vectors which are drawn from the pre-trained BERT model. And to enhance the effectiveness of the whole system, the pre-trained BERT model is fine-tuned by provided datasets before the procedure of embedding vectors extraction. Empirical results show the effectiveness of our model which obtained $9th$ position out of 34 teams with F1 score equals to 0.715.

1 Introduction

Suggestion mining is defined as the extraction of suggestions from unstructured text (Negi et al., 2018). Suggestion mining is still a relatively young research area as compared to other natural language processing issues like sentiment analysis (Negi and Buitelaar, 2015). While suggestion mining is of great commercial value for organisations to improve the quality of their entities by considering the positive and negative opinions collected from platforms. The target of this task is to automatically classify the sentences collected from online reviews and forums into two classes which are suggestion and non-suggestion respectively (Negi et al., 2019).

BERT which stands for **B**idirectional **E**ncoder **R**epresentation from **T**ransformers is the latest breakthrough in the field of NLP provided by Google Research (Devlin et al., 2018). It has substantially advanced the state-of-the-art in many NLP tasks, especially in question answering (Alberti et al., 2019). More importantly, it provides a widely applicable tool for representation learning which can be generalized to many NLP tasks.

For this subtask, we firstly learn the word or sentence embeddings utilizing the pre-trained BERT model. Then the embedding vectors are extracted from BERT as the input of the subsequent model. It is worth noting that we have fine-tuned the pre-trained BERT model with provided dataset before the embedding vectors are extracted. In other words, this part is equivalent to the conventional embedding layer. This strategy is a little bit like ELMO (Peters et al., 2018). As for the upper layer of this system, convolutional neural network (CNN) is adopted herein to process the features. Although CNN is originally invented for tackling computer vision issues, while it has subsequently been shown to be effective for many NLP tasks (Kim, 2014; Zhang and Wallace, 2015; Dong et al., 2015).

The remainder of the paper is organized as follows. Section 2 describes the detailed architecture of our system. Section 3 reports the experimental results on the given datasets. Finally, conclusions are drawn in Section 4.

2 System Description

Figure 1 gives a high-level overview of our approach. And we elaborate the details of implementation which mainly consists of following steps: (1) the preprocessing of raw data, (2) the word embedding learning via BERT model, (3) feature processing via CNN and sentences classification.

2.1 Data Preprocessing

The provided dataset is collected from feedback posts on Universal Windows Platform and annotated by (Negi et al., 2018). But the text is not standard enough as there are some spelling mistakes and few duplicate samples. To boost the performance of our system, we conduct some pre-

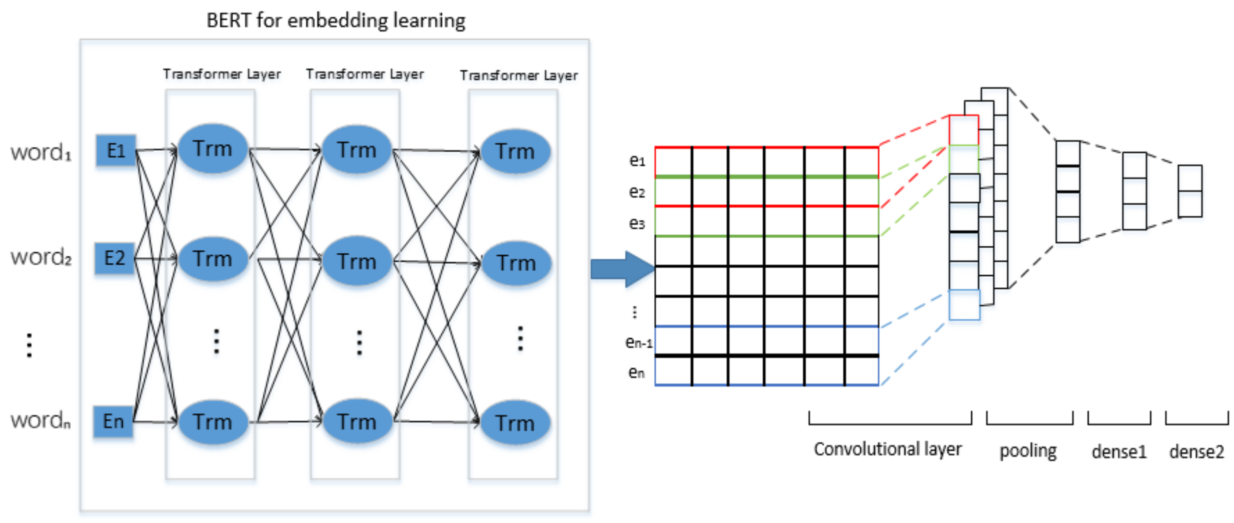

Figure 1: The architecture of our proposed model.

processing steps on the raw data. At first, web links are removed through regular expression as it does not contribute to the accuracy of classification. After that, we can take more meaningful words into consideration under the condition of a finite sentence length. And *ekphrasis* [1], a text processing tool, is utilized to conduct spelling correction (Baziotis et al., 2017). Then, all characters are converted to lowercase. Finally, duplicated samples would be excluded from the dataset.

2.2 Embedding Learning via BERT

Embedding layer usually encodes each word into a fixed-length vector for subsequent study. *Word2vec*, *Glove* and *FastText* are the most simple and popular word embedding algorithms (Mikolov et al., 2013; Pennington et al., 2014; Bojanowski et al., 2017). While there continue to be some drawbacks, such as they cannot encode the contextual information well. Recently, a few effective algorithms have been put forward such as *ELMO* and *openAI GPT* (Peters et al., 2018; Radford et al., 2018). These two pre-trained language models can encode rich syntactic and semantic information and distinguish the different meanings of a polysemy in diverse contexts, which traditional word embeddings methods cannot handle well. *ELMO* leverages the concatenation of independently trained left-to-right and right-to-left LSTM to generate features. Though LSTM can capture contextual information, the performance can be limited by the long distance of sequences to some extent. In order to deal with this problem, *openAI GPT* substitute *Transformer* for LSTM. *Transformer* rely entirely on attention mechanism to capture global dependencies (Vaswani et al., 2017).

BERT is the latest language representation model which also takes advantage of *Transformer*. Besides that, it uses the masked language model (MLM) and the bidirectional *Transformers* to capture the contextual information which has been proved to be effective (Devlin et al., 2018). In our system, we employ *BERT* as the embedding layer, in other words, we use the output of the last transformer layer from BERT as word embedding vectors. The version of pre-trained BERT model we used is BERT-BASE which has 12 layers of transformer blocks and the hidden size is equal to 768. It implies that the dimension of the output embedding vectors is equal to 768. We choose not to cover too much details of BERT as it has been elaborated on its website [2].

To boost the performance of our system by making this model better fit our data, a fine-tuning step is conducted before extracting the word embedding vectors from pre-trained model. And the fine-tuning parameters are given in Section 3.2.

2.3 Feature processing via CNN

CNN is originally invented for tackling the issues in the field of computer vision, while various C-

[1] github.com/cbaziotis/ekphrasis

[2] https://github.com/google-research/bert

NN models have subsequently been proven to be effective for many NLP tasks (Kalchbrenner et al., 2014; dos Santos and Gatti, 2014). In our work, we train a single layer CNN on the word embedding vectors drawn from BERT model. Let $e_i \in \mathbb{R}^k$ be the k-dimensional word embedding vector corresponding to the i-th word in the sentence. Then the vector representation of a sentence is denoted as Eq.1:

$$e_{1:n} = [e_1 \parallel e_2 \parallel e_3 \parallel ... \parallel e_n], \tag{1}$$

where n represents the length of sentences, and $\parallel$ denotes concat operation which can maintain the order of words in text. After that a filter involved in one-dimensional convolution operation is defined as $\mathbf{w} \in \mathbb{R}^{m \times k}$, then the convolution process can be defined as a function as Eq.2 (Kim, 2014):

$$p_i = f(\mathbf{w} \cdot e_{i:i+m-1} + b), \tag{2}$$

where p_i is a scalar which stands for the new local feature generated by a filter from a window of words $e_{i:i+m-1}$, in other words, only i-th to $i+m-1$-th words have been taken into consideration when generate i-th local feature. m is filter size which denotes m words is taken into calculation when generating a local feature. b is a bias and f is an activation function, it is $tanh$ exactly in our system. Finally, there are $n-m+1$ local features generated by a filter totally. Those local features can be concatenated as a global feature P:

$$P = [p_1 \parallel p_2 \parallel p_3 \parallel ... \parallel p_{n-m+1}], \tag{3}$$

where $P \in \mathbb{R}^{n-m+1}$ represents a feature map generated by a filter. Then a *max-over-time maxpooling* operation (Collobert et al., 2011) is applied to the feature maps which means that only the maximum value of P is reserved. If there are N_f filters, then N_f maximum values is generated through *maxpooling* operations. Those values can be organized as a new vector $Q \in \mathbb{R}^{N_f}$ as Eq.4:

$$Q = [max(P_1) \parallel max(P_2) \parallel ... \parallel max(P_{N_f})], \tag{4}$$

2.4 Dense layers

The pooling layer is followed by two dense layers with different number of neurons. *Dropout* (Hinton et al., 2012) is utilized to alleviate overfitting problem before the first dense layer. And we have tried different dropout rates to search the best configuration. Firstly, the output of pooling layer Q is fed into the first dense layer with 200 hidden neurons. The activation function of this dense layer is *relu* (Xu et al., 2015). Next is the second dense layer with two neurons and the corresponding activation function is *softmax*. Final output is the probability of which class the sample belongs to.

3 Experiments

3.1 Dataset

Classes	Train set	Trial Test set	Test set
0 (non-suggestions)	6415	296	746
1 (suggestions)	2085	296	87

Table 1: Data distribution

The available dataset released by organizer is split into three parts: train set, trial test set and test set. The positive and negative sample distribution of each part is described as Table 1. Apparently, there is class imbalance that the number of negative samples overwhelms the number of positive samples both in training set and test set. So for experiments, we fuse the train set and trail test set into a larger training set, and then split 10% samples as validation set randomly (8183 samples for training and 909 samples for validation). We train our model on the train set, tune the model parameters on the validation set, evaluate the model performance on the test set.

Model	Dropout	Macro average F1
Baseline	-	0.2676
Word2vec+CNN	0.4	0.3789
our model	0.1	0.7459
	0.2	0.7236
	0.3	0.7407
	0.4	0.7309
	0.5	0.7179
	0.6	0.7368
	0.7	0.7029

Table 2: The performance comparison.

Classes	Precision	Recall	F1 score
0 (non-suggestions)	0.98	0.96	0.97
1 (suggestions)	0.70	0.79	0.75

Table 3: The classification accuracy of different classes.

3.2 Experiment Results

As mentioned in Section 2.2, we conduct fine-tuning operation before extracting the word embedding vector from *BERT*. For fine-tuning, most hyperparameters are the same as the parameters

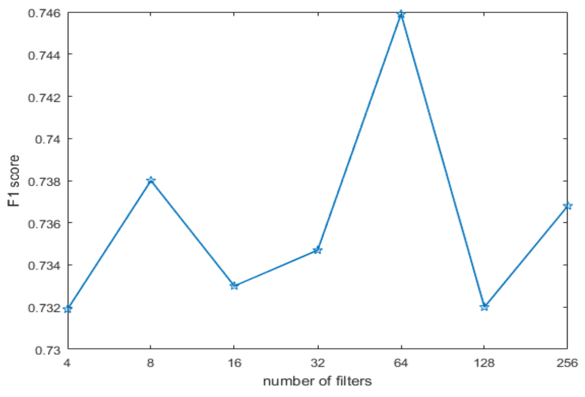

Figure 2: The impact of the number of filters.

