provement of using $Comb.$ compared to baseline is statistically significant. We notice again that when the TL baseline MD model uses a richer feature set, the obtained improvement from using RRL becomes smaller. We also observed that automatically aligned data helped capture most of the unseen mentions whereas the hand-aligned features helped decrease the number of false-alarms. It is important to notice that when features $Comb.$ is used with $Stem$ baseline model, the obtained F-measure (76.85) is 1.3 higher than the baseline model which uses lexical, stem and syntactic features – $Syntac$ (75.53). The type of errors which mostly occur and has not been fixed neither by using hand-aligned data, automatically aligned data nor the combination of both are the nominal mentions whose class depends fully on the context. For instance, the word موظف (mwZf - employee) which was considered as **O** by the MD model because it has not been seen in any of the parallel data in a context such as the following:

تعريف شكل الموظف المصري كان ...

transliterated as:

tEryf $kl AlmwZf AlmSry ...

and translated as: *"defining the life of the Egyptian employee ..."*

7 Previous Works

Several research works, in different NLP tasks, have shown that the use of an RRL to achieve a better performance in a resource-challenged language yields to successful results. In (Rogati et al., 2003), authors used a statistical machine translation (MT) system to build an Arabic stemmer. The obtained stemmer has a performance of 87.5%. In (Ide et al., 2002), authors use the aligned versions of George Orwell's *Nineteen Eighty-Four* in seven languages in order to determine sense distinctions which can be used in the Word Sense Disambiguation (WSD) task. They report that the automatically obtained tags are at least as reliable as the one made by human annotators. Similarly, (Ng et al., 2003) report a research study which uses an English-Chinese parallel corpus in order to extract sense-tagged training data. In (Hwa et al., 2002), authors report promising results of inducing Chinese dependency trees from English. The obtained model outperformed the baseline.

One of the significant differences between these works and the one we present in this paper is that instead of using the propagated annotation directly as training data we use it as an additional feature and thus allow the MEMM model to weigh each one of them. By doing so, the model is able to distinguish between the relevant and the irrelevant information propagated from the RRL.

Authors in (Zitouni and Florian, 2008) attempt to enhance an MD model of a foreign language by using an English MD system. They have used an MT system to (i) translate the text to English; (ii) run the English model on the translated text; (iii) and propagate outcome to the original text. The approach in (Zitouni and Florian, 2008) requires a MT system that needs more effort and resources to build when compared to a parallel corpus (used in our experiments); not all institutions may have access to MT and MD systems in plenty of language pairs.

8 Conclusions and Future Works

In this paper, we presented a novel approach that allows to exploit the richness, in terms of resources, of one language (English) to the benefit of a target language (Arabic). We achieved successful results by adopting a novel approach performing in three main steps, namely: (i) Annotate the English side of an English-to-Arabic parallel corpus automatically; (ii) Project the obtained annotation from English to Arabic via the parallel corpus; and (iii) Extract features of different linguistic motivations of the automatically tagged Arabic tokens. Thereafter, each of the extracted features is used to bootstrap Arabic MD system. We use different Arabic baseline MD models which employ different feature sets representing different levels of richness in resources. We also use both a one million word hand-aligned parallel corpus and a 22 million word automatically aligned one in order to study size vs. noise trade-off.

Results show that a statistically significant improvement is always observed even when the Arabic baseline MD model uses all the available resources. When we use the hand-aligned parallel corpus, we obtain up to 2.2 points improvement when the Arabic MD model has access to very limited resources. It decreases to 1.7 points when we use all the resources we could gather for the Arabic language. When no human-annotated data is available in the TL, we show that we can obtain a performance of 57.6 using only mention propagation from RRL. The results also show that a greater improvement is achieved when using a small hand-aligned corpus than using a 20 times bigger automatically aligned data. However, in case both of them are available, combining them leads to even higher results.

Abstract

Named-entity recognition (NER) is an important task required in a wide variety of applications. While rule-based systems are appealing due to their well-known "explainability," most, if not all, state-of-the-art results for NER tasks are based on machine learning techniques. Motivated by these results, we explore the following natural question in this paper: *Are rule-based systems still a viable approach to named-entity recognition?* Specifically, we have designed and implemented a high-level language *NERL* on top of SystemT, a general-purpose algebraic information extraction system. *NERL* is tuned to the needs of NER tasks and simplifies the process of building, understanding, and customizing complex rule-based named-entity annotators. We show that these customized annotators match or outperform the best published results achieved with machine learning techniques. These results confirm that we can reap the benefits of rule-based extractors' explainability without sacrificing accuracy. We conclude by discussing lessons learned while building and customizing complex rule-based annotators and outlining several research directions towards facilitating rule development.

1 Introduction

Named-entity recognition (NER) is the task of identifying mentions of rigid designators from text belonging to named-entity types such as persons, organizations and locations (Nadeau and Sekine, 2007). While NER over formal text such as news articles and webpages is a well-studied problem (Bikel et al., 1999; McCallum and Li, 2003; Etzioni et al., 2005), there has been recent work on NER over informal text such as emails and blogs (Huang et al., 2001; Poibeau and Kosseim, 2001; Jansche and Abney, 2002; Minkov et al., 2005; Gruhl et al., 2009). The techniques proposed in the literature fall under three categories: rule-based (Krupka and Hausman, 2001; Sekine and Nobata, 2004), machine learning-based (O. Bender and Ney, 2003; Florian et al., 2003; McCallum and Li, 2003; Finkel and Manning, 2009; Singh et al., 2010) and hybrid solutions (Srihari et al., 2001; Jansche and Abney, 2002).

1.1 Motivation

Although there are well-established rule-based systems to perform NER tasks, most, if not all, state-of-the-art results for NER tasks are based on machine learning techniques. However, the rule-based approach is still extremely appealing due to the associated transparency of the internal system state, which leads to better explainability of errors (Siniakov, 2010). Ideally, one would like to benefit from the transparency and explainability of rule-based techniques, while achieving state-of-the-art accuracy.

A particularly challenging aspect of rule-based NER in practice is domain customization — customizing existing annotators to produce accurate results in new domains. In machine learning-based systems, adapting to a new domain has traditionally involved acquiring additional labeled data and learning a new model from scratch. However, recent work has proposed more sophisticated approaches that learn a domain-independent base model, which can later be adapted to specific domains (Florian et

Customization Requirement : City, County or State names within sports articles may refer to a sports team or to the location itself.

Customization Solution (CS) :
Within sports articles,
Identify all occurrences of city/county/state as Organizations,
Except when a contextual clue indicates that the reference is to the location

Figure 1: Example Customization Requirement

```
// Core rules identify Organization and Location candidates

// Begin customization
// Identify articles covering sports event from article title
CR1 <SportsArticle> ← Evaluate Regular Expressions <R1>

// Identify locations in sports articles
CR2 Retain <Location> As <LocationMaybeOrg> If ContainedWithin <SportsArticle>

// City/County/State references (e.g., New York) may refer to the sports team in that city
CR3 Retain <LocationMaybeOrg> If Matches Dictionaries
     <'cities.dict','counties.dict','states.dict'>

// Some city references in sports articles may refer to the city (e.g., In Seattle )
// These references should not be reclassified as Organization
CR4 Discard <LocationMaybeOrg> If Matches Regular Expression <R2>
                                    on Left Context 2 Tokens

// City references to sports teams are added to Organization and removed from Location
CR5 Augment <Organization> With <LocationMaybeOrg>
// End customization

// Continuation of core rules
// Remove Locations that overlap with Organizations
     Discard <Location> If Overlaps Concepts <Organization>
```

Figure 2: Example Customization Rules in *NERL*

al., 2004; Blitzer et al., 2006; Jiang and Zhai, 2006; Arnold et al., 2008; Wu et al., 2009). Implementing a similar approach for rule-based NER typically requires a significant amount of manual effort to (a) identify the explicit semantic changes required for the new domain (e.g., differences in entity type definition), (b) identify the portions of the (complex) core annotator that should be modified for each difference and (c) implement the required customization rules without compromising the extraction quality of the core annotator. Domain customization of rule-based NER has not received much attention in the recent literature with a few exceptions (Petasis et al., 2001; Maynard et al., 2003; Zhu et al., 2005).

1.2 Problem Statement

In this paper, we explore the following natural question: Are rule-based systems still a viable approach to named-entity recognition? Specifically, (a) *Is it possible to build, maintain and customize rule-based NER annotators that match the state-of-the-art results obtained using machine-learning techniques?* and (b) *Can this be achieved with a reasonable amount of manual effort?*

1.3 Contributions

In this paper, we address the challenges mentioned above by (i) defining a taxonomy of the different types of customizations that a rule developer may perform when adapting to a new domain (Sec. 2), (ii) identifying a set of high-level operations required for building and customizing NER annotators, and (iii) exposing these operations in a domain-specific NER rule language, *NERL*, developed on top of SystemT (Chiticariu et al., 2010), a general-purpose algebraic information extraction system (Sec. 3). *NERL* is specifically geared towards building and customizing complex NER annotators and makes it easy to understand a complex annotator that may comprise hundreds of rules. It simplifies the identification of what portions need to be modified for a given customization requirement. It also makes individual customizations easier to implement, as illustrated by the following example.

Suppose we have to customize a domain-independent rule-based NER annotator for the CoNLL corpus (Tjong et al., 2003). Consider the two sports-related news articles in Fig. 1 from the corpus, where city names such as '*New York*' or '*Seattle*' can refer to either a *Location* or an *Organization* (the sports team based in that city). In the domain-independent annotator, city names were always identified as *Location*, as this subtle requirement was not considered during rule development. A customization to address this issue is shown in Fig. 1, which can be implemented in *NERL* with five rules (Fig. 2). This customization (explained in detail in Sec. 3) improved the $F_{\beta=1}$ score for *Organization* and *Location* by approximately 9% and 3%, respectively (Sec. 4).

We used *NERL* to customize a domain-independent rule-based NER annotator for three different domains – CoNLL03 (Tjong et al., 2003), Enron (Minkov et al., 2005) and ACE05 (NIST, 2005). Our experimental results (Sec. 4.3) demonstrate that the customized annotators have extraction quality better than the best-known results for

	Affects Single Entity Type	Affects Multiple Entity Types
Identify New Instances	C_S, C_{DD}, C_{DSD}	B_R
Modify Existing instances	C_{EB}, C_{DD}	C_{ATA}, C_G

Table 1: Categorizing NER Customizations

individual domains, which were achieved with machine learning techniques. The fact that we are able to achieve such results across multiple domains answers our earlier question and confirms that we can reap the benefits of rule-based extractors' explainability without sacrificing accuracy.

However, we found that even using *NERL*, the amount of manual effort and expertise required in rule-based NER may still be significant. In Sec. 5, we report on the lessons learned and outline several interesting research directions towards simplifying rule development and facilitating the adoption of the rule-based approach towards NER.

2 Domain Customization for NER

We consider NER tasks following the broad definition put forth by (Nadeau and Sekine, 2007), formally defined as follows:

Definition 1 *Named entity recognition is the task of identifying and classifying mentions of entities with one or more rigid designators, as defined by (Kripke, 1982).*

For instance, the identification of proper nouns representing persons, organizations, locations, product names, proteins, drugs and chemicals are considered as NER tasks.

Based on our experience of customizing NER annotators for multiple domains, we categorize the customizations involved into two main categories as listed below. This categorization motivates the design of *NERL* (Sec. 3).

Data-driven (C_{DD}): The most common NER customization is data-driven, where the customizations mostly involve the addition of new patterns and dictionary entries, driven by observations from the training data in the new domain. An example is the addition of a new rule to identify locations from the beginning of news articles (e.g., "BALTIMORE 1995-08-27" and "MURCIA , Spain 1996-09-10").

Application-driven: What is considered a valid named entity and its corresponding type can vary across application domains. The most common dimensions on which the definition of a named entity can vary are:

Entity Boundary (C_{EB}): Different application domains may have different definitions of where the same entity starts or ends. For example, a *Person* may (CoNLL03) or may not (Enron) include generational markers (e.g. "Jr." in "Bush Jr." or "IV" in "Henry IV").

Ambiguous Type Assignment (C_{ATA}): The exact type of a given named entity can be ambiguous. Different applications may assign different types for the same named entity. For instance, all instances of "White House" may be considered as *Location* (CoNLL03), or be assigned as *Facility* or *Organization* based on their context (ACE05). In fact, even within the same application domain, entities typically considered as of the same type may be assigned differently. For example, given "New York beat Seattle" and "Ethiopia beat Uganda", both '*New York*' and '*Ethiopia*' are teams referred by their locations. However, (Tjong et al., 2003) considers the former, which corresponds to a city, as an *Organization*, and the latter, which corresponds to a country, as a *Location*.

Domain-Specific Definition (C_{DSD}): Whether a given term is even considered a named entity may depend on the specific domain. As an example, consider the text "Commercialization Meeting - SBeck, BHall, BSuperty, TBusby, SGandhi-Gupta". Informal names such as '*SBeck*' and '*BHall*' may be considered as valid person names (Enron).

Scope(C_S): Each type of named entity usually contains several subtypes. For the same named entity task, different applications may choose to include different sets of subtypes. For instance, roads and buildings are considered part of *Location* in CoNLL03, while they are not included in ACE05.

Granularity(C_G): Name entity types are hierarchical. Different applications may define NER tasks at different granularities. For instance, in ACE05, *Organization* and *Location* entity types were split into four entity types (*Organization*, *Location*, *Geo-Political Entity* and *Facility*).

The different customizations are summarized as shown in Tab. 1, based on the following criteria: (i) whether the customization identifies new instances or modifies existing instances; and (ii) whether the customization affects single or multiple entities. For instance, C_S identifies new instances for a single entity type, as it adds instances of a new subtype for an existing entity type. Note that B_R in the table denotes the rules used to build the core annotator.

3 Named Entity Rule Language

3.1 Grammar vs. Algebraic NER

Traditionally, rule-based NER systems were based on the popular CPSL cascading grammar specification (Appelt and Onyshkevych, 1998). CPSL is designed so that rules that adhere to the standard can be executed efficiently with finite state transducers. Accordingly, the standard defines a rigid left-to-right execution model where a region of text can be matched by at most one rule according to a fixed rule priority, and where overlapping annotations are disallowed in the output of each grammar phase.

While it simplifies the design of CPSL engines, the rigidity of the rule matching semantics makes it difficult to express operations frequently used in rule-based information extraction. These limitations have been recognized in the literature, and several extensions have been proposed to allow more flexible matching semantics, and to allow overlapping annotations (Cunningham et al., 2000; Boguraev, 2003; Drozdzynski et al., 2004). However, even with these extensions, common operations such as filtering annotations (e.g. CR_4 in Fig. 2), are difficult to express in grammars and often require an escape to custom procedural code.

Recently, several declarative algebraic languages have been proposed for rule-based IE systems, notably AQL (Chiticariu et al., 2010) and Xlog (Shen et al., 2007). These languages are not constrained by the requirement that all rules map onto finite state transducers, and therefore can express a significantly richer semantics than grammar-based languages. In particular, the AQL rule language as implemented in SystemT (Chiticariu et al., 2010) can express many common operations used in rule-based information extraction without requiring custom code. In addition, the separation of extraction semantics from execution enables SystemT's rule optimizer and efficient runtime engine. Indeed, as shown in (Chiticariu et al., 2010), SystemT can deliver an order of magitude higher annotation throughput compared to a state-of-the-art CPSL-based IE system.

Since AQL is a general purpose information extraction rule language, similar to CPSL and JAPE, it exposes an expressive set of capabilities that go beyond what is required for NER tasks. These additional capabilities can make AQL rules more verbose than is necessary for implementing rules in the NER domain. For example, Fig. 3 shows how the same customization rule CR_4 from Fig. 2 can be implemented in JAPE or in AQL. Notice how implementing even a single customization may lead to defining complex rules (e.g. JAPE-R_1, AQL-R_1) and sometimes even using custom code (e.g. JAPE-R_2). As illustrated by this example, the rules in AQL and JAPE tend to be complex since some operations — e.g., filtering the outputs of one rule based on the outputs of another rule — that are common in NER rule sets require multiple rules in AQL or multiple grammar phases in JAPE.

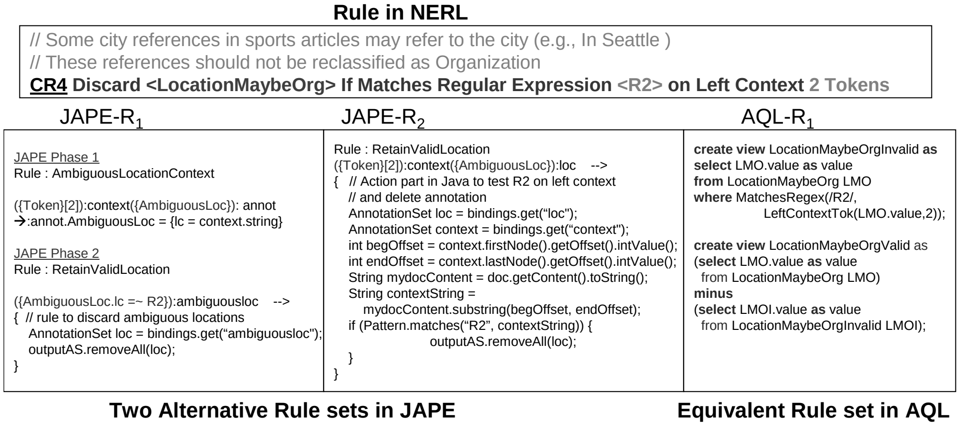
To make NER rules easier to develop and to understand, we designed and implemented Named Entity Rule Language (*NERL*) on top of SystemT. *NERL* is a declarative rule language designed specifically for named entity recognition. The design of *NERL* draws on our experience with building and customizing multiple complex NER annotators. In particular, we have identified the operations required in practice for such tasks, and expose these operations as built-in constructs in *NERL*. In doing so, we ensure that frequently performed operations can be expressed succinctly, so as not to complicate the rule set unnecessarily. As a result, *NERL* rules for named entity recognition tasks are significantly more compact and easy to understand than the equivalent AQL rules. At the same time, *NERL* rules can easily be compiled to AQL, allowing our NER rule development framework to take advantage of the capabilities of the SystemT rule optimizer and efficient runtime execution engine.

3.2 *NERL*

For the rest of this section, we focus on describing the types of rules supported in *NERL*. In Sec. 4, we shall demonstrate empirically that *NERL* can be successfully employed in building and customizing complex NER annotators.

A *NERL* rule has the following form:

$$\textit{IntConcept} \leftarrow RuleBody(\textit{IntConcept}_1, \textit{IntConcept}_2, \ldots)$$



Rule in NERL

```
// Some city references in sports articles may refer to the city (e.g., In Seattle )
// These references should not be reclassified as Organization
CR4 Discard <LocationMaybeOrg> If Matches Regular Expression <R2> on Left Context 2 Tokens
```

JAPE-R$_1$

```
JAPE Phase 1
Rule : AmbiguousLocationContext

({Token}[2]):context({AmbiguousLoc}): annot
→:annot.AmbiguousLoc = {lc = context.string}

JAPE Phase 2
Rule : RetainValidLocation

({AmbiguousLoc.lc =~ R2}):ambiguousloc    -->
{  // rule to discard ambiguous locations
   AnnotationSet loc = bindings.get(“ambiguousloc");
   outputAS.removeAll(loc);
}
```

JAPE-R$_2$

```
Rule : RetainValidLocation
({Token}[2]):context({AmbiguousLoc}):loc    -->
{   // Action part in Java to test R2 on left context
    // and delete annotation
    AnnotationSet loc = bindings.get(“loc");
    AnnotationSet context = bindings.get(“context");
    int begOffset = context.firstNode().getOffset().intValue();
    int endOffset = context.lastNode().getOffset().intValue();
    String mydocContent = doc.getContent().toString();
    String contextString =
       mydocContent.substring(begOffset, endOffset);
    if (Pattern.matches(“R2”, contextString)) {
                      outputAS.removeAll(loc);
    }
}
```

AQL-R$_1$

```
create view LocationMaybeOrgInvalid as
select LMO.value as value
from LocationMaybeOrg LMO
where MatchesRegex(/R2/,
              LeftContextTok(LMO.value,2));

create view LocationMaybeOrgValid as
(select LMO.value as value
  from LocationMaybeOrg LMO)
minus
(select LMOI.value as value
  from LocationMaybeOrgInvalid LMOI);
```

Two Alternative Rule sets in JAPE

Equivalent Rule set in AQL

Figure 3: Single Customization Rule expressed in *NERL*, JAPE and AQL

Intuitively, a *NERL* rule creates an intermediate concept or named entity (*IntConcept* for short) by applying a *NERL* rule on the input text and zero or more previously defined intermediate concepts.

***NERL* Rule Types** The types of rules supported in *NERL* are summarized in Tab. 2. In what follows, we illustrate these types by means of examples.

Feature definition (FD): FD rules identify basic features from text (e.g., *FirstName*, *LastName* and *CapsWord* features for identifying person names).

Candidate definition (CD): CD rules identify complete occurrences of the target entity. For instance, the Sequence rule "*LastName followed by ',' followed by FirstName*" identifies person annotations as a sequence of three tokens, where the first and third tokens occur in dictionaries containing last and first names.

Candidate Refinement (CR): CR rules are used to refine candidates generated for different annotation types. E.g., the *Filter* rule $CR3$ in Fig. 2 retains *LocationMaybeOrg* annotations that appear in one of several dictionaries.

Consolidation (CO): CO rules are used to resolve overlapping candidates generated by multiple CD rules. For instance, consider the text "Please see the following request from Dr. Kenneth Lim of the BAAQMD.". A CD rule may identify '*Dr. Kenneth Lim*' as a person, while another CD rule may identify '*Kenneth Lim*' as a candidate person. A consolidation rule is then used to merge these two annotations to produce a single annotation for '*Dr. Kenneth Lim*'.

***NERL* Examples** Within these categories, three types of rules deserve special attention, as they correspond to frequently used operations and are specifically designed to ensure compactness of the ruleset. In contrast, as discussed earlier (Fig. 3), each of these operations require several rules and possibly custom code in existing rule-based IE systems.

DynamicDict: The *DynamicDict* rule is used to create customized gazetteers on the fly. The following example shows the need for such a rule: While '*Clinton*' does not always refer to a person's last name (Clinton is the name of several cities in USA), in documents containing a full person name with '*Clinton*' as a last name (e.g., '*Hillary Clinton*') it is reasonable to annotate all references to the (possibly) ambiguous word '*Clinton*' as a person. This goal can be accomplished using the rule <*Create Dynamic Dictionary using Person with length 1 to 2 tokens*>, which creates a gazetteer on a per-document basis.

Filter: The *Filter* rule is used to discard/retain certain intermediate annotations based on predicates on the annotation text and its local context. Example filtering predicates include

- Discard C If Matches Regular Expression R
- Retain C If Contains Dictionary D on Local Context LC
- Discard C If Overlaps Concepts $C_1, C_2, \ldots$

ModifySpan: The *ModifySpan* rule is used to expand or trim the span of a candidate annotation. For instance, an *Entity Boundary* customization to include generational markers as part of a *Person* annotation can be implemented using a *ModifySpan* rule <*Expand Person Using Dictionary 'generation.dict' on RightContext 2 Tokens*>.

Using *NERL* Tab. 2 shows how different types of rules are used during rule building and customizations. Since B_R and C_S involve identifying one

Rule	*Category*	*Syntax*	B_R	C_{DD}		C_G
			C_S	C_{DSD}	C_{EB}	C_{ATA}
Dictionary	FD	**Evaluate Dictionaries** $< D_1, D_2, \ldots >$ with flags?	X	X		
Regex	FD	**Evaluate Regular Expressions** $< R_1, R_2, \ldots >$ with flags?	X	X		
PoS	FD	**Evaluate Part of Speech** $< P_1, P_2, \ldots >$ with language $< L >$?	X	X		
DynamicDict	FD	**Create Dynamic Dictionary** using *IntConcept* with flags?	X	X		
Sequence	CD	*IntConceptorString* multiplicity? (**followed by** *IntConceptorString* multiplicity?)+	X	X		
Filter	CR	**Discard/Retain** *IntConcept*(As *IntConcept*)? **If SatisfiesPredicate** on LocalContext	X	X		X
ModifySpan	CR	**Trim/Expand** *IntConcept* Using Dictionary $< D >$ on LocalContext	X		X	
Augment	CO	**Augment** *IntConcept* With *IntConcept*	X			X
Consolidate	CO	**Consolidate** *IntConcept* using ConsolidationPolicy	X			X

Table 2: Description of rules supported in *NERL*

or more entity (sub)types from scratch, all types of rules are used. C_{DD} and C_{DSD} identify additional instances for an existing type and therefore mainly rely on FD and CD rules. On the other hand, the customizations that modify existing instances (C_{EB},C_{ATA},C_G) require CR and CO rules.

Revisiting the example in Fig. 2, CR rules were used to implement a fairly sophisticated customization in a compact fashion, as follows. Rule CR_1 first identifies sports articles using a regular expression based on the article title. Rule CR_2 marks Locations within these articles as *LocationMaybeOrg* and Rule CR_3 only retains those occurrences that match a city, county or state name (e.g., '*Seattle*'). Rule CR_4 identifies occurrences that have a contextual clue confirming that the mention was to a location (e.g., '*In*' or '*At*'). These occurrences are already classified correctly as *Location* and do not need to be changed. Finally, CR_5 adds the remaining ambiguous mentions to *Organization*, which would be deleted from *Location* by a subsequent core rule.

4 Development and Customization of NER extractors with *NERL*

Using *NERL*, we have developed CoreNER, a domain-independent generic library for multiple NER extraction tasks commonly encountered in practice, including *Person*, *Organization*, *Location*, *EmailAddress*, *PhoneNumber*, *URL*, and *DateTime*, but we shall focus the discussion on the first three tasks (see Tab. 3 for entity definitions), since they are the most challenging. In this section, we first overview the process of developing CoreNER (Sec. 4.1). We then describe how we have customized CoreNER for three different domains (Sec. 4.2), and present a quality comparison with best published results obtained with state-of-the-art machine learning techniques (Sec. 4.3). The tasks we consider are not restricted to documents in a particular language, but due to limited availability of non-English corpora and extractors for comparison, our evaluation uses English-language text. In Sec. 5 we shall elaborate on the difficulties encountered while building and customizing CoreNER using *NERL* and the lessons we learned in the process.

4.1 Developing CoreNER

We have built our domain independent CoreNER library using a variety of formal and informal text (e.g. web pages, emails, blogs, etc.), and information from public data sources such as the US Census Bureau (Census, 2007) and Wikipedia.

The development process proceeded as follows. We first collected dictionaries for each entity type from different resources, followed by manual cleanup when needed to categorize entries collected into "strong" and "weak" dictionaries. For instance, we used US Census data to create several name dictionaries, placing ambiguous entries such as '*White*' and '*Price*' in a dictionary of *ambiguous last names*, while unambiguous entries such as '*Johnson*' and '*Williams*' went to the dictionary for *strict last names*. Second, we developed FD and CD rules to identify candidate entities based on the way named entities generally occur in text. E.g., <*Salutation CapsWord CapsWord*> and <*FirstName*

Type	Subtypes
PER	individual
LOC	Address, Boundary, Land-Region-Natural, Region-General, Region-International, Airport, Buildings-Grounds, Path, Plant, Subarea-Facility, Continent, Country-or-District, Nation, Population-Center, State-or-Province
ORG	Commercial, Educational, Government, Media, Medical-Science Non-Governmental

Table 3: NER Task Types and Subtypes

LastName> for *Person*, and <*CapsWord*{*1,3*} *OrgSuffix*> and <*CapsWord*{*1,2*} *Industry*> for *Organization*. We then added CR and CO rules to account for contextual clues and overlapping annotations (e.g., Delete *Person* annotations appearing within an *Organization* annotation).

The final CoreNER library consists of 104 FD (involving 68 dictionaries, 33 regexes and 3 dynamic dictionaries), 74 CD, 123 CR and 102 CO rules.

4.2 Customizing CoreNER

In this section we describe the process of customizing our domain-independent CoreNER library for several different datasets. We start by discussing our choice of datasets to use for customization.

Datasets For a rigorous evaluation of CoreNER's customizability, we require multiple datasets satisfying the following criteria: First, the datasets must cover diverse sources and styles of text. Second, the set of the most challenging NER tasks *Person*, *Organization* and *Location* (see Tab. 3) considered in CoreNER should be applicable to them. Finally, they should be publicly available and preferably have associated published results, against which we can compare our experimental results. Towards this end, we chose the following public datasets.

- CoNLL03 (Tjong et al., 2003): a collection of Reuters news stories. Consists of formal text.
- Enron (Minkov et al., 2005): a collection of emails with meeting information from the Enron dataset. Contains predominantly informal text.
- ACE05 (NIST, 2005)[1] a collection of broadcast news, broadcast conversations and newswire reports. Consists of both formal and informal text.

Customization Process The goal of customization is to refine the original CoreNER (hence referred to as CoreNER$_{orig}$) in order to improve its extraction quality on the training set (in terms of F$_{\beta=1}$) for each dataset individually. In addition, a development set is available for CoNLL03 (referred to as CoNLL03$_{dev}$), therefore we seek to improve F$_{\beta=1}$ on CoNLL03$_{dev}$ as well.

The customization process for each dataset proceeded as follows. First, we studied the entity definitions and identified their differences when compared with the definitions used for CoreNER$_{orig}$ (Tab. 3). We then added rules to account for the differences. For example, the definition of *Organization* in the CoNLL03 dataset contained a sports organization subtype, which was not considered when developing CoreNER. Therefore, we have used public data sources (e.g., Wikipedia) to collect and curate dictionaries of major sports associations and sport clubs from around the world. The new dictionaries, along with regular expressions identifying sports teams in sports articles were used for defining FD and CD rules such as CR_1 (Fig. 2). Finally, CR and CO rules were added to filter invalid candidates and augment the *Organization* type with the new sports subtype (similar in spirit to rules CR_4 and CR_5 in Fig. 2).

In addition to the train and development sets, the customization process for CoNLL03 also involved unlabeled data from the corpus as follows. 1) Since data-driven rules (C_{DD}) are often created based on a few instances from the training data, testing them on the unlabeled data helped fine tune the rules for precision. 2) CoNLL03 is largely dominated by sports news, but only a subset of all sports were represented in the train dataset. Using the unlabeled data, we were able to add C_{DD} rules for five additional types of sports, resulting in 0.31% improvement in F$_{\beta=1}$ score on CoNLL03$_{dev}$. 3) Unlabeled data was also useful in identifying domain-specific gazetteers by using simple extraction rules followed by a manual cleanup phase. For instance, for CoNLL03 we collected five gazetteers of organization and person names from the unlabeled data, resulting in 0.45% improvement in recall for CoNLL03$_{dev}$.

The quality of the customization on the train collections is shown in Tab. 5. The total number of rules added during customization for each of the three domains is listed in Tab. 4. Notice how rules of all four types are used both in the development

[1] The evaluation test set is not publicly available. Thus, following the example of (Florian et al., 2006), the publicly available set is split into a 80%/20% data split, with the last 20% of the data in chronological order selected as test data.

	FD	CD	CR	CO
CoreNER$_{orig}$	104	74	123	102
CoreNER$_{conll}$	179	56	284	71
CoreNER$_{enron}$	13	10	9	1
CoreNER$_{ace}$	83	35	117	26

Table 4: Rules added during customization

	Precision	**Recall**	**F$_{\beta=1}$**
CoreNER$_{conll}$	97.64	95.60	96.61
CoreNER$_{enron}$	91.15	92.58	91.86
CoreNER$_{ace}$	92.32	91.22	91.77

Table 5: Quality of customization on train datasets (%)

of the domain independent NER annotator, and during customizations for different domains. A total of 8 person weeks were spent on customizations, and we believe this effort is quite reasonable by rule-based extraction standards. For example, (Maynard et al., 2003) reports that customizing the ANNIE domain independent NER annotator developed using the JAPE grammar-based rule language for the ACE05 dataset required 6 weeks (and subsequent tuning over the next 6 months), resulting in improving the quality to 82% for this dataset. As we shall discuss shortly, *with similar manual effort, we were able to achieve results outperforming state-of-art published results on three different datasets, including* ACE05. However, one may rightfully argue that the process is still too lengthy impeding the widespread deployment of rule-based NER extraction. We elaborate on the effort involved and the lessons learned in the process in Sec. 5.

4.3 Evaluation of Customization

We now present an experimental evaluation of the customizability of CoreNER. The main goals are to investigate: (i) the feasibility of CoreNER customization for different application domains; (ii) the effectiveness of such customization compared to state-of-the-art results; (iii) the impact of different types of customization (Tab. 1); and (iv) how often different categories of *NERL* rules (Tab. 2) are used during customization.

We measured the effectiveness of customization using the improvement in extraction quality of the customized CoreNER over CoreNER$_{orig}$. As shown in Tab. 6, customization significantly improved F$_{\beta=1}$ score for CoreNER$_{orig}$ across all datasets. [2]

		Precision	**Recall**	**F$_{\beta=1}$**
CoNLL03$_{dev}$	CoreNER$_{orig}$	83.81	61.77	71.12
	CoreNER$_{conll}$	96.49	93.76	95.11
	Improvement	12.68	31.99	13.99
CoNLL03$_{test}$	CoreNER$_{orig}$	77.21	54.87	64.15
	CoreNER$_{conll}$	93.89	89.75	91.77
	Improvement	15.68	34.88	27.62
Enron	CoreNER$_{orig}$	85.06	69.55	76.53
	CoreNER$_{enron}$	88.41	82.39	85.29
	Improvement	3.35	12.84	8.76
ACE2005	CoreNER$_{orig}$	57.23	57.41	57.32
	CoreNER$_{ace}$	90.11	87.82	88.95
	Improvement	32.88	30.41	31.63

Table 6: Overall Improvement due to Customization (%)

			Precision	**Recall**	**F$_{\beta=1}$**
CoNLL03$_{dev}$	LOC	CoreNER$_{conll}$	**97.17**	95.37	**96.26**
		Florian	96.59	**95.65**	96.12
	ORG	CoreNER$_{conll}$	**93.70**	88.67	**91.11**
		Florian	90.85	**89.63**	90.24
	PER	CoreNER$_{conll}$	**97.79**	95.87	**96.82**
		Florian	96.08	**97.12**	96.60
CoNLL03$_{test}$	LOC	CoreNER$_{conll}$	**93.11**	91.61	**92.35**
		Florian	90.59	**91.73**	91.15
	ORG	CoreNER$_{conll}$	**92.25**	**85.31**	**88.65**
		Florian	85.93	83.44	84.67
	PER	CoreNER$_{conll}$	**96.32**	92.39	**94.32**
		Florian	92.49	**95.24**	93.85
Enron	PER	CoreNER$_{enron}$	**87.27**	**81.82**	**84.46**
		Minkov	81.1	74.9	77.9

Table 7: Comparison with state-of-the-art results(%)

We note that the extraction quality of CoreNER$_{orig}$ was low on CoNLL03 and ACE05 mainly due to differences in entity type definitions. In particular, sports organizations, which occurred frequently in the CoNLL03 collection, were not considered during the development of CoreNER$_{orig}$, while in ACE05, *ORG* and *LOC* entity types were split into four entity types (*Organization*, *Location*, *Geo-Political Entity* and *Facility*). Customizations such as C_S and C_G address the above changes in named-entity type definition and substantially improve the extraction quality of CoreNER$_{orig}$.

Next, we compare the extraction quality of the

[2] CoNLL03$_{dev}$ and CoNLL03$_{test}$ correspond to the development and test sets for CoNLL03 respectively.

customized CoreNER for CoNLL03 and Enron[3] with the corresponding best published results by (Florian et al., 2003) and (Minkov et al., 2005). Tab. 7 shows that our customized CoreNER *outperforms the corresponding state-of-the-art numbers for all the NER tasks* on both CoNLL03 and Enron. [4] These results demonstrate that high-quality annotators can be built by customizing CoreNER$_{orig}$ using *NERL*, with the final extraction quality matching that of state-of-the-art machine learning-based extractors.

It is worthwhile noting that the best published results for CoNLL03 (Florian et al., 2003) were obtained by using four different classifiers (Robust Risk Minimization, Maximum Entropy, Transformation-based learning, and Hidden Markov Model) and trying six different classifier combination methods. Compared to the best published result obtained by combining the four classifiers, the individual classifiers performed between 2.5-7.6% worse for *Location*, 5.6-15.2% for *Organization* and 3.9-14.0% for *Person*[5]. Taking this into account, the extraction quality advantage of customized CoreNER is significant when compared with the individual state-of-the-art classifiers.

Impact of Customizations by Type. While customizing CoreNER for the three datasets, all types of changes described in Sec. 2 were performed. We measured the impact of each type of customization by comparing the extraction quality of CoreNER$_{orig}$ with CoreNER$_{orig}$ enhanced with all the customizations of that type. From the results for CoNLL03 (Tab. 8), we make the following observations.

	# rules added			**Precision**	**Recall**	$\mathbf{F}_{\beta=1}$

Table 8: Impact by customization type on CoNLL03(%)

- Customizations that identify additional subtypes of entities (C_S) or modify existing instances for multiple types (C_{ATA}) have significant impact. This effect can be especially high when the missing subtype appears very often in the new domain (E.g., over 50% of the organizations in CoNLL03 are sports teams).
- Data-driven customizations (C_{DD}) rely on the aggregated impact of many rules. While individual rules may have considerable impact on their own (e.g., identifying all names that appear as part of a player list increases the recall of PER by over 6% on both CoNLL03$_{dev}$ and CoNLL03$_{test}$), the overall impact relies on the accumulative effect of many small improvements.
- Certain customizations (C_{EB} and C_{DSD}) provide smaller quality improvements, both per rule and in aggregate.

5 Lessons Learned

Our experimental evaluation shows that rule-based annotators can achieve quality comparable to that of state-of-the-art machine learning techniques. In this section we discuss three important lessons learned regarding the human effort involved in developing such rule-based extractors.

Usefulness of *NERL* We found *NERL* very helpful in that it provided a higher-level abstraction catered specifically towards NER tasks, thus hiding the complexity inherent in a general-purpose IE rule language. In doing so, *NERL* restricts the large space of operations possible within a general-purpose language to the small number of predefined "templates"

[3] We cannot meaningfully compare our results against previously published results for ACE05, which is originally used for mention detection while CoreNER considers only NER tasks.

[4] For Enron the comparison is reported only for *Person*, as labeled data is available only for that type.

[5] Extended version obtained via private communication.

listed in Tab. 2. (We have shown empirically that our choice of *NERL* rules is sufficient to achieve high accuracy for NER tasks.) Therefore, *NERL* simplifies development and maintenance of complex NER extractors, since one does not need to worry about multiple AQL statements or JAPE grammar phases for implementing a single conceptual operation such as filtering (see Fig. 3).

Is *NERL* Sufficient? Even using *NERL*, building and customizing NER rules remains a labor intensive process. Consider the example of designing the filter rule CR_4 from Fig. 3. First, one must examine multiple false positive *Location* entities to even decide that a filter rule is appropriate. Second, one must understand how those false positives were produced, and decide accordingly on the particular concept to be used as filter (*LocationMaybeOrg* in this case). Finally, one needs to decide how to build the filter. Tab. 9 lists all the attributes that need to be specified for a *Filter* rule, along with examples of the search space for each rule attribute.

Rule Attributes	**Examples of Search Space**
Location	Intermediate Concept to filter
Predicate Type	Matches Regex, Contains Dictionary, . . .
Predicate Parameter	Regular Expressions, Dictionary Entries, . . .
Context Type	Entity text, Left or Right context
Context Parameter	k tokens, l characters

Table 9: Search space explored while adding a *Filter* rule

This search space problem is not unique to filter rules. In fact, most rules in Tab. 2 have two or more rule attributes. Therefore, designing an individual *NERL* rule remains a time-consuming "trial and error" process, in which multiple "promising" combinations are implemented and evaluated individually before deciding on a satisfactory final rule.

Tooling for *NERL* The fact that *NERL* is a high-level language exposing a restricted set of operators can be exploited to reduce the human effort involved in building NER annotators by enabling the following tools:

Annotation Provenance Tools tracking provenance (Cheney et al., 2009) for *NERL* rules can help in explaining exactly which sequence of rules is responsible for producing a given false positive, thereby enabling one to quickly identify "misbehaved" rules. For instance, one can quickly narrow down the choices for the location where the filter rule CR_4 (Fig. 2) should be applied based on the provenance of the false positives. Similarly, tools for explaining false positives in the spirit of (Huang et al., 2008), are also conceivable.

Automatic Parameter Learning The most time-consuming part in building a rule often is to decide the value of its parameters, especially for FD and CR rules. For instance, while defining a CR rule, one has to choose values for the Predicate parameter and the Context parameter (see Tab. 9). Some parameter values can be learned – for example, dictionaries (Riloff, 1993) and regular expressions (Li et al., 2008).

Automatic Rule Refinement Tools automatically suggesting entire customization rules to a complex *NERL* program in the spirit of (Liu et al., 2010) can further reduce human effort in building NER annotators. With the help of such tools, one only needs to consider good candidate *NERL* rules suggested by the system without having to go through the conventional manual "trial and error" process.

6 Conclusion

In this paper, we described *NERL*, a high-level rule language for building and customizing NER annotators. We demonstrated that a complex NER annotator built using *NERL* can be effectively customized for different domains, achieving extraction quality superior to the state-of-the-art numbers. However, our experience also indicates that the process of designing the rules themselves is still manual and time-consuming. Finally, we discuss how *NERL* opens up several interesting research directions towards the development of sophisticated tooling for automating some of the rule development tasks.

Collective Cross-Document Relation Extraction Without Labelled Data

Limin Yao Sebastian Riedel Andrew McCallum
University of Massachusetts, Amherst
{lmyao,riedel,mccallum}@cs.umass.edu

Abstract

We present a novel approach to relation extraction that integrates information across documents, performs global inference and requires no labelled text. In particular, we tackle relation extraction and entity identification jointly. We use distant supervision to train a factor graph model for relation extraction based on an existing knowledge base (Freebase, derived in parts from Wikipedia). For inference we run an efficient Gibbs sampler that leads to linear time joint inference. We evaluate our approach both for an in-domain (Wikipedia) and a more realistic out-of-domain (New York Times Corpus) setting. For the in-domain setting, our joint model leads to 4% higher precision than an isolated local approach, but has no advantage over a pipeline. For the out-of-domain data, we benefit strongly from joint modelling, and observe improvements in precision of 13% over the pipeline, and 15% over the isolated baseline.

1 Introduction

Relation Extraction is the task of predicting semantic relations over entities expressed in structured or semi-structured text. This includes, for example, the extraction of employer-employee relations mentioned in newswire, or protein-protein interactions expressed in biomedical papers. It also includes the prediction of entity types such as country, citytown or person, if we consider entity types as unary relations.

A particularly attractive approach to relation extraction is based on *distant supervision*.[1] Here in place of annotated text, only an existing knowledge base (KB) is needed to train a relation extractor (Mintz et al., 2009; Bunescu and Mooney, 2007; Riedel et al., 2010). The facts in the KB are heuristically aligned to an unlabelled training corpus, and the resulting alignment is the basis for learning the extractor.

Naturally, the predictions of a distantly supervised relation extractor will be less accurate than those of a supervised one. While facts of existing knowledge bases are inexpensive to come by, the heuristic alignment to text will often lead to noisy patterns in learning. When applied to unseen text, these patterns will produce noisy facts. Indeed, we find that extraction precision still leaves much room for improvement. This room is not as large as in previous work (Mintz et al., 2009) where target text and training KB are closely related. However, when we use the knowledge base Freebase (Bollacker et al., 2008) and the New York Times corpus (Sandhaus, 2008), we observe very low precision. For example, the precision of the top-ranked 50 `nationality` relation instances is only 28%.

On inspection, it turns out that many of the errors can be easily identified: they amount to violations of basic compatibility constraints between facts. In particular, we observe unsatisfied *selectional preferences* of relations towards particular entity types as types of their arguments. An example is the fact that the first argument of `nationality` is always a `person` while the second is a `country`. A simple way to address this is a pipeline: first predict entity types, and then condition on these when predicting relations. However, this neglects the fact that relations could as well be used to help entity type prediction.

[1] Also called *self training*, or *weak supervision*.

While there is some existing work on enforcing such constraints in a joint fashion (Roth and Yih, 2007; Kate and Mooney, 2010; Riedel et al., 2009), they are not directly applicable here. The difference is the amount of facts they take into account at the same time. They focus on single sentence extractions, and only consider very few interacting facts. This allows them to work with exact optimization techniques such as (Integer) Linear Programs and still remain efficient.[2] However, when working on a sentence level they fail to exploit the redundancy present in a corpus. Moreover, the fewer facts they consider at the same time, the lower the chance that some of these will be incompatible, and that modelling compatibility will make a difference.

In this work we present a novel approach that performs relation extraction across documents, enforces selectional preferences, and needs no labelled data. It is based on an undirected graphical model in which variables correspond to facts, and factors between them measure compatibility. In order to scale up, we run an efficient Gibbs-Sampler at inference time, and train our model using SampleRank (Wick et al., 2009). In practice this leads to a runtime behaviour that is linear in the size of the corpus. For example, 200,000 documents take less than three hours for training and testing.

For evaluation we consider two scenarios. First we follow Mintz et al. (2009), use Freebase as source of distant supervision, and employ Wikipedia as source of unlabelled text—we will call this an in-domain setting. This scenario is somewhat artificial in that Freebase itself is partially derived from Wikipedia, and in practice we cannot expect text and training knowledge base to be so close. Hence we also evaluate our approach on the New York Times corpus (out-of-domain setting).

For in-domain data we make the following finding. When we compare to an isolated baseline that makes no use of entity types, our joint model improves average precision by 4%. However, it does not outperform a pipelined system. In the out-of-domain setting, our collective model substantially outperforms both other approaches. Compared to the isolated baseline, we achieve a 15% increase in precision. With respect to the pipeline approach, the increase is 13%.

In the following we will first give some background information on relation extraction with distant supervision. Then we will present our graphical model as well as the inference and learning techniques we apply. After discussing related work, we present our empirical results and conclude.

2 Background

In this section we will introduce the terminology and concepts we use throughout the paper. We will also give a brief introduction to relation extraction, in particular in the context of distant supervision.

2.1 Relations

We seek to extract facts about entities. Example entities would be the company founder BILL GATES, the company MICROSOFT, and the country USA. A *relation* R is a set of tuples $\mathbf{c}$ over entities. We will follow (Mintz et al., 2009) and call the term $R(c_1, \ldots c_n)$ with $\mathbf{c} \in R$ a *relation instance*.[3] It denotes the membership of the tuple $\mathbf{c}$ in the relation R. For example, `founded` (BILL GATES, MICROSOFT) is a relation instance denoting that BILL GATES and MICROSOFT are related in the `founded` relation.

In the following we will always consider some set of *candidate tuples* C that may or may not be related. We define $C_n \subset C$ to be set of all n-ary tuples in C. Note that while our definition considers general n-nary relations, in practice we will restrict us to unary and binary relations C_1 and C_2.

Following previous work (Mintz et al., 2009; Zelenko et al., 2003; Culotta and Sorensen, 2004) we make one more simplifying assumption: every candidate tuple can be member of at most one relation.

2.2 Entity Types

An entity can be of one or several *entity types*. For example, BILL GATES is a `person`, and a company `founder`. Entity types correspond to the special case of relations with arity one, and will be treated as such in the following.

[2] The pyramid algorithm of Kate and Mooney (2010) may scale well, but it is not clear how to apply their scheme to cross-document extraction.

[3] Other commonly used terms are relational facts, ground facts, ground atoms, and assertions.

We care about entity types for two reasons. First, they can be important for downstream applications: if consumers of our extracted facts know the type of entities, they can find them more easily, visualize them more adequately, and perform operations specific to these types (write emails to persons, book a hotel in a city, etc.). Second, they are useful for extracting binary relations due to selectional preferences—see section 2.6.

2.3 Mentions

In natural language text spans of tokens are used to refer to entities. We call such spans *entity mentions*. Consider, for example, the following sentence snippet:

(1) Political opponents of President **Evo Morales** of **Bolivia** have in recent days stepped up...

Here "Evo Morales" is an entity mention of president EVO MORALES, and "Bolivia" a mention of the country BOLIVIA he is the president of.

People often express relations between entities in natural language texts by mentioning the participating entities in specific syntactic and lexical patterns. We will refer to any tuple of mentions of entities $(e_1, \ldots e_n)$ in a sentence as *candidate mention tuple*. If such a candidate expresses the relation R, then it is a *relation mention* of the relation instance $R(e_1, \ldots, e_n)$.

Consider again example 1. Here the pair of entity mentions ("Evo Morales", "Bolivia") is a *candidate mention tuple*. In fact, in this case the candidate is indeed a *relation mention* of the relation instance `nationality` (EVO MORALES, BOLIVIA).

2.4 Relation Extraction

We define the task of relation extraction as follows. We are given a corpus of documents and a set of target relations. Then we are asked to predict all relation instances I so that for each $R(\mathbf{c}) \in I$ there exists at least one relation mention in the given corpus.

The above definition covers a range of existing approaches by varying over what we define as target corpus. On one end, we have extractors that process text on a per sentence basis (Zelenko et al., 2003; Culotta and Sorensen, 2004). On the other end, we have methods that take relation mentions from several documents and use these as input features (Mintz et al., 2009; Bunescu and Mooney, 2007).

There is a compelling reason for performing relation extraction within a larger scope that considers mentions across documents: redundancy. Often facts are mentioned in several sentences and documents. Some of these mentions may be difficult to parse, or they use unseen patterns. But the more mentions we consider, the higher the probability that one does parse, and fits a pattern we have seen in the training data.

Note that for relation extraction that considers more than a single mention we have to solve the coreference problem in order to determine which mentions refer to the same entity. In the following we will assume that coreference clusters are provided by a preprocessing step.

2.5 Distant Supervision

In relation extraction we often encounter a lack of explicitly annotated text, but an abundance of structured data sources such as company databases or collaborative knowledge bases like Freebase. In order to exploit this, many approaches use simple but effective heuristics to align existing facts with unlabelled text. This labelled text can then be used as training material of a supervised learner.

One heuristic is to assume that each candidate mention tuple of a training fact is indeed expressing the corresponding relation (Bunescu and Mooney, 2007). Mintz et al. (2009) refer to this as the *distant supervision assumption*.

Clearly, this heuristic can fail. Let us again consider the `nationality` relation between EVO MORALES and BOLIVIA. In an 2007 article of the New York Times we find this relation mention candidate:

(2) ...the troubles faced by **Evo Morales** in **Bolivia**...

This sentence does not directly express that EVO MORALES is a citizen of BOLIVIA, and hence violates the distant supervision assumption. The problem with this observation is that at training time we may learn a relatively large weight for the feature "<Entity1> in <Entity2>" associated with nationality. When testing our model we then encounter a sentence such as

(3) Arrest Warrant Issued for **Richard Gere** in **India**.

that leads us to extract that RICHARD GERE is a citizen of INDIA.

2.6 Global Consistency of Facts

As discussed above, distant supervision can lead to noisy extractions. However, such noise can often be easily identified by testing how compatible the extracted facts are to each other. In this work we are concerned with a particular type of compatibility: selectional preferences.

Relations require, or prefer, their arguments to be of certain types. For example, the nationality relation requires the first argument to be a person, and the second to be a country. On inspection, we find that these preferences are often not satisfied in a baseline distant supervision system akin to Mintz et al. (2009). This often results from patterns such as "<Entity1> in <Entity2>" that fire in many cases where <Entity2> is a location, but not a country.

3 Model

Our observations in the previous section suggest that we should (a) explicitly model compatibility between extracted facts, and (b) integrate evidence from several documents to exploit redundancy. In this work we choose a Conditional Random Field (CRF) to achieve this. CRFs are a natural fit for this task: They allow us to capture correlations in an explicit fashion, and to incorporate overlapping input features from multiple documents.

The hidden output variables of our model are $\mathbf{Y} = (Y_\mathbf{c})_{\mathbf{c} \in C}$. That is, we have one variable $Y_\mathbf{c}$ for each candidate tuple $\mathbf{c} \in C$. This variable can take as value any relation in C with the same arity as $\mathbf{c}$. See example relation variables in figure 1.

The observed input variables $\mathbf{X}$ consists of a family of variables $\mathbf{X_c} = \left(\mathbf{X}_\mathbf{c}^1, \dots \mathbf{X}_\mathbf{c}^m\right)_{m \in M}$ for each candidate tuple $\mathbf{c}$. Here $\mathbf{X}_\mathbf{c}^i$ stores relevant observations we make for the i-th candidate mention tuple of $\mathbf{c}$ in the corpus. For example, $\mathbf{X}^1_{\text{BILL GATES,MICROSOFT}}$ in figure 1 would contain, among others, the pattern "[M2] was founded by [M1]".

3.1 Factor Templates

Our conditional probability distribution over variables $\mathbf{X}$ and $\mathbf{Y}$ is defined using using a set $\mathcal{T}$ of *factor templates*. Each template $T_j \in \mathcal{T}$ defines a set of factors $\{(\mathbf{y}_i, \mathbf{x}_i)\}$, a set K_j of feature indices, parameters $\left\{\theta_k^j\right\}_{k \in K_j}$ and feature functions $\left\{f_k^j\right\}_{k \in K_j}$. Together they define the following conditional distribution:

$$p\left(\mathbf{y}|\mathbf{x}\right) = \frac{1}{Z_\mathbf{x}} \prod_{T_j \in \mathcal{T}} \prod_{(\mathbf{y}_i, \mathbf{x}_i) \in T_j} e^{\sum_{k \in K_j} \theta_k^j f_k^j(\mathbf{y}_i, \mathbf{x}_i)} \tag{4}$$

In our case the set $\mathcal{T}$ consists of four templates we will describe below. We construct this graphical model using FACTORIE (McCallum et al., 2009), a probabilistic programming language that simplifies the construction process, as well as inference and learning.

3.1.1 Bias Template

We use a bias template T_{Bias} that prefers certain relations *a priori* over others. When the template is unrolled, it creates one factor per variable $Y_\mathbf{c}$ for candidate tuple $\mathbf{c} \in C$. The template also consists of one weight θ_r^{Bias} and feature function f_r^{Bias} for each possible relation r. f_r^{Bias} fires if the relation associated with tuple $\mathbf{c}$ is r.

3.1.2 Mention Template

In order to extract relations from text, we need to model the correlation between relation instances and their mentions in text. For this purpose we define the template T_{Men} that connects each relation instance variable $Y_\mathbf{c}$ with its observed mention variables $\mathbf{X_c}$. Crucially, this template gathers mentions from multiple documents, and enables us to exploit redundancy.

The feature functions of this template are taken from Mintz et al. (2009). This includes features that inspect the lexical content between entity mentions in the same sentence, and the syntactic path between them. One example is

$$f_{101}^{\text{Men}}\left(y_\mathbf{c}, \mathbf{x_c}\right) \overset{\text{def}}{=} \begin{cases} 1 & y_\mathbf{c} = \texttt{founded} \wedge \exists i \text{ with} \\ & \text{"M2 was founded by M1"} \in \mathbf{x}_\mathbf{c}^i \\ 0 & \text{otherwise} \end{cases}.$$

Figure 1: Factor Graph of our model that captures selectional preferences and functionality constraints. For readability we only label a subsets of equivalent variables and factors. Note that the graph shows an example assignment to variables.

It tests whether for any mentions of the candidate tuple the phrase "founded by" appears between the mentions of the argument entities.

3.1.3 Selectional Preferences Templates

To capture the correlations between entity types and relations the entities participate in, we introduce the template T_{Joint}. It connects a relation instance variable $Y_{e_1,\ldots,e_n}$ to the individual entity type variables $Y_{e_1},\ldots,Y_{e_n}$. To measure the compatibility between relation and entity variables, we use one feature $f^{\text{Joint}}_{r,t_1\ldots t_a}$ (and weight $\theta^{\text{Joint}}_{r,t_1\ldots t_a}$) for each combination of relation and entity types $r, t_1 \ldots t_a$.

$f^{\text{Joint}}_{r,t_1\ldots t_a}$ fires when the factor variables are in the state $r, t_1 \ldots t_a$. For example, $f^{\text{Joint}}_{\texttt{founded},\texttt{person},\texttt{company}}$ fires if Y_{e_1} is in state `person`, Y_{e_2} in state `company`, and Y_{e_1,e_2} in state `founded`.

We also add a template T_{Pair} that measures the pairwise compatibility between the relation variable $Y_{e_1,\ldots,e_a}$ and each entity variable Y_{e_i} in isolation. Here we use features $f^{\text{Pair}}_{i,r,t}$ that fire if e_i is the i-th argument of $\mathbf{c}$, has the entity type t and the candidate tuple $\mathbf{c}$ is labelled as instance of relation r. For example, $f^{\text{Pair}}_{1,\texttt{founded},\texttt{person}}$ fires if Y_{e_1}(argument $i = 1$) is in state `person`, and Y_{e_1,e_2} in state `founded`, regardless of the state of Y_{e_2}.

3.2 Inference

There are two types of inference we have to perform: sampling from the posterior during training (see section 3.3), and finding the most likely configuration (aka MAP inference). In both settings we employ a Gibbs sampler (Geman and Geman, 1990) that randomly picks a variable $Y_{\mathbf{c}}$ and samples its relation value conditioned on its Markov Blanket. At test time we decrease the temperature of our sampler in order to find an approximation of the MAP solution.

3.3 Training

Most learning methods need to calculate the model expectations (Lafferty et al., 2001) or the MAP configuration (Collins, 2002) before making an update to the parameters. This step of inference is usually the bottleneck for learning, even when performed approximately.

SampleRank (Wick et al., 2009) is a rank-based learning framework that alleviates this problem by performing parameter updates *within* MCMC inference. Every pair of consecutive samples in the MCMC chain is ranked according to the model and the ground truth, and the parameters are updated when the rankings disagree. This update can follow different schemes, here we use MIRA (Crammer and Singer, 2003). This allows the learner to acquire more supervision per instance, and has led to efficient training for models in which inference is expensive and generally intractable (Singh et al., 2009).

4 Related Work

Distant Supervision Learning to extract relations by using distant supervision has raised much interest in recent years. Our work is inspired by Mintz et al. (2009) who also use Freebase as distant supervision source. We also heuristically align our knowledge base to text by making the distant supervision assumption (Bunescu and Mooney, 2007; Mintz et al., 2009). However, in contrast to these previous approaches, and other related distant supervision methods (Craven and Kumlien, 1999; Weld et al., 2009; Hoffmann et al., 2010), we perform relation extraction collectively with entity type prediction.

Schoenmackers et al. (2008) use entailment rules on assertion extracted by TextRunner to increase recall. They also perform cross-document probabilistic inference based on Markov Networks. However, they do not infer the types of entities and work in an open IE setting.

Selectional Preferences In the context of supervised relation extraction, selectional preferences have been applied. For example, Roth and Yih (2007) have used Linear Programming to enforce consistency between entity types and extracted relations. Kate and Mooney (2010) use a pyramid parsing scheme to achieve the same. Riedel et al. (2009) use Markov Logic to model interactions between event-argument relations for biomedical event extraction. However, their work is (a) supervised, and (b) performs extraction on a per-sentence basis.

Carlson et al. (2010) also use selectional preferences. However, instead of exploiting them for training a graphical model using distant supervision, they use selectional preferences to improve a bootstrapping process. Here in each iteration of bootstrapping, extracted facts that violate compatibility constraints will not be used to generate additional patterns in the next iteration.

5 Experiments

We set up experiments to answer the following questions: (i) Does the explicit modelling of selectional preferences improve accuracy? (ii) Can we also perform joint entity and relation extraction in a pipeline and achieve similar results? (iii) How does our cross-document approach scale?

To answer these questions we carry out experiments on two data sets, Wikipedia and New York Times articles, and use Freebase as distant supervision source for both.

5.1 Experimental Setup

We follow Mintz et al. (2009) and perform two types of evaluation: held-out and manual. In both cases we have a training and a test corpus of documents, and training and test sets of entities. For held-out evaluation we split the set of entities in Freebase into training and test sets. For manual evaluation we use all Freebase entities during training. For testing we use all entities that appear in the test document corpus.

For both training and testing we then choose the candidate tuples C that may or may not be relation instances. To pick the entities C_1 we want to predict entity types for, we choose all entities that are mentioned at least once in the train/test corpus. To pick the entity pairs C_2 that we want to predict the relations of, we choose those that appear at least once together in a sentence.

The set of candidates C will contain many tuples which are not related in any Freebase relations. For efficiency, we filter out a large fraction of these *negative* candidates for training. The number of negative examples we keep is chosen to be about 10 times the number of positive candidates. This number stems from trading-off the accuracy it leads to and the increased training time it requires.

For both manual and held-out evaluation we rank extracted test relation instances in the MAP state of the network. This state is found by sampling 20 iterations with a low temperature of 0.00001. The ranking is done according to the log linear score that the assigned relation for a candidate tuple gets from the factors in its Markov Blanket. For optimal performance, the score is normalized by the number of relation mentions.

For manual evaluation we pick the top ranked 50 relation instances for the most frequent relations. We ask three annotators to inspect the mentions of these relation instances to decide whether they are correct. Upon disagreement, we use majority vote. To summarize precisions across relations, we take their average, and their average weighted by the proportion of predicted instances for the given relation.

5.1.1 Data preprocessing

We preprocess our textual data as follows: We first use the Stanford named entity recognizer (Finkel et al., 2005) to find entity mentions in the corpus. The NER tagger segments each document into sentences and classifies each token into four categories: PERSON, ORGANIZATION, LOCATION and NONE. We treat consecutive tokens which share the same category as single entity mention. Then we associate these mentions with Freebase entities. This is achieved by performing a string match between entity mention phrases and the canonical names of entities as present in Freebase.

For each candidate tuple **c** with arity 2 and each of its mention tuples i we extract a set of features $\mathbf{X}_{\mathbf{c}}^{i}$ similar to those used in (Mintz et al., 2009): lexical, Part-Of-Speech (POS), named entity and syntactic features, i.e. features obtained from the dependency parsing tree of a sentence. We use the openNLP POS tagger[4] to obtain POS tags and employ the MaltParser (Nivre et al., 2004) for dependency parsing. For candidate tuples with arity 1 (entity types) we use the following features: the entity's word form, the POS sequence, the head of the entity in the dependency parse tree, the Stanford named entity tag, and the left and right words to the current entity mention phrase.

5.1.2 Configurations

We apply the following configurations of our factor graphs. As our baseline, and roughly equivalent to previous work (Mintz et al., 2009), we pick the templates T_{Bias} and T_{Men}. These describe a fully disconnected graph, and we will refer to this configuration as *isolated*. Next, we add the templates T_{Joint} and T_{Pair} to model selectional preferences, and refer to this setting as *joint*.

In addition, we evaluate how well selectional preferences can be captured with a simple *pipeline*. For this pipeline we first train an isolated system for entity type prediction. Then we use the output of the entity type prediction system as input for the relation extraction system.

5.1.3 Entity types and Relation types

Freebase contains many relation types and only a subset of those relation types occur frequently in the corpus. Since classes with very few training instances are generally hard to learn, we restrict ourselves to the 54 most frequently mentioned relations. These include, for example, `nationality`, `contains`, `founded` and `place_of_birth`. Note that we convert two Freebase non-binary temporal relations to binary relations: `employment_tenure` and `place_lived`. In both cases we simply disregard the temporal information in the Freebase data.

As our main focus is relation extraction, we restrict ourselves to entity types compatible with our selected relations. To this end we inspect the Freebase schema information provided for each relation, and include those entity types that are declared as arguments of our relations. This leads to 10 entity types including `person`, `citytown`, `country`, and `company`.

Note that a Freebase entity can have several types. We pick one of these by choosing the most specific one that is a member of our entity type subset, or `MISC` if no such member exists.

5.2 Wikipedia

In our first set of experiments we train and test using Wikipedia as the text corpus. This is a comparatively easy scenario because the facts in Freebase are partly derived from Wikipedia, hence there is an increased chance of properly aligning training facts and text. This is similar to the setting of Mintz et al. (2009).

5.2.1 Held Out Evaluation

We split 1,300,000 Wikipedia articles into training and test sets. Table 1 shows the statistics for this split. The last row provides the number of negative relation instances (candidates which are not related according to Freebase) associated with each data set.

Figure 2 shows the precision-recall curves of relation extraction for held-out data of various configurations. We notice a slight advantage of the joint approach in the low recall area. Moreover, the joint model predicts more relation instances, as can be seen by its longer line in the graph.

For higher recall, the joint model performs slightly worse. On closer inspection, we find that

[4] available at http://opennlp.sourceforge.net/

	Wikipedia		NYT	
	Train	Test	Train	Test
#Documents	900K	400K	177K	39K
#Entities	213K	137K	56K	27K
#Positive	36K	24K	5K	2K
#Negative	219K	590K	64K	94K

Table 1: The statistics of held-out evaluation on Wikipedia and New York Times.

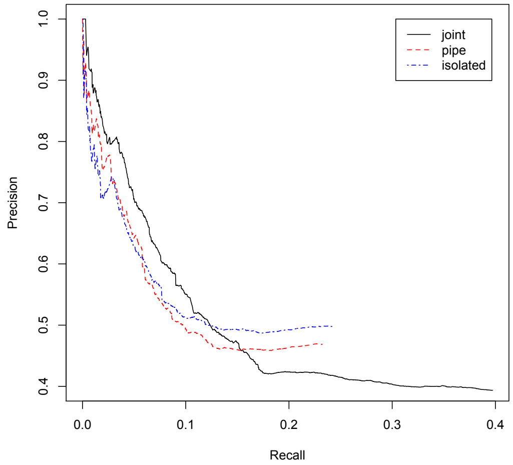

Figure 2: Precision-recall curves for various setups in Wikipedia held-out setting.

this observation is somewhat misleading. Many of the predictions of the joint model are not in the held-out test set derived from Freebase, but nevertheless correct. Hence, to understand if one system really outperforms another, we need to rely on manual evaluation.

Note that the figure only considers binary relations—for entity types all configurations perform similarly.

5.2.2 Manual Evaluation

As mentioned above, held-out evaluation in this context suffers from false negatives in Freebase. Table 2 therefore shows the results of our manual evaluation. They are based on the average, and weighted average, of the precisions for the relation instances of the most frequent relations. We notice that here all systems perform comparably for weighted average precision. For average precision we see an advantage for both the pipeline and the joint model over the isolated system.

	Isolated	Pipeline	Joint
Wikipedia	0.82	0.87	0.86
Wikipedia (w)	0.95	0.94	0.95
NYT	0.63	0.65	0.78
NYT (w)	0.78	0.82	0.94

Table 2: Average and weighted (w) average precision over frequent relations for New York Times and Wikipedia data, based on manual evaluation.

One reason for similar weighted average precisions is the fact that all approaches accurately predict a large number of `contains` instances. This is due to very regular and simple patterns in Wikipedia. For example, most articles on towns start with “A is a municipality in the district of B in C, D.” For these sentences, the relative position of two location mentions is a very good predictor of `contains`. When used as a feature, it leads to high precision for all models. And since `contains` instances are most frequent, and we take the weighted average, results are generally close to each other.

To summarize: in this in-domain setting, modelling compatibility between entity types and relations helps to improve average precision, but not weighted average precision. This holds for both the joint and the pipeline model. However, we will see how this changes substantially when moving to an out-of-domain scenario.

5.3 New York Times

For our second set of experiments we use New York Times data as training and test corpora. As we argued before, this is expected to be the more difficult—and more realistic—scenario.

5.3.1 Held-out Evaluation

We choose all articles of the New York times during 2005 and 2006 as training corpus. As test corpus we use the first 6 months of 2007.

Figure 3 shows precision-recall curves for our various setups. We see that jointly modelling entity

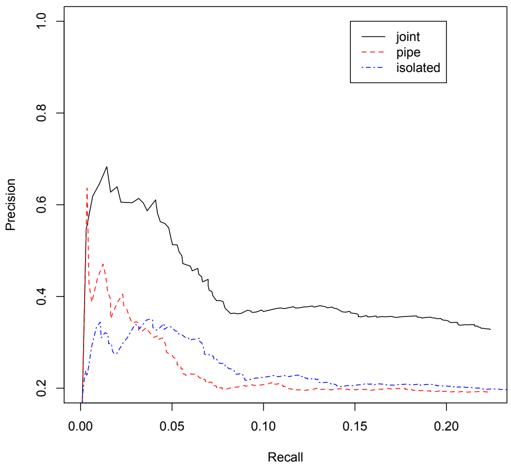

Figure 3: Precision-recall curves for various setups in New York Times held-out setting.

types and relations helps to improve precision.

Due to the smaller overlap between Freebase and NYT data, figure 3 also has to be taken with more caution. The systems may predict correct relation instances that just do not appear in Freebase. Hence manual evaluation is even more important.

When evaluating entity precision we find that for both models it is about 84%. This raises the question why the joint entity type and relation extraction model outperforms the pipeline on relations. We take a close look at the entities which participate in relations and find that joint model performs better on most entity types, for example, country and citytown. We also look at the relation instances which are predicted by both systems and find that the joint model does predict correct entity types when the pipeline mis-predicts. And exactly these mis-predictions lead the pipeline astray. Considering binary relation instances where the pipeline fails but the joint model does not, we observe an entity precision of 76% for the pipeline and 86% for our joint approach. The joint model fails to correctly predict some entity types that the pipeline gets right, but these tend to appear in contexts where relation instances are easy to extract without considering entity types.[5]

Relation Type	Iso.	Pipe	Joint
contains	0.92	0.98	0.96
nationality	0.28	0.64	0.82
plc_lived	0.88	0.70	0.96
plc_of_birth	0.32	0.20	0.25
works_for	0.96	0.98	0.98
plc_of_death	0.24	0.40	0.42
children	1.00	0.92	0.98
founded	0.42	0.34	0.71

Table 3: Precision at 50 for the most frequent relations on New York Times

5.3.2 Manual Evaluation

Manually evaluated precision for New York Times data can be seen in table 2. In contrast to the Wiki setting, here modelling entity types and relations jointly makes a substantial difference. For average precision, our joint model improves over the isolated baseline by 15%, and over the pipeline by 13%. Similar improvements can be observed for weighted average precision.

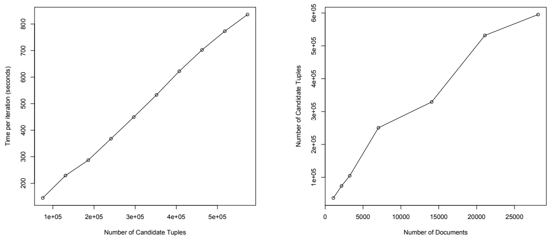
Let us look at a break-down of precisions with respect to different relations shown in table 3. We see dramatic improvements for nationality and founded when applying the joint model. Note that the nationality relation takes a larger part in the predicted relation instances of the joint model and hence contributes significantly to the weighted average precision.

5.4 Scalability

We propose to perform joint inference for large scale information extraction. An obvious concern in this scenario is scalability. In practice we find that inference (and hence learning) in our model scales linearly with the number of candidate tuples. This can be seen in figure 4a. It is to be expected since the number of candidates equals the number of variables the sampler has to process in each iteration.

The above observation also means that our approach scales linearly with corpus size. To illustrate

[5] Note that our learned preferences are soft, and hence can be violated in case of wrong entity type predictions.



(a) CPU time

(b) Candidate tuples

Figure 4: CPU time for one iteration per candidate tuple, and candidate tuples per document.

this, figure 4b shows how the number of candidates scales with the number of documents. Again we observe a linear behavior. Since both are linear, we can say that our joint approach is linear in the number of documents.

Total training and test times are moderate, too. For example, the held-out experiments with 200,000 NYT documents finish within three hours.

6 Conclusion

This paper presents a novel approach to extracting relational facts from text. Akin to previous work in relation extraction with distant supervision, we require no annotated text. However, instead extracting facts in isolation, we model interactions between facts in order to improve precision. In particular, we capture selectional preferences of relations. These preferences are modelled in a cross-document fashion using a large scale factor graph. We show inference and learning can be efficiently performed in linear time by Gibbs Sampling and SampleRank. When applied to out-of-domain text, this approach leads to a 15% increase in precision over an isolated baseline, and a 13% improvement over a pipelined system.

A crucial aspect of our approach is its extensibility. Since it is exclusively framed in terms of an undirected graphical model, it is conceptually easy to extend it to other types of compatibilities, such as functionality constraints. It could also be extended to tackle coreference resolution. Eventually we seek to model the complete process of the automatic construction of KB within this framework, and capture dependencies between extractions in a joint and principled fashion. As we have seen here, in particular when learning is less supervised and extractions are noisy, capturing such interactions is paramount.

Abstract

In this paper we introduce the new task of *social event* extraction from text. We distinguish two broad types of social events depending on whether only one or both parties are aware of the social contact. We annotate part of Automatic Content Extraction (ACE) data, and perform experiments using Support Vector Machines with Kernel methods. We use a combination of structures derived from phrase structure trees and dependency trees. A characteristic of our events (which distinguishes them from ACE events) is that the participating entities can be spread far across the parse trees. We use syntactic and semantic insights to devise a new structure derived from dependency trees and show that this plays a role in achieving the best performing system for both social event detection and classification tasks. We also use three data sampling approaches to solve the problem of data skewness. Sampling methods improve the F1-measure for the task of relation detection by over 20% absolute over the baseline.

1 Introduction

This paper introduces a novel natural language processing (NLP) task, *social event extraction*. We are interested in this task because it contributes to our overall research goal, which is to extract a social network from written text. The extracted social network can be used for various applications such as summarization, question-answering, or the detection of main characters in a story. For example, we manually extracted the social network of characters in *Alice in Wonderland* and ran standard social network analysis algorithms on the network. The most influential characters in the story were correctly detected. Moreover, characters occurring in a scene together were given same social roles and positions. Social network extraction has recently been applied to literary theory (Elson et al., 2010) and has the potential to help organize novels that are becoming machine readable.

We take a "social network" to be a network consisting of individual human beings and groups of human beings who are connected to each other by the virtue of participating in social events. We define social events to be events that occur between people where at least one person is aware of the other and of the event taking place. For example, in the sentence *John talks to Mary*, entities John and Mary are aware of each other and the talking event. In the sentence *John thinks Mary is great*, only John is aware of Mary and the event is the thinking event. In the sentence *Rabbit ran by Alice* there is no evidence about the cognitive states of Rabbit and Alice (because the Rabbit could have run by Alice without any one of them noticing each other). A text can describe a social network in two ways: explicitly, by stating the type of relationship between two individuals (e.g. husband-wife), or implicitly, by describing an event which creates or perpetuates a social relationship (e.g. *John talked to Mary*). We will call these types of events *social events*. We define two types of social events: **interaction**, in which both parties are aware of the social event (e.g., a conversation), and **observation**, in which only one party is aware of the interaction (e.g., thinking about or

spying on someone). Note that the notion of cognitive state is crucial to our definition. This paper is the first attempt to detect and classify social events present in text.

Our task is different from related tasks, notably from the Automated Content Extraction (ACE) relation and event extraction tasks because the events are different (they are a class of events defined through the effect on participants' cognitive state), and the linguistic realization is different. Mentions of entities[1] engaged in a social event are often quite distant from each other in the sentence (unlike in ACE relations where about 70% of relations are local, in our social event annotation, only 25% of the events are local. In fact, the average number of words between entities participating in any social event is 9.)

We use tree kernel methods (on structures derived from phrase structure trees and dependency trees) in conjunction with Support Vector Machines (SVMs) to solve our tasks. For the design of structures and type of kernel, we take motivation from a system proposed by Nguyen et al. (2009) which is a state-of-the-art system for relation extraction. Data skewness turns out to be a big challenge for the task of relation detection since there are many more pairs of entities without a relation as compared to pairs of entities that have a relation. In this paper we discuss three data sampling techniques that deal with this skewness and allow us to gain over 20% in F1-measure over our baseline system. Moreover, we introduce a new sequence kernel that outperforms previously proposed sequence kernels for the task of social event detection and plays a role to achieve the best performing system for the task of social event detection and classification.

The paper is structured as follows. In Section 2, we compare our work to existing work, notably the ACE extraction literature. In Section 3, we present our task in detail, and explain how we annotated our corpus. We also show why this is a novel task, and how it is different from the ACE extraction tasks. We then discuss kernel methods and the structures we use, and introduce our new structure in Section 4. In Section 5, we present the sampling methods used for experiments. In Section 6 we present our experiments and results for social event detection and social event classification tasks. We conclude in Section 7 and mention our future direction of research.

2 Literature Survey

There has not been much work in developing techniques for ACE event extraction as compared to ACE relation extraction. The most salient work for event extraction is Grishman et al. (2005) and Ji and Grishman (2008). To solve the task for event extraction, Grishman et al. (2005) mainly use a combination of pattern matching and statistical modeling techniques. They extract two kinds of patterns: 1) the sequence of constituent heads separating anchor and its arguments and 2) a predicate argument subgraph of the sentence connecting anchor to all the event arguments. In conjunction they use a set of Maximum Entropy based classifiers for 1) Trigger labeling, 2) Argument classification and 3) Event classification. Ji and Grishman (2008) further exploit a correlation between senses of verbs (that are triggers for events) and topics of documents.

Our work shares some similarities. However, instead of building different classifiers, we use kernel methods with SVMs that "naturally" combine various patterns. The structures we use for kernel methods are a super-set of the patterns used by Grishman et al. (2005). Moreover, in our work, we take gold annotation for entity mentions, and do not deal with the task of named entity detection or resolution. Finally, our social events are a broad class of event types, and they involve linguistic expressions for expressing interactions and cognition that do not seem to have a correlation with the topics of documents.

There has been much work in extracting ACE relations. The supervised approaches used for relation extraction can broadly be divided into three main categories: 1) feature-based approaches 2) kernel-based approaches and 3) a combination of feature and kernel based approaches. The state-of-the-art feature based approach is that of GuoDong et al. (2005). They use diverse lexical, syntactic and semantic knowledge for the task. The lexical features they use are words between, before, and after target entity mentions, the type of entity (Person, Organization etc.), the type of mention (named, nominal or pronominal) and a feature called overlap

[1] An *entity mention* is a reference of an entity in text. Also, we use *entities* and *people* interchangeably since the only entities we are interested in are people or groups of people.

that counts the number of other entity mentions and words between the target entities. To incorporate syntactic features they use features extracted from base phrase chunking, dependency trees and phrase structure trees. To incorporate semantic features, their approach uses resources like a country list and WordNet. GuoDong et al. (2005) report that 70% of the entities are embedded within each other or separated by just one word. This is a major difference to our task because most of our relations span over a long distance in a sentence.

Collins and Duffy (2002) are among the earliest researchers to propose the use of tree kernels for various NLP tasks. Since then kernels have been used for the task of relation extraction (Zelenko et al., 2002; Zhao and Grishman, 2005; Zhang et al., 2006; Moschitti, 2006b; Nguyen et al., 2009). For an excellent review of these techniques, see Nguyen et al. (2009). In addition, there has been some work that combines feature and kernel based methods (Harabagiu et al., 2005; Culotta and Jeffrey, 2004; Zhou et al., 2007). Apart from using kernels over dependency trees, Culotta and Jeffrey (2004) incorporate features like words, part of speech (POS) tags, syntactic chunk tag, entity type, entity level, relation argument and WordNet hypernym. Harabagiu et al. (2005) leverage this approach by adding more semantic feature derived from semantic parsers for FrameNet and PropBank. Zhou et al. (2007) use a context sensitive kernel in conjunction with features they used in their earlier publication (GuoDong et al., 2005). However, we take an approach similar to Nguyen et al. (2009). This is because it incorporates many of the features suggested in feature-based approaches by using combinations of various structures derived from phrase structure trees and dependency trees. In addition we use data sampling techniques to deal with the problem of data skewness. We not only try the structures suggested by Nguyen et al. (2009) but also introduce a new sequence structure on dependency trees. We discuss their structures and kernel method in detail in Section 4.

3 Social Event Annotation Data

3.1 Social Event Annotation

There has been much work in the past on annotating entities, relations and events in free text, most notably the ACE effort (Doddington et al., 2004). We leverage this work by annotating social events on the English part of ACE 2005 Multilingual Training Data[2] that has already been annotated for entities, relations and events. In Agarwal et al. (2010), we introduce a comprehensive set of social events which are conceptually different from the event annotation that already exists for ACE. Since our annotation task is complex and layered, in Agarwal et al. (2010) we present confusion matrices, Cohen's Kappa, and F-measure values for each of the decision points that the annotators go through in the process of selecting a type and subtype for an event. Our annotation scheme is reliable, achieving a moderate kappa for relation detection (0.68) and a high kappa for relation classification (0.86). We also achieve a high global agreement of 69.7% using a measure which is inspired by Automated Content Extraction (ACE) inter-annotator agreement measure. This compares favorably to the ACE annotation effort.

Following are the two broad types of social events that were annotated:

Interaction event (INR): When both entities participating in an event are aware of each other and of the social event, we say they have an INR relation. Consider the following Example (1).

(1) [Toujan Faisal], 54, {said} [she] was {informed} of the refusal by an [Interior Ministry committee] overseeing election preparations. INR

As is intuitive, if one person *informs* the other about something, both have to be cognizant of each other and of the *informing* event in which they are both participating.

Observation event (OBS): When only one person (out of the two people that are participating in an event) is aware of the other and of the social event, we say they have an OBS relation. Of the type OBS, there are three subtypes: Physical Proximity (PPR), Perception (PCR) and Cognition (COG). PPR requires that one entity can observe the other entity in real time not through a broadcast medium, in contrast to the subtype PCR, where one entity observes the other through media (TV, radio, magazines etc.) Any other observation event that is not PPR or PCR

[2] Version: 6.0, Catalog number: LDC2005E18

is COG. Consider the aforementioned Example (1). In this sentence, the event *said* marks a COG relation between **Toujan Faisal** and the **committee**. This is because, when one person talks about another person, the other person must be present in the first person's cognitive state without any requirement on physical proximity or external medium.

As the annotations revealed, PPR and PCR occurred only twice and once, respectively, in the part of ACE corpus we annotated. (They occur more frequently in another genre we are investigating such as literary texts.) We omit these extremely low-frequency categories from our current study; in this paper we build classifiers to detect and classify only INR and COG events.

3.2 Comparison Between Social Events and ACE Annotations

The ACE effort is about entity, relation and event annotation. We use their annotations for entity types PER.Individual and PER.Group and add our social event annotations. Our event annotations are different from ACE event annotations because we annotate text that expresses the cognitive states of the people involved, or allows the annotator to infer it. Therefore, at the top level of classification we differentiate between events in which only one entity is cognizant of the other (observation) versus events when both entities are cognizant of each other (interaction). This distinction is, we believe, novel in event or relation annotation.

Now we present statistics and examples to make clear how our annotations are different from ACE event annotations. The statistics are based on 62 documents from the ACE corpus. These files contain a total of 212 social events. We found a total of 63 candidate ACE events that had at least two Person entities involved. Out of these 63 candidate events, 54 match our annotations. The majority of social events that match the ACE events are of type INR. On analysis, we found that most of these correspond to the ACE event type CONTACT. Specifically, the "meeting" event, which is an ACE CONTACT event and an INR event according to our definition, is the major cause of overlap. However, our type INR has a broader definition than ACE type CONTACT. For example, in Example 1, we recorded an INR event between **Toujan Faisal** and **committee** (event span: *informed*). ACE does not record any event between these two entities because *informed* does not entail a CONTACT event for ACE event annotations. Another example that will clarify the difference is the following:

(2) In central Baghdad, [a Reuters cameraman] and [a cameraman for Spain's Telecinco] died when an American tank fired on the Palestine Hotel

ACE has annotated the above example as an event of type CONFLICT in which there are two entities that are of type person: the **Reuters cameraman** and the **cameraman for Spain's Telecinco**, both of which are arguments of type "Victim". Being an event that has two person entities involved makes the above sentence a potential social event. However, we do not record any event between these entities since the text does not reveal the cognitive states of the two entities; we do not know whether one was aware of the other.

ACE defines a class of social relations (PER-SOC) that records named relations like friendship, co-worker, long lasting etc. Also, there already exist systems that detect and classify these relations well. Therefore, even though these relations are directly relevant to our overall goal of social event extraction, we do not annotate, detect or classify these relations in this paper.

4 Tree Kernels, Discrete Structures, and Language

In this section, we give details of the structures and kernel we use for our classification tasks. We also discuss our motivation behind using these methods. Linear learning machines are one of the most popular machines used for classification problems. The objective of a typical classification problem is to learn a function that separates the data into different classes. The data is usually in the form of features extracted from abstract objects like strings, trees, etc. A drawback of learning by using complex functions is that complex functions do not generalize well and thus tend to over-fit. The research community therefore prefers linear classifiers over other complex classifiers. But more often than not, the data is not linearly separable. It can be made linearly separable by increasing the dimensionality of data but then learning suffers from the curse of dimensionality and classification becomes computationally intractable. This is where kernels come to the rescue. The well-known kernel trick aids us in finding similarity between feature vectors in a high dimensional space without having to write down the expanded feature space. The essence of kernel methods is that they compare two feature vectors in high dimensional space by using a dot product that is a function of the dot product of feature vectors in the lower dimensional space. Moreover, Convolution Kernels (first introduced by Haussler (1999)) can be used to compare abstract objects instead of feature vectors. This is because these kernels involve a recursive calculation over the "parts" of a discrete structure. This calculation is usually made computationally efficient using Dynamic Programming techniques. Therefore, Convolution Kernels alleviate the need of feature extraction (which usually requires domain knowledge, results in extraction of incomplete information and introduces noise in the data). Therefore, we use convolution kernels with a linear learning machine (Support Vector Machines) for our classification task.

Now we present the "discrete" structures followed by the kernel we used. We use the structures previously used by Nguyen et al. (2009), and propose one new structure. Although we experimented with all of their structures,[3] here we only present the ones that perform best for our classification task. All the structures and their combinations are derived from a variation of the underlying structures, Phrase Structure Trees (PST) and Dependency Trees (DT). For all trees we first extract their Path Enclosed Tree, which is the smallest common subtree that contains the two target entities (Moschitti, 2004). We use the Stanford parser (Klein and Manning, 2003) to get the basic PSTs and DTs. Following are the structures that we refer to in our experiments and results section:

PET: This refers to the smallest common phrase structure tree that contains the two target entities.

Dependency Words (DW) tree: This is the smallest common dependency tree that contains the two target entities. In Figure 1, since the target entities are at the leftmost and rightmost branch of the dependency tree, this is in fact a DW (ignoring the grammatical relations on the arcs).

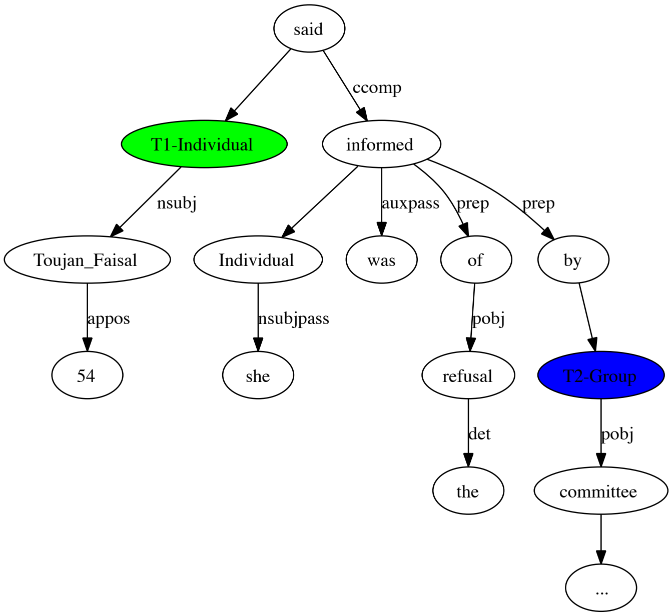

Figure 1: Dependency parse tree for the sentence (in the ACE corpus): "[Toujan Faisal], 54, {said} [she] was {informed} of the refusal by an [Interior Ministry committee] overseeing election preparations."

Grammatical Relation (GR) tree: If we replace the words at the nodes by their relation to their corresponding parent in DW, we get a GR tree. For example, in Figure 1, replacing *Toujan_Faisal* by *nsubj*, *54* by *appos*, *she* by *nsubjpass* and so on.

Grammatical Relation Word (GRW) tree: We get this tree by adding the grammatical relations as separate nodes between a node and its parent. For example, in Figure 1, adding *nsubj* as a node between *T1-Individual* and *Toujan_Faisal*, *appos* as a node between *54* and *Toujan_Faisal*, and so on.

Sequence Kernel of words (SK1): This is the sequence of words between the two entities, including their tags. For our example in Figure 1, it would be *T1-Individual Toujan Faisal 54 said she was informed of the refusal by an T2-Group Interior Ministry committee*.

Sequence in GRW tree (SqGRW): This is the new structure that we introduce which, to the best of

[3] We omitted SK6, which is the worst performing sequence kernel in (Nguyen et al., 2009).

our knowledge, has not been used before for similar tasks. It is the sequence of nodes from one target to the other in the GRW tree. For example, in Figure 1, this would be *Toujan_Faisal nsubj T1-Individual said ccomp informed prep by T2-Group pobj committee*.

We also use combinations of these structures (which we refer to as "combined-structures"). For example, PET_GR_SqGRW means we used the three structures (PET, GR and SqGRW) together with a kernel that calculates similarity between forests.

We use the Partial Tree (PT) kernel, first proposed by Moschitti (2006a), for structures derived from dependency trees and Subset Tree (SST) kernel, proposed by Collins and Duffy (2002), for structures derived from phrase structure trees. PT is a relaxed version of the SST; SST measures the similarity between two PSTs by counting all subtrees common to the two PSTs. However, there is one constraint: all daughter nodes of a node must be included. In PTs this constraint is removed. Therefore, in contrast to SSTs, PT kernels compare many more substructures. They have been used successfully by (Moschitti, 2004) for the task of semantic role labeling.

The choices we have made are motivated by the following considerations. We are interested in modeling classes of events which are characterized by the cognitive states of participants–who is aware of whom. The predicate-argument structure of verbs can encode much of this information very efficiently, and classes of verbs express their predicate-argument structure in similar ways. For example, many verbs of communication can express their arguments using the same pattern: *John talked/spoke/lectured/ranted/testified to Mary about Percy*. Independently of the verb, **John** is in a COG relation with **Percy** and in an INR relation with **Mary**. All these verbs allow us to drop either or both of the prepositional phrases, without altering the interpretation of the remaining constituents. And even more strikingly, any verb that can be put in that position is likely to have this interpretation; for example, we are likely to interpret the neologistic *John gazooked to Mary about Percy* as a similarly structured social event.

The regular relation between verb alternations and meaning components has been extensively studied (Levin, 1993; Schuler, 2005). This regularity in the syntactic predicate-argument structure allows us to overcome lexical sparseness. However, in order to exploit such regularities, we need to have access to a representation which makes the predicate-argument structure clear. Dependency representations do this. Phrase structure representations also represent predicate-argument structure, but in an indirect way through the structural configurations, and we expect this to increase the burden on the learner. (In some phrase structure representations, some arguments and adjuncts are not disambiguated.) When using dependency structures, the SST kernel is far less appealing, since it forces us to always consider all daughter nodes of a node. However, as we have seen, it is certain daughter nodes, such as the presence of a *to* PP and a *about* PP, which are important, while other daughters, such as temporal or locative adjuncts, should be disregarded. The PT kernel allows us to do this.

5 Sampling Methods

In this section we present the data sampling methods we use to deal with data skewness. We employ two well-known data sampling methods on the training data before creating a model for test data; random under-sampling and random over-sampling (Kotsiantis et al., 2006; Japkowicz, 2000; Weiss and Provost, 2001). These techniques are non-heuristic sampling methods that aim at balancing the class proportions by removing examples of the majority class and by duplicating instances of the minority class respectively. The reason for using these techniques is that learning is usually optimized to achieve high accuracy. Therefore, when presented with skewed training data, a classifier may learn the target concept with a high accuracy by only predicting the majority class. But if one looks at the precision, recall, and F-measure, of such a classifier, they will be very low for the minority class. Since, like other researchers, we are evaluating the goodness of a model based on its precision, recall and F-measure and not on the accuracy on the test set, either we should change the optimization function of the classifier or employ data sampling techniques. We employ the latter because by balancing the class ratio, we are presenting the classifier with a more challenging task of achieving a good accuracy when the majority base class is about 50%. The major drawbacks of the two techniques is that under-sampling throws away important information whereas over-sampling is prone to over-fitting (due to data duplication). As our results show, throwing away information about the majority class is much better than the system that tries to learn in an unbalanced scenario, but it performs worse than an approach using data duplication. Since we are using SVMs as a classifier, over-fitting is unlikely as reported by Kolcz et al. (2003).

In order to be sure that we are not over-fitting, we tried another sampling method proposed by Ha and Bunke (1997), which is shown to be good solution to avoid over-fitting by Chawla et al. (2002). This sampling technique proposes to generate synthetic examples of the minority class by "perturbing" the training data. Specifically, Ha and Bunke (1997) produced new synthetic examples for the task of handwritten character recognition by doing operations like rotation and skew on characters. The basic idea is to produce synthetic examples that are "close" to the real example from which these synthetic points are generated. Analogously, we tried two transformations on our dependency tree structures to produce synthetic examples. The first transformation is based on the observation that in control verb constructions, the matrix verb typically does not contribute to the interpretation as a social event or not. In this transformation, we lower the subject to an argument verb if it does not have a subject, and repeat this procedure iteratively. As it turned out, this transformation only occurred 15 times, and therefore it does not serve the purpose of over-sampling. We tried a more relaxed transformation on the rightmost target in the tree. Here, the observation is that for the COG social events, the second target may be very deeply embedded in the tree. For example, in Example 1, Toujan Faisal and the Interior Ministry Committee participate in a COG event (because Faisal is aware of the Committee during the saying event). However, the contents of what Faisal said is only relevant to the extent that it pertains to the committee. The depth of the embedding of the second target creates issues of data sparseness, as the path-enclosed trees become very large and very diverse. Our transformation, therefore, is to move the second target to its grandmother node, attaching it on the left, and to recalculate the path-enclosed tree, which is now smaller. This is repeated iteratively, so that a sentence with a deeply embedded second target can yield a large number of synthesized structures.

6 Experiments And Results

In this section we present experiments and results for our two tasks: social event detection and classification. For the social event detection task, we wish to validate the following research hypotheses. First, we aim to show the importance of using data sampling when evaluating on F-measure; specifically, we expect under-sampling to outperform no sampling, over-sampling to outperform under-sampling, and over-sampling with transformations to out perform over-sampling without transformations. In contrast, the social event classification task does not suffer from data skewness because the INR and COG relations; both occur almost the same number of times. Therefore, sampling methods may not be applied for this task. Second, for both tasks, we expect that a combination of kernels will out-perform individual kernels. Moreover, we expect that dependency trees will have a crucial role in achieving the best performance.

6.1 Experimental Set-up

We use part of ACE data that we annotated for social events. In all, we annotated 138 ACE documents. We retained the ACE entity annotations. We consider all entity mention pairs in a sentence. If our annotators recorded a relation between a pair of entity mentions, we say there is a relation between the corresponding entities. If there are any other pairs of entity mentions for the same pair of entity, we discard those. For all other pairs of entity mentions, we say there is no relation. Out of 138 files, four files did not have any positive or negative examples (because there were very few and sparse entity mentions in these four files). We found a total of 1291 negative examples, 172 examples belonging to class INR and 174 belonging to class COG.

We use Jet's sentence splitter[4] and the Stanford Parser (Klein and Manning, 2003) for phrase structure trees and dependency parses. For classifica-

[4] http://cs.nyu.edu/grishman/jet/jetDownload.html

tion, we used Alessandro Moschitti's SVM-Light-TK package (Moschitti, 2006b) which is built on the SVM-Light implementation of Joakhims (1999). For all our experiments, we perform 5-fold cross-validation. We randomly divide the whole corpus into 5 equal parts, such that no news story (or document) gets divided among two parts. For each fold, we then merge 4 parts to create a training corpus and treat the remaining part as a test corpus. By keeping individual news stories intact, we make sure that vocabulary specific to one story does not unrealistically improve the performance.