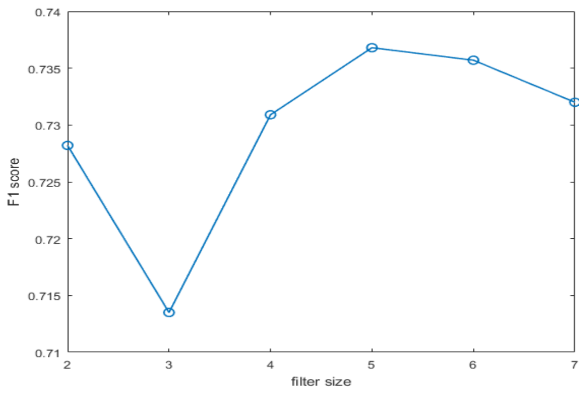

Figure 3: The impact of filter size.

of pre-trained model, with the exception of batch size, learning rate and number of training epochs. The mini-batch size is set at 32 and learning rate is set at 5e-5, the number of training epochs is configured as 5. The maximal length of sentences is configured as 50 and if the length of a sentence is less than 50, it will be padded with zero; otherwise, it will be truncated from the tail. For the CNN component, the filter size m is configured as 5 and the number of filters N_f is 64. And the dropout rates we have tried are ranged from 0.1 to 0.7 with a step of 0.1. The experimental results are shown in Table 2. In order to prove the effectiveness of word embeddings derived from BERT, we also employ Word2vec as comparison and the corresponding best dropout rate is 0.4. Obviously, no matter what the dropout rate is, our model consistently outperforms other models. And the best dropout rate of our model is around 0.1 for abovementioned configuration. While the best dropout rate may vary with other parameter configuration like filter size and the number of filters.

Table 3 shows the Precision, Recall and F1 score in term of different classes. Obviously, the system performance on negative samples is better than the performance on positive samples which is consistent with our intuition for the reason that the number of negative samples overwhelms the number of positive samples. Therefore, our system can learn more features of negative samples, which can help it recognize those negative samples accurately.

We also investigate the impact of the number of filters N_f on the classification performance with fixing the filter size m at 5 and the dropout rate at 0.1. The experimental result is shown as Figure 2. This model yields the best performance when the number of filters is equal to 64. Less filters cannot capture enough information while too many filters can result in information redundancy to some extent.

The impact of filter size on classification accuracy is shown as Figure 3. The most suitable filter size which means the window size of convolutional operation is $m = 5$. It is difficult for this system to catch the global semantic information if the window size is too small. While some local semantic information would be ignored if the window size of filter is too large. Hence, choosing a filter with moderate size is helpful for the performance improvement.

4 Conclusions

In this paper, we have proposed a neural model based on the pre-trained BERT model to deal with suggestion mining task. Our system can learn the representation of sentences or words effectively by leveraging BERT. Then the representations extracted from BERT is fed into a simple CNN layer. Experimental results show that our system is efficient on the given dataset.

As for future work, it is of necessity to tackle the imbalance between positive samples and negative samples through oversampling or undersampling. And we intend to study some innovative ways to incorporate BERT model like extracting not only the output of the last transformer layer but also the output of different transformer layers and integrating them with different weights.

ProblemSolver at SemEval-2019 Task 10: Sequence-to-Sequence Learning and Expression Trees

Xuefeng Luo, Alina Baranova, Jonas Biegert
Linguistics Department, University of Tuebingen, Germany
firstname.lastname@student.uni-tuebingen.de

Abstract

This paper describes our participation in SemEval-2019 shared task "Math Question Answering", where the aim is to create a program that could solve the Math SAT questions automatically as accurately as possible. We went with a dual-pronged approach, building a Sequence-to-Sequence Neural Network pre-trained with augmented data that could answer all categories of questions and a Tree system, which can only answer a certain type of questions. The systems did not perform well on the entire test data given in the task, but did decently on the questions they were actually capable of answering. The Sequence-to-Sequence Neural Network model managed to get slightly better than our baseline of guessing "A" for every question, while the Tree system additionally improved the results.

1 Introduction

The data set for the task (Hopkins et al., 2019) includes questions used in the Math SAT. There are three broad categories of questions: closed-vocabulary and open-vocabulary algebra questions, and geometry questions. All types of questions consist in large part of natural language. Closed-vocabulary algebra questions typically contain math equations and many math-specific words, while open-vocabulary algebra questions include more everyday vocabulary and quantities which are expressed in letters, numbers or a combination of both. Geometry questions are usually provided with diagrams the analysis of which is necessary for solving the problems. Most questions of all categories are multiple-choice questions with five possible options, but some questions have a numeric answer.

We present two systems to tackle these math problems. One of them, a sequence-to-sequence LSTM model pre-trained with augmented data, is applied to all three types of questions, while the other, a system based on expression trees produces answers exclusively for open-vocabulary algebra questions.

2 Related Work

In their work, Roy and Roth (2015) introduced binary *expression trees* that represent and solve math word problems. To choose the best expression tree out of all possible trees, the authors employed two classifiers: a relevance classifier, which determined if the quantity should be included into the expression tree, and a Lowest Common Ancestor (LCA) classifier, which output the most probable mathematical operation for a pair of quantities. Both classifiers were trained on gold annotations.

Subsequently, two other systems were developed based on Roy and Roth (2015). One of the systems belongs to the same authors and uses the concept of Unit Dependency Graphs (UDGs) to capture the information between units of the quantities (Roy and Roth, 2017). UDGs are then united with expression trees, allowing the information about dependencies between units improve the math problem solver.

Another system (Wang et al., 2018) suggests a method to improve Roy and Roth's approach. By applying deep reinforcement learning, which has proved to be suitable for problems with big search space, the authors achieve better accuracy and efficiency.

An earlier system introduced by Wang et al. (2017) used gated recurrent units (GRU, Chung et al., 2014) and long short-memory (LSTM, Hochreiter and Schmidhuber, 1997) to automatically solve simple math word problems by converting words into math equations.

3 Model Description

3.1 Sequence-to-Sequence Neural Network

Our model is based on a sample implementation provided by the Keras team (Chollet et al., 2015). This model was able to calculate addition, such as from “535+61” to “596” with a Sequence-to-Sequence model using LSTM (Hochreiter and Schmidhuber, 1997). Similar to this model, our model also had 128 hidden units and started with an embedding layer with an alphabet of 96 characters. The longest question was 650 characters. Then, we used a LSTM as encoder. For all dighits in the answers, we have seperate vectors representing them. Thus, we have repeated vectors of outputs 5 time, in order to represent 5 dighits. Our decoder was another LSTM layer with returing sequences, followed by a time distributed layer of dense layers where activation function was softmax. In addition to this, we added a 0.2-rate Dropout layer (Srivastava et al., 2014) after embeding layer, encoder LSTM and decoder LSTM, to prevent over-fitting. On top of that, we found that reversing and doubling the inputs can greatly improve training performance, according to Zaremba and Sutskever (2015). The seq2seq model is shown by Figure 1. We did not encoded answers along with questions. We only compared the answers strings to the questions' choices and made our decisions.

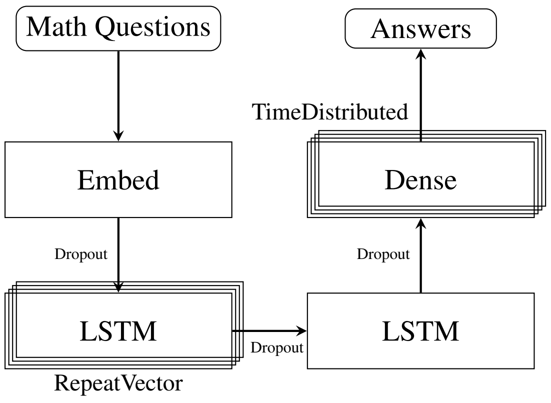

Figure 1: Seq2seq Model

We padded all answers into same length with extra space characters, but our model still was not able to produce exact answers with sequence-to-sequence. However, the sequences the model produced were good enough to predict the correct answer for multiple choice questions. For instance, for question “If $x+345 = 111$, what is the value of x?”, the output of the system would be “-234444”, which is very close to the correct answer “-234”. Thus, we wrote a program which was able to compare the initial characters (including “-”) regardless the extra characters at the end with answer options and predict the correct answer.

3.2 Tree System

The system of Roy and Roth (2015) has a lot of advantages: for instance, it can solve math problems that require multiple steps and different operations, and it can handle problems even if it did not see similar problems in the training set. That is why we chose to implement this approach for solving open-vocabulary algebra questions.

The expression trees the authors used in their system have a special structure that allows to calculate them in a simple and unambiguous way. In such a tree, the leaves are quantities extracted from the problem text, and the internal nodes are mathematical operations between the quantities. By calculating values of all internal nodes, one can obtain the value of the tree route, which corresponds to the answer of the problem.

Similarly to Roy and Roth (2015), we used the relevance and the LCA classifiers to evaluate all possible expression trees and choose the one that answers the problem correctly. However, instead of using gold annotations, we decided to train the classifiers on all the trees that result in right answers, partly because annotations were not available, and partly because we were curious how well the system could perform with no manual effort invested in annotating training data.

Tree evaluation was done by two simple multilayer perceptrons. As described earlier, the first one returns the probability of a given quantity to be relevant, as in a tree that answers the question correctly contains that quantity, the second one returns the probabilities for each of the possible operations to be the lowest common ancestor of a pair of given quantities in a tree that answers the question correctly.

For every possible tree per question, the product of the probabilities of each quantity to be relevant was added to the product of the probabilities of the lowest common ancestor of each quantity pair being correct. These scores, as well as the result of the tree were put in a list and ordered by score. The results of the trees were then matched against the answer options of each question and the answer option that was first matched in the list was given as the answer to the question. If the question had no answer options, the result of the highest rated tree was given as the answer to the question.

4 Experimental Settings

4.1 Sequence-to-Sequence Neural Network

4.1.1 Data Augmentation

Initially, we tried to trained our model directly on the questions, but it turned out that model could not learn at all. In total, we had slightly more than 1000 SAT questions, which was insufficient for an RNN model. Not to mention that the small training set contained questions with a variety of types – open- and closed-vocabulary algebra questions as well as geometry questions, leaving an even smaller training set for each subtype. Thus, data augmentation was a necessary step. In order to strengthen the connection of numbers, we did not provide original SAT data with numbers modified, but more than 600,000 simple closed-vocabulary algebra questions.

Among them, there were two types of questions augmented for our model. These included two types of questions within 3 digits like "If $x + 345 = 111$, what is the value of x?" and "If $x - 345 = 111$, what is the value of x?". Not only numbers and variable names were randomized but the positions of variables were switched. In toal, there were 614,236 questions, where "plus" had 330,620 and "minus" had 283,616 questions. Even though augmented data had large differences with SAT questions, results showed they still prodigiously contributed to our training.

4.1.2 Training

Rather than training our model together with original SAT data and augmented data, we chose to trained with augmented data first, and then continued to train with original data. There were 40 iterations of 614,236 questions dealing with addition and subtraction. Fractions were also present in the training set. After training with the augmented questions set, our model was trained with actual questions from the Math SAT. In total, there were 200 iterations of 805 Math SAT Questions. Nevertheless, since the training data was so small, it is highly possible that our model was prone to over-fitting to the training data.

Example 1
On a certain map, 100 miles is represented by 1 inch. What is the number of miles represented by 2.4 inches on this map?

4.2 Tree System

4.2.1 Quantities

Quantities were extracted from questions and answers using a rule-based approach. Before the extraction, all mentions of quantities were normalized to digits (e.g. *one* to *1*). Then, numbers, number-word combinations (e.g. *13-inch*), small letters denoting quantities (all letters except *a*) and LaTeX expressions were retrieved. LaTeX expressions that contained only numbers were transformed into numbers (e.g. \frac{*1*}{*10*} into *0.1*). In general, all questions that contained quantities other than numbers or the answer of which had several quantities were filtered out, leaving us with 75% of open-vocabulary questions from the training set. In the next stage, while constructing trees for the training data, we heuristically set the maximum number of quantities in a question to 7, which led to using 59% of the training data.

4.2.2 Operations and Tree Enumeration

Once quantities from the question were extracted, all their possible combinations were obtained, with size from two to the total number of quantities. The order of quantities in these combinations, however, stayed the same. Consider Example 1. For this word problem, the combination [100 2.4] would be possible, but the combination [2.4 100] would not.

For every combination obtained in the previous step, all possible expression trees with quantities as leaves and empty inner nodes were generated. These inner nodes were filled with all possible combinations of operation signs. As in earlier studies (Roy and Roth, 2017; Wang et al., 2018), we used six operations: apart from the standard $+$, $-$, $\times$ and $\div$, we included reverse operators $-_{\text{rev}}$ and $\div_{\text{rev}}$ to account for the fact that the order of quantities stays the same in their combinations.

Like Roy and Roth (2015), we implemented constraints that define *monotonic* trees. These constraints are concerned with the order of multiplication operator in regard to division operator, and the order of addition operator in relation to subtraction operator. However, unlike the authors, we used these constraints to decrease the number

System	Accuracy
Baseline (always "A")	14.3%
Baseline + seq2seq	15.0%
Baseline + trees	15.9%
Baseline + seq2seq + trees	16.7%

Table 1: Results

of trees resulting in right answers, not to guarantee that any monotonic tree for the solution expression has the same LCA operation for any pair of quantities in it, as in Roy and Roth (2015).

4.2.3 Features

We used UDPipe (Straka and Straková, 2017) to parse questions' text and extract features for the classifiers. The features are identical to the ones that Roy and Roth (2015) describe.

5 Results

The results that our systems achieved are shown in Table 1. Our official submission consists only of the neural network, which achieved 15%, with the accuracy on closed-vocabulary algebra questions being 16% and the accuracy on the other two categories being 15% each. This result, however, was achieved by guessing "A" whenever the question could not be answer by the model. When guessing is removed, the overall accuracy drops to 2%. However, on the 109 questions the model could actually answer, it achieved 21% accuracy.

In post-evaluation, after combining the results of the neural network and the tree system, we were able to achieve 17% accuracy overall by increasing the accuracy on open-vocabulary algebra questions by 20%. If we remove the guessing, the tree system achieves 3% accuracy overall, which stems from its 13% accuracy on open-vocabulary algebra questions. If we only count the questions that could actually be answered by the system, its accuracy would be equal to 26%. Without guessing, the combination of both systems produces 4% accuracy overall, with the distribution being 2% on closed-vocabulary algebra questions, 13% on open-vocabulary algebra questions and 0.4% on geometry questions. On the 205 questions answered by the combination of both systems, the accuracy was 23%.

6 Discussion/Conclusion

The results of our systems on the full data set are, frankly put, rather poor. Nevertheless, the tree system shows promising results in solving open-vocabulary questions, if it is refined and improved, while the neural network seems not to perform well on any specific type of questions, although its overall performance is similar to that of the tree system.

Concerning the neural network, it might be beneficial to focuse on specific types of questions, instead of trying to train a model that deals with mixed types of questions. RNN best learnt on closed- and open-vocabulary algebra questions, therefore training separate models for these types could be one way to improve the system. In addition to that, a much larger dataset is critical in enhancing the model, thus promoting the accuracy of its predictions. Lastly, data augmentation would further improve the model. If we were to train a versatile model for mixed types of math questions, we could perform data augmentation on each type.

The current problem of the tree system lies to a large extent within the quality of the tree evaluation. It heavily relies on answer options to be available, as the average index of the first tree that produces an answer option in the score list is 47 (for the test data). Therefore, the answer of the highest-rated tree would most likely be wrong. Other aspects that could be improved include choosing other features for the classifiers, decreasing the scores of trees with low amounts of quantities (those trees are currently overrated) or using a different machine learning algorithm altogether, such as deep reinforcement learning (e.g Wang et al., 2018).

Apart from that, using no additional quantities in constructing trees, and including every quantity once made it difficult to obtain trees that not only gave the right result for the questions from the training set, but also answered them in a right way. Moreover, expanding expression trees to problems that involve letters to denote quantities would definitely contribute to improving the performance of the tree system.

7 Acknowledgements

Part of the experiments reported on this paper was run on a Titan Xp donated by the NVIDIA Corporation.

Abstract

This article describes the system submitted by the RGCL-WLV team to the *SemEval 2019 Task 12: Toponym resolution in scientific papers*. The system detects toponyms using a bootstrapped machine learning (ML) approach which classifies names identified using gazetteers extracted from the GeoNames geographical database. The paper evaluates the performance of several ML classifiers, as well as how the gazetteers influence the accuracy of the system. Several runs were submitted. The highest precision achieved for one of the submissions was 89%, albeit it at a relatively low recall of 49%.

1 Introduction

Resolving a toponym, a proper name that refers to a real existing location, is a non-trivial task closely related to named entity recognition (NER) (Piskorski and Yangarber, 2013). For this reason, using an NER system to detect and assign location tags could seem a good way forward. However, NER systems may not be able to detect whether a name refers to a actual location or not (e.g., *London* in *London Bus Company*). In addition, location names are usually ambiguous, which means it is crucial that these are disambiguated in order to assign the correct coordinates.

While in the past the focus in toponym resolution has been on rule and gazetteer driven methods (Speriosu and Baldridge, 2013), more recent approaches also consider ML-based techniques. DeLozier et al. (2015) describe their ML-based approach, which does not require a gazetteer. The approach calculates the geographical profile of each word, which is refined using Wikipedia statistics, and then fed into an ML classifier. Speriosu and Baldridge (2013) also make use of an ML classifier which is text-driven. Geotags of documents are used to automatically generate a training set. Although the two previous approaches used two standard corpora for toponym resolution, consisting of news articles and 19th century civil war texts, there are wide areas of application for toponym resolution. For instance, Ireson and Ciravegna (2010) explore the use in social media, while Lieberman and Samet (2012) attempt to analyse news streams. Spitz et al. (2016) have also used an encyclopaedic dataset, compiled from Wikipedia, WordNet and GeoNames.

The focus of the SemEval 2019 Task 12 was toponym resolution in journal articles from the biomedical domain (Weissenbacher et al., 2019). The articles that had to be processed were case studies on the epidemiology of viruses, meaning that the developed systems can potentially be used to track viruses. The task was composed of three sub-tasks: (1) toponym detection, followed by (2) disambiguation and the assignment of the appropriate coordinates, as well as (3) the development of an end-to-end system.

This paper presents our participation in the first sub-task. Our system performs first a gazetteer look-up for locations, and then uses machine learning (ML) to classify whether or not it represents an actual location. The gazetteers are extracted from the online geographical database GeoNames, whilst the classification is carried out by feeding the context of potential locations in an ML classifier. The rest of the paper presents the system developed (Section 2), followed by its evaluation (Section 3). The paper finishes with conclusions.

2 System Description

The system developed for this task was designed as a pipeline consisting of three stages: text clean-

[*]The first two authors contributed equally to the paper.

ing, text processing and identification of locations. The rest of this section presents each of these stages. The system has been made available on online. [1]

2.1 Text Cleaning

The first processing stage identifies parts of the text which do not contain any locations that have to be identified according to the task guidelines. These parts include the references section of each text and the information about authors of the journal articles. In addition, the texts also contain genome sequences and abbreviations of chemicals, which resemble abbreviations for locations. Regular expressions were used to replace these text sequences with spaces. We chose to replace the sequences rather than remove them in order to keep the correct offsets of entities which are crucial in the evaluation process.

Not all the genome sequences were correctly identified due to the variability of how they are represented. As a result, not all these sequences were being replaced by spaces. This introduced noise in our processing pipeline. In addition, in some cases the regular expressions for excluding the references section would fail to correctly identify the boundaries of this section. Since this left large amounts of these texts blank, three texts did not have their respective references sections removed.

2.2 Text Processing

Once cleaned, the texts were processed using components from the ANNIE pipeline within GATE (Cunningham et al., 2002, 2011). The ANNIE pipeline was designed for named entity recognition tasks, but for our purpose we used only the tokeniser and gazetteer lookup components.

We produced three different gazetteers. The first one contained all locations from the GeoNames geographical database. The second gazetteer contained a list of cities from GeoNames with a population of over 5,000. The third gazetteer features a list of countries, capitals, and cities with a population larger than 15,000 people extracted from GeoNames. The default list of regions included with ANNIE was also used. A list of US regions as well as their abbreviated forms was added manually.

[1]https://github.com/TharinduDR/SemEval-2019-Task-12-Toponym-Resolution-in-Scientific-Papers

The output of this module was a list of annotations, including tokens boundaries and tokens matching the gazetteer entries. This information is then used by the ML classifier in the next step.

2.3 Identification of Locations

Once the texts are processed, the next task is to detect whether a candidate location really refers to a location. In addition to cases of common nouns which may also be used as a location, there are also cases where the location names were used as adjectives. For example, in the sentence *Other mutations observed in the HA gene of the Kentucky isolates have also been reported by others*, even though the gazetteer identifies *Kentucky* as a location it is actually referring to a virus entity. According to the guidelines, this should not be annotated as a location, making the task quite difficult.

Analysis of examples from the training data indicated that the context of candidate locations can be used to assess whether the detected word is an actual location or not. For this reason, we trained a machine learning model which uses the context of candidates to distinguish between real locations and falsely identified locations by the gazetteer look-up component. For the experiments presented here, we used a window of two words before and two words after the candidate location to obtain its context. More precisely, if the detected word from the gazetteer is ω_i, the context c_i was defined as,

$$c_i = \omega_{i-2} + \omega_{i-1} + \omega_i + \omega_{i+1} + \omega_{i+2} \qquad (1)$$

The annotated gold standard provided by the task organisers was used to create a training set which contained both positive and negative instances. Two machine learning approaches were considered for this word window classification task. The first approach was to use traditional machine learning models, while the other approach was to use neural network models.

2.3.1 Traditional ML Approach

There are multiple ways that words can be translated into a numerical representation before they can be used as features for a machine learning model. The commonly used representations convert sequences of words to a bag of words or tf-idf vectors. However, since their introduction, word embedding models (Mikolov et al., 2013) have been widely used as features for text classification tasks and have proven successful. In addition, they have the capability to represent the context better than tf-idf vectors. For this reason, we used the 300 dimensional word2vec embedding model trained on the Google news corpus.

The word windows had to be represented by a vector that can be fed as features to a machine learning model, while retaining a unique length over all the training and testing examples, in order to be input into a traditional machine learning model. There are many ways to represent a text window with word embeddings. Simply averaging the word embeddings of all words excluding stop words in a text has proven to be a strong baseline or feature across a multitude of tasks, such as short text similarity tasks (Kenter et al., 2016). Following that, the mean of word vectors in a particular word window was calculated in order to represent the whole word window with a vector, which is a 300 dimensional vector in this scenario. The vector calculated was used as features and fed into several machine learning classifiers such as Support Vector Machines (Cortes and Vapnik, 1995), Random Forest classifier (Breiman, 2001) and XGBoost (Chen and Guestrin, 2015). The parameters were tuned using 10-fold cross validation. For the implementation scikit-learn in python 3.6 was used.