6.2 Social Event Detection

Social event detection is the task of detecting if any social event exists between a pair of entities in a sentence. We formulate the problem as a binary classification task by labeling an example that does not have a social event as class -1 and by labeling an example that either has an INR or COG social event as class 1. First we present results for our baseline system. Our baseline system uses various structures and their combinations but without any data balancing. [5]

Kernel	P	R	F1
PET	70.28	21.46	32.38
GR	**87.79**	15.21	25.55
GRW	76.42	8.26	14.8
SqGRW	48.78	6.08	10.38
PET_GR	70.21	**27.76**	**38.89**
PET_GR_SqGRW	71.06	26.74	38.02
GR_SqGRW	82.0	24.47	36.12
GRW_SqGRW	68.19	17.01	25.06
GR_GRW_SqGRW	79.81	21.99	32.57

Table 1: Baseline System for the task of social event detection. The proportion of positive data in training and test set is 21.1% and 20.6% respectively.

Table 1 presents results for our baseline system. Grammatical relation tree structure (GR), a structure derived from dependency tree by replacing the words by their grammatical relations achieves the best precision. This is probably because the classifier learns that if both the arguments of a predicate contain target entities then it is a social event. Among kernels for single structures, the path enclosed tree for PSTs (PET) achieves the best recall. Furthermore, a combination of structures derived from PSTs and DTs performs best. The sequence kernels, perform much worse than SqGRW (F1-measure as low as 0.45). Since it is the same case for all subsequent experiments, we omit them from the discussion.

Kernel	P	R	F1
PET	28.89	77.06	41.96
GR	**35.68**	72.47	47.37
GRW	29.7	83.6	43.6
SqGRW	34.31	**84.15**	**48.61**
PET_GR	34.38	83.94	**48.52**
PET_GR_SqGRW	34.34	83.66	**48.52**
GR_SqGRW	33.45	81.73	47.27
GRW_SqGRW	32.87	**84.44**	47.11
GR_GRW_SqGRW	32.73	83.26	46.82

Table 2: Under-sampled system for the task of relation detection. The proportion of positive examples in the training and test corpus is 50.0% and 20.6% respectively.

We now turn to experiments involving sampling. Table 2 presents results for under-sampling, i.e. randomly removing examples belonging to the negative class until its size matches the positive class. Table 2 shows a large gain in F1-measure of 9.72% absolute over the baseline system (Table 1). We found that worst performing kernel with under-sampling is SK1 with an F1-measure of 39.2% which is better than the best performance without under-sampling. These results make it clear that doing under-sampling greatly improves the performance of the classifier, despite the fact that we are using less training data (fewer negative examples). This is as expected because we are evaluating on F1-measure and the classifier is optimizing for accuracy.

Table 3 presents results for over-sampling i.e. replicating positive examples to achieve an equal number of examples belonging to the positive and negative class. Table 3 shows that the gain over the baseline system now is 22.2% absolute. Also, the gain over the under-sampled system is 12.5%

[5] Although we experimented with many more structures and their combinations, due to space restrictions we mention only the top results.

Kernel	P	R	F1
PET	50.9	57.21	53.62
GR	43.57	67.21	52.59
GRW	46.05	64.15	53.31
SqGRW	42.4	**72.75**	53.5
PET_GR	56.42	66.2	60.63
PET_GR_SqGRW	**57.28**	66.26	**61.11**
GR_SqGRW	44.35	71.17	54.52
GRW_SqGRW	44.77	68.79	54.12
GR_GRW_SqGRW	46.79	71.54	56.45

Table 3: Over-sampled system for the task of relation detection. The proportion of positive examples in the training and test corpus is 50.0% and 20.6% respectively.

absolute. As in the baseline system, a combination of structures performs best. As in the under-sampled system, when the data is balanced, SqGRW (sequence kernel on dependency tree in which grammatical relations are inserted as intermediate nodes) achieves the best recall. Here, the PET and GR kernel perform similar: this is different from the results of (Nguyen et al., 2009) where GR performed much worse than PET for ACE data. This exemplifies the difference in the nature of our event annotations from that of ACE relations. Since the average distance between target entities in the surface word order is higher for our events, the phrase structure trees are bigger. This means that implicit feature space is much sparser and thus not the best representation.

PET	37.04	66.49	47.28
GR	40.39	71.14	51.27
GRW	45.16	66.82	53.47
SqGRW	42.88	70.67	53.22
PET_GR	45.33	70.26	54.71
PET_GR_SqGRW	45.26	**72.97**	**55.67**
GR_SqGRW	43.73	71.47	54.06
GRW_SqGRW	45.70	71.30	55.32
GR_GRW_SqGRW	**45.91**	71.90	**55.70**

Table 4: Over-sampled System with transformation for relation detection. The proportion of positive examples in the training and test corpus is 51.7% and 20.6% respectively.

Table 4 presents results for using the over-sampling method with transformation that produces synthetic positive examples by using a transformation on dependency trees such that the new synthetic examples are “close” to the original examples. This method achieves a gain 16.78% over the baseline system. We expected this system to perform better than the over-sampled system but it does not. This suggests that our over-sampled system is not over-fitting; a concern with using oversampling techniques.

6.3 Social Event Classification

For the social event classification task, we only consider pairs of entities that have an event. Since these events could only be INR or COG, this is a binary classification problem. However, now we are interested in both outcomes of the classification, while earlier we were only interested in knowing how well we were finding relations (and not in how well we were finding “non-relations”). Therefore, accuracy is the relevant metric (Table 5).

Kernel	Acc
PET	76.85
GR	71.04
GRW	76.22
SqGRW	75.78
PET_GR	76.34
PET_GR_SqGRW	**78.72**
GR_SqGRW	75.60
GRW_SqGRW	76.96
GR_GRW_SqGRW	77.29

Table 5: System for the task of relation classification. The two classes are INR and COG, and we evaluate using accuracy (Acc.). The proportion of INR relations in training and test set is 49.7% and 49.63% respectively.

Even though the task of reasoning if an event is about one-way or mutual cognition seems hard, our system beats the chance baseline by 28.72%. These results show that there are significant clues in the lexical and syntactic structures that help in differentiating between interaction and cognition social events. Once again we notice that the combination of kernels works better than single kernels alone, though the difference here is less pronounced. Among the combined-structure approaches, combinations with dependency-derived structures continue to outperform those not including dependency (the best all-phrase structure performer is PET_SK1 with 75.7% accuracy, not shown in Table 5).

7 Conclusion And Future Work

In this paper, we have introduced the novel tasks of social event detection and classification. We show that data sampling techniques play a crucial role for the task of relation detection. Through oversampling we achieve an increase in F1-measure of 22.2% absolute over a baseline system. Our experiments show that as a result of how language expresses the relevant information, dependency-based structures are best suited for encoding this information. Furthermore, because of the complexity of the task, a combination of phrase based structures and dependency-based structures perform the best. This revalidates the observation of Nguyen et al. (2009) that phrase structure representations and dependency representations add complimentary value to the learning task. We also introduced a new sequence structure (SqGRW) which plays a role in achieving the best accuracy for both, social event detection and social event classification tasks.

In the future, we will use other parsers (such as semantic parsers) and explore new types of linguistically motivated structures and transformations. We will also investigate the relation between classes of social events and their syntactic realization.

Acknowledgments

The work was funded by NSF grant IIS-0713548. We thank Dr. Alessandro Moschitti and Truc-Vien T. Nguyen for helping us with re-implementing their system. We acknowledge Boyi Xie for his assistance in implementing the system. We would also like to thank Dr. Claire Monteleoni and Daniel Bauer for useful discussions and feedback.

Abstract

In this paper, we focus on the opinion target extraction as part of the opinion mining task. We model the problem as an information extraction task, which we address based on Conditional Random Fields (CRF). As a baseline we employ the supervised algorithm by Zhuang et al. (2006), which represents the state-of-the-art on the employed data. We evaluate the algorithms comprehensively on datasets from four different domains annotated with individual opinion target instances on a sentence level. Furthermore, we investigate the performance of our CRF-based approach and the baseline in a single- and cross-domain opinion target extraction setting. Our CRF-based approach improves the performance by 0.077, 0.126, 0.071 and 0.178 regarding F-Measure in the single-domain extraction in the four domains. In the cross-domain setting our approach improves the performance by 0.409, 0.242, 0.294 and 0.343 regarding F-Measure over the baseline.

1 Introduction

The automatic extraction and analysis of opinions has been approached on several levels of granularity throughout the last years. As opinion mining is typically an enabling technology for another task, this overlaying system defines requirements regarding the level of granularity. Some tasks only require an analysis of the opinions on a document or sentence level, while others require an extraction and analysis on a term or phrase level. Amongst the tasks which require the finest level of granularity are: a) Opinion question answering - i.e. with questions regarding an entity as in "What do the people like / dislike about X?". b) Recommender systems - i.e. if the system shall only recommend entities which have received good reviews regarding a certain aspect. c) Opinion summarization - i.e. if one wants to create an overview of all positive / negative opinions regarding aspect Y of entity X and cluster them accordingly. All of these tasks have in common that in order to fulfill them, the opinion mining system must be capable of identifying what the opinions in the individual sentences are about, hence extract the opinion targets.

Our goal in this work is to extract opinion targets from user-generated discourse, a discourse type which is quite frequently encountered today, due to the explosive growth of Web 2.0 community websites. Typical sentences which we encounter in this discourse type are shown in the following examples. The opinion targets which we aim to extract are underlined in the sentences, the corresponding opinion expressions are shown in italics.

(1) While none of the features are *earth-shattering*, eCircles does provide a *great* place to keep in touch.

(2) Hyundai's *more-than-modest* refresh has largely addressed all the original car's *weaknesses* while maintaining its price *competitiveness*.

The extraction of opinion targets can be considered as an instance of an information extraction (IE) task (Cowie and Lehnert, 1996). Conditional

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1035–1045,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

Random Fields (CRF) (Lafferty et al., 2001) have been successfully applied to several IE tasks in the past (Peng and McCallum, 2006). A recurring problem, which arises when working with supervised approaches, concerns the domain portability. In the opinion mining context this question has been prominently investigated with respect to opinion polarity analysis (sentiment analysis) in previous research (Aue and Gamon, 2005; Blitzer et al., 2007). Terms as “unpredictable” can express a positive opinion when uttered about the storyline of a movie but a negative opinion when the handling of a car is described. Hence the effects of training and testing a machine learning algorithm for sentiment analysis on data from different domains have been analyzed in previous research. However to the best of our knowledge, these effects have not been investigated regarding the extraction of opinion targets.

The contribution of this paper is a CRF-based approach for opinion targets extraction which tackles the problem of domain portability. We first evaluate our approach in three different domains against a state-of-the art baseline system and then evaluate the performance of both systems in a cross-domain setting. We show that our CRF-based approach outperforms the baseline in both settings, and how the diffrerent combinations of features we introduce influence the results of our CRF-based approach. The remainder of this paper is structured as follows: In Section 2 we discuss the related work, and in Section 3 we describe our CRF-based approach. Section 4 comprises our experimental setup including the description of the dataset we employ in our experiments in Section 4.1 and the baseline system in Section 4.2. The results of our experiments and their discussion follow in Section 5. Finally we draw our conclusions in Section 6.

2 Related Work

In the following we will discuss the related work regarding opinion target extraction and domain adaptation in opinion mining. The discussion of the related work on opinion target extraction is separated in supervised and unsupervised approaches. We conclude with a discussion of the related work on domain adaptation in opinion mining.

2.1 Unsupervised Opinion Target Extraction

The first work on opinion target extraction was done on customer reviews of consumer electronics. Hu and Liu (2004) introduce the task of *feature based summarization*, which aims at creating an overview of the product features commented on in the reviews. Their approach relies on a statistical analysis of the review terms based on association mining. A dataset of customer reviews from five domains was annotated by the authors regarding mentioned product features with respective opinion polarities. The association mining based algorithm yields a precision of 0.72 and a recall of 0.80 in the extraction of a manually selected subset of product features. The same dataset of product reviews was used in the work of Yi et al. (2003). They present and evaluate a complete system for opinion extraction which is based on a statistical analysis based on the Likelihood Ratio Test for opinion target extraction. The Likelihood Ratio Test yields a precision of 0.97 and 1.00 in the task of opinion target (product feature) extraction, recall values are not reported.

Popescu and Etzioni (2005) present the OPINE system for opinion mining on product reviews. Their algorithm is based on an information extraction system, which uses the pointwise mutual information based on the hitcounts of a web-search engine as an input. They evaluate the opinion target extraction separately on the dataset by Hu and Liu (2004). OPINE’s precision is on average 22% higher than the association mining based approach, while having an average 3% lower recall.

Bloom et al. (2007) manually create taxonomies of opinion targets for two datasets. With a handcrafted set of dependency tree paths their algorithm identifies related opinion expressions and targets. Due to the lack of a dataset annotated with opinion expressions and targets, they just evaluate the accuracy of several aspects of their algorithm by manually assessing an output sample. Their algorithm yields an accuracy of 0.75 in the identification of opinion targets.

Kim and Hovy (2006) aim at extracting opinion holders and opinion targets in newswire with semantic role labeling. They define a mapping of the semantic roles identified with FrameNet to the respective opinion elements. As a baseline, they implement an approach based on a dependency parser, which identifies the targets following the dependencies of opinion expressions. They measure the overlap between two human annotators and their algorithm as well as the baseline system. The algorithm based on semantic role labeling yields an F-Measure of 0.315 with annotator1 and 0.127 with annotator2, while the baseline yields an F-Measure of 0.107 and 0.109 regarding opinion target extraction

2.2 Supervised Opinion Target Extraction

Zhuang et al. (2006) present a supervised algorithm for the extraction of opinion expression - opinion target pairs. Their algorithm learns the opinion target candidates and a combination of dependency and part-of-speech paths connecting such pairs from an annotated dataset. They evaluate their system in a cross validation setup on a dataset of user-generated movie reviews and compare it to the results of the Hu and Liu (2004) system as a baseline. Thereby, the system by Zhuang et al. (2006) yields an F-Measure of 0.529 and outperforms the baseline which yields an F-Measure of 0.488 in the task of extracting opinion target - opinion expression pairs.

Kessler and Nicolov (2009) solely focus on identifying which opinion expression is linked to which opinion target in a sentence. They present a dataset of car and camera reviews in which opinion expressions and opinion targets are annotated. Starting with this information, they train a machine learning classifier for identifying related opinion expressions and targets. Their algorithm receives the opinion expression and opinion target annotations as input during runtime. The classifier is evaluated using the algorithm by Bloom et al. (2007) as a baseline. The support vector machine based approach by Kessler and Nicolov (2009) yields an F-Measure of 0.698, outperforming the baseline which yields an F-Measure of 0.445.

2.3 Domain Adaptation in Opinion Mining

The task of creating a supervised algorithm, which when trained on data from domain A, also performs well on data from another domain B, is a domain adaptation problem (Daumé III and Marcu, 2006; Jiang and Zhai, 2007). Aue and Gamon (2005) have investigated this challenge very early in the task of document level sentiment classification (positive / negative). They observe that increasing the amount of training data raises the classification accuracy, but only if the training data is from one source domain. Increasing the training data by mixing domains does not yield any consistent improvements. Blitzer et al. (2007) introduce an extension to a structural correspondence learning algorithm, which was specifically designed to address the task of domain adaptation. Their enhancement aims at identifying pivot features, which are stable across domains. In a series of experiments in document level sentiment classification they show that their extension outperforms the original structural correspondence learning approach. In their error analysis, the authors observe the best results were reached when the training - testing combinations were *Books - DVDs* or *Electronics - Kitchen appliances*. They conclude that the topical relatedness of the domains is an important factor. Furthermore they observe that training the algorithm on a smaller amount of data from a similar domain is more effective than increasing the amount of training data by mixing domains.

3 CRF-based Approach for Opinion Target Extraction

In the following we will describe the features we employ as input for our CRF-based approach. As the development data, we used 29 documents from the movies dataset, 23 documents from the web-services dataset and 15 documents from the cars & cameras datasets.

Token
This feature represents the string of the current token as a feature. Even though this feature is rather obvious, it can have considerable impact on the target extraction performance. If the vocabulary of targets is rather compact for a certain domain (corresponding to a low target type / target ratio), the training data is likely to contain the majority of the target types, which should hence be a good indicator. We will refer to this feature as **tk** in our result tables.

POS
This feature represents the part-of-speech tag of the current token as identified by the Stanford POS Tagger[1]. It can provide some means of lexical disam-

[1] http://nlp.stanford.edu/software/tagger.shtml

biguation, e.g. indicate that the token "sounds" is a noun and not a verb in a certain context. At the same time, the CRF algorithm is provided with additional information to extract opinion targets which are multiword expressions, i.e. noun combinations. We will refer to this feature as **pos** in our result tables.

Short Dependency Path
Previous research has successfully employed paths in the dependency parse tree to link opinion expressions and the corresponding targets (Zhuang et al., 2006; Kessler and Nicolov, 2009). Both works identify direct dependency relations such as "amod" and "nsubj" as the most frequent and at the same time highly accurate connections between a target and an opinion expression. We hence label all tokens which have a direct dependency relation to an opinion expression in a sentence. The Stanford Parser[2] is employed for the constituent and dependency parsing. We will refer to this feature as **dLn** in our result tables.

Word Distance
From the work of Zhuang et al. (2006) we can infer that opinion expressions and their target(s) are not always connected via short paths in the dependency parse tree. Since we cannot capture such paths with the abovementioned feature we introduce another feature which acts as heuristic for identifying the target to a given opinion expression. Hu and Liu (2004) and Yi et al. (2003) have shown that (base) noun phrases are good candidates for opinion targets in the datasets of product reviews. We therefore label the token(s) in the closest noun phrase regarding word distance to each opinion expression in a sentence. We will refer to this feature as **wrdDist** in our result tables.

Opinion Sentence
With this feature, we simply label all tokens occurring in a sentence containing an opinion expression. This feature shall enable the CRF algorithm to distinguish between the occurence of a certain token in a sentence which contains an opinion vs. a sentence without an opinion. We will refer to this feature as **sSn** in our result tables.

Our goal is to extract individual instances of opinion targets from sentences which contain an opinion expression. This can be modeled as a sequence segmentation and labeling task. The CRF algorithm receives a sequence of tokens $t_1 ... t_n$ for which it has to predict a sequence of labels $l_1 ... l_n$. We represent the possible labels following the IOB scheme: *B-Target*, identifying the beginning of an opinion target, *I-Target* identifying the continuation of a target, and *O* for other (non-target) tokens. We model the sentences as a linear chain CRF, which is based on an undirected graph. In the graph, each node corresponds to a token in the sentence and edges connect the adjacent tokens as they appear in the sentence. In our experiments, we use the CRF implementation from the Mallet toolkit[3].

4 Experimental Setup

4.1 Datasets

In our experiments, we employ datasets from three different sources, which span four domains in total (see Table 1). All of them consist of reviews collected from Web 2.0 sites. The first dataset consists of reviews for 20 different movies collected from the Internet Movie Database. It was presented in Zhuang et al. (2006) and annotated regarding opinion target - opinion expression pairs. The second dataset consists of 234 reviews for two different web-services collected from epinions.com, as described in Toprak et al. (2010). The third dataset is an extended version of the data presented in Kessler and Nicolov (2009). The authors have provided us with additional documents, which have been annotated in the meantime. The version of the dataset used in our experiments consists of 179 blog postings regarding different digital cameras and 336 reviews of different cars. In the description of their annotation guidelines, Kessler and Nicolov (2009) refer to opinion targets as mentions. Mentions are all aspects of the review topic, which can be targets of expressed opinions. However, not only mentions which occur as opinion targets were originally annotated, but also mentions which occur in non-opinion sentences. In our experiments, we only use the mentions which occur as targets of opinion expressions.

[3] http://mallet.cs.umass.edu/

All three datasets contain annotations regarding the antecedents of anaphoric opinion targets. In our experimental setup, we do not require the algorithms to also correctly resolve the antecedent of an opinion target representy by a pronoun, as we are solely interested in evaluating the opinion target extraction not any anaphora resolution.

As shown in rows 4 and 5 of Table 1, the documents from the cars and the cameras datasets exhibit a much higher density of opinions per document. 53.5% of the sentences from the cars dataset contain an opinion and in the cameras dataset even 56.1% of the sentences contain an opinion, while in the movies and the web-services reviews just 22.1% and 22.4% of the sentences contain an opinion. Furthermore in the cars and the cameras datasets the lexical variability regarding the opinion targets is substantially larger than in the other two datasets: We calculate *target types* by counting the number of distinct opinion targets in a dataset. We divide this by the sum of all opinion target instances in the dataset. For the cars dataset this ratio is 0.440 and for the cameras dataset it is 0.433, while for the web-services dataset it is 0.306 and for the movies dataset only 0.122. In terms of reviews this means, that in the movie reviews the same movie aspects are repeatedly commented on, while in the cars and the cameras datasets many different aspects of these entities are discussed, which in turn each occur infrequently.

Table 1: Dataset Statistics

	movies	**web-services**	**cars**	**cameras**
Documents	1829	234	336	179
Sentences	24555	6091	10969	5261
Tokens / sentence	20.3	17.5	20.3	20.4
Sentences with target(s)	21.4%	22.4%	51.1%	54.0%
Sentences with opinion(s)	21.4%	22.4%	53.5%	56.1%
Targets	7045	1875	8451	4369
Target types	865	574	3722	1893
Tokens / target	1.21	1.35	1.29	1.42
Avg. targets / opinion sent.	1.33	1.37	1.51	1.53

4.2 Baseline System

In the task of opinion target extraction the supervised algorithm by Zhuang et al. (2006) represents the state-of-the-art on the movies dataset we also employ in our experiments. We therefore use it as a baseline. The algorithm learns two aspects from the labeled training data:

1. A set of opinion target candidates
2. A set of paths in a dependency tree which identify valid opinion target - opinion expression pairs

In our experiments, we learn the full set of opinion targets from the labeled training data in the first step. This is slightly different from the approach in (Zhuang et al., 2006), but we expect that this modification should be beneficial for the overall performance in terms of recall, as we do not remove any learned opinion targets from the candidate list. In the second step, the annotated sentences are parsed and a graph containing the words of a sentence is created, which are connected by the dependency relations between them. For each opinion target - opinion expression pair from the gold standard, the shortest path connecting them is extracted from the dependency graph. A path consists of the part-of-speech tags of the nodes and the dependency types of the edges. Example 3 shows a typical dependency path.

(3) NN - nsubj - NP - amod - JJ

During runtime, the algorithm identifies opinion targets from the candidate list in the training data. The opinion expressions are directly taken from the gold standard, as we focus on the opinion target extraction aspect in this work. The sentences are then parsed and if a valid path between a target and an opinion expression is found in the list of possible paths, then the pair is extracted. Since the dependency paths only identify pairs of single word target and opinion expression candidates, we employ a merging step. Extracted target candidates are merged into a multiword target if they are adjacent in a sentence. Thereby, the baseline system is also capable of extracting multiword opinion targets.

4.3 Metrics

We employ the following requirements in our evaluation of the opinion target extraction: An opinion target must be extracted with exactly the span boundaries as annotated in the gold standard. This is especially important regarding multiword targets. Extracted targets which partially overlap with the annotated gold standard are counted as errors. Hence a target extracted by the algorithm which does not exactly match the boundaries of a target in the gold standard is counted as a false positive (FP), e.g. if "battery life" is annotated as the target in the gold standard, only "battery" or "life" extracted as targets will be counted as FPs. Exact matches between the targets extracted by the algorithm and the gold standard are true positives (TP). We refer to the number of annotated targets in the gold standard as T_{GS}. Precision is calculated as $Precision = \frac{TP}{TP+FP}$, and recall is calculated as $Recall = \frac{TP}{T_{GS}}$. F-Measure is the harmonic mean of precision and recall.

5 Results and Discussion

We investigate the performance of the baseline and the CRF-based approach for opinion target extraction in a single- and cross-domain setting. The single-domain approach assumes that there is a set of training data available for the same domain as the domain the algorithm is being tested on. In this setup, we will both run the baseline and our CRF based system in a 10-fold cross-validation and report results macro averaged over all runs. In the cross-domain approach, we will investigate how the algorithm performs if given training data from domain A while being tested on another domain B. In this setting, we will train the algorithm on the entire dataset A, and test it on the entire dataset B, we hence report one micro averaged result set. In Subsection 5.1 we present the results of both the baseline system and our CRF-based approach in the single-domain setting, in Subsection 5.2 we present the results of the two systems in the cross-domain opinion target extraction.

Table 2: Single-Domain Extraction with Zhuang Baseline

Dataset	Precision	Recall	F-Measure
movies	0.663	0.592	0.625
web-services	0.624	0.394	0.483
cars	0.259	0.426	0.322
cameras	0.423	0.431	0.426

5.1 Single-Domain Results

5.1.1 Zhuang Baseline

As shown in Table 2, the state-of-the-art algorithm of Zhuang et al. (2006) performs best on the movie review dataset and worst on the cars dataset. The results on the movie dataset are higher than originally reported in (Zhuang et al., 2006) (Precision 0.483, Recall 0.585, F-Measure 0.529). We assume that this is due to two reasons: 1. In our task, the algorithm uses the opinion expression annotation from the gold standard. 2. We do not remove any learned opinion target candidates from the training data (See Section 4.2).

During training we observed that for each dataset the lists of possible dependency paths (see Example 3) contained several hundred entries, many of them only occurring once. We assume that the recall of the algorithm is limited by a large variety of possible dependency paths between opinion targets and opinion expressions, since the algorithm cannot link targets and opinion expressions in the testing data if there is no valid candidate dependency path. Furthermore, we observe that for the cars dataset the size of the dependency path candidate list (6642 entries) was approximately five times larger than the dependency graph candidate list for the web-services dataset (1237 entries), which has a comparable size regarding documents. At the same time, the list of target candidates of the cars dataset was approximately eight times larger than the target candidate list for the web-services dataset. We assume that a large number of both the target candidates as well as the dependency path candidates introduces many false positives during the target extraction, hence lowering the precision of the algorithm on the cars dataset considerably.

5.1.2 Our CRF-based Approach

Table 3 shows the results of the opinion target extraction using the CRF algorithm. Row 8 contains the results of the feature configuration, which yields the best performance regarding F-Measure across all datasets. We observe that our aproach outperforms the Zhuang baseline on all datasets. The gain in F-Measure is between 0.077 in the movies domain and 0.175 in the cars domain. Although the CRF-based approach clearly outperforms the baseline system on all four datasets, we also observe the same general trend regarding the individual results: The CRF yields the best results on the movies dataset and the worst results on the cars & cameras dataset.

As shown in the first row, the results when using just the token string and part-of-speech tags as features are very low, especially regarding recall. We observe that the higher the lexical variability of the opinion targets is in a dataset, the lower the results are. If we add the feature based on word distance (row 2), the recall is improved on all datasets, while the precision is slightly lowered on the movies and web-services datasets. The dependency path based feature performs better compared to the word distance heuristic as shown in row 3. The precision is considerably increased on all datasets, on the movies and cars & cameras datasets even reaching the overall highest value. At the same time, we observe an increase of recall on all datasets. The observation made in previous research that short paths in the dependency graph are a high precision indicator of related opinion expressions - opinion targets (Kessler and Nicolov, 2009) is confirmed on all datasets. Adding the information regarding opinion sentences to the basic features of the token string and the part-of-speech tag (row 4) yields the biggest improvements regarding F-Measure on the movies and web-services dataset (+0.433 / +0.383). On the cars & cameras dataset the recall is relatively low again. We assume that this is again due to the high lexical variability, so that the CRF algorithm will encounter many actual opinion targets in the testing data which have not occurred in the training data and will hence not be extracted.

As shown in row 5, if we combine the dependency graph based feature with the word distance heuristic, the results regarding F-Measure are consistently higher than the results of these features in isolation (rows 2 - 4) on all datasets. We conclude that these two features are complementary, as they apparently indicate different kinds of opinion targets which are then correctly extracted by the CRF. If we combine each of the opinion expression related features with the label which identifies opinion sentences in general (rows 6 & 7), we observe that this feature is also complementary to the others. On all datasets the results regarding F-Measure are consistently higher compared to the features in isolation (rows 2 - 4). Row 8 shows the results of all features in combination. Again, we observe the complementarity of the features, as the results of this feature combination are the best regarding F-Measure across all datasets.

In row 9 of the results, we exclude the token string as a feature. In comparison to the full feature combination of row 8 we observe a significant decrease of F-Measure on the movies and the web-services dataset. On the cars dataset we only observe a slight decrease of recall. Interestingly on the cameras dataset we even observe a slight increase of precision which compensates a slight decrease of recall, in turn resulting in stable F-Measure of 0.500 as in the full feature set of row 8.

We have run some additional experiments in which we did not rely on the annotated opinion expressions, but employed a general pupose subjectivity lexicon[4]. Already in the single-domain extraction, we observed that the results declined substantially (e.g. web-services F-Measure: 0.243, movies F-Measure: 0.309, cars F-Measure: 0.192 and cameras F-Measure: 0.198).

We performed a quantitative error analysis on the results of the CRF-based approach in the single-domain setting. In doing so, we focused on misclassifications of B-Target and I-Target instances, as the recall is consistently lower than the precision across all datasets. We observe that most of the recall errors result from one-word opinion targets or the beginning of opinion targets (B-Targets) being missclassified as non-targets (movies 83%, web-services 73%, cars 68%, cameras 64%). For the majority of these missclassifications neither the *dLn* nor the *wDs* features were present (movies 82%, web-services 56%, cars 64%, cameras 61%). We assume that our features cannot capture the structure of more complex sentences very well. Our results indicate that the *dLn* and *wDs* features are complementary, but apparently there are quite a few cases in which the opinion target is neither directly related to the opinion expression in the dependency graph nor close to it in the sentence. One of these sentences, in this case from a camera review, in shown in Example 4.

(4) A lens cap and a strap may not sound very important, but it makes a *huge difference* in the speed and usability of the camera.

In this sentence, the *dLn* and *wDs* features both labeled “speed” which was incorrectly extracted as the target of the opinion. None of the actual targets “lens cap”, “strap” and “camera” have a short dependency path to the opinion expression and “speed” is simply the closest noun to it. Note that although both “speed” and “usability” are attributes of a camera, the opinion in this sentence is about the “lens cap” and “strap”, hence only these attributes are annotated as targets.

5.2 Cross-Domain Results

5.2.1 Zhuang Baseline

Table 4 shows the results of the opinion target extraction with the state-of-the-art system in the cross-domain setting. We observe that the results on all domain combinations are very low. A quantitative error analysis has revealed that there is hardly any overlap in the opinion target candidates between domains, as reflected by the low recall in all configurations. The vocabularies of the opinion targets are too different, hence the performance of the algorithm by Zhuang et al. (2006) is so low. The overlap regarding the dependency paths between domains was however higher. Especially identical short paths could be found across domains which at the same time typically occured quite often. For future work it might be interesting to investigate how the algorithm by Zhuang et al. (2006) performs in the cross-domain setting if the target candidate learning is performed differently, e.g. with a statistical approach as outlined in Section 2.1.

5.2.2 CRF-based Approach

The results of the cross-domain target extraction with the CRF-based algorithm are shown in Table 5. Due to the increase of system configurations introduced by the training - testing data combinations, we had to limit results of the feature combinations reported in the Table. The feature combination *pos, sSn, wDs, dLn* yielded the best results regarding F-Measure. Hence, we report its result as the basic feature set. When comparing the results of the best performing feature / training data combination of our CRF-based approach with the baseline, we observe that our approach outperforms the baseline on all four domains. The gain in F-Measure is 0.409 in the movies domain, 0.242 in the web-services domain, 0.294 in the cars domain and 0.343 in the cameras domain.

Effects of Features

Interestingly with the best performing feature combination from the single-domain extraction, the results regarding recall in the cross-domain extraction are very low[5]. This is due to the fact that the CRF attributed a relatively large weight to the token string

[4] http://www.cs.pitt.edu/mpqa/

[5] Not shown in any result table due to limited space.

Table 4: Cross-Domain Extraction with Zhuang Baseline

Training	Testing	Precision	Recall	F-Measure
web-services	movies	**0.194**	0.032	0.055
cars	movies	0.032	0.034	0.033

movies + cars + cameras	web-services	0.074	0.100	0.080
movies	cars	0.182	0.014	0.026
web-services	cars	0.218	0.028	0.049
cameras	cars	**0.250**	0.121	0.163
cameras + web-services	cars	0.247	**0.131**	**0.171**
movies + web-services	cars	0.246	0.045	0.076
movies	cameras	0.108	0.012	0.022
web-services	cameras	**0.268**	0.048	0.082
cars	cameras	0.125	**0.160**	**0.140**
cars + web-services	cameras	0.119	0.157	0.136
movies + web-services	cameras	0.245	0.063	0.100

feature. As we also observed in the analysis of the baseline results, the overlap of the opinion target vocabularies between domains is low, which resulted in a very small number of targets extracted by the CRF. As shown in Table 5 the results are promising regarding F-Measure if we just leave the token feature out of the configuration.

Effects of Training Data

When analyzing the results of the different training - testing domain configurations we observe the following: In isolation training data from the cameras domain consistently yields the best results regarding F-Measure when the algorithm is run on the datasets from the other three domains. This is particularly interesting since the cameras dataset is the smallest of the four (see Table 1). We investigated whether the CRF algorithm was overfitting to the training datasets by reducing their size to the size of the cameras dataset. However, the reduction of the training data sizes never improved the extraction results regarding F-Measure for the movies, web-serviecs and cars datasets. The good results when training on the cameras dataset are in line with our observations from Section 5.1.2. We noticed that on the cameras dataset the results regarding F-Measure remained stable if the token feature is not used in the training.

In isolation, training only on the cars data yields the second highest results on the movies and web-services datasets and the highest results regarding F-Measure on the cameras data. However, the results of the cars + cameras training data combination indicate that the cameras data does not contribute any additional information during the learning, since the results on both the movies and the web-services datasets are lower than when training only on the cameras data.

Our results also confirm the insights gained by Blitzer et al. (2007), who observed that in cross-domain polarity analysis adding more training data is not always beneficial. Apparently even the smallest training dataset (cameras) contain enough feature instances to learn a model which performs well on the testing data.

We observe that the results of the cross-domain extraction regarding F-Measure come relatively close to the results of the single-domain setting, especially if the token string feature is removed there (see Table 3 row 9). On the cars and the cameras dataset the cross-domain results are even closer to the single-domain results. The features we employ seem to scale well across domains and compensate the difference between training and testing data and the lack of information regarding the target vocabu-

lary.

6 Conclusions

In this paper, we have shown how a CRF-based approach for opinion target extraction performs in a single- and cross-domain setting. We have presented a comparative evaluation of our approach on datasets from four different domains. In the single-domain setting, our CRF-based approach outperforms a supervised baseline on all four datasets. Our error analysis indicates that additional features, which can capture opinions in more complex sentences, are required to improve the performance of the opinion target extraction. Our CRF-based approach also yields promising results in the cross-domain setting. The features we employ scale well across domains, given that the opinion target vocabularies are substantially different. For future work, we might investigate how machine learning algorithms, which are specifically designed for the problem of domain adaptation (Blitzer et al., 2007; Jiang and Zhai, 2007), perform in comparison to our approach. Since three of the features we employed in our CRF-based approach are based on the respective opinion expressions, it is to investigate how to mitigate the possible negative effects introduced by errors in the opinion expression identification if they are not annotated in the gold standard. We observe similar challenges as Choi et al. (2005) regarding the analysis of complex sentences. Although our data is user-generated from Web 2.0 communities, a manual inspection has shown that the documents were of relatively high textual quality. It is to investigate to which extent the approaches taken in the analysis of newswire, such as identifying targets with coreference resolution, can also be applied to our task on user-generated discourse.

Abstract

In this paper, we investigate structured models for document-level sentiment classification. When predicting the sentiment of a subjective document (e.g., as positive or negative), it is well known that not all sentences are equally discriminative or informative. But identifying the useful sentences automatically is itself a difficult learning problem. This paper proposes a joint two-level approach for document-level sentiment classification that simultaneously extracts useful (i.e., subjective) sentences and predicts document-level sentiment based on the extracted sentences. Unlike previous joint learning methods for the task, our approach (1) does not rely on gold standard sentence-level subjectivity annotations (which may be expensive to obtain), and (2) optimizes directly for document-level performance. Empirical evaluations on movie reviews and U.S. Congressional floor debates show improved performance over previous approaches.

1 Introduction

Sentiment classification is a well-studied and active research area (Pang and Lee, 2008). One of the main challenges for document-level sentiment categorization is that not every part of the document is equally informative for inferring the sentiment of the whole document. Objective statements interleaved with the subjective statements can be confusing for learning methods, and subjective statements with conflicting sentiment further complicate the document categorization task. For example, authors of movie reviews often devote large sections to (largely objective) descriptions of the plot (Pang and Lee, 2004). In addition, an overall positive review might still include some negative opinions about an actor or the plot.

Early research on document-level sentiment classification employed conventional machine learning techniques for text categorization (Pang et al., 2002). These methods, however, assume that documents are represented via a flat feature vector (e.g., a bag-of-words). As a result, their ability to identify and exploit subjectivity (or other useful) information at the sentence-level is limited.

And although researchers subsequently proposed methods for incorporating sentence-level subjectivity information, existing techniques have some undesirable properties. First, they typically require gold standard sentence-level annotations (McDonald et al. (2007), Mao and Lebanon (2006)). But the cost of acquiring such labels can be prohibitive. Second, some solutions for incorporating sentence-level information lack mechanisms for controlling how errors propagate from the subjective sentence identification subtask to the main document classification task (Pang and Lee, 2004). Finally, solutions that attempt to handle the error propagation problem have done so by explicitly optimizing for the best *combination* of document- and sentence-level classification accuracy (McDonald et al., 2007). Optimizing for this compromise, when the real goal is to maximize only the document-level accuracy, can potentially hurt document-level performance.

In this paper, we propose a joint two-level model to address the aforementioned concerns. We formulate our training objective to directly optimize for

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1046–1056,
MIT, Massachusetts, USA, 9-11 October 2010.

document-level accuracy. Further, we do not require gold standard sentence-level labels for training. Instead, our training method treats sentence-level labels as hidden variables and *jointly learns* to predict the document label and those (subjective) sentences that best "explain" it, thus controlling the propagation of incorrect sentence labels. And by directly optimizing for document-level accuracy, our model learns to solve the sentence extraction subtask only to the extent required for accurately classifying document sentiment. A software implementation of our method is also publicly available.[1]

For the rest of the paper, we will discuss related work, motivate and describe our model, present an empirical evaluation on movie reviews and U.S. Congressional floor debates datasets and close with discussion and conclusions.

2 Related Work

Pang and Lee (2004) first showed that sentence-level extraction can improve document-level performance. They used a cascaded approach by first filtering out objective sentences and performing subjectivity extractions using a global min-cut inference. Afterward, the subjective extracts were converted into inputs for the document-level sentiment classifier. One advantage of their approach is that it avoids the need for explicit subjectivity annotations. However, like other cascaded approaches (e.g., Thomas et al. (2006), Mao and Lebanon (2006)), it can be difficult to control how errors propagate from the sentence-level subtask to the main document classification task.

Instead of taking a cascaded approach, one can directly modify the training of flat document classifiers using lower level information. For instance, Zaidan et al. (2007) used human annotators to mark the "annotator rationales", which are text spans that support the document's sentiment label. These annotator rationales are then used to formulate additional constraints during SVM training to ensure that the resulting document classifier is less confident in classifying a document that does not contain the rationale versus the original document. Yessenalina et al. (2010) extended this approach to use automatically generated rationales.

A natural approach to avoid the pitfalls associated with cascaded methods is to use joint two-level models that simultaneously solve the sentence-level and document-level tasks (e.g., McDonald et al. (2007), Zaidan and Eisner (2008)). Since these models are trained jointly, the sentence-level predictions affect the document-level predictions and vice-versa. However, such approaches typically require sentence-level annotations during training, which can be expensive to acquire. Furthermore, the training objectives are usually formulated as a compromise between sentence-level and document-level performance. If the goal is to predict well at the document-level, then these approaches are solving a much harder problem that is not exactly aligned with maximizing document-level accuracy.

Recently, researchers within both Natural Language Processing (e.g., Petrov and Klein (2007), Chang et al. (2010), Clarke et al. (2010)) and other fields (e.g., Felzenszwalb et al. (2008), Yu and Joachims (2009)) have analyzed joint multi-level models (i.e., models that simultaneously solve the main prediction task along with important subtasks) that are trained using limited or no explicit lower level annotations. Similar to our approach, the lower level labels are treated as hidden or latent variables during training. Although the training process is non-trivial (and in particular requires a good initialization of the hidden variables), it avoids the need for human annotations for the lower level subtasks. Some researchers have also recently applied hidden variable models to sentiment analysis, but they were focused on classifying either phrase-level (Choi and Cardie, 2008) or sentence-level polarity (Nakagawa et al., 2010).

3 Extracting Hidden Explanations

In this paper, we take the view that each document has a subset of sentences that best explains its sentiment. Consider the "annotator rationales" generated by human judges for the movie reviews dataset (Zaidan et al., 2007). Each rationale is a text span that was identified to support (or explain) its parent document's sentiment. Thus, these rationales can be interpreted as (something close to) a ground truth labeling of the explanatory segments. Using a dataset where each document contains only its rationales,

[1] http://projects.yisongyue.com/svmsle/

Algorithm 1 Inference Algorithm for (2)

```
Input: $x$
Output: $(y, s)$
$s_+ \leftarrow \mathrm{argmax}_{s \in S(x)} \vec{w}^T \Psi(x, +1, s)$
$s_- \leftarrow \mathrm{argmax}_{s \in S(x)} \vec{w}^T \Psi(x, -1, s)$
if $\vec{w}^T \Psi(x, +1, s_+) > \vec{w}^T \Psi(x, -1, s_-)$ then
    Return $(+1, s_+)$
else
    Return $(-1, s_-)$
end if
```

cross validation experiments using an SVM classifier yields 97.44% accuracy – as opposed to 86.33% accuracy when using the full text of the original documents. Clearly, extracting the best supporting segments can offer a tremendous performance boost.

We are interested in settings where human-extracted explanations such as annotator rationales might not be readily available, or are imperfect. As such, we will formulate the set of extracted sentences as latent or hidden variables in our model. Viewing the extracted sentences as latent variables will pose no new challenges during prediction, since the model is expected to predict all labels at test time. We will leverage recent advances in training latent variable SVMs (Yu and Joachims, 2009) to arrive at an effective training procedure.

4 Model

In this section, we present a two-level document classification model. Although our model makes predictions at both the document and sentence levels, it will be trained (and evaluated) only with respect to document-level performance. We begin by presenting the feature structure and inference method. We will then describe a supervised training algorithm based on structural SVMs, and finally discuss some extensions and design decisions.

Let x denote a document, $y = \pm 1$ denote the sentiment (for us, a binary positive or negative polarity) of a document, and s denote a subset of explanatory sentences in x. Let $\Psi(x, y, s)$ denote a joint feature map that outputs features describing the quality of predicting sentiment y using explanation s for document x. We focus on linear models, so given a (learned) weight vector $\vec{w}$, we can write the quality of predicting y (with explanation s) as

$$F(x, y, s; \vec{w}) = \vec{w}^T \Psi(x, y, s), \tag{1}$$

and a document-level sentiment classifier as

$$h(x; \vec{w}) = \underset{y=\pm 1}{\mathrm{argmax}} \max_{s \in S(x)} F(x, y, s; \vec{w}), \tag{2}$$

where $S(x)$ denotes the collection of feasible explanations (e.g., subsets of sentences) for x.

Let x^j denote the j-th sentence of x. We propose the following instantiation of (1),

$$\vec{w}^T \Psi(x, y, s) = \\ \frac{1}{N(x)} \sum_{j \in s} y \cdot \vec{w}_{pol}^T \psi_{pol}(x^j) + \vec{w}_{subj}^T \psi_{subj}(x^j), \tag{3}$$

where the first term in the summation captures the quality of predicting polarity y on sentences in s, the second term captures the quality of predicting s as the subjective sentences, and $N(x)$ is a normalizing factor (which will be discussed in more detail in Section 4.3). We represent the weight vector as

$$\vec{w} = \begin{bmatrix} \vec{w}_{pol} \\ \vec{w}_{subj} \end{bmatrix}, \tag{4}$$

and $\psi_{pol}(x^j)$ and $\psi_{subj}(x^j)$ denote the polarity and subjectivity features of sentence x^j, respectively. Note that ψ_{pol} and ψ_{subj} are disjoint by construction, i.e., $\psi_{pol}^T \psi_{subj} = 0$. We will present extensions in Section 4.5.

For example, suppose ψ_{pol} and ψ_{subj} were both bag-of-words feature vectors. Then we might learn a high weight for the feature corresponding to the word "think" in ψ_{subj} since that word is indicative of the sentence being subjective (but not necessarily indicating positive or negative polarity).

4.1 Making Predictions

Algorithm 1 describes our inference procedure. Recall from (2) that our hypothesis function predicts the sentiment label that maximizes (3). To do this, we compare the best set of sentences that explains a positive polarity prediction with the best set that explains a negative polarity prediction.

We now specify the structure of $S(x)$. In this paper, we use a cardinality constraint,

$$S(x) = \{s \subseteq \{1, \ldots, |x|\} \ : \ |s| \leq f(|x|)\}, \tag{5}$$

Algorithm 2 Training Algorithm for OP 1

```
1: Input: $\{(x_1, y_1), \ldots, (x_N, y_N)\}$ //training data
2: Input: $C$ //regularization parameter
3: Input: $(s_1, \ldots, s_N)$ //initial guess
4: $\vec{w} \leftarrow$ SSVMSolve($C, \{(x_i, y_i, s_i)\}_{i=1}^{N}$)
5: while $\vec{w}$ not converged do
6:     for $i = 1, \ldots, N$ do
7:         $s_i \leftarrow \mathrm{argmax}_{s \in S(x_i)} \vec{w}^T \Psi(x_i, y_i, s)$
8:     end for
9:     $\vec{w} \leftarrow$ SSVMSolve($C, \{(x_i, y_i, s_i)\}_{i=1}^{N}$)
10: end while
11: Return $\vec{w}$
```

where $f(|x|)$ is a function that depends only on the number of sentences in x. For example, a simple function is $f(|x|) = |x| \cdot 0.3$, indicating that at most 30% of the sentences in x can be subjective.

Using this definition of $S(x)$, we can then compute the best set of subjective sentences for each possible y by computing the joint subjectivity and polarity score of each sentence x^j in isolation,

$$y \cdot \vec{w}_{pol}^T \psi_{pol}(x^j) + \vec{w}_{subj}^T \psi_{subj}(x^j),$$

and selecting the top $f(|x|)$ as s (or fewer, if there are fewer than $f(|x|)$ that have positive joint score).

4.2 Training

For training, we will use an approach based on latent variable structural SVMs (Yu and Joachims, 2009).

Optimization Problem 1.

$$\min_{\vec{w}, \xi \geq 0} \frac{1}{2} \|\vec{w}\|^2 + \frac{C}{N} \sum_{i=1}^{N} \xi_i \tag{6}$$

s.t. $\forall i$:

$$\max_{s \in S_i} \vec{w}^T \Psi(x_i, y_i, s) \geq \max_{s' \in S(x_i)} \vec{w}^T \Psi(x_i, -y_i, s') + 1 - \xi_i \tag{7}$$

OP 1 optimizes the standard SVM training objective for binary classification. Each training example has a corresponding constraint (7), which is quantified over the best possible explanation of the training polarity label. Note that we never observe the true explanation for the training labels; they are the hidden or latent variables. The hidden variables are also ignored in the objective function.

As a result, one can interpret OP 1 to be directly optimizing a trade-off between model complexity (as measured using the 2-norm) and document-level classification error in the training set. This has two main advantages over related training approaches. First, it solves the multi-level problem jointly as opposed to separately, which avoids introducing difficult to control propagation errors. Second, it does not require solving the sentence-level task perfectly, and also does not require precise sentence-level training labels. In other words, our goal is to learn to identify the informative (subjective) sentences that best explain the training labels to the extent required for good document classification performance.

OP 1 is non-convex because of the constraints (7). To solve OP 1, we use the combination of the CCCP algorithm (Yuille and Rangarajan, 2003) with cutting plane training of structural SVMs (Joachims et al., 2009), as proposed in Yu and Joachims (2009). Suppose each constraint (7) is replaced by

$$\vec{w}^T \Psi(x_i, y_i, s_i) \geq \max_{s' \in S(x_i)} \vec{w}^T \Psi(x_i, -y_i, s') + 1 - \xi_i,$$

where s_i is some fixed explanation (e.g., an initial guess of the best explanation). Then OP 1 reduces to a standard structural SVM, which can be solved efficiently (Joachims et al., 2009). Algorithm 2 describes our training procedure. Starting with an initial guess s_i for each training example, the training procedure alternates between solving an instance of the resulting structural SVM (called *SSVMSolve* in Algorithm 2) using the currently best known explanations s_i (Line 9), and making a new guess of the best explanations (Line 7). Yu and Joachims (2009) showed that this alternating procedure for training latent variable structural SVMs is an instance of the CCCP procedure (Yuille and Rangarajan, 2003), and so is guaranteed to converge to a local optimum.

For our experiments, we do not train until convergence, but instead use performance on a validation set to choose the halting iteration. Since OP 1 is non-convex, a good initialization is necessary. To generate the initial explanations, one can use an off-the-shelf sentiment classifier such as OpinionFinder[2] (Wilson et al., 2005). For some datasets, there exist documents with annotated sentences, which we

[2] `http://www.cs.pitt.edu/mpqa/opinionfinderrelease/`

can treat either as the ground truth or another (very good) initial guess of the explanatory sentences.

4.3 Feature Representation

Like any machine learning approach, we must specify a useful set of features for the ψ vectors described above. We will consider two types of features.

Bag-of-words. Perhaps the simplest approach is to define ψ using a bag-of-words feature representation, with one feature corresponding to each word in the active lexicon of the corpus. Using such a feature representation might allow us to learn which words have high polarity (e.g., "great") and which are indicative of subjective sentences (e.g., "opinion").

Sentence properties. We can incorporate many useful features to describe sentence subjectivity. For example, subjective sentences might densely populate the end of a document, or exhibit spatial coherence (so features describing previous sentences might be useful for classifying the current sentence). Such features cannot be compactly incorporated into flat models that ignore the document structure.

For our experiments, we normalize each ψ_{subj} and ψ_{pol} to have unit 2-norm.

Joint Feature Normalization. Another design decision is the choice of normalization $N(x)$ in (3). Two straightforward choices are $N(x) = f(|x|)$ and $N(x) = \sqrt{f(|x|)}$, where $f(|x|)$ is the size constraint as described in (5). In our experiments we tried both and found the square root normalization to work better in practice; therefore all the experimental results are reported using $N(x) = \sqrt{f(|x|)}$. The appendix contains an analysis that sheds light on when square root normalization can be useful.

4.4 Incorporating Proximity Information

As mentioned in Section 4.3, it is possible (and likely) for subjective sentences to exhibit spatial coherence (e.g., they might tend to group together). To exploit this structure, we will expand the feature space of ψ_{subj} to include both the words of the current and previous sentence as follows,

$$\psi_{subj}(x, j) = \begin{bmatrix} \psi_{subj}(x^j) \\ \psi_{subj}(x^{j-1}) \end{bmatrix}.$$

The corresponding weight vector can be written as

$$\vec{w}'_{subj} = \begin{bmatrix} \vec{w}_{subj} \\ \vec{w}_{prevSubj} \end{bmatrix}.$$

By adding these features, we are essentially assuming that the words of the previous sentence are predictive of the subjectivity of the current sentence.

Alternative approaches include explicitly accounting for this structure by treating subjective sentence extraction as a sequence-labeling problem, such as in McDonald et al. (2007). Such structure formulations can be naturally encoded in the joint feature map. Note that the inference procedure in Algorthm 1 is still tractable, since it reduces to comparing the best sequence of subjective/objective sentences that explains a positive sentiment versus the best sequence that explains a negative sentiment. For this study, we chose not to examine this more expressive yet more complex structure.

4.5 Extensions

Though our initial model (3) is simple and intuitive, performance can depend heavily on the quality of latent variable initialization and the quality of the feature structure design. Consider the case where the initialization contains only objective sentences that do not convey any sentiment. Then all the features initially available during training are generated from these objective sentences and are thus useless for sentiment classification. In other words, too much useful information has been suppressed for the model to make effective decisions. To hedge against learning poor models due to using a poor initialization and/or a suboptimal feature structure, we now propose extensions that incorporate information from the entire document.

We identify the following desirable properties that any such extended model should satisfy:

(A) The model should be linear.

(B) The model should be trained jointly.

(C) The component that models the entire document should influence which sentences are extracted.

The first property stems from the fact that our approach relies on linear models. The second property is desirable since joint training avoids error propagation that can be difficult to control. The third property deals with the information suppression issue.

4.5.1 Regularizing Relative to a Prior

We first consider a model that satisfies properties (A) and (C). Using the representation in (4), we propose a training procedure that regularize $\vec{w}_{pol}$ relative to a prior model. Suppose we have a weight vector $\vec{w}_0$ which indicated the a priori guess of the contribution of each corresponding feature, then we can train our model using OP 2,

Optimization Problem 2.

$$\min_{\vec{w},\xi\geq 0} \frac{1}{2}\|\vec{w}-\vec{w}_0\|^2 + \frac{C}{N}\sum_{i=1}^{N}\xi_i$$

$$\textit{s.t.}\ \forall i:$$

$$\max_{s\in S_i} \vec{w}^T\Psi(x_i,y_i,s) \geq \max_{s'\in S(x_i)} \vec{w}^T\Psi(x_i,-y_i,s') + 1 - \xi_i$$

For our experiments, we use

$$\vec{w}_0 = \begin{bmatrix} \vec{w}_{doc} \\ 0 \end{bmatrix},$$

where $\vec{w}_{doc}$ denotes a weight vector trained to classify the polarity of entire documents. Then one can interpret OP 2 as enforcing that the polarity weights $\vec{w}_{pol}$ not be too far from $\vec{w}_{doc}$. Note that $\vec{w}_0$ must be available before training. Therefore this approach does not satisfy property (B).

4.5.2 Extended Feature Space

One simple way to satisfy all three aforementioned properties is to jointly model not only polarity and subjectivity of the extracted sentences, but also polarity of the entire document. Let $\vec{w}_{doc}$ denote the weight vector used to model the polarity of entire document x (so the document polarity score is then $\vec{w}_{doc}^T\psi_{pol}(x)$). We can also incorporate this weight vector into our structured model to compute a smoothed polarity score of each sentence via $\vec{w}_{doc}^T\psi_{pol}(x^j)$. Following this intuition, we propose the following structured model,

$$\vec{w}^T\Psi(x,y,s) = \frac{y}{N(x)}\left(\sum_{j\in s}\left(\vec{w}_{pol}^T\psi_{pol}(x^j) + \vec{w}_{doc}^T\psi_{pol}(x^j)\right)\right) + \frac{1}{N(x)}\left(\sum_{j\in s}\vec{w}_{subj}^T\psi_{subj}(x^j)\right) + y\cdot\vec{w}_{doc}^T\psi_{pol}(x)$$

where the weight vector is now

$$\vec{w} = \begin{bmatrix} \vec{w}_{pol} \\ \vec{w}_{subj} \\ \vec{w}_{doc} \end{bmatrix}.$$

Training this model via OP 1 achieves that $\vec{w}_{doc}$ is (1) used to model the polarity of the entire document, and (2) used to compute a smoothed estimate of the polarity of the extracted sentences. This satisfies all three properties (A), (B), and (C), although other approaches are also possible.

5 Experiments

5.1 Experimental Setup

We evaluate our methods using the Movie Reviews and U.S. Congressional Floor Debates datasets, following the setup used in previous work for comparison purposes.[3]

Movie Reviews. We use the movie reviews dataset from Zaidan et al. (2007) that was originally released by Pang and Lee (2004). This version contains annotated rationales for each review, which we use to generate an additional initialization during training (described below). We follow exactly the experimental setup used in Zaidan et al. (2007).[4]

U.S. Congressional Floor Debates. We also use the U.S. Congressional floor debates transcripts from Thomas et al. (2006). The data was extracted from GovTrack (http://govtrack.us), which has all available transcripts of U.S. floor debates in the House of Representatives in 2005. As in previous work, only debates with discussions of "controversial" bills were considered (where the losing side had at least 20% of the speeches). The goal is to predict the vote ("yea" or "nay") for the speaker of each speech segment. For our experiments, we evaluate our methods using the speaker-based speech-segment classification setting as described in Thomas et al. (2006).[5]

[3] Datasets in the required format for *SVM*^{sle} are available at `http://www.cs.cornell.edu/~ainur/data.html`

[4] Since the rationale annotations are available for nine out of 10 folds, we used the 10-th fold as the blind test set. We trained nine different models on subsets of size eight, used the remaining fold as the validation set, and then measured the average performance on the final test set.

[5] In the other setting described in Thomas et al. (2006) (segment-based speech-segment classification), around 39% of

Table 1: Summary of the experimental results for the Movie Reviews (top) and U.S. Congressional Floor Debates (bottom) datasets using *SVM*^{sle}, *SVM*^{sle} w/ Prior and *SVM*$^{sle}_{fs}$ with and without proximity features.

INITIALIZATION	*SVM*^{sle}	+ Prox.Feat.	*SVM*^{sle} w/ Prior	+ Prox.Feat.	*SVM*$^{sle}_{fs}$	+ Prox.Feat.
Random 30%	87.22	85.44	87.61	87.56	89.50	88.22
Last 30%	89.72 $*$	88.83	90.50 $*$	90.00 $*$	91.06 $\star$	91.22 $\star$
OpinionFinder	91.28 $\star$	90.89 $\star$	91.72 $\star$	93.22 $\star$	92.50 $\star$	92.39 $\star$
Annot.Rationales	91.61 $\star$	92.00 $\star$	92.67 $\star$	92.00 $\star$	92.28 $\star$	93.22 $\star$

INITIALIZATION	*SVM*^{sle}	+ Prox.Feat.	*SVM*^{sle} w/ Prior	+ Prox.Feat.	*SVM*$^{sle}_{fs}$	+ Prox.Feat.
Random 30%	78.84	73.14	78.49	76.40	77.33	73.84
Last 30%	73.26	73.95	71.51	73.60	67.79	73.37
OpinionFinder	77.33	79.53	77.09	78.60	77.67	77.09

– For Movie Reviews, the SVM baseline accuracy is 88.56%. A $\star$ (or $*$) indicates statically significantly better performance than baseline according to the paired t-test with $p < 0.001$ (or $p < 0.05$).
– For U.S. Congressional Floor Debates, the SVM baseline accuracy is 70.00%. Statistical significance cannot be calculated because the data comes in a single split.

Since our training procedure solves a non-convex optimization problem, it requires an initial guess of the explanatory sentences. We use an explanatory set size (5) of 30% of the number of sentences in each document, $L = \lceil 0.3 \cdot |x| \rceil$, with a lower cap of 1. We generate initializations using OpinionFinder (Wilson et al., 2005), which were shown to be a reasonable substitute for human annotations in the Movie Reviews dataset (Yessenalina et al., 2010).[6]

We consider two additional (baseline) methods for initialization: using a random set of sentences, and using the last 30% of sentence in the document. In the Movie Reviews dataset, we also use sentences containing human-annotator rationales as a final initialization option. No such manual annotations are available for the Congressional Debates.

5.2 Experimental Results

We evaluate three versions of our model: the initial model (3) which we call *SVM*^{sle} (**SVM**s for **S**entiment classification with **L**atent **E**xplanations), *SVM*^{sle} regularized relative to a prior as described in Section 4.5.1 which we refer to as *SVM*^{sle} w/ Prior,[7] and the feature smoothing model described in Section 4.5.2 which we call *SVM*$^{sle}_{fs}$. Due to the difficulty of selecting a good prior, we expect *SVM*$^{sle}_{fs}$ to exhibit the most robust performance.

Table 1 shows a comparison of our proposed methods on the two datasets. We observe that *SVM*$^{sle}_{fs}$ provides both strong and robust performance. The performance of *SVM*^{sle} is generally better when trained using a prior than not in the Movie Reviews dataset. Both extensions appear to hurt performance in the U.S. Congressional Floor Debates dataset. Using OpinionFinder to initialize our training procedure offers good performance across both datasets, whereas the baseline initializations exhibit more erratic performance behavior.[8] Unsurprisingly, initializing using human annotations (in the Movie Reviews dataset) can offer further improvement. Adding proximity features (as described in Section 4.4) in general seems to improve performance when using a good initialization, and hurts performance otherwise.

the documents in the whole dataset contain only 1-3 sentences, making it an uninteresting setting to analyze with our model.

[6] We select all sentences whose majority vote of OpinionFinder word-level polarities matches the document's sentiment. If there are fewer than L sentences, we add sentences starting from the end of the document. If there are more, we remove sentences starting from the beginning of the document.

[7] We either used the same value of C to train both standard SVM model and *SVM*^{sle} w/ Prior or used the best standard SVM model on the validation set to train *SVM*^{sle} w/ Prior. We chose the combination that works the best on the validation set.

[8] Using the random initialization on the U.S. Congressional Floor Debates dataset offers surprisingly good performance.

Table 2: Comparison of SVM^{sle}_{fs} with previous work on the Movie Reviews dataset. We considered two settings: when human annotations are available (Annot. Labels), and when they are unavailable (No Annot. Labels).

	METHOD	ACC
Baseline	SVM	88.56
Annot. Labels	Zaidan et al. (2007)	92.20

	SVM^{sle}_{fs}+ Prox.Feat.	77.09

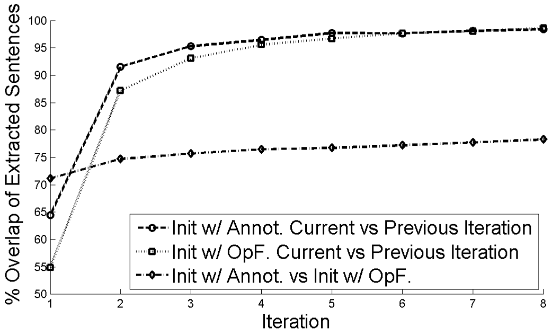

Figure 1: Overlap of extracted sentences from different SVM^{sle}_{fs} models on the Movie Reviews training set.

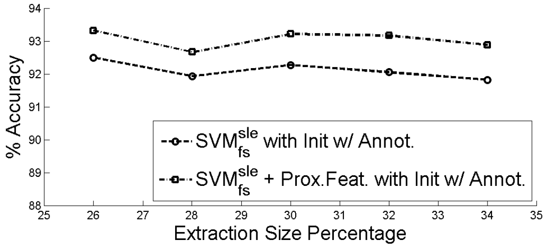

Figure 2: Test accuracy on the Movie Reviews dataset for SVM^{sle}_{fs} while varying extraction size.

Tables 2 and 3 show a comparison of SVM^{sle}_{fs} with previous work on the Movie Reviews and U.S. Congressional Floor Debates datasets, respectively. For the Movie Reviews dataset, we considered two settings: when human annotations are available, and when they are not (in which case we initialized using OpinionFinder). For the U.S. Congressional Floor Debates dataset we used only the latter setting, since there are no annotations available for this dataset. In all cases we observe SVM^{sle}_{fs} showing improved performance compared to previous results.

Training details. We tried around 10 different values for C parameter, and selected the final model based on the validation set. The training procedure alternates between training a standard structural SVM model and using the subsequent model to re-label the latent variables. We selected the halting iteration of the training procedure using the validation set. When initializing using human annotations for the Movie Reviews dataset, the halting iteration is typically the first iteration, whereas the halting iteration is typically chosen from a later iteration when initializing using OpinionFinder.

Figure 1 shows the per-iteration overlap of extracted sentences from SVM^{sle}_{fs} models initialized using OpinionFinder and human annotations on the Movie Reviews training set. We can see that training has approximately converged after about 10 iterations.[9] We can also see that both models iteratively learn to extract sentences that are more similar to each other than their respective initializations (the overlap between the two initializations is 57%). This is an indicator that our learning problem, despite being non-convex and having multiple local optima, has a reasonably large “good” region that can be approached using different initialization methods.

Varying the extraction size. Figure 2 shows how accuracy on the test set of SVM^{sle}_{fs} changes on the Movie Reviews dataset as a function of varying the extraction size $f(|x|)$ from (5). We can see that performance changes smoothly[10] (and so is robust), and that one might see further improvement from more

[9] The number of iterations required to converge is an upper bound on the number of iterations from which to choose the halting iteration (based on a validation set).

[10] The smoothness will depend on the initialization.

Table 4: Example ”yea” speech with ***Latent Explanations*** from the U.S. Congressional Floor Debates dataset predicted by SVM^{sle}_{fs} with OpinionFinder initialization. Latent Explanations are preceded by solid circles with numbers denoting their preference order (1 being most preferred by SVM^{sle}_{fs}). The five least subjective sentences are preceded by circles with numbers denoting the subjectivity order (1 being least subjective according to SVM^{sle}_{fs}).

❷ Mr. Speaker, I am proud to stand on the house floor today to speak in favor of the Stem Cell Research Enhancement Act, legislation which will bring hope to millions of people suffering from disease in this nation. ❸ I want to thank Congresswoman Degette and Congressman Castle for their tireless work in bringing this bill to the house floor for a vote.

① The discovery of embryonic stem cells is a major scientific breakthrough. ⑤ Embryonic stem cells have the potential to form any cell type in the human body. This could have profound implications for diseases such as Alzheimer’s, Parkinson’s, various forms of brain and spinal cord disorders, diabetes, and many types of cancer. ② According to the Coalition for the Advancement of Medical Research, there are at least 58 diseases which could potentially be cured through stem cell research.

That is why more than 200 major patient groups, scientists, and medical research groups and 80 Nobel Laureates support the Stem Cell Research Enhancement Act. ③ They know that this legislation will give us a chance to find cures to diseases affecting 100 million Americans.

I want to make clear that I oppose reproductive cloning, as we all do. I have voted against it in the past. ***❹ However, that is vastly different from stem cell research and as an ovarian cancer survivor, I am not going to stand in the way of science.***

Permitting peer-reviewed Federal funds to be used for this research, combined with public oversight of these activities, is our best assurance that research will be of the highest quality and performed with the greatest dignity and moral responsibility. The policy President Bush announced in August 2001 has limited access to stem cell lines and has stalled scientific progress.

As a cancer survivor, I know the desperation these families feel as they wait for a cure. ④ This congress must not stand in the way of that progress. ***❺ We have an opportunity to change the lives of millions, and I hope we take it. ❶ I urge my colleagues to support this legislation.***

careful tuning of the size constraint.

Examining an example prediction. Our proposed methods are not designed to extract interpretable explanations, but examining the extracted explanations might still yield meaningful information. Table 4 contains an example speech from the U.S. Congressional Floor Debates test set, with Latent Explanations found by SVM^{sle}_{fs} highlighted in boldface. This speech was made in support of the Stem Cell Research Enhancement Act. For comparison, Table 4 also shows the five least subjective sentences according to SVM^{sle}_{fs}. Notice that most of these “objective” sentences can plausibly belong to speeches made in opposition to bills that limit stem cell research funding. That is, they do not clearly indicate the speaker’s stance towards the specific bill in question. We can thus see that our approach can indeed learn to infer sentences that are essential to understanding the document-level sentiment.

6 Discussion

Making good structural assumptions simplifies the development process. Compared to methods that modify the training of flat document classifiers (e.g., Zaidan et al. (2007)), our approach uses fewer parameters, leading to a more compact and faster training stage. Compared to methods that use a cascaded approach (e.g., Pang and Lee (2004)), our approach is more robust to errors in the lower-level subtask due to being a joint model.

Introducing latent variables makes the training procedure more flexible by not requiring lower-level labels, but does require a good initialization (i.e., a reasonable substitute for the lower-level labels). We believe that the widespread availability of off-the-shelf sentiment lexicons and software, despite being developed for a different domain, makes this issue less of a concern, and in fact creates an opportunity for approaches like ours to have real impact.

One can incorporate many types of sentence-level information that cannot be directly incorporated into a flat model. Examples include scores from another sentence-level classifier (e.g., from Nakagawa et. al (2010)) or combining phrase-level polarity scores (e.g., from Choi and Cardie (2008)) for each sentence, or features that describe the position of the sentence in the document.

Most prior work on the U.S. Congressional Floor Debates dataset focused on using relationships between speakers such as agreement (Thomas et al., 2006; Bansal et al., 2008), and used a global mincut inference procedure. However, they require all test instances to be known in advance (i.e., their formulations are transductive). Our method is not limited to the transductive setting, and instead exploits a different and complementary structure: the latent explanation (i.e., only some sentences in the speech are indicative of the speaker's vote).

In a sense, the joint feature structure used in our model is the simplest that could be used. Our model makes no explicit structural dependencies between sentences, so the choice of whether to extract each sentence is essentially made independently of other sentences in the document. More sophisticated structures can be used if appropriate. For instance, one can formulate the sentence extraction task as a sequence labeling problem similar to (McDonald et al., 2007), or use a more expressive graphical model such as in (Pang and Lee, 2004; Thomas et al., 2006). So long as the global inference procedure is tractable or has a good approximation algorithm, then the training procedure is guaranteed to converge with rigorous generalization guarantees (Finley and Joachims, 2008). Since any formulation of the extraction subtask will suppress information for the main document-level task, one must take care to properly incorporate smoothing if necessary.

Another interesting direction is training models to predict not only sentiment polarity, but also whether a document is objective. For example, one can pose a three class problem ("positive", "negative", "objective"), where objective documents might not necessarily have a good set of (subjective) explanatory sentences, similar to (Chang et al., 2010).

7 Conclusion

We have presented latent variable structured models for the document sentiment classification task. These models do not rely on sentence-level annotations, and are trained jointly (over both the document and sentence levels) to directly optimize document-level accuracy. Experiments on two standard sentiment analysis datasets showed improved performance over previous results.

Our approach can, in principle, be applied to any classification task that is well modeled by jointly solving an extraction subtask. However, as evidenced by our experiments, proper training does require a reasonable initial guess of the extracted explanations, as well as ways to mitigate the risk of the extraction subtask suppressing too much information (such as via feature smoothing).

Appendix

Recall that all the ψ_{subj} and ψ_{pol} vectors have unit 2-norm, which is assumed here to be desirable. We now show that using $N(x) = \sqrt{f(|x|)}$ achieves a similar property for $\Psi(x, y, s)$. We can write the squared 2-norm of $\Psi(x, y, s)$ as

$$|\Psi(x,y,s)|^2 = \frac{1}{N(x)^2}\left[\sum_{j\in s} y\cdot\psi_{pol}(x^j) + \psi_{subj}(x^j)\right]^2$$
$$= \frac{1}{f(|x|)}\left[\left(\sum_{j\in s}\psi_{pol}(x^j)\right)^2 + \left(\sum_{j\in s}\psi_{subj}(x^j)\right)^2\right],$$

where the last equality follows from the fact that

$$\psi_{pol}(x^j)^T\psi_{subj}(x^j) = 0,$$

due to the two vectors using disjoint feature spaces by construction. The summation of the $\psi_{pol}(x^j)$ terms is written as

$$\begin{aligned}\left(\sum_{j\in s}\psi_{pol}(x^j)\right)^2 &= \sum_{j\in s}\sum_{i\in s}\psi_{pol}(x^j)^T\psi_{pol}(x^i)\\ &\approx \sum_{j\in s}\psi_{pol}(x^j)^T\psi_{pol}(x^j) \qquad (8)\\ &= \sum_{j\in s} 1 \le f(|x|),\end{aligned}$$

where (8) follows from the sparsity assumption that

$$\forall i \neq j:\ \psi_{pol}(x^j)^T\psi_{pol}(x^i) \approx 0.$$

A similar argument applies for the $\psi_{subj}(x^j)$ terms. Thus, by choosing $N(x) = \sqrt{f(|x|)}$ the joint feature vectors $\Psi(x, y, s)$ will have approximately equal magnitude as measured using the 2-norm.

Abstract

In this paper, we introduce a method that automatically builds text classifiers in a new language by training on already labeled data in another language. Our method transfers the classification knowledge across languages by translating the model features and by using an Expectation Maximization (EM) algorithm that naturally takes into account the ambiguity associated with the translation of a word. We further exploit the readily available unlabeled data in the target language via semi-supervised learning, and adapt the translated model to better fit the data distribution of the target language.

1 Introduction

Given the accelerated growth of the number of multilingual documents on the Web and elsewhere, the need for effective multilingual and cross-lingual text processing techniques is becoming increasingly important. There is a growing number of methods that use data available in one language to build text processing tools for another language, for diverse tasks such as word sense disambiguation (Ng et al., 2003), syntactic parsing (Hwa et al., 2005), information retrieval (Monz and Dorr, 2005), subjectivity analysis (Mihalcea et al., 2007), and others.

In this paper, we address the task of *cross-lingual text classification* (CLTC), which builds text classifiers for multiple languages by using training data in one language, thereby avoiding the costly and time-consuming process of labeling training data for each individual language. The main idea underlying our approach to CLTC is that although content can be expressed in different forms in different languages, there is a significant amount of knowledge that is shared for similar topics that can be effectively used to port topic classifiers across languages.

Previous methods for CLTC relied mainly on machine translation, by translating the training data into the language of the test data or vice versa, so that both training and test data belong to the same language. Monolingual text classification algorithms can then be applied on these translated data. Although intuitive, these methods suffer from two major drawbacks.

First, most off-the-shelf machine translation systems typically generate only their best translation for a given text. Since machine translation is known to be a notoriously hard problem, applying monolingual text classification algorithms directly on the erroneous translation of training or test data may severely deteriorate the classification accuracy.

Second, similar to domain adaptation in statistical machine learning, due to the discrepancy of data distribution between the training domain and test domain, data distribution across languages may vary because of the difference of culture, people's interests, linguistic expression in different language regions. So even if the translation of training or test data is perfectly correct, the cross language classifier may not perform as well as the monolingual one trained and tested on the data from the same language.

In this paper, we propose a new approach to CLTC, which trains a classification model in the source language and ports the model to the target language, with the translation knowledge learned using the EM algorithm. Unlike previous methods based on machine translation (Fortuna and Shawe-Taylor, 2005), our method takes into account dif-

MIT, Massachusetts, USA, 9-11 October 2010.

ferent possible translations for model features. The translated model serves as an initial classifier for a semi-supervised process, by which the model is further adjusted to fit the distribution of the target language. Our method does not require any labeled data in the target language, nor a machine translation system. Instead, the only requirement is a reasonable amount of unlabeled data in the target language, which is often easy to obtain.

In the following sections, we first review related work. In section 3, we introduce our method that translates the classification model with the translation knowledge learned using the EM algorithm. Section 4 describes model adaptation by training the translated model with unlabeled documents in the target language. Experiments and evaluations are presented in section 5 and finally we conclude the paper in section 6.

2 Related Work

Text classification has rightfully received a lot of attention from both the academic and industry communities, being one of the areas in natural language processing that has a very large number of practical applications. Text classification techniques have been applied to many diverse problems, ranging from topic classification (Joachims, 1997), to genre detection (Argamon et al., 1998), opinion identification (Pang and Lee, 2004), spam detection (Sahami et al., 1998), gender and age classification (Schler et al., 2006).

Text classification is typically formulated as a learning task, where a classifier learns how to distinguish between categories in a given set, using features automatically extracted from a collection of documents. In addition to the learning methodology itself, the accuracy of the text classifier also depends to a large extent upon the amount of training data available at hand. For instance, distinguishing between two categories for which thousands of manually annotated examples are already available is expected to perform better than trying to separate categories that have only a handful of labeled documents.

Some of the most successful approaches to date for text classification involve the use of machine learning methods, which assume that enough annotated data is available such that a classification model can be automatically learned. These include algorithms such as Naive Bayes (Joachims, 1997; McCallum and Nigam, 1998), Rocchio classifiers (Joachims, 1997; Moschitti, 2003), Maximum Entropy (Nigam et al., 1999) or Support Vector Machines (Vapnik, 1995; Joachims, 1998). If only a small amount of annotated data is available, the alternative is to use semi-supervised bootstrapping methods such as co-training or self-training, which can also integrate raw unlabeled data into the learning model (Blum and Mitchell, 1998; Nigam and Ghani, 2000).

Despite the attention that monolingual text classification has received from the research community, there is only very little work that was done on cross-lingual text classification. The work that is most closely related to ours is (Gliozzo and Strapparava, 2006), where a multilingual domain kernel is learned from comparable corpora, and subsequently used for the cross-lingual classification of texts. In experiments run on Italian and English, Gliozzo and Strapparava showed that the multilingual domain kernel exceeds by a large margin a bag-of-words approach. Moreover, they demonstrated that the use of a bilingual dictionary can drastically improve the performance of the models learned from corpora.

(Fortuna and Shawe-Taylor, 2005; Olsson et al., 2005) studied the use of machine translation tools for the purpose of cross language text classification and mining. These approaches typically translate the training data or test data into the same language, followed by the application of a monolingual classifier. The performance of such classifiers very much depends on the quality of the machine translation tools. Unfortunately, the development of statistical machine translation systems (Brown et al., 1993) is hindered by the lack of availability of parallel corpora and the quality of their output is often erroneous. Several methods were proposed (Shi et al., 2006; Nie et al., 1999) to automatically acquire a large quantity of parallel sentences from the web, but such web data is however predominantly confined to a limited number of domains and language pairs.

(Dai et al., 2007) experimented with the use of transfer learning for text classification. Although in this method the transfer learning is performed across different domains in the same language, the underlying principle is similar to CLTC in the sense that different domains or languages may share a significant amount of knowledge in similar classification tasks. (Blum and Mitchell, 1998) employed semi-supervised learning for training text classifiers. This method bootstraps text classifiers with only unlabeled data or a small amount of labeled training data, which is close to our setting that tries to leverage labeled data and unlabeled data in different languages to build text classifiers.

Finally, also closely related is the work carried out in the field of sentiment and subjectivity analysis for cross-lingual classification of opinions. For instance, (Mihalcea et al., 2007) use an English corpus annotated for subjectivity along with parallel text to build a subjectivity classifier for Romanian. Similarly, (Banea et al., 2008) propose a method based on machine translation to generate parallel texts, followed by a cross-lingual projection of subjectivity labels, which are used to train subjectivity annotation tools for Romanian and Spanish. A related, yet more sophisticated technique is proposed in (Wan, 2009), where a co-training approach is used to leverage resources from both a source and a target language. The technique is tested on the automatic sentiment classification of product reviews in Chinese, and showed to successfully make use of both cross-language and within-language knowledge.

3 Cross Language Model Translation

To make the classifier applicable to documents in a foreign language, we introduce a method where model features that are learned from the training data are translated from the source language into the target language. Using this translation process, a feature associated with a word in the source language is transferred to a word in the target language so that the feature is triggered when the word occurs in the target language test document.

In a typical translation process, the features would be translated by making use of a bilingual dictionary. However, this translation method has a major drawback, due to the ambiguity usually associated with the entries in a bilingual dictionary: a word in one language can have multiple translations in another language, with possibly disparate meanings. If an incorrect translation is selected, it can distort the classification accuracy, by introducing erroneous features into the learning model. Therefore, our goal is to minimize the distortion during the model translation process, in order to maximize the classification accuracy in the target language.

In this paper, we introduce a method that employs the EM algorithm to automatically learn feature translation probabilities from labeled text in the source language and unlabeled text in the target language. Using the feature translation probabilities, we can derive a classification model for the target language from a mixture model with feature translations.

3.1 Learning Feature Translation Probabilities with EM Algorithm

Given a document d from the document collection D in the target language, the probability of generating the document $P(d)$ is the mixture of generating d with different classes $c \in C$:

$$P(d) = \sum_c P(d|c)P(c)$$

In our cross-lingual setting, we view the generation of d given a class c as a two step process. In the first step, a pseudo-document d' is generated in the source language, followed by a second step, where d' is translated into the observed document d in the target language. In this generative model, d' is a latent variable that cannot be directly observed. Since d could have multiple translations d' in the source language, the probability of generating d can then be reformulated as a mixture of probabilities as in the following equation.

$$P(d) = \sum_c P(c) \sum_{d'} P(d|d', c)P(d'|c)$$

According to the bag-of-words assumption, the document translation probability $P(d|d', c)$ is the product of the word translation probabilities $P(w_i|w'_i, c)$, where w'_i in d' is the source language word that w_i is translated from. $P(d'|c)$ is the product of $P(w'_i|c)$. The formula is rewritten as:

$$P(d) = \sum_c P(c) \sum_{d'} \prod_{i=1}^{l} P(w_i|w'_i, c)P(w'_i|c)$$

where w_i is the i^{th} word of the document d with l words. The prior probability $P(c)$ and the probability of the source language word w' given class c are estimated using the labeled training data in the source language, so we use them as known parameters. $P(w_i|w'_i, c)$ is the probability of translating the word w'_i in the source language to the word w_i in the target language given class c, and these are the parameters we want to learn from the corpus in the target language.

Using the Maximum Likelihood Estimation (MLE) framework, we learn the model parameters θ – the translation probability $P(w_i|w'_i, c)$ – by maximizing the log likelihood of a collection of documents in the target language:

$$\begin{aligned} \widehat{\theta} &= argmax_\theta \sum_{j=1}^{m} log(P(d_j, \theta)) \\ &= argmax_\theta \sum_{j=1}^{m} log(\sum_{c} P(c) \sum_{d'} \\ &\quad \prod_{i=1}^{l_j} P(w_i|w'_i, c) P(w'_i|c)) \end{aligned}$$

where m is the number of documents in the corpus in the target language and l_j is the number of words in the document d_j.

In order to estimate the optimal values of the parameters, we use the EM algorithm (Dempster et al., 1977). At each iteration of EM we determine those values by maximizing the expectation using the parameters from the previous iteration and this iterative process stops when the change in the parameters is smaller than a given threshold. We can repeat the following two steps for the purpose above.

- E-step

$$\begin{aligned} P(w'c|w) &\leftarrow \frac{P(cw'w)}{P(w)} \\ &= \frac{P(w|w'c)P(w'c)}{\sum_c \sum_{w'} P(w|w'c)P(w'c)} \end{aligned} \tag{1}$$

- M-step

$$P(w|w'c) \leftarrow \frac{f(w)P(w'c|w)}{\sum_{w \in K} f(w)P(w'c|w)} \tag{2}$$

Here $f(w)$ is the occurrence frequency of the word w in the corpus. K is the set of translation candidates in the target language for the source language word w' according to the bilingual lexicon. P(w'c) is the probability of occurrence of the source language word w' under the class c. It can be estimated from the labeled source language training data available as follows and it is regarded as a known parameter of the model.

$$P(w'c) = \frac{f(w'c)}{\sum_{w' \in V} f(w'c)} \tag{3}$$

where V is the vocabulary of the source language. Algorithm 1 illustrates the EM learning process, where $n_{w'}$ denotes the number of translation candidates for w' according to the bilingual lexicon.

Our method requires no labeled training data in the target language. Many statistical machine translation systems such as IBM models (Brown et al., 1993) learn word translation probabilities from millions of parallel sentences which are mutual translations. However, large scale parallel corpora rarely exist for most language pairs. (Koehn and Knight, 2000) proposed to use the EM algorithm to learn word translation probabilities from non-parallel monolingual corpora. However, this method estimates only class independent translation probabilities $P(w_i|w'_i)$, while our approach is able to learn class specific translation probabilities

Algorithm 1 EM algorithm for learning translation probabilities

```
$D_l \leftarrow$ labeled data in the source language
$D_u \leftarrow$ unlabeled data in the target language
$L \leftarrow$ bilingual lexicon
Initialize $P_0(w|w'c) = \frac{1}{n_{w'}}$, where $(w, w') \in L$, otherwise $P_0(w|w'c) = 0$;
Compute $P(w'c)$ with $D_l$ according to equation 3
repeat
    Calculate $P_t(w'c|w)$ with $D_u$ based on $P_{t-1}(w|w'c)$ according to equation 1
    Calculate $P_t(w|w'c)$ based on $P_{t-1}(w'c|w)$ according to equation 2
until change of $P(w|w'c)$ is smaller than the threshold
return $P(w|w'c)$
```

$P(w_i|w'_i, c)$ by leveraging available labeled training data in the source language. For example, the probability of translating “bush” as “树丛” (small trees) is higher than translating as “布什” (U.S. president) when the category of the text is “botany.”

3.2 Model Translation

In order to classify documents in the target language, a straightforward approach to transferring the classification model learned from the labeled source language training data is to translate each feature from the bag-of-words model according to the bilingual lexicon. However, because of the translation ambiguity of each word, a model in the source language could be potentially translated into many different models in the target language. Thus, we think of the probability of the class of a target language document as the mixture of the probabilities by each translated model from the source language model, weighed by their translation probabilities.

$$P(c|d, m_t) \approx \textstyle\sum_{m'_t} P(m'_t|m_s, c)P(c|d, m'_t)$$

where m_t is the target language classification model and m'_t is a candidate model translated from the model m_s trained on the labeled training data in the source language. This is a very generic representation for model translation and the model m could be any type of text classification. Specifically in this paper, we take the Maximum Entropy (ME) model(Berger et al., 1996) as an example for the model translation across languages, since the ME model is one of the most widely used text classification models. The maximum entropy classifier takes the form

$$P(c|d) = \frac{1}{Z(d)} \prod_{w \in V} e^{\lambda_w f(w,c)}$$

where: V is the vocabulary of the language; $f(w, c)$ is the feature function associated with the word w and class c and its value is set to 1 when w occurs in d and the class is c or otherwise 0. λ_w is the feature weight for $f(w_i, c)$ indicating the importance of the feature in the model. During model translation, the feature weight for $f(w_i, c)$ is transferred to $f(w'_i, c)$ in the target language model, where w'_i is the translation of w_i. $Z(d)$ is the normalization factor which is invariant to c and hence we can omit it for classification since our objective is to find the best c. According to the formulation of the Maximum Entropy model, the document can be classified as follows.

$$\widehat{c} \;=\; argmax_{c \in C} \sum_{m'_t} P(m'_t|m_s, c) \prod_{i=1}^{v} e^{\lambda_{w_s^i} f(w_t^i, c)}$$

The model translation probability $P(m'_t|m_s, c)$ can be modeled as the product of the translation probabilities of each of its individual bag-of-words features $P(m'_t|m_s, c) \approx \prod_{i=1}^{l} P(w_t^i|w_s^i, c)$ and the classification model can be further written as

$$\widehat{c} \;=\; argmax_{c \in C} \sum_{m'_t} \prod_{i=1}^{v} P(w_t^i|w_s^i, c) e^{\lambda_{w_s^i} f(w_t^i, c)}$$

where feature translation probabilities $P(w_t^i|w_s^i, c)$ are estimated with the EM algorithm described in the previous section. Note that if the average number of translations for a word w is n and v is the number of words in the vocabulary there are n^v possible models m'_t translated from m_s. However, we can do the following mathematical transformation on the equation which leads to a polynomial time complexity algorithm. The idea is that instead of enumerating the exponential number of different translations of the entire model, we will instead handle one feature at a time.

$$\sum_{m'_t} \prod_{i=1}^{v} P(w_t^i|w_s^i, c) e^{\lambda_{w_s^i} f(w_t^i, c)} =$$
$$\sum_{j=1}^{n_1} P(w_t^{1j}|w_s^1, c) e^{\lambda_1 f(w_t^{1j}, c)} \sum_{m_t^{2,v}} \prod_{i=2}^{v} P(w_t^i|w_s^i, c) e^{\lambda_i f(w_t^i, c)}$$

Here w_1 is the first word in the vocabulary of the source language and w_{1j} is a translation of w_1 in the target language with n denoting the number its translations according to the bilingual lexicon. $\sum_{m_t^{2,v}}$ are all the target language models translated from the model consisting of the rest of the words w_2 ... w_v in the source language. This process is recursive until the last word w_s^v of the vocabulary and this transforms the equation into a polynomial form as follows.

$$\begin{aligned}&\sum_{m'_t}\prod_{i=1}^{v} P(w_t^i|w_s^i,c)e^{\lambda_{w_s^i} f(w_t^i,c)}\\ &= \prod_{i=1}^{v}\sum_{j=1}^{n_i} P(w_t^{ij}|w_s^i,c)e^{\lambda_{w_s^i} f(w_t^{ij},c)}\end{aligned}$$

Based on the above transformation, the class $\widehat{c}$ for the target language document d is then calculated with the following equation.

$$\widehat{c} = argmax_{c\in C}\prod_{i=1}^{v}\sum_{j=1}^{n_i} P(w_t^{ij}|w_s^i,c)e^{\lambda_{w_s^i} f(w_t^{ij},c)}$$

The time complexity of computing the above equation is $n \times v$.

4 Model Adaptation with Semi-Supervised Learning

In addition to translation ambiguity, another challenge in building a classifier using training data in a foreign language is the discrepancy of data distribution in different languages. Direct application of a classifier translated from a foreign model may not fit well the distribution of the current language. For example, a text about "sports" in (American) English may talk about "American football," "baseball," and "basketball," whereas Chinese tend to discuss about "soccer" or "table tennis."

To alleviate this problem, we employ semi-supervised learning in order to adapt the model to the target language. Specifically, we first start by using the translated classifier from English as an initial classifier to label a set of Chinese documents. The initial classifier is able to correctly classify a number of unlabeled Chinese documents with the knowledge transferred from English training data. For instance, words like "game(比赛)," "score(比分)," "athlete(运动员)," learned from English can still effectively classify Chinese documents. We then pick a set of labeled Chinese documents with high confidence to train a new Chinese classifier. The new classifier can then learn new knowledge from these Chinese documents. E.g. it can discover that words like "soccer(足球)" or "badminton(羽毛球)" occur frequently in the Chinese "sports" documents, while words that are frequently occurring in English documents such as "superbowl(超级碗)" and "NHL(全美冰球联盟)" do not occur as often. Re-training the classifier with the Chinese documents can adjust the feature weights for these words so that the model fits better the data distribution of Chinese documents, and thus it improves the classification accuracy. The new classifier then re-labels the Chinese documents and the process is repeated for several iterations. Algorithm 2 illustrates this semi-supervised learning process.

Algorithm 2 Semi-supervised learning for cross-lingual text classification

```
$L_s$ ← labeled data in the source language
$U_t$ ← unlabeled data in the target language
$C_s = train(L_s)$
$C_t = translate(C_s)$
repeat
    $Label(U, C_t)$
    $L \leftarrow select(confidence(U, C_t))$
    $C_t \leftarrow train(L)$
until stopping criterion is met
return $C_t$
```

The confidence score associated with the documents is calculated based on the probabilities of the class. For a binary classifier the confidence of classifying the document d is calculated as:

$$confidence(d) = \left|log(\frac{P(c|d)}{P(\overline{c}|d)})\right|$$

An unlabeled document is selected as training data for a new classifier when its confidence score is above a threshold.

5 Experiments and Evaluation

To evaluate the effectiveness of our method, we carry out several experiments. First, we compare the performance of our method on five different categories, from five different domains, in order to see its generality and applicability on different domains. We also run experiments with two different language pairs - English-Chinese and English-French - to see if the distance between language families influences the effectiveness of our method.

To determine the performance of the method with respect to other approaches, we compare the classification accuracy with that of a machine translation approach that translates the training (test) data from the source language to the target language, as well as with a classifier trained on monolingual training data in the target language.

Finally, we evaluate the performance of each of the two steps of our proposed method. First, we evaluate the model translated with the parameters learned with EM, and then the model after the semi-supervised learning for data distribution adaptation with different parameters, including the number of iterations and different amounts of unlabeled data.

5.1 Data Set

Since a standard evaluation benchmark for cross-lingual text classification is not available, we built our own data set from Yahoo! RSS news feeds. The news feed contains news articles from October 1st 2009 to December 31st 2009. We collected a total of 615731 news articles, categorized by their editors into topics such as "sports" or "business". We selected five categories for our experiments, namely "sports", "health", "business", "entertainment", "education". The Yahoo! RSS news feed includes news in many languages, including English, Chinese, French, Spanish, and others.

We experimented on two language pairs, English-Chinese and English-French, selected for their diversity: English and Chinese are disparate languages with very little common vocabulary and syntax, whereas English and French are regarded as more similar. We expect to evaluate the impact of the distance of languages on the effectiveness of our method. In both cases, English is regarded as the source language, where training data are available, and Chinese and French are the target languages for which we want to build text classifiers. Note that regardless of the language, the documents are assigned with one of the five category labels mentioned above. Table 1 shows the distribution of documents across categories and across languages.

Category	English	Chinese	French
sports	23764	14674	18398
health	15627	11769	12745
business	34619	23692	28740
entertainment	26876	21470	23756
education	16488	14353	15753

Table 1: number of documents in each class

Before building the classification model, several preprocessing steps are applied an all the documents. First, the HTML tags are removed, and advertisements and navigational information are also eliminated. For the Chinese corpus, all the Chinese characters with BIG5 encoding are converted into GB2312 and the Chinese texts are segmented into words. For the translation, we use the LDC bilingual dictionary[1] for Chinese English and "stardict" [2] for Spanish English.

5.2 Model Translation

To transfer a model learned in one language to another, we can translate all the bag-of-word features according to a bilingual lexicon. Due to the translation ambiguity of each feature word, we compare three different ways of model translation. One method is to equally assign probabilities to all the translations for a given source language word, and to translate a word we randomly pick a translation from all of its translation candidates. We denote this as "EQUAL" and it is our baseline method. Another way is to calculate the translation probability based on the frequencies of the translation words in the target language itself. For instance, the English word "bush" can be translated into "布什" , "树丛" or "套管" . We can obtain the following unigram counts of these translation words in our Yahoo! RSS news corpus.

count	translation	sense
582	布什	Goerge W. Bush
43	树丛	small trees
2	套管	canula

We can estimate that $P(布什|bush) = 582/(582 + 43 + 2) = 92.8\%$ and so forth. This method often allows us to estimate reasonable translation probabilities and we use "UNIGRAM" to denote this method. And finally the third model translation approach is to use the translation probability learned with the EM algorithm proposed in this paper. The initial parameters of the EM algorithm are set to the probabilities calculated with the "UNIGRAM" method and we use 4000 unlabeled documents in Chinese

[1] http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2002L27

[2] http://stardict.sourceforge.net/Dictionaries.php

to learn translation probabilities with EM. We first train an English classification model for the topic of "sport" and then translate the model into Chinese using translation probabilities estimated by the above three different methods. The three translated models are applied to Chinese test data and we measure the precision, recall and F-score as shown in Table 2.

Method	P	R	F
EQUAL	71.1	70.6	70.8
UNIGRAM	79.5	77.8	78.6
EM	83.1	84.7	83.9

Table 2: Comparison of different methods for model translation

From this table we can see that the baseline method has lowest classification accuracy due to the fact that it is unable to handle translation ambiguity since picking any one of the translation word is equally likely. "UNIGRAM" shows significant improvement over "EQUAL" as the occurrence count of the translation words in the target language can help disambiguate the translations. However occurrence count in a monolingual corpus may not always be the true translation probability. For instance, the English word "work" can be translated into "工作(labor)" and "工厂(factory)" in Chinese. However, in our Chinese monolingual news corpus, the count for "工厂(factory)" is more than that of "工作(labor)" even though "工作(labor)" should be a more likely translation for "work". The "EM" algorithm has the best performance as it is able to learn translation probabilities by looking at documents in both source language and target language instead of just a single language corpus.

5.3 Cross Language Text Classification

To evaluate the effectiveness of our method on cross language text classification, we implement several methods for comparison. In each experiment, we run a separate classification for each class, using a one-versus-all binary classification.

ML (Monolingual). We build a monolingual text classifier by training and testing the text classification system on documents in the same language. This method plays the role of an upper-bound, since the best classification results are expected when monolingual training data is available.

MT (Machine Translation). We use the Systran 5.0 machine translation system to translate the documents from one language into the other in two directions. The first direction translates the training data from the source language into the target language, and then trains a model in the target language. This direction is denoted as **MTS**. The second direction trains a classifier in the source language and translates the test data into the source language. This direction is denoted as **MTT**. In our experiments, Systran generates the single best translation of the text as most off-the-shelf machine translation tools do.

EM (Model Translation with EM). This is the first step of our proposed method. We used 4,000 unlabeled documents to learn translation probabilities with the EM algorithm and the translation probabilities are leveraged to translate the model. The rest of the unlabeled documents are used for other experimental purpose.

SEMI (Adapted Model after Semi-Supervised Learning). This is our proposed method, after both model translation and semi-supervised learning. In the semi-supervised learning, we use 6,000 unlabeled target language documents with three training iterations.

In each experiment, the data consists of 4,000 labeled documents and 1,000 test documents (e.g., in the cross-lingual experiments, we use 4,000 English annotated documents and 1,000 Chinese or French test documents). For a given language, the same test data is used across all experiments.

Table 3 shows the performance of the various classification methods. The **ML** (Monolingual) classifier has the best performance, as it is trained on labeled data in the target language, so that there is no information loss and no distribution discrepancy due to a model translation. The **MT** (machine translation) based approach scores the lowest accuracy, probably because the machine translation software produces only its best translation, which is often error-prone, thus leading to poor classification accuracy. In addition, the direct application of a classification model from one language to an-

education	78.8	81.8	80.3	72.1	74.8	73.5	72.3	72.7	72.5	73.8	76.2	75.0	76.3	80.1	78.2

Table 3: Comparison of different methods and different language pairs

other does not adapt to the distribution of the second language, even if the documents belong to the same domain. Comparing the two **MT** alternatives, we can see that translating the training data (**MTS**) has better performance than translating the test data (**MTT**). The reason is that when the model is trained on the translated training data, the model parameters are learned over an entire collection of translated documents, which is less sensitive to translation errors than translating a test document on which the classification is performed individually.

Our **EM** method for translating model features outperforms the machine translation approach, since it does not only rely on the best translation by the machine translation system, but instead takes into account all possible translations with knowledge learned specifically from the target language. Additionally, the **SEMI** (semi-supervised) learning is shown to further improve the classification accuracy. The semi-supervised learning is able to not only help adapt the translated model to fit the words distribution in the target language, but it also compensates the distortion or information loss during the model translation process as it can down-weigh the incorrectly translated features.

The improvement in performance for both the **EM** and the **SEMI** methods is consistent across the five different domains, which indicates that the methods are robust and they are insensitive to the domain of the data.

The performance of the two language pairs English-Chinese and English-French shows a difference as initially hypothesized. In both the **EM** and the **SEMI** models, the classification accuracy of English-French exceeds that of English-Chinese, which is probably explained by the fact that there is less translation ambiguity in similar languages, and they have more similar distributions. Note that the monolingual models in French and Chinese perform comparably, which means the difficulty of the test data is similar between the two target languages.

5.4 Model Adaptation with Semi-Supervised Learning

Finally, to gain further insights into our proposed adaptation method, we run several experiments with different parameters for the semi-supervised learning stage. As these experiments are very time consuming, we run them only on Chinese.

For each of the five categories, we train a classification model using the 4,000 training documents in English and then translate the model into Chinese with the translation parameters learned with **EM** on 20,000 unlabeled Chinese documents. Then we further train the translated model on a set of unlabeled Chinese documents using a different number of iterations and a different amount of unlabeled documents. Figures 1 and 2 show the results of these evaluations.

As the plots show, the use of unlabeled data in the target language can improve the cross-language classification by learning new knowledge in the target language. Larger amounts of unlabeled data in general help, although the marginal benefit drops with increasing amounts of data. Regarding the number of iterations, the best performance is

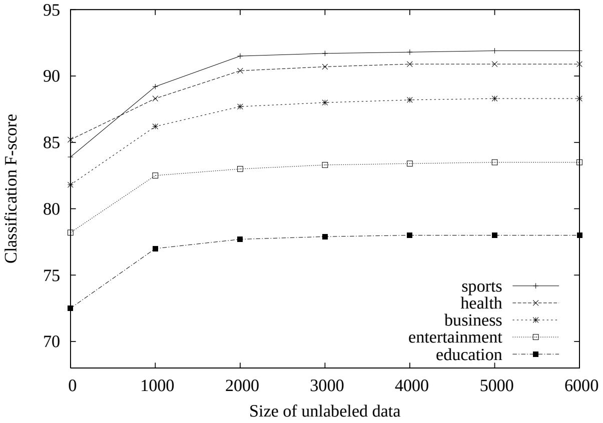

Figure 1: Change in classification F-score for an increasing amount of unlabeled data in the target language

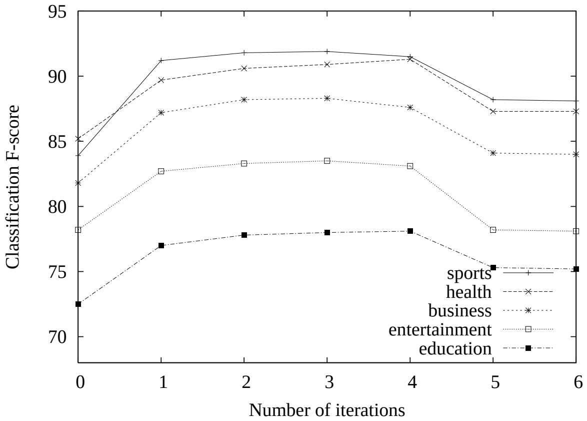

Figure 2: Change in classification F-score for a different number of iterations

achieved after 3-4 iterations.

6 Conclusions

In this paper, we proposed a novel method for cross-lingual text classification. Our method ports a classification model trained in a source language to a target language, with the translation knowledge being learned using the EM algorithm. The model is further tuned to fit the distribution in the target language via semi-supervised learning. Experiments on different datasets covering different languages and different domains show significant improvement over previous methods that rely on machine translation. Moreover, the cross-lingual classification accuracy obtained with our method was found to be close to the one achieved using monolingual text classification.

Abstract

In this paper we develop an approach to tackle the problem of verb selection for learners of English as a second language (ESL) by using features from the output of Semantic Role Labeling (SRL). Unlike existing approaches to verb selection that use local features such as n-grams, our approach exploits semantic features which explicitly model the usage context of the verb. The verb choice highly depends on its usage context which is not consistently captured by local features. We then combine these semantic features with other local features under the generalized perceptron learning framework. Experiments on both in-domain and out-of-domain corpora show that our approach outperforms the baseline and achieves state-of-the-art performance.

1 Introduction

Verbs in English convey actions or states of being. In addition, they also communicate sentiments and imply circumstances, e.g., in "*He got [gained] the scholarship after three interviews.*", the verb "*gained*" may indicate that the "*scholarship*" was competitive and required the agent's efforts; in contrast, "*got*" sounds neutral and less descriptive. Since verbs carry multiple important functions, misusing them can be misleading, e.g., the native speaker could be confused when reading "*I like looking [reading] books*". Unfortunately, according to (Gui and Yang, 2002; Yi et al., 2008), more than 30% of the errors in the Chinese Learner English Corpus (CLEC) are verb choice errors. Hence, it is useful to develop an approach to automatically detect and correct verb selection errors made by ESL learners.

However, verb selection is a challenging task because verbs often exhibit a variety of usages and each usage depends on a particular context, which can hardly be adequately described by conventional n-gram features. For instance, both "*made*" and "*received*" can complete "*I have __ a telephone call.*", where the usage context can be represented as "*made/received a telephone call*"; however, in "*I have __ a telephone call from my boss*", the prepositional phrase "*from my boss"* becomes a critical part of the context, which now cannot be described by n-gram features, resulting in only "*received*" being suitable.

Some researchers (Tetreault and Chodorow, 2008) exploited syntactic information and n-gram features to represent verb usage context. Yi et al. (2008) introduced an unsupervised web-based proofing method for correcting verb-noun collocation errors. Brockett et al. (2006) employed phrasal Statistical Machine Translation (SMT) techniques to correct countability errors. None of their methods incorporated semantic information.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1068–1076,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

Unlike the other papers, we derive features from the output of an SRL (Màrquez, 2009) system to explicitly model verb usage context. SRL is generally understood as the task of identifying the arguments of a given verb and assigning them semantic labels describing the roles they play. For example, given a sentence "*I want to watch TV tonight*" and the target predicate "*watch*", the output of SRL will be something like "*I [A0] want to watch [target predicate] TV [A1] tonight [AM-TMP].*", meaning that the action "*watch*" is conducted by the agent "*I*", on the patient "*TV*", and the action happens "*tonight*".

We believe that SRL results are excellent features for characterizing verb usage context for three reasons: (i) Intuitively, the predicate-argument structures generated by SRL systems capture major relationships between a verb and its contextual participants and consequently largely determine whether or not the verb usage is proper. For example, in "*I want to watch a match tonight.*", "*match*" is the patient of "*watch*", and "*watch ... match*" forms a collocation, suggesting "*watch"* is appropriately used. (ii) Predicate-argument structures abstract away syntactic differences in sentences with similar meanings, and therefore can potentially filter out lots of noise from the usage context. For example, consider "*I want to watch a football match on TV tonight*": if "*match*" is successfully identified as the agent of "*watch*", "*watch ... football*", which is unrelated to the usage of "*watch*" in this case, can be easily excluded from the usage context. (iii) Research on SRL has made great achievements, including human-annotated training corpora and state-of-the-art systems, which can be directly leveraged.

Taking an English sentence as input, our method first generates correction candidates by replacing each verb with verbs in its pre-defined confusion set; then for every candidate, it extracts SRL-derived features; finally our method scores every candidate using a linear function trained by the generalized perceptron learning algorithm (Collins, 2002) and selects the best candidate as output.

Experimental results show that SRL-derived features are effective in verb selection, but we also observe that noise in SRL output adversely increases feature space dimensions and the number of false suggestions. To alleviate this issue, we use local features, e.g., n-gram-related features, and achieve state-of-the-art performance when all features are integrated.

Our contributions can be summarized as follows:

1. We propose to exploit SRL-derived features to explicitly model verb usage context.
2. We propose to use the generalized perceptron framework to integrate SRL-derived (and other) features and achieve state-of-the-art performance on both in-domain and out-of-domain test sets.

Our paper is organized as follows: In the next section, we introduce related work. In Section 3, we describe our method. Experimental results and analysis on both in-domain and out-of-domain corpora are presented in Section 4. Finally, we conclude our paper with a discussion of future work in Section 5.

2 Related Work

SRL results are used in various tasks. Moldovan et al. (2004) classify the semantic relations of noun phrases based on SRL. Ye and Baldwin (2006) apply semantic role–related information to verb sense disambiguation. Narayanan and Harabagiu (2004) use semantic role structures for question answering. Surdeanu et al. (2003) employ predicate-argument structures for information extraction.

However, in the context of ESL error detection and correction, little study has been carried out on clearly exploiting semantic information. Brockett et al. (2006) propose the use of the phrasal statistical machine translation (SMT) technique to identify and correct ESL errors. They devise several heuristic rules to generate synthetic data from a high-quality newswire corpus and then use the synthetic data together with their original counterparts for SMT training. The SMT approach on the artificial data set achieves encouraging results for correcting countability errors. Yi et al. (2008) use web frequency counts to identify and correct determiner and verb-noun collocation errors. Compared with these methods, our approach explicitly models verb usage context by leveraging the SRL output. The SRL-based semantic features are integrated, along with the local features, into the generalized perceptron model.

3 Our Approach

Our method can be regarded as a pipeline consisting of three steps. Given as input an English sentence written by ESL learners, the system first checks every verb and generates correction candidates by replacing each verb with its confusion set. Then a feature vector that represents verb usage context is derived from the outputs of an SRL system and then multiplied with the feature weight vector trained by the generalized perceptron. Finally, the candidate with the highest score is selected as the output.

3.1 Formulation

We formulate the task as a process of generating and then selecting correction candidates:

$$s^* = \arg\max_{s \in GEN(s')} Score(s) \qquad (1)$$

Here s' denotes the input sentence for proofing, $GEN(s')$ is the set of correction candidates, and $Score(s)$ is the linear model trained by the perceptron learning algorithm, which will be discussed in section 3.4.

We call every target verb in s' a *checkpoint*. For example, "*sees*" is a checkpoint in "*Jane **sees** TV every day.*". Correction candidates are generated by replacing each checkpoint with its confusions. Table 1 shows a sentence with one checkpoint and the corresponding correction candidates.

Input	*Jane **sees** TV every day.*
Candidates	*Jane **watches** TV every day.*
	*Jane **looks** TV every day.*
	…

Table 1. Correction candidate list.

One state-of-the-art SRL system (Riedel and Meza-Ruiz, 2008) is then utilized to extract predicate-argument structures for each verb in the input, as illustrated in Table 2.

Semantic features are generated by combining the predicate with each of its arguments; e.g., "*watches_A0_Jane*", "*sees_A0_Jane*", "*watches_A1_TV*" and "*sees_A1_TV*" are semantic features derived from the semantic roles listed in Table 2.

Sentence	Semantic roles

*Jane **sees** TV every day*	*Predicate: sees;*
	A0: Jane;
	A1: TV;

*Jane **watches** TV every day*	*Predicate: watches;*
	A0: Jane;
	A1: TV;

Table 2. Examples of SRL outputs.

At the training stage, each sentence is labeled by the SRL system. Each correction candidate s is represented as a feature vector $\Phi(s) \in R^d$, where d is the total number of features. The feature weight vector is denoted as $\vec{w} \in R^d$, and $Score(s)$ is computed as follows:

$$Score(s) = \Phi(s) \cdot \vec{w} \qquad (2)$$

Finally, $Score(s)$ is applied to each candidate, and s^*, the one with the highest score, is selected as the output, as shown in Table 3.

	Correction candidate	Score
s^*	*Jane **watches** TV every day.*	10.8
	*Jane **looks** TV every day.*	0.8
	*Jane **reads** TV every day.*	0.2
	…	…

Table 3. Correction candidate scoring.

In the above framework, the basic idea is to generate correction candidates with the help of predefined confusion sets and apply the global linear model to each candidate to compute the degree of its fitness to the usage context that is represented as features derived from SRL results.

To make our idea practical, we need to solve the following three subtasks: (i) generating the confusion set that includes possible replacements for a given verb; (ii) representing the context with semantic features and other complementary features; and (iii) training the feature weight. We will describe our solutions to those subtasks in the rest of this section.

I	*have*	***made[opened]***	*an*	*American*	*bank*	*account*	*in*	*Boston*	*.*
[A0]		[Predicate]				[A1]	[AM-LOC]		

Table 4. An example of SRL output.

3.2 Generation of Verb Confusion Sets

Verb confusion sets are used to generate correction candidates. Due to the great number of verbs and their diversified usages, manually collecting all verb confusions in all scenarios is prohibitively time-consuming. To focus on the study of the effectiveness of semantic role features, we restrict our research scope to correcting verb selection errors made by Chinese ESL learners and select fifty representative verbs which are among the most frequent ones and account for more than 50% of ESL verb errors in the CLEC data set. For every selected verb we manually compile a confusion set using the following data sources:

1. Encarta treasures. We extract all the synonyms of verbs from the Microsoft Encarta Dictionary, and this forms the major source for our confusion sets.

2. English-Chinese Dictionaries. ESL learners may get interference from their mother tongue (Liu et al., 2000). For example, some Chinese people mistakenly say “see newspaper”, partially because the translation of “see” co-occurs with “newspaper” in Chinese. Therefore English verbs in the dictionary sharing more than two Chinese meanings are collected. For example, “*see*” and “*read*” are in a confusion set because they share the meanings of both “*看*” (“*to see*”*,* “*to read*”) and “*领会*” (“*to grasp*”) in Chinese.

3. An SMT translation table. We extract paraphrasing verb expressions from a phrasal SMT translation table learnt from parallel corpora (Och and Ney, 2004). This may help us use the implicit semantics of verbs that SMT can capture but a dictionary cannot, such as the fact that the verb

Note that verbs in any confusion set that we are not interested in are dropped, and that the verb itself is included in its own confusion set. We leave it to our future work to automatically construct verb confusions.

3.3 Verb Usage Context Features

The verb usage context[1] refers to its surrounding text, which influences the way one understands the expression. Intuitively, verb usage context can take the form of a collocation, e.g., “*watch … TV*” in “*I saw [watched] TV yesterday.*” ; it can also simply be idioms, e.g., we say “*kick one’s habit*” instead of “*remove one’s habit*”.

We use features derived from the SRL output to represent verb usage context. The SRL system accepts a sentence as input and outputs all arguments and the semantic roles they play for every verb in the sentence. For instance, given the sentence “*I have opened an American bank account in Boston.*” and the predicate “*opened*”, the output of SRL is listed in Table 4, where *A0* and *A1* are two core roles, representing the agent and patient of an action, respectively, and other roles starting with “*AM-*”are adjunct roles, e.g., *AM-LOC* indicates the location of an action. Predicate-argument structures keep the key participants of a given verb while dropping other unrelated words from its usage context. For instance, in “*My teacher said Chinese is not easy to learn.*”, the SRL system recognizes that “*Chinese*” is not the *A1*-argument of “*said*”. So “*say _ Chinese*”, which is irrelevant to the usage of *said*, is not extracted as a feature.

The SRL system, however, may output erroneous predicate-argument structures, which negatively affect the performance of verb selection. For instance, for the sentence “*He hasn’t done anything but take [make] a lot of money*”, “*lot*” is incorrectly identified as the patient of “*take*”, making it hard to select “*make*” as the proper verb even though “*make money*” forms a sound collocation. To tackle this issue, we use local textual features, namely features related to n-gram, chunk and chunk headword, as shown in Table 5. Back-off features are generated by replacing the word with its POS tag to alleviate data sparseness.

3.4 Perceptron Learning

We choose the generalized perceptron algorithm as our training method because of its easy implementation and its capability of incorporating various features. However, there are still two concerns about this perceptron learning approach: its ineffectiveness in dealing with inseparable samples and its ignorance of weight normalization that potentially limits its ability to generalize. In section 4.4 we show that the training error rate drops significantly to a very low level after several rounds of training, suggesting that the correct candidates can almost be separated from others. We also observe that our method performs well on an out-of-domain test corpus, indicating the good generalization ability of this method. We leave it to our future work to replace perceptron learning with other models like Support Vector Machines (Vapnik, 1995).

In Figure 1, s_i is the *i*th correct sentence within the training data. *T* and *N* represent the number of training iterations and training examples, respectively. $GEN(s^i)$ is the function that outputs all the possible corrections for the input sentence s^i with each *checkpoint* substituted by one of its confusions, as described in Section 3.1. We observe that the generated candidates sometimes contain reasonable outputs for the verb selection task, which should be removed. For instance, in "... *reporters could not take [make] notes or tape the conversation*", both "*take*" and "*make*" are suitable verbs in this context. To fix this issue, we trained a trigram language model using SRILM (Stolcke, 2002) on LDC data[2] , and calculated the logarithms of the language model score for the original sentence and its artificial manipulations. We only kept manipulations with a language model score that is *t* lower than that of the original sentence. We experimentally set *t* = *5*.

```
Inputs: training examples $s^i$, $i=1...N$
Initialization: $\vec{w}=0$
Algorithm:
  For $r= 1.. T$, $i= 1..N$
  Calculate $o=\arg\max_{s=Gen(s^i)} \Phi(s)\cdot\vec{w}$
  If $s^i \neq o$
      $\vec{w}=\vec{w}+\Phi(s^o)-\Phi(o)$
Outputs: $\vec{w}$
```

Figure 1. The perceptron algorithm, adapted from Collins (2002).

Φ in Figure 1 is the feature extraction function. $\Phi(o)$ and $\Phi(s^i)$ are vectors extracted from the output and oracle, respectively. A vector field is filled with 1 if the corresponding feature exists, or 0 otherwise; $\vec{w}$ is the feature weight vector, where positive elements suggest that the corresponding features support the hypothesis that the candidate is correct.

The training process is to update $\vec{w}$, when the output differs from the oracle. For example, when o is "*I want to **look** TV*" and s^i is "*I want to **watch** TV*", $\vec{w}$ will be updated.

We use the averaged Perceptron algorithm (Collins, 2002) to alleviate overfitting on the training data. The averaged perceptron weight vector is defined as

$$\vec{\gamma}=\frac{1}{TN}\sum_{\mathrm{i}=1..N,r=1..T}\vec{w}^{i,r} \qquad (3)$$

where $\vec{w}^{i,r}$ is the weight vector immediately after the *i*th sentence in the *r*th iteration.

4 Experiments

In this section, we compare our approach with the SMT-based approach. Furthermore, we study the contribution of predicate-argument-related features, and the performances on verbs with varying distance to their arguments.

4.1 Experiment Preparation

The training corpus for perceptron learning was taken from LDC2005T12. We randomly selected newswires containing target verbs from the *New York Times* as the training data. We then used the *OpenNLP* package[3] to extract sentences from the newswire text and to parse them into the corresponding tokens, POS tags, and chunks. The SRL system is built according to Riedel and Meza-Ruiz (2008), using the CoNLL-2008 shared task data for training. We assume that the newswire data is of high quality and free of linguistic errors, and finally we gathered 20000 sentences that contain any of the target verbs we were focusing on. We experimentally set the number of training rounds to $T = 50$.

We constructed two sets of testing data for in-domain and out-of-domain test purposes, respectively. To construct the in-domain test data, we first collected all the sentences that contain any of the verbs we were interested in from the previous unused LDC dataset; then we replaced any target verb in our list with a verb in its confusion set; next, we used the language-model-based pruning strategy described in 3.4 to drop possibly correct manipulations from the test data; and finally we randomly sampled 5000 sentences for testing.

To build the out-of-domain test dataset, we gathered 186 samples that contained errors related to the verbs we were interested in from English blogs written by Chinese and from the CLEC corpus, which were then corrected by an English native speaker. Furthermore, for every error involving the verbs in our target list, both the verb and the word that determines the error are marked by the English native speaker.

4.2 Baseline

We built up a phrasal SMT system with the word re-ordering feature disabled, since our task only concerns the substitution of the target verb. To construct the training corpus, we followed the idea in Brockett et al. (2006), and applied a similar strategy described in section 3.4 to the SRL system's training data to generate aligned pairs.

4.3 Evaluation Metric

We employed the following metrics adapted from (Yi et al., 2008): *revised precision (RP), recall of the correction (RC)* and *false alarm (FA).*

$$RP = \frac{\#\,of\ Correct\ Proofings}{\#\,of\ All\ Checkpoints} \tag{4}$$

RP reflects how many outputs are correct usages. The output is regarded as a correct suggestion if and only if it is exactly the same as the answer. Paraphrasing scenarios, for example, the case that the output is "*take notes*" and the answer is "*make notes*", are counted as errors.

$$RC = \frac{\#\,of\ Correct\ Modified\ Proofings}{\#\,of\ Total\ Errors} \tag{5}$$

RC indicates how many erroneous sentences are corrected among all the errors. It measures the system's coverage of verb selection errors.

$$FA = \frac{\#\,of\ Incorrect\ Modified\ Checkpoints}{\#\,of\ All\ Checkpoints} \tag{6}$$

FA is related to the cases where a correct verb is mistakenly replaced by an inappropriate one. These false suggestions are likely to disturb or even annoy users, and thus should be avoided as much as possible.

4.4 Results and Analysis

The training error curves of perceptron learning with different feature sets are shown in Figure 2. They drop to a low error rate and then stabilize after a few number of training rounds, indicating that most of the cases are linearly separable and that perceptron learning is applicable to the verb selection task.

We conducted feature selection by dropping features that occur less than *N* times. Here *N* was experimentally set to 5. We observe that, after feature selection, some useful features such as "*watch_A1_TV*" and "*see_A1_TV*" were kept, but some noisy features like *"Jane_A0_sees"* and *"Jane_A0_watches"* were removed, suggesting the effectiveness of this feature selection approach.

[3] http://opennlp.sourceforge.net/

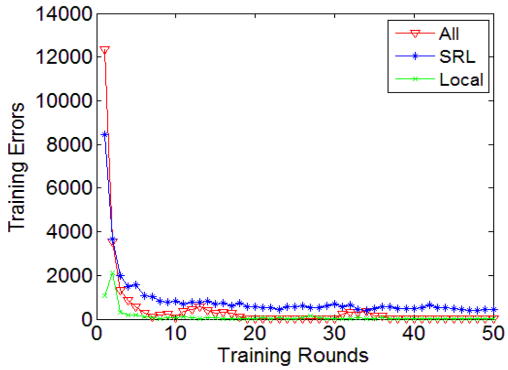

Figure 2. Training error curves of the perceptron.

We tested the baseline and our approach on the in-domain and out-of-domain corpora. The results are shown in Table 7 and 8, respectively.

In the in-domain test, the SMT-based approach has the highest false alarm rate, though its output with word insertions or deletions is not considered wrong if the substituted verb is correct. Our approach, regardless of what feature sets are used, outperforms the SMT-based approach in terms of all metrics, showing the effectiveness of perceptron learning for the verb selection task. Under the perceptron learning framework, we can see that the system using only SRL-related features has higher revised precision and recall of correction, but also a slightly higher false alarm rate than the system based on only local features. When local features and SRL-derived features are integrated together, the state-of-the-art performance is achieved with a 5% increase in recall, and minor changes in precision and false alarm.

In the out-of-domain test, the SMT-based approach performs much better than in the in-domain test, especially in terms of false alarm rate, indicating the SMT-based approach may favor short sentences. However, its recall drops greatly. We observe similar performance differences between the systems with different feature sets under the same perceptron learning framework, reaffirming the usefulness of the SRL-based features for verb selection.

We also conducted significance test. The results confirm that the improvements (SRL+Local vs. SMT-based) are statistically significant (p-value < 0.001) for both the open-domain and the in-domain experiments.

Furthermore, we studied the performance of our system on verbs with varying distance to their arguments on the out-of-domain test corpus.

Local	d<=2	2<d<=4	d>4
RP	64.3%	60.3%	59.4%
RC	34.6%	33.1%	28.9%
FA	3.0%	6.3%	5.0%
SRL	d<=2	2<d<=4	d>4
RP	65.1%	60.1%	62.1%
RC	40.3%	34.0%	36.9%
FA	5.0%	6.7%	6.3%

Table 9. Performance on verbs with different distance to their arguments on out-of-domain test data.

Table 9 shows that the system with only SRL-derived features performs significantly better than the system with only local features on the verb whose usage depends on a distant argument, i.e., one where the number of words between the predicate and the argument is larger than 4. To understand the reason, consider the following sentence:

"*It's raining outside. Please wear[take] the black raincoat with you.*"

	SMT-based	Our method		
		SRL	Local	SRL + Local
RP	48.4%	64.5%	62.2%	66.4%
RC	23.5%	40.2%	32.9%	46.4%
FA	13.3%	5.6%	4.2%	6.8%

Table 7. In-domain test results.

	SMT-based	Our method		
		SRL	Local	SRL + Local
RP	50.7%	64.0%	62.6%	65.5%
RC	13.5%	39.0%	33.3%	44.0%
FA	6.1%	5.5%	4.0%	6.5%

Table 8. Out-of-domain test results.

Intuitively, "*wear*" and "*take*" seem to fill the blank well, since they both form a collocation with "*raincoat*"*;* however, when *"with [AM-MNR] you*" is considered as part of the context, "*wear*" no longer fits it and "*take*" wins. In this case, the long-distance feature devised from *AM-MNR* helps select the suitable verb, while the trigram features cannot because they cannot represent the long distance verb usage context.

We also find some typical cases that are beyond the reach of the SRL-derived features. For instance, consider "*Everyone doubts [suspects] that Tom is a spy.*". Both of the verbs can be followed by a clause. However, the SRL system regards "*is*", the predicate of the clause, as the patient, resulting in features like "*doubt_A1_is*" and "*suspect_A1_is*", which capture nothing about verb usage context. However, if we consider the whole clause "*suspect_Tom is a spy*" as the patient, this could result in a very sparse feature that would be filtered. In the future, we will combine word-level and phrase-level SRL systems to address this problem.

Besides its incapability of handling verb selection errors involving clauses, the SRL-derived features fail to work when verb selection depends on deep meanings that cannot be captured by current shallow predicate-argument structures. For example, in "*He was wandering in the park, spending [killing] his time watching the children playing.*", though "*spending*" and "*killing*" fit the syntactic structure and collocation agreement, and express the meaning "*to allocate some time doing something*", the word "*wandering*" suggests that "*killing*" may be more appropriate. Current SRL systems cannot represent the semantic connection between two predicates and thus are helpless for this case. We argue that the performance of our system can be improved along with the progress of SRL.

5 Conclusions and Future Work

Verb selection is challenging because verb usage highly depends on the usage context, which is hard to capture and represent. In this paper, we propose to utilize the output of an SRL system to explicitly model verb usage context. We also propose to use the generalized perceptron learning framework to integrate SRL-derived features with other features. Experimental results show that our method outperforms the SMT-based system and achieves state-of-the-art performance when SRL-related features and other local features are integrated. We also show that, for cases where the particular verb usage mainly depends on its distant arguments, a system with only SRL-derived features performs much better than the system with only local features.

In the future, we plan to automatically construct confusion sets, expand our approach to more verbs and test our approach on a larger size of real data. We will try to combine the outputs of several SRL systems to make our system more robust. We also plan to further validate the effectiveness of the SRL-derived features under other learning methods like SVMs.

Acknowledgment

Abstract

In this paper, we conducted a systematic comparative analysis of language in different contexts of bursty topics, including web search, news media, blogging, and social bookmarking. We analyze (1) the content similarity and predictability between contexts, (2) the coverage of search content by each context, and (3) the intrinsic coherence of information in each context. Our experiments show that social bookmarking is a better predictor to the bursty search queries, but news media and social blogging media have a much more compelling coverage. This comparison provides insights on how the search behaviors and social information sharing behaviors of users are correlated to the professional news media in the context of bursty events.

1 Introduction

Search is easy. Every day people are repeating the queries they have used before, trying to access the same web pages. A smart search engine tracks the preference and returns it next time when it sees the same query. When I search for "msr" I always try to access *Microsoft research*; and even if I misspelled it, a smart search engine could suggest a correct query based on my query history, the current session of queries, and/or the queries that other people have been using.

Search is hard. I search for "social computing" because there was such a new program in NSF; but the search engine might have not yet noticed that. People use "msg" to access *monosodium glutamate* in most of the cases, but tonight there is a big game in *Madison square garden*. *H1N1* suddenly became a hot topic, followed by a burst of the rumor that *it was a hoax*, and then the *vaccine*. The information need of users changed dramatically during such a period. When a new event happens, the burst of new contents and new interests make it hard to predict what people would search and to suggest what queries they should use.

Web search is easy when the information need of the users is stable and when we have enough historical clicks. It becomes much more difficult when a new information need knocks the door or when there is a sudden change of the information need. Such a shift of the information need is usually caused by a burst of new events or new interests.

When we are lack of enough historical observations, why don't we seek help from other sources? A bursting event will not only influence what we search, but hopefully also affect *what we read*, *what we write*, and *what we tag*. Indeed, there is already considerable effort in seeking help from these sources, by the integration of news and blogs into search results or the use of social bookmarks to enhance search. These conclusions, however, are mostly drawn in a general context (e.g., with general search queries). To what extent are they useful when dealing with busty events? How is the bursting content in web search, news media, social media, and social bookmarks correlating and different from each other? Prior to the development of desirable applications (e.g. enhancing search results, query suggestion, keyword bidding on advertisement, etc) by integrating the information from all these sources, it is appealing to have an investigation of feasibility.

In this work, we conduct a systematic comparative study of what we search, what we read, what

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1077–1087,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

we write, and what we tag in the scenarios of *bursty events*. Specifically, we analyze the language used in different *contexts* of bursty events, including two different query log contexts, two news media contexts, two blog contexts, and an additional context of social bookmarks. A variety of experiments have been conducted, including the content similarity and cross-entropy between sources, the coverage of search queries in online media, and an in-depth semantic comparison of sources based on language networks.

In the rest of this paper, a summary of related work is briefly described in Section 2. We then present the experiments setup in Section 3, The results of the experiments is presented in Section 4. Finally, our major findings from the comparative analysis are drawn in Section 5.

2 Related Work

Recently, a rich body of work has focused on how to find the bursting patterns from time-series data using various approaches such as time-graph analysis (Kleinberg, 2003; Kuman et al., 2003), context-based analysis (Gabrilovich et al., 2004), moving-average analysis (Vlachos et al., 2004), and frequency analysis (Gruhl et al., 2005), etc. These methods are all related to the preprocessing step of our analysis: detecting bursty queries from the query log effectively.

The comparison of *two* web sources at a time is widely studied recently. (Sood et al., 2007) discussed how to leverage the relation between social tags and web blogs. (Lloyd et al., 2006; Gamon et al., 2008; Cointet et al., 2008) investigated the relations between news and blogs. Also some work has aimed to utilize one external web source to help web search. For example, (Diaz, 2009) integrated the news results into general search. (Bao et al., 2007; Heymann et al., 2008; Krause et al., 2008; Bischoff et al., 2008) focused on improving search by the social tags. Compared with the above, our comparison analysis tries to explore the interactions among *multiple* web sources including the search logs.

Similar to our work, some recent work (Adar et al., 2007; Sun et al., 2008) has addressed the comparison among multiple web sources. For example, (Adar et al., 2007) did a comprehensive correlation study among queries, blogs, news and TV results. However, different from the *content-free* analysis above, our work compares the sources based on the *content*.

Our work can lead to many useful search applications, such as query suggestion which takes as input a specific query and returns as output one or several suggested queries. The approaches include query term cooccurrence (Jones et al., 2006), query sessions (Radlinski and Joachims, 2005), and click-through (Mei et al., 2008), respectively.

3 Analysis Setup

Tasks of web information retrieval such as web search generally perform very well on frequent and *navigational* queries (Broder, 2002) such like “chicago” or “yahoo movies.” A considerable challenge in web search remains in how to handle *informational* queries, especially queries that reflect *new* information need and *suddenly changed* information need of users. Many such scenarios are caused by the emergence of bursty events (e.g., “van gogh” became a hot query in May 2006 since a Van Goghs portrait was sold for 40.3 million in New York during that time). The focus of this paper is to analyze how other online media sources react to those bursty events and how those reactions compare to the reaction in web search. This analysis thus serves as an primitive investigation of the feasibility of leveraging other sources to enhance the search of bursty topics.

Therefore, we focus on the “event-related” topics which present as bursty queries submitted to a search engine. These queries not only reflect the suddenly changed information need of users, but also trigger the correlated reactions in other online sources, such as news media, blog media, social bookmarks, etc. We begin with the extraction of bursty topics from the query log.

3.1 Bursty Topic Extraction

Search engine logs (or query logs) store the history of users’ search behaviors, which reflect users’ interests and information need. The query log of a commercial search engine consists of a huge amount of search records, each of which typically contains the following information: the query submitted by a user, the time at which the query was submitted, and/or the URL which the user clicked on after the query was submitted, etc. It is common practice to segment query log into search sessions, each of which represents one user's searching activities in a short period of time.

We explore a sample of the log of the Microsoft Live search engine[1], which contains $14.9M$ search records over 1 month (May 2006).

3.1.1 Find bursty queries from query log

How to extract the queries that represent bursty events? We believe that bursty queries present the pattern that its day-by-day search volume shows a significant spike – that is, the frequency that the user submit this query should suddenly increase at one specific time and drop down after a while. This assumption is consistent with existing work of finding bursty patterns in emails, scientific literature (Kleinberg, 2003), and blogs (Gruhl et al., 2005).

Following (Gruhl et al., 2005), we utilize a simple but effective method to collect bursty topics in the query log data as follows:

• We choose bigrams as the basic presentation of bursty topics since bigrams present the information need of users more clearly and completely than unigrams and also have a larger coverage in the query log comparing to n-grams ($n \geq 3$).

• We only consider the bigram queries which appear more frequently than a threshold s per month. This is reasonable since a bursty event usually causes a large volume of search activities.

• Let $f_{max}(q)$ be the maximum search volume of a query q in one day (i.e., day d). Let $\hat{f}_{-5}(q)$ be the *upper* bound of the daily search volume of q outside a time window of 5 days centered at day d. If $f_{max}(q)$ is "significantly higher" than $\hat{f}_{-5}(q)$ (i.e., $r_m = \hat{f}_{max}(q)/f_{-5}(q) > m$), we consider q as a query with a spike pattern (m is an empirical threshold).

• The ratio above may be vulnerable to the query that has more than one spike. To solve this, we define $\bar{f}_{-5}(q)$ as the *average* of daily search volume of q outside the same time window. This gives us an alternative ratio $r_a = f_{max}(q)/\bar{f}_{-5}(q)$. We further balance these two ratios by ranking the bursty queries using

$$score(q) = \alpha \cdot r_m(q) + (1 - \alpha) \cdot r_a(q) \quad (1)$$

By setting $s = 20$, $m = 2.5$, $\alpha = 0.8$ (based on several tests), we select the top 130 bigram queries which form the pool of bursty topics for our analysis. Table 1 shows some of these topics, covering multiple domains: politics, science, art, sports, entertainment, etc.

ID	Topic	ID	Topic
1	kentucky election	66	orlando hernandez
2	indiana election	75	daniel biechele
8	van goph	81	hurricane forecast
24	north korea	92	93 memorial
34	pacific quake	113	holloway case
52	florida fires	128	stephen colbert
63	hunger strike	130	bear attack

Table 1: Examples of News Topics

3.2 Context extraction from multiple sources

Once we select the pool of bursty topics, we gather the contexts of each topic from multiple sources: query log, news media, blog media, and social bookmarks. We assume that the language in these contexts will reflect the reactions of the bursty events in corresponding online media.

3.2.1 Super query context

The most straightforward context of bursty events in web search is the query string, which directly reflects the users' interests and perspectives in the topic. We therefore define the first type of context of a bursty topic in query log as the set of surrounding terms of that bursty bigram in the (longer) queries. For example, the word *aftermath* in the query "haiti earthquake aftermath" is a term in the context of the bursty topic *haiti earthquake*.

Formally, we define a *Super Query* of a bursty topic t, $sq(t)$, as the query which contains the bigram query t lexically as a substring. For each bursty topic t, we scan the whole query log Q and retrieve all the super queries of t to form the context which is represented by $SQ(t)$.

$$SQ(t) = \{q | q \in Q \quad and \quad q = sq(t)\}$$

[1] Now known as Bing: www.bing.com

$SQ(t)$ is defined as the super query context of t. For example, the super query context of ”kentucky election” contains terms such as “2006,” “results,” “christian county,” etc. These terms indicate what aspects the users are most interested in Kentucky Election during May 2006.

The super query context is widely explored by search engines to provide query expansion and query completion (Jones et al., 2006).

3.2.2 Query session context

Another interesting context of a bursty topic in query log is the sequence of queries that a user searches after he submitted the bursty query q. This context usually reflects how a user reformulates the representation of his information need and implicitly clarifies his interests in the topic.

We define a *Query Session* containing a bursty topic t, $qs(t)$, as the queries which are issued by the same user after he issued t, within 30 minutes. For each bursty topic t, we collect all the $qs(t)$ to form the query session context of t, $QS(t)$:

$$QS(t) = \{q | q \in Q \quad and \quad q \in qs(t)\}$$

In web search, the query session context is usually utilized to provide query suggestion and query reformulation (Radlinski and Joachims, 2005).

3.2.3 News contexts

News articles written by critics and journalists reflect the reactions and perspectives of such professional group of people to a bursty event. We collect news articles about these 130 bursty topics from Google News[2], by finding the most relevant news articles which (1) match the bursty topic t, (2) were published in May, 2006, and (3) were published by any of the five major news medias: CNN, NBC, ABC, New York Times and Washington Post.

We then retrieve the *title* and *body* of each news article. This provides us two contexts of each bursty topic t: the set of relevant news titles, $NT(t)$, and the set of relevant news bodies, $NB(t)$.

3.2.4 Blog contexts

Compared with news articles, blog articles are written by common users in the online communities, which are supposed to reflect the reactions and opinions of the public to the bursty events. We collect blog articles about these 130 topics from Google Blog[3], by finding the most relevant blog articles which (1) match the bursty topic t, (2) were published in May, 2006 (3) were published in the most popular blog community, Blogspot[4]. We then retrieve the *title* and *body* of each relevant blog post respectively. This provides another two contexts: the set of relevant blog titles, $BT(t)$, and the set of relevant blog bodies, $BB(t)$.

3.2.5 Social bookmarking context

Social bookmarks form a new source of social media that allows the users to tag the webpages they are interested in and share their tags with others. The tags are supposed to reflect how the users describe the content of the pages and their perspectives of the content in a concise way.

We use a sample of Delicious[5] bookmarks in May, 2006, which contains around $1.37M$ unique URLs. We observe that the bursty bigram queries are also frequently used as tags in Delicious. We thus construct another context of bursty events by collecting all the tags that are used to tag the same URLs as the bursty topic.

Formally, we define $DT(t)$ as the context of social tags of a topic t,

$$DT(t) = \{tag | \exists url, \quad s.t. \quad tag, t \in B(url)\},$$

where url is a URL and $B(url)$ stands for the set of all bookmarks of url.

3.3 Context Statistics

Now we have constructed the set of 130 bursty topics and 7 corresponding contexts from various sources. We believe that these contexts well represent the various types of online media and sources.

For each context, we then clean the data by removing stopwords and the bursty topic keywords themselves. We then represent it as either the set of unigrams or bigrams from this context. Table 2 shows the basic statistics of each context:

From Table 2 we observe the following facts:

- The query session context covers more terms (both unigrams and bigrams) than the super query

Table 2: Basic statistics of collections

context. In both contexts, the average number of unique bigrams is smaller than unigrams. This is because queries in search are usually very short. After removing stopwords and topic keywords, quite a few queries have no bigram in these contexts.

• News articles and blog articles cover most of the bursty topics and contain a rich set of unigrams and bigrams in the corresponding contexts.

• The Delicious context only covers less than 60% of bursty topics. We couldn't extract bigrams from bookmarks since delicious provides a "bag-of-tags" interface.

In Section 4, we present a comprehensive analysis of these different contexts of bursty topics, with three different types of comparison.

4 Experiment

In this section, we present a comprehensive comparative analysis of the different contexts, which represent the reactions to the bursty topics in corresponding sources.

4.1 Similarity & Predictability analysis

Our first task is to compare the content similarity of these sources. This will help us to understand how well the language usage in one context can be leveraged to predict the language usage in another context. This is especially useful to predict the content in web search. By representing each context of a bursty topic as a vector space model of unigrams/bigrams, we first compute and compare the average *cosine similarity* between contexts. We only include contexts with more than 5 unigram/bigrams into this comparison. The results are shown in Table A and Table B, respectively. Each table is followed by a heat map to visualize the pattern.

To investigate how well one source can predict the content of another, we also represent each context of a bursty topic as a unigram/bigram language model and compute the *Cross Entropy* (Kullback and Leibler, 1951) between every pairs of contexts. Cross Entropy measures how certain one probability distribution predicts another. We calculate such measure based on the following definition:

$$H_{CE}(m||n) = H(m) + D_{KL}(m||n)$$

We smooth the unigram language models using Laplace smoothing (Field, 1988) and the bigram language models using Katz back-off model (Katz, 1987).

The results are shown in Table C and Table D, followed by the corresponding heat maps. For each value $H_{CE}(m||n)$ in the table cell, m stands for the context in the row and n stands for the context in the column. Please note that in Figure 3, 4, a larger H_{CE} value corresponds to a lighter cell.

4.1.1 Results

From the results shown in Table A-D, or in Figure 1- 4 more visually, some interesting phenomena can be observed:

• Compared with other contexts, query session is much more similar to the super query. This makes sense because many super queries would be included in the query session.

• Compared with news and blog, the delicious context is closer to the query log context. In fact, delicious is reasonably close to all the other contexts. This means social tags could be an effective source to enhance bursty topics in web search in terms of query suggestion. However, as Table 2 shows, only less than 60% of topics can be covered by delicious tag. We have to explore other sources to make a comprehensive prediction.

• In the news and blog contexts, the title contexts are more similar to the query contexts than the body contexts. This may be because titles usually concisely describe the topic while bodies contain much more details and irrelevant contents.

Table 3: Cross-entropy among three sources

• News would be a better predictor of the query than blog in general. This is interesting, which indicates that many search activities may be initialized by reading the news.

• News and blogs are much more similar to each other than query logs. We hypothesize that this result reflects the behavior how people write blogs about bursty events – typically they may have read several news articles before writing their own blog. In the blog, they may directly quote or retell a part of the news article and then add their opinion.

• Table 3 reveals the generation relations among three sources: query, news and blog. From the upper table, we can observe that queries are more likely to be generated by news articles, rather than blog articles. From the lower table, we can observe that queries are more likely to generate blog articles(body), rather than news articles(body). This result is quite interesting, which indicates the users' actual behaviors: when a bursty event happens, users would search them from web *after* they read it from some *news articles*. And users would write their own blogs to discuss the event *after* they retrieve and digest information from the web.

• From Table 3 we also find that queries are more likely to generate news *title*, rather than blog *title*. It is natural since blogs are written by kinds of people. The content especially the title part contains more uncertainty.

4.1.2 Case study

We then conduct the analysis to the level of individual topics. Table 4 shows the correlation of each pair of contexts, computed based on the similarity between topics in SQ and corresponding topics in these contexts. We can observe that $News$ and $Blog$ are correlated with each other tightly. If one is a good predictor of bursty queries, the other one also tends to be.

	QS	NT	NB	BT	BB	DT
QS		0.46	0.59	0.58	**0.75**	0.46
NT			**0.73**	**0.79**	0.59	0.61
NB				**0.71**	**0.68**	0.61
BT					**0.78**	0.59
BB						0.48

Table 4: Correlations of the similarity with SQ

For some topics like "stephen colbert," and "three gorges," both $News$ and $Blog$ are quite similar to the queries, which implies some intrinsic properties (*coherence*) of these topics: users would refer to the same content when using the topic terms in different sources.

We also find that a few topics like "hot dogs," "bear attack," for which the similarity of $(SQ, News)$ and $(SQ, Blog)$ are both low. It is probably because these topics are too diverse and carries a lot of *ambiguity*.

Although in most cases they are correlated, sometimes $News$ and $Blog$ show different trends in the similarity to the queries. For example, $News$ is quite similar to the queries on the topics such as "holloway case" and "jazz fest" while $Blog$ is dissimilar. For these *unfamiliar* topics, users possibly search the web "after" they read the news articles and express their diverse opinions in the blog. In contrast, on the topics like "insurance rate" or "consolidation loans," $Blog$ is similar to the queries while $News$ is not. For these *daily-life-related* queries, users would express the similar opinions when they search or write blogs, while news articles typically report such "professional" viewpoints.

4.2 Coverage analysis

Are social bookmarks the best source to predict bursty content in search? It looks so from the similarity comparison, *if they have a good coverage of search contents*. In this experiment, we analyze the coverage of query contexts in other contexts in a systematic way. If the majority of terms in the super query context would be covered by a small proportion of top words from another source, this source has the potential.

4.2.1 Unigram coverage

We first analyze the coverage of unigrams from the super query context in four other contexts: QS, DT, $News$ (the combination of NT and NB) and $Blog$ (the combination of BT and BB) to compare with SQ. For each source, we rank the unigrams by frequency. Figure 5(a) shows the average trend of SQ-unigram coverage in different sources. The x-coordinate refers to the ratio of top unigrams in one source to the number of unigrams in SQ. For example, if SQ contains n unigrams, the ratio 2 stands for the top $2n$ unigrams in the other source. The y-coordinate refers to the coverage rate of SQ. We can observe that:

• Query Session naturally covers most of the super query terms (over 70%).

• Though delicious tags are more similar to queries than news and blog, as well as a relatively higher coverage rate than the other two while size ratio is small, the overall coverage rate is quite low: only 21.28%. Note that this is contradict to existing comparative studies between social bookmarks and search logs (Bischoff et al., 2008). Clearly, when considering bursty queries, the coverage and effectiveness of social bookmarks is much lower than considering all queries. Handling bursty queries is much more difficult; only using social bookmarks to predict queries is not a good choice. Other useful sources should be enrolled.

• As the growth of the size ratio, the coverage rate of news and blogs are both gradually increased. When stable, both of them arrive at a relatively high level (news: 66.36%, blog: 63.80%), which means news and blogs have a higher potential to predict the bursty topics in search. Moreover, in most cases, news is still prior to blog – not only the overall rate, but also the size ratio comparison while the coverage rate reaches 50% (news:109 $<$ blog:183).

4.2.2 Bigram Coverage

Also we analyze the bigram coverage. This time we only have 3 sources (no DT). We rank the bigrams by the pointwise mutual information instead of frequency, since not all the bigrams are "real" collocations. Figure 5(b) shows the results.

Different from the unigram coverage, except that the query session can naturally keep a high coverage rate (66.07%), both news and blog cover poorly. For this issue, we should re-consider the behavior that users search and write articles. News or blog articles consist of completed sentences and paragraphs which would contain plenty of meaningful bigrams. However search queries consist of keywords – relatively discrete and regardless of order. Therefore, except some proper nouns such as person's name, a lot of bigrams in the query log are formed in an ad-hoc way. Since the different expressions of search and writing, detecting unigrams is more informational than bigrams.

4.3 Coherence analysis

The above two experiments discuss the inter-relations among different contexts. In this section we will discuss the inner-relation within each particular context – when it comes to a particular bursty topic, how coherent is the information in each context? Does the discussion keep consistent, or slip into ambiguity?

We represent all the terms forming each context of a bursty topic as a weighted graph: $G = (V, E, W)$, where each $v \in V$ stands for each term, w_v stands for the weight of vertex v in G, and each $e \in E$ stands for the semantic closeness between a pair of terms (u, v) measured by $sim(u, v)$. We define the *density* of such a semantic graph as follows:

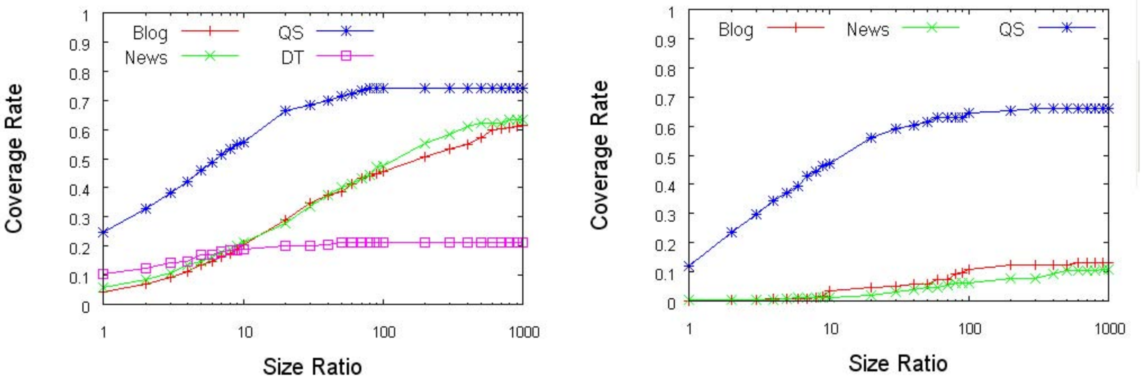
$$Den(G) = \frac{\Sigma_{u,v \in V, u \neq v} sim(u, v) w_u w_v}{\Sigma_{u,v \in V, u \neq v} w_u w_v} \quad (2)$$

If $sim(u, v)$ values the semantic similarity between u and v, a high value of $Den(G)$ implies that the whole context is semantically consistent. Otherwise, it may be diverse or ambiguous.

We build the graph of each context based on WordNet[6]. For a pair of words, WordNet provides a series of measures of the semantic similarity (Pedersen et al., 2004). We use the Path Distance Similarity (*path* for short) and Lin Similarity (*lin* for short) to measure $sim(u, v)$. Both measures range in $[0, 1]$.

For the convenience of computation, we choose the top 1100 unigrams ranked by term frequency in each source (if any) to represent the whole context on one specific topic.

[6] http://wordnet.princeton.edu/



(a) Unigram

(b) Bigram

Figure 5: Coverage results

4.3.1 Overall

Table 5 shows the average overall density of each sources over all the topics. From the table we can observe that QS has the lowest density in both of the measures. It is because the queries in one user session can easily shift to other (irrelevant) topics even in a short time.

Source	*path*	*lin*
SQ	0.098	0.128
QS	0.071	0.082
NT	0.103	0.129
NB	0.109	0.139
BT	0.099	0.109
BB	0.116	0.147
DT	0.102	0.127

Table 5: Overall Density

Another interesting phenomenon comes out that for either news or blog, the *body* is denser than the *title*, even if the body context contains much more terms. It can be explained by the roles of the title and the body in one article: the title contains a series of words which briefly summarize a topic while the body part would describe and discuss the title in details. When it maps to the semantic word network, the title tends to contain the vertices scattered in the graph, while the context of the body part would add more semantically related vertices around the original vertices to strength the relations. Thus, the body part has a higher density than the title part.

4.3.2 The trend analysis

Figure 6 shows the tendency of the density in each source. The x-coordinate refers to the TopN unigrams ranked by the term frequency in each source. From Figure 6 we can find that in most cases, the average density will gradually decrease while less important terms are added, which implies that the most important terms are denser, and other terms would disperse the topic.

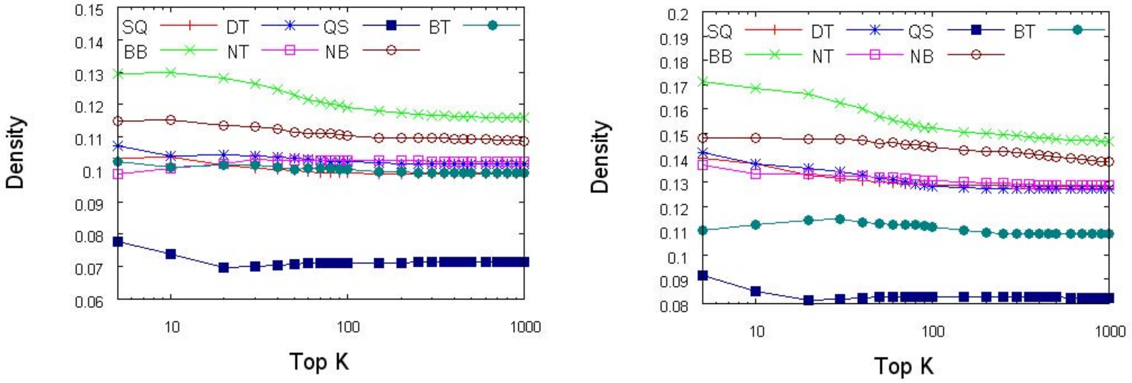
To better evaluate this tendency of each source, Table 6 shows the change rate of the highest density to the overall density measured by *lin*. We can easily find the following facts:

• The highest density is achieved when a small proportion of top terms are counted (6 sources for Top5 and one for Top20), which also supports our hypothesis: the more important, the more coherent.

• BB's density drops the fastest of all (15.1%), following by DT(10.6%). It may be because both blog and delicious tag are generated by many users. And the diversity of the users leads to different prospectives, which dilutes the context significantly.

• Both NT and NB drop quite slowly (5.8%, 6.8%), which means the professional journalists would have the relatively similar prospectives on the same topic. Thus the topic does not disperse too much. BT also keeps a high stability.

• Compared with news, blog is easier to disperse, which can be reflected by the density comparison between NT and BT. Although the density of BB is still higher than NT, we should notice that these two sources are not completely covered – about $3/4$ unigrams in these two contexts are not included in



(a) *path*

(b) *lin*

Figure 6: Trend of Density

the semantic networks. The curves clearly shows BB dropped faster than NB. One can expect that NB becomes denser than BB if all the unigrams in both sources are included in the network.

Source	Highest Den.	Overall Den.	Change
SQ	0.140(Top5)	0.128	-8.6%
QS	0.091(Top5)	0.082	-9.9%
NT	0.137(Top5)	0.129	-5.8%
NB	0.148(Top5)	0.139	-6.8%
BT	0.114(Top20)	0.109	-4.4%
BB	0.172(Top5)	0.147	-15.1%
DT	0.142(Top5)	0.127	-10.6%

Table 6: Tendency analysis of Density (Lin)

4.3.3 Case Study

From these 130 news topics, some of them shows a special tendency of coherence. For example, when more words are included, the density of the topic“three gorge” drops rapidly in most of the sources. The topic “florida fires” has the same trend. These topics are typically “*focus*” topics, which means users clearly pursue the unique event while they use these terms. Thus, the density in top unigrams is very high. It drops rapidly since users' personal interests and opinions toward to this event will be enrolled gradually.

In contrast, some topics like “heather mills,”, “insurance rate” express differently: their densities gradually increase with the growth of the terms. By observing these topics we find they are usually diverse topics (e.g: famous person name or entity name), which may lead to diverse search intentions of users. So the density of top unigrams is low and gradually increased since one main aspect is probably strengthened.

5 Conclusion and Future work

In this paper, we have studied and compared how the web content reacts to bursty events in multiple contexts of web search and online media. After a series of comprehensive experiments including content similarity and predictability, the coverage of search content, and semantic diversity, we found that social bookmarks are not enough to predict the queries because of a low coverage. Other sources like news and blogs need to be added. Furthermore, news can be seen as a consistent source which would not only trigger the discussion of bursty events in blogs but also in search queries.

When the target is to diversify the search results and query suggestions, blogs and social bookmarks are potentially useful accessory sources because of the high diversity of content.

Our work serves as a feasibility investigation of query suggestion for bursty events. Future work would address on how to systematically predict and recommend the bursty queries using online media, as well as a reasonable evaluation metrics upon it.

Abstract

Even the entire Web corpus does not *explicitly* answer all questions, yet inference can uncover many *implicit* answers. But where do inference rules come from?

This paper investigates the problem of *learning* inference rules from Web text in an unsupervised, domain-independent manner. The SHERLOCK system, described herein, is a first-order learner that acquires over 30,000 Horn clauses from Web text. SHERLOCK embodies several innovations, including a novel rule scoring function based on Statistical Relevance (Salmon et al., 1971) which is effective on ambiguous, noisy and incomplete Web extractions. Our experiments show that inference over the learned rules discovers three times as many facts (at precision 0.8) as the TEXTRUNNER system which merely extracts facts explicitly stated in Web text.

1 Introduction

Today's Web search engines locate pages that match keyword queries. Even sophisticated Web-based Q/A systems merely locate pages that contain an *explicit* answer to a question. These systems are helpless if the answer has to be inferred from multiple sentences, possibly on different pages. To solve this problem, Schoenmackers *et al.*(2008) introduced the HOLMES system, which infers answers from tuples extracted from text.

HOLMES's distinction is that it is domain independent and that its inference time is *linear* in the size of its input corpus, which enables it to scale to the Web. However, HOLMES's Achilles heel is that it requires hand-coded, first-order, Horn clauses as input. Thus, while HOLMES's inference *run time* is highly scalable, it requires substantial labor and expertise to hand-craft the appropriate set of Horn clauses for each new domain.

Is it possible to *learn* effective first-order Horn clauses automatically from Web text in a domain-independent and scalable manner? We refer to the set of ground facts derived from Web text as *open-domain theories*. Learning Horn clauses has been studied extensively in the Inductive Logic Programming (ILP) literature (Quinlan, 1990; Muggleton, 1995). However, learning Horn clauses from open-domain theories is particularly challenging for several reasons. First, the theories denote instances of an unbounded and unknown set of relations. Second, the ground facts in the theories are noisy, and incomplete. Negative examples are mostly absent, and certainly we cannot make the closed-world assumption typically made by ILP systems. Finally, the names used to denote both entities and relations are rife with both synonyms and polysymes making their referents ambiguous and resulting in a particularly noisy and ambiguous set of ground facts.

This paper presents a new ILP method, which is optimized to operate on open-domain theories derived from massive and diverse corpora such as the Web, and experimentally confirms both its effectiveness and superiority over traditional ILP algorithms in this context. Table 1 shows some example rules that were learned by SHERLOCK.

This work makes the following contributions:

1. We describe the design and implementation of the SHERLOCK system, which utilizes a novel, unsupervised ILP method to learn first-order Horn clauses from open-domain Web text.

Table 1: Example rules learned by SHERLOCK from Web extractions. Note that the italicized rules are unsound.

2. We derive an innovative scoring function that is particularly well-suited to unsupervised learning from noisy text. For Web text, the scoring function yields more accurate rules than several functions from the ILP literature.
3. We demonstrate the utility of SHERLOCK's automatically learned inference rules. Inference using SHERLOCK's learned rules identifies three times as many high quality facts (*e.g.*, precision $\geq$ 0.8) as were originally extracted from the Web text corpus.

The remainder of this paper is organized as follows. We start by describing previous work. Section 3 introduces the SHERLOCK rule learning system, with Section 3.4 describing how it estimates rule quality. We empirically evaluate SHERLOCK in Section 4, and conclude.

2 Previous Work

SHERLOCK is one of the first systems to learn first-order Horn clauses from open-domain Web extractions. The learning method in SHERLOCK belongs to the Inductive logic programming (ILP) subfield of machine learning (Lavrac and Dzeroski, 2001). However, classical ILP systems (*e.g.*, FOIL (Quinlan, 1990) and Progol (Muggleton, 1995)) make strong assumptions that are inappropriate for open domains. First, ILP systems assume high-quality, hand-labeled training examples for each relation of interest. Second, ILP systems assume that constants uniquely denote individuals; however, in Web text strings such as "dad" or "John Smith" are highly ambiguous. Third, ILP system typically assume complete, largely noise-free data whereas tuples extracted from Web text are both noisy and radically incomplete. Finally, ILP systems typically utilize negative examples, which are not available when learning from open-domain facts. One system that does not require negative examples is LIME (McCreath and Sharma, 1997); We compare SHERLOCK with LIME's methods in Section 4.3. Most prior ILP and Markov logic structure learning systems (*e.g.*, (Kok and Domingos, 2005)) are not designed to handle the noise and incompleteness of open-domain, extracted facts.

NELL (Carlson et al., 2010) performs coupled semi-supervised learning to extract a large knowledge base of instances, relations, and inference rules, bootstrapping from a few seed examples of each class and relation of interest and a few constraints among them. In contrast, SHERLOCK focuses mainly on learning inference rules, but does so without any manually specified seeds or constraints.

Craven *et al.*(1998) also used ILP to help information extraction on the Web, but required training examples and focused on a single domain.

Two other notable systems that learn inference rules from text are DIRT (Lin and Pantel, 2001) and RESOLVER (Yates and Etzioni, 2007). However, both DIRT and RESOLVER learn only a limited set of rules capturing synonyms, paraphrases, and simple entailments, not more expressive multi-part Horn clauses. For example, these systems may learn the rule X acquired $Y \implies X$ bought Y, which captures different ways of describing a purchase. Applications of these rules often depend on context (*e.g.*, if a person acquires a skill, that does not mean they bought the skill). To add the necessary context, ISP (Pantel et al., 2007) learned selectional preferences (Resnik, 1997) for DIRT's rules. The selectional preferences act as type restrictions

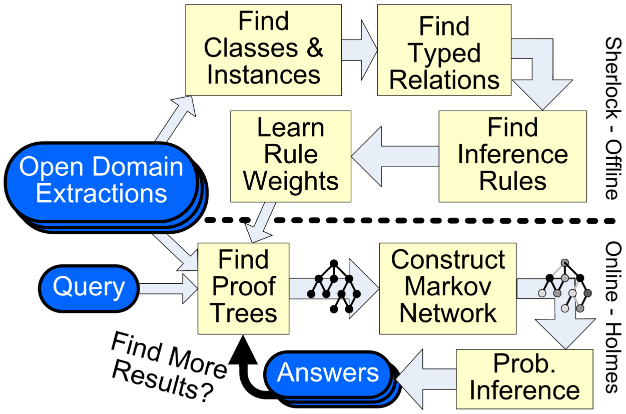

Figure 1: Architecture of SHERLOCK. SHERLOCK learns inference rules offline and provides them to the HOLMES inference engine, which uses the rules to answer queries.

on the arguments, and attempt to filter out incorrect inferences. While these approaches are useful, they are strictly more limited than the rules learned by SHERLOCK.

The Recognizing Textual Entailment (RTE) task (Dagan et al., 2005) is to determine whether one sentence entails another. Approaches to RTE include those of Tatu and Moldovan (2007), which generates inference rules from WordNet lexical chains and a set of axiom templates, and Pennacchiotti and Zanzotto (2007), which learns inference rules based on similarity across entailment pairs. In contrast with this work, RTE systems reason over full sentences, but benefit by being given the sentences and training data. SHERLOCK operates over simpler Web extractions, but is not given guidance about which facts may interact.

3 System Description

SHERLOCK takes as input a large set of open domain facts, and returns a set of weighted Horn-clause inference rules. Other systems (*e.g.*, HOLMES) use the rules to answer questions, infer additional facts, *etc.*

SHERLOCK's basic architecture is depicted in Figure 1. To learn inference rules, SHERLOCK performs the following steps:

1. Identify a "productive" set of classes and instances of those classes
2. Discover relations between classes
3. Learn inference rules using the discovered relations and determine the confidence in each rule

The first two steps help deal with the synonyms, homonyms, and noise present in open-domain theories by identifying a smaller, cleaner, and more cohesive set of facts to learn rules over.

SHERLOCK learns inference rules from a collection of open-domain extractions produced by TEXTRUNNER (Banko et al., 2007). The rules learned by SHERLOCK are input to an inference engine and used to find answers to a user's query. In this paper, SHERLOCK utilizes HOLMES as its inference engine when answering queries, and uses extracted facts of the form R(arg1, arg2) provided by the authors of TEXTRUNNER, but the techniques presented are more broadly applicable.

3.1 Finding Classes and Instances

SHERLOCK first searches for a set of well-defined classes and class instances. Instances of the same class tend to behave similarly, so identifying a good set of instances will make it easier to discover the general properties of the entire class.

Options for identifying interesting classes include manually created methods (WordNet (Miller et al., 1990)), textual patterns (Hearst, 1992), automated clustering (Lin and Pantel, 2002), and combinations (Snow et al., 2006). We use Hearst patterns because they are simple, capture how classes and instances are mentioned in Web text, and yield intuitive, explainable groups.

Hearst (1992) identified a set of textual patterns which indicate hyponymy (*e.g.*, '*Class* such as *Instance*'). Using these patterns, we extracted 29 million (instance, class) pairs from a large Web crawl. We then cleaned them using word stemming, normalization, and by dropping modifiers.

Unfortunately, the patterns make systematic errors (*e.g.*, extracting Canada as the name of a city from the phrase 'Toronto, Canada and other cities.') To address this issue, we discard the low frequency classes of each instance. This heuristic reduces the noise due to systematic error while still capturing the important senses of each word. Additionally, we use the extraction frequency to estimate the probability that a particular mention of an instance refers to each of its potential classes (*e.g.*, New York appears as a city 40% of the time, a state 35% of the time, and a place, area, or center the rest of the time).

Ambiguity presents a significant obstacle when learning inference rules. For example, the corpus contains the sentences ‘broccoli contains this vitamin’ and ‘this vitamin prevents scurvy,’ but it is unclear if the sentences refer to the same vitamin. The two main sources of ambiguity we observed are references to a more general class instead of a specific instance (*e.g.*, ‘vitamin’), and references to a person by only their first or last name. We eliminate the first by removing terms that frequently appear as the class name with other instances, and the second by removing common first and last names.

The 250 most frequently mentioned class names include a large number of interesting classes (*e.g.*, companies, cities, foods, nutrients, locations) as well as ambiguous concepts (*e.g.*, ideas, things). We focus on the less ambiguous classes by eliminating any class not appearing as a descendant of physical entity, social group, physical condition, or event in WordNet. Beyond this filtering we make no use of a type hierarchy and treat classes independently.

In our corpus, we identify 1.1 million distinct, cleaned (instance, class) pairs for 156 classes.

3.2 Discovering Relations between Classes

Next, SHERLOCK discovers how classes relate to and interact with each other. Prior work in relation discovery (Shinyama and Sekine, 2006) has investigated the problem of finding relationships between different classes. However, the goal of this work is to learn rules on top of the discovered typed relations. We use a few simple heuristics to automatically identify interesting relations.

For every pair of classes (C_1, C_2), we find a set of typed, candidate relations from the 100 most frequent relations in the corpus where the first argument is an instance of C_1 and the second argument is an instance of C_2. For extraction terms with multiple senses (*e.g.*, New York), we split their weight based on how frequently they appear with each class in the Hearst patterns.

However, many discovered relations are rare and meaningless, arising from either an extraction error or word-sense ambiguity. For example, the extraction ‘Apple is based in Cupertino’ gives some evidence that a fruit may possibly be based in a city. We attempt to filter out incorrectly-typed relations using two heuristics. We first discard any relation whose weighted frequency falls below a threshold, since rare relations are more likely to arise due to extraction errors or word-sense ambiguity. We also remove relations whose pointwise mutual information (PMI) is below a threshold T=$exp(2) \approx 7.4$:

$$PMI(R(C_1, C_2)) = \frac{p(R, C_1, C_2)}{p(R, \cdot, \cdot) * p(\cdot, C_1, \cdot) * p(\cdot, \cdot, C_2)}$$

where $p(R, \cdot, \cdot)$ is the probability a random extraction has relation R, $p(\cdot, C_1, \cdot)$ is the probability a random extraction has an instance of C_1 as its first argument, $p(\cdot, \cdot, C_2)$ is similar for the second argument, and $p(R, C_1, C_2)$ is the probability that a random extraction has relation R and instances of C_1 and C_2 as its first and second arguments, respectively. A low PMI indicates the relation occurred by random chance, which is typically due to ambiguous terms or extraction errors.

Finally, we use two TEXTRUNNER specific cleaning heuristics: we ignore a small set of stop-relations (‘be’, ‘have’, and ‘be *preposition*’) and extractions whose arguments are more than four tokens apart. This process identifies 10,000 typed relations.

3.3 Learning Inference Rules

SHERLOCK attempts to learn inference rules for each typed relation in turn. SHERLOCK receives a target relation, R, a set of observed examples of the relation, E^+, a maximum clause length k, a minimum support, s, and an acceptance threshold, t, as input. SHERLOCK generates all first-order, definite clauses up to length k, where R appears as the head of the clause. It retains each clause that:

1. Contains no unbound variables
2. Infers at least s examples from E^+
3. Scores at least t according to the score function

We now propose a novel score function, and empirically validate our choice in Sections 4.3 and 4.4.

3.4 Evaluating Rules by Statistical Relevance

The problem of evaluating candidate rules has been studied by many researchers, but typically in either a supervised or propositional context whereas we are learning first-order Horn-clauses from a noisy set of positive examples. Moreover, due to the incomplete nature of the input corpus and the imperfect yield of extraction—many true facts are not stated explicitly in the set of ground assertions used by the learner to evaluate rules.

The absence of negative examples, coupled with noise, means that standard ILP evaluation functions (*e.g.*, (Quinlan, 1990) and (Dzeroski and Bratko, 1992)) are not appropriate. Furthermore, when evaluating a particular rule with consequent C and antecedent A, it is natural to consider $p(C|A)$ but, due to missing data, this absolute probability estimate is often misleading: in many cases C will hold given A but the fact C is not mentioned in the corpus.

Thus to evaluate rules over extractions, we need to consider *relative* probability estimates. *I.e.*, is $p(C|A) \gg p(C)$? If so, then A is said to be *statistically relevant* to C (Salmon et al., 1971).

Statistical relevance tries to infer the simplest set of factors which explain an observation. It can be viewed as searching for the simplest propositional Horn-clause which increases the likelihood of a goal proposition g. The two key ideas in determining statistical relevance are discovering factors which substantially increase the likelihood of g (even if the probabilities are small in an absolute sense), and dismissing irrelevant factors.

To illustrate these concepts, consider the following example. Suppose our goal is to predict if New York City will have a storm (S). On an arbitrary day, the probability of having a storm is fairly low ($p(S) \ll 1$). However, if we know that the atmospheric pressure on that day is low, this substantially increases the probability of having a storm (although that absolute probability may still be small). According to the principle of statistical relevance, low atmospheric pressure (LP) is a factor which predicts storms (S :- LP), since $p(S|LP) \gg p(S)$.

The principle of statistical relevance also identifies and removes irrelevant factors. For example, let M denote the gender of New York's mayor. Since $p(S|LP, M) \gg p(S)$, it naïvely appears that storms in New York depend on the gender of the mayor in addition to the air pressure. The statistical relevance principle sidesteps this trap by removing any factors which are conditionally independent of the goal, given the remaining factors. For example, we observe $p(S|LP)$=$p(S|LP, M)$, and so we say that M is not statistically relevant to S. This test applies Occam's razor by searching for the simplest rule which explains the goal.

Statistical relevance appears useful in the open-domain context, since all the necessary probabilities can be estimated from only positive examples. Furthermore, approximating relative probabilities in the presence of missing data is much more reliable than determining absolute probabilities.

Unfortunately, Salmon defined statistical relevance in a propositional context. One technical contribution of our work is to lift statistical relevance to first order Horn-clauses as follows. For the Horn-clause $\mathtt{Head}(\mathtt{v}_1, ..., \mathtt{v}_n)$:-$\mathtt{Body}(\mathtt{v}_1, ..., \mathtt{v}_m)$ (where $\mathtt{Body}(\mathtt{v}_1, ..., \mathtt{v}_m)$ is a conjunction of function-free, non-negated, first-order relations, and $v_i \in V$ is the set of typed variables used in the rule), we say the body helps explain the head if:

1. Observing an instance of the body substantially increases the probability of observing the head.
2. The body contains no irrelevant (conditionally independent) terms.

We evaluate conditional independence of terms using ILP's technique of Θ-subsumption, ensuring there is no more general clause that is similarly predictive of the head. Formally, clause C_1 Θ-subsumes clause C_2 if and only if there exists a substitution Θ such that $C_1\Theta \subseteq C_2$ where each clause is treated as the set of its literals. For example, $\mathtt{R}(\mathtt{x}, \mathtt{y})$ Θ-subsumes $\mathtt{R}(\mathtt{x}, \mathtt{x})$, since $\{\mathtt{R}(\mathtt{x}, \mathtt{y})\}\Theta \subseteq \{\mathtt{R}(\mathtt{x}, \mathtt{x})\}$ when Θ=$\{\mathtt{y}/\mathtt{x}\}$. Intuitively, if C_1 Θ-subsumes C_2, it means that C_1 is more general than C_2.

Definition 1 *A first-order Horn-clause* $\mathtt{Head}(...)$:-$\mathtt{Body}(...)$ *is* statistically relevant *if* $p(\mathtt{Head}(...)|\mathtt{Body}(...)) \gg p(\mathtt{Head}(...))$ *and if there is no clause body* $\mathtt{B}'(...)\Theta \subseteq \mathtt{Body}(...)$ *such that* $p(\mathtt{Head}(...)|\mathtt{Body}(...)) \approx p(\mathtt{Head}(...)|\mathtt{B}'(...))$

In practice it is difficult to determine the probabilities exactly, so when checking for statistical relevance we ensure that the probability of the rule is at least a factor t greater than the probability of any subsuming rule, that is, $p(\mathtt{Head}(...)|\mathtt{Body}(...)) \geq t * p(\mathtt{Head}(...)|\mathtt{B}'(...))$

We estimate $p(\mathtt{Head}(...)|\mathtt{B}(...))$ from the observed facts by assuming values of $\mathtt{Head}(...)$ are generated by sampling values of $\mathtt{B}(...)$ as follows: for variables v_s shared between $\mathtt{Head}(...)$ and $\mathtt{B}(...)$, we sample values of v_s uniformly from all observed groundings of $\texttt{B}(...)$. For variables v_i, if any, that appear in $\texttt{Head}(...)$ but not in $\texttt{B}(...)$, we sample their values according to a distribution $p(v_i|class_i)$. We estimate $p(v_i|class_i)$ based on the relative frequency that v_i was extracted using a Hearst pattern with $class_i$.

Finally, we ensure the differences are statistically significant using the likelihood ratio statistic:

$$2N_r \sum_{\substack{\texttt{H}(...)\in \\ \{\texttt{Head}(...),\neg\texttt{Head}(...)\}}} p(\texttt{H}(...)|\texttt{Body}(...)) * log\frac{p(\texttt{H}(...)|\texttt{Body}(...))}{p(\texttt{H}(...)|\texttt{B}'(...))}$$

where $p(\neg\texttt{Head}(...)|\texttt{B}(...)) = 1-p(\texttt{Head}(...)|\texttt{B}(...))$ and N_r is the number of results inferred by the rule $\texttt{Head}(...)$:-$\texttt{Body}(...)$. This test is distributed approximately as χ^2 with one degree of freedom. It is similar to the *statistical significance* test used in mFOIL (Dzeroski and Bratko, 1992), but has two modifications since SHERLOCK doesn't have training data. In lieu of positive and negative examples, we use whether or not the inferred head value was observed, and compare against the distribution of a subsuming clause $\texttt{B}'(...)$ rather than a known prior.

This method of evaluating rules has two important differences from ILP under a closed world assumption. First, our probability estimates consider the fact that examples provide varying amounts of information. Second, statistical relevance finds rules with large increases in relative probability, not necessarily a large absolute probability. This is crucial in an open domain setting where most facts are false, which means the trivial rule that everything is false will have high accuracy. Even for true rules, the observed estimates $p(\texttt{Head}(...)|\texttt{Body}(...)) \ll 1$ due to missing data and noise.

3.5 Making Inferences

In order to benefit from learned rules, we need an inference engine; with its linear-time scalability, HOLMES is a natural choice (Schoenmackers et al., 2008). As input HOLMES requires a target atom $\texttt{H}(...)$, an evidence set E and weighted rule set R as input. It performs a form of *knowledge based model construction* (Wellman et al., 1992), first finding facts using logical inference, then estimating the confidence of each using a Markov Logic Network (Richardson and Domingos, 2006).

Prior to running inference, it is necessary to assign a weight to each rule learned by SHERLOCK. Since the rules and inferences are based on a set of noisy and incomplete extractions, the algorithms used for both weight learning and inference should capture the following characteristics of our problem:

C1. Any arbitrary unknown fact is highly unlikely to be true.

C2. The more frequently a fact is extracted from the Web, the more likely it is to be true. However, facts in E should have a confidence bounded by a threshold $p_{max} < 1$. E contains systematic extraction errors, so we want uncertainty in even the most frequently extracted facts.

C3. An inference that combines uncertain facts should be less likely than each fact it uses.

Next, we describe the needed modifications to the weight learning and inference algorithm to achieve the desired behavior.

3.5.1 Weight Learning

We use the discriminative weight learning procedure described by Huynh and Mooney (2008). Setting the weights involves counting the number of true groundings for each rule in the data (Richardson and Domingos, 2006). However, the noisy nature of Web extractions will make this an overestimate. Consequently, we compute $n_i(E)$, the number of true groundings of rule i, as follows:

$$n_i(E) = \sum_j \max_k \prod_{B(...)\in Body_{ijk}} p(B(...)) \qquad (1)$$

where E is the evidence, j ranges over heads of the rule, $Body_{ijk}$ is the body of the kth grounding for jth head of rule i, and $p(B(...))$ is approximated using a logistic function of the number of times $B(...)$ was extracted,[1] scaled to be in the range [0,0.75]. This models **C2** by giving increasing but bounded confidence for more frequently extracted facts. In practice, this also helps address **C3** by giving longer rules smaller values of n_i, which reflects that inferences arrived at through a combination of multiple, noisy facts should have lower confidence. Longer rules are also more likely to have multiple groundings that infer a particular head, so keeping only the most likely grounding prevents a head from receiving undue weight from any single rule.

[1] We note that this approximation is equivalent to an MLN which uses only the two rules defined in 3.5.2

Finally, we place a very strong Gaussian prior (*i.e.*, L_2 penalty) on the weights. Longer rules have a higher prior to capture the notion that they are more likely to make incorrect inferences. Without a high prior, each rule would receive an unduly high weight as we have no negative examples.

3.5.2 Probabilistic Inference

After learning the weights, we add the following two rules to our rule set:

1. `H`(...) with negative weight w_{prior}
2. `H`(...):-`ExtractedFrom`(`H`(...),$sentence_i$) with weight 1

The first rule models **C1**, by saying that most facts are false. The second rule models **C2**, by stating the probability of fact depends on the number of times it was extracted. The weights of these rules are fixed. We do not include these rules during weight learning as doing so swamps the effects of the other inference rules (*i.e.*, forces them to zero).

HOLMES attempts to infer the truth value of each ground atom `H`(...) in turn by treating all other extractions E in our corpus as evidence. Inference also requires computing $n_i(E)$ which we do according to Equation 1 as in weight learning.

4 Experiments

One can attempt to evaluate a rule learner by estimating the quality of learned rules, or by measuring their impact on a system that uses the learned rules. Since the notion of 'rule quality' is vague except in the context of an application, we evaluate SHERLOCK in the context of the HOLMES inference-based question answering system.

Our evaluation focuses on three main questions:

1. Does inference utilizing learned Horn rules improve the precision/recall of question answering and by how much?
2. How do different rule-scoring functions affect the performance of learning?
3. What role does each of SHERLOCK's components have in the resulting performance?

4.1 Methodology

Our objective with rule learning was to improve the system's ability to answer questions such as 'What foods prevent disease?' So we focus our evaluation on the task of computing as many instances as possible of an atomic pattern `Rel`(x, y). In this example, `Rel` would be bound to 'Prevents', x would have type 'Food' and y would have type 'Disease.'

But which relations should be used in the test? There is a large variance in behavior across relations, so examining any particular relation may give misleading results. Instead, we examine the global performance of the system by querying HOLMES for all open-domain relations identified in Section 3.2 as follows:

1. Score all candidate rules according to the rule scoring metric M, accept all rules with a score at least t_M (tuned on a small development set of rules), and learn weights for all accepted rules.
2. Find all facts inferred by the rules and use the rule weights to estimate the fact probabilities.
3. Reduce type information. For each fact, (*e.g.*, `BasedIn`(`Diebold`, `Ohio`)) which has been deduced with multiple type signatures (*e.g.*, Ohio is both a state and a geographic location), keep only the one with maximum probability (*i.e.*, conservatively assuming dependence).
4. Place all results into bins based on their probabilities, and estimate the precision and the number of correct facts in the bin using a random sample.

In these experiments we consider rules with up to $k = 2$ relations in the body. We use a corpus of 1 million raw extractions, corresponding to 250,000 distinct facts. SHERLOCK found 5 million candidate rules that infer at least two of the observed facts. Unless otherwise noted, we use SHERLOCK's rule scoring function to evaluate the rules (Section 3.4).

The results represent a wide variety of domains, covering a total of 10,672 typed relations. We observe between a dozen and 2,375 distinct, ground facts for each relation. SHERLOCK learned a total of 31,000 inference rules.[2] Learning all rules, rule

[2] The learned rules are available at: http://www.cs.washington.edu/research/sherlock-hornclauses/

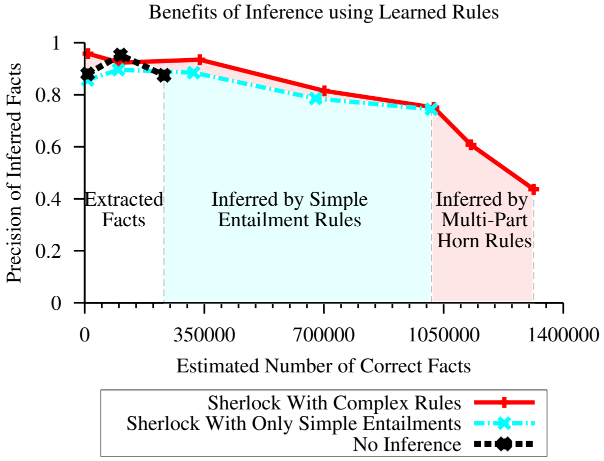

Figure 2: Inference discovers many facts which are not explicitly extracted, identifying 3x as many high quality facts (precision 0.8) and more than 5x as many facts overall. Horn-clauses with multiple relations in the body infer 30% more correct facts than are identified by simpler entailment rules, inferring many facts not present in the corpus in any form.

weights, and performing the inference took 50 minutes on a 72 core cluster. However, we note that for half of the relations SHERLOCK accepts no inference rules, and remind the reader that the performance on any particular relation may be substantially different, and depends on the facts observed in the corpus and on the rules learned.

4.2 Benefits of Inference

We first evaluate the utility of the learned Horn rules by contrasting the precision and number of correct and incorrect facts identified with and without inference over learned rules. We compare against two simpler variants of SHERLOCK. The first is a no-inference baseline that uses no rules, returning only facts that are explicitly extracted. The second baseline only accepts rules of length $k = 1$, allowing it to make simple entailments but not more complicated inferences using multiple facts.

Figure 2 compares the precision and estimated number of correct facts with and without inference. As is apparent, the learned inference rules substantially increase the number of known facts, quadrupling the number of correct facts beyond what are explicitly extracted.

The Horn rules having a body-length of two identify 30% more facts than the simpler length-one rules. Furthermore, we find the Horn rules yield slightly increased precision at comparable levels of recall, although the increase is not statistically significant. This behavior can be attributed to learning smaller weights for the length-two rules than the length-one rules, allowing the length-two rules provide a small amount of additional evidence as to which facts are true, but typically not enough to overcome the confidence of a more reliable length-one rule.

Analyzing the errors, we found that about one third of SHERLOCK's mistakes are due to metonymy and word sense ambiguity (*e.g.*, confusing Vancouver, British Columbia with Vancouver, Washington), one third are due to inferences based on incorrectly-extracted facts (*e.g.*, inferences based on the incorrect fact $\texttt{IsLocatedIn}(\texttt{New York}, \texttt{Suffolk County})$, which was extracted from sentences like 'Deer Park, New York is located in Suffolk County'), and the rest are due to unsound or incorrect inference rules (*e.g.*, $\texttt{BasedIn}(\texttt{Company}, \texttt{City})$:- $\texttt{BasedIn}(\texttt{Company}, \texttt{Country}) \wedge \texttt{CapitalOf}(\texttt{City}, \texttt{Country})$). Without negative examples it is difficult to distinguish correct rules from these unsound rules, since the unsound rules are correct more often than expected by chance.

Finally, we note that although simple, length-one rules capture many of the results, in some respects they are just rephrasing facts that are extracted in another form. However, the more complex, length-two rules synthesize facts extracted from multiple pages, and infer results that are not stated anywhere in the corpus.

4.3 Effect of Scoring Function

We now examine how SHERLOCK's rule scoring function affects its results, by comparing it with three rule scoring functions used in prior work:

LIME. The LIME ILP system (McCreath and Sharma, 1997) proposed a metric that generalized Muggleton's (1997) positive-only score function by modeling noise and limited sample sizes.

M-Estimate of rule precision. This is a common approach for handling noise in ILP (Dzeroski and Bratko, 1992). It requires negative examples, which we generated by randomly swapping arguments between positive examples.

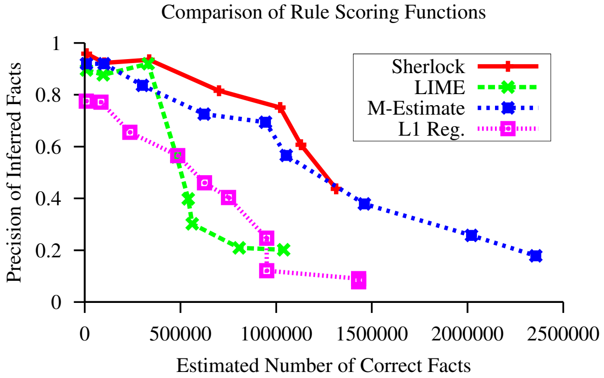

Figure 3: SHERLOCK identifies rules that lead to more accurate inferences over a large set of open-domain extracted facts, deducing 2x as many facts at precision 0.8.

L1 Regularization. As proposed in (Huynh and Mooney, 2008), this learns weights for all candidate rules using L_1-regularization (encouraging sparsity) instead of L_2-regularization, and retains only those with non-zero weight.

Figure 3 compares the precision and estimated number of correct facts inferred by the rules of each scoring function. SHERLOCK has consistently higher precision, and finds twice as many correct facts at precision 0.8.

M-Estimate accepted eight times as many rules as SHERLOCK, increasing the number of inferred facts at the cost of precision and longer inference times. Most of the errors in M-Estimate and L1 Regularization come from incorrect or unsound rules, whereas most of the errors for LIME stem from systematic extraction errors.

4.4 Scoring Function Design Decisions

SHERLOCK requires a rule to have statistical relevance and statistical significance. We perform an ablation study to understand how each of these contribute to SHERLOCK's results.

Figure 4 compares the precision and estimated number of correct facts obtained when requiring rules to be only statistically relevant, only statistically significant, or both. As is expected, there is a precision/recall tradeoff. SHERLOCK has higher precision, finding more than twice as many results at precision 0.8 and reducing the error by 39% at a recall of 1 million correct facts. Statistical significance finds twice as many correct facts as SHERLOCK, but the extra facts it discovers have precision < 0.4.

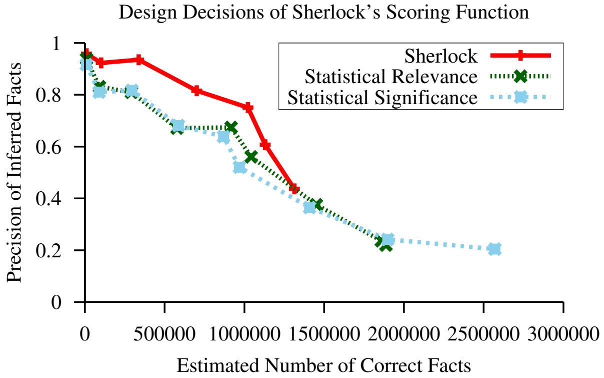

Figure 4: By requiring rules to have both statistical relevance and statistical significance, SHERLOCK rejects many error-prone rules that are accepted by the metrics individually. The better rule set yields more accurate inferences, but identifies fewer correct facts.

Comparing the rules accepted in each case, we found that statistical relevance and statistical significance each accepted about 180,000 rules, compared to about 31,000 for SHERLOCK. The smaller set of rules accepted by SHERLOCK not only leads to higher precision inferences, but also speeds up inference time by a factor of seven.

In a qualitative analysis, we found the statistical relevance metric overestimates probabilities for sparse rules, which leads to a number of very high scoring but meaningless rules. The statistical significance metric handles sparse rules better, but is still overconfident in the case of many unsound rules.

4.5 Analysis of Weight Learning

Finally, we empirically validate the modifications of the weight learning algorithm from Section 3.5.1.

The learned-rule weights only affect the probabilities of the inferred facts, not the inferred facts themselves, so to measure the influence of the weight learning algorithm we examine the recall at precision 0.8 and the area under the precision-recall curve (AuC). We build a test set by holding SHERLOCK's inference rules constant and randomly sampling 700 inferred facts. We test the effects of:

- Fixed *vs.* Variable Penalty - Do we use the same L_2 penalty on the weights for all rules or a stronger L_2 penalty for longer rules?
- Full *vs.* Weighted Grounding Counts - Do we count all unweighted rule groundings (as in (Huynh and Mooney, 2008)), or only the best weighted one (as in Equation 1)?

	Recall (p=0.8)	AuC
Variable Penalty, Weighted Counts (used by SHERLOCK)	**0.35**	**0.735**
Variable Penalty, Full Counts	0.28	0.726
Fixed Penalty, Weighted Counts	0.27	0.675
Fixed Penalty, Full Counts	0.17	0.488

Table 2: SHERLOCK's modified weight learning algorithm gives better probability estimates over noisy and incomplete Web extractions. Most of the gains come from penalizing longer rules more, but using weighted grounding counts further improves recall by 0.07, which corresponds to almost 100,000 additional facts at precision 0.8.

We vary each of these independently, and give the performance of all 4 combinations in Table 2.

The modifications from Section 3.5.1 improve both the AuC and the recall at precision 0.8. Most of the improvement is due to using stronger penalties on longer rules, but using the weighted counts in Equation 1 improves recall by a factor of 1.25 at precision 0.8. While this may not seem like much, the scale is such that it leads to almost 100,000 additional correct facts at precision 0.8.

5 Conclusion

This paper addressed the problem of learning first-order Horn clauses from the noisy and heterogeneous corpus of open-domain facts extracted from Web text. We showed that SHERLOCK is able to learn Horn clauses in a large-scale, domain-independent manner. Furthermore, the learned rules are valuable, because they infer a substantial number of facts which were not extracted from the corpus.

While SHERLOCK belongs to the broad category of ILP learners, it has a number of novel features that enable it to succeed in the challenging, open-domain context. First, SHERLOCK automatically identifies a set of high-quality extracted facts, using several simple but effective heuristics to defeat noise and ambiguity. Second, SHERLOCK is unsupervised and does not require negative examples; this enables it to scale to an unbounded number of relations. Third, it utilizes a novel rule-scoring function, which is tolerant of the noise, ambiguity, and missing data issues prevalent in facts extracted from Web text. The experiments in Figure 3 show that, for open-domain facts, SHERLOCK's method represents a substantial improvement over traditional ILP scoring functions.

Directions for future work include inducing longer inference rules, investigating better methods for combining the rules, allowing deeper inferences across multiple rules, evaluating our system on other corpora and devising better techniques for handling word sense ambiguity.

Constraints based Taxonomic Relation Classification

Abstract

Determining whether two terms in text have an ancestor relation (e.g. *Toyota* and *car*) or a sibling relation (e.g. *Toyota* and *Honda*) is an essential component of textual inference in NLP applications such as Question Answering, Summarization, and Recognizing Textual Entailment. Significant work has been done on developing stationary knowledge sources that could potentially support these tasks, but these resources often suffer from low coverage, noise, and are inflexible when needed to support terms that are not identical to those placed in them, making their use as general purpose background knowledge resources difficult. In this paper, rather than building a stationary hierarchical structure of terms and relations, we describe a system that, given two terms, determines the taxonomic relation between them using a machine learning-based approach that makes use of existing resources. Moreover, we develop a global constraint optimization inference process and use it to leverage an existing knowledge base also to enforce relational constraints among terms and thus improve the classifier predictions. Our experimental evaluation shows that our approach significantly outperforms other systems built upon existing well-known knowledge sources.

1 Introduction

Taxonomic relations that are read off of structured ontological knowledge bases have been shown to play important roles in many computational linguistics tasks, such as document clustering (Hotho et al., 2003), navigating text databases (Chakrabarti et al., 1997), Question Answering (QA) (Saxena et al., 2007) and summarization (Vikas et al., 2008). It is clear that the recognition of taxonomic relation between terms in sentences is essential to support textual inference tasks such as Recognizing Textual Entailment (RTE) (Dagan et al., 2006). For example, it may be important to know that a *blue Toyota* is neither a *red Toyota* nor a *blue Honda*, but that all are cars, and even Japanese cars. Work in Textual Entailment has argued quite convincingly (MacCartney and Manning, 2008; MacCartney and Manning, 2009) that many such textual inferences are largely compositional and depend on the ability to recognize some basic taxonomic relations such as the ancestor or sibling relations between terms. To date, these taxonomic relations can be read off manually generated ontologies such as Wordnet that explicitly represent these, and there has also been some work trying to extend the manually built resources using automatic acquisition methods resulting in structured knowledge bases such as the Extended WordNet (Snow et al., 2006) and the YAGO ontology (Suchanek et al., 2007).

However, identifying when these relations hold using fixed stationary hierarchical structures may be impaired by noise in the resource and by uncertainty in mapping targeted terms to concepts in the structures. In addition, for knowledge sources derived using bootstrapping algorithms and distributional semantic models such as (Pantel and Pennacchiotti, 2006; Kozareva et al., 2008; Baroni and Lenci, 2010), there is typically a trade-off between precision and recall, resulting either in a relatively accurate resource with low coverage or a noisy re-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1099–1109,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

source with broader coverage. In the current work, we take a different approach, identifying directly whether a pair of terms hold a taxonomic relation.