2.3.2 Neural Network Architectures

The representation described above performs poorly on classification tasks such as sentiment analysis, because it loses the word order in the same way it happens with the standard bag-of-words model, and fails to recognise many sophisticated linguistic phenomena (Le and Mikolov, 2014). For this reason, the second approach relies on neural networks which receive as input the embedding vectors corresponding to the context, but without performing any modification on it. Keras was used to implement these neural architectures.

Two neural architectures were developed. The first one was adopted from text classification research (Coates and Bollegala, 2018). As depicted in figure 1 it contains variants of Long Short-Term Memories (LSTMs) with self attention followed by average pooling and max pooling layers. It also has a dropout (Srivastava et al., 2014) between 2 dense layers after the concatenate layer. The model was trained with cyclical learning rate (Smith, 2017).

The pooling layers in the first architecture are considered as a very primitive type of routing

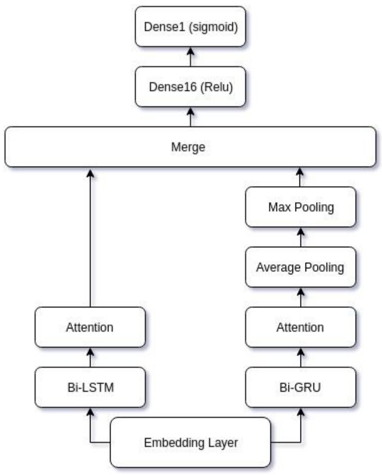

Figure 1: LSTM variant with self attention

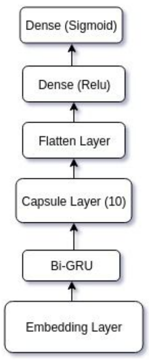

Figure 2: Capsule net architecture

mechanism. The solution that is proposed is a capsule network (Sabour et al., 2017). A capsule network with a bi-directional GRU was also experimented with for this data set. The complete architecture is shown in figure 2. There is a spatial drop out (Tompson et al., 2015) between the embedding layer and bi-directional GRU layer and there is also a dropout (Srivastava et al., 2014) between two dense layers after the capsule layer.

The results and evaluation criteria of both traditional approaches and neural network approaches are reported in the results section 3.

3 Results

3.1 Gazetteers

As described in the previous section, three different gazetteers were tested using the development and training sets. As the machine learning component of the system would make the final prediction, it was important to ensure the maximum number of candidate locations. Therefore, it was

Gazetteer	Precision	Recall	F-Score
GN all	0.2359	**0.7699**	0.3612
GN 5000+	**0.3584**	0.7563	0.4863
GN custom	**0.3546**	**0.7678**	0.4851

Table 1: Gazetteer evaluation results

vital to ensure the highest possible recall, while achieving acceptable precision results.

Table 1 shows the precision, recall and F-score values for each of the gazetteers, described in section 2, run on the training set. Rows one and two had a high recall but low precision, and a higher precision, but lower recall, respectively. Row three shows the results for the final gazetteer. It has the best balance between precision and recall, and was selected for use in the final system.

3.2 Identification of Locations

Locations in the training set were matched using the gazetteers and then extracted together with their respective word window, in order to compile a separate data set. This data was split into a training set and an evaluation set for the machine learning classifiers. The training set consisted of 80% of the total data set and the evaluation set, containing the gold standard annotations from the previous training set, had the rest of the 20%. The accuracy of each machine learning model evaluated on the evaluation set is shown in Table 2. Predictions were considered to be accurate if the machine learning model and the gold standard matched, including correct and incorrect classifications. All other cases were considered to be non-accurate.

Our baseline - a zero-R classifier predicting every instance as a falsely identified location had an accuracy of 71.95%. All of our machine learning models were able to outperform the baseline model significantly, even though the data set is in-balanced. The capsule net architecture, which provided the best performance at an accuracy of 88.73%, was selected for use in the final system.

3.3 Submission Results

After we had determined the best components for the system, the GN custom gazetteer and the bi-GRU + Capsule architecture, the whole system was evaluated on the test set. The submission results are presented in four categories, determined by the organisers. Table 3 shows the results for

ML Model	Accuracy
Zero-R	71.95%
Random Forest	84.21%
SVM	83.44%
XGBoost	85.80%
Bi-LSTM/Bi-GRU + Max Pooling	87.75%
Bi-GRU + Capsule	**88.73%**

Table 2: ML models evaluation results

Test	Precision	Recall	F-Score
Strict macro	0.8280	0.4746	0.6034
Strict micro	0.8168	0.3396	0.4798
Overlap macro	**0.8980**	**0.4969**	**0.6398**
Overlap micro	0.8936	0.3654	0.5187

Table 3: Final submission results

each. Overall, our system achieves the highest values in the overlap macro class, with the lowest in the strict micro class. The system tends to achieve acceptable precision scores, but at low recall values. This trend can most probably be explained by the fact that many candidate locations are not detected by the gazetteers. Together with the machine learning part discarding some proper locations, this has a dramatic affect on the recall.

4 Conclusion and Future Work

This paper presented the system we submitted to the *SemEval 2019 Task 12: Toponym resolution in scientific papers*. Evaluation of the system has shown that a pipeline that combines traditional string matching and advanced machine learning can offer promising results. It has demonstrated that a larger size of the gazetteer does not necessarily have a positive effect on performance. It has also made clear that a higher recall value for the gazetteer look-up component could provide a much better basis on which to train machine learning approaches. On the machine learning side, we have demonstrated that employing word embeddings together with state-of-the-art algorithms can be a viable way of classifying toponyms.

Due to time constraints, a large amount of different parameters, as well as optimizing the lookup algorithm and underlying gazetteers were not tested or carried out. For future research we hope to address these problems, so that a better basis on which to train machine learning architectures can be achieved, as well as more deep learning architectures.

Abstract

Toponym resolution is an important and challenging task in the neural language processing field, and has wide applications such as emergency response and social media geographical event analysis. Toponym resolution can be roughly divided into two independent steps, i.e., toponym detection and toponym disambiguation. In order to facilitate the study on toponym resolution, the SemEval 2019 task 12 is proposed, which contains three subtasks, i.e., toponym detection, toponym disambiguation and toponym resolution. In this paper, we introduce our system that participated in the SemEval 2019 task 12. For toponym detection, in our approach we use TagLM as the basic model, and explore the use of various features in this task, such as word embeddings extracted from pre-trained language models, POS tags and lexical features extracted from dictionaries. For toponym disambiguation, we propose a heuristics rule-based method using toponym frequency and population. Our systems achieved 83.03% strict macro F1, 74.50 strict micro F1, 85.92 overlap macro F1 and 78.47 overlap micro F1 in toponym detection subtask.

1 Introduction

Toponym resolution is an important task in the natural language processing field and has many applications such as emergency response and social media geographical event analysis(Gritta et al., 2018). Toponym resolution is usually modelled as a two-step task. The first step is toponym detection, which is a typical named entity recognition (NER) task. The second step is toponym disambiguation, which aims to map locations to its coordinates in the real world.

NER is a widely explored task and most NER methods can be applied to toponym detection. For example, Ratinov and Roth (2009) used n-grams, history predictions as the input features of conditional random fields (CRF) for toponym detection. Usually the performance of these methods heavily relies on the quality of hand-crafted features. However, manually selected features may be sub-optimal. Also, these methods cannot effectively exploit contextual information due to the dependency on bag-of-word features. In recent years, many neural network based methods have been proposed for NER. For example, Ma and Hovy (2016) proposed a CNN-LSTM-CRF model for NER. They use CNN layer to learn character features of each word, LSTM layer to learn the contextual word representations and CRF layer to predict the label jointly. Gregoric et al. (2018) proposed Parallel RNN architecture. They split a single LSTM into multiple equally-size ones with a penalty to promote diversity. However, these methods cannot utilize external knowledge to recognize entities, which is usually important to toponym detection. Usually, linguistic knowledge such as part-of-speech and dictionary knowledge may be useful for toponym detection, and they are easy to obtain. Therefore, in this paper, we aim to incorporate these external knowledge sources to enhance our neural model for toponym detection.

Similarly, there are many works on toponym disambiguation. Most of them are rule-based methods. They use some heuristics to rank the candidates and choose the highest one(Gritta et al., 2018). For example, Karimzadeh et al. (2013) used the geographical level(e.g. country, province and city), the Levenshtein Distance and the population of potential candidates to rank the candidate toponym and choose the highest one. However, the result of toponym disambiguation relied on corpus domain and the rule should be reconsidered when applied to different corpus.

For the toponym detection task, we use TagLM(Peters et al., 2017) as the basic model.

In our model, we first learn word representations from original characters, then learn contextual word representations by a stacked Bi-LSTM network, and finally use a CRF layer to jointly decode the label sequence. To enrich the representations of words, we incorporate various features such as pre-trained word embeddings, POS tags and lexicon features. For the toponym disambiguation task, we design a rule-based heuristics method by using toponym frequency and population to rank candidate toponyms. Our systems achieved 83.03% strict macro F1 in the toponym detection task, 67.21% in the toponym disambiguation task and 61.31% strict macro F1 in toponym resolution.

2 Our Approach

2.1 Toponym Detection

Our model is based on TagLm (Peters et al., 2017). As shown in Fig. 1, our model have three major components, i.e., *character encoder*, *feature concatenation* and *toponym detector*.

Usually, character patterns are important clues for toponym detection. For example, starting with a capital letter (e.g. Eastern Europe), all cased word (e.g. UK) and mixed cased word (e.g. HongKong) are very common in toponym names. Thus, we use a *character encoder* module to learn word representations from original characters. There are two layers in the *character encoder*. The first one is a character embedding layer. It converts each character in a word into a low-dimensional dense vector. The second one is a character-level CNN layer. It was used to capture local contextual information. We also apply a max pooling layer to build word representations by selecting the most salient features.

The *feature concatenation* module is used to concatenate different types of features. There are four types of additional features in our model, i.e., pre-trained word embeddings, pre-trained language model word representations, POS tag representations and lexicon representations. Usually, word embeddings are pre-trained on a large corpus and can provide rich semantic information. Thus, we use pre-trained word embeddings to enrich word representations by incorporating semantic information . However, word embeddings usually do not contain contextual information. Thus, we also incorporate word representations generated by pre-trained language models. Usually, toponyms have specific POS tags such as nouns. Following Wu et al. (2018), we also incorporate POS tag information to guide our model. There are two layers in our model to learn POS tag representations. The first one is a POS tag embedding layer, which learns low-dimensional embedding vectors for POS tags. The second one is a Bi-GRU layer. It was used to learn the syntax structure of sentences and output the hidden POS tag representations. In addition, since many toponyms can be found in toponym databases, lexical features may be useful for toponym detection. Due to our observations, toponym names are more likely to have low occurrence frequency in documents and less number of matched toponyms in the toponym database. Thus we constructed three one-hot vectors as lexical features. First, we counted the number of matched toponyms in the database for every word. They were quantified to different levels and represented by the first one-hot vectors. The second one-hot vectors were used to represent whether the first matched toponym 's names returned from the database were perfect matches. The third one-hot vectors were used to represent quantified occurrence frequency in the training set of every word. Besides, a three-layer feed-forward neural network (FFNN) was used to learn lexical representations for every word as a lexical representation.

The *toponym detector* module aims to predict the label of each word from its representations. There are two submodule in the toponym detector. The first one is a stacked Bi-LSTM network. Usually, global contexts are important for toponym detection. For example, in the sentence "Beijing is the capital of China", the words "capital" and "China" are all informative for toponym detection. Thus, we use a stacked Bi-LSTM network to learn hidden word representations based on global contexts. The second one is a CRF layer, which is used to decode the label sequence jointly (Lafferty et al., 2001). Usually, there is relatedness between the labels of neighbor words. For example, the label "I" (inside) can only appears after "B" (beginning). Thus, we use CRF to do joint label decoding.