Fixed resources, as we observe, are inflexible when dealing with targeted terms not being covered. This often happens when targeted terms have the same meaning, but different surface forms, than the terms used in the resources (e.g. *Toyota Camry* and *Camry*). We argue that it is essential to have a classifier that, given two terms, can build a semantic representation of the terms and determines the taxonomic relations between them. This classifier will make use of existing knowledge bases in multiple ways, but will provide significantly larger coverage and more precise results. We make use of a dynamic resource such as Wikipedia to guarantee increased coverage without changing our model and also perform normalization-to-Wikipedia to find appropriate Wikipedia replacements for outside-Wikipedia terms. Moreover, stationary resources are usually brittle because of the way most of them are built: using local relational patterns (e.g. (Hearst, 1992; Snow et al., 2005)). Infrequent terms are less likely to be covered, and some relations may not be supported well by these methods because their corresponding terms rarely appear in close proximity (e.g., an Israeli tennis player *Dudi Sela* and *Roger Federrer*). Our approach uses search techniques to gather relevant Wikipedia pages of input terms and performs a learning-based classification w.r.t. to the features extracted from these pages as a way to get around this brittleness.

Motivated by the needs of NLP applications such as RTE, QA, Summarization, and the compositionality argument alluded to above, we focus on identifying two fundamental types of taxonomic relations - *ancestor* and *sibling*. An ancestor relation and its directionality can help us infer that a statement with respect to the child (e.g. *cannabis*) holds for an ancestor (e.g. *drugs*) as in the following example, taken from a textual entailment challenge dataset:

> **T**: Nigeria's NDLEA has seized 80 metric tonnes of *cannabis* in one of its largest ever hauls, officials say.
>
> **H**: Nigeria seizes 80 tonnes of *drugs*.

Similarly, it is important to know of a sibling relation to infer that a statement about *Taiwan* may (without additional information) contradict a similar statement with respect to *Japan* since these are different countries, as in the following:

> **T**: A strong earthquake struck off the southern tip of *Taiwan* at 12:26 UTC, triggering a warning from Japan's Meteorological Agency that a 3.3 foot tsunami could be heading towards Basco, in the Philippines.
>
> **H**: An earthquake strikes *Japan*.

Several recent TE studies (Abad et al., 2010; Sammons et al., 2010) suggest to isolate TE phenomena, such as recognizing taxonomic relations, and study them separately; they discuss some of characteristics of phenomena such as contradiction from a similar perspective to ours, but do not provide a solution.

In this paper, we present **TA**xonomic **RE**lation **C**lassifier (TAREC), a system that classifies taxonomic relations between a given pair of terms using a machine learning based classifier. An integral part of TAREC is also our inference model that makes use of relational constraints to enforce coherency among several related predictions. TAREC does not aim at building or extracting a hierarchical structure of concepts and relations, but rather to directly recognize taxonomic relations given a pair of terms. Target terms are represented using vector of features that are extracted from retrieved corresponding Wikipedia pages. In addition, we make use of existing stationary ontologies to find related terms to the target terms, and classify those too. This allows us to make use of a constraint-based inference model (following (Roth and Yih, 2004; Roth and Yih, 2007) that enforces coherency of decisions across related pairs (e.g., if x is-a y and y is-a z, it cannot be that x is a sibling of z).

In the rest of the paper, after discussing related work in Section 2, we present an overview of TAREC in Section 3. The learning component and the inference model of TAREC are described in Sections 4 and 5. We experimentally evaluate TAREC in Section 6 and conclude our paper in Section 7.

2 Related Work

There are several works that aim at building taxonomies and ontologies which organize concepts and their taxonomic relations into hierarchical structures. (Snow et al., 2005; Snow et al., 2006) constructed classifiers to identify hypernym relationship between terms from dependency trees of large corpora. Terms with recognized hypernym relation are extracted and incorporated into a man-made lexical database, WordNet (Fellbaum, 1998), resulting in the *extended WordNet*, which has been augmented with over $400,000$ synsets. (Ponzetto and Strube, 2007) and (Suchanek et al., 2007) both mined Wikipedia to construct hierarchical structures of concepts and relations. While the former exploited Wikipedia category system as a conceptual network and extracted a taxonomy consisting of subsumption relations, the latter presented the YAGO ontology, which was automatically constructed by mining and combining Wikipedia and WordNet. A natural way to use these hierarchical structures to support taxonomic relation classification is to map targeted terms onto the hierarchies and check if they subsume each other or share a common subsumer. However, this approach is limited because constructed hierarchies may suffer from noise and require exact mapping (Section 6). TAREC overcomes these limitations by searching and selecting the top relevant articles in Wikipedia for each input term; taxonomic relations are then recognized based on the features extracted from these articles.

On the other hand, information extraction bootstrapping algorithms, such as (Pantel and Pennacchiotti, 2006; Kozareva et al., 2008), automatically harvest related terms on large corpora by starting with a few seeds of pre-specified relations (e.g. *is-a*, *part-of*). Bootstrapping algorithms rely on some scoring function to assess the quality of terms and additional patterns extracted during bootstrapping iterations. Similarly, but with a different focus, Open IE, (Banko and Etzioni, 2008; Davidov and Rappoport, 2008), deals with a large number of relations which are not pre-specified. Either way, the output of these algorithms is usually limited to a small number of high-quality terms while sacrificing coverage (or vice versa). Moreover, an Open IE system cannot control the extracted relations and this is essential when identifying taxonomic relations. Recently, (Baroni and Lenci, 2010) described a general framework of distributional semantic models that extracts significant contexts of given terms from large corpora. Consequently, a term can be represented by a vector of contexts in which it frequently appears. Any vector space model could then use the terms' vectors to cluster terms into categories. Sibling terms (e.g. *Honda*, *Toyota*), therefore, have very high chance to be clustered together. Nevertheless, this approach cannot recognize ancestor relations. In this paper, we compare TAREC with this framework only on recognizing sibling vs. no relation, in a strict experimental setting which pre-specifies the categories to which the terms belong.

3 An Overview of the TAREC Algorithm

3.1 Preliminaries

In the TAREC algorithm, a *term* refers to any mention in text, such as *mountain*, *George W. Bush*, *battle of Normandy*. TAREC does not aim at extracting terms and building a stationary hierarchical structure of terms, but rather recognize the taxonomic relation between any two given terms. TAREC focuses on classifying two fundamental types of taxonomic relations: *ancestor* and *sibling*. Determining whether two terms hold a taxonomic relation depends on a pragmatic decision of how far one wants to climb up a taxonomy to find a common subsumer. For example, *George W. Bush* is a child of *Presidents of the United States* as well as *people*, even more, that term could also be considered as a child of *mammals* or *organisms* w.r.t. the Wikipedia category system; in that sense, *George W. Bush* may be considered as a sibling of *oak* because they have *organisms* as a least common subsumer. TAREC makes use of a hierarchical structure as background knowledge and considers two terms to hold a taxonomic relation only if the relation can be recognized from information acquired by climbing up at most K levels from the representation of the target terms in the structure. It is also possible that the sibling relation can be recognized by clustering terms together by using vector space models. If so, two terms are siblings if they belong to the same cluster.

To cast the problem of identifying taxonomic relations between two terms x and y in a machine learning perspective, we model it as a multi-class classification problem. Table 1 defines four relations with some examples in our experiment data sets.

This paper focuses on studying a fundamental problem of recognizing taxonomic relations (given well-segmented terms) and leaves the orthogonal is-

Relation	Meaning	Examples	
		Term x	Term y
$x \leftarrow y$	x is an ancestor of y	actor	Mel Gibson
		food	rice
$x \rightarrow y$	x is a child of y	Makalu	mountain
		Monopoly	game
$x \leftrightarrow y$	x and y are siblings	Paris	London
		copper	oxygen
$x \not\leftrightarrow y$	x and y have no relation	Roja	C++
		egg	Vega

sues of how to take contexts into account and how it should be used in applications to a future work.

3.2 The Overview of TAREC

Assume that we already have a learned local classifier that can classify taxonomic relations between any two terms. Given two terms, TAREC uses Wikipedia and the local classifier in an inference model to make a final prediction on the taxonomic relation between these two. To motivate the need for an inference model, beyond the local classifier itself, we observe that the presence of other terms in addition to the two input terms, can provide some natural constraints on the possible taxonomic relations and thus can be used to make the final prediction (which we also refer as global prediction) more coherent. In practice, we first train a local classifier (Section 4), then incorporate it into an inference model (Section 5) to classify taxonomic relations between terms. The TAREC algorithm consists of three steps and is summarized in Figure 1 and explained below.

1. Normalizing input terms to Wikipedia: Although most commonly used terms have corresponding Wikipedia articles, there are still a lot of terms with no corresponding Wikipedia articles. For a non-Wikipedia term, we make an attempt to find a replacement by using Web search. We wish to find a replacement such that the taxonomic relation is unchanged. For example, for input pair (*Lojze Kovačič*, *Rudi Šeligo*), there is no English Wikipedia page for *Lojze Kovačič*, but if we can find *Marjan Rožanc* and use it as a replacement of *Lojze Kovačič* (two terms are siblings and refer to two writers), we can continue classifying the taxonomic relation of the pair (*Marjan Rožanc*, *Rudi Šeligo*). This part of the algorithm was motivated by (Sarmento et al., 2007). We first make a query with the two input terms (e.g. "*Lojze Kovačič*" AND "*Rudi Šeligo*") to search for list-structure snippets in Web documents[1] such as "... $\langle delimiter \rangle$ c_a $\langle delimiter \rangle$ c_b $\langle delimiter \rangle$ c_c $\langle delimiter \rangle$ ..." (the two input terms should be among c_a, c_b, c_c, ...). The delimiter could be commas, periods, or asterisks[2]. For snippets that contain the patterns of interest, we extract c_a, c_b, c_c etc. as replacement candidates. To reduce noise, we empirically constrain the list to contain at least 4 terms that are no longer than 20 characters each. The candidates are ranked based on their occurrence frequency. The top candidate with Wikipedia pages is used as a replacement.

2. Getting additional terms (Section 5.2): TAREC leverage an existing knowledge base to extract additional terms related to the input terms, to be used in the inference model in step 3.

3. Making global prediction with relational constraints (Section 5.1): TAREC performs several local predictions using the local classifier $\mathcal{R}$ (Section 4) on the two input terms and these terms with the additional ones. The global prediction is then inferred by enforcing relational constraints among the terms' relations.

4 Learning Taxonomic Relations

The local classifier of TAREC is trained on the pairs of terms with correct taxonomic relation labels (some examples are showed in Table 1). The trained classifier when applied on a new input pair of terms will return a real valued number which can be interpreted as the probability of the predicted label. In this section, we describe the learning features used

Table 2: Examples of texts and categories of Wikipedia articles.

by our local taxonomic relation classifier.

Given two input terms, we first build a semantic representation for each term by using a local search engine[3] to retrieve a list of top articles in Wikipedia that are relevant to the term. To do this, we use the following procedure: (1) Using both terms to make a query (e.g. *"George W. Bush"* AND *"Bill Clinton"*) to search in Wikipedia ; (2) Extracting important keywords in the titles and categories of the retrieved articles using TF-IDF (e.g. *president*, *politician*); (3) Combining each input term with the extracted keywords (e.g. *"George W. Bush"* AND *"president"* AND *"politician"*) to create a final query used to search for the term's relevant articles in Wikipedia. This is motivated by the assumption that the real world applications calling TAREC typically does so with two terms that are related in some sense, so our procedure is designed to exploit that. For example, it's more likely that term *Ford* in the pair (*George W. Bush*, *Ford*) refers to the former president of the United States, *Gerald Ford*, than the founder of Ford Motor Company, *Henry Ford*.

Once we have a semantic representation of each term, in the form of the extracted articles, we extract from it features that we use as the representation of the two input terms in our learning algorithm. It is worth noting that a Wikipedia page usually consists of a title (i.e. the term), a body text, and a list of categories to which the page belongs. Table 2 shows some Wikipedia articles. From now on, we use *the titles of* x, *the texts of* x, and *the categories of* x to refer to the titles, texts, and categories of the associated articles in the representation of x. Below are the learning features extracted for input pair (x,y).

Bags-of-words Similarity: We use cosine similarity metric to measure the degree of similarity between bags of words. We define four bags-of-words features as the degree of similarity between the texts and categories associated with two input terms x and y in Table 3. To collect categories of a term, we take the categories of its associated articles and go up K levels in the Wikipedia category system. In our experiments, we use abstracts of Wikipedia articles instead of whole texts.

Degree of similarity
texts(x) vs. categories(y)
categories(x) vs. texts(y)
texts(x) vs. texts(y)
categories(x) vs. categories(y)

Table 3: Bag-of-word features of the pair of terms (x,y); texts(.) and categories(.) are two functions that extract associated texts and categories from the semantic representation of x and y.

Association Information: This features represents a measure of association between the terms by considering their information overlap. We capture this feature by the pointwise mutual information (pmi) which quantifies the discrepancy between the probability of two terms appearing together versus the probability of each term appearing independently[4]. The pmi of two terms x and y is estimated as follows:

$$pmi(x, y) = log\frac{p(x, y)}{p(x)p(y)} = log\frac{Nf(x, y)}{f(x)f(y)},$$

where N is the total number of Wikipedia articles, and $f(.)$ is the function which counts the number of appearances of its argument.

Overlap Ratios: The overlap ratio features capture the fact that the titles of a term usually overlap with the categories of its descendants. We measure this overlap as the ratio of the number of common phrases used in the titles of one term and the categories of the other term. In our context, a phrase is

[3] E.g. http://lucene.apache.org/

[4] pmi is different than mutual information. The former applies to specific outcomes, while the latter is to measure the mutual dependence of two random variables.

considered to be a common phrase if it appears in the titles of one term and the categories of the other term and it is also of the following types: (1) the whole string of a category, or (2) the head in the root form of a category, or (3) the post-modifier of a category. We use the Noun Group Parser from (Suchanek et al., 2007) to extract the head and post-modifier from a category. For example, one of the categories of an article about *Chicago* is *Cities in Illinois*. This category can be parsed into a head in its root form *City*, and a post-modifier *Illinois*. Given term pair *(City, Chicago)*, we observe that *City* matches the head of the category *Cities in Illinois* of term *Chicago*. This is a strong indication that *Chicago* is a child of *City*.

We also use a feature that captures the overlap ratio of *common phrases* between the categories of two input terms. For this feature, we do not use the *post-modifier* of the categories. We use Jaccard similarity coefficient to measure these overlaps ratios.

5 Inference with Relational Constraints

Once we have a local multi-class classifier that maps a given pair of terms to one of the four possible relations, we use a constraint-based optimization algorithm to improve this prediction. The key insight behind the way we model the inference model is that if we consider more than two terms, there are logical constraints that restrict the possible relations among them. For instance, *George W. Bush* cannot be an ancestor or sibling of *president* if we are confident that *president* is an ancestor of *Bill Clinton*, and *Bill Clinton* is a sibling of *George W. Bush*. We call the combination of terms and their relations a *term network*. Figure 2 shows some n-term networks consisting of two input terms (x, y), and additional terms z, w, v.

The aforementioned observations show that if we can obtain additional terms that are related to the two target terms, we can enforce such coherency relational constraints and make a global prediction that would improve the prediction of the taxonomic relation between the two given terms. Our inference model follows constraint-based formulations that were introduced in the NLP community and were shown to be very effective in exploiting declarative background knowledge (Roth and Yih, 2004; Denis and Baldridge, 2007; Punyakanok et al., 2008; Chang et al., 2008).

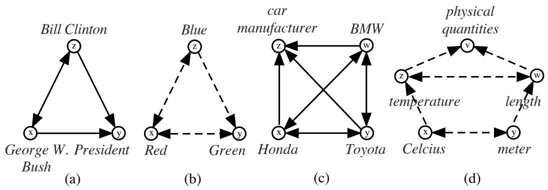

Figure 2: Examples of n-term networks with two input term x and y. (a) and (c) show valid combinations of edges, whereas (b) and (d) are two relational constraints. For simplicity, we do not draw *no relation* edges in (d).

5.1 Enforcing Coherency through Inference

Let x, y be two input terms, and $\mathcal{Z} = \{z_1, z_2, ..., z_m\}$ be a set of additional terms. For a subset $Z \in \mathcal{Z}$, we construct a set of term networks whose nodes are x, y and all elements in Z, and the edge, e, between every two nodes is one of four taxonomic relations whose weight, $w(e)$, is given by a local classifier (Section 4). If $l = |Z|$, there are $n = 2 + l$ nodes in each network, and $4^{\left[\frac{1}{2}n(n-1)\right]}$ term networks can be constructed. In our experiments we only use 3-term networks (i.e. $l = 1$). For example, for the input pair (*red*, *green*) and $\mathcal{Z} = \{blue, yellow\}$, we can construct 64 networks for the triple $\langle red, green, Z = \{blue\}\rangle$ and 64 networks for $\langle red, green, Z = \{yellow\}\rangle$ by trying all possible relations between the terms.

A *relational constraint* is defined as a term network consisting of only its "illegitimate" edge settings, those that belongs to a pre-defined list of invalid edge combinations. For example, Figure 2b shows an invalid network where *red* is a sibling of both *green* and *blue*, and *green* is an ancestor of *blue*. In Figure 2d, *Celcius* and *meter* cannot be siblings because they are children of two sibling terms *temperature* and *length*. The relational constraints used in our experiments are manually constructed.

Let $\mathcal{C}$ be a list of relational constraints. Equation (1) defines the network scoring function, which is a linear combination of the edge weights, $w(e)$, and the penalties, ρ_k, of term networks matching constraint $C_k \in \mathcal{C}$.

$$score(t) = \sum_{e \in t} w(e) - \sum_{k=1}^{|\mathcal{C}|} \rho_k d_{C_k}(t) \qquad (1)$$

function $d_{C_k}(t)$ indicates if t matches C_k. In our work, we use relational constraints as hard con-

YAGO Query Patterns

INPUT: term "x"

straints and set their penalty ρ_k to ∞. For a set of term networks formed by $\langle x, y, Z\rangle$ and all possible relations between the terms, we select the best network, $t^* = \text{argmax}_t score(t)$.

After picking the best term network t^* for every $Z \in \mathcal{Z}$, we make the final decision on the taxonomic relation between x and y. Let r denote the relation between x and y in a particular t^* (e.g. $r = x \leftrightarrow y$.) The set of all t^* is divided into 4 groups with respect to r (e.g. a group of all t^* having $r = x \leftrightarrow y$, a group of all t^* having $r = x \leftarrow y$.) We denote a group with term networks holding r as the relation between x and y by $\mathcal{T}_r$. To choose the best taxonomic relation, r^*, of x and y, we solve the objective function defined in Equation 2.

$$r^* = \text{argmax}_r \frac{1}{|\mathcal{T}_r|} \sum_{t^* \in \mathcal{T}_r} \lambda_{t^*} score(t^*) \qquad (2)$$

where λ_t is the weight of term network t, defined as the occurrence probability of t (regarding only its edges' setting) in the training data, which is augmented with additional terms. Equation (2) finds the best taxonomic relation of two input terms by computing the average score of every group of the best term networks representing a particular relation of two input terms.

5.2 Extracting Related Terms

In the inference model, we need to obtain other terms that are related to the two input terms. Hereafter, we refer to additional terms as *related terms*. The related term space is a space of direct ancestors, siblings and children in a particular resource.

We propose an approach that uses the YAGO ontology (Suchanek et al., 2007) to provide related terms. It is worth noting that YAGO is chosen over the Wikipedia category system used in our work because YAGO is a clean ontology built by carefully combining Wikipedia and WordNet.[5]

In YAGO model, all objects (e.g. *cities*, *people*, etc.) are represented as *entities*. To map our input terms to entities in YAGO, we use the MEANS relation defined in the YAGO ontology. Furthermore, similar entities are grouped into *classes*. This allows us to obtain direct ancestors of an entity by using the TYPE relation which gives the entity's classes. Furthermore, we can get ancestors of a class with the SUBCLASSOF relation[6]. By using three relations MEANS, TYPE and SUBCLASSOF in YAGO model, we can obtain Proposals for direct ancestors, siblings, and children, if any, for any input term. We then evaluate our classifier on all pairs, and run the inference to improve the prediction using the coherency constraints. Figure 3 presents three patterns that we used to query related terms from YAGO.

6 Experimental Study

In this section, we evaluate TAREC against several systems built upon existing well-known knowledge sources. The resources are either hierarchical structures or extracted by using distributional semantic models. We also perform several experimental analyses to understand TAREC's behavior in details.

6.1 Comparison to Hierarchical Structures

We create and use two main data sets in our experiments. **Dataset-I** is generated from 40 semantic classes of about 11,000 instances. The original semantic classes and instances were manually constructed with a limited amount of manual post-filtering and were used to evaluate information extraction tasks in (Paşca, 2007; Paşca and Van Durme, 2008) (we refer to this original data as **OrgData-I**). This dataset contains both terms with Wikipedia pages (e.g. *George W. Bush*) and non-Wikipedia terms (e.g. *hindu mysticism*). Pairs of terms are generated by randomly pairing semantic class names and instances. We generate disjoint training and test sets of 8,000 and 12,000 pairs of terms, respectively. We call the test set of this

[5] However, YAGO by itself is weaker than our approach in identifying taxonomic relations (see Section 6.)

[6] These relations are defined in the YAGO ontology.

dataset **Test-I**. **Dataset-II** is generated from 44 semantic classes of more than 10,000 instances used in (Vyas and Pantel, 2009)[7]. The original semantic classes and instances were extracted from Wikipedia lists. This data, therefore, only contains terms with corresponding Wikipedia pages. We also generate disjoint training and test sets of 8,000 and 12,000 pairs of terms, respectively, and call the test set of this dataset **Test-II**.[8]

Several semantic class names in the original data are written in short forms (e.g. *chemicalelem*, *proglanguage*). We expand these names to some meaningful names which are used by all systems in our experiments. For example, *terroristgroup* is expanded to *terrorist group*, *terrorism*. Table 1 shows some pairs of terms which are generated. Four types of taxonomic relations are covered with balanced numbers of examples in all data sets. To evaluate our systems, we use a snapshot of Wikipedia from July, 2008. After cleaning and removing articles without categories (except redirect pages), 5,503,763 articles remain. We index these articles using Lucene[9]. As a learning algorithm, we use a regularized averaged Perceptron (Freund and Schapire, 1999).

We compare TAREC with three systems that we built using recently developed large-scale hierarchical structures. **Strube07** is built on the latest version of a taxonomy, T_{Strube}, which was derived from Wikipedia (Ponzetto and Strube, 2007). It is worth noting that the structure of T_{Strube} is similar to the page structure of Wikipedia. For a fair comparison, we first generate a semantic representation for each input term by following the same procedure used in TAREC described in Section 4. The titles and categories of the articles in the representation of each input term are then extracted. Only titles and their corresponding categories that are in T_{Strube} are considered. A term is an ancestor of the other if at least one of its titles is in the categories of the other term. If two terms share a common category, they are considered siblings; and no relation, otherwise. The ancestor relation is checked first, then sibling, and finally no relation. **Snow06** uses the *extended WordNet* (Snow et al., 2006). Words in the extended WordNet can be common nouns or proper nouns. Given two input terms, we first map them onto the hierarchical structure of the extended WordNet by exact string matching. A term is an ancestor of the other if it can be found as an hypernym after going up K levels in the hierarchy from the other term. If two terms share a common subsumer within some levels, then they are considered as siblings. Otherwise, there is no relation between the two input terms. Similar to Strube07, we first check ancestor, then sibling, and finally no relation. **Yago07** uses the YAGO ontology (Suchanek et al., 2007) as its main source of background knowledge. Because the YAGO ontology is a combination of Wikipedia and WordNet, this system is expected to perform well at recognizing taxonomic relations. To access a term's ancestors and siblings, we use patterns 1 and 2 in Figure 3 to map a term to the ontology and move up on the ontology. The relation identification process is then similar to those of Snow06 and Strube07. If an input term is not recognized by these systems, they return *no relation*.

	Test-I	**Test-II**
Strube07	24.32	25.63
Snow06	41.97	36.26
Yago07	65.93	70.63
TAREC (local)	81.89	84.7
TAREC	**85.34**	**86.98**

Table 4: Evaluating and comparing performances, in accuracy, of the systems on **Test-I** and **Test-II**. TAREC (local) uses only our local classifier to identify taxonomic relations by choosing the relation with highest confidence.

Our overall algorithm, **TAREC**, is described in Figure 1. We manually construct a pre-defined list of 35 relational constraints to use in the inference model. We also evaluate our local classifier (Section 4), which is referred as **TAREC (local)**. To make classification decision with TAREC (local), for a pair of terms, we choose the predicted relation with highest confidence returned by the classifier.

In all systems compared, we vary the value of K[10] from 1 to 4. The best result of each system is reported. Table 4 shows the comparison of all systems evaluated on both Test-I and Test-II. Our systems, as shown, significantly outperform the other

[7] There were 50 semantic classes in the original dataset. We grouped some semantically similar classes for the purpose of classifying taxonomic relations.

[8] Published at http://cogcomp.cs.illinois.edu/page/software

[9] http://lucene.apache.org, version 2.3.2

[10] See Section 3.1 for the meaning of K.

systems. In Table 4, the improvement of TAREC over TAREC (local) on Test-I shows the contribution of both the normalization procedure (that is, going outside Wikipedia terms) and the global inference model to the classification decisions, whereas the improvement on Test-II shows only the contribution of the inference model, because Test-II contains only terms with corresponding Wikipedia articles.

Observing the results we see that our algorithms is doing significantly better that fixed taxonomies based algorithms. This is true both for TAREC (local) and for TAREC. We believe that our machine learning based classifier is very flexible in extracting features of the two input terms and thus in predicting their taxonomic Relation. On the other hand, other system rely heavily on string matching techniques to map input terms to their respective ontologies, and these are very inflexible and brittle. This clearly shows one limitation of using existing structured resources to classify taxonomic relations.

We do not use special tactics to handle polysemous terms. However, our procedure of building semantic representations for input terms described in Section 4 ties the senses of the two input terms and thus, implicitly, may get some sense information. We do not use this procedure in Snow06 because WordNet and Wikipedia are two different knowledge bases. We also do not use this procedure in Yago07 because in YAGO, a term is mapped onto the ontology by using the MEANS operator (in Pattern 1, Figure 3). This cannot follow our procedure.

6.2 Comparison to Harvested Knowledge

As we discussed in Section 2, the output of bootstrapping-based algorithms is usually limited to a small number of high-quality terms while sacrificing coverage (or vice versa). For example, the full Espresso algorithm in (Pantel and Pennacchiotti, 2006) extracted 69,156 instances of *is-a* relation with 36.2% precision. Similarly, (Kozareva et al., 2008) evaluated only a small number (a few hundreds) of harvested instances. Recently, (Baroni and Lenci, 2010) proposed a general framework to extract properties of input terms. Their **TypeDM** model harvested 5,000 significant properties for each term out of 20,410 noun terms. For example, the properties of *marine* include $\langle own, bomb\rangle$, $\langle use, gun\rangle$. Using vector space models we could measure the similarity between terms using their property vectors. However, since the information available in TypeDM does not support predicting the ancestor relation between terms, we only evaluate TypeDM in classifying sibling vs. no relation. We do this by giving a list of semantic classes using the following procedure: (1) For each semantic class, use some seeds to compute a centroid vector from the seeds' vectors in TypeDM, (2) each term in an input pair is classified into its best semantic class based on the cosine similarity between its vector and the centroid vector of the category, (3) two terms are siblings if they are classified into the same category; and have no relation, otherwise. Out of 20,410 noun terms in TypeDM, there are only 345 terms overlapping with the instances in OrgData-I and belonging to 10 significant semantic classes. For each semantic class, we randomly pick 5 instances as its seeds to make a centroid vector. The rest of the overlapping instances are randomly paired to make a dataset of 4,000 pairs of terms balanced in the number of sibling and no relation pairs. On this dataset, TypeDM achieves the accuracy of 79.75%. TAREC (local), with the local classifier trained on the training set (with 4 relation classes) of Dataset-I, gives 78.35% of accuracy. The full TAREC system with relational constraints achieves 82.65%. We also re-train and evaluate the local classifier of TAREC on the same training set but without ancestor relation pairs. This local classifier has an accuracy of 81.08%.

These results show that although the full TAREC system gives better performance, TypeDM is very competitive in recognizing sibling vs. no relation. However, TypeDM can only work in a limited setting where semantic classes are given in advance, which is not practical in real-world applications; and of course, TypeDM does not help to recognize ancestor relations between two terms.

6.3 Experimental Analysis

In this section, we discuss some experimental analyses to better understand our systems.

Precision and Recall: We want to study TAREC on individual taxonomic relations using Precision and Recall. Table 5 shows that TAREC performs very well on ancestor relation. Sibling and no relation are the most difficult relations to classify. In the same experimental setting on Test-I, Yago07

TAREC	Test-I		Test-II	
	Prec	Rec	Prec	Rec
$x \leftarrow y$	95.82	88.01	96.46	88.48
$x \rightarrow y$	94.61	89.29	96.15	88.86
$x \leftrightarrow y$	79.23	84.01	83.15	81.87
$x \not\leftrightarrow y$	73.94	79.9	75.54	88.27
Average	85.9	85.3	87.83	86.87

Table 5: Performance of TAREC on individual taxonomic relation.

	Wiki	**WordNet**	**non-Wiki**
Strube07	24.59	24.13	21.18
Snow06	41.23	46.91	34.46
Yago07	69.95	70.42	34.26
TAREC (local)	89.37	89.72	31.22
TAREC	**91.03**	**91.2**	**45.21**

Table 6: Performance of the systems on special data sets, in accuracy. On the non-Wikipedia test set, TAREC (local) simply returns sibling relation.

achieves 79.34% and 66.03% of average Precision and Recall, respectively. These numbers on Test-II are 81.33% and 70.44%.

Special Data Sets: We evaluate all systems that use hierarchical structures as background knowledge on three special data sets derived from Test-I. From 12,000 pairs in Test-I, we created a test set, **Wiki**, consisting of $10,456$ pairs with all terms in Wikipedia. We use the rest of $1,544$ pairs with at least one non-Wikipedia term to build a **non-Wiki** test set. The third dataset, **WordNet**, contains $8,625$ pairs with all terms in WordNet and Wikipedia. Table 6 shows the performance of the systems on these data sets. Unsurprisingly, Yago07 gets better results on Wiki than on Test-I. Snow06, as expected, gives better performance on the WordNet test set. TAREC still significantly outperforms these systems. The improvement of TAREC over TAREC (local) on the Wiki and WordNet test sets shows the contribution of the inference model, whereas the improvement on the non-Wikipedia test set shows the contribution of normalizing input terms to Wikipedia.

Contribution of Related Terms in Inference: We evaluate TAREC when the inference procedure is fed by related terms that are generated using a "gold standard" source instead of YAGO. To do this, we use the original data which was used to generate Test-I. For each term in the examples of Test-I, we get its ancestors, siblings, and children, if any, from the original data and use them as related terms in the inference model. This system is referred as **TAREC (Gold Infer.)**. Table 7 shows the results of the two systems on different K as the number of levels to go up on the Wikipedia category system. We see that TAREC gets better results when doing inference with better related terms. In this experiment, the two systems use the same number of related terms.

	K=1	K=2	K=3	K=4
TAREC	82.93	85.34	85.23	83.95
TAREC (Gold Infer.)	83.46	86.18	85.9	84.93

Table 7: Evaluating TAREC with different sources providing related terms to do inference.

7 Conclusions

We studied an important component of many computational linguistics tasks: given two target terms, determine that taxonomic relation between them. We have argued that static structured knowledge bases cannot support this task well enough, and provided empirical support for this claim. We have developed TAREC, a novel algorithm that leverages information from existing knowledge sources and uses machine learning and a constraint-based inference model to mitigate the noise and the level of uncertainty inherent in these resources. Our evaluations show that TAREC significantly outperforms other systems built upon existing well-known knowledge sources. Our approach generalizes and handles non-Wikipedia term well across semantic classes. Our future work will include an evaluation of TAREC in the context of textual inference applications.

Abstract

Although many algorithms have been developed to harvest lexical resources, few organize the mined terms into taxonomies. We propose (1) a semi-supervised algorithm that uses a root concept, a basic level concept, and recursive surface patterns to learn automatically from the Web hyponym-hypernym pairs subordinated to the root; (2) a Web based concept positioning procedure to validate the learned pairs' is-a relations; and (3) a graph algorithm that derives from scratch the integrated taxonomy structure of all the terms. Comparing results with WordNet, we find that the algorithm misses some concepts and links, but also that it discovers many additional ones lacking in WordNet. We evaluate the taxonomization power of our method on reconstructing parts of the WordNet taxonomy. Experiments show that starting from scratch, the algorithm can reconstruct 62% of the WordNet taxonomy for the regions tested.

1 Introduction

A variety of NLP tasks, including inference, textual entailment (Glickman et al., 2005; Szpektor et al., 2008), and question answering (Moldovan et al., 1999), rely on semantic knowledge derived from term taxonomies and thesauri such as WordNet. However, the coverage of WordNet is still limited in many regions (even well-studied ones such as the concepts and instances below Animals and People), as noted by researchers such as (Pennacchiotti and Pantel, 2006) and (Hovy et al., 2009) who perform automated semantic class learning. This happens because WordNet and most other existing taxonomies are manually created, which makes them difficult to maintain in rapidly changing domains, and (in the face of taxonomic complexity) makes them hard to build with consistency. To surmount these problems, it would be advantageous to have an automatic procedure that can not only augment existing resources but can also produce taxonomies for existing and new domains and tasks starting from scratch.

The main stages of automatic taxonomy induction are term extraction and term organization. In recent years there has been a substantial amount of work on term extraction, including semantic class learning (Hearst, 1992; Riloff and Shepherd, 1997; Etzioni et al., 2005; Pasca, 2004; Kozareva et al., 2008), relation acquisition between entities (Girju et al., 2003; Pantel and Pennacchiotti, 2006; Davidov et al., 2007), and creation of concept lists (Katz and Lin, 2003). Various attempts have been made to learn the taxonomic organization of concepts (Widdows, 2003; Snow et al., 2006; Yang and Callan, 2009). Among the most common is to start with a good ontology and then to try to position the missing concepts into it. (Snow et al., 2006) maximize the conditional probability of hyponym-hypernym relations given certain evidence, while (Yang and Callan, 2009) combines heterogenous features like context, co-occurrence, and surface patterns to produce a more-inclusive inclusion ranking formula. The obtained results are promising, but the problem of how to organize the gathered knowledge when there is no initial taxonomy, or when the initial taxonomy is grossly impoverished, still remains.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1110–1118,
MIT, Massachusetts, USA, 9-11 October 2010.

The major problem in performing taxonomy construction from scratch is that overall concept positioning is not trivial. It is difficult to discover whether concepts are unrelated, subordinated, or parallel to each other. In this paper, we address the following question: *How can one induce the taxonomic organization of concepts in a given domain starting from scratch?*

The contributions of this paper are as follows:

- An automatic procedure for harvesting hyponym-hypernym pairs given a domain of interest.
- A ranking mechanism for validating the learned is-a relations between the pairs.
- A graph-based approach for inducing the taxonomic organization of the harvested terms starting from scratch.
- An experiment on reconstructing WordNet's taxonomy for given domains.

Before focusing on the harvesting and taxonomy induction algorithms, we are going to describe some basic terminology following (Hovy et al., 2009). A **term** is an English word (for our current purposes, a noun or a proper name). A **concept** is an item in the classification taxonomy we are building. A **root concept** is a fairly general concept which is located on the high level of the taxonomy. A **basic-level concept** corresponds to the Basic Level categories defined in Prototype Theory in Psychology (Rosch, 1978). For example, a *dog*, not a mammal or a collie. An **instance** is an item in the classification taxonomy that is more specific than a concept. For example, *Lassie*, not a dog or collie .

The rest of the paper is organized as follows. Section 2 reviews related work. Section 3 describes the taxonomization framework. Section 4 discusses the experiments. We conclude in Section 5.

2 Related Work

The first stage of automatic taxonomy induction, term and relation extraction, is relatively well-understood. Methods have matured to the point of achieving high accuracy (Girju et al., 2003; Pantel and Pennacchiotti, 2006; Kozareva et al., 2008). The produced output typically contains flat lists of terms and/or ground instance facts ($lion$ is-a $mammal$) and general relation types ($mammal$ is-a $animal$).

Most approaches use either clustering or patterns to mine knowledge from structured and unstructured text. Clustering approaches (Lin, 1998; Lin and Pantel, 2002; Davidov and Rappoport, 2006) are fully unsupervised and discover relations that are not directly expressed in text. Their main drawback is that they may or may not produce the term types and granularities useful to the user. In contrast, pattern-based approaches harvest information with high accuracy, but they require a set of seeds and surface patterns to initiate the learning process. These methods are successfully used to collect semantic lexicons (Riloff and Shepherd, 1997; Etzioni et al., 2005; Pasca, 2004; Kozareva et al., 2008), encyclopedic knowledge (Suchanek et al., 2007), concept lists (Katz and Lin, 2003), and relations between terms, such as hypernyms (Ritter et al., 2009; Hovy et al., 2009) and part-of (Girju et al., 2003; Pantel and Pennacchiotti, 2006).

However, simple term lists are not enough to solve many problems involving natural language. Terms may be augmented with information that is required for knowledge-intensive tasks such as textual entailment (Glickman et al., 2005; Szpektor et al., 2008) and question answering (Moldovan et al., 1999). To support inference, (Ritter et al., 2010) learn the selectional restrictions of semantic relations, and (Pennacchiotti and Pantel, 2006) ontologize the learned arguments using WordNet.

Taxonomizing the terms is a very powerful method to leverage added information. Subordinated terms (hyponyms) inherit information from their superordinates (hypernyms), making it unnecessary to learn all relevant information over and over for every term in the language. But despite many attempts, no 'correct' taxonomization has ever been constructed for the terms of, say, English. Typically, people build term taxonomies (and/or richer structures like ontologies) for particular purposes, using specific taxonomization criteria. Different tasks and criteria produce different taxonomies, even when using the same basic level concepts. This is because most basic level concepts admit to multiple perspectives, while each task focuses on one, or at most two, perspectives at a time. For example, a dolphin is a Mammal (and not a Fish) to a biologist, but is a Fish (and hence not a Mammal) to a fisherman or anyone building or visiting an aquarium. More confusingly, a tiger and a puppy are both Mammals and hence belong close together in a typical taxonomy, but a tiger is a WildAnimal (in the perspective of Animal-Function) and a JungleDweller (in the perspective of Habitat), while a puppy is a Pet (as function) and a HouseAnimal (as habitat), which would place them relatively far from one another. Attempts at producing a single multi-perspective taxonomy fail due to the complexity of interaction among perspectives, and people are notoriously bad at constructing taxonomies adherent to a single perspective when given terms from multiple perspectives. This issue and the major alternative principles for taxonomization are discussed in (Hovy, 2002).

It is therefore not surprising that the second stage of automated taxonomy induction is harder to achieve. As mentioned, most attempts to learn taxonomy structures start with a reasonably complete taxonomy and then insert the newly learned terms into it, one term at a time (Widdows, 2003; Pasca, 2004; Snow et al., 2006; Yang and Callan, 2009). (Snow et al., 2006) guide the incremental approach by maximizing the conditional probability over a set of relations. (Yang and Callan, 2009) introduce a taxonomy induction framework which combines the power of surface patterns and clustering through combining numerous heterogeneous features.

Still, one would like a procedure to organize the harvested terms into a taxonomic structure starting fresh (i.e., without using an initial taxonomic structure). We propose an approach that bridges the gap between the term extraction algorithms that focus mainly on harvesting but do not taxonomize, and those that accept a new term and seek to enrich an already existing taxonomy. Our aim is to perform both stages: to extract the terms of a given domain and to induce their taxonomic organization without any initial taxonomic structure and information. This task is challenging because it is not trivial to discover both the hierarchically related and the parallel (perspectival) organizations of concepts. Achieving this goal can provide the research community with the ability to produce taxonomies for domains for which currently there are no existing or manually created ontologies.

3 Building Taxonomies from Scratch

3.1 Problem Formulation

We define our task as:

Task Definition: Given a root concept, a basic level concept or an instance, and recursive lexico-syntactic patterns, (1) harvest in bootstrapping fashion hyponyms and hypernyms subordinated to the root; (2) filter out erroneous information (extracted concepts and *isa* relations); (3) organize the harvested concepts into a taxonomy structure.

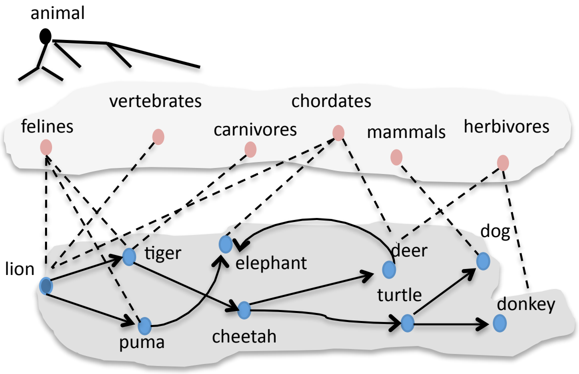

Figure 1: *Taxonomy Induction from Scratch.*

Figure 1 shows an example of the task. Starting with the root concept *animal* and the basic level concept *lion*, the algorithm learns new terms like *tiger, puma, deer, donkey* of class *animal*. Next for each basic level concept, the algorithm harvests hypernyms and learns that a *lion* is-a *vertebrate*, *chordate*, *feline* and *mammal*. Finally, the taxonomic structure of each basic level concept and its hypernyms is induced: *animal→chordate→vertebrate→mammal→feline→lion*.

3.2 Knowledge Harvesting

The main objective of our work is not the creation of a new harvesting algorithm, but rather the organization of the harvested information in a taxonomy structure starting from scratch. There are many algorithms for hyponym and hypernym harvesting from the Web. In our experiments, we use the doubly-anchored lexico-syntactic patterns and bootstrapping algorithm introduced by (Kozareva et al., 2008) and (Hovy et al., 2009).

We are interested in using this approach, because it is: (1) simple and easy to implement; (2) requires minimal supervision using only one root concept and a term to learn new hyponyms and hypernyms associated to the root; (3) reports higher precision than current semantic class algorithms (Etzioni et al., 2005; Pasca, 2004); and (4) adapts easily to different domains.

The general framework of the knowledge harvesting algorithm is shown in Figure 2.

```
 1. Given:
    a hyponym pattern $P_i$={$concept$ such as $seed$ and *}
    a hypernym pattern $P_c$={* such as $term_1$ and $term_2$}
    a root concept $root$
    a term called $seed$ for $P_i$
 2. build a query using $P_i$
 3. submit $P_i$ to Yahoo! or other search engine
 4. extract terms occupying the * position
 5. take terms from step 4 and go to step 2.
 6. repeat steps 2–5 until no new terms are found
 7. rank terms by outDegree
 8. for $\forall$ terms with outDegree>0, build a query
    using $P_c$
 9. submit $P_c$ to Yahoo! or other search engine
10. extract concepts (hypernyms) occupying the *
    position
11. rank concepts by inDegree
```

Figure 2: *Knowledge Harvesting Framework.*

The algorithm starts with a $root$ concept, *seed* term[1] of type *root* and a doubly-anchored pattern (DAP) such as '*<root> such as <seed> and **' which learns on the * position new terms of type *root*. The newly learned terms, which can be either instances, basic level or intermediate concepts, are placed into the position of the *seed* in the DAP pattern, and the bootstrapping process is repeated. The process ceases when no new terms are found.

To separate the true from incorrect terms, we use a graph-based algorithm in which each vertex u is a term, and an each edge $(u, v) \in E$ corresponds to the direction in which the term u discovered the term v. The graph is weighted $w(u, v)$ according to the number of times the term pair u-v is seen in unique web snippets. The terms are ranked by $outDegree(u)$= $\frac{\sum_{\forall(u,v)\in E} w(u,v)}{|V|-1}$ which counts the number of outgoing links of node u normalized by the total number of nodes in the graph excluding the current. The algorithm considers as true terms with $outDegree$>0.

All harvested terms are automatically fed into the hypernym extraction phase. We use the natural order in which the terms discovered each other and place them into an inverse doubly-anchored pattern (DAP^{-1}) '* *such as* <$term_1$> *and* <$term_2$>' to learn hypernyms on the * position. Similarly we build a graph with nodes h denoting the hypernyms and nodes t_1-t_2 denoting the term pairs. The edges $(h, t_1 - t_2) \in E'$ show the direction in which the term pair discovered the hypernym. The hypernyms are ranked by $inDegree(h)$= $\sum_{\forall(t_1-t_2,h)\in E'} w(t_1 - t_2, h)$ which rewards hypernyms that are frequently discovered by various term pairs. The output of the algorithm is a list of is-a relations between the learned terms (instances, basic level or intermediate concepts) and their corresponding hypernyms. For example, *deer is-a herbivore*, *deer is-a ruminant*, *deer is-a mammal*.

3.3 Graph-Based Taxonomy Induction

In the final stage of our algorithm, we induce the overall taxonomic structure using information about the pairwise positioning of the terms. In the knowledge harvesting and filtering phases, the algorithm learned is-a relations between the $root$ and the terms (instances, basic level or intermediate concepts), as well as the harvested hypernyms and the terms. The only missing information is the positioning of the intermediate concepts located between the basic level and the $root$ such as *mammals*, *vertibrates*, *felines*, *chordates*, among others.

We introduce a concept positioning (CP) procedure that uses a set of surface patterns: "X $such\ as$ Y", "X are Y $that$", "X $including$ Y", "X $like$ Y", "$such$ X as Y" to learn the hierarchical relations for all possible concept pairs. For each concept pair, say $chordates$ and $vertebrates$, we issue the two following queries:

(a) *chordates such as vertebrates*
(b) *vertebrates such as chordates*

[1] The input term can be an instance, a basic level or an intermediate concept. An intermediate concept is the one that is located between the basic level and root concepts.

If (a) returns more web hits than (b), then $chordates$ subsumes (or is broader than) $vertebrates$, otherwise $vertebrates$ subsumes $chordates$. For this pair the *such as* pattern returned 7 hits for (a) and 0 hits for (b), so that the overall magnitude of the direction of the relation is weak. To accumulate stronger evidence, we issue web queries with the remaining patterns. For the same concept pair, the overall magnitude of "X *including* Y" is 5820 hits for (a) and 0 for (b).

As shown in Figure 3, the concept positioning patterns cannot always determine the direct taxonomic organization between two concepts as in the case of *felines* and *chordates*, *felines* and *vertebrates*. One reason is that the concepts are located on distant taxonomic levels. We humans typically exemplify concepts using more proximate ones. Therefore, the concept positioning procedure can find evidence for the relation "*mammals→felines*", but not for "*chordates→felines*".

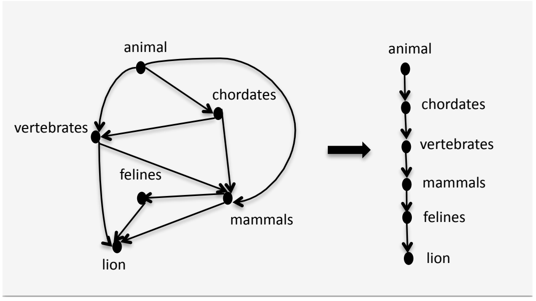

Figure 3: *Concept Positioning and Induced Taxonomy.*

After the concept positioning procedure has explored all concept pairs, we encounter two phenomena: (1) direct links between some concepts are missing and (2) multiple paths can be taken to reach from one concept to another.

To surmount these problems, we employ a graph based algorithm that finds the longest path in the graph G''=(V'', E''). The nodes V''=$\{it_1, h_1, h_2, .., h_n, r\}$ represent the input term, its hypernyms, and the $root$. An edge $(t_m, t_n) \in E''$ indicates that there is a path between the terms t_m and t_n. The direction $t_m \rightarrow t_n$ indicates the term subordination discovered during the CP procedure. The objective is to find the longest path in G'' between the $root$ and the input term. Intuitively, finding the longest paths is equivalent to finding the taxonomic organization of all concepts.

First, if present, we eliminate all cycles from the graph. Then, we find all nodes that have no predecessor and those that have no successor. Intuitively, a node with no predecessors p is likely to be positioned on the top of the taxonomy (e.g. $animal$), while a node with no successor s is likely to be located at the bottom (e.g. terms like *lion*, *tiger*, *puma*, or concepts like *krill predators* that could not be related to an instance or a basic level concept during the CP procedure). We represent the directed graph as an adjacency matrix $A = [a_{m,n}]$, where $a_{m,n}$ is 1 if (t_m, t_n) is an edge of G'', and 0 otherwise. For each (p, s) pair, we find the list of all paths connecting p with s. In the end, from all discovered candidate paths, the algorithm returns the longest one. The same graph-based taxonomization procedure is repeated for the rest of the basic level concepts and their hypernyms.

4 Experiments and Results

To evaluate the performance of a taxonomy induction algorithm, one can compare against a simple taxonomy composed of 2–3 levels. However, one cannot guarantee that the algorithm can learn larger hierarchies completely or correctly.

Animals provide a good example of the true complexity of concept organization: there are many types, they are of numerous kinds, people take numerous perspectives over them, and they are relatively well-known to human annotators. In addition, WordNet has a very rich and deep taxonomic structure for animals that can be used for direct comparison. We further evaluate our algorithm on the domains of *Plants* and *Vehicles*, which share some of these properties.

4.1 Data Collection

We have run the knowledge harvesting algorithm on the semantic classes *Animals*, *Plants* and *Vehicles* starting with only one seed example such as *lions*, *cucumbers* and *cars* respectively.

First, we formed and submitted the DAP pattern as web queries to Yahoo!Boss. We retrieved the top 1000 web snippets for each query. We kept all unique terms and term pairs. Second, we used the learned term pairs to form and submit new web queries DAP^{-1}. In this step, the algorithm harvested the hypernyms associated with each term. We kept all unique triples composed of a hypernym and the term pairs that extracted it. The algorithm ran until complete exhaustion for 8 iterations for *Animals*, 10 iterations for *Plants* and 18 iterations of *Vehicles*.

Table 1 shows the total number of terms extracted by the Web harvesting algorithm during the first stage. In addition, we show the number of terms that passed the $outDegree$ threshold. We found that the majority of the learned terms for *Animals* are basic level concepts, while for *Plants* and *Vehicles* they are a mixture of basic level and intermediate concepts.

	Animals	Plants	Vehicles
#Extracted Terms	1855	2801	1425
#outDegree(Term)$>$ 0	858	1262	581

Table 1: *Learned Terms.*

Since human based evaluation of all harvested terms is time consuming and costly, we have selected 90 terms located at the beginning, in the middle and in the end of the $outDegree$ ranking. Table 2 summarizes the results.

Plants	#CorrectByHand	#inWN	PrecByHand
rank[1-30]	29	28	.97
rank[420-450]	29	21	.97
rank[1232-1262]	27	19	.90
Vehicles	#CorrectByHand	#inWN	PrecByHand
rank[1-30]	29	27	.97
rank[193-223]	22	18	.73
rank[551-581]	25	19	.83

Table 2: *Term Evaluation.*

Independently, we can say that the precision of the harvesting algorithm is from 73 to 90%. In the case of *Vehicles*, we found that the learned terms in the middle ranking do not refer to the meaning of vehicle as a transportation devise, but to the meaning of vehicle as media (i.e. *seminar*, *newspapers*), communication and marketing. For the same category, the algorithm learned many terms which are missing from WordNet such as *BMW*, *bakkies*, *two-wheeler*, *all-terrain-vehicle* among others.

The second stage of the harvesting algorithm concerns hypernym extraction. Table 3 shows the total number of hypernyms harvested for all term pairs. The top 20 highly ranked concepts by $inDegree$ are the most descriptive terms for the domain. However, if we are interested in learning a larger set of hypernyms, we found that $inDegree$ is not sufficient by itself. For example, highly frequent but irrelevant hypernyms such as *meats*, *others* are ranked at the top of the list, while low frequent but relevant ones such as *protochordates*, *hooved-mammals*, *homeotherms* are discarded. This shows that we need to develop additional and more sensitive measures for hypernym ranking.

	Animals	Plants	Vehicles
#Extracted Hypernyms	1904	8947	2554
#inDegree(Hypernyms)$>$ 10	110	294	100

Table 3: *Learned Hypernyms.*

Table 4 shows some examples of the learned animal hypernyms which were annotated by humans as: correct but not present in WordNet; borderline which depending on the application could be valuable to have or exclude; and incorrect.

CorrectNotInWN	{colony|social} insects, grazers, monogastrics camelid, {mammalian|land|areal} predators {australian|african} wildlife, filter feeders hard shelled invertebrates, pelagics bottom dwellers
Borderline	prehistoric animals, large herbivores pocket pets, farm raised fish, roaring cats endangered mammals, mysterious hunters top predators, modern-snakes, heavy game
Incorrect	frozen foods, native mammals, red meats furry predators, others, resources, sorts products, items, protein

Table 4: *Examples of Learned Animal Hypernyms.*

The annotators found that 9% of the harvested is-a relations are missing from WordNet. For example, *cartilaginous_fish* → *shark*; *colony_insects*→ *bees*; *filter_feeders* → *tube_anemones* among others. This shows that despite its completeness, WordNet has still room for improvement.

4.2 A Test: Reconstructing WordNet

As previously discussed in (Hovy et al., 2009), it is extremely difficult even for expert to manually construct and evaluate the correctness of the harvested taxonomies. Therefore, we decided to evaluate the performance of our taxonomization approach reconstructing WordNet *Animals*, *Plants* and *Vehicles* taxonomies.

Given a domain, we select from 140 to 170 of the harvested terms. For each term, we retrieve all WordNet hypernyms located on the path between the input term and the $root$ that is *animal*, *plant* or *vehicle* depending on the domain of interest. We have found that 98% of the WordNet terms are also harvested by our knowledge acquisition algorithm. This means that being able to reconstruct WordNet's taxonomy is equivalent to evaluating the performance of our taxonomy induction approach.

Table 5 summarizes the characteristics of the taxonomies for the regions tested. For each domain, we show the total number of terms that must be organized, and the total number of is-a relations that must be induced.

	Animals	Plants	Vehicles
#terms	684	554	140
#is-a	4327	2294	412
average depth	6.23	4.12	3.91
max depth	12	8	7
min depth	1	1	1

Table 5: *Data for WordNet reconstruction.*

Among the three domains we have tested, *Animals* is the most complex and richest one. The maximum number of levels our algorithm must infer is 11, the minimum is 1 and the average taxonomic depth is 6.2. In total there are three basic level concepts (*longhorns*, *gaur* and *bullock*) with maximum depth, twenty terms (basic level and intermediate concepts) with minimum depth and ninety-eight terms (*wombat*, *viper*, *rat*, *limpkin*) with depth 6.

Plants is also a very challenging domain, because it contains a mixture of scientific and general terms such as *magnoliopsida* and *flowering plant*.

4.3 Evaluation

To evaluate the performance of our taxonomy induction approach, we use the following measures:

$$Precision = \frac{\#is{-}a\ found\ in\ WordNet\ and\ by\ system}{\#is{-}a\ found\ by\ system}$$

$$Recall = \frac{\#is{-}a\ found\ in\ WordNet\ and\ by\ system}{\#is{-}a\ found\ in\ WordNet}$$

Table 6 shows results of the taxonomy induction of the *Vehicles* domain using different concept positioning patterns. The most productive ones are: "X *are* Y *that*" and "X *including* Y". However, the highest yield is obtained when we combine evidence from all patterns.

Vehicles	Precision	Recall
X such as Y	.99 (174/175)	.42 (174/410)
X are Y that	.99 (206/208)	.50 (206/410)
X including Y	.96 (165/171)	.40 (165/410)
X like Y	.96 (137/142)	.33 (137/410)
such X as Y	.98 (44/45)	.11 (44/410)
AllPatterns	.99 (246/249)	**.60** (246/410)

Table 6: *Evaluation of the Induced Vehicle Taxonomy.*

Table 7 shows results of the taxonomization of the *Animals* and *Plants* domains. Overall, the obtained results are very encouraging given the fact that we started from scratch without the usage of any taxonomic structure. Precision is robust, but we must further improve recall. Our observation for the lower recall is that some intermediate concepts relate mostly to the high level ones, but not to the basic level concepts.

	Precision	Recall
Animals	.98 (1643/1688)	.38 (1643/4327)
Plants	.97 (905/931)	.39 (905/2294)

Table 7: *Evaluation of the Induced Animal and Plant Taxonomies.*

Figure 4 shows an example of the taxonomy induced by our algorithm for the *vipers*, *rats*, *wombats*, *ducks*, *emus*, *moths* and *penguins* basic level concepts and their WordNet hypernyms.

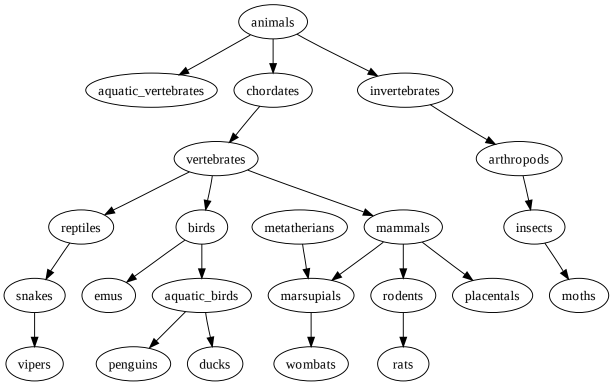

Figure 4: *Induced Taxonomy for Animals.*

The biggest challenge of the taxonomization process is the merging of independent taxonomic perspectives (a *deer* is a *grazer* in BehaviorByFeeding, a *wildlife* in BehaviorByHabitat, a *herd* in BehaviorSocialGroup and an *even-toed ungulate* in MorphologicalType) into a single hierarchy.

5 Conclusions and Future Work

We are encouraged by the ability of the taxonomization algorithm to reconstruct WordNet's *Animal* hierarchy, which is one of its most complete and elaborated. In addition, we have also evaluated the performance of our algorithm with the *Plant* and *Vehicle* WordNet hierarchies.

Currently, our automated taxonomization algorithm is able to build some of the quasi-independent perspectival taxonomies (Hovy et al., 2009). However, further research is required to develop methods that reliably (a) identify the number of independent perspectives a concept can take (or seems to take in the domain text), and (b) classify any harvested term into one or more of them. The result would greatly simplify the task of the taxonomization stage.

We note that despite this richness, WordNet has many concepts like *camelid*, *filter feeder*, *monogastrics* among others which are missing, but the harvesting algorithm can provide. Another promising line of research would investigate the combination of the two styles of taxonomization algorithms: first, the one described here to produce an initial (set of) taxonomies, and second, the term-insertion algorithms developed in prior work.

Abstract

In contrast with the booming increase of internet data, state-of-art QA (question answering) systems, otherwise, concerned data from specific domains or resources such as search engine snippets, online forums and Wikipedia in a somewhat isolated way. Users may welcome a more general QA system for its capability to answer questions of various sources, integrated from existed specialized sub-QA engines. In this framework, question classification is the primary task.

However, the current paradigms of question classification were focused on some specified type of questions, i.e. factoid questions, which are inappropriate for the general QA. In this paper, we propose a new question classification paradigm, which includes a question taxonomy suitable to the general QA and a question classifier based on MLN (Markov logic network), where rule-based methods and statistical methods are unified into a single framework in a fuzzy discriminative learning approach. Experiments show that our method outperforms traditional question classification approaches.

1 Introduction

During a long period of time, researches on question answering are mainly focused on finding short and concise answers from plain text for factoid questions driven by annual trackes such as CLEF, TREC and NTCIR. However, people usually ask more complex questions in real world which cannot be handled by these QA systems tailored to factoid questions.

During recent years, social collaborative applications begin to flourish, such as Wikipedia, Facebook, Yahoo! Answers and etc. A large amount of semi-structured data, which has been accumulated from these services, becomes new sources for question answering. Previous researches show that different sources are suitable for answering different questions. For example, the answers for factoid questions can be extracted from webpages with high accuracy, definition questions can be answered by corresponding articles in wikipedia(Ye et al., 2009) while community question answering services provide comprehensive answers for complex questions(Jeon et al., 2005). It will greatly enhance the overall performance if we can classify questions into several types, distribute each type of questions to suitable sources and trigger corresponding strategy to summarize returned answers.

Question classification (QC) in factoid QA is to provide constraints on answer types that allows further processing to pinpoint and verify the answer (Li and Roth, 2004). Usually, questions are classified into a fine grained content-based taxonomy(e.g. UIUC taxonomy (Li and Roth, 2002)). We cannot use these taxonomies directly. To guide question distribution and answer summarization, questions are classified according to their functions instead of contents.

Motivated by related work on user goal classification(Broder, 2002; Rose and Levinson, 2004) , we propose a function-based question classification category tailored to general QA. The category contain six types, namely **Fact**, **List**, **Reason**, **Solution**, **Definition** and **Navigation**. We will introduced this

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1119–1128,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

category in detail in Section 2.

To classify questions effectively, we unify rule-based methods and statistical methods into a single framework. Each question is splited into functional words and content words. We generate strict patterns from functional words and soft patterns from content words. Each strict pattern is a regular expression while each soft pattern is a bi-gram cluster. Given a question, we will evaluate its matching degree to each patterns. The matching degree is either 0 or 1 for strict pattern and between 0 and 1 for soft pattern. Finally, Markov logic network (MLN) (Richardson and Domingos, 2006) is used to combine and evaluate all the patterns.

The classical MLN maximize the probability of an assignment of truth values by evaluating the weights of each formula. However, the real world is full of uncertainty and is unnatural to be represented by a set of boolean values. In this paper, we propose fuzzy discriminative weight learning of Markov logic network. This method takes degrees of confidence of each evidence predicates into account thus can model the matching degrees between questions and soft patterns.

The remainder of this paper is organized as follows: In the next section we review related work on question classification, query classification and Markov logic network. Section 2 gives a detailed introduction to our new taxonomy for general QA. Section 4 introduces fuzzy discriminative weight learning of MLN and our methodology to extract strict and soft patterns. In Section 5 we compare our method with previous methods on Chinese question data from Baidu Zhidao and Sina iAsk. In the last section we conclude this work.

Although we build patterns and do experiments on Chinese questions, our method does not take advantage of the particularity of Chinese language and thus can be easily implemented on other languages.

2 Related Work

Many question taxonomies have been proposed in QA community. Lehnert (1977) developed the system QUALM based on thirteen conceptual categories which are based on a theory of memory representation. On the contrary, the taxonomy proposed by Graesser et al. (1992) has foundations both in theory and in empirical research. Both of these taxonomies are for open-domain question answering.

With the booming of internet, researches on question answering are becoming more practical. Most taxonomies proposed are focused on factoid questions, such as UIUC taxonomy (Li and Roth, 2002). UIUC taxonomy contains 6 coarse classes (**Abbreviation**, **Entity**, **Description**, **Human**, **Location** and **Numeric Value**) and 50 fine classes. All coarse classes are factoid oriented except **Description**. To classify questions effectively, Researchers have proposed features of different levels, such as lexical features, syntactic features (Nguyen et al., 2007; Moschitti et al., 2007) and semantic features (Moschitti et al., 2007; Li and Roth, 2004). Zhang and Lee (2003) compared five machine learning methods and found SVM outperformed the others.

In information retrieval community, researchers have described frameworks for understanding goals of user searches. Generally, web queries are classified into four types: **Navigational**, **Informational**, **Transactional** (Broder, 2002) and **Resource** (Rose and Levinson, 2004). Lee et al. (2005) automatically classify **Navigational** and **Informational** queries based on past user-click behavior and anchor-link distribution. Jansen and Booth (2010) investigate the correspondence between three user intents and eighteen topics. The result shows that user intents distributed unevenly among different topics.

Inspired by Rose and Levinson (2004)'s work in user goals classification, Liu et al. (2008) describe a three-layers cQA oriented question taxonomy and use it to determine the expected best answer types and summarize answers. Other than **Navigational**, **Informational** and **Transactional**, the first layer contains a new **Social** category which represents the questions that do not intend to get an answer but to elicit interaction with other people. **Informational** contains two subcategories **Constant** and **Dynamic**. **Dynamic** is further divided into **Opinion**, **Context-Dependent** and **Open**.

Markov logic network (MLN) (Richardson and Domingos, 2006) is a general model combining first-order logic and probabilistic graphical models in a single representation. Illustratively, MLN is a first-order knowledge base with a weight attached to each formula. The weights can be learnt ei-

TYPE	DESCRIPTION	EXAMPLES
1. Fact	People ask these questions for general facts. The expected answer will be a short phrase.	`Who is the president of United States?`

2. List	People ask these questions for a list of answers. Each answer will be a single phrase or a phrase with explanations or comments.	`List Nobel price winners in 1990s.`
		`Which movie star do you like best?`

3. Reason	People ask these questions for opinions or explanations. A good answer summary should contain a variety of opinions or comprehensive explanations. Sentence-level summarization can be employed.	`Is it good to drink milk while fasting?`
		`What do you think of Avatar?`

4. Solution	People ask these questions for problem shooting. The sentences in an answer usually have logical order thus the summary task cannot be performed on sentence level.	`What should I do during an earthquake?`
		`How to make pizzas?`

5. Definition	People ask these questions for description of concepts. Usually these information can be found in Wikipedia. If the answer is a too long, we should summarize it into a shorter one.	`Who is Lady Gaga?`
		`What does the Matrix tell about?`

6. Navigation	People ask these questions for finding websites or resources. Sometimes the websites are given by name and the resources are given directly.	`Where can I download the beta version of StarCraft 2?`

Table 1: Question Taxonomy for general QA

ther generatively (Richardson and Domingos, 2006) or discriminatively (Singla and Domingos, 2005). Huynh and Mooney (2008) applies -norm regularized MLE to select candidate formulas generated by a first-order logic induction system and prevent overfitting. MLN has been introduced to NLP and IE tasks such as semantic parsing (Poon et al., 2009) and entity relation extraction (Zhu et al., 2009).

3 A Question Taxonomy

We suggest a function-based taxonomy tailored to general QA systems by two principles. First, questions can be distributed into suitable QA subsystems according to their types. Second, we can employ suitable answer summarization strategy for each question type. The taxonomy is shown in Tab. 1.

At first glance, classifying questions onto this taxonomy seems a solved problem for English questions because of interrogative words. In most cases, a question starting with “Why” is for reason and “How” is for solution. But it is not always the case for other languages. From table 2 we can see two questions in Chinese share same function word “怎么样” but have different types.

In fact, even in English, only using interrogative words is not enough for function-based question classification. Sometimes the question content is crucial. For example, for question “Who is the current president of U.S. ?”, the answer is “Barak Obama” and the type is **Fact**. But for question “Who is Barak Obama?”, it will be better if we return the first paragraph from the corresponding Wiki article instead of a short phrase “current president of U.S.”. Therefore the question type will be **Definition**.

Compared to Wendy Lehnert’s or Arthur Graesser’s taxonomy, our taxonomy is more practical on providing useful information for question

Question	怎么样做宫保鸡丁？ How to cook Kung Pao Chicken?
Type	**Solution**
Question	大家觉得阿凡达怎么样？ What do you think of Avatar?
Type	**Reason**

Table 2: Two Chinese questions share same function words but have different types

extraction and summarization. Compared to ours, The UIUC taxonomy is too much focused on factoid questions. Apart from **Description**, all coarse types in UIUC can be mapped into **Fact**. The cQA taxonomy proposed in Liu et al. (2008) has similar goal with ours. But it is hard to automatically classify questions into that taxonomy, especially for types **Constant**, **Dynamic** and **Social**. Actually the author did not give implementation in the paper as well. To examine reasonableness of our taxonomy, we select and manually annotate 5800 frequent asked questions from Baidu Zhidao (see Section 5.1). The distribution of six types is shown in Fig. 1. 98.5 percent of questions can be categorized into our taxonomy. The proportion of each type is between 7.5% and 23.8%.

The type **Navigation** was originally proposed in IR community and did not cause too much concerns in previous QA researches. But from Fig. 1 we can see that navigational questions take a substantial proportion in cQA data.

Moreover, we can further develop subtypes for each type. For example, most categories in UIUC taxonomy can be regarded as refinement to **Fact** and **Navigation** can be refined into **Resource** and **Website**. We will not have further discussion on this issue.

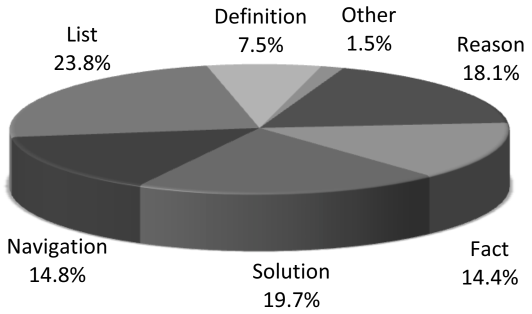

Figure 1: Distribution of six types in Baidu Zhidao data

4 Methodology

Many efforts have been made to take advantage of grammatical , semantic and lexical features in question classification. Zhang and Lee (2003) proposed a SVM based system which used tree kernel to incorporate syntactic features.

In this section, we propose a new question classification methodology which combines rule-based methods and statistical methods by Markov logic network. We do not use semantic and syntactic features for two reasons. First, the questions posted on online communities are casually written which cannot be accurately parsed by NLP tools, especially for Chinese. Second, the semantic and syntactic parsing are time consuming thus unpractical to be used in real systems.

We will briefly introduce MLN and fuzzy discriminative learning in section 4.1. The construction of strict patterns and soft patterns will be shown in 4.2 and 4.3. In section 4.4 we will give details on MLN construction, inference and learning.

4.1 Markov Logic Network

A first-order knowledge base contains a set of formulas constructed from logic operators and symbols for predicates, constants, variables and functions. An *atomic formula* or *atom* is a predicate symbol. Formulas are recursively constructed from atomic formulas using logical operators. The *grounding* of a predicate (formula) is a replacement of all of its arguments (variables) by constants. A *possible world* is an assignment of truth values to all possible groundings of all predicates.

In first-order KB, if a possible world violates even one formula, it has zero probability. Markov logic is a probabilistic extension and softens the hard constraints by assigning a weight to each formula. When a possible world violates one formula in the KB, it is less probable. The higher the weight, the greater the difference in log probability between a world that satisfies the formula and a world does not. Formally, Markov logic network is defined as follows:

Definition 1 *(Richardson & Domingos 2004) A Markov logic network L is a set of pairs (,), where is a formula in first-order logic and is a real number. Together with a finite set of constants C = , it defines a Markov network as follows:*

1. *contains one binary node for each possible grounding of each predicate appearing in L. The value of the node is 1 if the ground predicate is true, and 0 otherwise.*
2. *contains one feature for each possible grounding of each formula in L. The value of this feature is 1 if the ground formula is true, and 0 otherwise. The weight of the feature is the associated with in L.*

There is an edge between two nodes of iff the corresponding grounding predicates appear together in at least one grounding of one formula in . An MLN can be regarded as a template for constructing Markov networks. From Definition 1 and the definition of Markov networks, the probability distribution over possible worlds specified by the ground Markov network is given by

MLN weights can be learnt generatively(Richardson and Domingos, 2006) or discriminatively(Singla and Domingos, 2005). In discriminative weight learning, ground atom set is partitioned into a set of evidence atoms and a set of query atoms . The goal is to correctly predict the latter given the former. In this paper, we propose fuzzy discriminative weight learning which can take the prior confidence of each evidence atom into account.

Formally, we denote the ground formula set by . Suppose each evidence atom is given with a prior confidence , we define a confidence function as follows. For each ground atom , if then we have , else . For each ground non-atomic formulas, is defined on standard fuzzy operators, which are

We redefined the *conditional likelihood* of given as

Where is the set of ground formulas involving query atoms, is the set of formulas with at least one grounding involving a query atom and is the sum of confidence of the groundings of the ith formula involving query atoms. The gradient of the conditional log-likelihood (CLL) is

(1)

By fuzzy discriminative learning we can incorporate evidences of different confidence levels into one learning framework. Fuzzy discriminative learning will reduce to traditional discriminative learning when all prior confidences equal to 1.

4.2 Strict Patterns

In our question classification task, we find function words are much more discriminative and less sparse than content words. Therefore, we extract strict patterns from function words and soft patterns from content words. The definition of content and function words may vary with languages. In this paper, nouns, verbs, adjectives, adverbs, numerals and pronouns are regarded as content words and the rest are function words.

The outline of strict pattern extraction is shown in Alg. 1. In line 3, we build template by removing punctuations and replacing each character in each content word by a single dot. In line 4, we generate patterns from the template as follows. First we generate n-grams(n is between 2 and) from

```
Algorithm 1: Strict Pattern Extraction
  Input: Question Set ,
         Parameters and
  Output: Pattern Set
1 Initialize Pattern Set ;
2 for each Question do
3     String =ReplaceContentWords( , );
4     Pattern Set =GeneratePatterns( , );
5     for each Pattern in do
6         if in then
7             UpdateTypeFreq( , );
8         else
9             Add to ;
10 Merge similar patterns in ;
11 Sort by Information Gain on type
   frequencies;
12 return top Patterns in ;
```

during which each dot is treated as a character of zero length. For coverage concern, if a generated n-gram is not start(end) with dot, we build another n-gram by adding a dot before(behind) and add both and into n-gram set. Then for each n-gram, we replace each consecutive dot sequence by '.*' and the n-gram is transformed into a regular expression. A example is shown in Tab. 3. Although generated without exhaustively enumerating all possible word combinations, these regular expressions can capture most long range dependencies between function words.

Each pattern consists of a regular expression as well as its frequency in each type of questions. Still from Alg. 1, in line 5-9, if a pattern in question with type is found in , we just update the frequency of in , else is added to with only freq. equals to 1. In line 10, we merge similar patterns in . two patterns and are similar iff q Q`matchP` q p `matchP` q p , in which `matchP` is defined in Section 4.4.

Question	在网上可以开通网银吗？ Can I launch online banking services on internet?	
Template	在..可以....吗	
Patterns (=4)	.*以.*吗 .*可以.* .*可以.*吗.* .*在.*可以.*吗.* 在.*可以.* .*在.*可.*	.*以.*吗.* .*可以.*吗 .*在.*可以.* 在.*可.* 在.*可以.*吗

Table 3: Strict patterns generated from a question

Since a large number of patterns are generated, it is unpractical to evaluate all of them by Markov logic network. We sort patterns by information gain and only choose top "good" patterns in line 11-12 of Alg. 1. A "good" pattern should be discriminative and of wide coverage. The information gain IG of a pattern is defined as

IG

− − −

in which is the number of question types, is the probability of a question having type , (or −) is the probability of a question matching(or not matching) pattern . (or −) is the probability of a question having type given the condition that the question matches(or does not match) pattern . These probabilities can be approximately calculated by type and pattern frequencies on training data. From the definition we can see that information gain is suitable for pattern selection. The more questions a pattern matches and the more unevenly the matched questions distribute among questions types, the higher IG will be.

4.3 Soft Patterns

Apart from function words, content words are also important in function-based question classification. Content words usually contain topic information which can be a good complement to function words. Previous research on query classification(Jansen and Booth, 2010) shows that user intents distribute unevenly among topics. Moreover, questions given by users may be incomplete and contain not function words. For these questions, we can only predict the question types from topic information.

Compared with function words, content words distribute much more sparsely among questions.

When we represent topic information by content words (or bi-grams), since the training set are small and less frequent words (or bi-grams) are filtered to prevent over-fitting, those features would be too sparse to predict further unseen questions.

To solve this problem, we build soft patterns on question set. Each question is represented by a weighted vector of content bi-grams in which the weight is bi-gram frequency. Cosine similarity is used to compute the similarity between vectors. Then we cluster question vectors using a simple single-pass clustering algorithm(Frakes and Yates, 1992). That is, for each question, we compute its similarity with each centroid of existing cluster. If the similarity with nearest cluster is greater than a minimum similarity threshold , we assign this question to that cluster, else a new cluster is created for this question.

Each cluster is defined as a soft pattern. Unlike strict patterns, a question can match a soft pattern to some extent. In this paper, the degree of matching is defined as the cosine similarity between question and centroid of cluster. Soft patterns are flexible and could alleviate the sparseness of content words. Also, soft patterns can be pre-filtered by information gain described in 4.2 if necessary.

4.4 Implementation

Currently, we model patterns into MLN as follows. The main query predicate is Type(q,t), which is true iff question q has type t. For strict patterns, the evidence predicate MatchP(q,p) is true iff question q is matched by strict pattern p. The confidence of MatchP(q,p) is 1 for each pair of (q,p). For soft patterns, the evidence predicate MatchC(q,c) is true iff the similarity of question q and the cluster c is greater than a minimum similarity requirement . If MatchC(q,c) is false, its confidence is 1, else is the similarity between q and c.

We represent the relationship between patterns and types by a group of formulas below.

MatchP(q,+p) Type(q,+t) Type(q,t')

The "+p, +t" notation signifies that the MLN contains an instance of this formula for each (*pattern*, *type*) pair. For the sake of efficacy, for each pattern-type pair (p,t), if the proportion of type t in questions matching p is less than a minimum requirement , we remove corresponding formula from MLN.

Similarly, we incorporate soft patterns by

MatchC(q,+c) Type(q,+t) Type(q,t')

Our weight learner use -regularization (Huynh and Mooney, 2008) to select formulas and prevent overfitting. A good property of -regularization is its tendency to force parameters to exact zero by strongly penalizing small terms (Lee et al., 2006). After training, we can simply remove the formulas with zero weights.

Formally, to learn weight for each formula, we iteratively solve -norm regularized optimization problem:

where is -norm and parameter controls the penalization of non-zero weights. We implement the Orthant-Wise Limited-memory Quasi-Newton algorithm(Andrew and Gao, 2007) to solve this optimization.

Since we do not model relations among questions, the derived markov network can be broken up into separated subgraphs by questions and the gradient of CLL(Eq. 1) can be computed locally on each subgraph as

(2)

in which and are the evidence and query atoms involving question . Eq. 2 can be computed fast without approximation.

We initialize formula weights to the same positive value . Iteration started from uniform prior can always converge to a better local maximum than gaussian prior in our task.

5 Experiments

5.1 Data Preparation

To the best of our knowledge, there is not general QA system(the system which can potentially answer all kinds of questions utilizing data from heterogeneous sources) released at present. Alteratively, we test our methodology on cQA data based on observation that questions on cQA services are of various length, domain independent and wrote informally(even with grammar mistakes). General QA systems will meet these challenges as well.

In our experiments, both training and test data are from Chinese cQA services Baidu Zhidao and Sina iAsk. To build training set, we randomly select 5800 frequent-asked questions from Baidu Zhidao. A question is frequent-asked if it is lexically similar to at least five other questions. Then we ask 10 native-speakers to annotate these questions according to question title and question description. If an annotator cannot judge type from question title, he can view the question description. If type can be judged from the description, the question title will be replaced by a sentence selected from it. If not, this question will be labeled as **Other**.

Each question is annotated by two people. If a question is labeled different types, another annotator will judge it and make final decision. If this annotator cannot judge the type, this question will also be labeled as **Other**. As a result, disagreements show up on eighteen percents of questions. After the third annotator's judgment, the distribution of each type is shown in Fig. 1.

To examine the generalization capabilities, the test data is composed of 700 questions randomly selected from Baidu Zhidao and 700 questions from Sina iAsk. The annotation process on test data is as same as the one on training data.

5.2 Methods Compared and Results

We compare four methods listed as follows.

SVM with bi-grams. We extract bi-grams from questions on training data as features. After filtering the ones appearing only once, we collect 5700 bi-grams. LIBSVM(Chang and Lin, 2001)is used as the multi-class SVM classifier. All parameters are adjusted to maximize the accuracy on test data. We denote this method as "*SB*";

MLN with bi-grams. To compare MLN and SVM, we treat bi-grams as strict patterns. If a question contain a bi-gram, it matches the corresponding pattern. We set , and . As a result, 5700 bi-grams are represented by 10485 formulas. We denote this method as "*MB*";

MLN with strict patterns and bi-grams. We ask two native-speakers to write strict patterns for each type. The pattern writers can view training data for reference and write any Java-style regular expressions. Then we carefully choose 50 most reliable patterns. To overcome the low coverage, We also use the method described in Sec. 4.2 to automatically extract strict patterns from training set. We first select top 3000 patterns by information gain, merge these patterns with hand-crafted ones and combine similar patterns. Then we represent these patterns by formulas and learn the weight of each formula by MLN. After removing the formula with low weights, we finally retain 2462 patterns represented by 3879 formulas. To incorporate content information, we extract bi-grams from questions with function words removed and remove the ones with frequency lower than two. With bi-grams added, we get 8173 formulas in total. All parameters here are the same as in "*MB*". We denote this method as "*MSB*";

MLN with strict patterns and soft patterns. To incorporate content information, We cluster questions on training data with similarity threshold

and get 2588 clusters(soft patterns) which are represented by 3491 formulas. We these soft patterns with strict patterns extracted in "*MSB*", which add up to 7370 formulas. We set and the other parameters as same as in "*MB*". We denote this method as "*MSS*";

We separate test set into easy set and difficult set. A question is classified into easy set iff it contains function-words. As a result, the easy set contains 1253 questions. We measure the accuracy of these four methods on easy data and the whole test data. The results are shown in Tab 4. From the results we can see that all methods perform better on easy questions and MLN outperforms SVM using same bi-gram features. Although *MSS* is inferior to *MSB* on

	F. num	Easy data	All data
SB	NA	0.724	0.685
MB	10485	0.722	0.692
MSB	8173	**0.754**	0.714
MSS	7370	0.752	**0.717**

Table 4: Experimental results on Chinese cQA data

	F	L	S	R	D	N
Prec.	0.63	0.65	0.83	0.76	0.69	0.55
Recall	0.55	0.74	0.86	0.76	0.44	0.58
	0.59	0.69	0.84	0.76	0.54	0.56

Table 5: Precision, recall and F-score on each type

easy questions, it shows better overall performance and uses less formulas.

We further investigate the performance on each type. The precision, recall and -score of each type by method *MSS* are shown in Tab. 5. From the results we can see that the performance on **Solution** and **Reason** are significantly better than the others. It is because the strict patterns for this two types are simple and effective. A handful of patterns could cover a wide range of questions with high precision. It is difficult to distinguish **Fact** from **List** because strict patterns for these two types are partly overlap each other. Sometimes we need content information to determine whether the answer is unique. Since **List** appears more frequently than **Fact** on training set, MLN tend to misclassify **Fact** to **List** which lead to low recall of the former and low precision of the latter. The recall of **Definition** is very low because many definition questions on test set are short and only consists of content words(e.g. a noun phrase). This shortage could be remedied by building strict patterns on POStagging sequence.

Table 6: Selected soft patterns on training data

5.3 Case Study on Soft Patterns

To give an intuitive illustration of soft patterns, we show some of them clustered on training data in Tab. 6. For each soft pattern, we list five most frequent bi-grams and its distribution on each type(only top 3 frequent types are listed).

From the results we can see that soft patterns are consistent with our ordinary intuitions. For example, if user ask a questions about “TV series”, he is likely to ask for recommendation of recent TV series and the question have a great chance to be **List**. If user ask questions about “lose weight”, he probably ask something like “How can I lose weight fast?” or “Why my diet does not work?” . Thus the type is likely to be **Solution** or **Reason**.

6 Conclusion and Future Work

We have proposed a new question taxonomy tailored to general QA on heterogeneous sources. This taxonomy provide indispensable information for question distribution and answer summarization. We build strict patterns and soft patterns to represent the information in function words and content words. Also, fuzzy discriminative weight learning is proposed for unifying strict and soft patterns into Markov logic network.

Currently, we have not done anything fancy on the structure of MLN. We just showed that under uniform prior and L1 regularization, the performance of MLN is comparable to SVM. To give full play to the advantages of MLN, future work will focus on fast structure learning. Also, since questions on online communities are classified into categories by topic, we plan to perform joint question type inference on function-based taxonomy as well as topic-based taxonomy by Markov logic. The model will not only capture the relation between patterns and types but also the relation between types in different taxonomy.

Abstract

Recurrent event queries (REQ) constitute a special class of search queries occurring at regular, predictable time intervals. The freshness of documents ranked for such queries is generally of critical importance. REQ forms a significant volume, as much as 6% of query traffic received by search engines. In this work, we develop an improved REQ classifier that could provide significant improvements in addressing this problem. We analyze REQ queries, and develop novel features from multiple sources, and evaluate them using machine learning techniques. From historical query logs, we develop features utilizing query frequency, click information, and user intent dynamics within a search session. We also develop temporal features by time series analysis from query frequency. Other generated features include word matching with recurrent event seed words and time sensitivity of search result set. We use Naive Bayes, SVM and decision tree based logistic regression model to train REQ classifier. The results on test data show that our models outperformed baseline approach significantly. Experiments on a commercial Web search engine also show significant gains in overall relevance, and thus overall user experience.

1 Introduction

REQ pertains to queries about events which occur at regular, predictable time intervals, most often weekly, monthly, annually, bi-annually, etc. Naturally, users issue REQ periodically. REQ usually refer to:

Organized public events such as festivals, conferences, expos, sports competitions, elections: winter olympics, boston marathon, the International Ocean Research Conference, oscar night.

Public holidays and other noteworthy dates: labor day, date of Good Friday, Thanksgiving, black friday.

Products with annual model releases, such as car models: ford explorer, prius.

Lottery drawings: California lotto results.

TV shows and programs which are currently running: American idol, Inside Edition.

Cultural related activities: presidential election, tax return, 1040 form.

Our interest in studying REQ arises from the challenge imposed on Web search ranking. To illustrate this, we show an example in Fig. 1 that snapshots the real ranking results of the query, *EMNLP*, issued in 2010 when the authors composed this paper, on Google search engine. It is obvious the ranking is not satisfactory because the page about *EMNLP2008* is on the first position in 2010. Ideally, the page about *EMNLP2010* on the 6th position should be on the first position even if users don't explicitly issue the query, *EMNLP 2010*, because *EMNLP* is a REQ. The query, "EMNLP", implicitly, without a year qualifier, needs to be served the most recent pages about "EMNLP".

A better search ranking result cannot be achieved if we do not categorize "EMNLP" as a REQ, and provide special ranking treatment to such queries. Existing search engines adopt a fairly involved ranking algorithm to order Web search results by considering many factors. Time is an important factor but not the most critical. The page's ranking score mostly depends on other features such as tf-idf (Salton and McGill, 1983), BM25 (Jones

Figure 1: A real problematic ranking result by Google for a REQ query, “EMNLP”. The EMNLP2010 page should be on the 1st position.

et al., 2000), anchor text, historical clicks, pagerank (Brin and Page, 1998), and overall page quality. New pages about EMNLP2010 obtain less favorable feature values than the pages of 2009 earlier in terms of anchor text, click or pagerank because they have existed for a shorter time and haven’t accumulated sufficient popularity to make them stand out. Without special treatment, the new pages about “EMNLP2010” will typically not be ranked appropriately for the users.

Typically, a recurrent event is associated with a root, and spawns a large set of queries. Oscar, for instance, is a recurrent event about the annual Academy Award. Based on this, queries like “oscar best actress”, “oscar best dress”, “oscar best movie award”, are all recurrent event queries. As such, REQ is a highly frequent category of query in Web search. By Web search query log analysis, we observe that there about 5-6% queries of total query volume belongs to this category.

In this work, we learn if a query is in the REQ class, by effectively combining multiple features. Our features are developed through analysis of historical query logs. We discuss our approaches in detail in Section 3. We then develop a REQ classifier where all the features are integrated by machine learning models. We use Naive Bayes, SVM and decision tree based logistic regression models. These models are described in Section 4. Our experiments for REQ classifier and Web search ranking are detailed in Section 5 and 6.

2 Related Work

We found our work were related to two other problems: general query classification and time-sensitive query classification. For general query classification, the task is to assign a Web search query to one or more predefined categories based on its topics. In the query classification contest in KDD-CUP 2005 (Li et al., 2005), seven categories and 67 sub-categories were defined. The winning solution (Shen et al., 2005) used multiple classifiers integrated by ensemble method. The difficulties for query classification are from short queries, lack of labeled data, and query sense ambiguity. Most popular studies use query log, web search results, unlabeled data to enrich query classification (Shen et al., 2006; Beitzel et al., 2005), or use document classification to predict query classification (Broder et al.,). General query classification is also studied for query intent detection by (Li et al., 2008).

There are many prior works to study the time sensitivity issue in web search. For example, Baeza-Yates *et al.* (Baeza-Yates et al., 2002) studied the relation between the web dynamics, structure and page quality, and demonstrated that PageRank is biased against new pages. In T-Rank Light and T-Rank algorithms (Berberich et al., 2005), both activity (i.e., update rates) and freshness (i.e., timestamps of most recent updates) of pages and links are taken into account for link analysis. Cho *et al.* (Cho et al., 2005) proposed a page quality ranking function in order to alleviate the problem of popularity-based ranking, and they used the derivatives of PageRank to forecast future PageRank values for new pages. Pandey *et al.* (Pandey et al., 2005) studied the tradeoff between new page exploration and high-quality page exploitation, which is based on a ranking method to randomly promote some new pages so that they can accumulate links quickly.

More recently, Dong *et al.* (Dong et al., 2010a) proposed a machine-learned framework to improve ranking result freshness, in which novel features, modeling algorithms and editorial guideline are used to deal with time sensitivities of queries and documents. In another work (Dong et al., 2010b), they use micro-blogging data (e.g., Twitter data) to detect fresh URLs. Novel and effective features are also extracted for fresh URLs so that ranking recency in web search is improved.

Perhaps the most related work to this paper is the query classification approach used in (Zhang et al., 2009) and (Metzler et al., 2009), in which year qualified queries (YQQs) are detected based on heuristic rules. For example, a query containing a year stamp is an explicit YQQ; if the year stamp is removed from this YQQ, the remaining part of this query is also a YQQ, which is called implicit YQQ. Different ranking approaches were used in (Zhang et al., 2009) and (Metzler et al., 2009) where (Zhang et al., 2009) boosted pages of the most latest year while (Metzler et al., 2009) promoted pages of the most influential years. Similarly, Nunes *et al.* (Nunes, 2007) applied information extraction techniques to identify temporal expression in web search queries, and found 1.5% of queries containing temporal expression.

Dong *et al.* (Dong et al., 2010a) proposed a breaking-news query classifier with high accuracy and reasonable coverage, which works not by modeling each individual topic and tracking it over time, but by modeling each discrete time slot, and comparing the models representing different time slots. The buzziness of a query is computed as the language model likelihood difference between different time slots. In this approach, both query log and news contents are exploited to compute language model likelihood.

Diaz (Diaz, 2009) determined the newsworthiness of a query by predicting the probability of a user clicks on the news display of a query. In this framework, the data sources of both query log and news corpus are leveraged to compute contextual features. Furthermore, the online click feedback also plays a critical role for future click prediction.

Konig *et al.* (Knig et al., 2009) estimated the click-through rate for dedicated news search result with a supervised model, which is to satisfy the requirement of adapting quickly to emerging news event. Some additional corpora such as blog crawl and Wikipedia is used for buzziness inference. Compared with (Diaz, 2009), different feature and learning algorithms are used.

Elsas *et al.* (Elsas and Dumais, 2010) studied improving relevance ranking by detecting document content change to leverage temporal information.

3 Feature Generation

To better understand our work, we first introduce three terms. We subdivide all raw queries in query log into three categories: Explicit Timestamp, Implicit Timestamp, and No Timestamp. An Explicit Timestamp query contains at least one token being a time indicator. For example, *emnlp 2010*, *2007 December holiday calendar*, *amsterdam weather summer 2009*, *Google Q1 reports 2010*. These queries are considered to conatin time indicators, because we can regard {*2010, 2007, 2009*} as year indicator, *december* as *month* indicator, {*summer, Q1(first quarter)*} as *seasonal* indicator. To simplify our work, we only consider the *year* indicators, *2010, 2007, 2009*. Such *year* indicators are also the most important and most popular indicators, as noted in (Zhang et al., 2009). Any query containing at least one *year* indicator is an Explicit Timestamp query. Due to word sense ambiguity, some queries labeled as Explicit Timestamp by this method may have no connection with time such as *Windows Office 2007*, *2010 Sunset Boulevard*, or *call number 2008*. In this work, we tolerate this type of error because word sense disambiguation is a peripheral problem for this task.

Implicit Timestamp queries are resulted by removing all *year* indicators from the corresponding Explicit Timestamp queries. For example, the Implicit Timestamp query of *emnlp 2010* is *emnlp*. All other queries are No Timestamp queries because they have never been found together with a *year* indicator.

Classifying queries into the above three categories depends on the used query log. A search engine company partner provided us a query log from 08/01/2009 to 02/29/2010 for this research. We found the proportions of the three categories in this query log are 13.8% (Explicit), 17.1% (Implicit) and 69.1% (No Timestamp). These numbers could be slightly different depending on the source of query logs. Note that 17.1% of Implicit Timestamp queries in the query log is a significant number. However, not all Implicit Timestamp queries are REQ. Many Implicit Timestamp queries have no time sense. They belong to Implicit Timestamp just because users issued the query with a *year* indicator through varied intents. For example, “google” is found to be an Implicit Timestamp query since there were many “google 2008” or “google 2009” in the query log.

The next few sections introduce our work in recognizing recurrent event time sense for Implicit Timestamp queries. We first focus on features. There are many features that were exploited in REQ classifier. We extract these features from query log, query session log, click log, search results, time series and NLP morphological analysis.

3.1 Query log analysis

The following features are extracted from query log analysis:

QueryDailyFrequency: the total counts of the query divided by the number of the days in the period.

ExplicitQueryRatio: Ratio of number of counts query was issued with year and number of counts query was issued with or without year. This feature is the method used by (Zhang et al., 2009).

UniqExplicitQueryCount: Number of uniq Explicit Timestamp queries associated with query. For example, if a query was issued with query+2009 and query+2008, this feature’s value is two.

ChiSquareYearDist: this feature is the distance between two distributions: one is frequency distribution over years for all REQ queries. The other is that for single REQ query. It is calculated through following steps: (a) Aggregate the frequencies for all queries for all years. Suppose we observe all years from 2001 to 2010. So we can get vector, $E = (\frac{af_{10}}{sum1}, \frac{af_{09}}{sum1}, ..., \frac{af_{01}}{sum1})$ where af_i is the frequency sum of year 20i for all REQ queries. $sum1 = af_{10} + af_{09} + ... + af_{01}$, the sum of all year frequency. (b) Given a query, suppose we observe this query’s yearly frequency distribution is , $O^q = (qf_{10}, qf_{09}, , ..., qf_{01})$. qf_i is this query’s frequency for the year 20i. Pad the slot with zeros if no frequency found. The expected distribution for this query is, $E^q = (\frac{sum2*af_{10}}{sum1}, \frac{sum2*af_{09}}{sum1}, ..., \frac{sum2*af_{01}}{sum1})$, where $sum2 = qf_{10} + qf_{09} + ... + qf_{01}$ is sum of all year frequency for the query. (d) Calculate CHI-squared value to represent the different yearly frequency distribution between E^q and O^q according to $\chi^2 = \sum_{i=1}^{N} \frac{(O_i^q - E_i^q)^2}{E_i^q}$. Using CHI square distance as a method is widely used for statistical hypothesis test. We found it to be a useful feature for REQ classifier.

3.2 Query reformulation

If users cannot find the newest page by issuing Implicit Timestamp query, they may re-issue the query using an Explicit Timestamp query. We can detect this change in a search session (a 30 minutes period for each query). By finding this kind of behavior from users, we next extract three features.

UserSwitch: Number of unique users that switched from Implicit Timestamp queries to Explicit Timestamp queries.

YearSwitch: Number of unique year-like tokens switched by users in a query session.

NormalizedUserSwitch: Feature UserSwitch divided by QueryDailyFrequency.

3.3 Click log analysis

If a query is time sensitive, users may click a page that displays the year indicator on title or url. An example that shows year indicator on url is *www.lsi.upc.edu/events/emnlp2010/call.html*. Search engine click log saves all users’ click information. We used click log to derive the following features.

YearUrlTop5CTR: Aggregated click through rate (CTR) of all top five URLs containing a year indicator. CTR of an URL is defined as the number of clicks of an URL divided by the number of page views.

YearUrlFPCTR: Aggregated click through rate (CTR) of all first page URLs containing a year indicator.

3.4 Search engine result set

For each Implicited Timestamp query, we can scrape the search engine to get search results. We count the number of titles and urls that contain year indicator. We use this number as a feature, and generate 6 features.

TitleYearTop5: the number of titles containing a year indication on the top 5 results. This value is 4 in Fig. 1.

TitleYearTop10: the number of titles containing a year indication on the top 10 results. This value is 6 in Fig. 1.

TitleYearTop30: the number of titles containing a year indication on the top 30 results.

UrlYearTop5: the number of urls containing a year indication on the top 5 results. This value is 1 in Fig. 1.

UrlYearTop10: the number of urls containing a year indication on the top 10 results.

UrlYearTop30: the number of titles containing a year indication on the top 30 results.

3.5 Time series analysis

Recurrent event query has periodic occurrence pattern in time series. Top graph of Figure 2 shows the frequency change of the query, “Oscar”. The annual event usually starts from Oscar nomination as earlier as last year December to award announcement of February this year. So a small spike and a big spike are observed in the graph to indicate nomination period and ceremony period. There are a period of silence between the two periods. The frequency pattern keeps unchanged each year. We show three years (2007,8,9) in the graph. By making use of recurrent event queries’ periodic properties, we calculated the query period as a new feature.

We use autocorrelation to calculate the period.

$$R(\tau) = \frac{\sum_{t=1}^{N-\tau}(x_t - \mu)(x_{t+\tau} - \mu)}{\{\sum_{t=1}^{N-\tau}(x_t - \mu)^2(x_{t+\tau} - \mu)^2\}^{1/2}}$$

where $x(t)$ is query daily frequency. N is the number of days used for this query. We can get maximum of 3 years data for some queries but only a few months for others. $R(\tau)$ is autocorrelation function. Peaks (the local biggest $R(\tau)$ given a time window) can be detected from $R(\tau)$ plot. The period T is calculated as the duration between two neighbor peaks. $T = 365$ for the query, “Oscar”. The bottom graph of Fig. 2 shows the autocorrelation function plot for the query Oscar.

3.6 Recurrent event seed word list

Many recurrent event queries share some common words that have recurrent time sense. We list most frequently used recurrent seeds in Table 1. Those seeds are likely combined with other words to form new recurrent event queries. For example, the seed, “new”, can be used by queries “new bmw cars”, “whitney houston new songs”, “apple new iphone”, or “hairstyle new”.

new	results	top	schedule
football	festival	movie	world
show	day	best	tax
result	calendar	honda	ford
download	exam	nfl	miss
awards	toyota	tour	sale
american	fair	list	pictures
election	game	basketball	cup

Table 1: Top recurrent event seed words

To generate the seed list, we tokenized all the queries from Implicit Timestamp queries and split all the tokens. We then sort and unique all the tokens, and submit top tokens to professional editors who are asked to pick 8,000 seeds from the top frequent tokens. Some top tokens were removed if they are not qualified to form recurrent event queries. The editors took about four days to do the judgment according to the token’s time sense and examples of recurrent event queries. However, this is a one-time effort. A token will be in the seed if there are many recurrent event examples formed by this token, by editors’ judgment.

Table 1 shows 32 top seeds. Some seeds connect with time such as, “new, schedule, day, best, calendar”; some relate to sports, “football, game, nfl, tour, basketball, cup”; some about cars, “honda, ford, toyota”. The reason why “miss” is in the seeds is that there are many annual events about beauty contest such as “miss america, miss california, miss korea”.

We use the seed list to generate the following three features:

AveNumberTokensSeeds: number of tokens that is in the seed list divided by number of tokens in the query.

AveNumberTokensNotSeeds: number of tokens that is not in the seed list divided by number of tokens in the query.

DiffNumberTokensSeeds: The difference of the above two values.

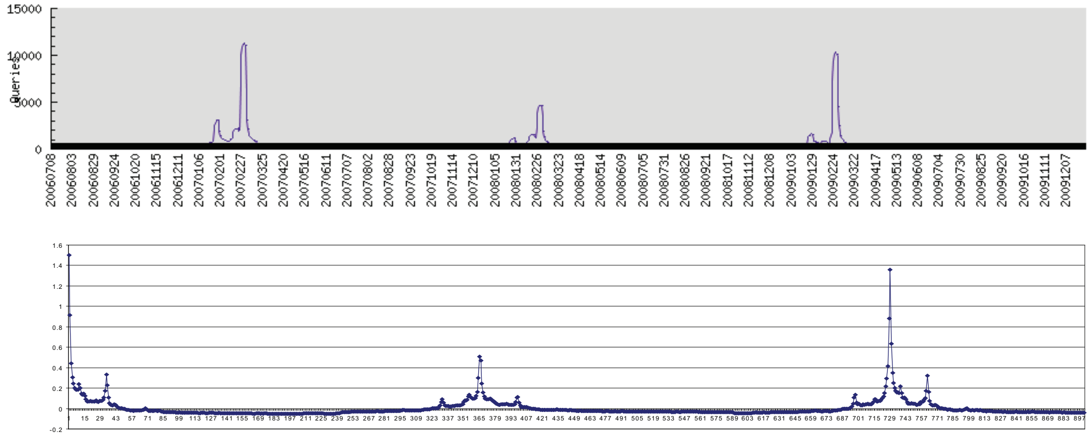

Figure 2: Frequency waveform(top) and corresponding autocorrelation curve (bottom) for query *Oscar*.

4 Learning Approach for REQ

The REQ classification is a typical machine learning task. Given M observed samples used for training data, $\{(\mathbf{x}_0, y_0), (\mathbf{x}_1, y_1), \cdots, (\mathbf{x}_M, y_M)\}$ where $\mathbf{x}_i$ is a feature vector we developed in last section for a given query. y_i is the observation value, $\{+1, -1\}$, indicating the class of REQ and non-REQ. The task is to find the class probability given an unknown feature vector, $\mathbf{x}'$, that is,

$$p(y = c|\mathbf{x}'), \quad c = +1, -1. \tag{1}$$

There are a lot of machine learning methods applicable to implement Eq. 1. In this work, we adopted three representative methods.

The first method is Naive Bayes method. This method treats features independent. If $\mathbf{x}$ is enxtended into feature vector, $\mathbf{x} = \{x_0, x_1, \cdots, x_N\}$ then,

$$p(y = c|\mathbf{x}) = \frac{1}{Z} p(c) \prod_{i=0}^{i=N} p(x_i|c)$$

The second method is SVM. In this work we used the tool for our experiments, LIBSVM (Chang and Lin, 2001). Because SVM is a well known approach and widely used in many classification task, we skip to describe how to use this tool. Readers can turn to the reference for more details.

The third method is based on decision tree based logistic regression model. The probability is given by the formula below,

$$p(y = c|\mathbf{x}) = \frac{1}{1 + e^{-f(\mathbf{x})}} \tag{2}$$

We employ Gradient Boosted Decision Tree algorithm (Friedman, 2001) to learn the function $f(X)$. Gradient Boosted Decision Tree is an additive regression algorithm consisting of an ensemble of trees, fitted to current residuals, gradients of the loss function, in a forward step-wise manner. It iteratively fits an additive model as

$$f_t(x) = T_t(x; \Theta) + \lambda \sum_{t=1}^{T} \beta_t T_t(x; \Theta_t)$$

such that certain loss function $L(y_i, f_T(x + i))$ is minimized, where $T_t(x; \Theta_t)$ is a tree at iteration t, weighted by parameter β_t, with a finite number of parameters, Θ_t and λ is the learning rate. At iteration t, tree $T_t(x; \beta)$ is induced to fit the negative gradient by least squares.
The optimal weights of trees β_t are determined by

$$\beta_t = \operatorname{argmin}_\beta \sum_{i}^{N} L(y_i, f_{t-1}(x_i) + \beta T(x_i, \theta))$$

Each node in the trees represents a split on a feature. The tuneable parameters in such a machine-learnt model include the number of leaf nodes in each tree, the relative contribution of score from each tree called the shrinkage, and total number of shallow decision trees.

The relative importance of a feature S_i, in such forests of decision trees, is aggregated over all the *m* shallow decision trees (Breiman et al., 1984) as follows:

$$S_i^2 = \frac{1}{M}\sum_{m=1}^{M}\sum_{n=1}^{L-1}\frac{w_l * w_r}{w_l + w_r}(y_l y_r)^2 I(v_t = i) \quad (3)$$

where v_t is the feature on which a split occurs, y_l and y_r are the mean regression responses from the right, and left sub-tree, and w_l and w_r are the corresponding weights to the means, as measured by the number of training examples traversing the left and right sub-trees.

5 REQ Learner Evaluation

We collected 6,000 queries labeled as either Recurrent or Non-recurrent by professional human editors. The 6,000 queries were sampled from Implicit Timestamp queries according to frequency distribution to be representative. We split the queries into 5,000 for training and 1,000 for test. For each query, we calculated features' values as described in Section 3.

The Naive Bayes method used single Gaussian function for each independent feature. Mean and variance were calculated from the training data.

As for LIBSVM, we used C-SVC, linear function as kernel and 1.0 of shrinkage.

The parameters used in the regression model were 20 of trees, 20 of nodes and 0.8 of learning rate (shrinkage).

The test results are shown in Fig. 3, recall-precision curve. We set a series of threshold to the probability of $c = +1$ calculated by Eq. 1 so that we can get the point values of recall and precision in Fig. 3. For example, if we set a threshold of 0.6, a query with a probability larger than 0.6 is classified as REQ. Otherwise, it is non-REQ. The precision is a measure of correctly classified REQ queries divided by all classified REQ queries. The recall is a measure of correctly classified REQ queries divided by all REQ queries in test data.

In addition to the three plots, we also show the results using only one feature, ExplicitQueryRatio, for comparison with the classification method used by (Zhang et al., 2009).All the three models using all features performed better than the existing method using ExplicitQueryRatio. The highest improvement was achieved by GBDT regression tree model. The results of Naive Bayes were lower than SVM and GBDTree. This model is weaker because it treats features independently. Typically SVMs and GBDT gives comparable results on a large class of problems. Since for this task we use features from different sources, the feature values are designed to have larger dynamic range, which is better handled by GBDT.

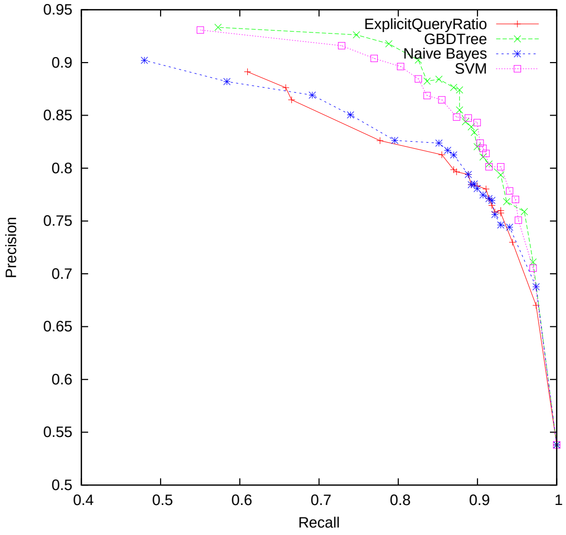

Figure 3: Comparison of precision and recall rate between our method and the existing method.

The features' importance ranked by Equation 3 is shown in Table 2. We list the top 10 features. The No.1 important feature is ExplicitQueryRatio. The second and seventh features are from search session analysis by counting users who changed queries from Implicit Timestamp to Explicit Timestamp. This is a strong source of features. The time series analysis feature is ranked No.3. Calculation of this feature needs two years query log to be much more effective, but we didn't get so large data for many queries. One of the features from recurrent event seed list is ranked No.4. This is also an important feature source. The ChiSquareYearDist feature is ranked 5th, that proves the recurrent event query frequency has a statistical distribution pattern over years. TitleYearTop30 and TitleYearTop10 that are derived from scraping results are ranked the 9th and 10th important.

Fig. 4 shows the distribution of feature values for

Feature	Rank	Score
ExplicitQueryRatio	1	100
NormalizedUserSwitch	2	71.7
AutoCorrelation	3	54.0
AveNumberTokenSeeds	4	48.7
ChiSquareYearDist	5	36.3
YearUrlFPCTR	6	19.1
UserSwitch	7	11.7
QueryDailyFreq	8	10.7
TitleYearTop30	9	10.6
TitleYearTop10	10	5.8

Table 2: Top 10 most important features: rank and importance score (100 is maximum)

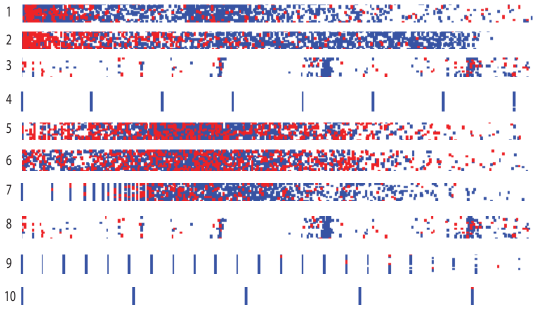

Figure 4: Feature value distribution of all data (blue=REQ, red=non-REQ)

each sample of the 6,000 data, where each point represents a query and each line represents a feature's value for all queries. One point is a query. The features are ordered according to feature importance of Table 2. The "blue" points indicate REQ queries and the "red" points, non-REQ queries. Some features are continuous like the 1st and 2nd. Some feature values are discrete like the last two indicating TitleYearTop30 and TitleYearTop10. There are "red" samples in the 4th feature but overlapped with and covered by "blue" samples visually.

In the Table 3, we show F-Measure values as we gradually added features from the feature, ExplicitQueryRatio, according to feature importance in Table 2. We listed the F-Measure values under three threshold, 0.6, 0.7 and 0.8. Higher threshold will increase classifier precision rate but reduce recall rate. F-Measure is a metric combining precision rate and recall rate. It is clearly observed that the classifier performance is improved as more features are used.

	Threshold		
Feature	0.6	0.7	0.8
ExplicitQueryRatio	0.833	0.833	0.752
+NormalizedUserSwitch	0.840	0.837	0.791
+AutoCorrelation	0.850	0.839	0.823
+AveNumberTokenSeeds	0.857	0.854	0.834
+ChiSquareYearDist	0.857	0.864	0.839
+YearUrlFPCTR	0.869	0.867	0.837
+UserSwitch	0.862	0.862	0.846
+QueryDailyFreq	0.860	0.852	0.847
+TitleYearTop30	0.854	0.853	0.843
+TitleYearTop10	0.858	0.861	0.852
+All	0.876	0.867	0.862

Table 3: F-Measures as varying thresholds by adding top features.

Query	Probability
ncaa men's basketball tournament	0.999
bmw 328i sedan reviews	0.999
new apple iphone release	0.932
sigir	0.920
new york weather in april	0.717
academy awards reviews	0.404
google ipo	0.120
adidas jp	0.082

Table 4: Probabilities of example queries by GBDT tree classifier

Some query examples, and their scores from our model are listed in Table 4. The last two examples, *google ipo* and *adidas jp*, have very low values, and are not REQs. The first four queries are typical REQs. They have higher values of features ExplicitQueryRatio,Normalized UserSwitch and YearUrlFPCTR. Although both *new apple iphone release reviews* and *academy awards reviews* are about reviews, *academy awards reviews* has lower value of NormalizedUserSwitch and ChiSquareYearDist could be the reason for a lower score.

6 Web Search Ranking

In this section, we use the approach proposed by (Zhang et al., 2009) to test the REQ classifier for Web search ranking. In their approach, search ranking is altered by boosting pages with most recent year if the query is a REQ. The year indicator

		DCG@5			DCG@1		
bucket	#(query)	Organic	Our's	% over Organic	Organic	Ours	% over Organic
[0.0,0.1]	59	6.87	6.96	1.48(-2.3)	4.08	4.19	2.69(-1.07)
[0.1,0.2]	76	5.86	6.01	2.52(0.98)	2.88	2.91	1.14(1.69)
[0.2,0.3]	85	6.33	6.41	1.24(2.12)	3.7	3.7	0.0(0.8)
[0.3,0.4]	75	5.18	5.24	1.18(-0.7)	2.92	2.95	1.14(1.37)
[0.4,0.5]	78	4.96	4.82	-2.84(-1.35)	2.5	2.42	-3.06(0)
[0.5,0.6]	84	5.4	5.37	-0.45(-0.3)	2.82	2.85	1.05(-1.5)
[0.6,0.7]	78	4.78)	5.19)	8.42(3.64)	2.56	2.83	10.75(4.1)
[0.7,0.8]	80	4.45	4.60	3.41(3.19)	2.21	2.26	1.98(2.8)
[0.8,0.9]	78	4.81	4.96	3.15(4.79)	2.32	2.33	0.55(0.65)
[0.9,1.0]	107	5.08	5.50	**8.41***(4.41)	2.64	3.09	**16.78***(1.36)
[0.0,1.0]	800	5.33	5.47	**2.74***(2.17)	2.83	2.93	**3.6***(1.26)

Table 5: REQ learner improves search engine organic results. The numbers in the brackets are by Zhang's methods. Direct comparison with Zhang's method is valid only in the last line, using all queries. A sign “$*$” indicates statistical significance (p-value<0.05)

can be detected either from title or URL of the result. For clarity, we re-write their ranking function as below,

$$F(q,d) = R(q,d) + [e(d_o, d_n) + k]e^{\lambda\alpha(q)}$$

where the ranking function, $F(q,d)$, consists of two parts: the base function $R(q,d)$ plus boosting. If the query q is not a REQ, boosting is set to zero. Otherwise, boosting is decided by $e(d_o, d_n)$, k, λ and $\alpha(q)$. $e(d_o, d_n)$ is the difference of base ranking score between the oldest page and the newest page. If the newest page has a lower ranking score than the oldest page, then the difference is added to the newest page to promote the ranking of the newest page.

$\alpha(q)$ is the confidence score of a REQ query. It is the value of Eq. 1. λ and k are two empirical parameters. (Zhang et al., 2009)'s work has experimented the effects of using different value of λ and k ($\lambda = 0$ equals to no discounts for ranking adjustment). We used $\lambda = 0.4$ and $k = 0.3$ which were the best configuration in (Zhang et al., 2009).

For evaluating our methods, we randomly extracted 800 queries from the Implicit Timestamp queries. We scraped a commercial search engine using the 800 queries. We extracted the top five search results for each query under three configures: organic search engine results, (Zhang et al., 2009)'s method and ours using REQ classifier. We asked human editors to judge all the scraped (query, url) pairs. Editors assign five grades according to relevance between query and articles: Perfect, Excellent, Good, Fair, and Bad. For example, a “Perfect” grade means the content of the url match exactly the query intent.

We use Discounted Cumulative Gain (DCG) (Jarvelin and Kekalainen, 2002) at rank k as our primary evaluation metrics to measure retrieval performance. DCG is defined as,

$$DCG@k = \sum_{i=1}^{k} \frac{2^{r(i)} - 1}{log_2(1+i)}$$

where $r(i) \in \{0 \dots 4\}$ is the relevance grade of the ith ranked document.

The Web search ranking results are shown in Table 5. We used GBDT tree learning methods because it achieved the best results. We divided 800 test queries into 10 buckets according to the classifier probability. The bucket, [0.0,0.1], contains the query with a classifier probability greater than 0 but less than 0.1. Our results are compared with organic search results, but we also show the improvements over search organic by (Zhang et al., 2009) in the brackets. Because Zhang's approach output different classifier values from Ours for the same query, buckets of the same range in the Table contain different queries. Hence, it is inappropriate to compare

Zhang's with Ours for the same buckets except the last row where we used all the queries.

Our classifier's overall performance is much better than the organic search results. We achieved 2.74% DCG@5 gain and 3.6% DCG@1 gain over organic search for all queries. The gains are higher than (Zhang et al., 2009)'s results with regards to improvement over organic results. By direct comparison, Ours was 2.7% better than Zhangs significantly in terms of DCG@1 by Wilcoxon significant test. DCG@5 is 1.1% better, but not significant. The table also show that the higher buckets with higher probability achieved higher DCG gain than the lower buckets overall. Our approach observed 16.78% DCG@1 gain for bucket [0.9,1.0]. This shows that our methods are very effective.

7 Conclusions

We found most of REQ are long tail queries that pose a major challenge to Web search. We have demonstrated learning REQ is important for Web search. this type of queries can't be solved in traditional ranking method. We found building a REQ classifier was a good solution. Our work described using machine learning method to build REQ classifier. Our proposed methods are novel comparing with traditional query classification methods. We identified and developed features from query log, search session, click and time series analysis. We applied several ML approaches including Naive Bayes, SVM and GBDT tree to implement REQ learner. Finally, we show through ranking experiments that the methods we proposed are very effective and beneficial for search engine ranking.

Staying Informed: Supervised and Semi-Supervised Multi-view Topical Analysis of Ideological Perspective

Abstract

With the proliferation of user-generated articles over the web, it becomes imperative to develop automated methods that are aware of the ideological-bias implicit in a document collection. While there exist methods that can classify the ideological bias of a given document, little has been done toward understanding the nature of this bias on a topical-level. In this paper we address the problem of modeling ideological perspective on a topical level using a factored topic model. We develop efficient inference algorithms using Collapsed Gibbs sampling for posterior inference, and give various evaluations and illustrations of the utility of our model on various document collections with promising results. Finally we give a Metropolis-Hasting inference algorithm for a semi-supervised extension with decent results.

1 Introduction

With the avalanche of user-generated articles over the web, it is quite important to develop models that can recognize the ideological bias behind a given document, summarize where this bias is manifested on a topical level, and provide the user with alternate views that would help him/her staying informed about different perspectives. In this paper, we follow the notion of ideology as defines by Van Dijk in (Dijk, 1998) as “a set of general abstract beliefs commonly shared by a group of people.” In other words, an ideology is a set of ideas that directs one's goals, expectations, and actions. For instance, *freedom of choice* is a general aim that directs the actions of“liberals”, whereas *conservation of values* is the parallel for “conservatives”.

We can attribute the lexical variations of the word content of a document to three factors:

- **Writer Ideological Belief.** A liberal writer might use words like freedom and choice regardless of the topical content of the document. These words define the abstract notion of belief held by the writer and its frequency in the document largely depends on the writer's style.
- **Topical Content.** This constitutes the main source of the lexical variations in a given document. For instance, a document about abortion is more likely to have facts related to abortion, health, marriage and relationships.
- **Topic-Ideology Interaction.** When a liberal thinker writes about abortion, his/her abstract beliefs are materialized into a set of concrete opinions and stances, therefore, we might find words like: pro-choice and feminism. On the contrary, a conservative writer might stress issues like pro-life, God and faith.

Given a collection of ideologically-labeled documents, our goal is to develop a computer model that *factors* the document collection into a representation that reflects the aforementioned three sources of lexical variations. This representation can then be used for:

- **Visualization.** By visualizing the abstract notion of belief in each ideology, and the way each ideology approaches and views mainstream topics, the user can view and contrast each ideology side-by-side and build the right mental landscape that acts as the basis for his/her future decision making.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1140–1150,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

- **Classification or Ideology Identification.** Given a document, we would like to tell the user from which side it was written, and explain the ideological bias in the document at a topical level.

- **Staying Informed: Getting alternative views[1].** Given a document written from perspective A, we would like the model to provide the user with other documents that represent alternative views about the same topic addressed in the original document.

In this paper, we approach this problem using Topic Models (Blei et al., 2003). We introduce a factored topic model that we call multi-view Latent Dirichlet Allocation or mview-LDA for short. Our model views the word content of each document as the result of the interaction between the document's idealogical and topical dimensions. The rest of this paper is organized as follows. First, in Section 2, we review related work, and then present our model in Section 3. Then in Section 4, we detail a collapsed Gibbs sampling algorithm for posterior inference. Sections 5 and 6 give details about the dataset used in the evaluation and illustrate the capabilities of our model using both qualitative and quantitative measures. Section 7 describes and evaluates the efficacy of a semi-supervised extension, and finally in Section 8 we conclude and list several directions for future research.

2 Related Work

Ideological text is inherently subjective, thus our work is related to the growing area of subjectivity analysis(Wiebe et al., 2004; Riloff et al., 2003). The goal of this area of research is to learn to discriminate between subjective and objective text. In contrast,in modeling ideology, we aim toward contrasting two or more ideological perspectives each of which is subjective in nature. Further more, subjective text can be classified into sentiments which gave rise to a surge of work in automatic opinion mining (Wiebe et al., 2004; Yu and Hatzivassiloglou, 2003; Pang et al., 2002; Turney and Littman, 2003; Popescu and Etzioni, 2005) as well as sentiment analysis and product review mining (Nasukawa and Yi, 2003; Hu and Liu, 2004; Pang and Lee, 2008; Branavan et al., 2008; Titov and McDonald, 2008; Titov and McDonald, 2008; Mei et al., 2007; Ling et al., 2008). The research goal of sentiment analysis and classification is to identify language used to convey positive and negative opinions, which differs from contrasting two ideological perspectives. While ideology can be expressed in the form of a sentiment toward a given topic,like abortion, ideological perspectives are reflected in many ways other than sentiments as we will illustrate later in the paper. Perhaps more related to this paper is the work of (Fortuna et al., 2008; Lin et al., 2008) whose goal is to detect bias in news articles via discriminative and generative approaches, respectively. However, this work still addresses ideology at an abstract level as opposed to our approach of modeling ideology at a topical level. Finally, independently, (Paul and Girju, 2009) gives a construction similar to ours however for a different task [2].

3 Multi-View Topic Models

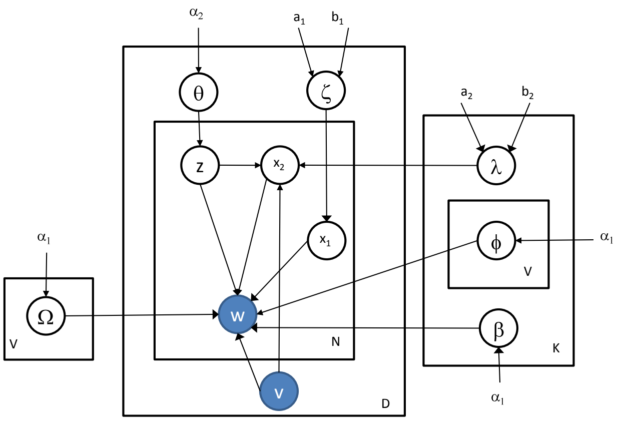
In this section we introduce multi-view topic models, or mview-LDA for short. Our model, mview-LDA, views each document as the result of the interaction between its topical and idealogical dimensions. The model seeks to explain lexical variabilities in the document by attributing this variabilities to one of those dimensions or to their interactions. Topic models, like LDA, define a generative process for a document collection based on a set of parameters. LDA employs a semantic entity known as *topic* to drive the generation of the document in question. Each topic is represented by a topic-specific word distribution which is modeled as a multinomial distribution over words, denoted by $\mathrm{Multi}(\beta)$. The generative process of LDA proceeds as follows:

1. Draw topic proportions $\theta_d|\alpha \sim \mathrm{Dir}(\alpha)$.
2. For each word
   (a) Draw a topic $z_n|\theta_d \sim \mathrm{Mult}(\theta_d)$.
   (b) Draw a word $w_n|z_n, \beta \sim \mathrm{Multi}(\beta_{z_n})$.

In step 1 each document d samples a topic-mixing vector θ_d from a Dirichlet prior. The component $\theta_{d,k}$

[1] In this paper, we use the words ideology, view, perspective interchangeably to denote the same concept

[2] In fact, we only get to know about this related work after our paper was accepted



Variable	Meaning
w	word
v	document's ideology
z	topic
x_1, x_2	word switches, one per word (see text)
θ	document-specific distribution over topics
ξ	document's expected usage of the ideology's background topic
Ω	ideology's background-topic
β	ideology-independent topic distribution
ϕ	ideology-specific topic distribution
λ	topic bias across ideology

Figure 1: A plate diagram of the graphical model.

of this vector defines how likely topic k will appear in document d. For each word in the document w_n, a topic indicator z_n is sampled from θ_d, and then the word itself is sampled from a topic-specific word distribution specified by this indicator. Thus LDA can capture and represent lexical variabilities via the components of θ_d which represents the topical content of the document. In the next section we will explain how our new model mview-LDA can capture other sources of lexical variabilities beyond topical content.

3.1 Multi-View LDA

As we noted earlier, LDA captures lexical variabilities due to topical content via θ_d and the set of topics $\beta_{1:K}$. In mview-LDA each document d is tagged with the ideological view it represents via the observed variable v_d which takes values in the discrete range: $\{1, 2, \cdots, V\}$ as shown in Fig. 1. For simplicity, lets first assume that $V = 2$. The topics $\beta_{1:K}$ retain the same meaning: a set of K multinomial distributions each of which represents a given theme or factual topic. In addition, we utilize an ideology-specific topic Ω_v which is again a multinomial distribution over the same vocabulary. Ω_v models the abstract belief shared by all the documents written from view v. In other words, if v denotes the liberal perspective, then Ω_v gives high probability to words like progressive, choice, etc. Moreover, we defined a set of $K \times V$ topics that we refer to as ideology-specific topics. For example, topic $\phi_{v,k}$ represents how ideology v addresses topic k. The generative process of a document d with ideological view v_d proceeds as follows:

```
1. Draw $\xi_d \sim \mathrm{Beta}(a_1, b_1)$
2. Draw topic proportions $\theta_d|\alpha \sim \mathrm{Dir}(\alpha_2)$.
3. For each word $w_n$
   (a) Draw $x_{n,1} \sim \mathrm{Bernoulli}(\xi_d)$
   (b) If$(x_{n,1} = 1)$
       i. Draw $w_n|x_{n,1} = 1 \ \sim\ \mathrm{Multi}(\Omega_{v_d})$
   (c) If$(x_{n,1} = 0)$
       i. Draw $z_n|\theta_d \sim \mathrm{Mult}(\theta_d)$.
       ii. Draw $x_{n,2}|v_d, z_n \sim \mathrm{Bernoulli}(\lambda_{z_n})$
       iii. If$(x_{n,2} = 1)$
           A. Draw $w_n|z_n, \beta \sim \mathrm{Multi}(\beta_{z_n})$.
       iv. If$(x_{n,2} = 0)$
           A. Draw $w_n|v_d, z_n \sim \mathrm{Multi}(\phi_{v_d,z_n})$.
```

In step 1, we draw a document-specific biased coin,ξ_d. The bias of this coin determines the proportions of words in the document that are generated from its ideology background topic Ω_{v_d}. As in LDA, we draw the document-specific topic proportion θ_d from a Dirichlet prior. θ_d thus controls the lexical variabilities due to topical content inside the document.

To generate a word w_n, we first generate a coin flip $x_{n,1}$ from the coin ξ_d. If it turns head, then we proceed to generate this word from the ideology-specific topic associated with the document's ideological view v_d. In this case, the word is drawn independently of the topical content of the document, and thus accounts for the lexical variation due to the ideology associated with the document. The proportion of such words is document-specific by design and depends on the writer's style to a large degree. If $x_{n,1}$ turns to be tail,we proceed to the next step and draw a topic-indicator z_n. Now, we have two choices: either to generate this word directly from the ideology-independent portion of the topic β_{z_n}, or to draw the word from the ideology-specific portion ϕ_{v_d,z_n}. The choice here is **not** document specific, but rather depends on the interaction between the ideology and the specific topic in question. If the ideology associated with the document holds a strong opinion or view with regard to this topic, then we expect that most of the time we will take the second choice, and generate w_n from ϕ_{v_d,z_n}; and vice versa. This decision is controlled by the Bernoulli variable λ_{z_n}. Therefore, in step $c.ii$, we first generate a coin flip $x_{n,2}$ from λ_{z_n}. Based on $x_{n,2}$ we either generate the word from the ideology-independent portion of the topic β_{z_n}, and this constitutes how the model accounts for lexical variation due to the topical content of the document, or generate the word from the ideology-specific portion of the topic ϕ_{v_d,z_n}, and this specifies how the model accounts for lexical variation due to the interaction between the topical and ideological dimensions of the document.

Finally, it is worth mentioning that the decision to model λ_{z_n}[3] at the topic-ideology level rather than at the document level, as we have done with ξ_d, stems from our goal to capture ideology-specific behavior on a corpus level rather than capturing document-specific writing style. However, it is worth mentioning that if one truly seeks to measure the degree of bias associated with a given document,then one can compute the frequency of the event $x_{n,2} = 0$ from posterior samples. In this case, λ_{z_n} acts as the prior bias only. Moreover, computing the frequency of the event $x_{n,2} = 0$ and $z_n = k$ gives the document's bias toward topic k per se.

Finally, it is worth mentioning that all multinomial topics in the model: β, Ω, ϕ are generated once for the whole collection from a symmetric Dirichlet prior, similarly, all bias variables, $\lambda_{1:K}$ are sampled from a Beta distribution also once at the beginning of the generative process.

4 Posterior Inference Via Collapsed Gibbs Sampling

The main tasks can be summarized as follows:

- **Learning**: Given a collection of documents, find a point estimate of the model parameters (i.e. $\beta, \Omega, \phi, \lambda$,etc.).
- **Inference**: Given a new document, and a point estimate of the model parameters, find the posterior distribution of the latent variables associated with the document at hand: $(\theta_d, \{x_{n,1}\}, \{z_n\}, \{x_{n,2}\})$.

Under a hierarchical Bayesian setting, like the approach we took in this paper, both of these tasks can be handled via posterior inference. Under the generative process, and hyperparmaters choices, outlined in section 3, we seek to compute:

$$P(\mathbf{d}_{1:D}, \beta_{1:K}, \mathbf{\Omega}_{1:V}, \phi_{\mathbf{1:V},\mathbf{1:K}}, \lambda_{1:K} | \alpha, a, b, \mathbf{w}, \mathbf{v}),$$

where $\mathbf{d}$ is a shorthand for the hidden variables $(\theta_d, \xi_d, \mathbf{z}, \mathbf{x_1}, \mathbf{x_2})$ in document d. The above posterior probability is unfortunately intractable,and we approximate it via a collapsed Gibbs sampling procedure (Griffiths and Steyvers, 2004; Gelman et al., 2003) by integrating out, i.e. collapsing, the following hidden variables: the topic-mixing vectors θ_d and the ideology bias ξ_d for each document, as well as all the multinomial topic distributions: $(\beta, \Omega$ and $\phi)$ in addition to the ideology-topic biases given by the set of λ random variables.

Therefore, the state of the sampler at each iteration contains only the following topic indicators and coin flips for each document:$(\mathbf{z}, \mathbf{x_1}, \mathbf{x_2})$. We alternate sampling each of these variables conditioned on its Markov blanket until convergence. At convergence, we can calculate expected values for all the parameters that were integrated out, especially for the topic distributions, for each document's latent representation (mixing-vector) and for all coin biases. To ease the calculation of the Gibbs sampling update equations we keep a set of sufficient statistics (SS) in the form of co-occurrence counts and sum matrices of the form C^{EQ}_{eq} to denote the number of times instance e appeared with instance q. For example, C^{WK}_{wk} gives the number of times word w was sampled from the ideology-independent portion of

[3] In an earlier version of the work we modeled λ on a per-ideology basis, however, we found that using a single shared λ results in more robust results

topic k. Moreover, we follow the standard practice of using the subscript $-i$ to denote the same quantity it is added to without the contribution of item i. For example,$C^{WK}_{wk,-i}$ is the same as C^{WK}_{wk} without the contribution of word w_i. For simplicity, we might drop dependencies on the document whenever the meaning is implicit form the context.

For word w_n in document d, instead of sampling $z_n, x_{n,1}, x_{n,2}$ independently, we sample them as a block as follows:

$$P(x_{n,1} = 1|w_n = w, v_d = v) \propto$$
$$(C^{DX_1}_{d1,-n} + a_1) \times \frac{C^{VW}_{vw,-n} + \alpha_1}{\sum_{w'}(C^{VW}_{vw',-n} + \alpha_1)}$$

$$P(x_{n,1} = 0, x_{2,n} = 1, z_n = k|w_n = w, v_d = v)$$
$$\propto (C^{DX_1}_{d0,-n} + b_1) \times \frac{C^{KX_2}_{k1,-n} + a_2}{C^{KX_2}_{k1,-n} + C^{KX_2}_{k0,-n} + a_2 + b_2}$$
$$\times \frac{C^{KW}_{kw,-n} + \alpha_1}{\sum_{w'}(C^{KW}_{kw',-n} + \alpha_1)} \times \frac{C^{DK}_{dk,-n} + \alpha_2}{\sum_{k'}(C^{DK}_{dk',-n} + \alpha_2)}$$

$$P(x_{n,1} = 0, x_{2,n} = 0, z_n = k|w_n = w, v_d = v)$$
$$\propto (C^{DX_1}_{d0,-n} + b_1) \times \frac{C^{KX_2}_{k0,-n} + b_2}{C^{KX_2}_{k1,-n} + C^{KX_2}_{k0,-n} + a_2 + b_2}$$
$$\times \frac{C^{VKW}_{vkw,-n} + \alpha_1}{\sum_{w'}(C^{VKW}_{vkw',-n} + \alpha_1)} \times \frac{C^{DK}_{dk,-n} + \alpha_2}{\sum_{k'}(C^{DK}_{dk',-n} + \alpha_2)}$$

The above three equations can be normalized to form a $2 * K + 1$ multinomial distribution: one component for generating a word from the ideology topic, K components for generating the word from the ideology-independent portion of topic $k = 1, \cdots, K$, and finally K components for generating the word from the ideology-specific portion of topic $k = 1, \cdots, K$. Each of these $2 * K + 1$ cases corresponds to a unique assignment of the variables $z_n, x_{n,1}, x_{n,2}$. Therefore, our Gibbs sampler just repeatedly draws sample from this $2*K+1$-components multinomial distribution until convergence. Upon convergence, we compute point estimates for all the collapsed variables by a simple marginalization of the appropriate count matrices. During **inference**, we hold the corpus-level count matrices fixed, and keep sampling from the above $2*K+1$-component multinomial while only changing the document-level count matrices: C^{DK}, C^{DX_1} until convergence. Upon convergence, we compute estimates for ξ_d and θ_d by normalizing C^{DK} and C^{DX_1} (or possibly averaging this quantity across posterior samples). As we mentioned in Section 3, to compute the ideology-bias in addressing a given topic say k in a given document, say d, we can simply compute the expected value of the event $x_{n,2} = 0$ and $z_n = k$ across posterior samples.

5 Data Sets

We evaluated our model over three datasets: the bitterlemons croups and a two political blog-data set. Below we give details of each dataset.

5.1 The Bitterlemons dataset

The bitterlemons corpus consists of the articles published on the website `http://bitterlemons.org/`. The website is set up to contribute to mutual understanding between Palestinians and Israelis through the open exchange of ideas. Every week, an issue about the Israeli-Palestinian conflict is selected for discussion, and a Palestinian editor and an Israeli editor contribute one article each addressing the issue. In addition, the Israeli and Palestinian editors invite one Israeli and one Palestinian to express their views on the issue. The data was collected and pre-proceed as describes in (Lin et al., 2008). Overall, the dataset contains 297 documents written from the Israeli's point of view, and 297 documents written from the Palestinian's point of view. On average each document contains around 740 words. After trimming words appearing less than 5 times, we ended up with a vocabulary size of 4100 words. We split the dataset randomly and used 80% of the documents for training and the rest for testing.

5.2 The Political Blog Datasets

The first dataset refereed to as *Blog-1* is a subset of the data collected and processed in (Yano et al., 2009). The authors in (Yano et al., 2009) collected blog posts from blog sites focusing on American politics during the period November 2007 to October 2008. We selected three blog sites from this dataset: the Right Wing News (right-ideology) ; the Carpetbagger, and Daily Kos as representatives

Figure 2: Illustrating the big picture overview over the bitterlemons dataset using few topics. Each box lists the top words in the corresponding multinomial topic distribution. See text for more details

of the liberal view (left-ideology). After trimming short posts of less than 20 words, we ended up with 2040 posts distributed as 1400 from the left-wing and the rest from the right-wing. On average, each post contains around 100 words and the total size of the vocabulary is 14276 words. For this dataset, we followed the train-test split in (Yano et al., 2009). In this split each blog is represented in both training and test sets. Thus this dataset does not measure the model's ability to generalize to a totally different writing style.

The second dataset refereed to as *Blog-2* is similar to Blog-1 in its topical content and time frame but larger in its blog coverage (Eisenstein and Xing, 2010). Blog-2 spans 6 blogs: three from the left-wing and three from the right-wing. The dataset contains 13246 posts. After removing words that appear less then 20 times, the total vocabulary becomes 13236 with an average of 200 words per post. We used 4 blogs (2 from each view) for training and held two blogs (one from each view) for testing. Thus this dataset measures the model's ability to generalize to a totally new blog.

6 Experimental Results

In this section we gave various qualitative and quantitative evaluations of our model over the datasets listed in Section 5. For all experiments, we set $\alpha_1 = .01, \alpha_2 = .1, a = 1$ and $b = 1$. We run Gibbs sampling during training for 1000 iterations. During inference, we ran Gibbs sampling for 300 iterations, and took 10 samples, with 50-iterations lag, for evaluations.

6.1 Visualization and Browsing

One advantage of our approach is its ability to create a "big-picture" overview of the interaction between ideology and topics. In figure 2 we show a portion of that diagram over the bitterlemons dataset. First note how the ideology-specific topics in both ideology share the top-three words, which highlights that the two ideologies seek peace even though they still both disagree on other issues. The figure gives example of three topics: the US role, the Roadmap peace process, and the Arab involvement in the conflict (the name of these topics were hand-crafted). For each topic, we display the top words in the ideology-independent part of the topic (β), along with top words in each ideology's view of the topic (ϕ).

For example, when discussing the roadmap process, the Palestinian view brings the following issues: [the Israeli side should] implement the obligatory points in this agreement, stop expansion of settlements, and move forward to the commitments brought by this process. On the other hand, the Israeli side brings the following points: [Israelis] need to build confidence [with Palestinian], address the role of terrorism on the implementation of the process, and ask for a positive recognition of Israel from the different Palestinian political parties. As we can see, the ideology-specific portion of the topic **needn't** always represent a **sentiment** shared by its members toward a given topic, but it might rather includes extra important dimensions that need to be taken into consideration when addressing this topic.

Another interesting topic addresses the involvement of the neighboring Arab countries in the conflict. From the Israeli point of view, Israel is worried about the existence of hizballah [in lebanon] and its relationship with radical Iran, and how this might affect the Palestinian-uprising (Intifada) and Jihad. From the other side, the Palestinians think that the Arab neighbors need to be involved in the peace process and negotiations as some of these countries like Syria and Lebanon are involved in the conflict.

The user can use the above chart as an entry point to retrieve various documents pertinent to a given topic or to a given view over a specific topic. For instance, if the user asks for a representative sample of the Israeli(Palestinian) view with regard to the roadmap process, the system can first retrieve documents tagged with the Israeli(Palestinian) view and having a high topical value in their latent representation θ over this topic. Finally, the system then sorts these documents by how much bias they show over this topic. As we discussed in Section 4, this can be done by computing the expected value of the event $x_{n,2} = 0$ and $z_n = k$ where k is the topic under consideration.

6.2 Classification

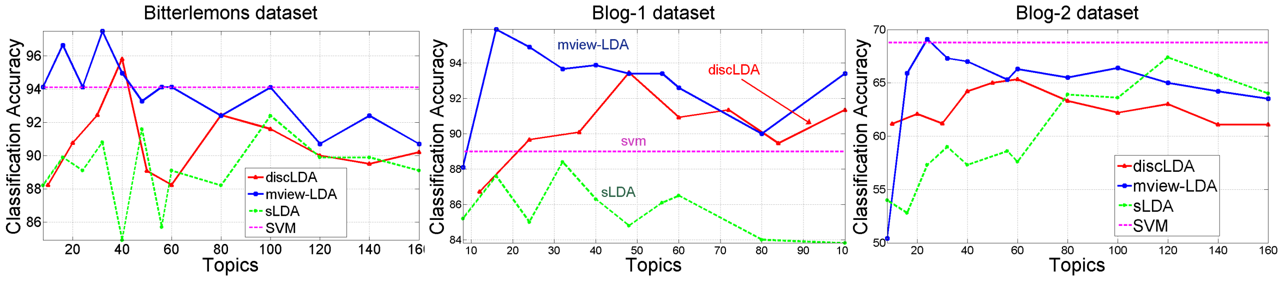
We have also performed a classification task over all the datasets. The Scenario proceeded as follows. We train a model over the training data with various number of topics. Then given a test document, we predict its ideology using the following equation:

$$v_d = \arg max_{v \in V} P(\mathbf{w_d}|v); \qquad (1)$$

We use three baselines. The first baseline is an SVM classifier trained on the normalized word frequency of each document. We trained SVM using a regularization parameter in the range $\{1, 10, 20, \cdots, 100\}$ and report the best result (i.e. no cross-validation was performed). The other two are supervised LDA models: supervised LDA (sLDA) (Wang et. al., 2009; Blei and McCauliffe, 2007) and discLDA (Lacoste-Julien et al., 2008). discLDA is a conditional model that divides the available number of topics into class-specific topics and shared-topics. Since the code is not publicly available, we followed the same strategy in the original paper and share $0.1K$ topics across ideologies and then divide the rest of the topics between ideologies[4]. However, unlike our model, there are no internal relationships between these two sets of topics. The decision rule employed by discLDA is very similar to the one we used for mview-LDA in Eq (1). For sLDA, we used the publicly available code by the authors.

As shown in Figure 3, our model performs better than the baselines over the three datasets. We should note from this figure that mview-LDA peaks at a small number of topics, however, each topic is represented by three multinomials. Moreover, it is evident from the figure that the experiment over the blog-2 dataset which measures each model's ability to generalizes to a totally unseen new blog is a harder task than generalizing to unseen posts form the same blog. However, our model still performs competitively with the SVM baseline. We believe that separating each topic into an ideology-independent part and ideology-specific part is the key behind this performance, as it is expected that the new blogs would still share much of the ideology-independent parts of the topics and hopefully would use similar (but

[4] (Lacoste-Julien et al., 2008) gave an optimization algorithm for learning the topic structure (transformation matrix), however since the code is not available, we resorted to one of the fixed splitting strategies mentioned in the paper. We tried other splits but this one gives the best results



(a) (b) (c)

Figure 3: Classification accuracy over the Bitterlemons dataset in (a) and over the two blog datasets in (b) and (c). For SVM we give the best result obtained across a wide range of the SVM's regularization parameter(not the cross-validation result).

no necessarily all) words from the ideology-specific parts of each topic when addressing this topic.

Finally, it should be noted that the bitterlemons dataset is a multi-author dataset and thus the models were tested on some authors that were not seen during training, however, two factors contributed to the good performance by all models over this dataset. The first being the larger size of each document (740 words per document as compared to 200 words per post in blog-2) and the second being the more formal writing style in the bitterlemons dataset.

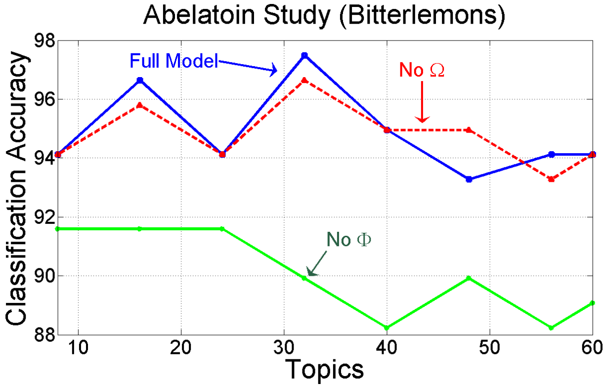


Figure 4: An Ablation study over the bitterlemons dataset.

6.3 An Ablation Study

To understand the contribution of each component of our model, we conducted an ablation study over the bitterlemons dataset. In this experiment we turned-off one feature of our model at a time and measured the classification performance. The results are shown in Figure 4. Full, refers to the full model; No-Ω refers to a model in which the ideology-specific background topic Ω is turned-off; and No-ϕ refers to a model in which the ideology-specific portions of the topics are turned-off. As evident from the figure, ϕ is more important to the model than Ω and the difference in performance between the full model and the No-ϕ model is rather significant. In fact without ϕ the model has little power to discriminate between ideologies beyond the ideology-specific background topic Ω.

6.4 Retrieval: Getting the Other Views

To evaluate the ability of our model in finding alternative views toward a given topic, we conducted the following experiment over the Bitterlemons corpus. In this corpus each document is associated with a meta-topic that highlights the issues addressed in this document like: "A possible Jordanian role", "Demography and the conflict",etc. There are a total of 148 meta-topics. These topics were not used in fitting our model but we use them in the evaluation as follows. We divided the dataset into 60% for training and 40% for testing. We trained mview-LDA over the training set, and then used the learned model to infer the latent representation of the test documents as well as their ideologies. We then used each document in the training set as a query to retrieve documents from the test set that address the same meta-topic in the query document but from the other-side's perspective. Note that we have access to the view of the query document but not the view of the test document. Moreover, the value of the meta-topic is only used to construct the ground-truth result of each query over the test set. In addition to mview-LDA, we also implemented a strong baseline using SVM+Dirichlet smoothing that we will refer to as LM. In this baseline, we build an SVM classifier over the training set, and use Dirichlet-smoothing to represent each document (in test and training set) as a multinomial-distribution over the vocabulary. Given a query document d, we rank documents in

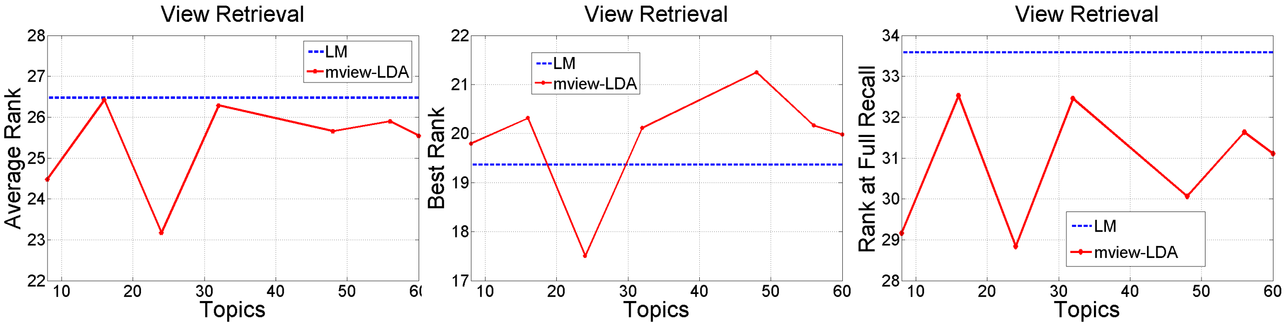

Figure 5: Evaluating the performance of the view-Retrieval task. Figure compare performance between mview-LD vs. an SVM+a smoothed language model approach using three measures: average rank, best rank and rank at full recall. (*Lower better*)

.

the test set by each model as follows:

- mview-LDA: we computed the cosine-distance between $\theta_d^{\mathrm{mv-LDA}-shared}$ and $\theta_{d'}^{\mathrm{mv-LDA-shared}}$ weighted by the probability that d' is written from a different view than v_d. The latter quantity can be computed by normalizing $P(v|d')$. Moreover, $\theta_{d,k}^{\mathrm{mv-LDA}-shared} \propto \sum_n I\big[(x_{n,1}=0) \text{ and } (x_{n,2}=1) \text{ and } (z_n=k)\big]$, and n ranges over words in document d. Intuitively, we would like $\theta_d^{\mathrm{mv-LDA}-shared}$ to reflect variation due to the topical content, but not ideological view of the document.

- LM: For a document d', we apply the SVM classifier to get $P(v|d')$, then we measure similarity by computing the cosine-distance between the smoothed multinomial-distribution of d and d'. We combine these two components as in mview-LDA.

Finally we rank documents in the test set in a descending-order and evaluate the resulting ranking using three measures: the rank at full recall (lowest rank), average rank, and best rank of the ground-truth documents as they appear in the predicted ranking. Figure 5 shows the results across a number of topics. From this figure, it is clear that our model outperforms this baseline over all measures. It should be noted that this is a very hard task since the meta-topics are very fine-grained like: Settlements revisited, The status of the settlements, Is the roadmap still relevant?,The ceasefire and the roadmap: a progress report,etc. We did not attempt to cluster these meta-topics since our goal is just to compare our model against the baseline.

7 A Semi-Supervised Extension

In this section we present and assess the efficacy of a semi-supervised extension of mview-LDA. In this setting, the model is given a set of ideologically-labeled documents and a set of unlabeled documents. One of the key advantages of using a probabilistic graphical model is the ability to deal with hidden variables in a principled way. Thus the only change needed in this case is adding a single step in the sampling algorithm to sample the ideology v of an unlabeled document as follows:

$$P(v_d = v|rest) \quad \propto \quad P(\mathbf{w_d}|v_d = v, \mathbf{z_d}, \mathbf{x_{1,d}}, \mathbf{x_{2,d}})$$

Note that the probability of the indicators $(\mathbf{x_{1,d}}, \mathbf{x_{2,d}}, \mathbf{z_d})$ do not depend on the view of the document and thus got absorbed in the normalization constant, and thus one only needs to measures the likelihood of generating the words in the document under the view v. We divide the words into three groups: $A_d = \{w_n | x_{n,1} = 1\}$ is the set of words generated from the view-background topic, $B_{d,k} = \{w_n | z_n = k, x_{n,1} = 0, x_{n,2} = 1\}$ is the set of words generated from β_k, and $C_{d,k} = \{w_n | z_n = k, x_{n,1} = 0, x_{n,2} = 0\}$ is the set of words generated from $\phi_{k,v}$. The probability of $B_{d,k}$ does not depend on the value of v and thus can be absorbed into the normalization factor. Therefore, we only need to compute the following probability:$P(A_d, C_{d,1:K}|v_d = v, rest)$=

$$\prod_k \int_{\phi_{k,v}} P(C_{d,k}|\phi_{k,v}, rest) p(\phi_{k,v}|rest) d\phi_{k,v}$$
$$\times \quad \int_\Omega P(A_d|\Omega, rest) p(\Omega|rest) d\Omega \qquad (2)$$

All the integrals in (2) reduce to the ratio of two log partition functions. For example, the product of integrals containing $C_{d,k}$ reduce to:

$$\prod_k \frac{\prod_w \Gamma\Big(C_{dkw}^{DKW,X_2=0} + C_{vkw,-d}^{VKW} + \alpha_1\Big)}{\Gamma\Big(\sum_w \big[C_{dkw}^{DKW,X_2=0} + C_{vkw,-d}^{VKW} + \alpha_1\big]\Big)} \times \frac{\Gamma\Big(\sum_w \big[C_{vkw}^{VKW} + \alpha_1\big]\Big)}{\prod_w \Gamma\Big(C_{vkw,-d}^{VKW} + \alpha_1\Big)} \tag{3}$$

Unfortunately, the above scheme does not mix well because the value of the integrals in (2) are very low for any view other than the view of the document in the current state of the sampler. This happens because of the tight coupling between v_d and the indicators $(\mathbf{x_1}, \mathbf{x_2}, \mathbf{z})$. To remedy this problem we used a Metropolis-Hasting step to sample $(v_d, \mathbf{x_1}, \mathbf{x_2}, \mathbf{z})$ jointly. We construct a set of V proposals each of which is indexed by a possible view: $q_v(\mathbf{x_1}, \mathbf{x_2}, \mathbf{z}) = P(\mathbf{x_1}, \mathbf{x_2}, \mathbf{z} | v_d = v, \mathbf{w_d})$. Since we have a collection of proposal distributions, we select one of them at random at each step. To generate a sample from $q_{v*}()$, we run a few iterations of a restricted Gibbs scan over the document d conditioned on fixing $v_d = v*$ and then take the last sample jointly with $v*$ as our proposed new state. With probability min(r,1), the new state $(v*, \mathbf{x_1}*, \mathbf{x_2}*, \mathbf{z}*)$ is accepted, otherwise the old state is retained. The acceptance ratio,r, is computed as: $r = \frac{p(\mathbf{w_d}|v*, \mathbf{x_1}*, \mathbf{x_2}*, \mathbf{z}*)}{p(\mathbf{w_d}|v, \mathbf{x_1}, \mathbf{x_2}, \mathbf{z})}$, where the non-* variables represent the current state of the sampler. It is interesting to note that the above acceptance ratio is equivalent to a likelihood ratio test. We compute the marginal probability $P(\mathbf{w_d}|..)$ using the estimated-theta method (Wallach et al., 2009).

We evaluated the semi-supervised extension using the blog-2 dataset as follows. We reveal $R\%$ of the labels in the training set; then we train mview-LDA only over the labeled portion and train the semi-supervised version (ss-mview-LDA) on both the labeled and unlabeled documents. Finally we evaluate the classification performance on the test set. We used $R = \{20, 40, 80\}$. The results are given in Table 1 which shows a decent improvement over the supervised mview-LDA.

R	mview-LDA	ss-mview-LDA
80	65.60	66.41
60	62.31	65.43
20	60.87	63.25

Table 1: Classification performance of the semi-supervised model. R is the ratio of labeled documents.

8 Discussion and Future Work

In this paper, we addressed the problem of modeling ideological perspective at a topical level. We developed a factored topic model that we called multiView-LDA or mview-LDA for short. mview-LDA factors a document collection into three set of topics: ideology-specific, topic-specific, and ideology-topic ones. We showed that the resulting representation can be used to give a bird-eyes' view to where each ideology stands with regard to mainstream topics. Moreover, we illustrated how the latent structure induced by the model can by used to perform bias-detection at the document and topic level, and retrieve documents that represent alternative views.

It is important to mention that our model induces a hierarchical structure over the topics, and thus it is interesting to contrast it with hierarchical topic models like hLDA (Blei et al., 2003) and PAM (Li and McCallum, 2006; Mimno et al., 2007). First, these models are unsupervised in nature, while our model is supervised. Second, the semantic of the hierarchical structure in our model is different than the one induced by those models since documents in our model are constrained to use a specific portion of the topic structure while in those models documents can freely sample words from any topic. Finally,in the future we plan to extend our model to perform joint modeling and summarization of idealogical discourse.

Abstract

We present a novel approach for (written) dialect identification based on the discriminative potential of entire words. We generate Swiss German dialect words from a Standard German lexicon with the help of hand-crafted phonetic/graphemic rules that are associated with occurrence maps extracted from a linguistic atlas created through extensive empirical fieldwork. In comparison with a character-n-gram approach to dialect identification, our model is more robust to individual spelling differences, which are frequently encountered in non-standardized dialect writing. Moreover, it covers the whole Swiss German dialect continuum, which trained models struggle to achieve due to sparsity of training data.

1 Introduction

Dialect identification (dialect ID) can be viewed as an instance of language identification (language ID) where the different languages are very closely related. Written language ID has been a popular research object in the last few decades, and relatively simple algorithms have proved to be very successful. The central question of language ID is the following: given a segment of text, which one of a predefined set of languages is this segment written in? Language identification is thus a classification problem.

Dialect identification comes in two flavors: spoken dialect ID and written dialect ID. These two tasks are rather different. Spoken dialect ID relies on speech recognition techniques which may not cope well with dialectal diversity. However, the acoustic signal is also available as input. Written dialect ID has to deal with non-standardized spellings that may occult real dialectal differences. Moreover, some phonetic distinctions cannot be expressed in orthographic writing systems and limit the input cues in comparison with spoken dialect ID.

This paper deals with written dialect ID, applied to the Swiss German dialect area. An important aspect of our model is its conception of the dialect area as a continuum without clear-cut borders. Our dialect ID model follows a bag-of-words approach based on the assumption that every dialectal word form is defined by a probability with which it may occur in each geographic area. By combining the cues of all words of a sentence, it should be possible to obtain a fairly reliable geographic localization of that sentence.

The main challenge is to create a lexicon of dialect word forms and their associated probability maps. We start with a Standard German word list and use a set of phonetic, morphological and lexical rules to obtain the Swiss German forms. These rules are manually extracted from a linguistic atlas. This linguistic atlas of Swiss German dialects is the result of decades-long empirical fieldwork.

This paper is organized as follows. We start with an overview of relevant research (Section 2) and present the characteristics of the Swiss German dialect area (Section 3). Section 4 deals with the implementation of word transformation rules and the corresponding extraction of probability maps from the linguistic atlas of German-speaking Switzerland. We present our dialect ID model in Section 5 and discuss its performance in Section 6 by relating it to a baseline n-gram model.

2 Related work

Various language identification methods have been proposed in the last three decades. Hughes et al. (2006) and Řehůřek and Kolkus (2009) provide recent overviews of different approaches. One of the simplest and most popular approaches is based on character n-gram sequences (Cavnar and Trenkle, 1994). For each language, a character n-gram language model is learned, and test segments are scored by all available language models and labeled with the best scoring language model. Related approaches involve more sophisticated learning techniques (feature-based models, SVM and other kernel-based methods).

A completely different approach relies on the identification of entire high-frequency words in the test segment (Ingle, 1980). Other models have proposed to use morpho-syntactic information.

Dialect ID has usually been studied from a speech processing point of view. For instance, Biadsy et al. (2009) classify speech material from four Arabic dialects plus Modern Standard Arabic. They first run a phone recognizer on the speech input and use the resulting transcription to build a trigram language model. Classification is done by minimizing the perplexity of the trigram models on the test segment.

An original approach to the identification of Swiss German dialects has been taken by the *Chochichästli-Orakel*.[1] By specifying the pronunciation of ten predefined words, the web site creates a probability map that shows the likelihood of these pronunciations in the Swiss German dialect area. Our model is heavily inspired by this work, but extends the set of cues to the entire lexicon.

As mentioned, the ID model is based on a large Swiss German lexicon. Its derivation from a Standard German lexicon can be viewed as a case of lexicon induction. Lexicon induction methods for closely related languages using phonetic similarity have been proposed by Mann and Yarowsky (2001) and Schafer and Yarowsky (2002), and applied to Swiss German data by Scherrer (2007).

The extraction of digital data from hand-drawn dialectological maps is a time-consuming task. Therefore, the data should be made available for different uses. Our Swiss German raw data is accessible on an interactive web page (Scherrer, 2010), and we have proposed ideas for reusing this data for machine translation and dialect parsing (Scherrer and Rambow, 2010). An overview of digital dialectological maps for other languages is available on `http://www.ericwheeler.ca/atlaslist`.

3 Swiss German dialects

The German-speaking area of Switzerland encompasses the Northeastern two thirds of the Swiss territory, and about two thirds of the Swiss population define (any variety of) German as their first language.

In German-speaking Switzerland, dialects are used in speech, while Standard German is used nearly exclusively in written contexts (diglossia). It follows that all (adult) Swiss Germans are bidialectal: they master their local dialect and Standard German. In addition, they usually have no difficulties understanding Swiss German dialects other than their own.

Despite the preference for spoken dialect use, written dialect data has been produced in the form of dialect literature and transcriptions of speech recordings made for scientific purposes. More recently, written dialect has been used in electronic media like blogs, SMS, e-mail and chatrooms. The Alemannic Wikipedia contains about 6000 articles, among which many are written in a Swiss German dialect.[2] However, all this data is very heterogeneous in terms of the dialects used, spelling conventions and genre.

4 Georeferenced word transformation rules

The key component of the proposed dialect ID model is an automatically generated list of Swiss German word forms, each of which is associated with a map that specifies its likelihood of occurrence over German-speaking Switzerland. This word list is generated with the help of a set of transformation rules, taking a list of Standard German words as a starting point. In this section, we present the different types of rules and how they can be extracted from a dialectological atlas.

[1] `http://dialects.from.ch`

[2] `http://als.wikipedia.org`; besides Swiss German, the Alemannic dialect group encompasses Alsatian, South-West German Alemannic and Vorarlberg dialects of Austria.

4.1 Orthography

Our system generates written dialect words according to the Dieth spelling conventions without diacritics (Dieth, 1986).[3] These are characterized by a transparent grapheme-phone correspondence and are widely used by dialect writers. However, they are by no means enforced or even taught.

This lack of standardization is problematic for dialect ID. We have noted two major types of deviations from the Dieth spelling conventions in our data. First, Standard German orthography may unduly influence dialect spelling. For example, *spiele* is modelled after Standard German *spielen* 'to play', although the vowel is a short monophthong in Swiss German and should thus be written *spile* (*ie* represents a diphthong in Dieth spelling). Second, dialect writers do not always distinguish short and long vowels, while the Dieth conventions always use letter doubling to indicate vowel lengthening. Future work will incorporate these fluctuations directly into the dialect ID model.

Because of our focus on written dialect, the following discussion will be based on written representations, but IPA equivalents are added for convenience.

4.2 Phonetic rules

Our work is based on the assumption that many words show predictable phonetic differences between Standard German and the different Swiss German dialects. Hence, in many cases, it is not necessary to explicitly model word-to-word correspondences, but a set of phonetic rules suffices to correctly transform words.

For example, the word-final sequence *nd* [nd̥] (as in Standard German *Hund* 'dog'[4]) is maintained in most Swiss German dialects. However, it has to be transformed to *ng* [ŋ] in Berne dialect, to *nn* [n] in Fribourg dialect, and to *nt* [nt] in Valais and Uri dialects.

This phenomenon is captured in our system by four transformation rules *nd* → *nd*, *nd* → *ng*, *nd* → *nn* and *nd* → *nt*. Each rule is *georeferenced*, i.e. linked to a probability map that specifies its validity in every geographic point. These four *rules* capture one single linguistic *phenomenon*: their left-hand side is the same, and they are geographically complementary.

Some rules apply uniformly to all Swiss German dialects (e.g. the transformation *st* [st] → *scht* [ʃt]). These rules do not immediately contribute to the dialect identification task, but they help to obtain correct Swiss German forms that contain other phonemes with better localization potential.

More information about the creation of the probability maps is given in Sections 4.5 and 4.6.

4.3 Lexical rules

Some differences at the word level cannot be accounted for by pure phonetic alternations. One reason are idiosyncrasies in the phonetic evolution of high frequency words (e.g. Standard German *und* 'and' is reduced to *u* in Bern dialect, where the phonetic rules would rather suggest **ung*). Another reason is the use of different lexemes altogether (e.g. Standard German *immer* 'always' corresponds to *geng*, *immer*, or *all*, depending on the dialect). We currently use lexical rules mainly for function words and irregular verb stems.

4.4 Morphological rules

The transformation process from inflected Standard German word forms to inflected Swiss German word forms is done in two steps. First, the word stem is adapted with phonetic or lexical rules, and then, the affixes are generated according to the morphological features of the word.

Inflection markers also provide dialect discrimination potential. For example, the verbal plural suffixes offer a surprisingly rich (and diachronically stable) interdialectal variation pattern.

4.5 The linguistic atlas SDS

One of the largest research projects in Swiss German dialectology has been the elaboration of the *Sprachatlas der deutschen Schweiz* (SDS), a linguistic atlas that covers phonetic, morphological and lexical differences of Swiss German dialects. Data collection and publication were carried out between 1939 and 1997 (Hotzenköcherle et al., 1962-1997). Linguistic data were collected in about 600 villages (*inquiry points*) of German-speaking Switzerland, and

[3] Of course, these spelling conventions make use of umlauts like in Standard German. There is another variant of the Dieth conventions that uses additional diacritics for finer-grained phonetic distinctions.

[4] Standard German *nd* is always pronounced [nt] following a general final devoicing rule; we neglect that artifact as we rely only on graphemic representations.

resulted in about 1500 published maps (see Figure 1 for an example).

Each map represents a linguistic phenomenon that potentially yields a set of transformation rules. For our experiments, we selected a subset of the maps according to the perceived importance of the described phenomena. There is no one-to-one correspondence between maps and implemented phenomena, for several reasons. First, some SDS maps represent information that is best analyzed as several distinct phenomena. Second, a set of maps may illustrate the same phenomenon with different words and slightly different geographic distributions. Third, some maps describe (especially lexical) phenomena that are becoming obsolete and that we chose to omit.

As a result, our rule base contains about 300 phonetic rules covering 130 phenomena, 540 lexical rules covering 250 phenomena and 130 morphological rules covering 60 phenomena. We believe this coverage to be sufficient for the dialect ID task.

4.6 Map digitization and interpolation

Recall the *nd*-example used to illustrate the phonetic rules above. Figure 1 shows a reproduction of the original, hand-drawn SDS map related to this phenomenon. Different symbols represent different phonetic variants of the phenomenon.[5] We will use this example in this section to explain the preprocessing steps involved in the creation of georeferenced rules.

In a first preprocessing step, the hand-drawn map is digitized manually with the help of a geographical information system. The result is shown in Figure 2. To speed up this process, variants that are used in less than ten inquiry points are omitted. (Many of these small-scale variants likely have disappeared since the data collection in the 1940s.) We also collapse minor phonetic variants which cannot be distinguished in the Dieth spelling system.

The SDS maps, hand-drawn or digitized, are point maps. They only cover the inquiry points, but do not provide information about the variants used in other locations. Therefore, a further preprocessing step interpolates the digitized point maps to obtain surface maps. We follow Rumpf et al. (2009) to create kernel density estimators for each variant. This method is

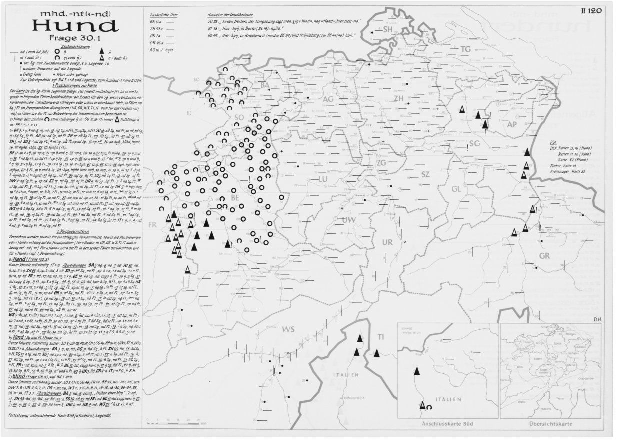

Figure 1: Original SDS map for the transformation of word-final *-nd*. The map contains four major linguistic variants, symbolized by horizontal lines (*-nd*), vertical lines (*-nt*), circles (*-ng*), and triangles (*-nn*) respectively. Minor linguistic variants are symbolized by different types of circles and triangles.

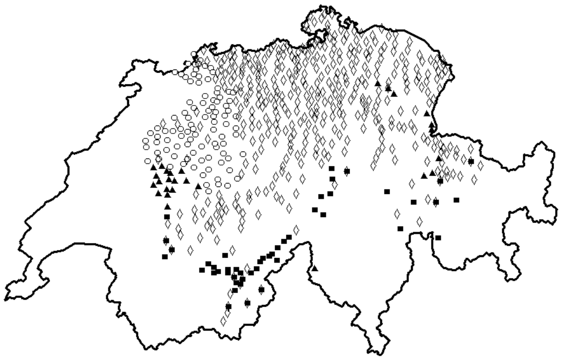

Figure 2: Digitized equivalent of the map in Figure 1.

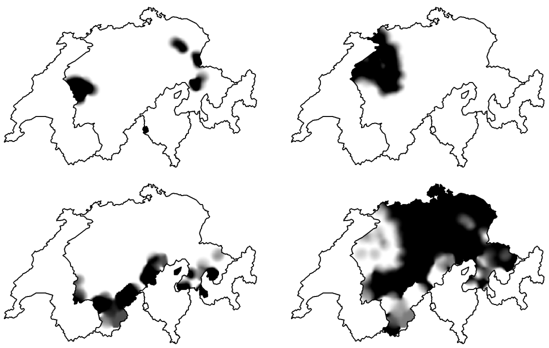

Figure 3: Interpolated surface maps for the variants *-nn* (upper left), *-ng* (upper right), *-nt* (lower left) and *-nd* (lower right). Black areas represent a probability of 1, white areas a probability of 0.

[5] We define a *variant* simply as a string that may occur on the right-hand side of a transformation rule.

less sensitive to outliers than simpler linear interpolation methods.[6] The resulting surface maps are then normalized such that at each point of the surface, the weights of all variants sum up to 1. These normalized weights can be interpreted as conditional probabilities of the corresponding transfer rule: $p(r \mid t)$, where r is the rule and t is the geographic location (represented as a pair of longitude and latitude coordinates) situated in German-speaking Switzerland. (We call the set of all points in German-speaking Switzerland *GSS*.) Figure 3 shows the resulting surface maps for each variant. Surface maps are generated with a resolution of one point per square kilometer.

As mentioned above, rules with a common left-hand side are grouped into phenomena, such that at any given point $t \in GSS$, the probabilities of all rules r describing a phenomenon Ph sum up to 1:

$$\underset{t \in GSS}{\forall} \sum_{r \in Ph} p(r \mid t) = 1$$

5 The model

The dialect ID system consists of a Swiss German lexicon that associates word forms with their geographical extension (Section 5.1), and of a testing procedure that splits a sentence into words, looks up their geographical extensions in the lexicon, and condenses the word-level maps into a sentence-level map (Sections 5.2 to 5.4).

5.1 Creating a Swiss German lexicon

The Swiss German word form lexicon is created with the help of the georeferenced transfer rules presented above. These rules require a lemmatized, POS-tagged and morphologically disambiguated Standard German word as an input and generate a set of dialect word/map tuples: each resulting dialect word is associated with a probability map that specifies its likelihood in each geographic point.

To obtain a Standard German word list, we extracted all leaf nodes of the TIGER treebank (Brants et al., 2002), which are lemmatized and morphologically annotated. These data also allowed us to obtain word frequency counts. We discarded words with one single occurrence in the TIGER treebank, as well as forms that contained the genitive case or preterite tense attribute (the corresponding grammatical categories do not exist in Swiss German dialects).

The transfer rules are then applied sequentially on each word of this list. The notation $w_0 \overset{*}{\rightarrow} w_n$ represents an iterative derivation leading from a Standard German word w_0 to a dialectal word form w_n by the application of n transfer rules of the type $w_i \rightarrow w_{i+1}$. The probability of a derivation corresponds to the joint probability of the rules it consists of. Hence, the probability map of a derivation is defined as the **pointwise product** of all rule maps it consists of:

$$\underset{t \in GSS}{\forall} p(w_0 \overset{*}{\rightarrow} w_n \mid t) = \prod_{k=0}^{n-1} p(w_i \rightarrow w_{i+1} \mid t)$$

Note that in dialectological transition zones, there may be several valid outcomes for a given w_0.

The Standard German word list extracted from TIGER contains about 36,000 entries. The derived Swiss German word list contains 560,000 word forms, each of which is associated with a map that specifies its regional distribution.[7] Note that proper nouns and words tagged as “foreign material” were not transformed. Derivations that did not obtain a probability higher than 0.1 anywhere (because of geographically incompatible transformations) were discarded.

5.2 Word lookup and dialect identification

At test time, the goal is to compute a probability map for a text segment of unknown origin.[8] As a preprocessing step, the segment is tokenized, punctuation markers are removed and all words are converted to lower case.

The identification process can be broken down in three levels:

1. The probability map of a text segment depends on the probability maps of the words contained in the segment.

2. The probability map of a word depends on the probability maps of the derivations that yield the word.

[6] A comparison of different interpolation methods will be the object of future work.

[7] Technically, we do not store the probability map, but the sequence of rule variants involved in the derivation. The probability map is restored from this rule sequence at test time.

[8] The model does not require the material to be syntactically well-formed. Although we use complete sentences to test the system, any sequence of words is accepted.

3. The probability map of a derivation depends on the probability maps of the rules it consists of.

In practice, every word of a given text segment is looked up in the lexicon. If this lookup does not succeed (either because its Standard German equivalent did not appear in the TIGER treebank, or because the rule base lacked a relevant rule), the word is skipped. Otherwise, the lookup yields *m* derivations from *m* different Standard German words.[9] The lexicon already contains the probability maps of the derivations (see 5.1), so that the third level does not need to be discussed here. Let us thus explain the first two levels in more detail, in reverse order.

5.3 Computing the probability map for a word

A dialectal word form may originate in different Standard German words. For example, the three derivations *sind [VAFIN]* $\xrightarrow{*}$ *si* (valid only in Western dialects), *sein [PPOSAT]* $\xrightarrow{*}$ *si* (in Western and Central dialects), and *sie [PPER]* $\xrightarrow{*}$ *si* (in the majority of Swiss German dialects) all lead to the same dialectal form *si*.

Our system does not take the syntactic context into account and therefore cannot determine which derivation is the correct one. We approximate by choosing the most probable one in each geographic location. The probability map of a Swiss German word *w* is thus defined as the **pointwise maximum**[10] of all derivations leading to *w*, starting with different Standard German words $w_0^{(j)}$:

$$\underset{t \in GSS}{\forall} \; p(w \mid t) = \max_j p(w_0^{(j)} \xrightarrow{*} w \mid t)$$

This formula does not take into account the relative frequency of the different derivations of a word. This may lead to unintuitive results. Consider the two derivations *der [ART]* $\xrightarrow{*}$ *dr* (valid only in Western dialects) and *Dr. [NN]* $\xrightarrow{*}$ *dr* (valid in all dialects). The occurrence of the article *dr* in a dialect text is a good indicator for Western Swiss dialects, but it is completely masked by the potential presence of the abreviation *Dr.* in all dialects. We can avoid this by weighting the derivations by the **word frequency** of w_0: the article *der* is much more frequent than the abreviation *Dr.* and is thus given more weight in the identification task. This weighting can be justified on dialectological grounds: frequently used words tend to show higher interdialectal variation than rare words.

Another assumption in the above formula is that each derivation has the same **discriminative potential**. Again, this is not true: a derivation that is valid in only 10% of the Swiss German dialect area is much more informative than a derivation that is valid in 95% of the dialect area. Therefore, we propose to weight each derivation by the proportional size of its validity area. The discriminative potential of a derivation *d* is defined as follows:[11]

$$DP(d) = 1 - \frac{\sum_{t \in GSS} p(d \mid t)}{|GSS|}$$

The experiments in Section 6 will show the relative impact of these two weighting techniques and of the combination of both with respect to the unweighted map computation.

5.4 Computing the probability map for a segment

The probability of a text segment *s* can be defined as the joint probability of all words *w* contained in the segment. Again, we compute the **pointwise product** of all word maps. In contrast to 5.1, we performed some smoothing in order to prevent erroneous word derivations from completely zeroing out the probabilities. We assumed a minimum word probability of $\phi = 0.1$ for all words in all geographic points:

$$\underset{t \in GSS}{\forall} \; p(s \mid t) = \prod_{w \in s} \max(\phi, p(w \mid t))$$

Erroneous derivations were mainly due to non-implemented lexical exceptions.

6 Experiments and results

6.1 Data

In order to evaluate our model, we need texts annotated with their gold dialect. We have chosen to use the Alemannic Wikipedia as a main data source.

[9] Theoretically, two derivations can originate at the same Standard German word and yield the same Swiss German word, but nevertheless use different rules. Our system handles such cases as well, but we are not aware of such cases occurring with the current rule base.

[10] Note that these derivations are alternatives and not joint events. This is thus not a joint probability.

[11] d is a notational abreviation for $w_0 \xrightarrow{*} w_n$.

Wikipedia name	Abbr.	Pop.	Surface
Baseldytsch	BA	8%	1%
Bärndütsch	BE	17%	13%
Seislertütsch	FR	2%	1%
Ostschwizertütsch	OS	14%	8%
Wallisertiitsch	WS	2%	7%
Züritüütsch	ZH	22%	4%

Table 1: The six dialect regions selected for our tests, with their annotation on Wikipedia and our abreviation. We also show the percentage of the German-speaking population living in the regions, and the percentage of the surface of the region relative to the entire country.

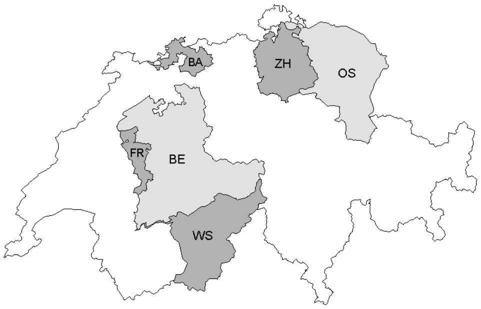

Figure 4: The localization of the six dialect regions used in our study.

The Alemannic Wikipedia allows authors to write articles in any dialect, and to annotate the articles with their dialect. Eight dialect categories contained more than 10 articles; we selected six dialects for our experiments (see Table 1 and Figure 4).

We compiled a test set consisting of 291 sentences, distributed across the six dialects according to their population size. The sentences were taken from different articles. In addition, we created a development set consisting of 550 sentences (100 per dialect, except FR, where only 50 sentences were available). This development set was also used to train the baseline model discussed in section 6.2.

In order to test the robustness of our model, we collected a second set of texts from various web sites other than Wikipedia. The gold dialect of these texts could be identified through metadata.[12] This information was checked for plausibility by the first author. The Web data set contains 144 sentences (again distributed according to population size) and is thus roughly half the size of the Wikipedia test set.

Table 2: Performances of the 5-gram model on Wikipedia test data (left) and Web test data (right). The columns refer to precision, recall and F-measure respectively. The average is weighted by the relative population sizes of the dialect regions.

The Wikipedia data contains an average of 17.8 words per sentence, while the Web data shows 14.9 words per sentence on average.

6.2 Baseline: N-gram model

To compare our dialect ID model, we created a baseline system that uses a character-n-gram approach. This approach is fairly common for language ID and has also been successfully applied to dialect ID (Biadsy et al., 2009). However, it requires a certain amount of training data that may not be available for specific dialects, and it is uncertain how it performs with very similar dialects.

We trained 2-gram to 6-gram models for each dialect with the SRILM toolkit (Stolcke, 2002), using the Wikipedia development corpus. We scored each sentence of the Wikipedia test set with each dialect model. The predicted dialect was the one which obtained the lowest perplexity.[13]

The 5-gram model obtained the best overall performance, and results on the Wikipedia test set were surprisingly good (see Table 2, leftmost columns).[14] Note that in practice, 100% accuracy is not always achievable; a sentence may not contain a sufficient localization potential to assign it unambiguously to one dialect.

[12] We mainly chose websites of local sports and music clubs, whose localization allowed to determine the dialect of their content.

[13] We assume that all test sentences are written in one of the six dialects.

[14] All results represent percentage points. We omit decimal places as all values are based on 100 or less data points. We did not perform statistical significance tests on our data.

However, we suspect that these results are due to overfitting. It turns out that the number of Swiss German Wikipedia authors is very low (typically, one or two active writers per dialect), and that every author uses distinctive spelling conventions and writes about specific subjects. For instance, most ZH articles are about Swiss politicians, while many OS articles deal with religion and mysticism. Our hypothesis is thus that the n-gram model learns to recognize a specific author and/or topic rather than a dialect. This hypothesis is confirmed on the Web data set: the performances drop by 15 percentage points or more (same table, rightmost columns; the performance drops are similar for $n = [2..6]$).

In all our evaluations, the average F-measures for the different dialects are weighted according to the relative population sizes of the dialect regions because the size of the test corpus is proportional to population size (see Section 6.1).[15]

We acknowledge that a training corpus of only 100 sentences per dialect provides limited insight into the performance of the n-gram approach. We were able to double the training corpus size with additional Wikipedia sentences. With this extended corpus, the 4-gram model performed better than the 5-gram model. It yielded a weighted average F-measure of 79% on Wikipedia test data, but only 43% on Web data. The additional increase on Wikipedia data (+17% absolute with respect to the small training set), together with the decrease on Web data (−3% absolute) confirms our hypothesis of overfitting. An ideal training corpus should thus contain data from several sources per dialect.

To sum up, n-gram models can yield good performance even with similar dialects, but require large amounts of training data from different sources to achieve robust results. For many small-scale dialects, such data may not be available.

6.3 Our model

The n-gram system presented above has no geographic knowledge whatsoever; it just consists of six distinct language models that could be located anywhere. In contrast, our model yields probability maps of German-speaking Switzerland. In order to evaluate its performance, we thus had to determine the geographic localization of the six dialect regions defined by the Wikipedia authors (see Table 1). We defined the regions according to the respective canton boundaries and to the German-French language border in the case of bilingual cantons. The result of this mapping is shown in Figure 4.

The predicted dialect region of a sentence s is defined as the region in which the most probable point has a higher value than the most probable point in any other region:

$$Region(s) = \arg\max_{Region} \left(\max_{t \in Region} p(s \mid t) \right)$$

Experiments were carried out for the four combinations of the two derivation-weighting techniques presented in Section 5.3 and for the two test sets (Wikipedia and Web). Results are displayed in Tables 3 to 6. The majority of FR sentences were misclassified as BE, which reflects the geographic and linguistic proximity of these regions.

The tables show that frequency weighting helps on both corpora: the discriminative potential only slightly improves performance on the web corpus. Crucially, the two techniques are additive, so in combination, they yield the best overall results. In comparison with the baseline model, there is a performance drop of about 16 percent absolute on Wikipedia data. In contrast, our model is very robust and outperforms the baseline model on the Web test set by about 7 percent absolute.

These results seem to confirm what we suggested above: that the n-gram model overfitted on the small Wikipedia training corpus. Nevertheless, it is still surprising that our model has a lower performance on Wikipedia than on Web data. The reason for this discrepancy probably lies in the spelling conventions assumed in the transformation rules: it seems that Web writers are closer to these (implicit) spelling conventions than Wikipedia authors. This may be explained by the fact that many Wikipedia articles are translations of existing Standard German articles, and that some words are not completely adapted to their dialectal form. Another reason could be that Wikipedia articles use a proportionally larger amount of proper nouns and low-frequency words which can-

[15] Roughly, this weighting can be viewed as a prior (the probability of the text being constant):

$$p(dialect \mid text) = p(text \mid dialect) * p(dialect)$$

not be found in the lexicon and which therefore reduce the localization potential of a sentence.

However, one should note that the word-based dialect ID model is not limited on the six dialect regions used for evaluation here. It can be used with any size and number of dialect regions of German-speaking Switzerland. This contrasts with the n-gram model which has to be trained specifically on every dialect region; in this case, the Swiss German Wikipedia only contains two additional dialect regions with an equivalent amount of data.

6.4 Variations

In the previous section, we have defined the predicted dialect region as the one in which the most probable point (**maximum**) has a higher probability than the most probable point of any other region. The results suggest that this metric penalizes small regions (BA, FR, ZH). In these cases, it is likely that the most probable point is slightly outside the region, but that the largest part of the probability mass is still inside the correct region. Therefore, we tested another approach: we defined the predicted dialect region as the one in which the **average** probability is higher than the average probability in any other region:

$$Region(s) = \arg\max_{Region} \left(\frac{\sum_{t \in Region} p(s \mid t)}{|Region|} \right)$$

This metric effectively boosts the performance on the smaller regions, but comes at a cost for larger regions (Table 7). We also combined the two metrics by using the **maximum** metric for the three larger regions and the **average** metric for the three smaller ones (the cutoff lies at 5% of the Swiss territory). This combined metric further improves the performance of our system while relying on an objective measure of region surface.

We believe that region surface as such is not so crucial for the metrics discussed above, but rather serves as a proxy for linguistic heterogeneity. Geographically large regions like BE tend to have internal dialect variation, and averaging over all dialects in the region leads to low figures. In contrast, small regions show a quite homogeneous dialect landscape that may protrude over adjacent regions. In this case, the probability peak is less relevant than the average probability in the entire region. Future work will attempt to come up with more fine-grained measures of

linguistic heterogeneity in order to test these claims.

7 Future work

In our experiments, the word-based dialect identification model skipped about one third of all words (34% on the Wikipedia test set, 39% on the Web test set) because they could not be found in the lexicon. While our model does not require complete lexical coverage, this figure shows that the system can be improved. We see two main possibilities of improvement. First, the rule base can be extended to better account for lexical exceptions, orthographic variation and irregular morphology. Second, a mixed approach could combine the benefits of the word-based model with the n-gram model. This would require a larger, more heterogeneous set of training material for the latter in order to avoid overfitting. Additional training data could be extracted from the web and automatically annotated with the current model in a semi-supervised approach.

In the evaluation presented above, the task consisted of identifying the dialect of single sentences. However, one often has access to longer text segments, which makes our evaluation setup harder than necessary. This is especially important in situations where a single sentence may not always contain enough discriminative material to assign it to a unique dialect. Testing our dialect identification system on the paragraph or document level could thus provide more realistic results.

8 Conclusion

In this paper, we have compared two empirical methods for the task of dialect identification. The n-gram method is based on the approach most commonly used in NLP: it is a supervised machine learning approach where training data of the type we need to process is annotated with the desired outcome of the processing.

Our second approach – the main contribution of this paper – is quite different. The empirical component consists in a collection of data (the SDS atlas) which is not of the type we want to process, but rather embodies some features of the data we ultimately want to process. We therefore analyze this data in order to extract empirically grounded knowledge for more general use (the creation of the georeferenced rules), and then use this knowledge to perform the dialect ID task in conjunction with an unrelated data source (the Standard German corpus).

Our choice of method was of course related to the fact that few corpora, annotated or not, were available for our task. But beyond this constraint, we think it may be well worthwhile for NLP tasks in general to move away from a narrow machine learning paradigm (supervised or not) and to consider a broader set of empirical resources, sometimes requiring methods which are quite different from the prevalent ones.

Abstract

The computation of meaning similarity as operationalized by vector-based models has found widespread use in many tasks ranging from the acquisition of synonyms and paraphrases to word sense disambiguation and textual entailment. Vector-based models are typically directed at representing words in isolation and thus best suited for measuring similarity out of context. In his paper we propose a probabilistic framework for measuring similarity in context. Central to our approach is the intuition that word meaning is represented as a probability distribution over a set of latent senses and is modulated by context. Experimental results on lexical substitution and word similarity show that our algorithm outperforms previously proposed models.

1 Introduction

The computation of meaning similarity as operationalized by vector-based models has found widespread use in many tasks within natural language processing (NLP). These range from the acquisition of synonyms (Grefenstette, 1994; Lin, 1998) and paraphrases (Lin and Pantel, 2001) to word sense disambiguation (Schuetze, 1998), textual entailment (Clarke, 2009), and notably information retrieval (Salton et al., 1975).

The popularity of vector-based models lies in their unsupervised nature and ease of computation. In their simplest incarnation, these models represent the meaning of each word as a point in a high-dimensional space, where each component corresponds to some co-occurring contextual element (Landauer and Dumais, 1997; McDonald, 2000; Lund and Burgess, 1996). The advantage of taking such a geometric approach is that the similarity of word meanings can be easily quantified by measuring their distance in the vector space, or the cosine of the angle between them.

Vector-based models do not explicitly identify the different senses of words and consequently represent their meaning invariably (i.e., irrespective of co-occurring context). Consider for example the adjective *heavy* which we may associate with the general meaning of “dense” or “massive”. However, when attested in context, *heavy* may refer to an overweight person (e.g., *She is short and heavy but she has a heart of gold.*) or an excessive cannabis user (e.g., *Some heavy users develop a psychological dependence on cannabis.*).

Recent work addresses this issue *indirectly* with the development of specialized models that represent word meaning in context (Mitchell and Lapata, 2008; Erk and Padó, 2008; Thater et al., 2009). These methods first extract typical co-occurrence vectors representing a *mixture* of senses and then use vector operations to either obtain contextualized representations of a target word (Erk and Padó, 2008) or a representation for a set of words (Mitchell and Lapata, 2009).

In this paper we propose a probabilistic framework for representing word meaning and measuring similarity in context. We model the meaning of isolated words as a probability distribution over a set of latent senses. This distribution reflects the *a priori*, out-of-context likelihood of each sense. Because sense ambiguity is taken into account *directly* in the

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1162–1172,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

vector construction process, contextualized meaning can be modeled naturally as a change in the original sense distribution. We evaluate our approach on word similarity (Finkelstein et al., 2002) and lexical substitution (McCarthy and Navigli, 2007) and show improvements over competitive baselines.

In the remainder of this paper we give a brief overview of related work, emphasizing vector-based approaches that compute word meaning in context (Section 2). Next, we present our probabilistic framework and different instantiations thereof (Sections 3 and 4). Finally, we discuss our experimental results (Sections 5 and 6) and conclude the paper with future work.

2 Related work

Vector composition methods construct representations that go beyond individual words (e.g., for phrases or sentences) and thus by default obtain word meanings in context. Mitchell and Lapata (2008) investigate several vector composition operations for representing short sentences (consisting of intransitive verbs and their subjects). They show that models performing point-wise multiplication of component vectors outperform earlier proposals based on vector addition (Landauer and Dumais, 1997; Kintsch, 2001). They argue that multiplication approximates the intersection of the meaning of two vectors, whereas addition their union. Mitchell and Lapata (2009) further show that their models yield improvements in language modeling.

Erk and Padó (2008) employ selectional preferences to contextualize occurrences of target words. For example, the meaning of a verb in the presence of its object is modeled as the multiplication of the verb's vector with the vector capturing the inverse selectional preferences of the object; the latter are computed as the centroid of the verbs that occur with this object. Thater et al. (2009) improve on this model by representing verbs in a second order space, while the representation for objects remains first order. The meaning of a verb boils down to restricting its vector to the features active in the argument noun (i.e., dimensions with value larger than zero).

More recently, Reisinger and Mooney (2010) present a method that uses clustering to produce multiple sense-specific vectors for each word. Specifically, a word's contexts are clustered to produce groups of similar context vectors. An average prototype vector is then computed separately for each cluster, producing a set of vectors for each word. These cluster vectors can be used to determine the semantic similarity of both isolated words and words in context. In the second case, the distance between prototypes is weighted by the probability that the context belongs to the prototype's cluster. Erk and Padó (2010) propose an exemplar-based model for capturing word meaning in context. In contrast to the prototype-based approach, no clustering takes place, it is assumed that there are as many senses as there are instances. The meaning of a word in context is the set of exemplars most similar to it.

Unlike Reisinger and Mooney (2010) and Erk and Padó (2010) our model is probabilistic (we represent word meaning as a distribution over a set of latent senses), which makes it easy to integrate and combine with other systems via mixture or product models. More importantly, our approach is conceptually simpler as we use a single vector representation for isolated words as well as for words in context. A word's different meanings are simply modeled as changes in its sense distribution. We should also point out that our approach is not tied to a specific sense induction method and can be used with different variants of vector-space models.

3 Meaning Representation in Context

In this section we first describe how we represent the meaning of individual words and then move on to discuss our model of inducing meaning representations in context.

Observed Representations Most vector space models in the literature perform computations on a co-occurrence matrix where each row represents a *target* word, each column a document or another neighboring word, and each entry their co-occurrence frequency. The raw counts are typically mapped into the components of a vector in some space using for example conditional probability, the log-likelihood ratio or tf-idf weighting. Under this representation, the similarity of word meanings can be easily quantified by measuring their distance in the vector space, the cosine of the angle between them, or their scalar product.

Our model assumes the same type of input data, namely a co-occurrence matrix, where rows correspond to *target* words and columns to *context features* (e.g., co-occurring neighbors). Throughout this paper we will use the notation t_i with $i : 1..I$ to refer to a target word and c_j with $j : 1..J$ to refer to context features. A cell (i, j) in the matrix represents the frequency of occurrence of target t_i with context feature c_j over a corpus.

Meaning Representation over Latent Senses We further assume that the target words t_i $i : 1...I$ found in a corpus share a global set of meanings or senses $Z = \{z_k | k : 1...K\}$. And therefore the meaning of individual target words can be described as a distribution over this set of senses. More formally, a target t_i is represented by the following vector:

$$\mathbf{v(t_i) = (P(z_1|t_i), ..., P(z_K|t_i))} \qquad (1)$$

where component $P(z_1|t_i)$ is the probability of sense z_1 given target word t_i, component $P(z_2|t_i)$ the probability of sense z_2 given t_i and so on.

The intuition behind such a representation is that a target word can be described by a set of core meanings and by the frequency with which these are attested. Note that the representation in (1) is not fixed but parametrized with respect to an input corpus (i.e., it only reflects word usage as attested in that corpus). The senses $z_1 \dots z_K$ are latent and can be seen as a means of reducing the dimensionality of the original co-occurrence matrix.

Analogously, we can represent the meaning of a target word given a context feature as:

$$\mathbf{v(t_i, c_j) = (P(z_1|t_i, c_j), ..., P(z_K|t_i, c_j))} \qquad (2)$$

Here, target t_i is again represented as a distribution over senses, but is now modulated by a specific context c_j which reflects actual word usage. This distribution is more "focused" compared to (1); the context helps disambiguate the meaning of the target word, and as a result fewer senses will share most of the probability mass.