2.2 Toponym Disambiguation

Toponym disambiguation is a down-stream task of toponym detection. Due to the lack of dictionary knowledge, it's difficult for a neural network to do toponym disambiguation. Thus, we propose

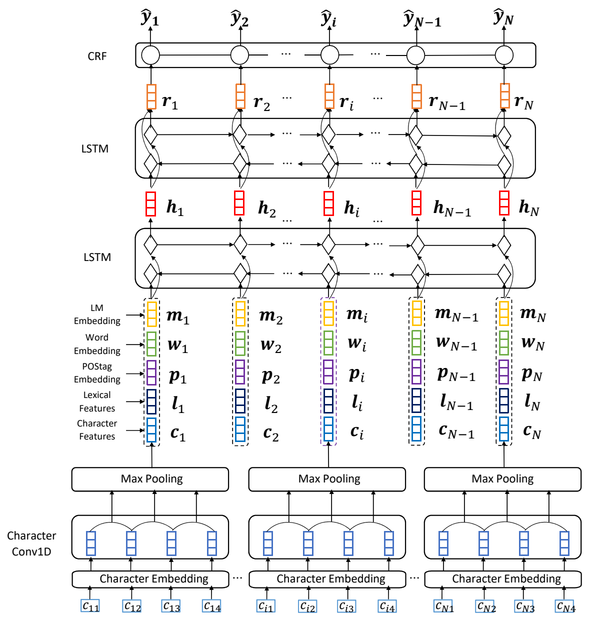

Figure 1: The architecture of our model for toponym detection.

a rule-based heuristic method for toponym disambiguation. An observation is that among the toponym candidates returned by the database, the toponym with higher frequency is more likely to be mentioned. In addition, the toponym with higher population may also have a higher probability to be mentioned. Therefore, we propose a heuristic algorithm named Most Frequency - Most Population (mFmP). If a toponym appears in the train set, we will select the highest frequency id as the output. Otherwise, we will select the toponym with the most population as output.

3 Experiment

3.1 Experimental Settings

We conduct experiments on science reports provided the SemEval-2019 task 12. The data set is composed of 72 full-text journal articles in open access. There are four different metrics to evaluate the prediction performance, i.e., strict macro F1, strict micro F1, overlap macro F1 and overlap micro F1.

In the toponym detection task, we used NLTK[1] for sentence segmentation, word tokenization and POS tagging. We used ELMo(Reimers and Gurevych, 2017) and BERT(Devlin et al., 2018) model to generate 1024-dimensional contextualized word embeddings. We used GeoNames[2] to construct lexical feature. The BIO tagging scheme(Sang and Veenstra, 1999) was used in the toponym detection task. In the toponym disambiguation task, we use GeoNames database to retrieve candidate toponyms.

In our approach, the three word embedding vectors we used (Glove(Pennington et al., 2014), word2vec(Mikolov et al., 2013), fasttext(Bojanowski et al., 2017)) were all 300-dimensional. The dimension of the character embedding was set to 100. The character CNN had 100 filters, and their window size was set to 3. The sizes of the 3-layer FFNN were respectively set to 256, 256, and 128. We set the dimension of POS tag embeddings to 128. The Bi-GRU layer for POS tag representation learning was 64-dimensional. The two Bi-LSTM layers for capturing long-distance and short-distance information were 128-dimensional and 64-dimensional. To mitigate overfitting, we added 20% dropout to each layer. We used Adam as the optimizer for model training.

In our approach, we used transductive learning techniques to further improve the performance of our approach. We first trained our model on the train set, and then applied our model to the test set to generate pseudo labeled data. Finally, we jointly trained our model on the combination of the training and test sets. In addition, we use model ensemble strategy to reduce the uncertainty of our model(Wu et al., 2017). We trained our model for 10 times independently and the final predictions are made by voting.

3.2 Performance Evaluation

In this section, we compare our approach with several baseline methods to evaluate the performance of our approach. The baseline methods are listed as follows. (1) **Baseline**: a baseline system provided by SemEval 2019 task 12(Davy et al., 2019). It uses n-grams as input and a FFNN network to predict label. The input features includes word embedding and character features. (2) **CNN-CRF**: a two-layer CNN and a CRF layer with word embedding for toponym detection. (3) **LSTM-CRF**: a two layer LSTM and a CRF layer with word embedding for toponym detection.

The comparative results are listed in Table 1. According to these experimental results, we have several observations. First, *LSTM-CRF* outperforms *CNN-CRF*. This may be because CNN can

method	strict macro F1	strict micro F1
baseline	**84.00**	77.59
mFmP	83.58	**78.14**

Table 2: Performance evaluation of toponym disambiguation.

only capture local information, instead, LSTM can utilize global information. This indicates that capturing global contextual information have the potential to improve the performance of toponym detection. Second, the baseline method outperforms *LSTM-CRF* and *CNN-CRF*. This may because *LSTM-CRF* and *CNN-CRF* did not use character-level features, which shows the effect of character-level information on the performance of toponym detection. In addition, the performances of *CNN-CRF* and *LSTM-CRF* are very poor. This may because these two models only use word embedding to enhance the model's semantic information. And this word embedding is not trained on science reports dataset, which may make these two methods lack of semantic information. Third, our approach outperformed all these baseline methods. This is because our approach use pre-trained word embeddings and language model to enhance the semantic information of model, use character-level word representations to capture character patterns of toponym names, and features, i.e., lexicon features and POStag features, to add extract information. This result validates the effectiveness of our model.

The results for toponym disambiguation are listed in Table 2. Baseline method selected toponym with highest population among candidate toponyms. The performance of our method is similar to baseline method. This may be because high frequency toponyms are often with large population.

Method	SMA	SMI	OMA	OMI
WE	77.50	62.61	83.82	69.33
WE+CE	81.75	66.16	85.78	70.16
TagLM	85.04	81.78	90.39	89.61
TagLM+POS	83.64	78.35	90.03	88.87
TagLM+LEX	**85.37**	77.77	90.91	86.57
TagLM+POS+LEX	84.10	**82.36**	**91.36**	**90.72**

Table 3: Influence of different features on the performance of our model. WE, CE, POS, LEX respectively denote toponym detector using word embedding, character encoder, POS tag representations and lexicon representations as input.

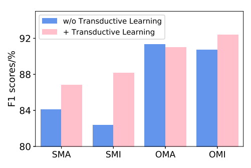
3.3 Influence of Different Features

In this section, we conduct several experiments to evaluate the effect of each type of features we used. We added different types of features to our toponym detector gradually to conduct our experiments. The experimental results are listed in Table. 3. According to Table. 3, we have several observations.

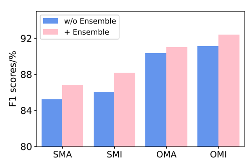
First, the WE+CE method consistently outperforms WE. This indicates that character-level word representations can make our model detect toponym names effectively. Second, the performance of TagLM is much better than the performances of WE and WE+CE. This may because WE and WE+CE method can only obtain semantic information from word embedding and training data, which is not enough. Incorporating word embedding vectors generated by pre-trained language models could enhance the semantic information of our model. Third, after incorporating POS tag embedding or lexical feature into our model separately, the performances of these two models declined. This may be because the POS tag and lexical features of several samples are inaccurate, which incorporate misleading information into our model. Forth, incorporating these two features into our model together improve the performance of our model. This may be because both features have inherent relatedness and our model is more easily to exploit useful information from the combination of both features.

3.4 Influence of Transductive Learning and Model Ensemble

In this section, we conduct several experiments to evaluate the influence of transductive learning and model ensemble on the performance of our model. The experimental results are shown in Figure. 2.



(a) Influence of transductive learning.



(b) Influence of model ensemble

Figure 2: Influence of transductive learning and model ensemble.

According to Figure. 2, we can find both transductive learning and ensemble strategy can improve the performance of our model. This indicates that our model could be more robust by incorporating more training samples and voting scheme.

4 Conclusion

In this paper, we introduce our system participating in the SemEval-2019 task 12. For the toponym detection, we use a TagLM model with various features to enrich word representations. In addition, we use a transductive learning method and ensemble strategy to further improve the performance of our model. For toponym disambiguation, we propose a heuristics rule-based method based on toponym frequency and population. Our systems achieve 83.03% strict macro F1 in toponym detection, 67.21% strict macro F1 in toponym disambiguation and 61.31% strict macro F1 in toponym resolution.

dietz@cs.unh.edu

Abstract

The SemEval-2019 Task 12 is toponym resolution in scientific papers. We focus on Subtask 1: Toponym Detection which is the identification of spans of text for place names mentioned in a document. We propose two methods: 1) sliding window convolutional neural network using ELMo embeddings (CNN-ELMo), and 2) sliding window multi-Layer perceptron using ELMo embeddings (MLP-ELMo). We also submit a bi-directional LSTM with Conditional Random Fields (bi-LSTM) as a strong baseline given its state-of-art performance in Named Entity Recognition (NER) task. Our best performing model is CNN-ELMo with a F1 of 0.844 which was below bi-LSTM F1 of 0.862 when evaluated on overlap macro detection. Eight teams participated in this subtask with a total of 21 submissions.

1 Introduction

Toponyms are textual spans of text identifying geospatial locations. This can range from the canonical name of populated places, such as "London" to direct or indirect mentions of geographic entities. The parsing of geographic locations from unstructured text is considered an open challenge due to domain diversity, place name ambiguity, metonymic language and often limited leveraging of context (Gritta et al., 2018). Many scientific publications contain toponyms which can be challenging to extract automatically. Specifically, names of institutions and viruses often contain geographic references which may confuse the extractor. Often, the extractor needs to handle noisy text parsed from PDF versions of scientific articles which can introduce artifacts.

In Task 12, a toponym is defined to include proper names and geographic entities but to exclude indirect mentions of places and metonyms. Additional discussion of the motivation and task description is available at the task web site.[1]

2 Related Work

There is significant work in the area of toponym detection (Matsuda et al., 2015; D. Lieberman et al., 2010) and the closely related fields of named entity recognition (NER) (Li et al., 2018) and entity mention detection (EMD) (Shen et al., 2015) with many different approaches. State-of-the-art named entity detection models have historically employed a combination of hand-crafted features, rules, natural language processing (NLP), string-pattern matching, and domain knowledge using supervised learning on manually annotated corpora (Piskorski and Yangarber, 2018). A common approach to toponym detection has been to utilize place name gazetteers which are directories of geographic names and their corresponding geolocations to perform string matching of place names in text (D. Lieberman et al., 2010).

Contemporary approaches in entity detection have utilized neural-based architectures. (Collobert et al., 2011) propose a window-based, multi-layer, dense feed-forward neural architecture using word embeddings concatenated with orthographic features and a gazetteer as an input layer with a hard Tanh output layer for superior performance on a standard NER task. Huang et al. (2015) utilise a bi-directional LSTM with a sequential conditional random layer using a gazetteer and Senna word embeddings to obtain superior performance. Magge et al. (2018) achieves state-of-the-art results in toponym detection by utilizing a window-based deep neural network, word embeddings trained on a domain-specific corpus, orthographic features, and a gazetteer.

Table 1: Gold Standard Corpus Statistics

	Documents	Tokens	Toponyms
Train	72	396,668	3,637
Valid	32	179,443	2,141
Test	45	253,159	4,616
Total	149	829,720	10,394

3 Data

A gold standard corpus, composed of 150 full text journal articles in open access from PubMed Central (PMC), is provided by the task organizers.[2] Additional information can be found at Weissenbacher et al. (2017) for the general approach followed by the task organizers for developing the corpus. Table 1 highlights the gold standard corpus statistics.