In order to create the context-aware representations defined in (2) we must estimate the probabilities $P(z_k|t_i, c_j)$ which can be factorized as the product of $P(t_i, z_k)$, the joint probability of target t_i and latent sense z_k, and $P(c_j|z_k, t_i)$, the conditional probability of context c_j given target t_i and sense z_k:

$$P(z_k|t_i, c_j) = \frac{P(t_i, z_k)P(c_j|z_k, t_i)}{\sum_k P(t_i, z_k)P(c_j|z_k, t_i)} \qquad (3)$$

Problematically, the term $P(c_j|z_k, t_i)$ is difficult to estimate since it implies learning a total number of $K \times I$ J-dimensional distributions. We will therefore make the simplifying assumption that target words t_i and context features c_j are conditionally independent given sense z_k:

$$P(z_k|t_i, c_j) \approx \frac{P(z_k|t_i)P(c_j|z_k)}{\sum_k P(z_k|t_i)P(c_j|z_k)} \qquad (4)$$

Although not true in general, the assumption is relatively weak. We do not assume that words and context features occur independently of each other, but only that they are generated independently given an assigned meaning. A variety of latent variable models can be used to obtain senses $z_1 \dots z_K$ and estimate the distributions $P(z_k|t_i)$ and $P(c_j|z_k)$; we give specific examples in Section 4.

Note that we abuse terminology here, as the senses our models obtain are not lexicographic meaning distinctions. Rather, they denote coarse-grained senses or more generally topics attested in the document collections our model is trained on. Furthermore, the senses are not word-specific but global (i.e., shared across all words) and modulated either within or out of context probabilistically via estimating $P(z_k|t_i, c_j)$ and $P(z_k|t_i)$, respectively.

4 Parametrizations

The general framework outlined above can be parametrized with respect to the input co-occurrence matrix and the algorithm employed for inducing the latent structure. Considerable latitude is available when creating the co-occurrence matrix, especially when defining its columns, i.e., the linguistic contexts a target word is attested with. These contexts can be a small number of words surrounding the target word (Lund and Burgess, 1996; Lowe and McDonald, 2000), entire paragraphs, documents (Salton et al., 1975; Landauer and Dumais, 1997) or even syntactic dependencies (Grefenstette, 1994; Lin, 1998; Padó and Lapata, 2007).

Analogously, a number of probabilistic models can be employed to induce the latent senses. Examples include Probabilistic Latent Semantic Analysis (PLSA, Hofmann (2001)), Probabilistic Principal Components Analysis (Tipping and Bishop, 1999), non-negative matrix factorization (NMF, Lee and Seung (2000)), and latent Dirichlet allocation (LDA, Blei et al. (2003)). We give a more detailed description of the latter two models as we employ them in our experiments.

Non-negative Matrix Factorization Non-negative matrix factorization algorithms approximate a non-negative input matrix V by two non-negative factors W and H, under a given loss function. W and H are reduced-dimensional matrices and their product can be regarded as a compressed form of the data in V:

$$V_{I,J} \approx W_{I,K} H_{K,J} \tag{5}$$

where W is a basis vector matrix and H is an encoded matrix of the basis vectors in equation (5). Several loss functions are possible, such as mean squared error and Kullback-Leibler (KL) divergence. In keeping with the formulation in Section 3 we opt for a probabilistic interpretation of NMF (Gaussier and Goutte, 2005; Ding et al., 2008) and thus minimize the KL divergence between WH and V.

$$\min \sum_{i,j} (V_{i,j} \log \frac{V_{i,j}}{WH_{i,j}} - V_{i,j} + WH_{i,j}) \tag{6}$$

Specifically, we interpret matrix V as $V_{ij} = P(t_i, c_j)$, and matrices W and H as $P(t_i, z_k)$ and $P(c_j|z_k)$, respectively. We can also obtain the following more detailed factorization: $P(t_i, c_j) = \sum_k P(t_i)P(z_k|t_i)P(c_j|z_k)$.

Le WH denote the factors in a NMF decomposition of an input matrix V and B be a diagonal matrix with $B_{kk} = \sum_j H_{kj}$. $B^{-1}H$ gives a row-normalized version of H. Similarly, given matrix WB, we can define a diagonal matrix A, with $A_{ii} = \sum_k (WB)_{ik}$. $A^{-1}WB$ row-normalizes matrix WB. The factorization WH can now be rewritten as:

$$WH = AA^{-1}WBB^{-1}H = A(A^{-1}WB)(B^{-1}H)$$

which allows us to interpret A as $P(t_i)$, $A^{-1}WB$ as $P(z_k|t_i)$ and $B^{-1}H$ as $P(c_j|z_k)$. These interpretations are valid since the rows of $A^{-1}WB$ and of $B^{-1}H$ sum to 1, matrix A is diagonal with trace 1 because elements in WH sum to 1, and all entries are non-negative.

Latent Dirichlet Allocation LDA (Blei et al., 2003) is a probabilistic model of text generation. Each document d is modeled as a distribution over K topics, which are themselves characterized by distributions over words. The individual words in a document are generated by repeatedly sampling a topic according to the topic distribution and then sampling a single word from the chosen topic.

More formally, we first draw the mixing proportion over topics θ_d from a Dirichlet prior with parameters α. Next, for each of the N_d words w_{dn} in document d, a topic z_{dn} is first drawn from a multinomial distribution with parameters θ_{dn}. The probability of a word token w taking on value i given that topic $z = j$ is parametrized using a matrix β with $b_{ij} = P(w = i|z = j)$. Integrating out θ_d's and z_{dn}'s, gives $P(D|\alpha, \beta)$, the probability of a corpus (or document collection):

$$\prod_{d=1}^{M} \int P(\theta_d|\alpha) \left(\prod_{n=1}^{N_d} \sum_{z_{dn}} P(z_{dn}|\theta_d) P(w_{dn}|z_{dn}, \beta) \right) d\theta_d$$

The central computational problem in topic modeling is to obtain the posterior distribution $P(\theta, \mathbf{z}|\mathbf{w}, \alpha, \beta)$ of the hidden variables $\mathbf{z} = (z_1, z_2, \ldots, z_N)$. given a document $\mathbf{w} = (w_1, w_2, \ldots, w_N)$. Although this distribution is intractable in general, a variety of approximate inference algorithms have been proposed in the literature. We adopt the Gibbs sampling procedure discussed in Griffiths and Steyvers (2004). In this model, $P(w = i|z = j)$ is also a Dirichlet mixture (denoted ϕ) with symmetric priors (denoted β).

We use LDA to induce senses of target words based on context words, and therefore each row t_i in the input matrix transforms into a document. The frequency of t_i occurring with context feature c_j is the number of times word c_j is encountered in the "document" associated with t_i. We train the LDA model on this data to obtain the θ and ϕ distributions. θ gives the sense distributions of each target t_i: $\theta_{ik} = P(z_k|t_i)$ and ϕ the context-word distribution for each sense z_k: $\phi_{kj} = P(c_j|z_k)$.

5 Experimental Set-up

In this section we discuss the experiments we performed in order to evaluate our model. We describe the tasks on which it was applied, the corpora used for model training and our evaluation methodology.

Tasks The probabilistic model presented in Section 3 represents words via a set of induced senses. We experimented with two types of semantic space based on NMF and LDA and optimized parameters for these models on a word similarity task. The latter involves judging the similarity $sim(t_i, t'_i) = sim(v(t_i), v(t'_i))$ of words t_i and t'_i out of context, where $v(t_i)$ and $v(t'_i)$ are obtained from the output of NMF or LDA, respectively. In our experiments we used the data set of Finkelstein et al. (2002). It contains 353 pairs of words and their similarity scores as perceived by human subjects.

The contextualized representations were next evaluated on lexical substitution (McCarthy and Navigli, 2007). The task requires systems to find appropriate substitutes for target words occurring in context. Typically, systems are given a set of substitutes, and must produce a ranking such that appropriate substitutes are assigned a higher rank compared to non-appropriate ones. We made use of the SemEval 2007 Lexical Substitution Task benchmark data set. It contains 200 target words, namely nouns, verbs, adjectives and adverbs, each of which occurs in 10 distinct sentential contexts. The total set contains 2,000 sentences. Five human annotators were asked to provide substitutes for these target words. Table 1 gives an example of the adjective *still* and its substitutes.

Following Erk and Padó (2008), we pool together the total set of substitutes for each target word. Then, for each instance the model has to produce a ranking for the total substitute set. We rank the candidate substitutes based on the similarity of the contextualized target and the out-of-context substitute, $sim(v(t_i, c_j), v(t'_i))$, where t_i is the target word, c_j a context word and t'_i a substitute. Contextualizing just one of the words brings higher discriminative power to the model rather than performing comparisons with the target and its substitute embedded in an identical context (see also Thater et al. (2010) for a similar observation).

Sentences	Substitutes
It is important to apply the herbicide on a *still* day, because spray drift can kill non-target plants.	calm (5) not-windy (1) windless (1)
A movie is a visual document comprised of a series of *still* images.	motionless (3) unmoving (2) fixed (1) stationary (1) static (1)

Table 1: Lexical substitution data example for the adjective *still*; numbers in parentheses indicate the frequency of the substitute.

Model Training All the models we experimented with use identical input data, i.e., a bag-of-words matrix extracted from the GigaWord collection of news text. Rows in this matrix are target words and columns are their co-occurring neighbors, within a symmetric window of size 5. As context words, we used a vocabulary of the 3,000 most frequent words in the corpus.[1]

We implemented the classical NMF factorization algorithm described in Lee and Seung (2000). The input matrix was normalized so that all elements summed to 1. We experimented with four dimensions K: $[600 - 1000]$ with step size 200. We ran the algorithm for 150 iterations to obtain factors W and H which we further processes as described in Section 4 to obtain the desired probability distributions. Since the only parameter of the NMF model is the factorization dimension K, we performed two independent runs with each K value and averaged their predictions.

The parameters for the LDA model are the number of topics K and Dirichlet priors α and β. We experimented with topics K: $[600 - 1400]$, again with step size 200. We fixed β to 0.01 and tested two values for α: $\frac{2}{K}$ (Porteous et al., 2008) and $\frac{50}{K}$ (Griffiths and Steyvers, 2004). We used Gibbs sampling on the "document collection" obtained from the input matrix and estimated the sense distributions as described in Section 4. We ran the chains for 1000 iter-

[1] The GigaWord corpus contains 1.7B words; we scale down all the counts by a factor of 70 to speed up the computation of the LDA models. All models use this reduced size input data.

ations and averaged over five iterations $[600-1000]$ at lag 100 (we observed no topic drift).

We measured similarity using the scalar product, cosine, and inverse Jensen-Shannon (IJS) divergence (see (7), (8), and (9), respectively):

$$\mathrm{sp}(v,w) =< v,w >= \sum_i v_i w_i \qquad (7)$$

$$\cos(v,w) = \frac{\langle v,w\rangle}{||v||\,||w||} \qquad (8)$$

$$\mathrm{IJS}(v,w) = \frac{1}{\mathrm{JS(v,w)}} \qquad (9)$$

$$\mathrm{JS(v,w)} = \frac{1}{2}\mathrm{KL}(v|m) + \frac{1}{2}\mathrm{KL}(w|m) \qquad (10)$$

where m is a shorthand for $\frac{1}{2}(v+w)$ and KL the Kullback-Leibler divergence, $\mathrm{KL}(v|w) = \sum_i v_i log(\frac{v_i}{w_i})$.

Among the above similarity measures, the scalar product has the most straightforward interpretation as the probability of two targets sharing a common meaning (i.e., the sum over all possible meanings). The scalar product assigns 1 to a pair of identical vectors if and only if $P(z_i) = 1$ for some i and $P(z_j) = 0, \forall j \neq i$. Thus, only fully disambiguated words receive a score of 1. Beyond similarity, the measure also reflects how "focused" the distributions in question are, as very ambiguous words are unlikely to receive high scalar product values.

Given a set of context words, we contextualize the target using one context word at a time and compute the overall similarity score by multiplying the individual scores.

Baselines Our baseline models for measuring similarity out of context are Latent Semantic Analysis (Landauer and Dumais, 1997) and a simple semantic space without any dimensionality reduction.

For LSA, we computed the $U\Sigma V$ SVD decomposition of the original matrix to rank $k = 1000$. Any decomposition of lower rank can be obtained from this by setting rows and columns to 0. We evaluated decompositions to ranks K: [200 − 1000], at each 100 step. Similarity computations were performed in the lower rank approximation matrix $U\Sigma V$, as originally proposed in Deerwester et al. (1990), and in matrix U which maps the words into the concept space. It is common to compute SVD decompositions on matrices to which prior weighting schemes have been applied. We experimented with tf-idf weighting and line normalization.

Our second baseline, the simple semantic space, was based on the original input matrix on which we applied several weighting schemes such as point-wise mutual information, tf-idf, and line normalization. Again, we measured similarity using cosine, scalar product and inverse JS divergence. In addition, we also experimented with Lin's (1998) similarity measure:

$$\mathrm{lin}(v,w) = \frac{\sum_{i\in I(v)\cap I(w)}(v_i + w_i)}{\sum_{i\in I(v)} v_i + \sum_{l\in I(w)} w_i} \qquad (11)$$

where the values in v and w are point-wise mutual information, and $I(\cdot)$ gives the indices of positive values in a vector.

Our baselines for contextualized similarity were vector addition and vector multiplication which we performed using the simple semantic space (Mitchell and Lapata, 2008) and dimensionality reduced representations obtained from NMF and LDA. To create a ranking of the candidate substitutes we compose the vector of the target with its context and compare it with each substitute vector. Given a set of context words, we contextualize the target using each context word at a time and multiply the individual scores.

Evaluation Method For the word similarity task we used correlation analysis to examine the relationship between the human ratings and their corresponding vector-based similarity values. We report Spearman's ρ correlations between the similarity values provided by the models and the mean participant similarity ratings in the Finkelstein et al. (2002) data set. For the lexical substitution task, we compare the system ranking with the gold standard ranking using Kendall's τ_b rank correlation (which is adjusted for tied ranks). For all contextualized models we defined the context of a target word as the words occurring within a symmetric context window of size 5. We assess differences between models using stratified shuffling (Yeh, 2000).[2]

[2] Given two system outputs, the null hypothesis (i.e., that the two predictions are indistinguishable) is tested by randomly mixing the individual instances (in our case sentences) of the two outputs. We ran a standard number of 10000 iterations.

Model	Spearman ρ
SVS	38.35
LSA	49.43
NMF	**52.99**
LDA	**53.39**
LSA$_{\text{MIX}}$	49.76
NMF$_{\text{MIX}}$	51.62
LDA$_{\text{MIX}}$	51.97

Table 2: Results on out of context word similarity using a simple co-occurrence based vector space model (SVS), latent semantic analysis, non-negative matrix factorization and latent Dirichlet allocation as individual models with the best parameter setting (LSA, NMF, LDA) and as mixtures (LSA$_{\text{MIX}}$, NMF$_{\text{MIX}}$, LDA$_{\text{MIX}}$).

6 Results

Word Similarity Our results on word similarity are summarized in Table 2. The simple co-occurrence based vector space (SVS) performed best with tf-idf weighting and the cosine similarity measure. With regard to LSA, we obtained best results with initial line normalization of the matrix, $K = 600$ dimensions, and the scalar product similarity measure while performing computations in matrix U. Both NMF and LDA models are generally better with a larger number of senses. NMF yields best performance with $K = 1000$ dimensions and the scalar product similarity measure. The best LDA model also uses the scalar product, has $K = 1200$ topics, and α set to $\frac{50}{K}$.

Following Reisinger and Mooney (2010), we also evaluated mixture models that combine the output of models with varying parameter settings. For both NMF and LDA we averaged the similarity scores returned by all runs. For comparison, we also present an LSA mixture model over the (best) middle interval K values. As can be seen, the LSA model improves slightly, whereas NMF and LDA perform worse than their best individual models.[3] Overall, we observe that NMF and LDA yield significantly ($p < 0.01$) better correlations than LSA and the simple semantic space, both as individual models and as mixtures.

Model	Kendall's τ_b
SVS	11.05
Add-SVS	12.74
Add-NMF	12.85
Add-LDA	12.33
Mult-SVS	14.41
Mult-NMF	13.20
Mult-LDA	12.90
Cont-NMF	14.95
Cont-LDA	13.71
Cont-NMF$_{\text{MIX}}$	**16.01**
Cont-LDA$_{\text{MIX}}$	**15.53**

Table 3: Results on lexical substitution using a simple semantic space model (SVS), additive and multiplicative compositional models with vector representations based on co-occurrences (Add-SVS, Mult-SVS), NMF (Add-NMF, Mult-NMF), and LDA (Add-LDA, Mult-LDA) and contextualized models based on NMF and LDA with the best parameter setting (Cont-NMF, Cont-LDA) and as mixtures (Cont-NMF$_{\text{MIX}}$, Cont-LDA$_{\text{MIX}}$).

Lexical Substitution Our results on lexical substitution are shown in Table 3. As a baseline we also report the performance of the simple semantic space that does not use any contextual information. This model returns the same ranking of the substitute candidates for each instance, based solely on their similarity with the target word. This is a relatively competitive baseline as observed by Erk and Padó (2008) and Thater et al. (2009).

We report results with contextualized NMF and LDA as individual models (the best word similarity settings) and as mixtures (as described above). These are in turn compared against additive and multiplicative compositional models. We implemented an additive model with pmi weighting and Lin's similarity measure which is defined in an additive fashion. The multiplicative model uses tf-idf weighting and cosine similarity, which involves multiplication of vector components. Other combinations of weighting schemes and similarity measures delivered significantly lower results. We also report results for these models when using the NMF and LDA reduced representations.

[3] It is difficult to relate our results to Reisinger and Mooney (2010), due to differences in the training data and the vector representations it gives rise to. As a comparison, a baseline configuration with tf-idf weighting and the cosine similarity measure yields a correlation of 0.38 with our data and 0.49 in Reisinger and Mooney (2010).

Model	Adv	Adj	Noun	Verb
SVS	22.47	14.38	09.52	7.98
Add-SVS	22.79	14.56	11.59	10.00
Mult-SVS	22.85	16.37	13.59	11.60
Cont-NMF$_{\text{MIX}}$	**26.13**	**17.10**	15.16	**14.18**
Cont-LDA$_{\text{MIX}}$	21.21	16.00	**16.31**	13.67

Table 4: Results on lexical substitution for different parts of speech with a simple semantic space model (SVS), two compositional models (Add-SVS, Mult-SVS), and contextualized mixture models with NMF and LDA (Cont-NMF$_{\text{MIX}}$, Cont-LDA$_{\text{MIX}}$), using Kendall's τ_b correlation coefficient.

All models significantly ($p < 0.01$) outperform the context agnostic simple semantic space (see SVS in Table 3). Mixture NMF and LDA models are significantly better than all variants of compositional models ($p < 0.01$); the individual models are numerically better, however the difference is not statistically significant. We also find that the multiplicative model using a simple semantic space (Mult-SVS) is the best performing compositional model, thus corroborating the results of Mitchell and Lapata (2009). Interestingly, dimensionality compositional models. This indicates that the better results we obtain are due to the probabilistic formulation of our contextualized model as a whole rather than the use of NMF or LDA. Finally, we observe that the Cont-NMF model is slightly better than Cont-LDA, however the difference is not statistically significant.

To allow comparison with previous results reported on this data set, we also used the Generalized Average Precision (GAP, Kishida (2005)) as an evaluation measure. GAP takes into account the order of candidates ranked correctly by a hypothetical system, whereas average precision is only sensitive to their relative position. The best performing models are Cont-NMF$_{\text{MIX}}$ and Cont-LDA$_{\text{MIX}}$ obtaining a GAP of 42.7% and 42.9%, respectively. Erk and Padó (2010) report a GAP of 38.6% on this data set with their best model.

Table 4 shows how the models perform across different parts of speech. While verbs and nouns seem to be most difficult, we observe higher gains from the use of contextualized models. Cont-LDA$_{\text{MIX}}$ obtains approximately 7% absolute gain for nouns and Cont-NMF$_{\text{MIX}}$ approximately 6% for verbs. All contextualized models obtain smaller improvements for adjectives. For adverbs most models do not improve over the no-context setting, with the exception Cont-NMF$_{\text{MIX}}$.

Senses		Word Distributions
TRAFFIC	(0.18)	*road, traffic, highway, route, bridge*
MUSIC	(0.04)	*music, song, rock, band, dance, play*
FAN	(0.04)	*crowd, fan, people, wave, cheer, street*
VEHICLE	(0.04)	*car, truck, bus, train, driver, vehicle*

Table 5: Induced senses of *jam* and five most likely words given these senses using an LDA model; sense probabilities are shown in parentheses.

Finally, we also qualitatively examined how the context words influence the sense distributions of target words using examples from the lexical substitution dataset and the output of an individual Cont-LDA model. In many cases, a target word starts with a distribution spread over a larger number of senses, while a context word shifts this distribution to one majority sense. Consider, for instance, the target noun *jam* in the following sentence:

(1) With their transcendent, improvisational jams and Mayan-inspired sense of a higher, metaphysical purpose, the band's music delivers a spiritual sustenance that has earned them a very devoted core following.

Table 5 shows the out-of-context senses activated for *jam* together with the five most likely words associated with them.[4] Sense probabilities are also shown in parentheses. As can be seen, initially two traffic-related and two music-related senses are activated, however with low probabilities. In the presence of the context word *band*, we obtain a much more "focused" distribution, in which the MUSIC sense has 0.88 probability. The system ranks *riff* and *gig* as the most likely two substitutes for *jam*. The gold annotation also lists *session* as a possible substitute.

In a large number of cases, the target is only partially disambiguated by a context word and this is also reflected in the resulting distribution. An ex-

[4] Sense names are provided by the authors in an attempt to best describe the clusters (i.e., topics for LDA) to which words are assigned.

ample is the word *bug* which initially has a distribution triggering the SOFTWARE (0.09, *computer, software, microsoft, windows*) and DISEASE (0.06, *disease, aids, virus, cause*) senses. In the context of *client*, *bug* remains ambiguous between the senses SECRET-AGENCY (0.34, *agent, secret, intelligence, FBI)*) and SOFTWARE (0.29):

(2) We wanted to give our client more than just a list of bugs and an invoice — we wanted to provide an audit trail of our work along with meaningful productivity metrics.

There are also cases where the contextualized distributions are not correct, especially when senses are domain specific. An example is the word *function* occurring in its mathematical sense with the context word *distribution*. However, the senses that are triggered by this pair all relate to the "service" sense of *function*. This is a consequence of the newspaper corpus we use, in which the mathematical sense of *function* is rare. We also see several cases where the target word and one of the context words are assigned senses that are locally correct, but invalid in the larger context. In the following example:

(3) Check the shoulders so it hangs well, stops at hips or below, and make sure the pants are long enough.

The pair *(check, shoulder)* triggers senses INJURY (0.81, *injury, left, knee, shoulder*) and BALL-SPORTS (0.10, *ball, shot, hit, throw*). However, the sentential context ascribes a meaning that is neither related to injury nor sports. This suggests that our models could benefit from more principled context feature aggregation.

Generally, verbs are not as good context words as nouns. To give an example, we often encounter the pair *(let, know)*, used in the common "inform" meaning. The senses we obtain for this pair, are, however, rather uninformative general verb classes: {*see, know, think, do*} (0.57) and {*go, say, do, can*} (0.20). This type of error can be eliminated in a space where context features are designed to best reflect the properties of the target words.

7 Conclusions

In this paper we have presented a general framework for computing similarity in context. Key in this framework is the representation of word meaning as a distribution over a set of global senses where contextualized meaning is modeled as a change in this distribution. The approach is conceptually simple, the same vector representation is used for isolated words and words in context without being tied to a specific sense induction method or type of semantic space.

We have illustrated two instantiations of this framework using non-negative matrix factorization and latent Dirichlet allocation for inducing the latent structure, and shown experimentally that they outperform previously proposed methods for measuring similarity in context. Furthermore, both of them benefit from mixing model predictions over a set of different parameter choices, thus making parameter tuning redundant.

The directions for future work are many and varied. Conceptually, we have defined our model in an asymmetric fashion, i.e., by stipulating a difference between target words and contextual features. However, in practice, we used vector representations that do not distinguish the two: target words and contextual features are both words. This choice was made to facilitate comparisons with the popular bag-of-words vector space models. However, differentiating target from context representations may be beneficial particularly when the similarity computations are embedded within specific tasks such as the acquisition of paraphrases, the recognition of entailment relations, and thesaurus construction. Also note that our model currently contextualizes target words with respect to individual contexts. Ideally, we would like to compute the collective influence of several context words on the target. We plan to further investigate how to select or to better aggregate the entire set of features extracted from a context.

Abstract

We introduce *tiered clustering*, a mixture model capable of accounting for varying degrees of shared (context-independent) feature structure, and demonstrate its applicability to inferring distributed representations of word meaning. Common tasks in lexical semantics such as word relatedness or selectional preference can benefit from modeling such structure: Polysemous word usage is often governed by some common background metaphoric usage (e.g. the senses of *line* or *run*), and likewise modeling the selectional preference of verbs relies on identifying commonalities shared by their typical arguments. Tiered clustering can also be viewed as a form of soft feature selection, where features that do not contribute meaningfully to the clustering can be excluded. We demonstrate the applicability of tiered clustering, highlighting particular cases where modeling shared structure is beneficial and where it can be detrimental.

1 Introduction

Word meaning can be represented as high-dimensional vectors inhabiting a common space whose dimensions capture semantic or syntactic properties of interest (e.g. Erk and Pado, 2008; Lowe, 2001). Such *vector-space* representations of meaning induce measures of word similarity that can be tuned to correlate well with judgements made by humans. Previous work has focused on designing feature representations and semantic spaces that capture salient properties of word meaning (e.g. Curran, 2004; Gabrilovich and Markovitch, 2007; Landauer and Dumais, 1997), often leveraging the distributional hypothesis, i.e. that similar words appear in similar contexts (Miller and Charles, 1991; Pereira et al., 1993).

Since vector-space representations are constructed at the lexical level, they conflate multiple word meanings into the same vector, e.g. collapsing occurrences of *bank*$_{\text{institution}}$ and *bank*$_{\text{river}}$. Methods such as *Clustering by Committee* (Pantel, 2003) and *multi-prototype* representations (Reisinger and Mooney, 2010) address this issue by performing word-sense disambiguation across word occurrences, and then building meaning vectors from the disambiguated words. Such approaches can readily capture the structure of homonymous words with several unrelated meanings (e.g. *bat* and *club*), but are not suitable for representing the common metaphor structure found in highly polysemous words such as *line* or *run*.

In this paper, we introduce *tiered clustering*, a novel probabilistic model of the *shared structure* often neglected in clustering problems. Tiered clustering performs *soft* feature selection, allocating features between a Dirichlet Process clustering model and a background model consisting of a single component. The background model accounts for features commonly shared by all occurrences (i.e. context-independent feature variation), while the clustering model accounts for variation in word usage (i.e. context-dependent variation, or *word senses*; Table 1).

Using the tiered clustering model, we derive a multi-prototype representation capable of capturing varying degrees of sharing between word senses, and demonstrate its effectiveness in lexical semantic tasks where such sharing is desirable. In particular we show that tiered clustering outperforms the multi-prototype approach for (1) selectional preference (Resnik, 1997; Pantel et al., 2007), i.e. predict-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1173–1182,
MIT, Massachusetts, USA, 9-11 October 2010.

ing the typical filler of an argument slot of a verb, and (2) word-relatedness in the presence of highly polysemous words. The former case exhibits a high degree of explicit structure, especially for more selectionally restrictive verbs (e.g. the set of things that can be *eaten* or can *shoot*).

The remainder of the paper is organized as follows: Section 2 gives relevant background on the methods compared, Section 3 outlines the multi-prototype model based on the Dirichlet Process mixture model, Section 4 derives the tiered clustering model, Section 5 discusses similarity metrics, Section 6 details the experimental setup and includes a micro-analysis of feature selection, Section 7 presents results applying tiered clustering to word relatedness and selectional preference, Section 8 discusses future work, and Section 9 concludes.

2 Background

Models of the *attributional similarity* of concepts, i.e. the degree to which concepts overlap based on their attributes (Turney, 2006), are commonly implemented using vector-spaces derived from (1) word collocations (Schütze, 1998), directly leveraging the distributional hypothesis (Miller and Charles, 1991), (2) syntactic relations (Padó and Lapata, 2007), (3) structured corpora (e.g. Gabrilovich and Markovitch (2007)) or (4) latent semantic spaces (Finkelstein et al., 2001; Landauer and Dumais, 1997). Such models can be evaluated based on their correlation with human-reported lexical similarity judgements using e.g. the WordSim-353 collection (Finkelstein et al., 2001). Distributional methods exhibit a high degree of scalability (Gorman and Curran, 2006) and have been applied broadly in information retrieval (Manning et al., 2008), large-scale taxonomy induction (Snow et al., 2006), and knowledge acquisition (Van Durme and Paşca, 2008).

Reisinger and Mooney (2010) introduced a *multi-prototype* approach to vector-space lexical semantics where individual words are represented as collections of "prototype" vectors. This representation is capable of accounting for homonymy and polysemy, as well as other forms of variation in word usage, like similar context-dependent methods (Erk and Pado, 2008). The set of vectors for a word is determined by unsupervised *word sense discovery* (Schütze, 1998), which clusters the contexts in which a word appears. Average prototype vectors are then computed separately for each cluster, producing a distributed representation for each word.

Table 1: Example tiered clustering representation of words with varying degrees of polysemy. Each boxed set shows the most common background (shared) features, and each prototype captures one thematic usage of the word. For example, *wizard* is broken up into a background cluster describing features common to all usages of the word (e.g., *magic* and *evil*) and several genre-specific usages (e.g. *Merlin*, *fairy tales* and *Harry Potter*).

Distributional methods have also proven to be a powerful approach to modeling *selectional preference* (Padó et al., 2007; Pantel et al., 2007), rivaling methods based on existing semantic resources such as WordNet (Clark and Weir, 2002; Resnik, 1997) and FrameNet (Padó, 2007) and performing nearly as well as supervised methods (Herdağdelen and Baroni, 2009). Selectional preference has been shown to be useful for, e.g., resolving ambiguous attachments (Hindle and Rooth, 1991), word sense disambiguation (McCarthy and Carroll, 2003) and semantic role labeling (Gildea and Jurafsky, 2002).

3 Multi-Prototype Models

Representing words as mixtures over several prototypes has proven to be a powerful approach to vector-space lexical semantics (Pantel, 2003; Pantel et al., 2007; Reisinger and Mooney, 2010). In this section we briefly introduce a version of the multi-prototype model based on the Dirichlet Process Mixture Model (DPMM), capable of inferring automatically the number of prototypes necessary for each word (Rasmussen, 2000). Similarity between two DPMM word-representations is then computed as a function of their cluster centroids (§5), instead of the centroid of all the word's occurrences.

Multiple prototypes for each word w are generated by clustering feature vectors $v(c)$ derived from each occurrence $c \in \mathcal{C}(w)$ in a large textual corpus and collecting the resulting cluster centroids $\pi_k(w), k \in [1, K_w]$. This approach is commonly employed in unsupervised word sense discovery; however, we do not assume that clusters correspond to word senses. Rather, we only rely on clusters to capture meaningful variation in word usage.

Instead of assuming all words can be represented by the same number of clusters, we allocate representational flexibility dynamically using the DPMM. The DPMM is an infinite capacity model capable of assigning data to a variable, but finite number of clusters K_w, with probability of assignment to cluster k proportional to the number of data points previously assigned to k. A single parameter η controls the degree of smoothing, producing more uniform clusterings as $\eta \to \infty$. Using this model, the number of clusters no longer needs to be fixed a priori, allowing the model to allocate expressivity dynamically to concepts with richer structure. Such a model naturally allows the word representation to allocate additional capacity for highly polysemous words, with the number of clusters growing logarithmically with the number of occurrences. The DPMM has been used for rational models of concept organization (Sanborn et al., 2006), but to our knowledge has not yet been applied directly to lexical semantics.

4 Tiered Clustering

Tiered clustering allocates features between two submodels: a (context-dependent) DPMM and a single (context-independent) *background* component. This model is similar structurally to the feature selective clustering model proposed by Law et al. (2002). However, instead of allocating entire feature *dimensions* between model and background components, assignment is done at the level of individual feature occurrences, much like topic assignment in Latent Dirichlet Allocation (LDA; Griffiths et al., 2007). At a high level, the tiered model can be viewed as a combination of a multi-prototype model and a single-prototype back-off model. However, by leveraging both representations in a joint framework, uninformative features can be removed from the clustering, resulting in more semantically tight clusters.

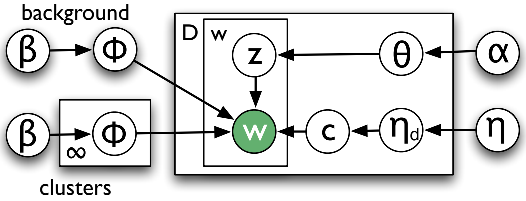

Figure 1: Plate diagram for the tiered clustering model with cluster indicators drawn from the Chinese Restaurant Process.

Concretely, each word occurrence $\mathbf{w}_d$ first selects a cluster $\boldsymbol{\phi}_d$ from the DPMM; then each feature $w_{i,d}$ is generated from either the background model $\boldsymbol{\phi}_{\text{back}}$ or the selected cluster $\boldsymbol{\phi}_d$, determined by the tier indicator $z_{i,d}$. The full generative model for tiered clustering is given by

$$\begin{array}{rcll}
\theta_d|\alpha & \sim & \text{Beta}(\alpha) & d \in D, \\
\boldsymbol{\phi}_d|\boldsymbol{\beta}, G_0 & \sim & \text{DP}(\boldsymbol{\beta}, G_0) & d \in D, \\
\boldsymbol{\phi}_{\text{back}}|\boldsymbol{\beta}_{\text{back}} & \sim & \text{Dirichlet}(\boldsymbol{\beta}_{\text{back}}) & \\
z_{i,d}|\theta_d & \sim & \text{Bernoulli}(\theta_d) & i \in |\mathbf{w}_d|, \\
w_{i,d}|\boldsymbol{\phi}_d, z_{i,d} & \sim & \begin{cases} \text{Mult}(\boldsymbol{\phi}_{\text{back}}) \\ \quad (z_{i,d} = 1) \\ \text{Mult}(\boldsymbol{\phi}_d) \\ \quad \text{(otherwise)} \end{cases} & i \in |\mathbf{w}_d|,
\end{array}$$

where $\boldsymbol{\alpha}$ controls the per-data tier distribution smoothing and $\boldsymbol{\beta}$ controls the uniformity of the DP cluster allocation. The DP is parameterized by a base measure G_0, controlling the per-cluster term distribution smoothing; which use a Dirichlet with hyperparameter η, as is common (Figure 1).

Since the background topic is shared across all occurrences, it can account for features with *context-independent* variance, such as stop words and other high-frequency noise, as well as the central tendency of the collection (Table 1). Furthermore, it is possible to put an asymmetric prior on η, yielding more fine-grained control over the assumed *uniformity* of the occurrence of noisy features, unlike in the model proposed by Law et al. (2002).

Although exact posterior inference is intractable in this model, we derive an efficient *collapsed Gibbs sampler* via analogy to LDA (Appendix 1).

5 Measuring Semantic Similarity

Due to its richer representational structure, computing similarity in the multi-prototype model is less straightforward than in the single prototype case. Reisinger and Mooney (2010) found that simply averaging all similarity scores over all pairs of prototypes (sampled from the cluster distributions) performs reasonably well and is robust to noise. Given two words w and w', this *AvgSim* metric is

$$\text{AvgSim}(w, w') \overset{\text{def}}{=} \frac{1}{K_w K_{w'}} \sum_{j=1}^{K_w} \sum_{k=1}^{K_{w'}} d(\pi_k(w), \pi_j(w'))$$

K_w and $K_{w'}$ are the number of clusters for w and w' respectively, and $d(\cdot, \cdot)$ is a standard distributional similarity measure (e.g. cosine distance). As cluster sizes become more uniform, AvgSim tends towards the single prototype similarity,[1] hence the effectiveness of AvgSim stems from boosting the influence of small clusters.

Tiered clustering representations offer more possibilities for computing semantic similarity than multi-prototype, as the background prototype can be treated separately from the other prototypes. We make use of a simple sum of the distance between the two background components, and the AvgSim of the two sets of clustering components.

6 Experimental Setup

6.1 Corpus

Word occurrence statistics are collected from a snapshot of English Wikipedia taken on Sept. 29th, 2009. Wikitext markup is removed, as are articles with fewer than 100 words, leaving 2.8M articles with a total of 2.05B words. Wikipedia was chosen due to its semantic breadth.

6.2 Evaluation Methodology

We evaluate the tiered clustering model on two problems from lexical semantics: word relatedness and selectional preference. For the word relatedness evaluation, we compared the predicted similarity of word pairs from each model to two collections of human similarity judgements: WordSim-353 (Finkelstein et al., 2001) and the Princeton Evocation relations (WN-Evocation, Ma et al., 2009).

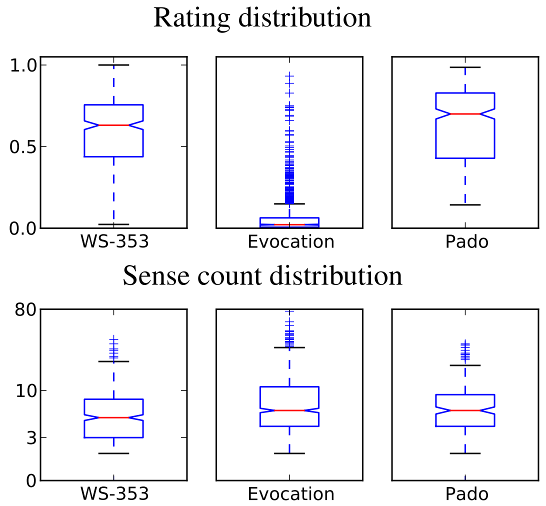

Figure 2: (**top**) The distribution of ratings (scaled [0,1]) on WS-353, WN-Evocation and Padó datasets. (**bottom**) The distribution of sense counts for each data set (log-domain), collected from WordNet 3.0.

WS-353 contains between 13 and 16 human similarity judgements for each of 353 word pairs, rated on a 1–10 integer scale. WN-Evocation is significantly larger than WS-353, containing over 100k similarity comparisons collected from trained human raters. Comparisons are assigned to only 3-5 human raters on average and contain a significantly higher fraction of zero- and low-similarity items than WS-353 (Figure 2), reflecting more accurately real-world lexical semantics settings. In our experiments we discard all comparisons with fewer than 5 ratings and then sample 10% of the remaining pairs uniformly at random, resulting in a test set with 1317 comparisons.

For selectional preference, we employ the *Padó* dataset, which contains 211 verb-noun pairs with human similarity judgements for how plausible the noun is for each argument of the verb (2 arguments per verb, corresponding roughly to subject and object). Results are averaged across 20 raters; typical inter-rater agreement is $\rho = 0.7$ (Padó et al., 2007).

In all cases correlation with human judgements is computed using Spearman's nonparametric rank correlation (ρ) with average human judgements

[1] This can be problematic for certain clustering methods that specify uniform priors over cluster sizes; however the DPMM naturally exhibits a linear decay in cluster sizes with the $\mathbb{E}[\#\text{ clusters of size } M] = \eta/M$.

(Agirre et al., 2009).

6.3 Feature Representation

In the following analyses we confine ourselves to representing word occurrences using unordered unigrams collected from a window of size T=10 centered around the occurrence, represented using *tf-idf* weighting. Feature vectors are pruned to a fixed length f, discarding all but the highest-weight features (f is selected via empirical validation, as described in the next section). Finally, semantic similarity between word pairs is computed using cosine distance (ℓ_2-normalized dot-product).[2]

6.4 Feature Pruning

Feature pruning is one of the most significant factors in obtaining high correlation with human similarity judgements using vector-space models, and has been suggested as one way to improve sense disambiguation for polysemous verbs (Xue et al., 2006). In this section, we calibrate the single prototype and multi-prototype methods on WS-353, reaching the limit of human and oracle performance and demonstrating robust performance gains even with semantically impoverished features. In particular we obtain ρ=0.75 correlation on WS-353 using *only* unigram collocations and ρ=0.77 using a fixed-K multi-prototype representation (Figure 3; Reisinger and Mooney, 2010). This result rivals average human performance, obtaining correlation near that of the supervised oracle approach of Agirre et al. (2009).

The optimal pruning cutoff depends on the feature weighting and number of prototypes as well as the feature representation. *t-test* and χ^2 features are most robust to feature noise and perform well even with no pruning; *tf-idf* yields the best results but is most sensitive to the pruning parameter (Figure 3). As the number of features increases, more pruning is required to combat feature noise.

Figure 4 breaks down the similarity pairs into four quantiles for each data set and then shows correlation separately for each quantile. In general the more polarized data quantiles (1 and 4) have higher correlation, indicating that fine-grained distinctions in semantic distance are easier for those sets.[3] Feature pruning improves correlations in quantiles 2–4 while reducing correlation in quantile 1 (lowest similarity). This result is to be expected as more features are necessary to make fine-grained distinctions between dissimilar pairs.

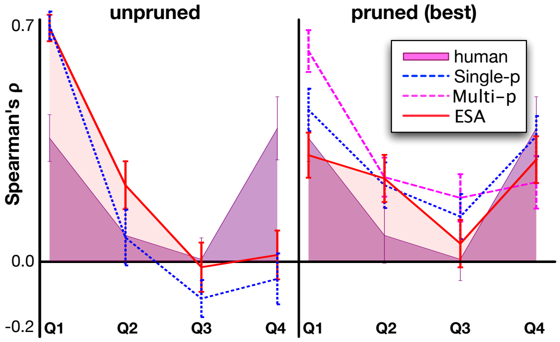

Figure 4: Correlation results on WS-353 broken down over quantiles in the human ratings. Quantile ranges are shown in Figure 2. In general ratings for highly similar (dissimilar) pairs are more predictable (quantiles 1 and 4) than middle similarity pairs (quantiles 2, 3). ESA shows results for a more semantically rich feature set derived using Explicit Semantic Analysis (Gabrilovich and Markovitch, 2007).

7 Results

We evaluate four models: (1) the standard single-prototype approach, (2) the DPMM multi-prototype approach outlined in §3, (3) a simple combination of the multi-prototype and single-prototype approaches (MP+SP)[4] and (4) the tiered clustering approach (§4). Each data set is divided into 5 quantiles based on per-pair average sense counts,[5] collected from WordNet 3.0 (Fellbaum, 1998); examples of pairs in the *high-polysemy* quantile are shown in Table 2. Unless otherwise specified, both DPMM multi-prototype and tiered clustering

[2] (**Parameter robustness**) We observe lower correlations on average for T=25 and T=5 and therefore observe T=10 to be near-optimal. Substituting weighted Jaccard similarity for cosine does not significantly affect the results in this paper.

[3] The fact that the per-quantile correlation is significantly lower than the full correlation e.g. in the human case indicates that fine-grained ordering (within quantile) is more difficult than coarse-grained (between quantile).

[4] (**MP+SP**) Tiered clustering's ability to model both shared and idiosyncratic structure can be easily approximated by using the single prototype model as the shared component and multi-prototype model as the clustering. However, unlike in the tiered model, all features are assigned to *both* components. We demonstrate that this simplification actually hurts performance.

[5] Despite many skewed pairs (e.g. line has 36 senses while insurance has 3), we found that arithmetic average and geometric average perform the same.

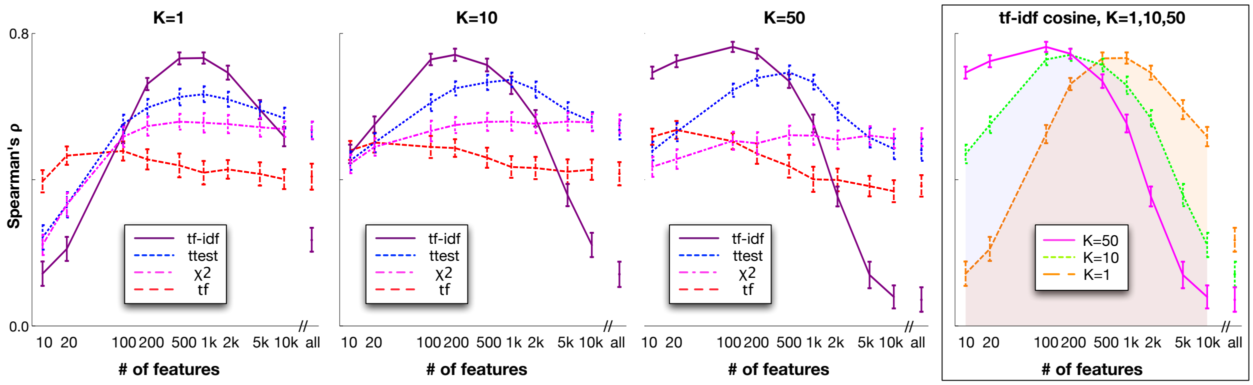

Figure 3: Effects of feature pruning and representation on WS-353 correlation broken down across multi-prototype representation size. In general *tf-idf* features are the most sensitive to pruning level, yielding the highest correlation for moderate levels of pruning and significantly lower correlation than other representations without pruning. The optimal amount of pruning varies with the number of prototypes used, with fewer features being optimal for more clusters. Bars show 95% confidence intervals.

Tiered	76.9±0.5	27.2	43.0%
high polysemy	83.1±1.0	24.2	43.0%

Table 3: Spearman's correlation on the WS-353 data set. *All* refers to the full set of pairs, *high polysemy* refers to the top 20% of pairs, ranked by sense count. $\mathbb{E}[C]$ is the average number of clusters employed by each method and *background* is the average percentage of features allocated by the tiered model to the background cluster. 95% confidence intervals are computed via bootstrapping.

use symmetric Dirichlet hyperparameters, β=0.1, η=0.1, and tiered clustering uses α=10 for the background/clustering allocation smoother.

7.1 WordSim-353

Correlation results for WS-353 are shown in Table 3. In general the approaches incorporating multiple prototypes outperform single prototype ($\rho = 0.768$ vs. $\rho = 0.734$). The tiered clustering model does not significantly outperform either the multi-prototype or MP+SP models on the full set, but yields significantly higher correlation on the high-polysemy set.

The tiered model generates more clusters than DPMM multi-prototype (27.2 vs. 14.8), despite using the same hyperparameter settings: Since words commonly shared across clusters have been allocated to the background component, the cluster components have less overlap and hence the model naturally allocates more clusters.

Examples of the tiered clusterings for several words from WS-353 are shown in Table 1 and corresponding clusters from the multi-prototype approach are shown in Table 4. In general the background component does indeed capture commonalities between all the sense clusters (e.g. all wizards use magic) and hence the tiered clusters are more semantically pure. This effect is most visible in *thematically polysemous* words, e.g. *radio* and *wizard*.

7.2 Evocation

Compared to WS-353, the WN-Evocation pair set is sampled more uniformly from English word pairs and hence contains a significantly larger fraction of unrelated words, reflecting the fact that word sim-

Table 6: Spearman's correlation on the Padó data set.

ilarity is a sparse relation (Figure 2 top). Furthermore, it contains proportionally more highly polysemous words relative to WS-353 (Figure 2 bottom).

On WN-Evocation, the single prototype and multi-prototype do not differ significantly in terms of correlation (ρ=0.198 and ρ=0.201 respectively; Table 5), while SP+MP yields significantly lower correlation (ρ=0.176), and the tiered model yields significantly higher correlation (ρ=0.224). Restricting to the top 20% of pairs with highest human similarity judgements yields similar outcomes, with single prototype, multi-prototype and SP+MP statistically indistinguishable (ρ=0.239, ρ=0.227 and ρ=0.235), and tiered clustering yielding significantly higher correlation (ρ=0.277). Likewise tiered clustering achieves the most significant gains on the high polysemy subset.

7.3 Selectional Preference

Tiered clustering is a natural model for verb selectional preference, especially for more selectionally restrictive verbs: the set of words that appear in a particular argument slot naturally have some kind of commonality (i.e. they can be *eaten* or can *promise*). The background component of the tiered clustering model can capture such general argument structure. We model each verb argument slot in the Padó set with a separate tiered clustering model, separating terms co-occurring with the target verb according to which slot they fill.

On the Padó set, the performance of the DPMM multi-prototype approach breaks down and it yields significantly lower correlation with human norms than the single prototype (ρ=0.202 vs. ρ=0.258; Table 6), due to its inability to capture the shared structure among verb arguments. Furthermore combining with the single prototype does not significantly change its performance (ρ=0.197). Moving to the tiered model, however, yields significant improvements in correlation over the other models (ρ=0.294), primarily improving correlation in the case of highly polysemous verbs and arguments.

8 Discussion and Future Work

We have demonstrated a novel model for distributional lexical semantics capable of capturing both shared (context-independent) and idiosyncratic (context-dependent) structure in a set of word occurrences. The benefits of this tiered model were most pronounced on a selectional preference task, where there is significant shared structure imposed by conditioning on the verb. Although our results on the Padó are not state of the art,[6] we believe this to be due to the impoverished vector-space design; tiered clustering can be applied to more expressive vector spaces, such as those incorporating dependency parse and FrameNet features.

One potential explanation for the superior performance of the tiered model vs. the DPMM multi-prototype model is simply that it allocates more clusters to represent each word (Reisinger and Mooney, 2010). However, we find that decreasing the hyperparameter β (decreasing vocabulary smoothing and hence increasing the effective number of clusters) beyond $\beta = 0.1$ actually hurts multi-prototype performance. The additional clusters do not provide more semantic content due to significant background similarity.

Finally, the DPMM multi-prototype and tiered clustering models allocate clusters based on the variance of the underlying data set. We observe a *negative* correlation (ρ=-0.33) between the number of clusters allocated by the DPMM and the number of word senses found in WordNet. This result is most likely due to our use of unigram context window features, which induce clustering based on thematic rather than syntactic differences. Investigating this issue is future work.

(**Future Work**) The word similarity experiments can be expanded by breaking pairs down further into highly homonymous and highly polysemous pairs, using e.g. WordNet to determine how closely related the senses are. With this data it would be interesting to validate the hypothesis that the percentage of features allocated to the background cluster is correlated with the degree of homonymy.

The basic tiered clustering can be extended with additional background tiers, allocating more expressivity to model background feature variation. This class of models covers the spectrum between a pure topic model (all background tiers) and a pure clustering model and may be reasonable when there is believed to be more background structure (e.g. when jointly modeling all verb arguments). Furthermore, it is straightforward to extend the model to a two-tier, two-clustering structure capable of additionally accounting for commonalities *between* arguments.

Applying more principled feature selection approaches to vector-space lexical semantics may yield more significant performance gains. Towards this end we are currently evaluating two classes of approaches for setting pruning parameters per-word instead of globally: (1) *subspace clustering*, i.e. unsupervised feature selection (e.g., Parsons et al., 2004) and (2) *multiple clustering*, i.e. finding feature partitions that lead to disparate clusterings (e.g., Shafto et al., 2006).

9 Conclusions

This paper introduced a simple probabilistic model of *tiered clustering* inspired by feature selective clustering that leverages feature exchangeability to allocate data features between a clustering model and shared component. The ability to model background variation, or shared structure, is shown to be beneficial for modeling words with high polysemy, yielding increased correlation with human similarity judgements modeling word relatedness and selectional preference. Furthermore, the tiered clustering model is shown to significantly outperform related models, yielding qualitatively more precise clusters.

A Collapsed Gibbs Sampler

In order to sample efficiently from this model, we leverage the Chinese Restaurant Process representation of the DP (cf., Aldous, 1985), introducing a per-word-occurrence cluster indicator c_d. Word occurrence features are then drawn from a combination of a single cluster component indicated by c_d and the background topic.

By exploiting conjugacy, the latent variables $\boldsymbol{\theta}$, $\boldsymbol{\phi}$ and η_d can be integrated out, yielding an efficient

[6] E.g., Padó et al. (2007) report ρ=0.515 on the same data.

collapsed Gibbs sampler. The likelihood of word occurrence d is given by

$$P(\mathbf{w}_d|\mathbf{z}, c_d, \boldsymbol{\phi}) = \\ \prod_i P(w_{i,d}|\boldsymbol{\phi}_{c_d})^{\delta(z_{d,i}=0)} P(w_{i,d}|\boldsymbol{\phi}_{\text{noise}})^{\delta(z_{d,i}=1)}.$$

Hence, this model can be viewed as a two-topic variant of LDA with the addition of a per-word-occurrence (i.e. document) cluster indicator.[7] The update rule for the latent tier indicator $\mathbf{z}$ is similar to the update rule for 2-topic LDA, with the background component as the first topic and the second topic being determined by the per-word-occurrence cluster indicator $\boldsymbol{c}$.

We can efficiently approximate $p(\mathbf{z}|\mathbf{w})$ via Gibbs sampling, which requires the complete conditional posteriors for all $z_{i,d}$. These are

$$P(z_{i,d} = t|\mathbf{z}_{-(i,d)}, \mathbf{w}, \alpha, \beta) = \\ \frac{n_t^{(w_{i,d})} + \beta}{\sum_w (n_t^{(w)} + \beta)} \frac{n_t^{(d)} + \alpha}{\sum_j (n_j^{(d)} + \alpha)}.$$

where $\mathbf{z}_{-(i,d)}$ is shorthand for the set $\mathbf{z} - \{z_{i,d}\}$, $n_t^{(w)}$ is the number of occurrences of word w in topic t not counting $w_{i,d}$ and $n_t^{(d)}$ is the number of features in occurrence d assigned to topic t, not counting $w_{i,d}$.

Likewise sampling the cluster indicators conditioned on the data $p(\boldsymbol{c}_d|\mathbf{w}, \boldsymbol{c}_{-d}, \alpha, \eta)$ decomposes into the DP posterior over cluster assignments and the cluster-conditional Multinomial-Dirichlet word-occurrence likelihood $p(\boldsymbol{c}_d|\mathbf{w}, \boldsymbol{c}_{-d}, \alpha, \eta) = p(\boldsymbol{c}_d|\boldsymbol{c}_{-d}, \eta) p(\mathbf{w}_d|\mathbf{w}_{-d}, \boldsymbol{c}, \mathbf{z}, \alpha)$ given by

$$P(c_d = k_{\text{old}}|\boldsymbol{c}_{-d}, \alpha, \eta) \propto \\ \underbrace{\left(\frac{m_k^{(-d)}}{m_{\blacksquare}^{(-d)} + \eta}\right)}_{p(\boldsymbol{c}_d|\boldsymbol{c}_{-d}, \eta)} \underbrace{\frac{C(\alpha + \overrightarrow{\boldsymbol{n}}_k^{(-d)} + \overrightarrow{\boldsymbol{n}}_{\blacksquare}^{(d)}))}{C(\alpha + \overrightarrow{\boldsymbol{n}}_k^{(-d)})}}_{p(\mathbf{w}_d|\mathbf{w}_{-d}, \boldsymbol{c}, \mathbf{z}, \alpha)}$$

$$P(c_d = k_{\text{new}}|\boldsymbol{c}_{-d}, \alpha, \eta) \propto \frac{\eta}{m_{\blacksquare}^{(-d)} + \eta} \frac{C(\alpha + \overrightarrow{\boldsymbol{n}}_{\blacksquare}^{(d)})}{C(\alpha)}$$

where $m_k^{(-d)}$ is the number of occurrences assigned to k not including d, $\overrightarrow{\boldsymbol{n}}_k^{(d)}$ is the vector of counts of words from occurrence $\mathbf{w}_d$ assigned to cluster k (i.e. words with $\mathbf{z}_{i,d} = 0$) and $C(\cdot)$ is the normalizing constant for the Dirichlet $C(\boldsymbol{a}) = \Gamma(\sum_{j=1}^m a_j)^{-1} \prod_{j=1}^m \Gamma(a_j)$ operating over vectors of counts $\boldsymbol{a}$.

[7] Effectively, the tiered clustering model is a special case of the *nested* Chinese Restaurant Process with the tree depth fixed to two (Blei et al., 2003).

Nouns are vectors, adjectives are matrices: Representing adjective-noun constructions in semantic space

Abstract

We propose an approach to adjective-noun composition (AN) for corpus-based distributional semantics that, building on insights from theoretical linguistics, represents nouns as vectors and adjectives as data-induced (linear) functions (encoded as matrices) over nominal vectors. Our model significantly outperforms the rivals on the task of reconstructing AN vectors not seen in training. A small post-hoc analysis further suggests that, when the model-generated AN vector is not similar to the corpus-observed AN vector, this is due to anomalies in the latter. We show moreover that our approach provides two novel ways to represent adjective meanings, alternative to its representation via corpus-based co-occurrence vectors, both outperforming the latter in an adjective clustering task.

1 Introduction

An influential approach for representing the meaning of a word in NLP is to treat it as a vector that codes the pattern of co-occurrence of that word with other expressions in a large corpus of language (Sahlgren, 2006; Turney and Pantel, 2010). This approach to semantics (sometimes called *distributional semantics*) naturally captures word clustering, scales well to large lexicons and doesn't require words to be manually disambiguated (Schütze, 1997). However, until recently it has been limited to the level of content words (nouns, adjectives, verbs), and it hasn't tackled in a general way *compositionality* (Frege, 1892; Partee, 2004), that crucial property of natural language which allows speakers to derive the meaning of a complex linguistic constituent from the meaning of its immediate syntactic subconstituents.

Formal semantics (FS), the research program stemming from Montague (1970b; 1973), has opposite strengths and weaknesses. Its core semantic notion is the sentence, not the word; at the lexical level, it focuses on the meaning of function words; one of its main goals is to formulate recursive compositional rules that derive the quantificational properties of complex sentences and their antecedent-pronoun dependencies.

Given its focus on quantification, FS treats the meanings of nouns and verbs as pure *extensions*: nouns and (intransitive) verbs are properties, and thus denote sets of individuals. Adjectives are also often assumed to denote properties: in this view red_{adj} would be the set of 'entities which are red', $plastic_{adj}$, the set of 'objects made of plastic', and so forth. In the simplest case, the meaning of an attributive adjective-noun (AN) constituent can be obtained as the intersection of the adjective and noun extensions A∩N:

[red car] = $\{\ldots$ *red objects* $\ldots\} \cap \{\ldots$ *cars* $\ldots\}$

However, the intersective method of combination is well-known to fail in many cases (Kamp, 1975; Montague, 1970a; Siegel, 1976): for instance, a *fake gun* is not a *gun*. Even for *red*, the manner in which the color combines with a noun will be different in *red Ferrari* (the outside), *red watermelon* (the inside), *red traffic light* (the signal). These problems have prompted a more flexible FS representation for attributive adjectives — functions from the meaning of a noun onto the meaning of a modified noun (Montague, 1970a). This mapping could now be sensitive to the particular noun the adjective receives, and it does not need to return a subset of the

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1183–1193,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

original noun denotation (as in the case of *fake N*). However, FS has nothing to say on how these functions should be constructed.

In the last few years there have been attempts to build compositional models that use distributional semantic representations as inputs (see Section 2 below), most of them focusing on the combination of a verb and its arguments. This paper addresses instead the combination of nouns and attributive adjectives. This case was chosen as an interesting testbed because it has the property of recursivity (it applies in *black dog*, but also in *large black dog*, etc.), and because very frequent adjectives such as *different* are at the border between content and function words. Following the insight of FS, we treat attributive adjectives as *functions* over noun meanings; however, noun meanings are vectors, not sets, and the functions are learnt from corpus-based noun-AN vector pairs.

Original contribution We propose and evaluate a new method to derive distributional representations for ANs, where an adjective is a linear function from a vector (the noun representation) to another vector (the AN representation). The linear map for a specific adjective is learnt, using linear regression, from pairs of noun and AN vectors extracted from a corpus.

Outline Distributional approaches to compositionality are shortly reviewed in Section 2. In Section 3, we introduce our proposal. The experimental setting is described in Section 4. Section 5 provides some empirical justification for using corpus-harvested AN vectors as the target of our function learning and evaluation benchmark. In Section 6, we show that our model outperforms other approaches at the task of approximating such vectors for unseen ANs. In Section 7, we discuss how adjectival meaning can be represented in our model and evaluate this representation in an adjective clustering task. Section 8 concludes by sketching directions for further work.

2 Related work

The literature on compositionality in vector-based semantics encompasses various related topics, some of them not of direct interest here, such as how to encode word order information in context vectors (Jones and Mewhort, 2007; Sahlgren et al., 2008) or sophisticated composition methods based on tensor products, quantum logic, etc., that have not yet been empirically tested on large-scale corpus-based semantic space tasks (Clark and Pulman, 2007; Rudolph and Giesbrecht, 2010; Smolensky, 1990; Widdows, 2008). Closer to our current purposes is the general framework for vector composition proposed by Mitchell and Lapata (2008), subsuming various earlier proposals. Given two vectors $\mathbf{u}$ and $\mathbf{v}$, they identify two general classes of composition models, (linear) additive models:

$$\mathbf{p} = \mathbf{A}\mathbf{u} + \mathbf{B}\mathbf{v} \tag{1}$$

where $\mathbf{A}$ and $\mathbf{B}$ are weight matrices, and multiplicative models:

$$\mathbf{p} = \mathbf{C}\mathbf{u}\mathbf{v}$$

where $\mathbf{C}$ is a weight tensor projecting the $\mathbf{uv}$ tensor product onto the space of $\mathbf{p}$. Mitchell and Lapata derive two simplified models from these general forms. Their simplified additive model $\mathbf{p} = \alpha\mathbf{u} + \beta\mathbf{v}$ was a common approach to composition in the earlier literature, typically with the scalar weights set to 1 or to normalizing constants (Foltz et al., 1998; Kintsch, 2001; Landauer and Dumais, 1997). Mitchell and Lapata also consider a constrained version of the multiplicative approach that reduces to component-wise multiplication, where the i-th component of the composed vector is given by: $p_i = u_i v_i$. The simplified additive model produces a sort of (statistical) union of features, whereas component-wise multiplication has an intersective effect. They also evaluate a weighted combination of the simplified additive and multiplicative functions. The best results on the task of paraphrasing noun-verb combinations with ambiguous verbs (*sales slump* is more like *declining* than *slouching*) are obtained using the multiplicative approach, and by weighted combination of addition and multiplication (we do not test model combinations in our current experiments). The multiplicative approach also performs best (but only by a small margin) in a later application to language modeling (Mitchell and Lapata, 2009). Erk and Padó (2008; 2009) adopt the same formalism but focus on the nature of input vectors, suggesting that when a verb is composed with a noun, the noun component is given by an average of verbs that the noun is typically object of (along similar lines, Kintsch (2001) also focused on composite input vectors, within an additive framework). Again, the multiplicative model works best in Erk and Padó's experiments.

The above-mentioned researchers do not exploit corpus evidence about the $\mathbf{p}$ vectors that result from composition, despite the fact that it is straightforward (at least for short constructions) to extract direct distributional evidence about the composite items from the corpus (just collect co-occurrence information for the composite item from windows around the contexts in which it occurs). The main innovation of Guevara (2010), who focuses on adjective-noun combinations (AN), is to use the co-occurrence vectors of observed ANs to train a supervised composition model (we became aware of Guevara's approach after we had developed our own model, that also exploits observed ANs for training). Guevara adopts the full additive composition form from Equation (1) and he estimates the $\mathbf{A}$ and $\mathbf{B}$ weights using partial least squares regression. The training data are pairs of adjective-noun vector concatenations, as input, and corpus-derived AN vectors, as output. Guevara compares his model to the simplified additive and multiplicative models of Mitchell and Lapata. Observed ANs are nearer, in the space of observed and predicted test set ANs, to the ANs generated by his model than to those from the alternative approaches. The additive model, on the other hand, is best in terms of shared neighbor count between observed and predicted ANs.

In our empirical tests, we compare our approach to the simplified additive and multiplicative models of Mitchell and Lapata (the former with normalization constants as scalar weights) as well as to Guevara's approach.

3 Adjectives as linear maps

As discussed in the introduction, we will take adjectives in attributive position to be functions from one noun meaning to another. To start simple, we assume here that adjectives in the attributive position (AN) are linear functions from n-dimensional (noun) vectors onto n-dimensional vectors, an operation that can be expressed as multiplication of the input noun column vector by a $n \times n$ matrix, that is our representation for the adjective (in the language of linear algebra, an adjective is an endomorphic linear map in noun space). In the framework of Mitchell and Lapata, our approach derives from the additive form in Equation (1) with the matrix multiplying the adjective vector (say, $\mathbf{A}$) set to $\mathbf{0}$:

$$\mathbf{p} = \mathbf{B}\mathbf{v}$$

where $\mathbf{p}$ is the observed AN vector, $\mathbf{B}$ the weight matrix representing the adjective at hand, and $\mathbf{v}$ a noun vector. In our approach, the weight matrix $\mathbf{B}$ is specific to a single adjective – as we will see in Section 7 below, it is our representation of the meaning of the adjective.

Like Guevara, we estimate the values in the weight matrix by partial least squares regression. In our case, the independent variables for the regression equations are the dimensions of the corpus-based vectors of the component nouns, whereas the AN vectors provide the dependent variables. Unlike Guevara, (i) we train separate models for each adjective (we learn adjective-specific functions, whereas Guevara learns a generic "AN-slot" function) and, consequently, (ii) corpus-harvested adjective vectors play no role for us (their values would be constant across the training input vectors).

A few considerations are in order. First, although we use a supervised learning method (least squares regression), we do not need hand-annotated data, since the target AN vectors are automatically collected from the corpus just like vectors for single words are. Thus, there is no extra "external knowledge" cost with respect to unsupervised approaches. Second, our approach rests on the assumption that the corpus-derived AN vectors are interesting objects that should constitute the target of what a composition process tries to approximate. We provide preliminary empirical support for this assumption in Section 5 below. Third, we have some reasonable hope that our functions can capture to a certain extent the polysemous nature of adjectives: we could learn, for example, a *green* matrix with large positive weights mapping from noun features that pertain to concrete objects to color dimensions of the output vector (*green chair*), as well as large positive weights from features characterizing certain classes of abstract concepts to political/social dimensions in the output (*green initiative*). Somewhat optimistically, we hope that *chair* will have near-0 values on the relevant abstract dimensions, like *initiative* on the concrete features, and thus the weights will not interfere. We do not evaluate this claim specifically, but our quantitative evaluation in Section 6 shows that our approach does best with high frequency, highly ambiguous adjectives. Fourth, the approach is naturally syntax-sensitive, since we train it on observed data for a specific syntactic position: we would train separate linear models for, say, the same adjective in attributive (AN) and predicative (N is A) position. As a matter of fact, the current model is too syntax-sensitive and does not capture similarities across different constructions. Finally, although adjective representations are not directly harvested from corpora, we can still meaningfully compare adjectives to each other or other words by using their estimated matrix, or an average vector for the ANs that contain them: both options are tested in Section 7 below.

4 Experimental setup

4.1 Corpus

We built a large corpus by concatenating the Web-derived ukWaC corpus (`http://wacky.sslmit.unibo.it/`), a mid-2009 dump of the English Wikipedia (`http://en.wikipedia.org`) and the British National Corpus (`http://www.natcorp.ox.ac.uk/`). This **concatenated corpus**, tokenized, POS-tagged and lemmatized with the TreeTagger (Schmid, 1995), contains about 2.83 billion tokens (excluding punctuation, digits, etc.). The ukWaC and Wikipedia sections can be freely downloaded, with full annotation, from the ukWaC site.

We performed some of the list extraction and checking operations we are about to describe on a more manageable data-set obtained by selecting the first 100M tokens of ukWaC; we refer to this subset as the **sample corpus** below.

4.2 Vocabulary

We could in principle limit ourselves to collecting vectors for the ANs to be analyzed (the *AN test set*) and their components. However, to make the analysis more challenging and interesting, we populate the semantic space where we will look at the behaviour of the ANs with a large number of adjectives and nouns, as well as further ANs not in the test set. We refer to the overall list of items we build semantic vectors for as the *extended vocabulary*. We use a subset of the extended vocabulary containing only nouns and adjectives (the *core vocabulary*) for feature selection and dimensionality reduction, so that we do not implicitly bias the structure of the semantic space by our choice of ANs.

To construct the **AN test set**, we first selected 36 adjectives across various classes: size (*big, great, huge, large, major, small, little*), denominal (*American, European, national, mental, historical, electronic*), colors (*white, black, red, green*) positive evaluation (*nice, excellent, important, appropriate*), temporal (*old, recent, new, young, current*), modal (*necessary, possible*), plus some common abstract antonymous pairs (*difficult, easy, good, bad, special, general, different, common*). We were careful to include intersective cases such as *electronic* as well as non-intersective adjectives that are almost function words (the modals, *different*, etc.). We extracted all nouns that occurred at least 300 times in post-adjectival position in the sample corpus, excluding some extremely frequent temporal and measure expressions such as *time* and *range*, for a total of 1,420 distinct nouns. By crossing the selected adjectives and nouns, we constructed a test set containing 26,440 ANs, all attested in the sample corpus (734 ANs per adjective on average, ranging from 1,337 for *new* to 202 for *mental*).

The **core vocabulary** contains the top 8K most frequent noun lemmas and top 4K adjective lemmas from the concatenated corpus (excluding the top 50 most frequent nouns and adjectives). The **extended vocabulary** contains this core plus (i) the 26,440 test ANs, (ii) the 16 adjectives and 43 nouns that are components of these ANs and that are not in the core set, and (iii) 2,500 more ANs randomly sampled from those that are attested in the sample corpus, have a noun from the same list used for the test set ANs, and an adjective that occurred at least 5K times in the sample corpus. In total, the extended vocabulary contains 40,999 entries: 8,043 nouns, 4,016 adjectives and 28,940 ANs.

4.3 Semantic space construction

Full co-occurrence matrix The 10K lemmas (nouns, adjectives or verbs) that co-occur with the largest number of items in the core vocabulary constitute the dimensions (columns) of our co-occurrence matrix. Using the concatenated corpus, we extract sentence-internal co-occurrence counts of all the items in the extended vocabulary with the 10K dimension words. We then transform the raw counts into Local Mutual Information (LMI) scores (LMI is an association measure that closely approximates the Log-Likelihood Ratio, see Evert (2005)).

Dimensionality reduction Since, for each test set adjective, we need to estimate a regression model for each dimension, we want a compact space with relatively few, dense dimensions. A natural way to do this is to apply the Singular Value Decomposition (SVD) to the co-occurrence matrix, and represent the items of interest with their coordinates in the space spanned by the first n right singular vectors. Applying SVD is independently justified because, besides mitigating the dimensionality problem, it often improves the quality of the semantic space (Landauer and Dumais, 1997; Rapp, 2003; Schütze, 1997). To avoid bias in favour of dimensions that capture variance in the test set ANs, we applied SVD to the core vocabulary subset of the co-occurrence matrix (containing only adjective and noun rows). The core 12K×10K matrix was reduced using SVD to a 12K×300 matrix. The other row vectors of the full co-occurrence matrix (including the ANs) were projected onto the same reduced space by multiplying them by a matrix containing the first n right singular vectors as columns. Merging the items used to compute the SVD and those projected onto the resulting space, we obtain a 40,999×300 matrix representing 8,043 nouns, 4,016 adjectives and 28,940 ANs. This reduced matrix constitutes a realistically sized semantic space, that also contains many items that are not part of our test set, but will be potential neighbors of the observed and predicted test ANs in the experiments to follow. The quality of the SVD reduction itself was independently validated on a standard similarity judgment data-set (Rubenstein and Goodenough, 1965), obtaining similar (and state-of-the-art-range) Pearson correlations of vector cosines and human judgments in both the original ($r = .70$) and reduced ($r = .72$) spaces.

There are several parameters involved in constructing a semantic space (choice of full and reduced dimensions, co-occurrence span, weighting method). Since our current focus is on alternative composition methods evaluated on a shared semantic space, exploring parameters pertaining to the construction of the semantic space is not one of our priorities, although we cannot of course exclude that the nature of the underlying semantic space affects different composition methods differently.

4.4 Composition methods

In the proposed **adjective-specific linear map** (*alm*) method, an AN is generated by multiplying an adjective weight matrix with a noun (column) vector. The j weights in the i-th row of the matrix are the coefficients of a linear regression predicting the values of the i-th dimension of the AN vector as a linear combination of the j dimensions of the component noun. The linear regression coefficients are estimated separately for each of the 36 tested adjectives from the corpus-observed noun-AN pairs containing that adjective (observed adjective vectors are not used). Since we are working in the 300-dimensional right singular vector space, for each adjective we have 300 regression problems with 300 independent variables, and the training data (the noun-AN pairs available for each test set adjective) range from about 200 to more than 1K items. We estimate the coefficients using (multivariate) partial least squares regression (PLSR) as implemented in the R `pls` package (Mevik and Wehrens, 2007). With respect to standard least squares estimation, this technique is more robust against over-training by effectively using a smaller number of orthogonal "latent" variables as predictors (Hastie et al., 2009, Section 3.4), and it exploits the multivariate nature of the problem (different regressions for each AN vector dimension to be predicted) when determining the latent dimensions. The number of latent variables to be used in the core regression are a free parameter of PLSR. For efficiency reasons, we did not optimize it. We picked instead 50 latent variables, by the rule-of-thumb reasoning that for any adjective we can use at least 200 noun-AN pairs for training, and the independent-variable-to-training-item ratio will thus never be above 1/4. We adopt a leave-one-out training regime, so that each target AN is generated by an adjective matrix that was estimated from all the other ANs with the same adjective, minus the target.

We use PLSR with 50 latent variables also for our re-implementation of Guevara's (2010) **single linear map** (*slm*) approach, in which a single regression matrix is estimated for all ANs across adjectives. The training data in this case are given by the concatenation of the observed adjective and noun vectors (600 independent variables) coupled with the corresponding AN vectors (300 dependent variables). For each target AN, we randomly sample 2,000 other adjective-noun-AN tuples for training (with larger training sets we run into memory problems), and use the resulting coefficient matrix to generate the AN vector from the concatenated target adjective and noun vectors.

Additive AN vectors (*add* method) are obtained by summing the corresponding adjective and noun vectors after normalizing them (non-normalized addition was also tried, but it did not work nearly as well as the normalized variant). **Multiplicative** vectors (*mult* method) were obtained by component-wise multiplication of the adjective and noun vectors (normalization does not matter here since it amounts to multiplying the composite vector by a scalar, and the cosine similarity measure we use is scale-invariant). Finally, the *adj* and *noun* baselines use the **adjective** and **noun** vectors, respectively, as surrogates of the AN vector.

For the *add*, *mult*, *adj* and *noun* methods, we ran the tests of Section 6 not only in the SVD-reduced space, but also in the original 10K-dimensional co-occurrence space. Only the *mult* method achieved better performance in the original space. We conjecture that this is because the SVD dimensions can have negative values, leading to counter-intuitive results with component-wise multiplication (multiplying large opposite-sign values results in large negative values). We tried to alleviate this problem by assigning a 0 to composite dimensions where the two input vectors had different signs. The resulting performance was better but still below that of *mult* in original space. Thus, in Section 6 we report *mult* results from the full co-occurrence matrix; reduced space results for all other methods.

5 Study 1: ANs in semantic space

The actual distribution of ANs in the corpus, as recorded by their co-occurrence vectors, is fundamental to what we are doing. Our method relies on the hypothesis that the semantics of AN composition does not depend on the independent distribution of adjectives themselves, but on how adjectives transform the distribution of nouns, as evidenced by observed pairs of noun-AN vectors. Moreover, coherently with this view, our evaluation below will be based on how closely the models approximate the observed vectors of unseen ANs.

That our goal in modeling composition should be to approximate the vectors of observed ANs is in a sense almost trivial. Whether we synthesize an AN for generation or decoding purposes, we would want the synthetic AN to look as much as possible like a real AN in its natural usage contexts, and co-occurrence vectors of observed ANs are a summary of their usage in actual linguistic contexts. However, it might be the case that the specific resources we used for our vector construction procedure are not appropriate, so that the specific observed AN vectors we extract are not reliable (e.g., they are so sparse in the original space as to be uninformative, or they are strictly tied to the domains of the input corpora). We provide here some preliminary qualitative evidence that this is in general not the case, by tapping into our own intuitions on where ANs should be located in semantic space, and thus on how sensible their neighbors are.

First, we computed centroids from normalized SVD space vectors of all the ANs that share the same adjective (e.g., the normalized vectors of *American adult*, *American menu*, etc., summed to construct the *American N* centroid). We looked at the nearest neighbors of these centroids in semantic space among the 41K items (adjectives, nouns and ANs) in our extended vocabulary (here and in all experiments below, similarity is quantified by the cosine of the angle between two vectors). As illustrated for a random sample of 9 centroids in Table 1 (but applying to the remaining 27 adjectives as well), centroids are positioned in intuitively reasonable areas of the space, typically near the adjective itself or the corresponding noun (the noun *green* near *green N)*, prototypical ANs for that adjective (*black face*), elements related to the definition of the adjective (*mental activity*, *historical event*, *green colour*, *quick* and *little cost* for *easy N*), and so on.

American N	*black N*	*easy N*
Am. representative Am. territory Am. source	black face black hand black (n)	easy start quick little cost
green N	*historical N*	*mental N*
green (n) red road green colour	historical hist. event hist. content	mental activity mental experience mental energy
necessary N	*nice N*	*young N*
necessary necessary degree sufficient	nice good bit nice break	youthful young doctor young staff

Table 1: Nearest 3 neighbors of centroids of ANs that share the same adjective.

How about the neighbors of specific ANs? Table 2 reports the nearest 3 neighbors of 9 randomly selected ANs involving different adjectives (we inspected a larger random set, coming to similar conclusions to the ones emerging from this table).

bad luck	*electronic communication*	*historical map*
bad bad weekend good spirit	elec. storage elec. transmission purpose	topographical atlas hist. material
important route	*nice girl*	*little war*
important transport important road major road	good girl big girl guy	great war major war small war
red cover	*special collection*	*young husband*
black cover hardback red label	general collection small collection archives	small son small daughter mistress

Table 2: Nearest 3 neighbors of specific ANs.

The nearest neighbors of the corpus-based AN vectors in Table 2 make in general intuitive sense. Importantly, the neighbors pick up the composite meaning rather than that of the adjective or noun alone. For example, *cover* is an ambiguous word, but the *hardback* neighbor relates to its "front of a book" meaning that is the most natural one in combination with *red*. Similarly, it makes more sense that a *young husband* (rather than an old one) would have *small sons* and *daughters* (not to mention the *mistress*!).

We realize that the evidence presented here is of a very preliminary and intuitive nature. Indeed, we will argue in the next section that there are cases in which the corpus-derived AN vector might not be a good approximation to our semantic intuitions about the AN, and a model-composed AN vector is a better semantic surrogate. One of the most important avenues for further work will be to come to a better characterization of the behaviour of corpus-observed ANs, where they work and where the don't. Still, the neighbors of average and AN-specific vectors of Tables 1 and 2 suggest that, for the bulk of ANs, such corpus-based co-occurrence vectors are semantically reasonable.

6 Study 2: Predicting AN vectors

Having tentatively established that the sort of vectors we can harvest for ANs by directly collecting their corpus co-occurrences are reasonable representations of their composite meaning, we move on to the core question of whether it is possible to reconstruct the vector for an unobserved AN from information about its components. We use nearness to the corpus-observed vectors of held-out ANs as a very direct way to evaluate the quality of model-generated ANs, since we just saw that the observed ANs look reasonable (but see the caveats at the end of this section). We leave it to further work to assess the quality of the generated ANs in an applied setting, for example adapting Mitchell and Lapata's paraphrasing task to ANs. Since the observed vectors look like plausible representations of composite meaning, we expect that the closer the model-generated vectors are to the observed ones, the better they should also perform in any task that requires access to the composite meaning, and thus that the results of the current evaluation should correlate with applied performance.

More in detail, we evaluate here the composition methods (and the *adjective* and *noun* baselines) by computing, for each of them, the cosine of the test set AN vectors they generate (the "predicted" ANs) with the 41K vectors representing our extended vocabulary in semantic space, and looking at the position of the corresponding observed ANs (that were not used for training, in the supervised approaches) in the cosine-ranked lists. The lower the rank, the better the approximation. For efficiency reasons, we flatten out the ranks after the top 1,000 neighbors.

The results are summarized in Table 3 by the median and the other quartiles, calculated across all 26,440 ANs in the test set. These measures (unlike mean and variance) are not affected by the cut-off after 1K neighbors. To put the reported results into perspective, a model with a first quartile rank of 999 does very significantly better than chance (the binomial probability of $1/4$ or more of 26,440 trials being successful with $\pi = 0.024$ is virtually 0, where the latter quantity is the probability of an observed AN being at rank 999 or lower according to a geometric distribution with $\pi = 1/40999$).

method	*25%*	*median*	*75%*
alm	17	170	≥1K
add	27	257	≥1K
noun	72	448	≥1K
mult	279	≥1K	≥1K
slm	629	≥1K	≥1K
adj	≥1K	≥1K	≥1K

Table 3: Quartile ranks of observed ANs in cosine-ranked lists of predicted AN neighbors.

Our proposed method, *alm*, emerges as the best approach. The difference with the second best model, *add* (the only other model that does better than the non-trivial baseline of using the component noun vector as a surrogate for AN), is highly statistically significant (Wilcoxon signed rank test, $p < 0.00001$). If we randomly downsample the AN set to keep an equal number of ANs per adjective (200), the difference is still significant with p below the same threshold, indicating that the general result is not due to a better performance of *alm* on a few common adjectives.[1]

Among the alternative models, the fact that the performance of *add* is decidedly better than that of *mult* is remarkable, since earlier studies found that multiplicative models are, in general, better than additive ones in compositionality tasks (see Section 2 above). This might depend on the nature of AN composition, but there are also more technical issues at hand: (i) we are not sure that previous studies normalized before summing like we did, and (ii) the multiplicative model, as discussed in Section 4, does not benefit from SVD reduction. The single linear mapping model (*slm*) proposed by Guevara (2010) is doing even worse than the multiplicative method, suggesting that a single set of weights does not provide enough flexibility to model a variety of adjective transformations successfully. This is at odds with Guevara's experiment in which *slm* outperformed *mult* and *add* on the task of ranking predicted ANs with respect to a target observed AN. Besides various differences in task definition and model implementation, Guevara trained his model on ANs that include a wide variety of adjectives, whereas our training data were limited to ANs containing one of our 36 test set adjectives. Future work should re-evalute the performance of Guevara's approach in our task, but under his training regime.

Looking now at the *alm* results in more detail, the best median ranks are obtained for very frequent adjectives. The top ones are *new* (median rank: 34), *great* (79), *American* (82), *large* (82) and *different* (97). There is a high inverse correlation between median rank and adjective frequency (Spearman's $\rho = -0.56$). Although from a statistical perspective it is expected that we get better results where we have more data, from a linguistic point of view it is interesting that *alm* works best with extremely frequent, highly polysemous adjectives like *new*, *large* and *different*, that border on function words – a domain where distributional semantics has generally not been tested.

Although, in relative terms and considering the difficulty of the task, *alm* performs well, it is still far from perfect – for 27% *alm*-predicted ANs, the observed vector is not even in the top 1K neighbor set! A qualitative look at some of the most problematic examples indicates however that a good proportion of them might actually not be instances where our model got the AN vector wrong, but cases of anomalous observed ANs. The left side of Table 4 compares the nearest neighbors (excluding each other) of the observed and *alm*-predicted vectors in 10 ran-

[1] The semantic space in which we rank the observed ANs with respect to their predicted counterparts also contain the observed vectors of nouns and ANs that were used to train *alm*. We do not see how this should affect performance, but we nevertheless repeated the evaluation leaving out, for each AN, the observed items used in training, and we obtained the same results reported in the main text (same ordering of method performance, and very significant difference between *alm* and *add*).

SIMILAR			DISSIMILAR		
adj N	*obs. neighbor*	*pred. neighbor*	*adj N*	*obs. neighbor*	*pred. neighbor*
common understanding	common approach	common vision	American affair	Am. development	Am. policy
different authority	diff. objective	diff. description	current dimension	left (a)	current element
different partner	diff. organisation	diff. department	good complaint	current complaint	good beginning
general question	general issue	*same*	great field	excellent field	gr. distribution
historical introduction	hist. background	*same*	historical thing	different today	hist. reality
necessary qualification	nec. experience	*same*	important summer	summer	big holiday
new actor	new cast	*same*	large pass	historical region	large dimension
recent request	recent enquiry	*same*	special something	little animal	special thing
small drop	droplet	drop	white profile	chrome (n)	white show
young engineer	young designer	y. engineering	young photo	important song	young image

Table 4: Left: nearest neighbors of observed and *alm*-predicted ANs (excluding each other) for a random set of ANs where rank of observed w.r.t. predicted is 1. Right: nearest neighbors of predicted and observed ANs for random set where rank of observed w.r.t. predicted is $\geq 1K$.

domly selected cases where the observed AN is the nearest neighbor of the predicted one. Here, the ANs themselves make sense, and the (often shared) neighbors are also sensible (*recent enquiry* for *recent request*, *common approach* and *common vision* for *common understanding*, etc.). Moving to the right, we see 10 random examples of ANs where the observed AN was at least 999 neighbors apart from the *alm* prediction. First, we notice some ANs that are difficult to interpret out-of-context (*important summer*, *white profile*, *young photo*, *large pass*, ...). Second, at least subjectively, we find that in many cases the nearest neighbor of predicted AN is actually more sensible than that of observed AN: *current element* (vs. *left*) for *current dimension*, *historical reality* (vs. *different today*) for *historical thing*, *special thing* (vs. *little animal*) for *special something*, *young image* (vs. *important song*) for *young photo*. In the other cases, the predicted AN neighbor is at least not obviously worse than the observed AN neighbor.

There is a high inverse correlation between the frequency of occurrence of an AN and the rank of the observed AN with respect to the predicted one ($\rho = -0.48$), suggesting that our model is worse at approximating the observed vectors of rare forms, that might, in turn, be those for which the corpus-based representation is less reliable. In these cases, dissimilarities between observed and expected vectors, rather than signaling problems with the model, might indicate that the predicted vector, based on a composition function learned from many examples, is *better* than the one directly extracted from the corpus. The examples in the right panel of Table 4 bring some preliminary support to this hypothesis, to be systematically explored in future work.

7 Study 3: Comparing adjectives

If adjectives are functions, and not corpus-derived vectors, is it still possible to compare them meaningfully? We explore two ways to accomplish this in our framework: one is to represent adjectives by the average of the AN vectors that contain them (the centroid vectors whose neighbors are illustrated in Table 1 above), and the other to compare them based on the 300×300 weight matrices we estimate from noun-AN pairs (we unfold these matrices into 90K-dimensional vectors). We compare the quality of these representations to that of the standard approach in distributional semantics, i.e., representing the adjectives directly with their corpus co-occurrence profile vectors (in our case, projected onto the SVD-reduced space).

We evaluate performance on the task of clustering those 19 adjectives in our set that can be relatively straightforwardly categorized into general classes comprising a minimum of 4 items. The test set built according to these criteria contains 4 classes: color (*white*, *black*, *red*, *green*), positive evaluation (*nice*, *excellent*, *important*, *major*, *appropriate*), time (*recent*, *new*, *current*, *old*, *young*), and size (*big*, *huge*, *little*, *small*, *large*). We cluster with the CLUTO toolkit (Karypis, 2003), using the *repeated bisections with global optimization* method, accepting all of CLUTO's default values for this choice. Cluster quality is evaluated by percentage *purity* (Zhao and Karypis, 2003). If n_r^i is the number of items from the *i*-th true (gold standard) class assigned to the *r*-th cluster, n is the total number of items and k the number of clusters, then: $Purity = \frac{1}{n}\sum_{r=1}^{k} \max_i(n_r^i)$. We calculate empirical 95% confidence intervals around purity by a heuristic bootstrap procedure based on 10K resamplings of the data set (Efron and Tibshirani, 1994). The random baseline distribution is obtained by 10K random assignments of adjectives to the clusters, under the constraint that no cluster is empty.

Table 5 shows that all methods are significantly better than chance. Our two "indirect" representations achieve similar performance, and they are (slightly) better than the traditional method based on adjective co-occurrence vectors. We conclude that, although our approach does not provide a direct encoding of adjective meaning in terms of such independently collected vectors, it does have meaningful ways to represent their semantic properties.

input	*purity*
matrix	73.7 (68.4-94.7)
centroid	73.7 (63.2-94.7)
vector	68.4 (63.2-89.5)
random	45.9 (36.8-57.9)

Table 5: Percentage purity in adjective clustering with bootstrapped 95% confidence intervals.

8 Conclusion

The work we reported constitutes an encouraging start for our approach to modeling (AN) composition. We suggested, along the way, various directions for further studies. We consider the following issues to be the most pressing ones.

We currently train each adjective-specific model separately: We should explore hierarchical modeling approaches that exploit similarities across adjectives (and possibly syntactic constructions) to estimate better models.

Evaluation-wise, the differences between observed and predicted ANs must be analyzed more extensively, to support the claim that, when their vectors differ, model-based prediction improves on the observed vector. Evaluation in a more applied task should also be pursued – in particular, we will design a paraphrasing task similar to the one proposed by Mitchell and Lapata to evaluate noun-verb constructions.

Since we do not collect vectors for the "functor" component of a composition process (for AN constructions, the adjective), our approach naturally extends to processes that involve bound morphemes, such as affixation, where we would not need to collect independent co-occurrence information for the affixes. For example, to account for *re-* prefixation we do not need to collect a *re-* vector (required by all other approaches to composition), but simply vectors for a set of *V*/*reV* pairs, where both members of the pairs are words (e.g., *consider*/*reconsider*).

Our approach can also deal, out-of-the-box, with recursive constructions (*sad little red hat*), and can be easily extended to more abstract constructions, such as *determiner N* (mapping *dog* to *the/a/one dog*). Still, we need to design a good testing scenario to evaluate the quality of such model-generated constructions.

Ultimately, we want to compose larger and larger constituents, up to full sentences. It remains to be seen if the approach we proposed will scale up to such challenges.

Practical Linguistic Steganography using Contextual Synonym Substitution and Vertex Colour Coding

Abstract

Linguistic Steganography is concerned with hiding information in natural language text. One of the major transformations used in Linguistic Steganography is synonym substitution. However, few existing studies have studied the practical application of this approach. In this paper we propose two improvements to the use of synonym substitution for encoding hidden bits of information. First, we use the Web 1T Google n-gram corpus for checking the applicability of a synonym in context, and we evaluate this method using data from the SemEval lexical substitution task. Second, we address the problem that arises from words with more than one sense, which creates a potential ambiguity in terms of which bits are encoded by a particular word. We develop a novel method in which words are the vertices in a graph, synonyms are linked by edges, and the bits assigned to a word are determined by a vertex colouring algorithm. This method ensures that each word encodes a unique sequence of bits, without cutting out large number of synonyms, and thus maintaining a reasonable embedding capacity.

1 Introduction

Steganography is concerned with hiding information in a cover medium, in order to facilitate covert communication, such that the presence of the information is imperceptible to a user (human or computer). Much of the existing research in steganography has used images as cover media; however, given the ubiquitous nature of electronic text, interest is growing in using natural language as the cover medium. Linguistic Steganography—lying at the intersection of Computational Linguistics and Computer Security—is concerned with making changes to a cover text in order to embed information, in such a way that the changes do not result in ungrammatical or unnatural text.

A related area is natural language watermarking, in which changes are made to a text in order to identify it, for example for copyright purposes. An interesting watermarking application is "traitor tracing", in which documents are changed in order to embed individual watermarks. These marks can then be used to later identify particular documents, for example if a set of documents—identical except for the changes used to embed the watermarks— have been sent to a group of individuals, and one of the documents has been leaked to a newspaper.

In terms of security, a linguistic stegosystem should impose minimum embedding distortion to the cover text so that the resulting stegotext in which a message is camouflaged is inconspicuous, resulting in high *imperceptibility*. In addition, since steganography aims at covert communication, a linguistic stegosystem should allow sufficient embedding capacity, known as the *payload*. There is a fundamental tradeoff between imperceptibility and payload, since any attempt to embed more information via changes to the cover text increases the chance of introducing anomalies into the text and therefore raising the suspicion of an observer.

A linguistic transformation is required to embed information. Transformations studied in previous work include lexical substitution (Chapman and Davida, 1997; Bolshakov, 2004; Taskiran et al., 2006; Topkara et al., 2006b), phrase paraphrasing (Chang and Clark, 2010), sentence structure manipulations (Atallah et al., 2001a; Atallah et al., 2001b;

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1194–1203,
MIT, Massachusetts, USA, 9-11 October 2010.

Liu et al., 2005; Meral et al., 2007; Murphy, 2001; Murphy and Vogel, 2007; Topkara et al., 2006a) and semantic transformations (Atallah et al., 2002; Vybornova and Macq, 2007). Many of these transformations require some sophisticated NLP tools; for example, in order to perform semantic transformations on text, word sense disambiguation, semantic role parsing and anaphora resolution tools may be required. However, the current state-of-the-art in language technology is arguably not good enough for secure linguistic steganography based on sophisticated semantic transformations, and the level of robustness required to perform practical experiments has only just become available. Hence many existing linguistic stegosystems are proof-of-concept implementations with little practical evaluation of the imperceptibility or payload.

1.1 Synonym substitution

Synonym substitution is a relatively straightforward linguistic steganography method. It substitutes selected words with the same part of speech (PoS) synonyms, and does not involve operating on the sentence structure so the modification can be guaranteed to be grammatical. Another advantage of this method is that many languages are profuse in synonyms, and so there is a rich source of information carriers compared with other text transformations.

There are two practical difficulties associated with hiding bits using synonym subsitution. The first is that words can have more than one sense. In terms of WordNet (Fellbaum, 1998), which is the electronic dictionary we use, words can appear in more than one synset. This is a problem because a word may be assigned different bit strings in the different synsets, and the receiver does not know which of the senses to use, and hence does not know which hidden bit string to recover. Our solution to this problem is a novel vertex colouring method which ensures that words are always assigned the same bit string, even when they appear in different synsets.

The second problem is that many synonyms are only applicable in certain contexts. For example, the words in the WordNet synset {*bridge*, *span*} share the meaning of "a structure that allows people or vehicles to cross an obstacle such as a river or canal or railway etc.". However, *bridge* and *span* cannot be substutited for each other in the sentence "suspension bridges are typically ranked by the length of their main span", and doing so would likely raise the suspicion of an observer due to the resulting anomaly in the text.

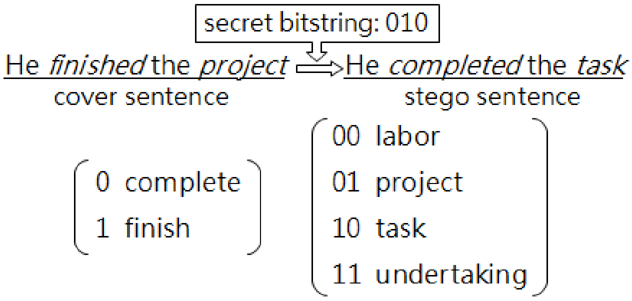

Figure 1: An example of the basic algorithm

Our solution to this problem is to perform a contextual check which utilises the Web 1T n-gram Google n-gram corpus.[1] We evaluate the method using the data from the English Lexical Substitution task for SemEval-2007.[2] The resulting precision of our lexical substitution system can be seen as an indirect measure of the imperceptibility of the stegosystem, whereas the recall can be seen as an indirect measure of the payload.

The paper is organised so that the contextual check is described first, and this is evaluated independently of the steganographic application. Then the vertex colouring method is presented, and finally we show how the contextual check can be integrated with the vertex colouring coding method to give a complete stegsosystem. For readers unfamiliar with linguistic steganogaphy, Section 2 has some examples of how bits can be hidden using textual transformations. Also, Chang and Clark (2010) is a recent NLP paper which describes the general linguistic steganography framework.