4 Approach

Our approach is motivated by the simplicity and strong performance of windows-based approaches on the NER and toponym task with the strong performance of deep contextual embeddings on related NLP tasks. Two different neural based approaches are undertaken by the team: 1) sliding windows convolutional neural network using deep embeddings, and 2) sliding window multi-layer perceptron using deep embeddings. The embeddings are composed of an ELMo contextual embedding concatenated with hand-crafted features.

4.1 Embeddings

The ELMo embeddings (Gardner et al., 2018) are learned functions of the internal states of a deep bidirectional language model (biLM) that has been pre-trained on the 1B Word Benchmark. These vectors are developed from the concatenation of each of the 1,024 length vector outputs from the model for each token and are a function of the complete input sentence.

For each token in the context of its sentence, a vector representation is generated by concatenating the ELMo model embedding with the one-hot encoding of orthographic features and an additional flag bit indicating if the token was contained within the set of gazetteer tokens. This resulted in a vector of length 3,081 for each token. A padding vector of all 0s was used for the sliding window neural models.

[2]We are unable to successfully parse one of the documents from the train set due to an encoding error

4.2 Hand-crafted Features

Hand-crafted features were added as they slightly improve model performance when compared to using the ELMo embeddings alone for the input layer to the neural models.

Orthographic Features: a one hot encoding is assigned to each token based on its orthographic structure: only numeric, all lower case alphabetic characters, all upper case alphabetic characters, title-case alphabetic characters, mixed case (not title-case) alphabetic characters, alphabetic characters with numeric, padding token, and the "other" for the remaining tokens not matched by previously listed features. Alphabetic characters are UTF-8.

Gazeteer Features: a set of toponynm tokens is generated from the entries in GeoNames.[3] For example, for the entry in Geonames,"Gulf of Mexico", the tokens "Gulf", "of", and "Mexico" are added to the toponym set. This is used as a binary feature for the presence of the parsed token in the constructed Geonames token set.

4.3 Implementation details

The documents are parsed into sentences and tokenized using the open-source NLP library Spacy.[4]

Pre-trained embeddings are provided by Pyysalo et al. (2013).[5] which are generated from Wikipedia, PubMed, and PMC texts using the word2vec tool. They are 200-dimensional vectors trained using the skip-gram model with a window size of 5, hierarchical softmax training, and a frequent word subsampling threshold of 0.001. These vectors are used in the baseline and the bi-LSTM with CRF models.

ELMo embeddings are generated using the AllenNLP tool .[6] The deep learning library Keras 2.2.1 [7] is used for training the neural models. Tensorflow 1.12[8] is the backend used for training and evaluating all of the models attempted. In training the models, the Adam optimizer in Keras is used. Additional code and data will be available in an on-line appendix.[9]

4.4 Models

We compare the following models:

MLP-ELMo: A sliding window (size = 5) is applied to each sentence with padding vectors applied to boundary tokens. The input layer to the neural models is a 5 x 3081 matrix using the ELMo-based embeddings. The input layer is connected to two fully connected layers with 128 hidden units each and relu activation. The output is a sigmoid with a binary output to indicate if the token is part of a toponym.

CNN-ELMo: A sliding window (size = 5) is applied to each sentence with padding vectors applied to boundary tokens. The input layer is a 5 x 3081 layer. The input layer is two 1d convolutional layers with filter sizes of 250 and a kernel size of 3. A global 1-d max pooling layer follows the convolutional layers. Two fully connected layers with 100 hidden units each and relu activation follow max pooling. A sigmoid function is applied in output layer to indicate if the token is part of a toponym.

4.5 Baseline

Two models are used for evaluation: 1) a sliding window mlp provided by the task organizers, and 2) bi-LSTM with CRF. The bi-LSTM with CRF model demonstrates state-of-the-art results on NER and is used as an additional strong benchmark for model comparison.

MLP-Baseline: The task organizers provide a state-of-the-art geoparser as a strong baseline. The system has a specific component for toponym detection using a two-layer feedforward neural network (200 hidden units per layer) as described in Magge et al. (2018). The baseline features a sliding window (size = 5) over each sentence using Wikipedia-Pubmed-PMC word2vec embeddings for token encoding. The baseline did not include a gazetter-based lookup but did incorporate orthographic structure of the tokens: 1) All Caps - ASCII, 2) First letter capitalized - ASCII, and 3) first letter not-capitalized - ASCII. The baseline also uses separately trained vectors if the token contained a digit or unknown token in the vocabulary.

Bi-LSTM-Baseline: This strong baseline implementation utilizes the code developed by Reimers and Gurevych (2017).[10] Input sentences for the model are generated in the CoNLL format with the IOB representation for labeled toponyms in the training data. The embeddings are the Wikipedia-Pubmed-PMC word2vec vectors. Each LSTM has a size of 100 and is trained with a dropout of 0.25. Character embeddings are generated using a convolutional neural network and the maximum character length is 50. The model is fit over 25 training epochs.

5 Experiment Evaluation

5.1 Metrics

The metrics for evaluation are precision, recall and F-measure. Two variants are provided for toponym detection: strict and overlapping measures. In the strict measure, mentions match the gold standard if they match exact span boundaries. In the overlapping measure, a match occurs when the mention and gold standard share any common span of text.

There are two methods for computing precision and recall: micro averaging, and macro averaging. In micro averaging the corpus of documents is treated as one large document when calculating precision and recall. In macro averaging precision, recall and f-measure are calculated on a per document basis, and then the results are averaged.

5.2 Results

The model results are shown in Tables 2, 3, 4, and 5. The best model in the task by the Team "DM_NLP" (Davy Weissenbacher, 2019) is provided for comparison with the results our team achieves. The F1 scores of the two sliding window models and the bi-LSTM benchmark outperforms the task benchmark on all metrics. Each model is run once with a random model parameter initialization. The MLP-ELMo model had a similar feedforward structure and approach as the baseline neural model. The primary difference is the embedding vectors used. For both strict and overlap toponym detection, MLP-ELMo model achieves the same or higher precision and recall than the baseline.

The convolutional network using the ELMo-based embeddings exhibits higher performance on the f1 score relative to MLP-ELMo, however precision is higher and recall is lower for both strict and overlap measures.

The best performing model is the bi-LSTM with CRF method. This shows that the sliding window models with deep contextual embeddings did

Table 2: Overlap Macro

Run	P	R	F1

Table 5: Strict Micro

Run	P	R	F1
Bi-LSTM-Baseline	**0.835**	**0.650**	**0.731**
CNN-ELMo	0.807	0.618	0.700
MLP-ELMo	0.782	0.646	0.707
MLP-Baseline	0.775	0.603	0.678
DM_NLP	0.929	0.856	0.891

not achieve state-of-art performance on this task. However, bi-LSTM with CRF has lower performance than the best model submitted for the task which indicates that other approaches can exceed the performance of a state-of-the-art Named Entity Recognition model.

Fine tuning shows that a window size of 5 yields the best performance on the validation set during training for the sliding window neural models. The sliding window neural models do not require many epochs of training with approximately only three required before overfitting of the training data becomes evident. Adding dropout to training did not appear to improve sliding window model performance.

6 Conclusion

The best performing submission by our team is bi-LSTM with CRF. This is not surprising as this technique has achieved state-of-the-art results in NER NLP tasks. The sliding window models we propose are similar in the approach as the task baseline model. The ELMo-based embeddings do achieve a boost in performance relative to baseline given the richer context and character structure they embed. This indicates that the ELMo-derived embeddings are superior in the task to embeddings trained on a domain-specific corpus using word2vec. However, for both overlap and strict macro the recall for MLP-ELMo is identical to the baseline model.

Bi-LSTM with CRF and the baseline neural model are noteworthy in that they are both able to extract toponym mentions only using context from embeddings to acheive high-quality results without relying on the presence of a gazetteer. An open question is if a gazetter or other knowledge graph structure could be incorporated into a deep neural model using contextual embeddings to achieve superior performance. It is also not clear why CNN-ELMo has lower recall than MLP-ELMo and baseline.

The results suggest that a sliding window model can be enhanced by better-quality embeddings and a convolutional component. The sliding window model approach is attractive due to its relatively straight-forward implementation and quick training time. The results achieved by bi-LSTM with CRF and the model submitted by DM_NLP, suggest that other approaches may ultimately generate superior performance on the toponym detection task.

Abstract

This paper describes our submission to *SemEval-2019 Task 12 on toponym resolution in scientific papers*. We train separate NER models for toponym detection over text extracted from tables vs. text from the body of the paper, and train another auxiliary model to eliminate mis-detected toponyms. For toponym disambiguation, we use an SVM classifier with hand-engineered features. Our best model achieved a strict micro-F1 score of 80.92% and overlap micro-F1 score of 86.88% in the toponym detection subtask, ranking 2nd out of 8 teams on F1 score. For toponym disambiguation and end-to-end resolution, we officially ranked 2nd and 3rd, respectively.

1 Introduction

Toponym resolution (TR) refers to the task of automatically assigning geographic references to place names in text, which has applications in question answering and information retrieval tasks (Leidner, 2008; Daoud and Huang, 2013; Vasardani et al., 2013), user geolocation prediction (Roller et al., 2012; Han et al., 2014; Rahimi et al., 2015), and historical research (Grover et al., 2010).

This paper describes our system entry to the *Toponym resolution in scientific paper task of SemEval 2019* (Weissenbacher et al., 2019). The task consists of three subtasks: toponym detection, toponym disambiguation, and end-to-end toponym resolution.

For the toponym detection task, we extract tables from the full text and train separate BiLSTM-ATTN models for each. For tables, the model captures the horizontal row-wise structure of the table. For non-table content, the model can capture syntactic and semantic features. In both cases, we use a deep contextualized word representation — ELMo (Peters et al., 2018) — to represent each token. After detecting toponyms, we use an organization name detection model to eliminate mis-detected toponyms that are actually part of an organization name. For the toponym disambiguation task, we first construct a candidate set by searching toponyms on GeoNames.[1] Then, we manually construct features based on search results, and finally, train an SVM model to disambiguate the locations. For the end-to-end resolution task, we pipeline the two aforementioned steps.

Our work makes the following contributions:

- we show that training separate models for table and non-table portions of the paper is better than simply training one model over the full text;
- we show that contextualized word representation boosts performance;
- we show that auxiliary organization name recognition model is helpful for toponym detection, and better than training a single named entity recognizer (NER).

2 Toponym Detection

Figure 1 shows our workflow on the toponym detection task, which consist of 4 parts: (a) preprocessing, which contains tokenization, table extraction and sentence segmentation; (b) training and inference for the toponym detection model; (c) post-processing, to combine detected words into toponyms; and (d) refinement of the results by incorporating an auxiliary model.

2.1 Pre-processing

Tables are ubiquitous in scientific articles, and differ in structure to text in the body of the paper, in

[1]GeoNames, https://www.geonames.org/ is a freely available global placename database.

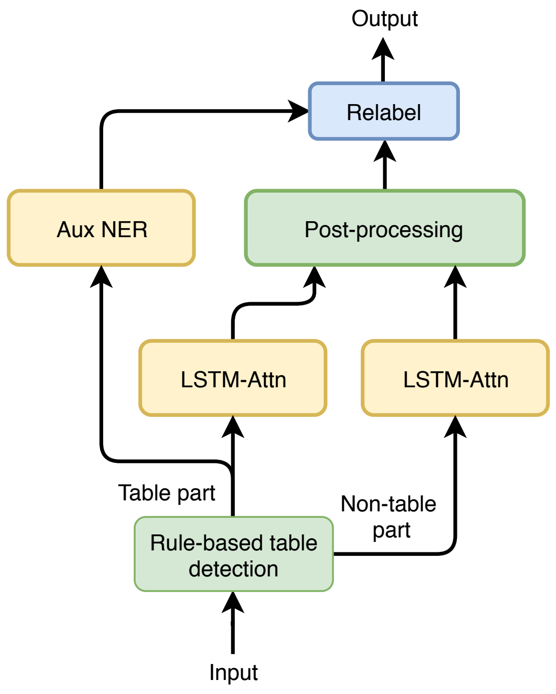

Figure 1: Toponym detection workflow

terms of syntactic structure. As such, training a single text embedding model over both the main body of text and tables will likely lead to sub-optimal representations, leading us to train separate models for: (1) tables, and (2) the remainder of the text content of the paper. To extract tables from the plain text dump provided by the shared task organisers, we use a rule-based table detection method.

We first tokenize the entire article, as part of which we treat all punctuation as a separator. In the process of table extraction, we process the raw text line-by-line rather than performing sentence tokenization. We treat numbers, OOV tokens (using GloVe vocabulary), |, and - as table elements, and consider lines with more than 70% of table elements to be table rows. Three or more consecutive table rows are considered to make up a table. In this way, we extract tables from the plain text dump of the articles. Note that the original PDF versions of papers were not made available by the task organizers, meaning that it wasn't possible to use vision-based methods to identify tables.

For the remainder of the text dump not detected as tables, we perform tokenization, remove hyphens caused by line breaks, and then perform sentence segmentation using SpaCy.[2] Sentences that are shorter than 5 tokens in length are concatenated with the preceding and proceeding sentences to make up a single sentence. By expanding short sentences, richer context can be exploited by both ELMo and the RNN-based model.

[2]https://spacy.io

2.2 Contextual Representation

We use ELMo (Peters et al., 2018) word representations in this paper, which are learned from the internal states of a deep bidirectional language model (biLM), pre-trained on a large text corpus. ELMo representations are purely character-based, allowing the network to use morphological clues to form robust representations for out-of-vocabulary tokens unseen in training. They are also robust to syntactic disfluencies caused by the fine-grainedness of word segmentation. For the purposes of empirical comparison, we also report on experiments using GloVe (Pennington et al., 2014) embeddings.

2.3 Models

For toponym extraction in the table part, we experimented with two kinds of models. The first is a token-level model which is described in Magge et al. (2018). In this model, each training instance consists of an input word, the word's context, and a label indicating whether the word is a part of a toponym. The context of the word is formed by the words in its neighbourhood, which is a window of words centred on the given word. We experimented with two- and three-layer feed-forward models.

The second model is built with RNN and self-attention (Vaswani et al., 2017). Although an RNN is able to make predictions over long sequences, the documents in this task are too long for an RNN, and at the same time, the size of the training data is not sufficient to train an RNN. As such, we split each document with several sentences and make predictions on separate sentences (hidden states are not passed through sentences). We use a two-layer bidirectional LSTM (Hochreiter and Schmidhuber, 1997) to capture the sequential information of the body and table contents, and use self-attention to enhance the connection of each token in the line. We consider the paper body content to have semantic information which can be captured by a sequential model like a BiLSTM. However, for tables, it is not clear that sequential information across cells in a table row should be processed as a sequence. Therefore, we use self-attention to learn the table structure over an entire line. We consider each sentence as a matrix which we denote as L, where $L \in \mathbb{R}^{t\times h}$; t represents the number of tokens in the line, and h is the dimensionality of the embedding representation. To improve training efficiency, we pack l lines into a single batch, thereby making L become a three-dimensional tensor $L \in \mathbb{R}^{l\times t\times h}$. We pad short lines to make the same length as the longest line in a batch, and set the embedding of each padding word to a zero vector with dimensionality h.

We first encode each line with a two-layer bidirectional LSTM, denoted as:

$$L' = \text{BiLSTM}(L) \tag{1}$$

Then, we feed L' into the attention model to encode structural information. The attention model can be denoted as follows:

$$\begin{aligned}&\text{Attn}(Q, K, V; \theta_Q, \theta_K, \theta_V) = \\ &\text{Softmax}\left(\frac{f(Q;\theta_Q)f(K;\theta_K)^\top}{\sqrt{h}}\right) f(V;\theta_V)\end{aligned} \tag{2}$$

This style of attention is named scaled dot-product attention by Vaswani et al. (2017), where $Q, K, V \in \mathbb{R}^{t\times h}$ represent the query, key, and value, respectively, and can be described as mapping a query and a set of key–value pairs to an output, where the query, keys, values, and output are all vectors. In this model, we use tokens in the same line to represent the query, key, and value, and use the attention function Attn to find self-correlations among them. Meanwhile, in Eqn 2 we define f to be a one-layer feed-forward network with different parameter sets $\theta_Q, \theta_K, \theta_V$, which we denote as $f(X;\theta)$. This allows us to learn the correlation with these three parameter sets. We use the following attention function:

$$L'' = \text{Attn}(L', L', L') \tag{3}$$

Finally, we pass L'' into a 3-layer feed-forward network denoted as g, using layer normalization in each layer to increase the training speed. The output of the feed-forward block is passed into the output layer with a residual connection with L'', denoted as:

$$\hat{y} = \phi(g(L'') + L'') \tag{4}$$

The architecture of the model is shown in Figure 2.

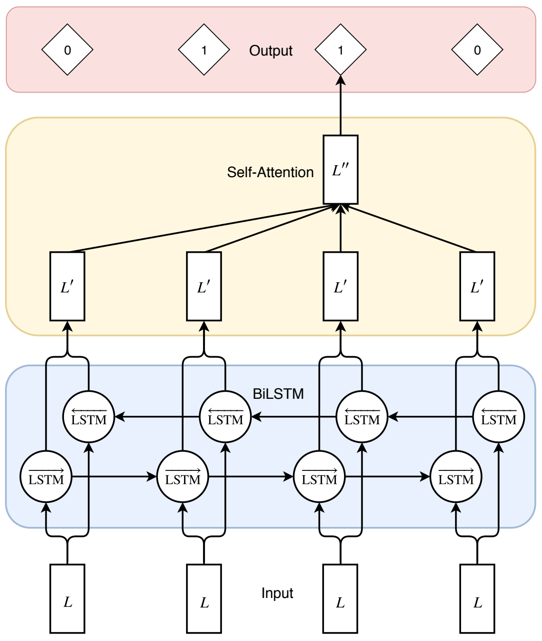

Figure 2: RNN with self attention

2.4 Post-processing

Since we are training a sequence labelling model, result segmentation and combination is necessary. For instance, the sentence *AIV H9N2 was spread to New York, Washington DC and Ottawa* contains three toponyms, and 5 tokens which are contained in those toponyms (e.g. the words *New* and *York* are combined into one toponym). An external gazetteer[3] downloaded from GeoNames, and an in-house place name abbreviation library were used.

We first restore all abbreviations in order to facilitate matching in the gazetteer. We then combine all consecutive tokens that were labelled as a toponym. After this, two different segmentation methods were used: (1) longest string match in the gazetteer; and (2) no segmentation. The result shows that the second method is better because of the limitation of string matching. We think using a better toponym match method like searching via Geonames rather than string matching could achieve better results.

2.5 Auxiliary Model

The single NER model picks up on features such as the word-initial character being uppercase, that are also common in non-toponym named entities, possibly resulting in toponym named entity FPs.

Combined	BiLSTM+Attn+Aux	91.35	82.83	86.88	84.69	77.48	80.92

Table 1: Performance of different models. “Table” refers to the performance on the table part, and “Non-table” the non-table part; “Single” refers to the single model on the entire article; “Combined” refers to the combination of the two models on table and non-table parts; and “+Aux” refers to the use of the auxiliary model to eliminate misdetected toponyms.

For example, in the phrase *The Royal Melbourne Hospital*, the word *Melbourne* should not be detected as toponym according to the competition setting. This issue was also identified by Dredze et al. (2009).

In this paper, we use two methods to tackle this. The first is to train a single NER to detect toponyms and organization names together. The second is to train an organization name recognizer to correct misdetected toponyms in organization names.

We used the WikiNER (Nothman et al., 2012) dataset to train an organization detection model, and applied it to our dataset. Then we build an organization type set containing *Institute, School, Hospital* etc.. Finally, we re-label toponyms that are part of a corresponding organization name as non-toponyms.

3 Toponym Disambiguation

We used a support vector machine to disambiguate toponyms. For each detected toponym, we first search for it on Geonames, and keep the top 20 records as candidate results. Features are constructed from this, as follows:

- **History Result**: If the toponym appears in the training set, history result refers to the ranking of the number of times the Geonames ID appears as a standard answer. For instance, the toponym *Melbourne* appears 13 times in training, of which 12 occurrence have Geonames ID 2158177 and 1 has ID 7839805, so the history result feature for 2158177 is 1, 7839805 is 2, and all other Geonames IDs are 3.
- **Population**: The ranking of the population of the candidate.
- **GeoNames Feature Codes**: The feature class codes of Geonames records, e.g. *A* represents country, state, region,...; *P* city, village,...; etc.
- **Name Similarity**: The ranking of the string similarity of the toponym and Name item in each record.
- **AncestorsNames Correlation**: The ranking of matching words of the AncestorsNames item in each record.

4 Experiments and Results

4.1 Experiment Setting

The model architecture used for the toponym detection task is depicted in Figure 2. We use the Adam (Kingma and Ba, 2015) optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-9}$ and an initial learning rate of $1e^{-3}$. A dropout (Srivastava et al., 2014) rate of 0.5 is used to prevent overfitting. The hidden size (d) of the model is 300, and cross-entropy loss is used for training.

To compare different word embeddings, we use pre-trained 300-dimensional GloVe embeddings and pre-trained 1024 dimensional EMLo embeddings, respectively. We do not update the word embeddings during training.

Embedding	Precision	Recall	F1
GloVe	80.47	75.03	77.65
ELMo	**84.69**	**77.48**	**80.92**

Table 2: Performance of different word representations

4.2 Results

We randomly selected 10 articles from the training set to manually evaluate the table extraction method: 26 out of 27 tables were detected, and 3 non-table parts were misidentified as tables. 62% of tables are exactly accurate, or in other words, 38% tables have some lines misidentified.

Table 1 shows the subtask 1 performance (precision, recall and F1 score) of different models on the table and non-table parts. Strict and overlapping micro measures results are reported. In the strict measure, model outputs are considered to match with the gold standard annotations if they cover the exact same span of text; whereas in the overlapping measure, the model output is considered to match if it overlap in span with the gold-standard. From Table 1, we see that self-attention improves the results on both table and non-table parts, but is particularly effective for the table part. Experimental results on the non-table part are further improved by incorporating the auxiliary model. Finally, the combined model perform is better than a single model on entire articles.

Table 2 shows the subtask 1 performance of different word representations. From that, we find that using ELMo representation is much better than using GloVe embeddings. The reason is that our tokenization method separates many words like *I'm*, *let's*, which ELMo can generate a contextualized representation for, while GloVe cannot. Furthermore, there are many numbers and OOVs in the tables, the GloVe embedding for which is a random 300-dimensional vector that does not provide useful context information.

5 Conclusions

In this work, we presented a method for toponym detection and disambiguation in scientific papers, in the context of Sem-Eval 2019 Task 12, using an LSTM model and SVM model respectively. We extract tables from plain text, and train a dedicated model for each to improve overall performance due to the different structures of tables and the body of text. We also demonstrated the performance of the different models for toponym detection, with our final submission coming in 2nd (among 8).