2 Related Work

In the original work on linguistic steganography in the late 1990s, Winstein proposed an information hiding algorithm using a block coding method to encode synonyms, so that the selection of a word from a synset directly associates with part of the secret bitstring (Bergmair, 2007). Figure 1 illustrates the embedding procedure of this approach. In this example, the bitstring to be embedded is 010, which

[1] www.ldc.upenn.edu/Catalog/docs/LDC2006T13/readme.txt

[2] http://www.dianamccarthy.co.uk/task10index.html

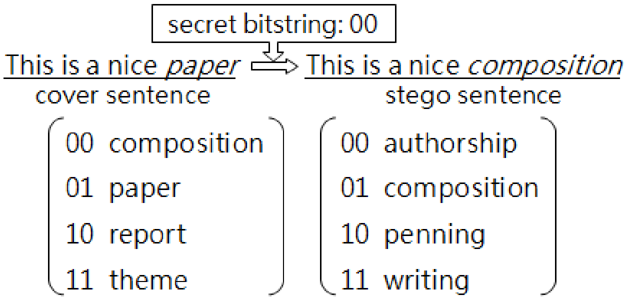

Figure 2: An example of applying the basic algorithm to overlapping synsets

can be divided into two codewords, 0 and 10, and the information carriers in the cover text are the words *finished* and *project*. According to the encoding dictionary, *complete* represents 0, and *task* represents 10; hence these words are chosen and replace the original words in the cover text (with suitable suffixation). The stego sentence "He completed the task" is then sent to the receiver. In order to recover the message, the receiver only needs a copy of the encoding dictionary, and the decoding algorithm simply reverses the process used to encode the hidden bits. Note that the receiver does not need the original cover text to recover the information.

This algorithm requires synonym sets to be disjoint; i.e. no word may appear in more than one synonym set, since overlapping synsets may cause ambiguities during the decoding stage. Figure 2 shows what happens when the basic algorithm is applied to two overlapping synonym sets. As can be seen from the example, *composition* is represented by two different codewords and thus the secret bitstring cannot be reliably recovered, since the receiver does not know the original cover word or the sense of the word. In order to solve this problem, we propose a novel coding method based on vertex colouring, described in Section 4.

In addition to the basic algorithm, Winstein proposed the T-Lex system using synonym substitution as the text transformation. In order to solve the problem of words appearing in more than one synonym set, Winstein defines *interchangeable words* as words that belong to the same synsets, and only uses these words for substitution. Any words that are not interchangeable are discarded and not available for carrying information. The advantage in this approach is that interchangeable words always receive the same codeword. The disadvantage is that many synonyms need to be discarded in order to achieve this property. Winstein calculates that only 30% of WordNet can be used in such a system.

Another stegosystem based on synonym substitution was proposed by Bolshakov (2004). In order to ensure both sender and receiver use the same synsets, Bolshakov applied *transitive closure* to overlapping synsets to avoid the decoding ambiguity. Applying transitive closure leads to a merger of all the overlapping synsets into one set which is then seen as the synset of a target word. Consider the overlapping synsets in Figure 2 as an example. After applying transitive closure, the resulting set is {'authorship', 'composition', 'paper', 'penning', 'report', 'theme', 'writing'}.

Bolshakov (2004) also uses a method to determine whether a substitution is applicable in context, using a collocation-based test. Finally, the collocationally verified synonyms are encoded by using the block coding method. This is similar to our use of the Google n-gram data to check for contextual applicability.

The disadvantage of Bolshakov's system is that all words in a synonym transitive closure chain need to be considered, which can lead to very large sets of synonyms, and many which are not synonymous with the original target word. In contrast, our proposed method operates on the original synonym sets without extending them unnecessarily.

3 Proposed Method and Experiments

3.1 Resources

We use WordNet (Fellbaum, 1998) to provide sets of synonyms (synsets) for nouns, verbs, adjectives and adverbs. Since the purpose of using WordNet is to find possible substitutes for a target word, those synsets containing only one entry are not useful and are ignored by our stegosystem. In addition, our stegosystem only takes single word substitution into consideration in order to avoid the confusion of finding information-carrying words during the decoding phase. For example, if the cover word 'complete' is replaced by 'all over', the receiver would not know whether the secret message is embedded in the word 'over' or the phrase 'all over'. Table 1 shows the statistics of synsets used in our stegosystem.

	noun	verb	adj	adv
# of synsets	16,079	4,529	6,655	964
# of entries	30,933	6,495	14,151	2,025
average set size	2.56	2.79	2.72	2.51
max set size	25	16	21	8

Table 1: Statistics of synsets used in our stegosystem

For the contextual check we use the Google Web 1T 5-gram Corpus (Brants and Franz, 2006) which contains counts for n-grams from unigrams through to five-grams obtained from over 1 trillion word tokens of English Web text. The corpus has been used for many tasks such as spelling correction (Islam and Inkpen, 2009; Carlson et al., 2008) and multi-word expression classification (Kummerfeld and Curran, 2008). Moreover, for the SemEval-2007 English Lexical Substitution Task, which is similar to our substitution task, six out of ten participating teams utilised the Web 1T corpus.

3.2 Synonym Checking Method

In order to measure the degree of acceptability in a substitution, the proposed filter calculates a substitution score for a synonym by using the observed frequency counts in the Web n-gram corpus. The method first extracts contextual n-grams around the synonym and queries the n-gram frequency counts from the corpus. For each n, the total count f_n is calculated by summing up individual n-gram frequencies, for every contextual n-gram containing the target word. We define a *count function* $Count(w) = \sum_{n=2}^{5} log(f_n)$ where $log(0)$ is defined as zero. If $Count(w) = 0$, we assume the word w is unrelated to the context and therefore is eliminated from consideration. We then find the maximum $Count(w)$ called max from the remaining words. The main purpose of having max is to score each word relative to the most likely synonym in the group, so even in less frequent contexts which lead to smaller frequency counts, the score of each synonym can still indicate the degree of feasibility. The substitution score is defined as $Score(w) = Count(w) \div max$. The hypothesis is that a word with a high score is more suitable for the context, and we apply a threshold so that synonyms having a score lower than the threshold are discarded.

f_2=525,856	high *pole*	3,544
	pole .	522,312
f_3=554	very high *pole*	84
	high *pole* .	470
f_4=72	a very high *pole*	72
	very high *pole* .	0
f_5=0	not a very high *pole*	0
	a very high *pole* .	0
Count('*pole*')=log(f_2)+log(f_3)+log(f_4)+log(f_5)=23		
Score('*pole*')=Count('*pole*')/max=0.44>0.37		

Figure 3: An example of using the proposed synonym checking method

Figure 3 demonstrates an example of calculating the substitution score for the synonym 'pole' given the cover sentence "This is not a very high *bar*." First of all, various contextual n-grams are extracted from the sentence and the Web n-gram corpus is consulted to obtain their frequency counts. $Count(\text{'pole'})$ is then calculated using the n-gram frequencies. Suppose the threshold is 0.37, and the max score is 52. Since $Count(\text{'pole'})$ is greater than zero and the substitution score $Score(\text{'pole'})$ is 0.44, the word 'pole' is determined as acceptable for this context (even though it may not be, depending on the meaning of 'bar' in this case).

3.3 Evaluation Data

In order to evaluate the proposed synonym checking method, we need some data to test whether our method can pick out acceptable substitutions. The English Lexical Substitution task for SemEval-2007 has created human-annotated data for developing systems that can automatically find feasible substitutes given a target word in context. This data comprises 2010 sentences selected from the English Internet Corpus[3], and consists of 201 words: nouns, verbs, adjectives and adverbs each with ten sentences containing that word. The five annotators were asked to provide up to three substitutes for a target word in the context of a sentence, and were permitted to consult a dictionary or thesaurus of their choosing.

We use the sentences in this gold standard as the cover text in our experiments so that the substitutes provided by the annotators can be the positive data for evaluating the proposed synonym check-

[3] http://corpus.leeds.ac.uk/internet.html

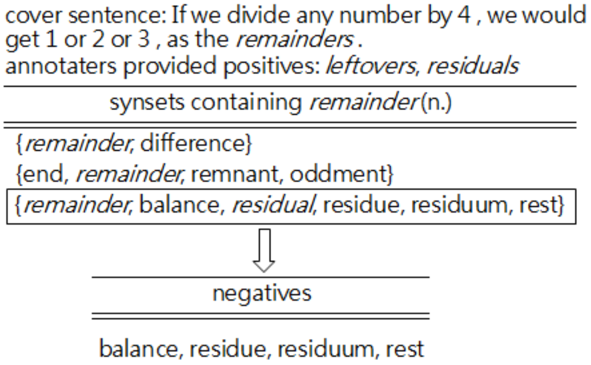
	noun	verb	adj	adv
# of target words	59	54	57	35
# of sentences	570	527	558	349
# of positives	2,343	2,371	2,708	1,269
# of negatives	1,914	1,715	1,868	884

Table 2: Statistics of experimental data

ing methods. Since we only take into consideration the single word substitutions for the reason described earlier, multi-word substitutes are removed from the positive data. Moreover, we use WordNet as the source of providing candidate substitutes in our stegosystem, so if a human-provided substitute does not appear in any synsets of its target word in WordNet, there is no chance for our system to replace the target word with the substitute and therefore, the substitute can be eliminated. Table 2 presents the statistics of the positive data for our experiments.

Apart from positive data, we also need some negative data to test whether our method has the ability to filter out bad substitutions. Since the annotators were allowed to refer to a dictionary or thesaurus, we assume that annotators used WordNet as one of the reference resources while generating candidates. Hence we assume that, if a word in the correct synset for a target word is not in the set produced by the human annotators, then it is inappropriate for that context and a suitable negative example. This method is appropriate because our steganography system has to distinguish between good and bad synonyms from WordNet, given a particular context.

For the above reasons, we extract the negative data for our experiments by first matching positive substitutes of a target word to all the synsets that contain the target word in WordNet. The synset that includes the most positive substitutes is used to represent the meaning of the target word. If there is more than one synset containing the highest number of positives, all the synsets are taken into consideration. We then randomly select up to six single-word synonyms other than positive substitutes from the chosen synset(s) as negative instances of the target word. Figure 4 shows an example of automatically collected negative data from WordNet given a target word and its positive substitutes. The synset {‘remainder’, ‘balance’, ‘residual’, ‘residue’, ‘residuum’, ‘rest’} is selected for negative data collection since it contains one of the positives while the other synsets do not. We assume the selected synset represents the meaning of the original word, and those synonyms in the synset which are not annotated as positives must have a certain degree of mismatch to the context. Therefore, from this example, ‘balance’, ‘residue’, ‘residuum’ and ‘rest’ are extracted as negatives to test whether our synonym checking method can pick out bad substitutions from a set of words sharing similar or the same meaning.



cover sentence: If we divide any number by 4 , we would get 1 or 2 or 3 , as the *remainders* .
annotaters provided positives: *leftovers, residuals*
synsets containing *remainder*(n.)
{*remainder*, difference}
{end, *remainder*, remnant, oddment}
{*remainder*, balance, *residual*, residue, residuum, rest}
negatives
balance, residue, residuum, rest

Figure 4: An example of automatic negative data

	noun	verb	adj	adv
# of true negatives	234	201	228	98
# of false negatives	9	20	28	16

Table 3: Annotation results for negative data

In order to examine whether the automatically collected instances are true negatives and hence form a useful test set, a sample of automatically generated negatives was selected for human evaluation. For each PoS one sentence of each different target word is selected, which results in roughly 13% of the collected negative data, and every negative substitute of the selected sentences was judged by the second author. As can be seen from the annotation results shown in Table 3, most of the instances are true negatives, and only a few cases are incorrectly chosen as false negatives. Since the main purpose of the data set is to test whether the proposed synonym checking method can guard against inappropriate synonym substitutions and be integrated in the stegosystem, it is reasonable to have a few false negatives in our experimental data. Also, it is more harmless to rule out a permissible substitu-

PoS	Acc%	P%	R%	F%	Threshold
noun	70.2	70.0	80.2	74.7	0.58
verb	68.1	69.7	79.5	74.3	0.56
adj	72.5	72.7	85.7	78.7	0.48
adv	73.7	76.4	80.1	78.2	0.54

Table 4: Performance of the synonym checking method

tion than including an inappropriate replacement for a stegosystem in terms of the security. Table 2 gives the statistics of the automatically collected negative data for our experiments.

Note that, although we use the data from the lexical substitution task, our task is different: the possible substitutions for a target word need to be fixed in advance for linguistic steganography (in order for the receiver to be able to recover the hidden bits), whereas for the lexical substitution task participants were asked to discover possible replacements.

3.4 Results

The performance of the proposed checking method is evaluated in terms of accuracy, precision, recall and balanced F-measure. Accuracy represents the percentage of correct judgements over all acceptable and unacceptable substitutions. Precision is the percentage of substitutions judged acceptable by the method which are determined to be suitable synonyms by the human judges. Recall is the percentage of substitutions determined to be feasible by the human annotators which are also judged acceptable by the method. The interpretation of the measures for a stegosystem is that a higher precision value implies a better security level since good substitutions are less likely to be seen as suspicious by the observer; whereas a larger recall value means a greater payload capacity since words are being substituted where possible and therefore embedding as much information as possible.

In order to derive sensible threshold values for each PoS, 5-fold cross-validation was implemented to conduct the experiments. For each fold, 80% of the data is used to find the threshold value which maximises the accuracy, and that threshold is then applied to the remaining 20% to get the final result. Table 4 gives the results for the synonym checking method and the average threshold values over the 5 folds. In addition, we are interested in the effect of various thresholds on the system performance. Figure 5 shows the precision and recall values with respect to different thresholds for each PoS. From the graphs we can clearly see the trade-off between precision and recall. Although a higher precision can be achieved by using a higher threshold value, for example noun's substitutions almost reach 90% precision with threshold equal to 0.9, the large drop in recall means many applicable synonyms are being eliminated. In other words, the trade-off between precision and recall implies the trade-off between imperceptibility and payload capacity for linguistic steganography. Therefore, the practical threshold setting would depend on how steganography users want to trade off imperceptibility for payload.

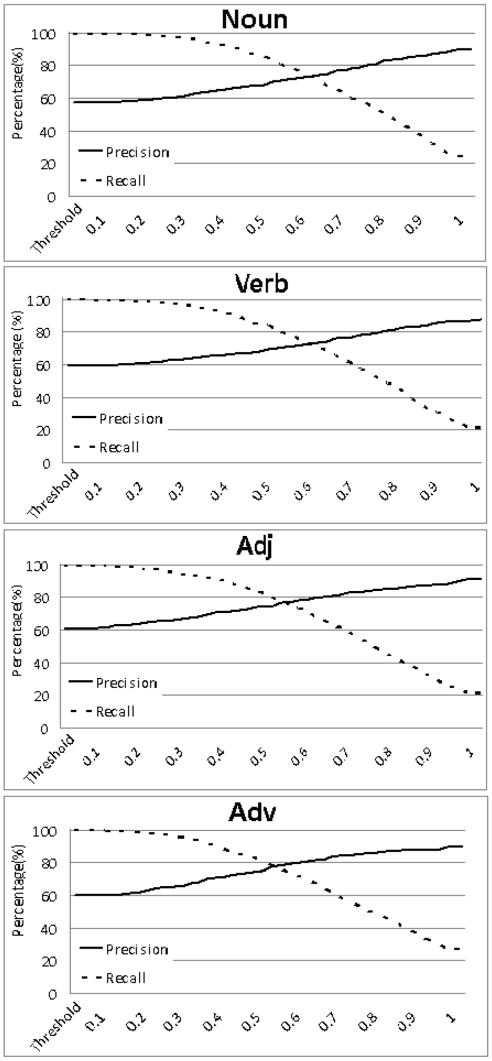


Figure 5: System performance under various thresholds

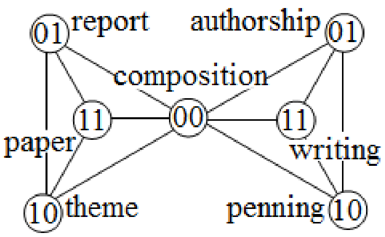

Figure 6: An example of coloured synonym graph

4 Proposed Stegosystem

4.1 The Vertex Coloring Coding Method

In this section, we propose a novel coding method based on vertex colouring by which each synonym is assigned a unique codeword so the usage of overlapping synsets is not problematic for data embedding and extracting. A vertex colouring is a labelling of the graph's vertices with colours subject to the condition that no two adjacent vertices share the same colour. The smallest number of colours required to colour a graph G is called its chromatic number $\chi(G)$, and a graph G having chromatic number $\chi(G) = k$ is called a k-chromatic graph. The main idea of the proposed coding method is to represent overlapping synsets as an undirected k-chromatic graph called a synonym graph which has a vertex for each word and an edge for every pair of words that share the same meaning. A synonym is then encoded by a codeword that represents the colour assigned by the vertex colouring of the synonym graph. Figure 6 shows the use of four different colours, represented by '00', '01', '10' and '11', to colour the 4-chromatic synonym graph of the two overlapping synsets in Figure 2. Now, the overlapped word 'composition' receives a unique codeword no matter which synset is considered, which means the replacement of 'paper' to 'composition' in Figure 2 will not cause an ambiguity since the receiver can apply the same coding method to derive identical codewords used by the sender.

99.6% of synsets in WordNet have size less than 8, which means most of the synsets cannot exhaust more than a 2-bit coding space (i.e. we can only encode at most 2 bits using a typical synset). Therefore, we restrict the chromatic number of a synonym graph G to $1 < \chi(G) \leq 4$, which implies the maximum size of a synset is 4. When $\chi(G) = 2$, each vertex is assigned a single-bit codeword either '0' or '1' as shown in Figure 7(a). When $\chi(G) = 3$, the overlapping set's size is either 2 or 3, which cannot exhaust the 2-bit coding space although codewords '00', '01' and '10' are initially assigned to each vertex. Therefore, only the most significant bits are used to represent the synonyms, which we call *codeword reduction*. After the codeword reduction, if a vertex has the same codeword, say '0', as all of its neighbors, the vertex's codeword must be changed to '1' so that the vertex would be able to accommodate either secret bit '0' or '1', which we call *codeword correction*. Figure 7(b) shows an example of the process of codeword reduction and codeword correction for $\chi(G) = 3$. For the case of $\chi(G) = 4$, codeword reduction is applied to those vertices that themselves or their neighboring vertices have no access to all the codewords '00', '01', '10' and '11'. For example, vertices a, b, c, e and f in Figure 7(c) meet the requirement of needing codeword reduction. The codeword correction process is then further applied to vertex f to rectify its accessibility.

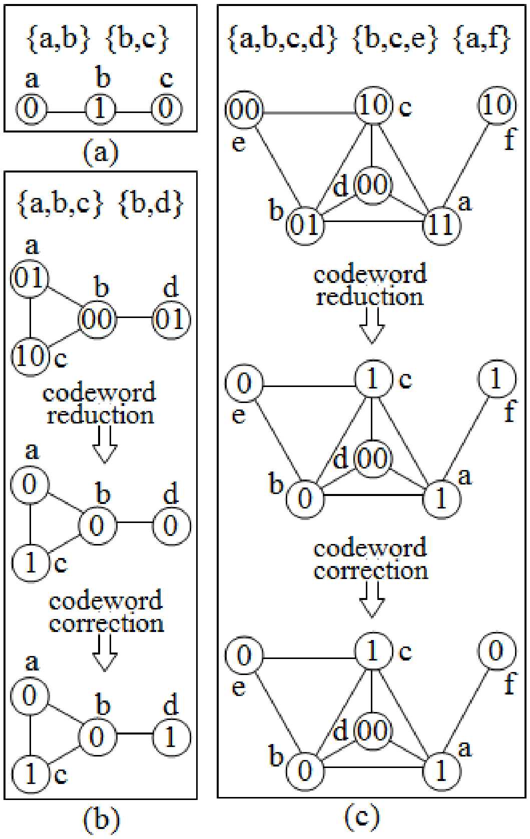

Figure 7: Examples of 2,3,4-chromatic synonym graphs

Figure 8 describes a greedy algorithm for constructing a coded synonym graph using at most 4 colours, given n synonyms w_1, w_2,$\ldots$, w_n in the overlapping synsets. Let us define a function $E(w_i, w_j)$ which returns an edge between w_i and w_j if w_i and w_j are in the same synset; otherwise returns false. Another function $C(w_i)$ returns the colour of the synonym w_i. The procedure loops through all the input synonyms. For each iteration, the procedure first finds available colours for the target synonym w_i. If there is no colour available, namely all the four colours have already been given to w_i's neighbors, w_i is randomly assigned one of the four colours; otherwise, w_i is assigned one of the available colours. After adding w_i to the graph G, the procedure checks whether adding an edge of w_i to graph G would violate the vertex colouring. After constructing the coloured graph, codeword reduction and codeword correction as previously described are applied to revise improper codewords.

4.2 Proposed Lexical Stegosystem

Figure 9 illustrates the framework of our lexical stegosystem. Note that we have preprocessed WordNet by excluding multi-word synonyms and single-entry synsets. A possible information carrier is first found in the cover sentence. We define a possible information carrier as a word in the cover sentence that belongs to at least one synset in WordNet. The synsets containing the target word, and all other synsets which can be reached via the synonym relation, are then extracted from WordNet (i.e. we build the connected component of WordNet which contains the target word according to the synonym relation). Words in these sets are then examined by the Google n-gram contextual checking method to eliminate inappropriate substitutions. If there is more than one word left and if words which pass the filter all belong to the same synset, the block coding method is used to encode the words; otherwise the vertex colouring coding is applied. Finally, according to the secret bitstring, the system selects the synonym that shares an edge with the target word and has as its codeword the longest potential match with the secret bitstring.

We use the connected component of WordNet containing the target word as a simple method to ensure that both sender and receiver colour-code the same graph. It is important to note, however, that the sender only considers the synonyms of the target word as potential substitutes; the connected component is only used to consistently assign the codes.

```
INPUT: a synonym list $w_1$, $w_2$,$\ldots$, $w_n$ and an
empty graph $G$
OUTPUT: a coded synonym graph $G$ using at
most four colours

FOR every synonym $w_i$ in the input list
    initialize four colours as available for $w_i$
    FOR every $w_j$ in graph $G$
        IF $E(w_i, w_j)$ THEN
            set $C(w_j)$ as unavailable
        END IF
    END FOR
    IF there is a colour available THEN
        assign one of the available colours
        to $w_i$
    ELSE
        assign one of the four colours to $w_i$
    END IF
    ADD $w_i$ to graph $G$
    FOR every $w_j$ in graph $G$
        IF $E(w_i, w_j)$ and $C(w_i)$ is not
        equal to $C(w_j)$ THEN
            ADD edge $E(w_i, w_j)$ to $G$
        END IF
    END FOR
END FOR
codeword reduction
codeword correction
OUTPUT graph $G$
```

Figure 8: Constructing a coloured synonym graph

For the decoding process, the receiver does not need the original text for extracting secret data. An information carrier can be found in the stegotext by referring to WordNet in which related synonyms are extracted. Those words in the related sets undergo the synonym checking method and then are encoded by either block coding or vertex colouring coding scheme depending on whether the remaining words are in the same synset. Finally, the secret bitstring is implicit in the codeword of the information carrier and therefore can be extracted.

We demonstrate how to embed secret bit 1 in the

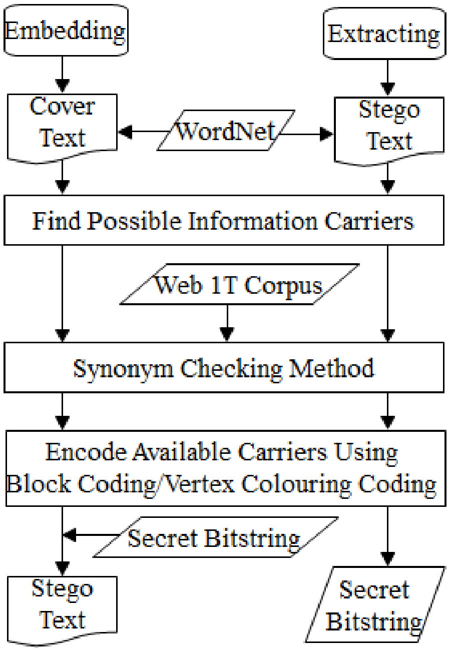

Figure 9: Framework of the proposed lexical stegosystem

sentence “it is a *shame* that we could not reach the next stage.” A possible information carrier ‘shame’ is first found in the sentence. Table 5 lists the related synsets extracted from WordNet. The score of each word calculated by the synonym checking method using the Web 1T Corpus is given as a subscript. Assume the threshold score is 0.27. The output of the synonym checking method is shown at the right side of Table 5. Since the remaining words do not belong to the same synset, the vertex colouring coding method is then used to encode the words. Figure 10(a) is the original synset graph in which each vertex is assigned one of the four colours; Figure 10(b) is the graph after applying codeword reduction. Although both ‘disgrace’ and ‘pity’ are encoded by ‘1’, ‘pity’ is chosen to replace the cover word since it has a higher score. Finally, the stegotext is generated, “it is a *pity* that we could not reach the next stage.”

As a rough guide to the potential payload with this approach, we estimate that, with a threshold of 0.5 for the contextual check, the payload would be slightly higher than 1 bit per newspaper sentence.

cover sentence:
It is a *shame* that we could not reach the next stage

original synsets	retained synsets
$\{commiseration_{.28}, pity_{.97}, ruth_{.13}, pathos_{.31}\}$	$\{commiseration, pity, pathos\}$
$\{pity_{.97}, shame_{1}\}$	$\{pity, shame\}$
$\{compassion_{.49}, pity_{.97}\}$	$\{compassion, pity\}$
$\{condolence_{.27}, commiseration_{.28}\}$	$\{commiseration\}$
$\{pathos_{.31}, poignancy_{.31}\}$	$\{pathos, poignancy\}$
$\{shame_{1}, disgrace_{.84}, ignominy_{.24}\}$	$\{shame, disgrace\}$
$\{compassion_{.49}, compassionateness_{0}\}$	$\{compassion\}$
$\{poignance_{.12}, poignancy_{.31}\}$	$\{poignancy\}$

Table 5: Synsets of ‘shame’ before and after applying the synonym checking method

5 Conclusions

One of the contributions of this paper is to develop a novel lexical stegosystem based on vertex colouring coding which improves the data embedding capacity compared to existing systems. The vertex colouring coding method represents synonym substitution as a synonym graph so the relations between words can be clearly observed. In addition, an automatic system for checking synonym acceptability in context is integrated in our stegosystem to ensure information security. For future work, we would like to explore more linguistic transformations that can meet the requirements of linguistic steganography — retaining the meaning, grammaticality and style of the original text. In addition, it is crucial to have a full evaluation of the linguistic stegosystem in terms of imperceptibility and payload capacity so we can know how much data can be embedded before the cover text reaches its maximum distortion which is tolerated by a human judge.

Abstract

Inducing a grammar directly from text is one of the oldest and most challenging tasks in Computational Linguistics. Significant progress has been made for inducing dependency grammars, however the models employed are overly simplistic, particularly in comparison to supervised parsing models. In this paper we present an approach to dependency grammar induction using tree substitution grammar which is capable of learning large dependency fragments and thereby better modelling the text. We define a hierarchical non-parametric Pitman-Yor Process prior which biases towards a small grammar with simple productions. This approach significantly improves the state-of-the-art, when measured by head attachment accuracy.

1 Introduction

Grammar induction is a central problem in Computational Linguistics, the aim of which is to induce linguistic structures from an unannotated text corpus. Despite considerable research effort this unsupervised problem remains largely unsolved, particularly for traditional phrase-structure parsing approaches (Clark, 2001; Klein and Manning, 2002). Phrase-structure parser induction is made difficult due to two types of ambiguity: the constituent structure and the constituent labels. In particular the constituent labels are highly ambiguous, firstly we don't know *a priori* how many there are, and secondly labels that appear high in a tree (e.g., an *S* category for a clause) rely on the correct inference of all the latent labels below them. However recent work on the induction of dependency grammars has proved more fruitful (Klein and Manning, 2004). Dependency grammars (Mel′čuk, 1988) should be easier to induce from text compared to phrase-structure grammars because the set of labels (heads) are directly observed as the words in the sentence.

Approaches to unsupervised grammar induction, both for phrase-structure and dependency grammars, have typically used very simplistic models (Clark, 2001; Klein and Manning, 2004), especially in comparison to supervised parsing models (Collins, 2003; Clark and Curran, 2004; McDonald, 2006). Simple models are attractive for grammar induction because they have a limited capacity to overfit, however they are incapable of modelling many known linguistic phenomena. We posit that more complex grammars could be used to better model the unsupervised task, provided that active measures are taken to prevent overfitting. In this paper we present an approach to dependency grammar induction using a tree-substitution grammar (TSG) with a Bayesian non-parametric prior. This allows the model to learn large dependency fragments to best describe the text, with the prior biasing the model towards fewer and smaller grammar productions.

We adopt the split-head construction (Eisner, 2000; Johnson, 2007) to map dependency parses to context free grammar (CFG) derivations, over which we apply a model of TSG induction (Cohn et al., 2009). The model uses a hierarchical Pitman-Yor process to encode a backoff path from TSG to CFG rules, and from lexicalised to unlexicalised rules. Our best lexicalised model achieves a head attachment accuracy of of 55.7% on Section 23 of the WSJ data set, which significantly improves over state-of-the-art and far exceeds an EM baseline (Klein and Manning, 2004) which obtains 35.9%.

MIT, Massachusetts, USA, 9-11 October 2010.

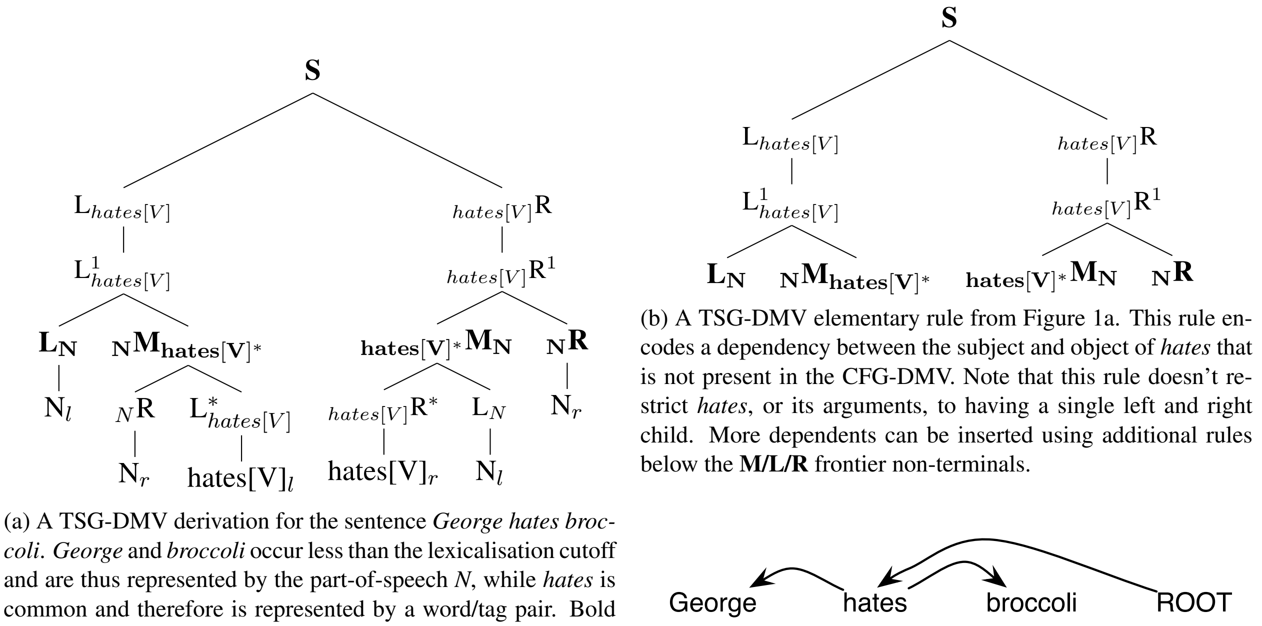
CFG Rule	DMV Distribution	Description
$\mathrm{S} \rightarrow \mathrm{L}_H\ {}_H\mathrm{R}$	$p(root = H)$	The head of the sentence is H.
$\mathrm{L}_H \rightarrow \mathrm{H}_l$	$p(STOP \mid dir = L, head = H, val = 0)$	H has no left children.
$\mathrm{L}_H \rightarrow \mathrm{L}^1_H$	$p(CONT \mid dir = L, head = H, val = 0)$	H has at least one left child.
$\mathrm{L}^*_H \rightarrow \mathrm{H}_l$	$p(STOP \mid dir = L, head = H, val = 1)$	H has no more left children.
$\mathrm{L}^*_H \rightarrow \mathrm{L}^1_H$	$p(CONT \mid dir = L, head = H, val = 1)$	H has another left child.
${}_H\mathrm{R} \rightarrow \mathrm{H}_r$	$p(STOP \mid dir = R, head = H, val = 0)$	H has no right children.
${}_H\mathrm{R} \rightarrow {}_H\mathrm{R}^1$	$p(CONT \mid dir = R, head = H, val = 0)$	H has at least one right child.
${}_H\mathrm{R}^* \rightarrow \mathrm{H}_r$	$p(STOP \mid dir = R, head = H, val = 1)$	H has no more right children.
${}_H\mathrm{R}^* \rightarrow {}_H\mathrm{R}^1$	$p(CONT \mid dir = R, head = H, val = 1)$	H has another right child.
$\mathrm{L}^1_H \rightarrow \mathrm{L}_C\ {}_C\mathrm{M}_{H^*}$	$p(C \mid dir = L, head = H)$	C is a left child of H.
${}_H\mathrm{R}^1 \rightarrow {}_{H^*}\mathrm{M}_C\ {}_C\mathrm{R}$	$p(C \mid dir = R, head = H)$	C is a right child of H.
${}_C\mathrm{M}_{H^*} \rightarrow {}_C\mathrm{R}\ \mathrm{L}^*_H$	$p = 1$	Unambiguous
${}_{H^*}\mathrm{M}_C \rightarrow {}_H\mathrm{R}^*\ \mathrm{L}_C$	$p = 1$	Unambiguous

Table 1: The CFG-DMV grammar schema. Note that the actual CFG is created by instantiating these templates with part-of-speech tags observed in the data for the variables H and C. Valency (*val*) can take the value 0 (no attachment in the direction (*dir*) d) and 1 (one or more attachment). L and R indicates child dependents left or right of the parent; superscripts encode the stopping and valency distributions, X^1 indicates that the head will continue to attach more children and X^* that it has already attached a child.

2 Background

The most successful framework for unsupervised dependency induction is the Dependency Model with Valence (DMV) (Klein and Manning, 2004). This model has been adapted and extended by a number of authors and currently represents the state-of-the-art for dependency induction (Cohen and Smith, 2009; Headden III et al., 2009). Eisner (2000) introduced the *split-head* algorithm which permits efficient $\mathcal{O}(|\mathbf{w}|^3)$ parsing complexity by replicating (splitting) each terminal and processing left and right dependents separately. We employ the related *fold-unfold* representation of Johnson (2007) that defines a CFG equivalent of the split-head parsing algorithm, allowing us to easily adapt CFG-based grammar models to dependency grammar. Table 1 shows the equivalent CFG grammar for the DMV model (CFG-DMV) using the unfold-fold transformation. The key insight to understanding the non-terminals in this grammar is that the subscripts encode the terminals at the boundaries of the span of that non-terminal. For example the non-terminal L_H encodes that the right most terminal spanned by this constituent is H (and the reverse for ${}_H\mathrm{R}$), while ${}_A\mathrm{M}_B$ encodes that A and B are the left-most and right-most terminals of the span. The * and ^{1} superscripts are used to encode the valency of the head, both indicate that the head has at least one attached dependent in the specified direction. This grammar allows $\mathcal{O}(|\mathbf{w}|^3)$ parsing complexity which follows from the terminals of the dependency tree being observed, such that each span of the parse chart uniquely specifies its possible heads (either the leftmost, rightmost or both) and therefore the number of possible non-terminals for each span is constant. The transform is illustrated in figures 1a and 1c which show the CFG tree for an example sentence and the equivalent dependency tree.

Normally DMV based models have been trained on part-of-speech tags of the words in a sentence, rather than the words themselves. Headden III et al. (2009) showed that performance could be improved by including high frequency words as well as tags in their model. In this paper we refer to such models as *lexicalised*; words which occur more than one hundred times in the training corpus are represented by a word/tag pair, while those less frequent are represented simply by their tags. We are also able to show that this basic approach to lexicalisation improves the performance of our models.



(a) A TSG-DMV derivation for the sentence *George hates broccoli*. *George* and *broccoli* occur less than the lexicalisation cutoff and are thus represented by the part-of-speech *N*, while *hates* is common and therefore is represented by a word/tag pair. Bold nodes indicate frontier nodes of elementary trees.

(b) A TSG-DMV elementary rule from Figure 1a. This rule encodes a dependency between the subject and object of *hates* that is not present in the CFG-DMV. Note that this rule doesn't restrict *hates*, or its arguments, to having a single left and right child. More dependents can be inserted using additional rules below the **M/L/R** frontier non-terminals.

(c) A traditional dependency tree representation of the parse tree in Figure 1a before applying the lexicalisation cutoff.

Figure 1: TSG-DMV representation of dependency trees.

3 Lexicalised TSG-DMV

The models we investigate in this paper build upon the CFG-DMV by defining a *Tree Substitution Grammar* (TSG) over the space of CFG rules. A TSG is a 4-tuple, $G = (T, N, S, R)$, where T is a set of *terminal symbols*, N is a set of *non-terminal symbols*, $S \in N$ is the distinguished *root non-terminal* and R is a set of productions (rules). The productions take the form of *elementary trees* – tree fragments of height ≥ 1, where each internal node is labelled with a non-terminal and each leaf is labelled with either a terminal or a non-terminal. Non-terminal leaves are called *frontier non-terminals* and form the substitution sites in the generative process of creating trees with the grammar.

A *derivation* creates a tree by starting with the root symbol and rewriting (substituting) it with an elementary tree, then continuing to rewrite frontier non-terminals with elementary trees until there are no remaining frontier non-terminals. We can represent derivations as sequences of elementary trees, $\mathbf{e}$, by specifying that during the generation of the tree each elementary tree is substituted for the left-most frontier non-terminal. Figure 1a shows a TSG derivation for the dependency tree in Figure 1c where bold nonterminal labels denote substitution sites (root/frontier nodes in the elementary trees).

The probability of a derivation, $\mathbf{e}$, is the product of the probabilities of its component rules,

$$P(\mathbf{e}) = \prod_{c \to e \in \mathbf{e}} P(e|c)\,. \qquad (1)$$

where each rewrite is assumed conditionally independent of all others given its root nonterminal, $c = \text{root}(e)$. The probability of a tree, t, and string of words, $\mathbf{w}$, are

$$P(t) = \sum_{\mathbf{e}:\text{tree}(\mathbf{e})=t} P(\mathbf{e}) \text{ and } P(\mathbf{w}) = \sum_{t:\text{yield}(t)=\mathbf{w}} P(t)\,,$$

respectively, where tree($\mathbf{e}$) returns the tree for the derivation $\mathbf{e}$ and yield(t) returns the string of terminal symbols at the leaves of t.

A *Probabilistic Tree Substitution Grammar* (PTSG), like a PCFG, assigns a probability to each rule in the grammar, denoted $P(e|c)$. The probability of a derivation, $\mathbf{e}$, is the product of the probabilities of its component rules. Estimating a PTSG requires learning the sufficient statistics for $P(e|c)$ in (1) based on a training sample. Parsing involves finding the most probable tree for a given string ($\arg\max_t P(t|\mathbf{w})$). This is typically approximated by finding the most probable derivation which can be done efficiently using the CYK algorithm.

3.1 Model

In this work we propose the Tree Substitution Grammar Dependency Model with Valence (TSG-DMV). We define a hierarchical non-parametric TSG model on the space of parse trees licensed by the CFG grammar in Table 1. Our model is a generalisation of that of Cohn et al. (2009) and Cohn et al. (2011). We extend those works by moving from a single level Dirichlet Process (DP) distribution over rules to a multi-level Pitman-Yor Process (PYP), and including lexicalisation. The PYP has been shown to generate distributions particularly well suited to modelling language (Teh, 2006; Goldwater et al., 2006). Teh (2006) used a hierarchical PYP to model backoff in language models, we leverage this same capability to model backoff in TSG rules. This effectively allows smoothing from lexicalised to unlexicalised grammars, and from TSG to CFG rules.

Here we describe our deepest model which has a four level hierarchy, depicted graphically in Table 2. In Section 5 we evaluate different subsets of this hierarchy. The topmost level of our model describes lexicalised elementary elementary fragments (e) as produced by a PYP,

$$\begin{aligned} e|c &\sim G_c \\ G_c|a_c, b_c, \mathrm{P}^{\mathrm{lcfg}} &\sim \mathrm{PYP}(a_c, b_c, \mathrm{P}^{\mathrm{lcfg}}(\cdot|c)) \,, \end{aligned}$$

where a_c and b_c control the strength of the backoff distribution $\mathrm{P}^{\mathrm{lcfg}}$. The space of lexicalised TSG rules will inevitably be very sparse, so the base distribution $\mathrm{P}^{\mathrm{lcfg}}$ backs-off to calculating the probability of a TSG rules as the product of the CFG rules it contains, multiplied by a geometric distribution over the size of the rule.

$$\begin{aligned} \mathrm{P}^{\mathrm{lcfg}}(e|c) &= \prod_{f \in \mathrm{F}(e)} s_{f_c} \prod_{i \in \mathrm{I}(e)} (1 - s_{i_c}) \\ &\quad \times A(\text{lex-cfg-rules}(e|c)) \\ \alpha|c &\sim A_c \\ A_c|a_c^{\mathrm{lcfg}}, b_c^{\mathrm{lcfg}}, \mathrm{P}^{\mathrm{cfg}} &\sim \mathrm{PYP}(a_c^{\mathrm{lcfg}}, b_c^{\mathrm{lcfg}}, \mathrm{P}^{\mathrm{cfg}}(\cdot|c)), \end{aligned}$$

where $I(e)$ are the set of internal nodes in e excluding the root, $F(e)$ are the set of frontier non-terminal nodes, and c_i is the non-terminal symbol for node i and s_c is the probability of stopping expanding a node labelled c. The function lex-cfg-rules$(e|c)$ returns the CFG rules internal to e, each of the form $c' \rightarrow \alpha$; each CFG rule is drawn from the back-off distribution, $A_{c'}$. We treat s_c as a parameter which is estimated during training, as described in Section 4.2.

The next level of backoff ($\mathrm{P}^{\mathrm{cfg}}$) removes the lexicalisation from the CFG rules, describing the generation of a lexicalised rule by first generating an unlexicalised rule from a PYP, then generating the lexicalisaton from a uniform distribution over words:[1]

$$\begin{aligned} \mathrm{P}^{\mathrm{cfg}}(\alpha|c) &= B(\text{unlex}(\alpha)|\text{unlex}(c)) \\ &\quad \times \frac{1}{|\mathbf{w}|^{|\alpha|}} \\ \alpha'|c' &\sim B_{c'} \\ B_{c'}|a_{c'}^{\mathrm{cfg}}, b_{c'}^{\mathrm{cfg}}, \mathrm{P}^{\mathrm{sh}} &\sim \mathrm{PYP}(a_{c'}^{\mathrm{cfg}}, b_{c'}^{\mathrm{cfg}}, \mathrm{P}^{\mathrm{sh}}(\cdot|c')), \end{aligned}$$

where unlex$(\cdot)$ removes the lexicalisation from non-terminals leaving only the tags.

The final base distribution over CFG-DMV rules (P^{sh}) is inspired by the *skip-head* smoothing model of Headden III et al. (2009). This model showed that smoothing the DMV by removing the heads from the CFG rules significantly improved performance. We replicate this behavior through a final level in our hierarchy which generates the CFG rules without their heads, then generates the heads from a uniform distribution:

$$\begin{aligned} \mathrm{P}^{\mathrm{sh}}(\alpha|c) &= C(\text{drop-head}(c \rightarrow \alpha)) \times \frac{1}{|P|} \\ \alpha|c &\sim C_c \\ C_c|a_c^{\mathrm{sh}}, b_c^{\mathrm{sh}} &\sim \mathrm{PYP}(a_c^{\mathrm{sh}}, b_c^{\mathrm{sh}}, \text{Uniform}(\cdot|c)), \end{aligned}$$

where drop-head$(\cdot)$ removes the symbols that mark the head on the CFG rules, and P is the set of part-of-speech tags. Each stage of backoff is illustrated in Table 2, showing the rules generated from the TSG elementary tree in Figure 1b.

Note that while the supervised model of Cohn et al. (2009) used a fixed back-off PCFG distribution, this model implicitly infers this distribution within

[1] All unlexicalised words are actually given the generic UNK symbol as their lexicalisation.

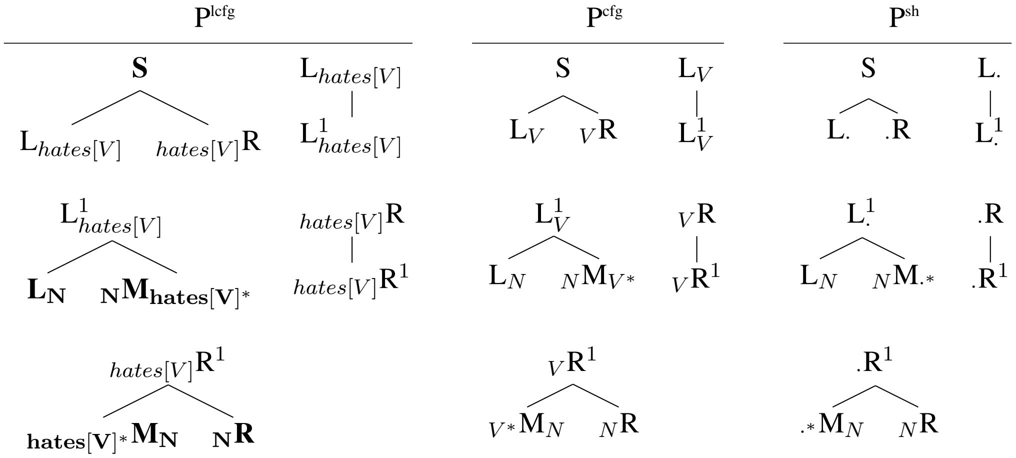


Table 2: Backoff trees for the elementary tree in Figure 1b.

its hierarchy, essentially learning the DMV model embedded in the TSG.

In this application to dependency grammar our model is capable of learning tree fragments which group CFG parameters. As such the model can learn to condition dependency links on the valence, e.g. by combining $\mathrm{L}_H \rightarrow \mathrm{L}^1_H$ and $\mathrm{L}^1_H \rightarrow \mathrm{L}_C\ {}_C\mathrm{M}_{H^*}$ rules into a single fragment the model can learn a parameter that the leftmost child of H is C. By linking together multiple L^1_H or ${}_H\mathrm{R}^1$ non-terminals the model can learn groups of dependencies that occur together, e.g. tree fragments representing the complete preferred argument frame of a verb.

4 Inference

4.1 Training

To train our model we use Markov Chain Monte Carlo sampling (Geman and Geman, 1984). Where previous supervised TSG models (Cohn et al., 2009) permit an efficient local sampler, the lack of an observed parse tree in our unsupervised model makes this sampler not applicable. Instead we use a recently proposed blocked Metroplis-Hastings (MH) sampler (Cohn and Blunsom, 2010) which exploits a factorisation of the derivation probabilities such that whole trees can be sampled efficiently. See Cohn and Blunsom (2010) for details. That algorithm is applied using a dynamic program over an observed tree, the generalisation to our situation of an inside pass over the space of all trees is straightforward.

A final consideration is the initialisation of the sampler. Klein and Manning (2004) emphasised the importance of the initialiser for achieving good performance with their model. We employ the same *harmonic* initialiser as described in that work. The initial derivations for our sampler are the Viterbi derivations under the CFG parameterised according to this initialiser.

4.2 Sampling hyperparameters

We treat the hyper-parameters $\{(a^x_c, b^x_c, s_c), c \in N\}$ as random variables in our model and infer their values during training. We choose quite vague priors for each hyper-parameter, encoding our lack of information about their values.

We place prior distributions on the PYP discount a_c and concentration b_c hyperparamters and sample their values using a slice sampler. We use the range doubling slice sampling technique of (Neal, 2003) to draw a new sample of a'_c from its conditional distribution.[2] For the discount parameters a_c we employ a uniform Beta distribution, as we have no strong prior knowledge of what its value should be ($a_c \sim \mathrm{Beta}(1, 1)$). Similarly, we treat the concentration parameters, b_c, as being generated by a vague gamma prior, $b_c \sim \mathrm{Gamma}(1, 1)$, and sample a new value b'_c using the same slice-sampling approach as for a_c:

$$P(b_c|\mathbf{z}) \propto P(\mathbf{z}|b_c) \times \mathrm{Gamma}(b_c|1, 1).$$

[2] We made use of the slice sampler included in Mark Johnson's Adaptor Grammar implementation http://www.cog.brown.edu/~mj/Software.htm.

Corpus	Words	Sentences

Section 22 ($\|\mathbf{x}\| \leq 10$)	1805	258
Section 23 ($\|\mathbf{x}\| \leq 10$)	2649	398
Section 23 ($\|\mathbf{x}\| \leq \infty$)	49368	2416

Table 3: Corpus statistics for the training and testing data for the TSG-DMV model. All models are trained on the gold standard part-of-speech tags after removing punctuation.

We use a vague Beta prior for the stopping probabilities in $\mathrm{P}^{\mathrm{lcfg}}$, $s_c \sim \mathrm{Beta}(1, 1)$.

All the hyper-parameters are resampled after every 10th sample of the corpus derivations.

4.3 Parsing

Unfortunately finding the maximising parse tree for a string under our TSG-DMV model is intractable due to the inter-rule dependencies created by the PYP formulation. Previous work has used Monte Carlo techniques to sample for one of the maximum probability parse (MPP), maximum probability derivation (MPD) or maximum marginal parse (MMP) (Cohn et al., 2009; Bod, 2006). We take a simpler approach and use the Viterbi algorithm to calculate the MPD under an approximating TSG defined by the last set of derivations sampled for the corpus during training. Our results indicate that this is a reasonable approximation, though the experience of other researchers suggests that calculating the MMP under the approximating TSG may also be beneficial for DMV (Cohen et al., 2008).

5 Experiments

We follow the standard evaluation regime for DMV style models by performing experiments on the text of the WSJ section of the Penn. Treebank (Marcus et al., 1993) and reporting head attachment accuracy. Like previous work we pre-process the training and test data to remove punctuation, training our unlexicalised models on the gold-standard part-of-speech tags, and including words occurring more than 100 times in our lexicalised models (Headden III et al., 2009). It is very difficult for an unsupervised model to learn from long training sentences as they contain a great deal of ambiguity, therefore the majority of DMV based models have been trained on sentences restricted in length to ≤ 10 tokens.[3] This has the added benefit of decreasing the runtime for experiments. We present experiments with this training scenario. The training data comes from sections 2-21, while section 23 is used for evaluation. An advantage of our sampling based approach over previous work is that we infer all the hyperparameters, as such we don't require the use of section 22 for tuning the model.

The models are evaluated in terms of head attachment accuracy (the percentage of correctly predicted head indexes for each token in the test data), on two subsets of the testing data. Although we can argue that unsupervised models are better learnt from short sentences, it is much harder to argue that we don't then need to be able to parse long sentences with a trained model. The most commonly employed test set mirrors the training data by only including sentences ≤ 10. In this work we focus on the accuracy of our models on the whole of section 23, without any pruning for length. The training and testing corpora statistics are presented in Table 3. Subsequent to the evaluation reported in Table 4 we use section 22 to report the correlation between heldout accuracy and the model log-likelihood (LLH) for analytic purposes.

As we are using a sampler during training, the result of any single run is non-deterministic and will exhibit a degree of variance. All our reported results are the mean and standard deviation (σ) from forty sampling runs.

5.1 Discussion

Table 4 shows the head attachment accuracy results for our TSG-DMV, plus many other significant previously proposed models. The subset of hierarchical priors used by each model is noted in brackets.

The performance of our models is extremely encouraging, particularly the fact that it achieves the highest reported accuracy on the full test set by a considerable margin. On the $|\mathbf{w}| \leq 10$ test set all the TSG-DMVs are second only to the L-EVG model of Headden III et al. (2009). The L-EVG model extends DMV by adding additional lexicalisation,

[3] See Spitkovsky et al. (2010a) for an exception to this rule.

Table 4: Mean and variance for the head attachment accuracy of our TSG-DMV models (highlighted) with varying backoff paths, and many other high performing models. Citations indicate where the model and result were reported. Our models labelled TSG used an unlexicalised top level G_c PYP, while those labelled LexTSG used the full lexicalised G_c.

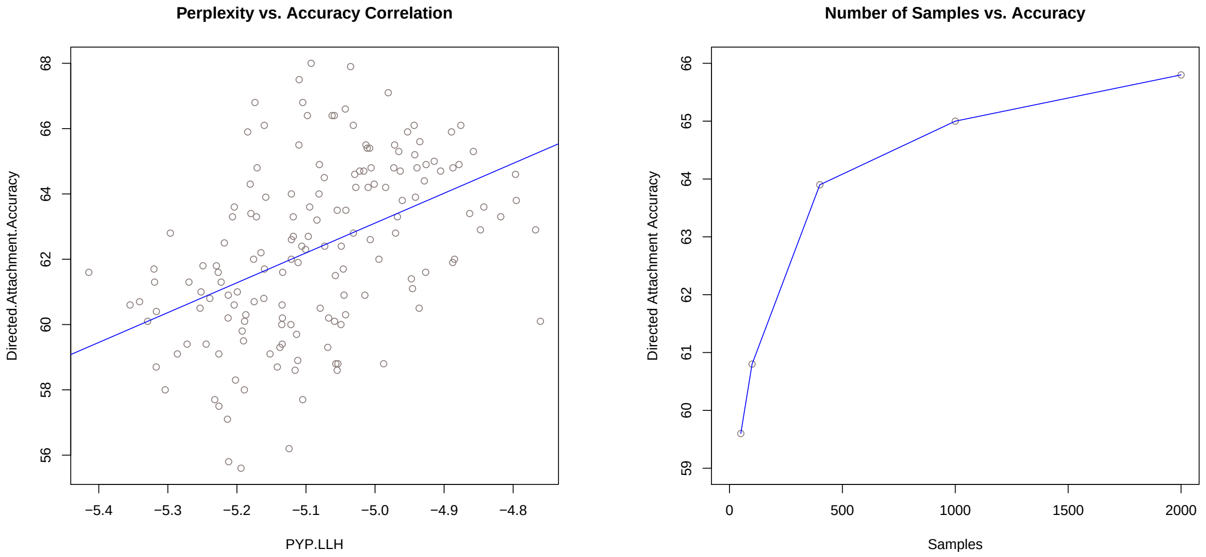
valency conditioning, interpolated back-off smoothing and a random initialiser. In particular Headden III et al. (2009) shows that the random initialiser is crucial for good performance, however this initialiser requires training 1000 models to select a single best model for evaluation and results in considerable variance in test set performance. Note also that our model exhibits considerably less variance than those induced using this random initialiser, suggesting that the combination of the harmonic initialiser and blocked-MH sampling may be a more practicable training regime.

The recently proposed Adaptor Grammar DMV model of Cohen et al. (2010) is similar in many way to our TSG model, incorporating a Pitman Yor prior over units larger than CFG rules. As such it is surprising that our model is performing significantly better than this model. We can identify a number of differences that may impact these results: the Adaptor Grammar model is trained using variational inference with the space of tree fragments truncated, while we employ a sampler which can nominally explore the full space of tree fragments; and the adapted tree fragments must be complete subtrees (i.e. they don't contain variables), whereas our model can make use of arbitrary tree fragments. An interesting avenue for further research would be to extend the variational algorithm of Cohen et al. (2010) to our TSG model, possibly speeding inference and allowing easier parallelisation.

In Figure 2a we graph the model LLH on the training data versus the head attachment accuracy on the heldout set. The graph was generated by running 160 models for varying numbers of samples and evaluating their accuracy. This graph indicates that the improvements in the posterior probability of the model are correlated with the evaluation, though the correlation is not as high as we might require in order to use LLH as a model selection criteria similar to Headden III et al. (2009). Further refinements to the model could improve this correlation.

The scaling perfomance of the model as the number of samples is increased is shown in Figure 2b. Performance improves as the training data is sampled for longer, and continues to trend upwards beyond 1000 samples (the point for which we've reported results in Table 4). This suggests that longer sampling runs – and better inference techniques – could yield further improvements.

For further analysis Table 5 shows the accuracy of the model at predicting the head for frequent types, while Table 6 shows the performance on dependencies of various lengths. We emphasise that these results are for the single best performing sampler run on the heldout corpus and there is considerable variation in the analyses produced by each sampler. Unsurprisingly, the model appears to be more accurate when predicting short dependencies, a result that is also reflected in the per type accuracies. The model is relatively good at identifying the root verb in each sentence, especially those headed by past tense verbs (VBD, *was*), and to a lesser degree VBPs (*are*). Conjunctions such as *and* pose a particular difficulty when evaluating dependency models as the correct modelling of these remains a



(a) Correlation ($R^2 = 0.2$) between the training LLH of the PYP Model and heldout directed head attachment accuracy (WSJ Section 22, $|\mathbf{w}| \leq 10$) for LexTSG-DMV ($\mathrm{P}^{\mathrm{lcfg}}$, $\mathrm{P}^{\mathrm{cfg}}$, P^{sh}).

(b) Mean heldout directed head attachment accuracy (WSJ Section 22, $|\mathbf{w}| \leq 10$) versus the number of samples used during training for LexTSG-DMV ($\mathrm{P}^{\mathrm{lcfg}}$, $\mathrm{P}^{\mathrm{cfg}}$, P^{sh}).

Figure 2

contentious linguistic issue and it's not clear what the 'correct' analysis should be. Our model gets a respectable 75% accuracy for *and* conjunctions, but for conjunctions (CC) as a whole, the model performs poorly (39%).

Table 7 list the most frequent TSG rules lexicalised with *has*. The most frequent rule is simply the single level equivalent of the DMV terminal rule for *has*. Almost as frequent is rule 3, here the grammar incorporates the terminal into a larger elementary fragment, encoding that it is the head of the past participle occuring immediately to it's right. This shows the model's ability to learn the verb's argument position conditioned on both the head and child type, something lacking in DMV. Rule 7 further refines this preferred analysis for *has been* by lexicalising both the head and child. Rules (4,5,8,10) employ similar conditioning for proper and ordinary nouns heading noun phrases to the left of *has*. We believe that it is the ability of the TSG to encode stronger constraints on argument positions that leads to the model's higher accuracy on longer sentences, while other models do well on shorter sentences but relatively poorly on longer ones (Spitkovsky et al., 2010c).

6 Conclusion

In this paper we have made two significant contributions to probabilistic modelling and grammar induction. We have shown that it is possible to successfully learn hierarchical Pitman-Yor models that encode deep and complex backoff paths over highly structured latent spaces. By applying these models to the induction of dependency grammars we have also been able to advance the state-of-the-art, increasing the head attachment accuracy on section 23 of the Wall Street Journal Corpus by more than 5%.

Further gains in performance may come from an exploration of the backoff paths employed within the model. In particular more extensive experimentation with alternate priors and larger training data may allow the removal of the lexicalisation cutoff which is currently in place to counter sparsity.

We envisage that in future many grammar formalisms that have been shown to be effective in supervised parsing, such as categorial, unification and tree adjoining grammars, will prove amenable to unsupervised induction using the hierarchical nonparametric modelling approaches we have demonstrated in this paper.

It Depends on the Translation: Unsupervised Dependency Parsing via Word Alignment

Samuel Brody
Dept. of Biomedical Informatics
Columbia University
samuel.brody@dbmi.columbia.edu

Abstract

We reveal a previously unnoticed connection between dependency parsing and statistical machine translation (SMT), by formulating the dependency parsing task as a problem of word alignment. Furthermore, we show that two well known models for these respective tasks (DMV and the IBM models) share common modeling assumptions. This motivates us to develop an alignment-based framework for unsupervised dependency parsing. The framework (which will be made publicly available) is flexible, modular and easy to extend. Using this framework, we implement several algorithms based on the IBM alignment models, which prove surprisingly effective on the dependency parsing task, and demonstrate the potential of the alignment-based approach.

1 Introduction

Both statistical machine translation (SMT) and unsupervised dependency parsing have seen a surge of interest in recent years, as the need for large scale data processing has increased. The problems addressed by each of the fields seem quite different at first glance. However, in this paper, we reveal a strong connection between them and show that the problem of dependency parsing can be formulated as one of word alignment within the sentence. Furthermore, we show that the two models that are arguably the most influential in their respective fields, the IBM models 1-3 (Brown et al., 1993) and Klein and Manning's (2004) *Dependency Model with Valence* (DMV), share a common set of modeling assumptions.

Based on this connection, we develop a framework which uses an alignment-based approach for unsupervised dependency parsing. The framework is flexible and modular, and allows us to explore different modeling assumptions. We demonstrate these properties and the merit of the alignment-based parsing approach by implementing several dependency parsing algorithms based on the IBM alignment models and evaluating their performance on the task. Although the algorithms are not competitive with state-of-the-art systems, they outperform the right-branching baseline and approach the performance of DMV. This is especially surprising when we consider that the IBM models were not originally designed for the task. These results are encouraging and indicate that the alignment-based approach could serve as the basis for competitive dependency parsing systems, much as DMV did.

This paper offers two main contributions. First, by revealing the connection between the two tasks, we introduce a new approach to dependency parsing, and open the way for use of SMT alignment resources and tools for parsing. Our experiments with the IBM models demonstrate the potential of this approach and provide a strong motivation for further development. The second contribution is a publicly-available framework for exploring new alignment models. The framework uses Gibbs sampling techniques and includes our sampling-based implementations of the IBM models (see Section 3.4). The sampling approach makes it easy to modify the existing models and add new ones. The framework can be used both for dependency parsing and for bilingual word alignment.

The rest of the paper is structured as follows. In Section 2 we present a brief overview of those works in the fields of dependency parsing and alignment for statistical machine translation which are directly

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1214–1222,
MIT, Massachusetts, USA, 9-11 October 2010.

relevant to this paper. Section 3 describes the connection between the two problems, examines the shared assumptions of the DMV and IBM models, and describes our framework and algorithms. In Section 4 we present our experiments and discuss the results. We conclude in Section 5.

2 Background and Related Work

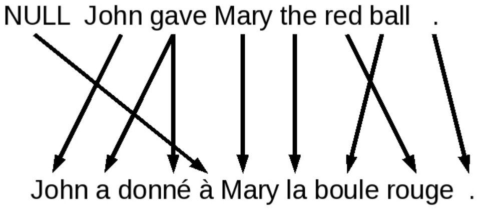
2.1 Unsupervised Dependency Parsing

In recent years, the field of supervised parsing has advanced tremendously, to the point where highly accurate parsers are available for many languages. However, supervised methods require the manual annotation of training data with parse trees, a process which is expensive and time consuming. Therefore, for domains and languages with minimal resources, unsupervised parsing is of great importance.

Early work in the field focused on models that made use primarily of the co-occurrence information of the head and its argument (Yuret, 1998; Paskin, 2001). The introduction of DMV by Klein and Manning (2004) represented a shift in the direction of research in the field. DMV is based on a linguistically motivated generative model, which follows common practice in *supervised* parsing and takes into consideration the distance between head and argument, as well as the valence (the capacity of a head word to attach arguments). Klein and Manning (2004) also shifted from a lexical representation of the sentences to representing them as part-of-speech sequences. DMV strongly outperformed previous models and was the first unsupervised dependency induction system to achieve accuracy above the right-branching baseline. Much subsequent work in the field has focused on modifications and extensions of DMV, and it is the basis for today's state-of-the-art systems (Cohen and Smith, 2009; Headden III et al., 2009).

2.2 Alignment for SMT

SMT treats translation as a machine learning problem. It attempts to learn a translation model from a parallel corpus composed of sentences and their translations. The IBM models (Brown et al., 1993) represent the first generation of word-based SMT models, and serve as a starting point for most current SMT systems (e.g., Moses, Koehn et al. 2007; Hiero, Chiang 2005). The models employ the notion of *alignment* between individual words in the source and translation. An example of such an alignment is given in Figure 1.



NULL John gave Mary the red ball .
John a donné à Mary la boule rouge .

Figure 1: An example of an alignment between an English sentence (top) and its French translation (bottom).

The IBM models all seek to maximize $Pr(f|e)$, the probability of a French translation f of an English sentence e. This probability is broken down by taking into account all possible alignments a between e and f, and their probabilities:

$$Pr(f|e) = \sum_{a} Pr(f,a|e) \tag{1}$$

Each of the IBM models is based on the previous one in the series, and adds another level of latent parameters which take into account a specific characteristic of the data.

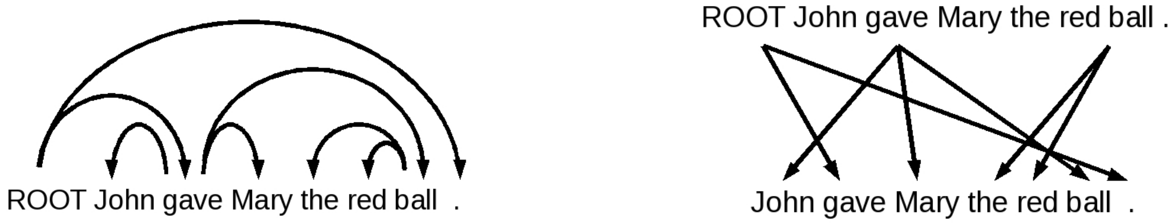
3 Alignment-based Dependency Parsing

3.1 The Connection

The task of dependency parsing requires finding a parse tree for a sentence, where two words are connected by an edge if they participate in a syntactic dependency relation. When dealing with unlabeled dependencies, the exact nature of the relationship is not determined. An example of a dependency parse of a sentence is given in Figure 2 (left).

Another possible formulation of the problem is as follows. Find a set of pairwise relations (s_i, s_j) connecting a dependent word s_j with its head word s_i in the sentence. This alternate formulation allows us to view the problem as one of alignment of a sentence to itself, as shown in Figure 2 (right).

Given this perspective on the problem, it makes sense to examine existing alignment models, compare them to dependency parsing models, and see if they can be successfully employed for the dependency parsing task.



ROOT John gave Mary the red ball .

Figure 2: **Left:** An example of an unlabeled dependency parse of a sentence. **Right:** The same parse, in the form of an alignment between a head words (top) and their dependents (bottom).

3.2 Comparing IBM & DMV Assumptions

Lexical Association The core assumption of IBM Model 1 is that the lexical identities of the English and French words help determine whether they should be aligned. The same assumption is made in all the dependency models mentioned in Section 2 regarding a head and its dependent (although DMV uses word classes instead of the actual words).

Location IBM Model 2 adds the consideration of difference in location between the English and French words when considering the likelihood of alignment. One of the improvements contributing to the success of DMV was the notion of distance, which was absent from previous models (see Section 3 in Klein and Manning 2004).

Fertility IBM Model 3 adds the notion of *fertility*, or the idea that different words in the source language tend to generate different numbers of words in the target language. This corresponds to the notion of *valence*, used by Klein and Manning (2004), and the other major contributor to the success of DMV (ibid.).

Null Source The IBM models all make use of an additional “null” word in every sentence, which has special status. It is attached to words in the translation that do not correspond to a word in the source. It is treated separately when calculating distance (since it has no location) and fertility. In these characteristics, it is very similar to the “root” node, which is artificially added to parse trees and used to represent the head of words which are not dependents of any other word in the sentence.

In examining the core assumptions of the IBM models, we note that there is a strong resemblance to those of DMV. The similarity is at an abstract level since the nature of the relationship that each model attempts to detect is quite different. The IBM models look for an equivalence relationship between lexical items in two languages, whereas DMV addresses functional relationships between two elements with distinct meanings. However, both attempt to model a similar set of factors, which they posit will be important to their respective tasks[1]. This similarity motivates the work presented in the rest of the paper, i.e, exploring the use of the IBM alignment models for dependency parsing. It is important to note that the IBM models do not address many important factors relevant to the parsing task. For instance, they have no notion of a parse tree, a deficit which may lead to degenerate solutions and malformed parses. However, they serve as a good starting point for exploring the alignment approach to parsing, as well as discovering additional factors that need to be addressed under this approach.

3.3 Experimental Framework

We developed a Gibbs sampling framework for alignment-based dependency parsing[2]. The traditional approach to alignment uses Expectation Maximization (EM) to find the optimal values for the latent variables. In each iteration, it considers all possible alignments for each pair of sentences, and

[1] These abstract notions (lexical association, proximity, tendencies towards few or many relations, and allowing for unassociated items) play an important role in many relation-detection tasks (e.g., co-reference resolution, Haghighi and Klein 2010).

[2] Available for download at:
`http://people.dbmi.columbia.edu/~sab7012`

chooses the optimal one based on the current parameter estimates. The sampling method, on the other hand, only considers a small change in each step - that of re-aligning a previously aligned target word to a new source. The reason for our choice is the ease of modification of such sampling models. They allow for easy introduction of further parameters and more complex probabilistic functions, as well as Bayesian priors, all of which are likely to be helpful in development[3].

Under the sampling framework, the model provides the probability of changing the alignment $A[i]$ of a target word i from a previously aligned source word j to a new one $\hat{j}$. In all the models we consider, this probability is proportional to the ratio between the scores of the old sentence alignment A and the new one $\hat{A}$, which differs from the old only in the realignment of i to $\hat{j}$.

$$P(A[i] = j \Rightarrow A[i] = \hat{j}\,) \sim \frac{P_{model}(\hat{A})}{P_{model}(A)} \tag{2}$$

As a starting point for our dependency parsing model, we re-implemented the first three IBM models [4] in the sampling framework.

3.4 Reformulating the IBM models

IBM Model 1 According to this model, the probability of an alignment between target word i and source word $\hat{j}$ depends only on the lexical identities of the two words w_i and $w_{\hat{j}}$ respectively. This gives us equation 3.

$$\begin{aligned} P(A[i] \Rightarrow \hat{j}\,) &\sim \frac{P_{model}(\hat{A})}{P_{model}(A)} = \frac{\prod_k P(w_k, w_{A[k]})}{\prod_{k'} P(w_{k'}, w_{\hat{A}[k']})} \\ P(A[i] \Rightarrow \hat{j}\,) &\sim \frac{P(w_i, w_{\hat{j}})}{P(w_i, w_j)} \end{aligned} \tag{3}$$

In our implementation we assume the alignment follows a Chinese Restaurant Process (CRP), where the probability of w_i aligning to w_j is proportional to the number of times they have been aligned in the past (the rest of the data), as follows:

$$P(w_i, w_{\hat{j}}) = \frac{\#(w_i, w_j) + \alpha_1/V}{\#(*, w_j) + \alpha_1} \tag{4}$$

Here, $\#(w_i, w_j)$ represents the number of times the target word w_i was observed to be aligned to w_j in the rest of the data, and $*$ stands for any word, V is the size of the vocabulary, and α_1 is a hyperparameter of the CRP, which can also be viewed as a smoothing factor.

IBM Model 2 The original IBM model 2 is a distortion model that assumes that the probability of an alignment between target word i and source word $\hat{j}$ depends only on the locations of the words, i.e., the values i and $\hat{j}$, taking into account the different lengths l and m of the source and target sentences, respectively. For dependency parsing, where we align sentences to themselves, $l = m$. This gives us equation 5.

$$\begin{aligned} P(A[i] \Rightarrow \hat{j}\,) &\sim \frac{P_{model}(\hat{A})}{P_{model}(A)} = \frac{P(i, \hat{j}, l)}{P(i, j, l)} \\ P(i, \hat{j}, l) &= \frac{\#(i, \hat{j}, l) + \alpha_2/D}{\#(i, *, l) + \alpha_2} \end{aligned} \tag{5}$$

Again, we assume a CRP when choosing a distortion value, where D is the expected number of distance values (set to 10 in our experiments), α_2 is the CRP hyperparameter, $\#(i, j, l)$ is the number of times a target word in position i was aligned to a source word in position j in sentences of length l, and $\#(i, *, l)$ is the number of times word in position i was aligned (to any source position) in sentences of length l.

Even without the need for handling different lengths for source and target sentences, this model is complex and requires estimating a separate probability for each triplet (i, j, l). In addition, the assumption that the distance distribution depends only on the sentence length and is similar for all tokens seems unreasonable, especially when dealing with part-of-speech tokens and dependency relations. Such concerns have been mentioned in the SMT literature and were shown to be justified in our experiments (see Sec. 4). For this reason, we

[3] Preliminary experiments using the EM approach via the GIZA++ toolkit (Och and Ney, 2003) resulted in similar performance to that of the sampling method for IBM Models 1 and 2. However, we were unable to explore the use of Model 3 under that framework, since the implementation of the model was strongly coupled to other, SMT-specific, optimizations and heuristics.

[4] Our implementation, as well as some core components in our framework, are based on code kindly provided by Chris Dyer.

also implemented an alternate distance model, based loosely on Liang et al. (2006). Under the alternate model, the probability of an alignment between target word i and source word $\hat{j}$ depends on the distance between them, their order, the sentence length, and the word type of the head, according to equation 6.

$$P(i,\hat{j},l) = \frac{\#[w_i,(i\text{-}\hat{j}),l] + \alpha_3/D}{\#(w_i,*,l)+\alpha_3} \tag{6}$$

IBM Model 3 This model handles the notion of fertility (or valence). Under this model, the probability of an alignment depends on how many target words are aligned to each of the source words. Each source word type $w_{\hat{j}}$, has a distribution specifying the probability of having n aligned target words. The probability of an alignment is proportional to the product of the probabilities of the fertilities in the alignment and takes into account the special status of the null word (represented by the index $j = 0$). This probability is given in Equation 7, which is based on Equation 32 in Brown et al. (1993)[5].

$$P(A) \sim \binom{l-\phi_0}{\phi_0} p_0^{l-2\phi_0} p_1^{\phi_0} \prod_{j=1}^{l} \phi_j! \frac{\#(w_j,\phi_j)+\alpha_4/F}{\#(w_j,*)+\alpha_4} \tag{7}$$

Here, ϕ_j denotes the number of target words aligned to the j-th source word in alignment A. p_1 and p_0 sum to 1 and are used to derive the probability that there will be ϕ_0 null-aligned words in a sentence containing l words[6]. $\#(w_j,\phi_j)$ represents the number of times source word w_j was observed to have ϕ_j dependent target words, $\#(w_j,*)$ is the number of times w_j appeared in the data, F is the expected number of fertility values (5 in our experiments), and α_4 is the CRP hyperparameter.

Combining the Models The original IBM models work in an incremental fashion, with each model using the output of the previous one as a starting point and adding a new component to the probability distribution. The dependency parsing framework employs a similar approach. It uses the alignments learned by the previous model as the starting point of the next and combines the probability distributions of each component via a product model. This allows for the easy introduction of new models which consider different aspects of the alignment and complement each other.

Preventing Self-Alignment When adapting the alignment approach to dependency parsing, we view the task as that of aligning a sentence to itself. One issue we must address is preventing the degenerate solution of aligning each word to itself. For this purpose we introduce a simple model into the product which gives zero probability to alignments which contain a word aligned to itself, as in equation 8.

$$P(A[i]=\hat{j}\,) = \begin{cases} 0 & \text{if } i = \hat{j} \\ \frac{1}{l-1} & \text{otherwise} \end{cases} \tag{8}$$

4 Experiments

4.1 Data

We evaluated our model on several corpora. The first of these was the Penn. Treebank portion of the Wall Street Journal (WSJ). We used the Constituent-to-Dependency Conversion Tool[7] to convert the treebank format into CoNLL format.

We also made use of the Danish and Dutch datasets from the CoNLL 2006 shared task[8]. Since we do not make use of annotation, we can induce a dependency structure on the entire dataset provided (disregarding the division into training and testing).

Following Klein and Manning (2004), we used the gold-standard part-of-speech sequences rather than the lexical forms and evaluated on sentences containing 10 or fewer tokens after removal of punctuation.

4.2 Results

Table 1 shows the results of the IBM Models on the task of directed (unlabeled) dependency parsing. We compare to the right-branching baseline used by Klein and Manning (2004). For the WSJ10 corpus, the authors reported 43.2% accuracy for DMV and 33.6% for the baseline. Although there are small

[5] The transitional version of this equation depends on whether either the old source word (j) or the new one ($\hat{j}$) are null, and is omitted for brevity. Further details can be found in Brown et al. (1993) Section 4.4 and Equation 43.

[6] For details, see Brown et al. (1993) Equation 31.

differences in evaluation, as evidenced by the difference between our baseline scores, IBM Models 2 and 3 outperform the baseline by a large margin and Model 3 approaches the performance of DMV. On the Dutch and Danish datasets, the trends are similar. On the latter dataset, even Model 1 outperforms the right-branching baseline. However, the Danish dataset is unusual (see Buchholz and Marsi 2006) in that the alternate adjacency baseline of left-branching (also mentioned by Klein and Manning 2004) is extremely strong and achieves 48.8% directed accuracy.

4.3 Analysis

In order to better understand what our alignment model was learning, we looked at each component element individually.

Lexical Association To explore what Model 1 was learning, we analyzed the resulting probability tables for association between tokens. Table 2 shows the most likely dependency attachment for the top ten most common parts-of-speech. The model is clearly learning meaningful connections between parts of speech (determiners and adjectives to nouns, adverbs to verbs, etc.), but there is little notion of directionality, and cycles can exist. For instance, the model learns the connection between determiner and noun, but is unsure which is the head and which the dependent. A similar connection is learned between *to* and verbs in the base form (VB). This inconsistency is, to a large extent, the result of the deficiencies of the model, stemming from the fact that the IBM models were designed for a different task and are not trying to learn a well-formed tree. However, there is a strong linguistic basis to consider the directionality of these relations difficult. There is some debate among linguists as to whether the head of a noun phrase is the noun or the determiner[9] (see Abney 1987). Each can be seen as a different kind of head element, performing a different function, similarly to the multiple types of dependency relations identified in Hudson's (1990) Word Grammar. A similar case can be made regarding the head of an infinitive phrase. The infinitive form of the verb may be considered the lexical head, determining the predicate, while *to* can be seen as the functional head, encoding inflectional features, as in Chomsky's (1981) Government & Binding model[10].

Distance Models The original IBM distortion model (Model 2), which does not differentiate between words types and looks only at positions, has an accuracy of 33.43% on the WSJ10 corpus. In addition, it tends to strongly favor left-branching attachment (57.2% of target words were attached to the word immediately to their right, 22.6% to their left, as opposed to 31% and 25.8% in the gold standard). The alternative distance model we proposed, which takes into account the identity of the head word, achieves better accuracy and is closer to the gold standard balance (43.5% right and 35.3% left).

Figure 3 shows the distribution of the location of the dependent relative to the head word (at position 0) for several common parts-of-speech. It is interesting to see that singular and plural nouns (NN, NNS) behave similarly. They both have a strong preference for local attachment and a tendency towards a left-dependent (presumably the determiner, see above Table 2). Pronouns (NNP), on the other hand, are more likely to attach to the right since they are not modified by determiners. Verbs in past (VBZ) and present (VBD, VBP) forms have similar behavior, with a flatter distribution of dependent locations, whereas the base form (VB) attaches almost exclusively to the preceding token, presumably

[9] In fact, the original DMV chose the determiner as the head (see discussion in Klein and Manning 2004, Section 3).

[10] We thank an anonymous reviewer for elucidating this point.

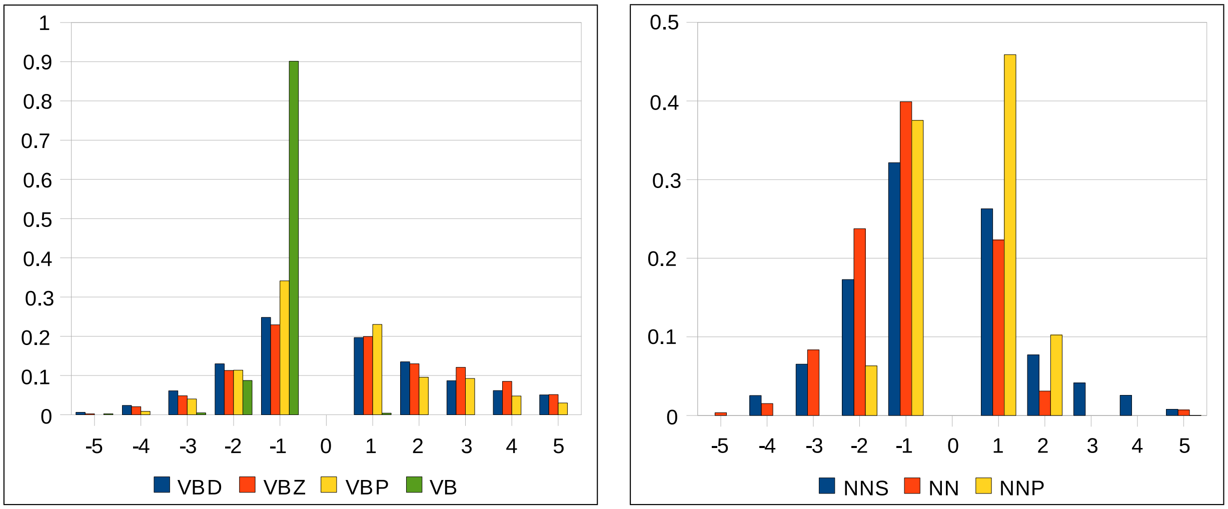

Figure 3: Distribution of head-to-dependent distance for several types of verbs (left) and nouns (right), as learned by our alternate distance model.

to (see Table 2).

Fertility Figure 4 shows the distribution of fertility values for several common parts of speech. Verbs have a relatively flat distribution with a longer tail as compared to nouns, which means they are likely to have a larger number of arguments. Once again, the base form (VB) exhibits different behavior from the other verbs forms, taking almost exclusively one argument. This is likely an effect of the strong connection between base form verbs and the preceding word *to*.

Hyper-Parameters Each of our models requires a value for its CRP hyperparameter (see Section 3.4). In this work, since parameter estimation was not our focus, we set the hyperparameters to be approximately $\frac{1}{K}$, where K is the number of possible values, according to the rule of thumb common in the literature. Specifically, we chose $\alpha_1 = 0.01, \alpha_3 = 0.05, \alpha_4 = 0.1$. We investigated the effect of these choices on performance in a separate set of experiments, which showed that small variations (up to an order of magnitude) in these parameters had little effect on the results.

In addition to the CRP parameters, Model 3 requires a value for p_1, the null fertility hyperparameter. In our experiments, we found that this hyperparameter had a very strong effect on results if it was above 0.1, creating many spurious null alignments. However, below that threshold, the effects were small. In the experiments reported here, we set $p_1 = 0.01$.

Initialization One issue with DMV, which is often mentioned, is its sensitivity to initialization. We tested our model with random initialization (uniform alignment probabilities) and with an approximation of the ad-hoc “harmonic” initialization described in Klein and Manning (2004) and found no noticeable difference in accuracy.

4.4 Discussion

The accuracy achieved by the IBM models (Table 1) is surprisingly high, given the fact that the IBM models were not designed with dependency parsing in mind. It is likely that customizing the models to the task will result in even better performance. Our findings in Section 4.3 support this hypothesis. The analysis showed that the lack of tree structure in the model impacted the learning, and therefore it is expected that a component which enforces tree structure (prevents cycles) will be beneficial.

Although it lacks an inherent notion of tree structure, the alignment-based approach has several advantages over the head-outward approach of DMV and related models. It can consider the alignment as a whole and take into account global sentence constraints, not just head-dependent relations. These may also include tree-structure constraints common to the head-outward approaches, but can be more flexible in how they are addressed. For instance,

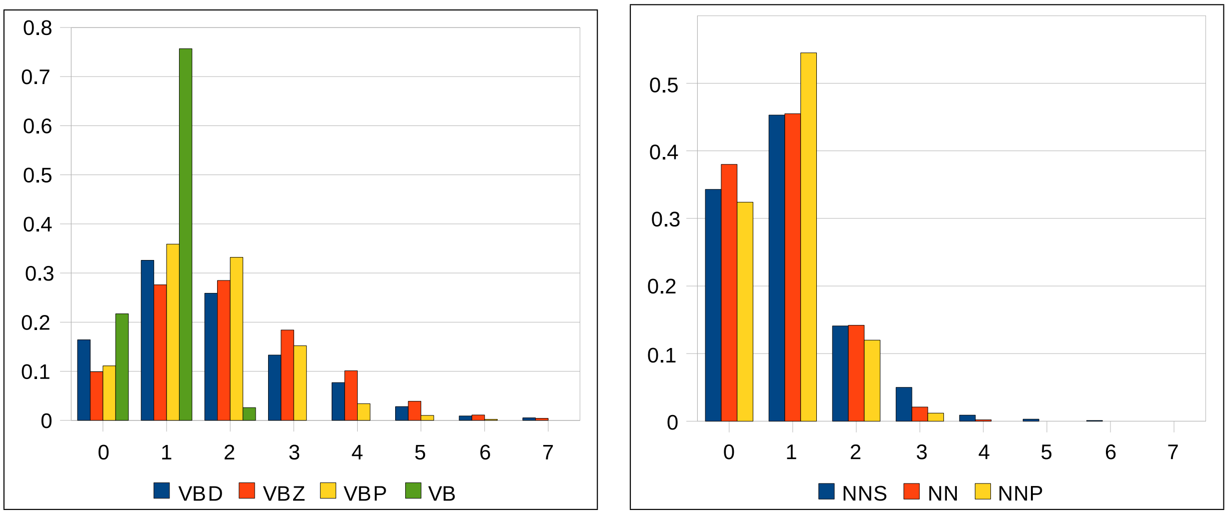

Figure 4: Distribution of fertility values for several types of verbs (left) and nouns (right), as learned by IBM Model 3.

DMV's method of modeling tree structure does not allow non-projective dependencies, whereas an alignment-based model may choose to allow or constrain non-projectivity, as learned from the data. Another advantage of our alignment-based models is the fact that they are not strongly sensitive to initialization and can be started from a set of random alignments.

5 Conclusions and Future Work

We have described an alternative formulation of dependency parsing as a problem of word alignment. This connection motivated us to explore the possibility of using alignment tools for the task of unsupervised dependency parsing. We chose to experiment with the well-known IBM alignment models which share a set of similar modeling assumptions with Klein and Manning's (2004) *Dependency Model with Valence*. Our experiments showed that the IBM models are surprisingly effective at the dependency parsing task, outperforming the right-branching baseline and approaching the accuracy of DMV. Our results demonstrate that the alignment approach can be used as a foundation for dependency parsing algorithms and motivates further research in this area.

There are many interesting avenues for further research. These include improving and extending the existing IBM models, as well as introducing new models that are specifically designed for the parsing task and represent relevant linguistic considerations (e.g., enforcing tree structure, handling crossing dependencies, learning left- or right-branching tendencies).

In Spitkovsky et al. (2010), the authors show that a gradual increase in the complexity of the data can aid the learning process. The IBM approach demonstrated the benefit of a gradual increase of *model* complexity. It would be interesting to see if the two approaches could be successfully combined.

Finally, although we use our framework for dependency parsing, the sampling approach and the framework we developed can be used to explore new models for bilingual word alignment. Furthermore, an alignment-based parsing method is expected to integrate well with SMT bi-lingual alignment models and may, therefore, be suitable for combined models which use parse trees to improve word alignment (e.g., Burkett et al. 2010).

Acknowledgments

I would like to thank Chris Dyer for providing the basis for the sampling implementation. I would also like to thank Chris, Adam Lopez, Trevor Cohn, Adam Faulkner and the anonymous reviewers for their time and effort and their helpful comments and suggestions.

Abstract

This paper addresses the problem of learning to map sentences to logical form, given training data consisting of natural language sentences paired with logical representations of their meaning. Previous approaches have been designed for particular natural languages or specific meaning representations; here we present a more general method. The approach induces a probabilistic CCG grammar that represents the meaning of individual words and defines how these meanings can be combined to analyze complete sentences. We use higher-order unification to define a hypothesis space containing all grammars consistent with the training data, and develop an online learning algorithm that efficiently searches this space while simultaneously estimating the parameters of a log-linear parsing model. Experiments demonstrate high accuracy on benchmark data sets in four languages with two different meaning representations.

1 Introduction

A key aim in natural language processing is to learn a mapping from natural language sentences to formal representations of their meaning. Recent work has addressed this problem by learning semantic parsers given sentences paired with logical meaning representations (Thompson & Mooney, 2002; Kate et al., 2005; Kate & Mooney, 2006; Wong & Mooney, 2006, 2007; Zettlemoyer & Collins, 2005, 2007; Lu et al., 2008). For example, the training data might consist of English sentences paired with lambda-calculus meaning representations:

Sentence: which states border texas
Meaning: $\lambda x.state(x) \wedge next\_to(x, tex)$

Given pairs like this, the goal is to learn to map new, unseen, sentences to their corresponding meaning.

Previous approaches to this problem have been tailored to specific natural languages, specific meaning representations, or both. Here, we develop an approach that can learn to map any natural language to a wide variety of logical representations of linguistic meaning. In addition to data like the above, this approach can also learn from examples such as:

Sentence: hangi eyaletin texas ye siniri vardir
Meaning: $answer(state(borders(tex)))$

where the sentence is in Turkish and the meaning representation is a variable-free logical expression of the type that has been used in recent work (Kate et al., 2005; Kate & Mooney, 2006; Wong & Mooney, 2006; Lu et al., 2008).

The reason for generalizing to multiple languages is obvious. The need to learn over multiple representations arises from the fact that there is no standard representation for logical form for natural language. Instead, existing representations are ad hoc, tailored to the application of interest. For example, the variable-free representation above was designed for building natural language interfaces to databases.

Our approach works by inducing a combinatory categorial grammar (CCG) (Steedman, 1996, 2000). A CCG grammar consists of a language-specific lexicon, whose entries pair individual words and phrases with both syntactic and semantic information, and a universal set of combinatory rules that

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1223–1233,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

project that lexicon onto the sentences and meanings of the language via syntactic derivations. The learning process starts by postulating, for each sentence in the training data, a single multi-word lexical item pairing that sentence with its complete logical form. These entries are iteratively refined with a restricted higher-order unification procedure (Huet, 1975) that defines all possible ways to subdivide them, consistent with the requirement that each training sentence can still be parsed to yield its labeled meaning.

For the data sets we consider, the space of possible grammars is too large to explicitly enumerate. The induced grammar is also typically highly ambiguous, producing a large number of possible analyses for each sentence. Our approach discriminates between analyses using a log-linear CCG parsing model, similar to those used in previous work (Clark & Curran, 2003, 2007), but differing in that the syntactic parses are treated as a hidden variable during training, following the approach of Zettlemoyer & Collins (2005, 2007). We present an algorithm that incrementally learns the parameters of this model while simultaneously exploring the space of possible grammars. The model is used to guide the process of grammar refinement during training as well as providing a metric for selecting the best analysis for each new sentence.

We evaluate the approach on benchmark datasets from a natural language interface to a database of US Geography (Zelle & Mooney, 1996). We show that accurate models can be learned for multiple languages with both the variable-free and lambda-calculus meaning representations introduced above. We also compare performance to previous methods (Kate & Mooney, 2006; Wong & Mooney, 2006, 2007; Zettlemoyer & Collins, 2005, 2007; Lu et al., 2008), which are designed with either language- or representation- specific constraints that limit generalization, as discussed in more detail in Section 6. Despite being the only approach that is general enough to run on all of the data sets, our algorithm achieves similar performance to the others, even outperforming them in several cases.

2 Overview of the Approach

The goal of our algorithm is to find a function $f : x \rightarrow z$ that maps sentences x to logical expressions z. We learn this function by inducing a probabilistic CCG (PCCG) grammar from a training set $\{(x_i, z_i)|i = 1 \ldots n\}$ containing example (sentence, logical-form) pairs such as ("New York borders Vermont", $next\_to(ny, vt)$). The induced grammar consists of two components which the algorithm must learn:

- A CCG lexicon, Λ, containing lexical items that define the space of possible parses y for an input sentence x. Each parse contains both syntactic and semantic information, and defines the output logical form z.
- A parameter vector, θ, that defines a distribution over the possible parses y, conditioned on the sentence x.

We will present the approach in two parts. The lexical induction process (Section 4) uses a restricted form of higher order unification along with the CCG combinatory rules to propose new entries for Λ. The complete learning algorithm (Section 5) integrates this lexical induction with a parameter estimation scheme that learns θ. Before presenting the details, we first review necessary background.

3 Background

This section provides an introduction to the ways in which we will use lambda calculus and higher-order unification to construct meaning representations. It also reviews the CCG grammar formalism and probabilistic extensions to it, including existing parsing and parameter estimation techniques.

3.1 Lambda Calculus and Higher-Order Unification

We assume that sentence meanings are represented as logical expressions, which we will construct from the meaning of individual words by using the operations defined in the lambda calculus. We use a version of the typed lambda calculus (cf. Carpenter (1997)), in which the basic types include e, for entities; t, for truth values; and i for numbers. There are also function types of the form $\langle e, t\rangle$ that are assigned to lambda expressions, such as $\lambda x.state(x)$, which take entities and return truth values. We represent the meaning of words and phrases using lambda-calculus expressions that can contain constants, quantifiers, logical connectors, and lambda abstractions.

The advantage of using the lambda calculus lies in its generality. The meanings of individual words and phrases can be arbitrary lambda expressions, while the final meaning for a sentence can take different forms. It can be a full lambda-calculus expression, a variable-free expression such as $answer(state(borders(tex)))$, or any other logical expression that can be built from the primitive meanings via function application and composition.

The higher-order unification problem (Huet, 1975) involves finding a substitution for the free variables in a pair of lambda-calculus expressions that, when applied, makes the expressions equal each other. This problem is notoriously complex; in the unrestricted form (Huet, 1973), it is undecidable. In this paper, we will guide the grammar induction process using a restricted version of higher-order unification that is tractable. For a given expression h, we will need to find expressions for f and g such that either $h = f(g)$ or $h = \lambda x.f(g(x))$. This limited form of the unification problem will allow us to define the ways to split h into subparts that can be recombined with CCG parsing operations, which we will define in the next section, to reconstruct h.

3.2 Combinatory Categorial Grammar

CCG (Steedman, 2000) is a linguistic formalism that tightly couples syntax and semantics, and can be used to model a wide range of language phenomena. For present purposes a CCG grammar includes a lexicon Λ with entries like the following:

$$\begin{array}{l}
\text{New York} \vdash NP : ny \\
\text{borders} \vdash S\backslash NP/NP : \lambda x\lambda y.next\_to(y,x) \\
\text{Vermont} \vdash NP : vt
\end{array}$$

where each lexical item $w \vdash X : h$ has words w, a syntactic category X, and a logical form h expressed as a lambda-calculus expression. For the first example, these are "New York," NP, and ny. CCG syntactic categories may be atomic (such as S, NP) or complex (such as $S\backslash NP/NP$).

CCG combines categories using a set of *combinatory rules*. For example, the forward ($>$) and backward ($<$) *application* rules are:

$$\begin{array}{lclr}
X/Y : f \quad Y : g & \Rightarrow & X : f(g) & (>) \\
Y : g \quad X\backslash Y : f & \Rightarrow & X : f(g) & (<)
\end{array}$$

These rules apply to build syntactic and semantic derivations under the control of the word order information encoded in the slash directions of the lexical entries. For example, given the lexicon above, the sentence *New York borders Vermont* can be parsed to produce:

$$\begin{array}{cccl}
\text{New York} & \text{borders} & \text{Vermont} & \\
\cline{1-1}\cline{2-2}\cline{3-3}
NP & (S\backslash NP)/NP & NP & \\
ny & \lambda x\lambda y.next\_to(y,x) & vt & \\
\cline{2-3}
 & \multicolumn{2}{c}{(S\backslash NP)} & > \\
 & \multicolumn{2}{c}{\lambda y.next\_to(y,vt)} & \\
\cline{1-3}
\multicolumn{3}{c}{S} & < \\
\multicolumn{3}{c}{next\_to(ny,vt)} &
\end{array}$$

where each step in the parse is labeled with the combinatory rule ($- >$ or $- <$) that was used.