University of Arizona at SemEval-2019 Task 12: Deep-Affix Named Entity Recognition of Geolocation Entities

Vikas Yadav, Egoitz Laparra, Ti-Tai Wang, Mihai Surdeanu, Steven Bethard
University of Arizona
{vikasy,laparra,twang03,msurdeanu,bethard}@email.arizona.edu

Abstract

We present the Named Entity Recognition (NER) and disambiguation model used by the University of Arizona team (UArizona) for SemEval 2019 task 12. We achieved fourth place on tasks 1 and 3. We implemented a deep-affix based LSTM-CRF NER model for task 1, which utilizes only character, word, prefix and suffix information for the identification of geolocation entities. Despite using just the training data provided by task organizers and not using any lexicon features, we achieved 78.85% strict micro F-score on task 1. We used the unsupervised population heuristics for task 3 and achieved 52.99% strict micro-F1 score in this task.

1 Introduction

Geoparsing is the task of detecting geolocation phrases in unstructured text and normalizing them to a unique identifier, e.g. GeoNames[1] IDs. Although many automatic resolvers have been released in the past years, their performance fluctuates when applied to different domains (Gritta et al., 2018b). Most have also not been applied to and evaluated on scientific publications. The SemEval 2019 Shared Task 12: Toponym Resolution in Scientific Papers (Weissenbacher et al., 2019) aims to boost the research on geoparsing for the scientific domain by focusing on epidemiology journal articles.

The task includes three sub-tasks: toponym detection, toponym disambiguation, and end-to-end toponym resolution. The first one requires participants to detect the text boundaries of all toponym mentions in articles. In toponym disambiguation, the toponym mentions are known, and the resolver has to align them to their precise coordinates through GeoNames IDs. For the last sub-task, the resolver must perform both detection and disambiguation.

In this paper, we present the description of our system for SemEval 2019 Shared Task 12, in which we focus mainly on toponym detection. For this sub-task, we propose a recurrent neural network that combines word, character and affix information. By making use of the baseline provided by the organizers for toponym disambiguation, we also obtain results for the end-to-end sub-task.

2 Related Work

Toponym detection and resolution has been widely studied, and various systems (Gritta et al., 2018b) have been proposed for these tasks. Toponym detection has been implemented on texts from various sources like social media (Karagoz et al., 2016), PubMed articles (Magge et al., 2018) etc. Various named entity recognition (NER) systems including rule-based (Gritta et al., 2018b), machine learning-based (Karagoz et al., 2016), and deep learning-based (Magge et al., 2018) have been implemented for detecting toponyms.

The disambiguation step has been tackled previously using both supervised models and unsupervised heuristic based approaches. For example, Turton (2008) presented a rule based system for disambiguating locations from PubMed abstracts. Weissenbacher et al. (2015) presented results from *Population* and *Distance* heuristics (discussed in Section 4.3) for the disambiguation task on PubMed articles. The authors also presented an SVM model with population, distance and set of meta-data as input which achieved higher performance than both the individual heuristics. Gritta et al. (2018a) used a feedforward neural network approach for the disambiguation of geolocations.

[1] http://www.geonames.org/

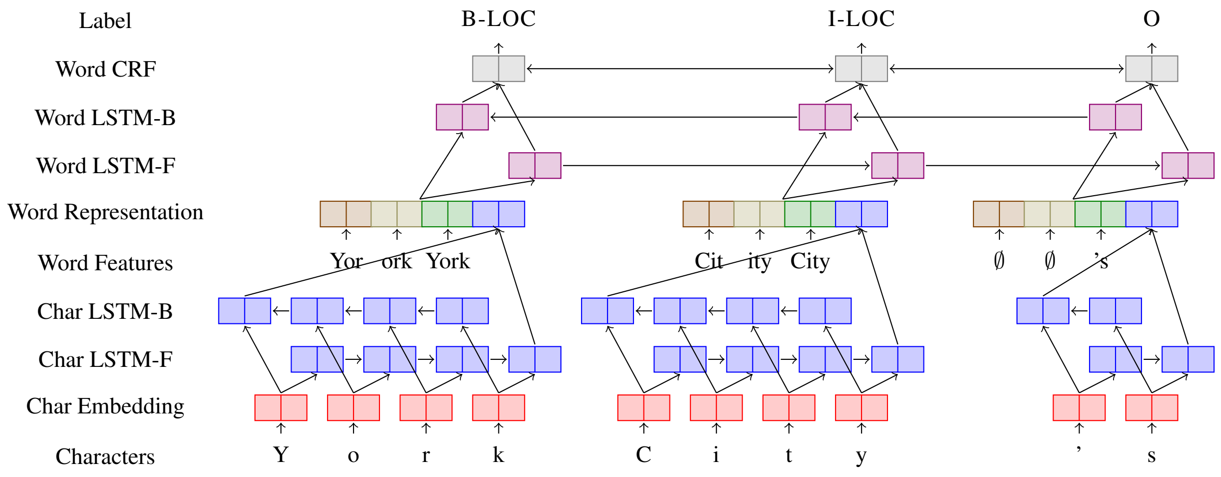

Figure 1: Word+character+affix neural network architecture from Yadav et al. (2018).

3 Data and Baseline

The corpus of the task is composed of 150 journal articles downloaded from PubMed Central. After removing the author names, acknowledgments and references, titles and body text were fully annotated. The annotators identified and labelled toponyms with their corresponding coordinates according to GeoNames. For cases not found in GeoNames, they used Google Maps and Wikipedia. If the coordinates of a toponym were not available in any of these resources the special value N/A was used. The data is provided in Brat format (Stenetorp et al., 2012). The organizers also released a strong baseline that combines the model by Magge et al. (2018) for toponomy detection and the *Population* heuristic described in (Weissenbacher et al., 2015) for disambiguation.[2]

4 Approach

4.1 Preprocessing

We used the tokenizer included in the baseline provided by the organizers as we observed it provided the best final results among other options (see Section 5.3). Again using baseline system preprocessing codes, we converted the data into CoNLL 2003 format (Tjong Kim Sang and De Meulder, 2003) for task 1. Following our prior work (Yadav and Bethard, 2018), we have used a BIO encoding instead of the IO encoding provided by the baseline system.

[2] https://github.com/amagge/semeval-ffnn-baseline

4.2 Toponym Detection

We used the model proposed by Yadav et al. (2018) for Named Entity Recognition (NER), shown in figure 1, which uses character, word and affix information. In this architecture, a word is represented by concatenating its word embedding, an LSTM representation over the characters of the word, and learned embeddings for prefixes and suffixes of the word[3]. Then another LSTM is used at the sentence level to give a contextual representation of each word. These representations of words in the sentence are given to a CRF layer to finally predict the NER label.

4.3 Toponym Resolution

Weissenbacher et al. (2015) presented two heuristics for disambiguation of geolocation - *Population* and *Distance*. These two heuristics are often used as features with other meta-data such as the user location meta-data in a Twitter account (Zhang and Gelernter, 2014), GenBank meta-data (Weissenbacher et al., 2015), etc.

In the *Population* heuristic, the system simply assigns the geonameID of the most populous[4] candidate for the current location. For the *Distance* heuristic, the system selects the candidate which is at the minimum distance from all candidates of all other toponyms in the same document. Many previous works (Weissenbacher et al., 2015; Zhang and Gelernter, 2014; Weissenbacher et al., 2019) have shown that the most populous location is often referenced more in the text documents and performs

[3] The affix vocabulary consisted of all three-character affixes that occurred at least 50 times in the training data.

[4] Population retrieved from the GeoNames database.

better than the distance heuristics. Thus, we use the *Population* heuristic as our disambiguation model.

5 Experiments

Using the original fully annotated training set, we achieved 77.3% strict micro-Fscore (mean performance of 3 runs) on the validation set. However, the organizers provided two additional large (but weakly) annotated NER datasets: *POS*, which contains sentences having at least 1 location phrase, and *NEG*, which has sentences with no mention of location entities. We experimented with both these datasets in both joint and transfer learning.

5.1 Joint Learning

In the joint learning experiment, we trained the model on a training set by concatenating the *POS* data with the original training data. In this configuration, we achieved 81.4% strict micro-F score (mean performance of 3 runs) on the validation set, a 4 point improvement over the original experiment.

5.2 Transfer Learning

In this experiment, we first trained our model on just the *POS* set and further fine tuned it on the original training data provided for the task. The intuition here was to use the weakly annotated data only to get a good initialization for the "real" training on the manually annotated data, rather than training on both together and possibly getting misled by the noise in the weakly annotated data. We achieved 83.7% strict micro-F score (mean performance of 3 runs) on the validation set. This is an improvement of 2.3 F over the simple joint learning experiment, and 6.4 F over the model using only the original training data.

5.3 Effects of Tokenization

The effect of tokenization on NER performance has been shown in the past (Akkasi et al., 2016; Xu et al., 2018). For this reason, we evaluated our model trained on the original training data, using various custom tokenization functions, and saw the strict micro-F1 score vary from 72% to 77% in the validation set.

The NLTK regexp tokenizer resulted in 70% strict F1-score. We wrote several rules to improve this tokenizer which further improved the performance by 4%.

Parameter	value
Word embedding (GloVe) size	300
Character embedding size	50
Affix embedding size	30
Word LSTM hidden state size	50
Character LSTM hidden state size	25
Learning rate	0.15
Learning rate decay	0.99
Batch size	100
Optimizer	SGD

Table 1: Hyperparameters for training the model.

However, the custom tokenization implemented by the shared task organizers in the baseline model performed the best, achieving 77% on the validation set when trained on just the original training data. In this case, we also wrote a few additional rules to improve the tokenization but achieved marginal improvements in the overall performance.

5.4 Hyperparameters

We trained the Yadav et al. (2018) model using the parameters in Table 1. For transfer learning from *POS* data, we first trained the model for 40 epochs. We then retrained this model on the original training data for 80 epochs with 20 as the early stopping patience. After training on the original training data, we retrained this model on train+development data for another 40 epochs. For the final evaluation, we submitted the models at epoch = 25, 35 and 40. Epoch 35 achieved the best performance among the three submissions.

The software is available at `https://github.com/vikas95/Pref_Suff_Span_NN`.

6 Results

We achieved the 4^{th} position in both task 1 (toponym detection) and task 3 (end-to-end toponym resolution) as shown in tables table 2 and table 3, respectively. Although it has been shown previously that adding lexicon features improves the overall performance of several NER models (Yadav and Bethard, 2018; Gritta et al., 2018b), we have focused on extraction of context information using LSTMs over character, word and affixes of the word. Hence, our resource-independent NER model achieves competitive results, despite not using any dictionary information. Also, we have just used the training data provided by the task organizers and did not use any external training data or

lexicon resources.

We used the unsupervised *Population* heuristic which is fast and simple to implement for disambiguating toponyms. As shown by Weissenbacher et al. (2015), feeding features like population, distance, and other meta-data to machine learning models often achieved higher performances. However, as shown here, the *Population* heuristic serves as a strong baseline for this disambiguation task.

7 Future Work

We plan to include the following features in our current model:

- Part of Speech (POS) features – as per the annotations guidelines, locations that were used as adjectives were not labelled in the annotation process. We will explore the effect of adding POS feature representation to the word, character and affix representations.

- Inclusion of geoname dictionary – our current approach is resource independent. We will include dictionary features in the next version of our model, to understand how much signal can be inferred from local information, and how much must come from world knowledge.

- Using domain-specific embeddings – we relied on pretrained GloVe embeddings for our submissions. In future versions of our software, we will explore domain-specific embeddings, i.e., trained on scientific texts, as well as contextualized embeddings such as FLAIR (Akbik et al., 2018).