CCG also includes combinatory rules of forward ($>$ **B**) and backward ($<$ **B**) *composition*:

$$\begin{array}{llr}
X/Y : f \quad Y/Z : g & \Rightarrow X/Z : \lambda x.f(g(x)) & (> \mathbf{B}) \\
Y\backslash Z : g \quad X\backslash Y : f & \Rightarrow X\backslash Z : \lambda x.f(g(x)) & (< \mathbf{B})
\end{array}$$

These rules provide for a relaxed notion of constituency which will be useful during learning as we reason about possible refinements of the grammar.

We also allow vertical slashes in CCG categories, which act as wild cards. For example, with this extension the forward application combinator ($>$) could be used to combine the category $S/(S|NP)$ with any of $S\backslash NP$, S/NP, or $S|NP$. Figure 1 shows two parses where the composition combinators and vertical slashes are used. These parses closely resemble the types of analyses that will be possible under the grammars we learn in the experiments described in Section 8.

3.3 Probabilistic CCGs

Given a CCG lexicon Λ, there will, in general, be many possible parses for each sentence. We select the most likely alternative using a log-linear model, which consists of a feature vector ϕ and a parameter vector θ. The joint probability of a logical form z constructed with a parse y, given a sentence x is

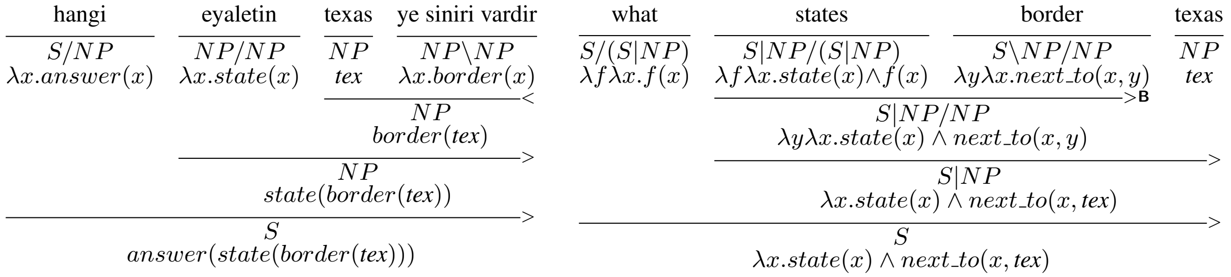

Figure 1: Two examples of CCG parses with different logical form representations.

defined as:

$$P(y,z|x;\theta,\Lambda) = \frac{e^{\theta\cdot\phi(x,y,z)}}{\sum_{(y',z')} e^{\theta\cdot\phi(x,y',z')}} \qquad (1)$$

Section 7 defines the features used in the experiments, which include, for example, lexical features that indicate when specific lexical items in Λ are used in the parse y. For parsing and parameter estimation, we use standard algorithms (Clark & Curran, 2007), as described below.

The parsing, or inference, problem is to find the most likely logical form z given a sentence x, assuming the parameters θ and lexicon Λ are known:

$$f(x) = \arg\max_z p(z|x;\theta,\Lambda) \qquad (2)$$

where the probability of the logical form is found by summing over all parses that produce it:

$$p(z|x;\theta,\Lambda) = \sum_y p(y,z|x;\theta,\Lambda) \qquad (3)$$

In this approach the distribution over parse trees y is modeled as a hidden variable. The sum over parses in Eq. 3 can be calculated efficiently using the inside-outside algorithm with a CKY-style parsing algorithm.

To estimate the parameters themselves, we use stochastic gradient updates (LeCun et al., 1998). Given a set of n sentence-meaning pairs $\{(x_i,z_i) : i = 1...n\}$, we update the parameters θ iteratively, for each example i, by following the local gradient of the conditional log-likelihood objective $O_i = \log P(z_i|x_i;\theta,\Lambda)$. The local gradient of the individual parameter θ_j associated with feature ϕ_j and training instance (x_i,z_i) is given by:

$$\begin{aligned}\frac{\partial O_i}{\partial \theta_j} &= E_{p(y|x_i,z_i;\theta,\Lambda)}[\phi_j(x_i,y,z_i)] \\ &\quad -E_{p(y,z|x_i;\theta,\Lambda)}[\phi_j(x_i,y,z)]\end{aligned} \qquad (4)$$

As with Eq. 3, all of the expectations in Eq. 4 are calculated through the use of the inside-outside algorithm on a pruned parse chart. In the experiments, each chart cell was pruned to the top 200 entries.

4 Splitting Lexical Items

Before presenting a complete learning algorithm, we first describe how to use higher-order unification to define a procedure for splitting CCG lexical entries. This splitting process is used to expand the lexicon during learning. We seed the lexical induction with a multi-word lexical item $x_i \vdash S{:}z_i$ for each training example (x_i,z_i), consisting of the entire sentence x_i and its associated meaning representation z_i. For example, one initial lexical item might be:

$$\text{New York borders Vermont} \vdash S{:}next\_to(ny,vt) \qquad (5)$$

Although these initial, sentential lexical items can parse the training data, they will not generalize well to unseen data. To learn effectively, we will need to split overly specific entries of this type into pairs of new, smaller, entries that generalize better. For example, one possible split of the lexical entry given in (5) would be the pair:

$$\text{New York borders} \vdash S/NP : \lambda x.next\_to(ny,x),$$
$$\text{Vermont} \vdash NP : vt$$

where we broke the original logical expression into two new ones $\lambda x.next\_to(ny,x)$ and vt, and paired them with syntactic categories that allow the new lexical entries to be recombined to produce the original analysis. The next three subsections define the set of possible splits for any given lexical item. The process is driven by solving a higher-order unification problem that defines all of the ways of splitting the logical expression into two parts, as described in Section 4.1. Section 4.2 describes how to construct syntactic categories that are consistent with the two new fragments of logical form and which will allow the new lexical items to recombine. Finally, Section 4.3 defines the full set of lexical entry pairs that can be created by splitting a lexical entry.

As we will see, this splitting process is overly prolific for any single language and will yield many lexical items that do not generalize well. For example, there is nothing in our original lexical entry above that provides evidence that the split should pair "Vermont" with the constant vt and not $\lambda x.next\_to(ny, x)$. Section 5 describes how we estimate the parameters of a probabilistic parsing model and how this parsing model can be used to guide the selection of items to add to the lexicon.

4.1 Restricted Higher-Order Unification

The set of possible splits for a logical expression h is defined as the solution to a pair of higher-order unification problems. We find pairs of logical expressions (f, g) such that either $f(g) = h$ or $\lambda x.f(g(x)) = h$. Solving these problems creates new expressions f and g that can be recombined according to the CCG combinators, as defined in Section 3.2, to produce h.

In the unrestricted case, there can be infinitely many solution pairs (f, g) for a given expression h. For example, when $h = tex$ and $f = \lambda x.tex$, the expression g can be anything. Although it would be simple enough to forbid vacuous variables in f and g, the number of solutions would still be exponential in the size of h. For example, when h contains a conjunction, such as $h = \lambda x.city(x) \wedge major(x) \wedge in(x, tex)$, any subset of the expressions in the conjunction can be assigned to f (or g).

To limit the number of possible splits, we enforce the following restrictions on the possible higher-order solutions that will be used during learning:

- **No Vacuous Variables:** Neither g or f can be a function of the form $\lambda x.e$ where the expression e does not contain the variable x. This rules out functions such as $\lambda x.tex$.
- **Limited Coordination Extraction:** The expression g cannot contain more than N of the conjuncts that appear in any coordination in h. For example, with $N = 1$ the expression $g = \lambda x.city(x) \wedge major(x)$ could not be used as a solution given the h conjuction above. We use $N = 4$ in our experimental evaluation.
- **Limited Application:** The function f cannot contain new variables applied to any non-variable subexpressions from h. For example, if $h = \lambda x.in(x, tex)$, the pair $f = \lambda q.q(tex)$ and $g = \lambda y\lambda x.in(x, y)$ is forbidden.

Together, these three restrictions guarantee that the number of splits is, in the worst case, an N-degree polynomial of the number of constants in h. The constraints were designed to increase the efficiency of the splitting algorithm without impacting performance on the development data.

4.2 Splitting Categories

We define the set of possible splits for a category $X : h$ with syntax X and logical form h by enumerating the solution pairs (f, g) to the higher-order unification problems defined above and creating syntactic categories for the resulting expressions. For example, given $X : h = S\backslash NP : \lambda x.in(x, tex)$, $f = \lambda y\lambda x.in(x, y)$, and $g = tex$, we would produce the following two pairs of new categories:

$$(S\backslash NP/NP{:}\lambda y\lambda x.in(x, y) \ , \ NP{:}tex)$$
$$(NP{:}tex \ , \ S\backslash NP\backslash NP{:}\lambda y\lambda x.in(x, y))$$

which were constructed by first choosing the syntactic category for g, in this case NP, and then enumerating the possible directions for the new slash in the category containing f. We consider each of these two steps in more detail below.

The new syntactic category for g is determined based on its type, $T(g)$. For example, $T(tex) = e$ and $T(\lambda x.state(x)) = \langle e, t\rangle$. Then, the function $C(T)$ takes an input type T and returns the syntactic category of T as follows:

$$C(T) = \begin{cases} NP & \text{if } T = e \\ S & \text{if } T = t \\ C(T_2)|C(T_1) & \text{when } T = \langle T_1, T_2\rangle \end{cases}$$

The basic types e and t are assigned syntactic categories NP and S, and all functional types are assigned categories recursively. For example $C(\langle e, t\rangle) = S|NP$ and $C(\langle e, \langle e, t\rangle\rangle) = S|NP|NP$. This definition of CCG categories is unconventional in that it never assigns atomic categories to functional types. For example, there is no distinct syntactic category N for nouns (which have semantic type $\langle e, t\rangle$). Instead, the more complex category $S|NP$ is used.

Now, we are ready to define the set of all category splits. For a category $A = X{:}h$ we can define

$$\mathrm{S}_C(A) = \{\mathrm{FA}(A) \cup \mathrm{BA}(A) \cup \mathrm{FC}(A) \cup \mathrm{BC}(A)\}$$

which is a union of sets, each of which includes splits for a single CCG operator. For example, FA$(X{:}h)$ is the set of category pairs

$$\mathrm{FA}(X{:}h) = \{(X/Y{:}f, Y{:}g) \mid h{=}f(g) \wedge Y{=}C(T(g))\}$$

where each pair can be combined with the forward application combinator, described in Section 3.2, to reconstruct $X{:}h$.

The remaining three sets are defined similarly, and are associated with the backward application and forward and backward composition operators, respectively:

$$\mathrm{BA}(X{:}h) = \{(Y{:}g, X\backslash Y{:}f) \mid h{=}f(g) \wedge Y{=}C(T(g))\}$$

$$\mathrm{FC}(X/Y{:}h) = \{(X/W{:}f, W/Y{:}g) \mid h{=}\lambda x.f(g(x)) \wedge W{=}C(T(g(x)))\}$$

$$\mathrm{BC}(X\backslash Y{:}h) = \{(W\backslash Y{:}g, X\backslash W{:}f) \mid h{=}\lambda x.f(g(x)) \wedge W{=}C(T(g(x)))\}$$

where the composition sets FC and BC only accept input categories with the appropriate outermost slash direction, for example FC$(X/Y{:}h)$.

4.3 Splitting Lexical Items

We can now define the lexical splits that will be used during learning. For lexical entry $w_{0:n} \vdash A$, with word sequence $w_{0:n} = \langle w_0, \ldots, w_n\rangle$ and CCG category A, define the set S_L of splits to be:

$$\mathrm{S}_L(w_{0:n}{\vdash}A) = \{(w_{0:i}{\vdash}B, w_{i+1:n}{\vdash}C) \mid 0 \leq i < n \wedge (B, C) \in \mathrm{S}_C(A)\}$$

where we enumerate all ways of splitting the words sequence $w_{0:n}$ and aligning the subsequences with categories in $\mathrm{S}_C(A)$, as defined in the last section.

5 Learning Algorithm

The previous section described how a splitting procedure can be used to break apart overly specific lexical items into smaller ones that may generalize better to unseen data. The space of possible lexical items supported by this splitting procedure is too large to explicitly enumerate. Instead, we learn the parameters of a PCCG, which is used both to guide the splitting process, and also to select the best parse, given a learned lexicon.

Figure 2 presents the unification-based learning algorithm, UBL. This algorithm steps through the data incrementally and performs two steps for each training example. First, new lexical items are induced for the training instance by splitting and merging nodes in the best correct parse, given the current parameters. Next, the parameters of the PCCG are updated by making a stochastic gradient update on the marginal likelihood, given the updated lexicon.

Inputs and Initialization The algorithm takes as input the training set of n (sentence, logical form) pairs $\{(x_i, z_i) : i = 1...n\}$ along with an NP list, Λ_{NP}, of proper noun lexical items such as $\mathrm{Texas} \vdash NP{:}tex$. The lexicon, Λ, is initialized with a single lexical item $x_i \vdash S : z_i$ for each of the training pairs along with the contents of the NP list. It is possible to run the algorithm without the initial NP list; we include it to allow direct comparisons with previous approaches, which also included NP lists. Features and initial feature weights are described in Section 7.

Step 1: Updating the Lexicon In the lexical update step the algorithm first computes the best correct parse tree y^* for the current training example and then uses y^* as input to the procedure NEW-LEX, which determines which (if any) new lexical items to add to Λ. NEW-LEX begins by enumerating all pairs $(C, w_{i:j})$, for $i < j$, where C is a category occurring at a node in y^* and $w_{i:j}$ are the (two or more) words it spans. For example, in the left parse in Figure 1, there would be four pairs: one with the category $C = NP\backslash NP{:}\lambda x.border(x)$ and the phrase $w_{i:j}$ ="ye siniri vardir", and one for each non-leaf node in the tree.

For each pair $(C, w_{i:j})$, NEW-LEX considers introducing a new lexical item $w_{i:j} {\vdash} C$, which allows for the possibility of a parse where the subtree rooted at C is replaced with this new entry. (If C is a leaf node, this item will already exist.) NEW-LEX also considers adding each pair of new lexical items that is obtained by splitting $w_{i:j}{\vdash}C$ as described in Section 4, thereby considering many different ways of reanalyzing the node. This process creates a set of possible new lexicons, where each lexicon expands

Λ in a different way by adding the items from either a single split or a single merge of a node in y^*.

For each potential new lexicon Λ', NEW-LEX computes the probability $p(y^*|x_i, z_i; \theta', \Lambda')$ of the original parse y^* under Λ' and parameters θ' that are the same as θ but have weights for the new lexical items, as described in Section 7. It also finds the best new parse $y' = \arg\max_y p(y|x_i, z_i; \theta', \Lambda')$.[1] Finally, NEW-LEX selects the Λ' with the largest difference in log probability between y' and y^*, and returns the new entries in Λ'. If y^* is the best parse for every Λ', NEW-LEX returns the empty set; the lexicon will not change.

Step 2: Parameter Updates For each training example we update the parameters θ using the stochastic gradient updates given by Eq. 4.

Discussion The alternation between refining the lexicon and updating the parameters drives the learning process. The initial model assigns a conditional likelihood of one to each training example (there is a single lexical item for each sentence x_i, and it contains the labeled logical form z_i). Although the splitting step often decreases the probability of the data, the new entries it produces are less specific and should generalize better. Since we initially assign positive weights to the parameters for new lexical items, the overall approach prefers splitting; trees with many lexical items will initially be much more likely. However, if the learned lexical items are used in too many incorrect parses, the stochastic gradient updates will down weight them to the point where the lexical induction step can merge or re-split nodes in the trees that contain them. This allows the approach to correct the lexicon and, hopefully, improve future performance.

```
Inputs: Training set $\{(x_i, z_i) : i = 1 \ldots n\}$ where each
    example is a sentence $x_i$ paired with a logical form
    $z_i$. Set of NP lexical items $\Lambda_{NP}$. Number of iterations $T$. Learning rate parameter $\alpha_0$ and cooling
    rate parameter $c$.
Definitions: The function NEW-LEX($y$) takes a parse
    $y$ and returns a set of new lexical items found by
    splitting and merging categories in $y$, as described
    in Section 5. The distributions $p(y|x, z; \theta, \Lambda)$ and
    $p(y, z|x; \theta, \Lambda)$ are defined by the log-linear model,
    as described in Section 3.3.
Initialization:
  • Set $\Lambda = \{x_i \vdash S : z_i\}$ for all $i = 1 \ldots n$.
  • Set $\Lambda = \Lambda \cup \Lambda_{NP}$
  • Initialize $\theta$ using coocurrence statistics, as described in Section 7.
Algorithm:
    For $t = 1 \ldots T, i = 1 \ldots n$ :
    Step 1: (Update Lexicon)
        • Let $y^* = \arg\max_y p(y|x_i, z_i; \theta, \Lambda)$
        • Set $\Lambda = \Lambda \cup$ NEW-LEX($y^*$) and expand the
          parameter vector $\theta$ to contain entries for the
          new lexical items, as described in Section 7.
    Step 2: (Update Parameters)
        • Let $\gamma = \frac{\alpha_0}{1+c\times k}$ where $k = i + t \times n$.
        • Let $\Delta = E_{p(y|x_i,z_i;\theta,\Lambda)}[\phi(x_i, y, z_i)]$
                  $-E_{p(y,z|x_i;\theta,\Lambda)}[\phi(x_i, y, z)]$
        • Set $\theta = \theta + \gamma\Delta$
Output: Lexicon $\Lambda$ and parameters $\theta$.
```

6 Related Work

Previous work has focused on a variety of different meaning representations. Several approaches have been designed for the variable-free logical representations shown in examples throughout this paper. For example, Kate & Mooney (2006) present a method (KRISP) that extends an existing SVM learning algorithm to recover logical representations. The WASP system (Wong & Mooney, 2006) uses statistical machine translation techniques to learn synchronous context free grammars containing both words and logic. Lu et al. (2008) (Lu08) developed a generative model that builds a single hybrid tree of words, syntax and meaning representation. These algorithms are all language independent but representation specific.

Other algorithms have been designed to recover lambda-calculus representations. For example, Wong & Mooney (2007) developed a variant of WASP (λ-WASP) specifically designed for this alternate representation. Zettlemoyer & Collins (2005, 2007) developed CCG grammar induction techniques where lexical items are proposed according to a set of hand-engineered lexical templates.

[1] This computation can be performed efficiently by incrementally updating the parse chart used to find y^*.

Our approach eliminates this need for manual effort.

Another line of work has focused on recovering meaning representations that are not based on logic. Examples include an early statistical method for learning to fill slot-value representations (Miller et al., 1996) and a more recent approach for recovering semantic parse trees (Ge & Mooney, 2006). Exploring the extent to which these representations are compatible with the logic-based learning approach we developed is an important area for future work.

Finally, there is work on using categorial grammars to solve other, related learning problems. For example, Buszkowski & Penn (1990) describe a unification-based approach for grammar discovery from bracketed natural language sentences and Villavicencio (2002) developed an approach for modeling child language acquisition. Additionally, Bos et al. (2004) consider the challenging problem of constructing broad-coverage semantic representations with CCG, but do not learn the lexicon.

7 Experimental Setup

Features We use two types of features in our model. First, we include a set of *lexical features*: For each lexical item $L \in \Lambda$, we include a feature ϕ_L that fires when L is used. Second, we include *semantic features* that are functions of the output logical expression z. Each time a predicate p in z takes an argument a with type $T(a)$ in position i it triggers two binary indicator features: $\phi_{(p,a,i)}$ for the predicate-argument relation; and $\phi_{(p,T(a),i)}$ for the predicate argument-type relation.

Initialization The weights for the semantic features are initialized to zero. The weights for the lexical features are initialized according to coocurrance statistics estimated with the Giza++ (Och & Ney, 2003) implementation of IBM Model 1. We compute translation scores for (word, constant) pairs that cooccur in examples in the training data. The initial weight for each ϕ_L is set to ten times the average score over the (word, constant) pairs in L, except for the weights of seed lexical entries in Λ_{NP} which are set to 10 (equivalent to the highest possible coocurrence score). We used the learning rate $\alpha_0 = 1.0$ and cooling rate $c = 10^{-5}$ in all training scenarios, and ran the algorithm for $T = 20$ iterations. These values were selected with cross validation on the Geo880 development set, described below.

Data and Evaluation We evaluate our system on the GeoQuery datasets, which contain natural-language queries of a geographical database paired with logical representations of each query's meaning. The full Geo880 dataset contains 880 (English-sentence, logical-form) pairs, which we split into a development set of 600 pairs and a test set of 280 pairs, following Zettlemoyer & Collins (2005). The Geo250 dataset is a subset of Geo880 containing 250 sentences that have been translated into Turkish, Spanish and Japanese as well as the original English. Due to the small size of this dataset we use 10-fold cross validation for evaluation. We use the same folds as Wong & Mooney (2006, 2007) and Lu et al. (2008), allowing a direct comparison.

The GeoQuery data is annotated with both lambda-calculus and variable-free meaning representations, which we have seen examples of throughout the paper. We report results for both representations, using the standard measures of *Recall* (percentage of test sentences assigned correct logical forms), *Precision* (percentage of logical forms returned that are correct) and *F1* (the harmonic mean of *Precision* and *Recall*).

Two-Pass Parsing To investigate the trade-off between precision and recall, we report results with a two-pass parsing strategy. When the parser fails to return an analysis for a test sentence due to novel words or usage, we reparse the sentence and allow the parser to skip words, with a fixed cost. Skipping words can potentially increase recall, if the ignored word is an unknown function word that does not contribute semantic content.

8 Results and Discussion

Tables 1, 2, and 3 present the results for all of the experiments. In aggregate, they demonstrate that our algorithm, UBL, learns accurate models across languages and for both meaning representations. This is a new result; no previous system is as general.

We also see the expected tradeoff between precision and recall that comes from the two-pass parsing approach, which is labeled UBL-s. With the ability to skip words, UBL-s achieves the highest recall of all reported systems for all evaluation conditions.

Table 2: Performance across languages on Geo250 with lambda-calculus meaning representations.

However, UBL achieves much higher precision and better overall F1 scores, which are generally comparable to the best performing systems.

The comparison to the CCG induction techniques of ZC05 and ZC07 (Table 3) is particularly striking. These approaches used language-specific templates to propose new lexical items and also required as input a set of hand-engineered lexical entries to model phenomena such as quantification and determiners. However, the use of higher-order unification allows UBL to achieve comparable performance while automatically inducing these types of entries.

For a more qualitative evaluation, Table 4 shows a selection of lexical items learned with high weights for the lambda-calculus meaning representations. Nouns such as “state” or “estado” are consistently learned across languages with the category $S|NP$, which stands in for the more conventional N. The algorithm also learns language-specific constructions such as the Japanese case markers “no” and “wa”, which are treated as modifiers that do not add semantic content. Language-specific word order is also encoded, using the slash directions of the CCG categories. For example, “what” and “que” take their arguments to the right in the wh-initial English and Spanish. However, the Turkish wh-word “nelerdir” and the Japanese question marker “nan desu ka” are sentence final, and therefore take their arguments to the left. Learning regularities of this type allows UBL to generalize well to unseen data.

UBL-s	**84.3**	85.2	84.7	**87.9**	88.5	88.2

Table 3: Performance on the Geo880 data set, with varied meaning representations.

There is less variation and complexity in the learned lexical items for the variable-free representation. The fact that the meaning representation is deeply nested influences the form of the induced grammar. For example, recall that the sentence “what states border texas” would be paired with the meaning $answer(state(borders(tex)))$. For this representation, lexical items such as:

$$\begin{aligned}&\text{what} \vdash S/NP : \lambda x.answer(x)\\&\text{states} \vdash NP/NP : \lambda x.state(x)\\&\text{border} \vdash NP/NP : \lambda x.borders(x)\\&\text{texas} \vdash NP : tex\end{aligned}$$

can be used to construct the desired output. In practice, UBL often learns entries with only a single slash, like those above, varying only in the direction, as required for the language. Even the more complex items, such as those for quantifiers, are consistently simpler than those induced from the lambda-calculus meaning representations. For example, one of the most complex entries learned in the experiments for English is the smallest $\vdash NP\backslash NP/(NP|NP){:}\lambda f \lambda x.smallest\_one(f(x))$.

There are also differences in the aggregate statistics of the learned lexicons. For example, the average length of a learned lexical item for the (lambda-calculus, variable-free) meaning representations is:

(1.21,1.08) for Turkish, (1.34,1.19) for English, (1.43,1.25) for Spanish and (1.63,1.42) for Japanese. For both meaning representations the model learns significantly more multiword lexical items for the somewhat analytic Japanese than the agglutinative Turkish. There are also variations in the average number of learned lexical items in the best parses during the final pass of training: 192 for Japanese, 206 for Spanish, 188 for English and 295 for Turkish. As compared to the other languages, the morpologically rich Turkish requires significantly more lexical variation to explain the data.

Finally, there are a number of cases where the UBL algorithm could be improved in future work. In cases where there are multiple allowable word orders, the UBL algorithm must learn individual entries for each possibility. For example, the following two categories are often learned with high weight for the Japanese word "chiisai":

$$NP/(S|NP)\backslash(NP|NP){:}\lambda f\lambda g.argmin(x, g(x), f(x))$$
$$NP|(S|NP)/(NP|NP){:}\lambda f\lambda g.argmin(x, g(x), f(x))$$

and are treated as distinct entries in the lexicon. Similarly, the approach presented here does not model morphology, and must repeatedly learn the correct categories for the Turkish words "nehri," "nehir," "nehirler," and "nehirlerin", all of which correspond to the logical form $\lambda x.river(x)$.

English
population of $\vdash NP/NP : \lambda x.population(x)$

9 Conclusions and Future Work

This paper has presented a method for inducing probabilistic CCGs from sentences paired with logical forms. The approach uses higher-order unification to define the space of possible grammars in a language- and representation-independent manner, paired with an algorithm that learns a probabilistic parsing model. We evaluated the approach on four languages with two meaning representations each, achieving high accuracy across all scenarios.

For future work, we are interested in exploring the generality of the approach while extending it to new understanding problems. One potential limitation is in the constraints we introduced to ensure the tractability of the higher-order unification procedure. These restrictions will not allow the approach to induce lexical items that would be used with, among other things, many of the type-raised combinators commonly employed in CCG grammars. We are also interested in developing similar grammar induction techniques for context-dependent understanding problems, such as the one considered by Zettlemoyer & Collins (2009). Such an approach would complement ideas for using high-order unification to model a wider range of language phenomena, such as VP ellipsis (Dalrymple et al., 1991).

Abstract

We present an approach to grammar induction that utilizes syntactic universals to improve dependency parsing across a range of languages. Our method uses a single set of manually-specified language-independent rules that identify syntactic dependencies between pairs of syntactic categories that commonly occur across languages. During inference of the probabilistic model, we use posterior expectation constraints to require that a minimum proportion of the dependencies we infer be instances of these rules. We also automatically refine the syntactic categories given in our coarsely tagged input. Across six languages our approach outperforms state-of-the-art unsupervised methods by a significant margin.[1]

1 Introduction

Despite surface differences, human languages exhibit striking similarities in many fundamental aspects of syntactic structure. These structural correspondences, referred to as *syntactic universals*, have been extensively studied in linguistics (Baker, 2001; Carnie, 2002; White, 2003; Newmeyer, 2005) and underlie many approaches in multilingual parsing. In fact, much recent work has demonstrated that learning cross-lingual correspondences from corpus data greatly reduces the ambiguity inherent in syntactic analysis (Kuhn, 2004; Burkett and Klein, 2008; Cohen and Smith, 2009a; Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010).

Table 1: The manually-specified universal dependency rules used in our experiments. These rules specify head-dependent relationships between coarse (i.e., unsplit) syntactic categories. An explanation of the ruleset is provided in Section 5.

In this paper, we present an alternative grammar induction approach that exploits these structural correspondences by declaratively encoding a small set of universal dependency rules. As input to the model, we assume a corpus annotated with coarse syntactic categories (i.e., high-level part-of-speech tags) and a set of universal rules defined over these categories, such as those in Table 1. These rules incorporate the definitional properties of syntactic categories in terms of their interdependencies and thus are universal across languages. They can potentially help disambiguate structural ambiguities that are difficult to learn from data alone — for example, our rules prefer analyses in which verbs are dependents of auxiliaries, even though analyzing auxiliaries as dependents of verbs is also consistent with the data. Leveraging these universal rules has the potential to improve parsing performance for a large number of human languages; this is particularly relevant to the processing of low-resource

languages. Furthermore, these universal rules are compact and well-understood, making them easy to manually construct.

In addition to these universal dependencies, each specific language typically possesses its own idiosyncratic set of dependencies. We address this challenge by requiring the universal constraints to only hold in expectation rather than absolutely, i.e., we permit a certain number of violations of the constraints.

We formulate a generative Bayesian model that explains the observed data while accounting for declarative linguistic rules during inference. These rules are used as expectation constraints on the posterior distribution over dependency structures. This approach is based on the posterior regularization technique (Graça et al., 2009), which we apply to a variational inference algorithm for our parsing model. Our model can also optionally refine common high-level syntactic categories into per-language categories by inducing a clustering of words using Dirichlet Processes (Ferguson, 1973). Since the universals guide induction toward linguistically plausible structures, automatic refinement becomes feasible even in the absence of manually annotated syntactic trees.

We test the effectiveness of our grammar induction model on six Indo-European languages from three language groups: English, Danish, Portuguese, Slovene, Spanish, and Swedish. Though these languages share a high-level Indo-European ancestry, they cover a diverse range of syntactic phenomenon. Our results demonstrate that universal rules greatly improve the accuracy of dependency parsing across all of these languages, outperforming current state-of-the-art unsupervised grammar induction methods (Headden III et al., 2009; Berg-Kirkpatrick and Klein, 2010).

2 Related Work

Learning with Linguistic Constraints Our work is situated within a broader class of unsupervised approaches that employ declarative knowledge to improve learning of linguistic structure (Haghighi and Klein, 2006; Chang et al., 2007; Graça et al., 2007; Cohen and Smith, 2009b; Druck et al., 2009; Liang et al., 2009a). The way we apply constraints is closest to the latter two approaches of posterior regularization and generalized expectation criteria.

In the posterior regularization framework, constraints are expressed in the form of expectations on posteriors (Graça et al., 2007; Ganchev et al., 2009; Graça et al., 2009; Ganchev et al., 2010). This design enables the model to reflect constraints that are difficult to encode via the model structure or as priors on its parameters. In their approach, parameters are estimated using a modified EM algorithm, where the E-step minimizes the KL-divergence between the model posterior and the set of distributions that satisfies the constraints. Our approach also expresses constraints as expectations on the posterior; we utilize the machinery of their framework within a variational inference algorithm with a mean field approximation.

Generalized expectation criteria, another technique for declaratively specifying expectation constraints, has previously been successfully applied to the task of dependency parsing (Druck et al., 2009). This objective expresses constraints in the form of preferences over model expectations. The objective is penalized by the square distance between model expectations and the prespecified values of the expectation. This approach yields significant gains compared to a fully unsupervised counterpart. The constraints they studied are corpus- and language-specific. Our work demonstrates that a small set of language-independent universals can also serve as effective constraints. Furthermore, we find that our method outperforms the generalized expectation approach using corpus-specific constraints.

Learning to Refine Syntactic Categories Recent research has demonstrated the usefulness of automatically refining the granularity of syntactic categories. While most of the existing approaches are implemented in the supervised setting (Finkel et al., 2007; Petrov and Klein, 2007), Liang et al. (2007) propose a non-parametric Bayesian model that learns the granularity of PCFG categories in an unsupervised fashion. For each non-terminal grammar symbol, the model posits a Hierarchical Dirichlet Process over its refinements (subsymbols) to automatically learn the granularity of syntactic categories. As with their work, we also use non-parametric priors for category refinement and employ variational methods for inference. However, our goal is to apply category refinement to dependency parsing, rather than to PCFGs, requiring a substantially different model formulation. While Liang et al. (2007) demonstrated empirical gains on a synthetic corpus, our experiments focus on unsupervised category refinement on real language data.

Universal Rules in NLP Despite the recent surge of interest in multilingual learning (Kuhn, 2004; Cohen and Smith, 2009a; Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010), there is surprisingly little computational work on linguistic universals. On the acquisition side, Daumé III and Campbell (2007) proposed a computational technique for discovering universal implications in typological features. More closely related to our work is the position paper by Bender (2009), which advocates the use of manually-encoded cross-lingual generalizations for the development of NLP systems. She argues that a system employing such knowledge could be easily adapted to a particular language by specializing this high level knowledge based on the typological features of the language. We also argue that cross-language universals are beneficial for automatic language processing; however, our focus is on learning language-specific adaptations of these rules from data.

3 Model

The central hypothesis of this work is that unsupervised dependency grammar induction can be improved using universal linguistic knowledge. Toward this end our approach is comprised of two components: a probabilistic model that explains how sentences are generated from latent dependency structures and a technique for incorporating declarative rules into the inference process.

We first describe the generative story in this section before turning to how constraints are applied during inference in Section 4. Our model takes as input (i.e., as observed) a set of sentences where each word is annotated with a coarse part-of-speech tag. Table 2 provides a detailed technical description of our model's generative process, and Figure 1 presents a model diagram.

For each observed coarse symbol s:

1. Draw top-level infinite multinomial over subsymbols $\beta_s \sim \mathrm{GEM}(\gamma)$.
2. For each subsymbol z of symbol s:
   (a) Draw word emission multinomial $\phi_{sz} \sim \mathrm{Dir}(\phi_0)$.
   (b) For each context value c:
      i. Draw child symbol generation multinomial $\theta_{szc} \sim \mathrm{Dir}(\theta_0)$.
      ii. For each child symbol s':
         A. Draw second-level infinite multinomial over subsymbols $\pi_{s'szc} \sim \mathrm{DP}(\alpha, \beta_{s'})$.

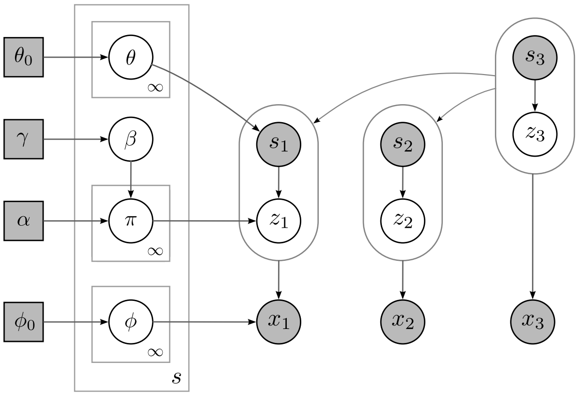
For each tree node i generated in context c by parent symbol s' and parent subsymbol z':

1. Draw coarse symbol $s_i \sim \mathrm{Mult}(\theta_{s'z'})$.
2. Draw subsymbol $z_i \sim \mathrm{Mult}(\pi_{s_i s' z' c})$.
3. Draw word $x_i \sim \mathrm{Mult}(\phi_{s_i z_i})$.

Table 2: The generative process for model parameters and parses. In the above GEM, DP, Dir, and Mult refer respectively to the stick breaking distribution, Dirichlet process, Dirichlet distribution, and multinomial distribution.

Generating Symbols and Words We describe how a single node of the tree is generated before discussing how the entire tree structure is formed. Each node of the dependency tree is comprised of three random variables: an observed coarse symbol s, a hidden refined subsymbol z, and an observed word x. In the following let the parent of the current node have symbol s' and subsymbol z'; the root node is generated from separate root-specific distributions. Subsymbol refinement is an optional component of the full model and can be omitted by deterministically equating s and z. As we explain at the end of this section, without this aspect the generative story closely resembles the classic dependency model with valence (DMV) of Klein and Manning (2004).

First we draw symbol s from a finite multinomial



s	-	coarse symbol (observed)
z	-	refined subsymbol
x	-	word (observed)
θ_{szc}	-	distr over child coarse symbols for each parent s and z and context c
β_s	-	top-level distr over subsymbols for s
$\pi_{ss'z'c}$	-	distr over subsymbols for each s, parent s' and z', and context c
ϕ_{sz}	-	distr over words for s and z

Figure 1: Graphical representation of the model and a summary of the notation. There is a copy of the outer plate for each distinct symbol in the observed coarse tags. Here, node 3 is shown to be the parent of nodes 1 and 2. Shaded variables are observed, square variables are hyperparameters. The elongated oval around s and z represents the two variables jointly. For clarity the diagram omits some arrows from θ to each s, π to each z, and ϕ to each x.

distribution with parameters $\theta_{s'z'c}$. As the indices indicate, we have one such set of multinomial parameters for every combination of parent symbol s' and subsymbol z' along with a *context* c. Here the context of the current node can take one of six values corresponding to every combination of direction (left or right) and valence (first, second, or third or higher child) with respect to its parent. The prior (base distribution) for each $\theta_{s'z'c}$ is a symmetric Dirichlet with hyperparameter θ_0.

Next we draw the refined syntactic category subsymbol z from an infinite multinomial with parameters $\pi_{ss'z'c}$. Here the selection of π is indexed by the current node's coarse symbol s, the symbol s' and subsymbol z' of the parent node, and the context c of the current node.

For each unique coarse symbol s we tie together the distributions $\pi_{ss'z'c}$ for all possible parent and context combinations (i.e., s', z', and c) using a Hierarchical Dirichlet Process (HDP). Specifically, for a single s, each distribution $\pi_{ss'z'c}$ over subsymbols is drawn from a DP with concentration parameter α and base distribution β_s over subsymbols. This base distribution β_s is itself drawn from a GEM prior with concentration parameter γ. By formulating the generation of z as an HDP, we can share parameters for a single coarse symbol's subsymbol distribution while allowing for individual variability based on node parent and context. Note that parameters are not shared across different coarse symbols, preserving the distinctions expressed via the coarse tag annotations.

Finally, we generate the word x from a finite multinomial with parameters ϕ_{sz}, where s and z are the symbol and subsymbol of the current node. The ϕ distributions are drawn from a symmetric Dirichlet prior.

Generating the Tree Structure We now consider how the structure of the tree arises. We follow an approach similar to the widely-referenced DMV model (Klein and Manning, 2004), which forms the basis of the current state-of-the-art unsupervised grammar induction model (Headden III et al., 2009). After a node is drawn we generate children on each side until we produce a designated STOP symbol. We encode more detailed valence information than Klein and Manning (2004) and condition child generation on parent valence. Specifically, after drawing a node we first decide whether to proceed to generate a child or to stop conditioned on the parent symbol and subsymbol and the current context (direction and valence). If we decide to generate a child we follow the previously described process for constructing a node. We can combine the stopping decision with the generation of the child symbol by including a distinguished STOP symbol as a possible outcome in distribution θ.

No-Split Model Variant In the absence of subsymbol refinement (i.e., when subsymbol z is set to be identical to coarse symbol s), our model simplifies in some respects. In particular, the HDP generation of z is obviated and word x is drawn from a word distribution ϕ_s indexed solely by coarse symbol s. The resulting simplified model closely resembles DMV (Klein and Manning, 2004), except that it 1) explicitly generate words x rather than only part-of-speech tags s, 2) encodes richer context and valence information, and 3) imposes a Dirichlet prior on the symbol distribution θ.

4 Inference with Constraints

We now describe how to augment our generative model of dependency structure with constraints derived from linguistic knowledge. Incorporating arbitrary linguistic rules directly in the generative story is challenging as it requires careful tuning of either the model structure or priors for each constraint. Instead, following the approach of Graça et al. (2007), we constrain the posterior to satisfy the rules in expectation during inference. This effectively biases the inference toward linguistically plausible settings.

In standard variational inference, an intractable true posterior is approximated by a distribution from a tractable set (Bishop, 2006). This tractable set typically makes stronger independence assumptions between model parameters than the model itself. To incorporate the constraints, we further restrict the set to only include distributions that satisfy the specified expectation constraints over hidden variables.

In general, for some given model, let θ denote the entire set of model parameters and z and x denote the hidden structure and observations respectively. We are interested in estimating the posterior $p(\theta, z \mid x)$. Variational inference transforms this problem into an optimization problem where we try to find a distribution $q(\theta, z)$ from a restricted set $\mathcal{Q}$ that minimizes the KL-divergence between $q(\theta, z)$ and $p(\theta, z \mid x)$:

$$\begin{aligned}&\mathrm{KL}(q(\theta, z) \parallel p(\theta, z \mid x)) \\ &\quad = \int q(\theta, z) \log \frac{q(\theta, z)}{p(\theta, z, x)} d\theta dz + \log p(x).\end{aligned}$$

Rearranging the above yields:

$$\log p(x) = \mathrm{KL}(q(\theta, z) \parallel p(\theta, z \mid x)) + \mathcal{F},$$

where $\mathcal{F}$ is defined as

$$\mathcal{F} \equiv \int q(\theta, z) \log \frac{p(\theta, z, x)}{q(\theta, z)} d\theta dz. \quad (1)$$

Thus $\mathcal{F}$ is a lower bound on likelihood. Maximizing this lower bound is equivalent to minimizing the KL-divergence between $p(\theta, z \mid x)$ and $q(\theta, z)$. To make this maximization tractable we make a mean field assumption that q belongs to a set $\mathcal{Q}$ of distributions that factorize as follows:

$$q(\theta, z) = q(\theta)q(z).$$

We further constrain q to be from the subset of $\mathcal{Q}$ that satisfies the expectation constraint $E_q[f(z)] \leq b$ where f is a deterministically computable function of the hidden structures. In our model, for example, f counts the dependency edges that are an instance of one of the declaratively specified dependency rules, while b is the proportion of the total dependencies that we expect should fulfill this constraint.[2]

With the mean field factorization and the expectation constraints in place, solving the maximization of $\mathcal{F}$ in (1) separately for each factor yields the following updates:

$$q(\theta) = \underset{q(\theta)}{\operatorname{argmin}} \ \mathrm{KL}\left(q(\theta) \parallel q'(\theta)\right), \quad (2)$$

$$q(z) = \underset{q(z)}{\operatorname{argmin}} \ \mathrm{KL}\left(q(z) \parallel q'(z)\right)$$

$$s.t. \quad E_{q(z)}[f(z)] \leq b, \quad (3)$$

where

$$q'(\theta) \propto \exp E_{q(z)}[\log p(\theta, z, x)], \quad (4)$$

$$q'(z) \propto \exp E_{q(\theta)}[\log p(\theta, z, x)]. \quad (5)$$

We can solve (2) by setting $q(\theta)$ to $q'(\theta)$ — since $q(z)$ is held fixed while updating $q(\theta)$, the expectation function of the constraint remains constant during this update. As shown by Graça et al. (2007), the update in (3) is a constrained optimization problem and can be solved by performing gradient search on its dual:

$$\underset{\lambda}{\operatorname{argmin}} \ \lambda^\top b + \log \sum_z q'(z) \exp(-\lambda^\top f(z)) \quad (6)$$

For a fixed value of λ the optimal $q(z) \propto q'(z) \exp(-\lambda^\top f(z))$. By updating $q(\theta)$ and $q(z)$ as in (2) and (3) we are effectively maximizing the lower bound $\mathcal{F}$.

[2] Constraints of the form $E_q[f(z)] \geq b$ are easily imposed by negating $f(z)$ and b.

4.1 Variational Updates

We now derive the specific variational updates for our dependency induction model. First we assume the following mean-field factorization of our variational distribution:

$$q(\beta, \theta, \pi, \phi, z) = q(z) \cdot \prod_{s'} q(\beta_{s'}) \cdot \prod_{z'=1}^{T} q(\phi_{s'z'}) \cdot \prod_{c} q(\theta_{s'z'c}) \cdot \prod_{s} q(\pi_{ss'z'c}), \tag{7}$$

where s' varies over the set of unique symbols in the observed tags, z' denotes subsymbols for each symbol, c varies over context values comprising a pair of direction (left or right) and valence (first, second, or third or higher) values, and s corresponds to child symbols.

We restrict $q(\theta_{s'z'c})$ and $q(\phi_{s'z'})$ to be Dirichlet distributions and $q(z)$ to be multinomial. As with prior work (Liang et al., 2009b), we assume a degenerate $q(\beta) \equiv \delta_{\beta^*}(\beta)$ for tractability reasons, i.e., all mass is concentrated on some single β^*. We also assume that the top level stick-breaking distribution is truncated at T, i.e., $q(\beta)$ assigns zero probability to integers greater than T. Because of the truncation of β, we can approximate $q(\pi_{ss'z'c})$ with an asymmetric finite dimensional Dirichlet.

The factors are updated one at a time holding all other factors fixed. The variational update for $q(\pi)$ is given by:

$$q(\pi_{ss'z'c}) = \text{Dir}\left(\pi_{ss'z'c}; \alpha\beta + E_{q(z)}[C_{ss'z'c}(z)]\right),$$

where term $E_{q(z)}[C_{ss'z'c}(z)]$ is the expected count w.r.t. $q(z)$ of child symbol s and subsymbol z in context c when generated by parent symbol s' and subsymbol z'.

Similarly, the updates for $q(\theta)$ and $q(\phi)$ are given by:

$$q(\theta_{s'z'c}) = \text{Dir}\left(\theta_{s'z'c}; \theta_0 + E_{q(z)}[C_{s'z'c}(s)]\right),$$
$$q(\phi_{s'z'}) = \text{Dir}\left(\phi_{s'z'}; \phi_0 + E_{q(z)}[C_{s'z'}(x)]\right),$$

where $C_{s'z'c}(s)$ is the count of child symbol s being generated by the parent symbol s' and subsymbol z' in context c and $C_{s'z'x}$ is the count of word x being generated by symbol s' and subsymbol z'.

The only factor affected by the expectation constraints is $q(z)$. Recall from the previous section that the update for $q(z)$ is performed via gradient search on the dual of a constrained minimization problem of the form:

$$q(z) = \operatorname*{argmin}_{q(z)} \text{KL}(q(z) \parallel q'(z)).$$

Thus we first compute the update for $q'(z)$:

$$q'(z) \propto \prod_{n=1}^{N} \prod_{j=1}^{len(n)} \big(\exp E_{q(\phi)}[\log \phi_{s_{nj} z_{nj}}(x_{nj})] \times \exp E_{q(\theta)}[\log \theta_{s_{h(nj)} z_{h(nj)} c_{nj}}(s_{nj})] \times \exp E_{q(\pi)}[\log \pi_{s_{nj} s_{h(nj)} z_{h(nj)} c_{nj}}(z_{nj})]\big),$$

where N is the total number of sentences, $len(n)$ is the length of sentence n, and index $h(nj)$ refers to the head of the jth node of sentence n. Given this $q'(z)$ a gradient search is performed using (6) to find the optimal λ and thus the primal solution for updating $q(z)$.

Finally, we update the degenerate factor $q(\beta_s)$ with the projected gradient search algorithm used by Liang et al. (2009b).

5 Linguistic Constraints

Universal Dependency Rules We compile a set of 13 universal dependency rules consistent with various linguistic accounts (Carnie, 2002; Newmeyer, 2005), shown in Table 1. These rules are defined over coarse part-of-speech tags: Noun, Verb, Adjective, Adverb, Pronoun, Article, Auxiliary, Preposition, Numeral and Conjunction. Each rule specifies a part-of-speech for the head and argument but does not provide ordering information.

We require that a minimum proportion of the posterior dependencies be instances of these rules in expectation. In contrast to prior work on rule-driven dependency induction (Druck et al., 2009), where each rule has a separately specified expectation, we only set a single minimum expectation for the proportion of all dependencies that must match one of the rules. This setup is more relevant for learning with universals since individual rule frequencies vary greatly between languages.

1. Identify non-recursive NPs:
   - All nouns, pronouns and possessive marker are part of an NP.
   - All adjectives, conjunctions and determiners immediately preceding an NP are part of the NP.
2. The first verb or modal in the sentence is the headword.
3. All words in an NP are headed by the last word in the NP.
4. The last word in an NP is headed by the word immediately before the NP if it is a preposition, otherwise it is headed by the headword of the sentence if the NP is before the headword, else it is headed by the word preceding the NP.
5. For the first word set its head to be the headword of the sentence. For each other word set its headword to be the previous word.

Table 3: English-specific dependency rules.

English-specific Dependency Rules For English, we also consider a small set of hand-crafted dependency rules designed by Michael Collins[3] for deterministic parsing, shown in Table 3. Unlike the universals from Table 1, these rules alone are enough to construct a full dependency tree. Thus they allow us to judge whether the model is able to improve upon a human-engineered deterministic parser. Moreover, with this dataset we can assess the additional benefit of using rules tailored to an individual language as opposed to universal rules.

6 Experimental Setup

Datasets and Evaluation We test the effectiveness of our grammar induction approach on English, Danish, Portuguese, Slovene, Spanish, and Swedish. For English we use the Penn Treebank (Marcus et al., 1993), transformed from CFG parses into dependencies with the Collins head finding rules (Collins, 1999); for the other languages we use data from the 2006 CoNLL-X Shared Task (Buchholz and Marsi, 2006). Each dataset provides manually annotated part-of-speech tags that are used for both training and testing. For comparison purposes with previous work, we limit the cross-lingual experiments to sentences of length 10 or less (not counting punctuation). For English, we also explore sentences of length up to 20.

The final output metric is directed dependency accuracy. This is computed based on the Viterbi parses produced using the final unnormalized variational distribution $q(z)$ over dependency structures.

Hyperparameters and Training Regimes Unless otherwise stated, in experiments with rule-based constraints the expected proportion of dependencies that must satisfy those constraints is set to 0.8. This threshold value was chosen based on minimal tuning on a single language and ruleset (English with universal rules) and carried over to each other experimental condition. A more detailed discussion of the threshold's empirical impact is presented in Section 7.1.

Variational approximations to the HDP are truncated at 10. All hyperparameter values are fixed to 1 except α which is fixed to 10.

We also conduct a set of *No-Split* experiments to evaluate the importance of syntactic refinement; in these experiments each coarse symbol corresponds to only one refined symbol. This is easily effected during inference by setting the HDP variational approximation truncation level to one.

For each experiment we run 50 iterations of variational updates; for each iteration we perform five steps of gradient search to compute the update for the variational distribution $q(z)$ over dependency structures.

7 Results

In the following section we present our primary cross-lingual results using universal rules (Section 7.1) before performing a more in-depth analysis of model properties such as sensitivity to ruleset selection and inference stability (Section 7.2).

[3] Personal communication.

	DMV	PGI	No-Split	HDP-DEP
English	47.1	62.3	71.5	**71.9** (0.3)
Danish	33.5	41.6	48.8	**51.9** (1.6)
Portuguese	38.5	63.0	54.0	**71.5** (0.5)
Slovene	38.5	48.4	50.6	**50.9** (5.5)
Spanish	28.0	58.4	64.8	**67.2** (0.4)
Swedish	45.3	58.3	**63.3**	62.1 (0.5)

Table 4: Directed dependency accuracy using our model with universal dependency rules (No-Split and HDP-DEP), compared to DMV (Klein and Manning, 2004) and PGI (Berg-Kirkpatrick and Klein, 2010). The DMV results are taken from Berg-Kirkpatrick and Klein (2010). Bold numbers indicate the best result for each language. For the full model, the standard deviation in performance over five runs is indicated in parentheses.

7.1 Main Cross-Lingual Results

Table 4 shows the performance of both our full model (HDP-DEP) and its No-Split version using universal dependency rules across six languages. We also provide the performance of two baselines — the dependency model with valence (DMV) (Klein and Manning, 2004) and the phylogenetic grammar induction (PGI) model (Berg-Kirkpatrick and Klein, 2010).

HDP-DEP outperforms both DMV and PGI across all six languages. Against DMV we achieve an average absolute improvement of 24.1%. This improvement is expected given that DMV does not have access to the additional information provided through the universal rules. PGI is more relevant as a point of comparison, since it is able to leverage multilingual data to learn information similar to what we have declaratively specified using universal rules. Specifically, PGI reduces induction ambiguity by connecting language-specific parameters via phylogenetic priors. We find, however, that we outperform PGI by an average margin of 7.2%, demonstrating the benefits of explicit rule specification.

An additional point of comparison is the lexicalized unsupervised parser of Headden III et al. (2009), which yields the current state-of-the-art unsupervised accuracy on English at 68.8%. Our method also outperforms this approach, without employing lexicalization and sophisticated smoothing as they do. This result suggests that combining the complementary strengths of their approach and ours can yield further performance improvements.

English			
Rule Excluded	Acc	Loss	Gold Freq
Preposition → Noun	61.0	10.9	5.1
Verb → Noun	61.4	10.5	14.8
Noun → Noun	64.4	7.5	10.7
Noun → Article	64.7	7.2	8.5

Spanish			
Rule Excluded	Acc	Loss	Gold Freq
Preposition → Noun	53.4	13.8	8.2
Verb → Noun	61.9	5.4	12.9
Noun → Noun	62.6	4.7	2.0
Root → Verb	65.4	1.8	12.3

Table 5: Ablation experiment results for universal dependency rules on English and Spanish. For each rule, we evaluate the model using the ruleset excluding that rule, and list the most significant rules for each language. The second last column is the absolute loss in performance compared to the setting where all rules are available. The last column shows the percentage of the gold dependencies that satisfy the rule.

Table 4 also shows the *No-Split* results where syntactic categories are not refined. We find that such refinement usually proves to be beneficial, yielding an average performance gain of 3.7%. However, we note that the impact of incorporating splitting varies significantly across languages. Further understanding of this connection is an area of future research.

Finally, we note that our model exhibits low variance for most languages. This result attests to how the expectation constraints consistently guide inference toward high-accuracy areas of the search space.

Ablation Analysis Our next experiment seeks to understand the relative importance of the various universal rules from Table 1. We study how accuracy is affected when each of the rules is removed one at a time for English and Spanish. Table 5 lists the rules with the greatest impact on performance when removed. We note the high overlap between the most significant rules for English and Spanish.

We also observe that the relationship between a rule's frequency and its importance for high accuracy is not straightforward. For example, the "Preposition → Noun" rule, whose removal degrades accuracy the most for both English and Span-

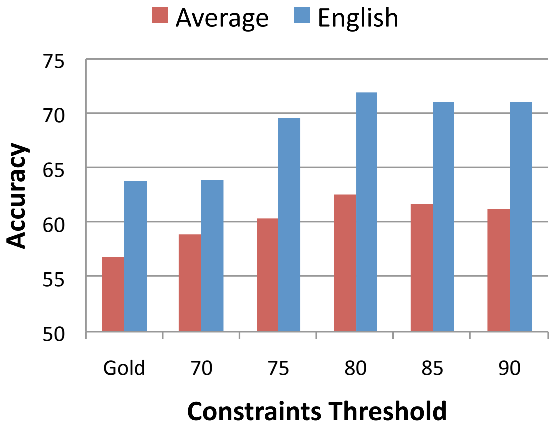


Figure 2: Accuracy of our model with different threshold settings, on English only and averaged over all languages. "Gold" refers to the setting where each language's threshold is set independently to the proportion of gold dependencies satisfying the rules — for English this proportion is 70%, while the average proportion across languages is 63%.

ish, is not the most frequent rule in either language. This result suggests that some rules are harder to learn than others regardless of their frequency, so their presence in the specified ruleset yields stronger performance gains.

Varying the Constraint Threshold In our main experiments we require that at least 80% of the expected dependencies satisfy the rule constraints. We arrived at this threshold by tuning on the basis of English only. As shown in Figure 2, for English a broad band of threshold values from 75% to 90% yields results within 2.5% of each other, with a slight peak at 80%.

To further study the sensitivity of our method to how the threshold is set, we perform *post hoc* experiments with other threshold values on each of the other languages. As Figure 2 also shows, on average a value of 80% is optimal across languages, though again accuracy is stable within 2.5% between thresholds of 75% to 90%. These results demonstrate that a single threshold is broadly applicable across languages.

Interestingly, setting the threshold value independently for each language to its "true" proportion based on the gold dependencies (denoted as the "Gold" case in Figure 2) does not achieve optimal performance. Thus, knowledge of the true language-specific rule proportions is not necessary for high accuracy.

		Length	
		≤ 10	≤ 20
Universal Dependency Rules			
1	HDP-DEP	71.9	50.4

Table 6: Directed accuracy of our model (HDP-DEP) on sentences of length 10 or less and 20 or less from WSJ with different rulesets and with no rules, along with various baselines from the literature. Entries in this table are numbered for ease of reference in the text.

7.2 Analysis of Model Properties

We perform a set of additional experiments on English to gain further insight into HDP-DEP's behavior. Our choice of language is motivated by the fact that a wide range of prior parsing algorithms were developed for and tested exclusively on English. The experiments below demonstrate that 1) universal rules alone are powerful, but language- and dataset-tailored rules can further improve performance; 2) our model learns jointly from the rules and data, outperforming a rules-only deterministic parser; 3) the way we incorporate posterior constraints outperforms the generalized expectation constraint framework; and 4) our model exhibits low variance when seeded with different initializations. These results are summarized in Table 6 and discussed in detail below; line numbers refer to entries in Table 6. Each run of HDP-DEP below is with syntactic refinement enabled.

Impact of Rules Selection We compare the performance of HDP-DEP using the universal rules versus a set of rules designed for deterministically parsing the Penn Treebank (see Section 5 for details).

As lines 1 and 5 of Table 6 show, language-specific rules yield better performance. For sentences of length 10 or less, the difference between the two rulesets is a relatively small 1.9%; for longer sentences, however, the difference is a substantially larger 15.7%. This is likely because longer sentences tend to be more complex and thus exhibit more language-idiosyncratic dependencies. Such dependencies can be better captured by the refined language-specific rules.

We also test model performance when no linguistic rules are available, i.e., performing unconstrained variational inference. The model performs substantially worse (line 2), confirming that syntactic category refinement in a fully unsupervised setup is challenging.

Learning Beyond Provided Rules Since HDP-DEP is provided with linguistic rules, a legitimate question is whether it improves upon what the rules encode, especially when the rules are complete and language-specific. We can answer this question by comparing the performance of our model seeded with the English-specific rules against a deterministic parser that implements the same rules. Lines 4 and 5 of Table 6 demonstrate that the model outperforms a rules-only deterministic parser by 3.8% for sentences of length 10 or less and by 3.5% for sentences of length 20 or less.

Comparison with Alternative Semi-supervised Parser The dependency parser based on the generalized expectation criteria (Druck et al., 2009) is the closest to our reported work in terms of technique. To compare the two, we run HDP-DEP using the 20 rules given by Druck et al. (2009). Our model achieves an accuracy of 64.9% (line 7) compared to 61.3% (line 6) reported in their work. Note that we do not rely on rule-specific expectation information as they do, instead requiring only a single expectation constraint parameter.[4]

Model Stability It is commonly acknowledged in the literature that unsupervised grammar induction methods exhibit sensitivity to initialization. As in the previous section, we find that the presence of linguistic rules greatly reduces this sensitivity: for HDP-DEP, the standard deviation over five randomly initialized runs with the English-specific rules is 1.5%, compared to 4.5% for the parser developed by Headden III et al. (2009) and 8.0% for DMV (Klein and Manning, 2004).

8 Conclusions

In this paper we demonstrated that syntactic universals encoded as declarative constraints improve grammar induction. We formulated a generative model for dependency structure that models syntactic category refinement and biases inference to cohere with the provided constraints. Our experiments showed that encoding a compact, well-accepted set of language-independent constraints significantly improves accuracy on multiple languages compared to the current state-of-the-art in unsupervised parsing.

While our present work has yielded substantial gains over previous unsupervised methods, a large gap still remains between our method and fully supervised techniques. In future work we intend to study ways to bridge this gap by 1) incorporating more sophisticated linguistically-driven grammar rulesets to guide induction, 2) lexicalizing the model, and 3) combining our constraint-based approach with richer unsupervised models (e.g., Headden III et al. (2009)) to benefit from their complementary strengths.

Acknowledgments

The authors acknowledge the support of the NSF (CAREER grant IIS-0448168, grant IIS-0904684, and a Graduate Research Fellowship). We are especially grateful to Michael Collins for inspiring us toward this line of inquiry and providing deterministic rules for English parsing. Thanks to Taylor Berg-Kirkpatrick, Sabine Iatridou, Ramesh Sridharan, and members of the MIT NLP group for their suggestions and comments. Any opinions, findings, conclusions, or recommendations expressed in this paper are those of the authors, and do not necessarily reflect the views of the funding organizations.

[4] As explained in Section 5, having a single expectation parameter is motivated by our focus on parsing with universal rules.

What's with the Attitude? Identifying Sentences with Attitude in Online Discussions

Abstract

Mining sentiment from user generated content is a very important task in Natural Language Processing. An example of such content is threaded discussions which act as a very important tool for communication and collaboration in the Web. Threaded discussions include e-mails, e-mail lists, bulletin boards, newsgroups, and Internet forums. Most of the work on sentiment analysis has been centered around finding the sentiment toward products or topics. In this work, we present a method to identify the attitude of participants in an online discussion toward one another. This would enable us to build a signed network representation of participant interaction where every edge has a sign that indicates whether the interaction is positive or negative. This is different from most of the research on social networks that has focused almost exclusively on positive links. The method is experimentally tested using a manually labeled set of discussion posts. The results show that the proposed method is capable of identifying attitudinal sentences, and their signs, with high accuracy and that it outperforms several other baselines.

1 Introduction

Mining sentiment from text has a wide range of applications from mining product reviews on the Web (Morinaga et al., 2002; Turney and Littman, 2003) to analyzing political speeches (Thomas et al., 2006). Automatic methods for sentiment mining are very important because manual extraction of them is very costly, and inefficient. A new application of sentiment mining is to automatically identify attitudes between participants in an online discussion. An automatic tool to identify attitudes will enable us to build a signed network representation of participant interaction in which the interaction between two participants is represented using a positive or a negative edge. Even though using signed edges in social network studies is clearly important, most of the social networks research has focused only on positive links between entities. Some work has recently investigated signed networks (Leskovec et al., 2010; Kunegis et al., 2009), however this work was limited to a few number of datasets in which users were allowed to explicitly add negative, as well as positive, relations. This work will pave the way for research efforts to examine signed social networks in more detail. It will also allow us to study the relation between explicit relations and the text underlying those relation.

Although similar, identifying sentences that display an attitude in discussions is different from identifying opinionated sentences. A sentence in a discussion may bear opinions about a definite target (e.g., price of a camera) and yet have no attitude toward the other participants in the discussion. For instance, in the following discussion Alice's sentence has her opinion against something, yet no attitude toward the recipient of the sentence, Bob.

> Alice: "You know what, he turned out to be a great disappointment"
> Bob: "You are completely unqualified to judge this great person"

However, Bob shows strong attitude toward Alice. In this work, we look at ways to predict whether a sentence displays an attitude toward the text recipient. An attitude is the mental position of one participant with regard to another participant. it could be either positive or negative. We consider features which takes into account the entire structure of sentences at different levels or generalization. Those

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1245–1255,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

features include lexical items, part-of-speech tags, and dependency relations. We use all those patterns to build several pairs of models that represent sentences with and without attitude.

The rest of the paper is organized as follows. In Section 2 we review some of the related prior work on identifying polarized words and subjectivity analysis. We explain the problem definition and discuss our approach in Sections 3 & 4. Finally, in Sections 5 & 6 we introduce our dataset and discuss the experimental setup. Finally, we conclude in Section 7.

2 Related Work

Identifying the polarity of individual words is a well studied problem. In previous work, Hatzivassiloglou and McKeown (1997) propose a method to identify the polarity of adjectives. They use a manually labeled corpus to classify each conjunction of an adjective as "the same orientation" as the adjective or "different orientation". Their method can label simple in "simple and well-received" as the same orientation and simplistic in "simplistic but well-received" as the opposite orientation of well-received. Although the results look promising, the method would only be applicable to adjectives since noun conjunctions may collocate regardless of their semantic orientations (e.g., "rise and fall").

In other work, Turney and Littman (2003) use statistical measures to find the association between a given word and a set of positive/negative seed words. In order to get word co-occurrence statistics they use the "near" operator from a commercial search engine on a given word and a seed word.

In more recent work, Takamura et al. (2005) used the spin model to extract word semantic orientation. First, they construct a network of words using definitions, thesaurus, and co-occurrence statistics. In this network, each word is regarded as an electron, which has a spin and each spin has a direction taking one of two values: up or down. Then, they use the energy point of view to propose that neighboring electrons tend to have the same spin direction, and therefore neighboring words tend to have the same polarity orientations. Finally, they use the mean field method to find the optimal solution for electron spin directions.

Previous work has also used WordNet, a lexical database of English, to identify word polarity. Specifically, Hu and Liu (2004) use WordNet synonyms and antonyms to predict the polarity of any given word with unknown polarity. They label each word with the polarity of its synonyms and the opposite polarity of its antonyms. They continue in a bootstrapping manner to label all unlabeled instances. This work is very similar to (Kamps et al., 2004) in which a network of WordNet synonyms is used to find the shortest path between any given word, and the words "good" and "bad". Kim and Hovy (Kim and Hovy, 2004) used WordNet synonyms and antonyms to expand two lists of positive and negative seed words. Similarly, Andreevskaia and Bergler (2006) used WordNet to expand seed lists with fuzzy sentiment categories, in which words could be more central to one category than the other. Finally, Kanayama and Nasukawa (2006) used syntactic features and context coherency, defined as the tendency for same polarities to appear successively, to acquire polar atoms.

All the work mentioned above focus on the task of identifying the polarity of individual words. Our proposed work is identifying attitudes in sentences that appear in online discussions. Perhaps the most similar work to ours is the prior work on subjectivity analysis, which is to identify text that present opinions as opposed to objective text that present factual information (Wiebe, 2000). Prior work on subjectivity analysis mainly consists of two main categories: The first category is concerned with identifying the subjectivity of individual phrases and words regardless of the sentence and context they appear in (Wiebe, 2000; Hatzivassiloglou and Wiebe, 2000; Banea et al., 2008). In the second category, subjectivity of a phrase or word is analyzed within its context (Riloff and Wiebe, 2003; Yu and Hatzivassiloglou, 2003; Nasukawa and Yi, 2003; Popescu and Etzioni,). A good study of the applications of subjectivity analysis from review mining to email classification is given in (Wiebe, 2000). Somasundaran et al. (2007) develop genre-speci.c lexicons using interesting function word combinations for detecting opinions in meetings. Despite similarities, our work is different from subjectivity analysis because the later only discriminates between opinions and facts. A discussion sentence may display an opinion about some topic yet no attitude. The language constituents considered in opinion detection may be different from those used to detect attitude. Moreover, extracting attitudes from online discussions is different from targeting subjective expressions (Josef Ruppenhofer and Wiebe, 2008; Kim and Hovy, 2004). The later usually has a limited set of targets that compete for the subjective expressions (for example in movie review, targets could be: director, actors, plot, and so forth). We cannot use similar methods because we are working on an open domain where anything could be a target. A very detailed survey that covers techniques and approaches in sentiment analysis and opinion mining could be found in (Pang and Lee, 2008).

There is also some related work on mining online discussions. Lin et al (2009) proposes a sparse coding-based model simultaneously model semantics and structure of threaded discussions. Shen et al (2006) proposes three clustering methods for exploiting the temporal information in the streams, as well as an algorithm based on linguistic features to analyze the discourse structure information. Huang et al (2007) used an SVM classifier to extract (thread-title, reply) pairs as chat knowledge from online discussion forums to support the construction of a chatbot for a certain domain. Other work has focused on the structure of questions and question-answer pairs in online forums and discussions (Ding et al., 2008; Cong et al., 2008).

3 Problem Definition

Assume we have a set of sentences exchanged between participants in an online discussion. Our objective is to identify sentences that display an attitude from the text writer to the text recepient from those that do not. An attitude is the mental position of one particpant with regard to another participant. An attitude may not be directly observable, but rather inferred from what particpants say to one another. The attitude could be either positive or negative. Strategies for showing a positive attitude may include agreement, and praise, while strategies for showing a negative attitude may include disagreement, insults, and negative slang. After identifying sentences that display an attitude, we also predict the sign (positive or negative) of that attitude.

4 Approach

In this section, we describe a model which, given a sentence, predicts whether it carries an attitude from the text writer toward the text recipient or not. Any given piece of text exchanged between two participants in a discussion could carry an attitude toward the text recipient, an attitude towards the topic, or no attitude at all. As we are only interested in attitudes between participants, we limit our study to sentences that use second person pronouns. Second person pronouns are usually used in conversational genre to indicate that the text writer is addressing the text recipient. After identifying those sentences, we do some pre-processing to extract the most relevant fragments. We examine these fragments to to identify the polarity of every word in the sentence. Every word could be assigned a semantic orientation. The semantic orientation could be either positive, negative, or neutral. The existence of polarized words in any sentence is an important indicator of whether it carries an attitude or not.

The next step is to extract several patterns at different levels of generalization representing any given sentence. We use those patterns to build two Markov models for every kind of patterns. The first model characterizes the relation between different tokens for all patterns that correspond to sentences that have an attitude. The second model is similar to the first one, but it uses all patterns that correspond to sentences that do not have an attitude. Given a new sentence, we extract the corresponding patterns and estimate the likelihood of every pattern being generated from the two corresponding models. We then compare the likelihood of the sentence under the two models and use this as a feature to predict the existence of an attitude. A pair of models will be built for every kind of patterns. If we have n different patterns, we will have n different likelihood ratios that come from n pairs of models.

4.1 Word Polarity Identification

Identifying the polarity of words is an important step for our method. Our word identification module is similar to the work in (Annon, 2010). We construct a graph where each node represent a word/part-of-speech pair. Two nodes are linked if the words are related. We use WordNet (Miller, 1995) to link related words based on synonyms, hypernyms, and similar to relations. For words that do not appear in Wordnet, we used Wiktionary, a collaboratively constructed dictionary. We also add some links based on co-occurrence statistics between words as from a large corpus. The resulting graph is a graph $G(W, E)$ where W is a set of word/part-of-speech pairs, and E is the set of edges connecting related words.

We define a random walk model on the graph, where the set of nodes correspond to the state space of the random walk. Transition probabilities are calculated by normalizing the weights of the edges out of every node. Let $S+$ and $S-$ be two sets of vertices representing seed words that are already labeled as either positive or negative respectively. We used the list of labeled seeds from (Hatzivassiloglou and McKeown, 1997) and (Stone et al., 1966). For any given word w, we calculate the mean hitting time between w, and the two seed sets $h(w|S+)$, and $h(w|S-)$. The mean hitting time $h(i|k)$ is defined as the average number of steps a random walker, starting in state $i \neq k$, will take to enter state k for the first time (Norris, 1997). If $h(w|S+)$ is greater than $h(w|S-)$, the word is classified as negative, otherwise it is classified as positive. We also use the method described in (Wilson et al., 2005) to determine the contextual polarity of the identified words. The set of features used to predict contextual polarity include word, sentence, polarity, structure, and other features.

4.2 Identifying Relevant Parts of Sentences

The writing style in online discussion forums is very informal. Some of the sentence are very long, and punctuation marks are not always properly used. To solve this problem, we decided to use the grammatical structure of sentences to identify the most relevant part of sentences that would be the subject of further analysis. Figure 1 shows a parse tree representing the grammatical structure of a particular sentence. If we closely examine the sentence, we will notice that we are only interested in a part of the sentence that includes the second person pronoun ”you“. We extract this part, by starting at the word of interest , in this case ”you“, and go up in the hierarchy till we hit the first sentence clause. Once, we reach a sentence clause, we extract the corresponding text if it is grammatical, otherwise we go up one more level to the closest sentence clause. We used the Stanford parser to generate the grammatical structure of sentences (Klein and Manning, 2003).

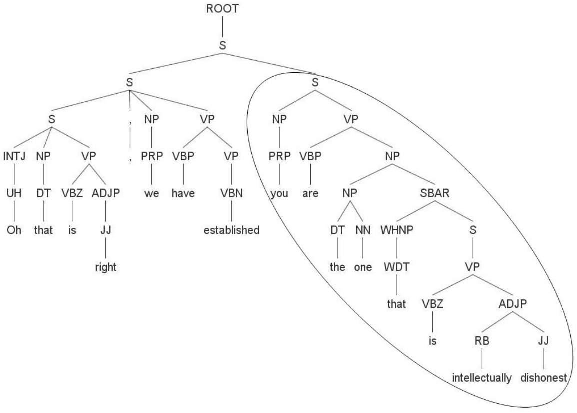

Figure 1: An example showing how to identify the relevant part of a sentence.

4.3 Sentences as Patterns

The fragments we extracted earlier are more relevant to our task and are more suitable for further analysis. However, these fragments are completely lexicalized and consequently the performance of any analysis based on them will be limited by data sparsity. We can alleviate this by using more general representations of words. Those general representations can be used a long with words to generate a set of patterns that represent each fragment. Each pattern consists of a sequence of tokens. Examples of such patterns could use lexical items, part-of-speech (POS) tags, word polarity tags, and dependency relations.

We use three different patterns to represent each fragments:

- Lexical patterns: All polarized words are replaces with the corresponding polarity tag, and all other words are left as is.
- Part-of-speech patterns: All words are replaced with their POS tags. Second person pronouns are left as is. Polarized words are replaced with their polarity tags and their POS tags.
- Dependency grammar patterns: the shortest path connecting every second person pronoun

to the closed polarized word is extracted. The second person pronoun, the polarized word tag, and the types of the dependency relations along the path connecting them are used as a pattern. It has been shown in previous work on relation extraction that the shortest path between any two entities captures the the information required to assert a relationship between them (Bunescu and Mooney, 2005). Every polarized word is assigned to the closest second person pronoun in the dependency tree. This is only useful for sentences that have polarized words.

Table 1 shows the different kinds of representations for a particular sentence. We use text, part-of-speech tags, polarity tags, and dependency relations. The corresponding patterns for this sentence are shown in Table 2.

4.4 Building the Models

Given a set of patterns representing a set of sentences, we can build a graph $G = V, E, w$ where V is the set of all possible token that may appear in the patterns. $E = V \times V$ is the set of possible transitions between any two tokens. $w : E \rightarrow [0..1]$ is a weighting function that assigns to every pair of states (i, j) a weight $w(i, j)$ representing the probability that we have a transition from state i to state j.

This graph corresponds to a Markovian model. The set of states are the vocabulary, and the the transition probabilities between states are estimated using Maximum Likelihood estimation as follows:

$$P_{ij} = \frac{N_{ij}}{N_i}$$

where N_{ij} is the number of times we saw a transition from i to state j, and N_i is the total number of times we saw state i in the training data. This is similar to building a language model over the language of the patterns.

We build two such models for every kind of patterns. The first model is built using all sentences that appeared in the training dataset and was labeled as having an attitude, and the second model is built using all sentences in the training dataset that do not have an attitude. If we have n kinds of patterns, we will build one such pair for every kind of patterns. Hence, we will end up with $2n$ models.

4.5 Identifying Sentences with Attitude

We split our training data into two splits; the first containing all sentences that have an attitude and the second containing all sentences that do not have an attitude. Given the methodology described in the previous section, we build n pairs of Markov models. Given any sentence, we extract the corresponding patterns and estimate the log likelihood that this sequence of tokens was generated from every model.

Given a model M, and sequence of tokens $T = (T_1, T_2, \ldots TS_n)$, the probability of this token sequence being generated from M is:

$$P_M(T) = \prod_{i=2}^{n} P(T_i|T_1, \ldots, T_{i-1}) = \prod_{i=2}^{n} W(T_{i-1}, T_i)$$

where n is the number of tokens in the pattern, and W is the probability transition function.

The log likelihood is then defined as:

$$LL_M(T) = \sum_{i=2}^{n} \log W(T_{i-1}, T_i)$$

For every pair of models, we may use the ratio between the two likelihoods as a feature:

$$f = \frac{LL_{M_{att}}(T)}{LL_{M_{noatt}}(T)}$$

where T is the token sequence, $LL_{M_{att}}(T)$ is the log likelihood of the sequence given the attitude model, and $LL_{M_{noatt}}(T)$ is the log likelihood of the pattern given the no-attitude model.

Given the n kinds of patterns, we can calculate three different features. A standard machine learning classifier is then trained using those features to predict whether a given sentence has an attitude or not.

4.6 Identifying the Sign of an Attitude

To determine the orientation of an attitude sentence, we tried two different methods. The first method assumes that the orientation of an attitude sentence is directly related to the polarity of the words it contains. If the sentence has only positive and neutral

Table 1: Tags used for building patterns

Text	That makes your claims so ignorant
POS	That/DT makes/VBZ your/PRP$ claims/NNS so/RB ignorant/JJ
Polarity	That/O makes/O your/O claims/O so/O ignorant/NEG
Dependency	your $\xrightarrow{\text{poss}}$ claims $\xrightarrow{\text{nsubj}}$ ignorant

Table 2: Sample patterns

Lexical pattern	That makes your claims so NEG
POS pattern	DT VBZ your_PRP$ NNS RB NEG_JJ
Dependency pattern	your poss nsubj NEG

words, it is classified as positive. If the sentence has only negative and neutral words, it is classified as negative. If the sentence has both positive and negative words, we calculate the summation of the polarity scores of all positive words and that of all negative words. The polarity score of a word is an indicator of how strong of a polarized word it is. If the former is greater, we classify the sentence as positive,otherwise we classify the sentence as negative.

The problem with this method is that it assumes that all polarized words in a sentence with an attitude target the text recipient. Unfortunately, that is not always correct. For example, the sentence ”You are completely unqualified to judge this great person” has a positive word ”great” and a negative word ”unqualified”. The first method will not be able to predict whether the sentence is positive or negative. To solve this problem, we use another method that is based on the paths that connect polarized words to second person pronouns in a dependency parse tree. For every positive word w , we identify the shortest path connecting it to every second person pronoun in the sentence then we compute the average length of the shortest path connecting every positive word to the closest second person pronoun. We repeat for negative words and compare the two values. The sentence is classified as positive if the average length of the shortest path connecting positive words to the closest second person pronoun is smaller than the corresponding value for negative words. Otherwise, we classify the sentence as negative.

5 Data

Our data was randomly collected from a set of discussion groups. We collected a large number of threads from the first quarter of 2009 from a set of Usenet discussion groups. All threads were in English, and had 5 posts or more. We parsed the downloaded threads to identify the posts and senders. We kept posts that have quoted text and discarded all other posts. The reason behind that is that participants usually quote other participants text when they reply to them. This restriction allows us to identify the target of every post, and raises the probability that the post will display an attitude from its writer to its target. We plan to use more sophsticated methods for reconstructing the reply structure like the one in (Lin et al., 2009). From those posts, we randomly selected approximately 10,000 sentences that use second person pronouns. We explained earlier how second person pronouns are used in discussions genres to indicate the writer is targeting the text recipient. Given a random sentence selected from some random discussion thread, the probability that the sentence does not have an attitude is significantly larger than the probability that it will have an attitude. Hence, restricting our dataset to posts with quoted text and sentences with second person pronouns is very important to make sure that we will have a considerable amount of attitudinal sentences. The data was tokenized, sentence-split, part-of-speech tagged with the OpenNLP toolkit. It was parsed with the Stanford dependency parser (Klein and Manning, 2003).

5.1 Annotation Scheme

The goals of the annotation scheme are to distinguish sentences that display an attitude from those that do not. Sentences could display either a negative or a positive attitude. Disagreement, insults, and negative slang are indicators of negative attitude.

	A	B	C	D
A	-	82.7	80.6	82.1
B	81.0	-	81.9	82.9
C	77.8	78.2	-	83.8
D	78.3	77.7	78.6	-

Table 3: Inter-annotator agreement

Agreement, and praise are indicators of positive attitude. Our annotators were instructed to read every sentence and assign two labels to it. The first specifies whether the sentence displays an attitude or not. The existence of an attitude was judged on a three point scale: attitude, unsure, and no-attitude. The second is the sign of the attitude. If an attitude exists, annotators were asked to specify whether the attitude is positive or negative. To evaluate inter-annotator agreement, we use the agr operator presented in (Wiebe et al., 2005). This metric measures the precision and recall of one annotator using the annotations of another annotator as a gold standard. The process is repeated for all pairs of annotators, and then the harmonic mean of all values is reported. Formally:

$$agr(A|B) = \frac{|A \cap B|}{|A|} \tag{1}$$

where A, and B are the annotation sets produced by the two reviewers. Table 3 shows the value of the agr operator for all pairs of annotators. The harmonic mean of the agr operator is 80%. The agr operator was used over the Kappa Statistic because the distribution of the data was fairly skewed.

6 Experiments

6.1 Experimental Setup

We performed experiments on the data described in the previous section. The number of sentences with an attitude was around 20% of the entire dataset. The class imbalance caused by the small number of attitude sentences may hurt the performance of the learning algorithm (Provost, 2000). A common way of addressing this problem is to artificially rebalance the training data. To do this we down-sample the majority class by randomly selecting, without replacement, a number of sentences without an attitude that equals the number of sentences with an attitude. That resulted in a balanced subset, approximately 4000 sentences, that we used in our experiments.

We used Support Vector Machines (SVM) as a classifier. We optimized SVM separately for every experiment. We used 10-fold cross validation for all tests. We evaluate our results in terms of precision, recall, accuracy, and F1. Statistical significance was tested using a 2-tailed paired t-test. All reported results are statistically significant at the 0.05 level. We compare the proposed method to several other baselines that will be described in the next subsection. We also perform experiments to measure the performance if we mix features from the baselines and the proposed method.

6.2 Baselines

The first baseline is based on the hypothesis that the existence of polarized words is a strong indicator that the sentence has an attitude. As a result, we use the number of polarized word in the sentence, the percentage of polarized words to all other words, and whether the sentences has polarized words with mixed or same sign as features to train an SVM classifier to detect attitude.

The second baseline is based on the proximity between the polarized words and the second person pronouns. We assume that every polarized word is associated with the closest second person pronoun. Let w be a polarized word and $p(w)$ be the closes second person pronoun, and $surf\_dist(w, p(w))$ be the surface distance between w and $p(w)$. This baseline uses the minimum, maximum, and average of $surf\_dist(w, p(w))$ for all polarized words as features to train an SVM classifier to identify sentences with attitude.

The next baseline uses the dependency tree distance instead of the surface distance. We assume that every polarized word is associated to the second person pronoun that is connected to it using the smallest shortest path. The $dep\_dist(w, p(w))$ is calculated similar to the previous baselines but using the dependency tree distance. The minimum, maximum, and average of this distance for all polarized words are used as features to train an SVM classifier.

6.3 Results and Discussion

Figure 2 compares the accuracy, precision, and recall of the proposed method (ML), the polarity based classifier (POL), the surface distance based classifier (Surf_Dist), and the dependency distance based classifier (Dep_Dist). The values are selected to optimize F1. The figure shows that the surface distance based classifier behaves poorly with low accuracy, precision, and recall. The two other baselines behave poorly as well in terms of precision and accuracy, but they do very well in terms of recall. We looked at some of the examples to understand why those two baselines achieve very high recall. It turns out that they tend to predict most sentences that have polarized words as sentences with attitude. This results in many false positives and low true negative rate. Achieving high recall at the expense of losing precision is trivial. On the other hand, we notice that the proposed method results in very close values of precision and recall at the optimum F1 point.

To better compare the performance of the proposed method and the baseline, we study the the precision-recall curves for all methods in Figure 3. We notice that the proposed method outperforms all baselines at all operating points. We also notice that the proposed method provides a nice trade-off between precision and recall. This allows us some flexibility in choosing the operating point. For example, in some applications we might be interested in very high precision even if we lose recall, while in other applications we might sacrifice precision in order to get high recall. On the other hand, we notice that the baselines always have low precision regardless of recall.

Table 4 shows the accuracy, precision, recall, and F1 for the proposed method and all baselines. It also shows the performance when we add features from the baselines to the proposed method, or merge some of the baselines. We see that we did not get any improvement when we added the baseline features to the proposed method. We believe that the proposed method captures all the information captured by the baselines and more.

Our proposed method uses three different features that correspond to the three types of patterns we use to represent every sentence. To understand the contributions of every feature, we measure the performance of every feature by itself and also all possible combinations of pairs of features. We compare that to the performance we get when using all features in Table 5. We see that the part-of-speech patterns performs better than the text patterns. This makes sense because the former suffers from data sparsity. Dependency patterns performs best in terms of recall, while part-of-speech patterns outperform all others in terms of precision, and accuracy. All pairs of features outperform any single feature that belong to the corresponding pair in terms of F1. We also notice that using the three features results in better performance when compared to all other combinations. This shows that every kind of pattern captures slightly different information when compared to the others. It also shows that merging the three features improves performance.

One important question is how much data is required to the proposed model. We constructed a learning curve, shown in Figure 4, by fixing the test set size at one tenth of the data, and varying the training set size. We carried out ten-fold cross validation as with our previous experiments. We see that adding more data continues to increase the accuracy, and that accuracy is quite sensitive to the training data. This suggests that adding more data to this model could lead to even better results.

We also measured the accuracy of the two methods we proposed for predicting the sign of attitudes. The accuracy of the first model that only uses the count and scores of polarized words was 95%. The accuracy of the second method that used dependency distance was 97%.

6.4 Error Analysis

We had a closer look at the results to find out what are the reasons behind incorrect predictions. We found two main reasons. First, errors in predicting word polarity usually propagates and results in errors in attitude prediction. The reasons behind incorrect word polarity predictions is ambiguity in word senses and infrequent words that have very few connection in thesaurus. A possible solution to this type of errors is to improve the word polarity identification module by including word sense disambiguation and adding more links to the words graph using glosses or co-occurrence statistics. The second reason is that some sentences are sarcastic in nature. It is so difficult to identify such sentences. Identifying sarcasm should be addressed as a separate problem. A method that utilizes holistic approaches that takes context and previous interactions between discussion participants into consideration could be used to address it.

Method	Accuracy	Precision	Recall	F1
ML	80.3	81.0	79.4	80.2
POL	73.1	66.4	93.9	77.7

7 Conclusions

We have shown that training a supervised Markov model of text, part-of-speech, and dependecy patterns allows us to identify sentences with attitudes from sentences without attitude. This model is more accurate than several other baselines that use features based on the existence of polarized word, and proximity between polarized words and second person pronouns both in text and dependecy trees. This method allows to extract signed social networks from multi-party online discussions. This opens the door to research efforts that go beyond standard social network analysis that is based on positve links only. It also allows us to study dynamics behind interactions in online discussions, the relation between text and social interactions, and how groups form and break in online discussions.

Abstract

We propose two hashing-based solutions to the problem of fast and effective personal names spelling correction in People Search applications. The key idea behind our methods is to learn hash functions that map similar names to similar (and compact) binary codewords. The two methods differ in the data they use for learning the hash functions - the first method uses a set of names in a given language/script whereas the second uses a set of bilingual names. We show that both methods give excellent retrieval performance in comparison to several baselines on two lists of misspelled personal names. More over, the method that uses bilingual data for learning hash functions gives the best performance.

1 Introduction

Over the last few years, People Search has emerged as an important search service. Unlike general Web Search and Enterprise Search where users search for information on a wide range of topics including people, products, news, events, etc., People Search is about people. Hence, personal names are used predominantly as queries in People Search. As in general Web Search, a good percentage of queries in People Search is misspelled. Naturally, spelling correction of misspelled personal names plays a very important role in not only reducing the time and effort needed by users to find people they are searching for but also in ensuring good user experience.

Spelling errors in personal names are of a different nature compared to those in general text. Long before People Search became widely popular, researchers working on the problem of personal name matching had recognized the human tendency to be inexact in recollecting names from the memory and specifying them. A study of personal names in hospital databases found that only 39% of the errors in the names were single typographical errors (Friedman and Sideli, 1992)[1]. Further, multiple and long distance typographical errors (*Gregzorz Kondrak* for *Grzegorz Kondrak*), phonetic errors (as in *Erik Bryl* for *Eric Brill*), cognitive errors (as in *Silvia Cucerzan* for *Silviu Cucerzan*) and word substitutions (as in *Rob Moore* for *Bob Moore*) are observed relatively more frequently in personal names compared to general text.

In addition to within-the-word errors, People Search queries are plagued by errors that are not usually seen in general text. The study by Friedman and Sideli discovered that 36% of the errors were due to addition or deletion of a word (as in *Ricardo Baeza* for *Ricardo Baeza-Yates*) (Friedman and Sideli, 1992). Although word addition and deletion generally do not come under the purview of spelling correction, in People Search they are important and need to be addressed.

Standard approaches to general purpose spelling correction are not well-suited for correcting misspelled personal names. As pointed out by (Cucerzan and Brill, 2004), these approaches either try to correct individual words (and will fail to correct *Him Clijsters* to *Kim Clijsters*) or employ features based on relatively wide context windows

[1] In contrast, 80% of misspelled words in general text are due to single typographical errors as found by (Damerau, 1964).

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1256–1265,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

which are not available for queries in Web Search and People Search. Spelling correction techniques meant for general purpose web-queries require large volumes of training data in the form of query logs for learning the error models (Cucerzan and Brill, 2004), (Ahmad and Kondrak, 2005). However, query logs are not available in some applications (e.g. Email address book search). Further, unlike general purpose web-queries where word order often matters, in People Search word order is lax (e.g. I might search for either *Kristina Toutanova* or *Toutanova Kristina*). Therefore, spelling correction techniques that rely crucially on bigram and higher order language models will fail on queries with a different word order than what is observed in the query log.

Unlike general purpose Web Search where it is not reasonable to assume the availability of a high-coverage trusted lexicon, People Search typically employs large authoritative name directories. For instance, if one is searching for a friend on Facebook, the correct spelling of the friend's name exists in the Facebook people directory[2] (assuming that the friend is a registered user of Facebook at the time of the search). Similarly, if one is searching for a contact in Enterprise address book, the correct spelling of the contact is part of the address book. In fact, even in Web Search, broad-coverage name directories are available in the form of Wikipedia, IMDB, etc. The availability of large authoritative name directories that serve as the source of trusted spellings of names throws open the possibility of correcting misspelled personal names with the help of name matching techniques (Pfeifer et al., 1996), (Christen, 2006), (Navarro et al., 2003). However, the best of the name matching techniques can at best work with a few thousand names to give acceptable response time and accuracy. They do not scale up to the needs of People Search applications where the directories can have millions of names.

In this work, we develop hashing-based name similarity search techniques and employ them for spelling correction of personal names. The motivation for using hashing as a building block of spelling correction is the following: given a query, we want to return the global best match in the name directory that exceeds a similarity threshold. As matching the query with the names in the directory is a time consuming task especially for large name directories, we solve the search problem in two stages:

- NAME_BUCKETING: For each token of the query, we do an approximate nearest neighbor search of the name tokens of the directory and produce a list of candidates, i.e., tokens that are approximate matches of the query token. Using the list of candidate tokens, we extract the list of candidate names which contain at least one approximately matching token.

- NAME_MATCHING: We do a rigorous matching of the query with candidate names.

Clearly, our success in finding the right name suggestion for the query in the NAME_MATCHING stage depends crucially on our success in getting the right name suggestion in the list of candidates produced by the NAME_BUCKETING stage search. Therefore, we need a name similarity search technique that can ensure very high recall without producing too many candidates. Hashing is best suited for this task of fast and approximate name matching. We hash the query tokens as well as directory tokens into d bit binary codes. With binary codes, finding approximate matches for a query token is as easy as finding all the database tokens that are at a Hamming distance of r or less from the query token in the binary code representation (Shakhnarovich et al., 2008), (Weiss et al., 2008). When the binary codes are compact, this search can be done in a fraction of a second on directories containing millions of names on a simple processor.

Our contributions are:

- We develop a novel data-driven technique for learning hash functions for mapping similar names to similar binary codes using a set of names in a given language/script (i.e. monolingual data). We formulate the problem of learning hash functions as an optmization problem whose relaxation can be solved as a generalized Eigenvalue problem. (Section 2.1).

- We show that hash functions can also be learnt using bilingual data in the form of name equivalents in two languages. We formulate the

[2] http://www.facebook.com/directory/people/

problem of learning hash functions as an optmization problem whose relaxation can be solved using Canonical Correlation Analysis. (Section 2.2)

- We develop new similarity measures for matching names (Section 3.1).
- We evaluate the two methods systematically and compare our performance against multiple baselines. (Section 5).

2 Learning Hash Functions

In this section, we develop two techniques for learning hash functions using names as training data. In the first approach, we use monolingual data consisting of names in a language whereas in the second we use bilingual name pairs. In both techniques, the key idea is the same: we learn hash functions that map similar names in the training data to similar codewords.

2.1 M-HASH: Learning with Monolingual Names Data

Let (s, s') be a pair of names and $w(s, s')$ be their similarity[3]. We are given a set of name pairs $T = \{(s, s')\}$ as the training data. Let $\phi(s) \in R^{d_1}$ be the feature representation of s. We want to learn a hash function f that maps each name to a d bit codeword: $f : s \mapsto \{-1, 1\}^d$. We also want the Hamming distance of the codeword of s to the codeword of s' be small when $w(s, s')$ is large. Further, we want each bit of the codewords to be either 1 or -1 with equal probablity and the successive bits of the codewords to be uncorrelated. Thus we arrive at the following optimization problem[4]:

$$\begin{aligned} minimize: &\quad \sum_{(s,s')\in T} w\left(s, s'\right) \left\|f(s) - f\left(s'\right)\right\|^2 \\ s.t.: & \\ &\quad \sum_{s:(s,s')\in T} f(s) = 0 \\ &\quad \sum_{s:(s,s')\in T} f(s)\, f(s)^T = \rho^2 I_d \\ &\quad f(s), f\left(s'\right) \in \{-1, 1\}^d \end{aligned}$$

where I_d is an identity matrix of size $d \times d$.

Note that the second constraint helps us avoid the trap of mapping all names to the same codeword and thereby making the Hamming error zero while satisfying the first and last constraints.

It can be shown that the above minimization problem is NP-hard even for 1-bit codewords (Weiss et al., 2008). Further, the optimal solution gives codewords only for the names in the training data. As we want f to be defined for all s, we address the out-of-sample extension problem by relaxing f as follows[5]:

$$f_R(s) = A^T \phi(s) = \left(a_1^T \phi(s), \ldots, a_d^T \phi(s)\right)^T \quad (1)$$

where $A = [a_1, \ldots, a_d] \in R^{d_1 \times d}$ is a rank d matrix ($d \leq d_1$).

After the linear relaxation (Equation 1), the first constraint simply means that the data be centered, i.e., have zero mean. We center Φ by subtracting the mean of Φ from every $\phi(s) \in \Phi$ to get $\hat{\Phi}$.

Subsequent to the above relaxation, we get the following optimization problem:

$$\begin{aligned} minimize: &\quad Tr\ A^T \hat{\Phi} L \hat{\Phi}^T A && (2) \\ s.t.: & && (3) \\ &\quad A^T \hat{\Phi} \hat{\Phi}^T A = \rho^2 I_d && (4) \end{aligned}$$

where L is the graph Laplacian for the similarity matrix W defined by the pairwise similarities $w(s, s')$.

The minimization problem can be transformed into a generalized Eigenvalue problem and solved efficiently using either Cholesky factorization or QZ algorithm (Golub and Van Loan, 1996):

$$\hat{\Phi} L \hat{\Phi}^T A = \hat{\Phi} \hat{\Phi}^T A \Lambda \quad (5)$$

where Λ is a $d \times d$ diagonal matrix.

Once A has been estimated from the training data, the codeword of a name s can be produced by binarizing each coordinate of $f_R(s)$:

$$f(s) = \left(sgn\left(a_1^T \phi(s)\right), \ldots, sgn\left(a_d^T \phi(s)\right)\right)^T \quad (6)$$

where $sgn(u) = 1$ if $u > 0$ and -1 otherwise for all $u \in R$.

[3] We used 1− length normalized Edit Distance between s and s' as $w(s, s')$.

[4] Note that the Hamming distance of a codeword y to another codeword y' is $\frac{1}{4}\left\|y - y'\right\|^2$.

[5] In contrast to our approach, Spectral Hashing, a well-known hashing technique, makes the unrealistic assumption that the training data is sampled from a multidimensional uniform distribution to address the out-of-sample extension problem (Weiss et al., 2008).

In the reminder of this work, we call the system that uses the hash function learnt from monolingual data as *M-HASH*.

2.2 B-HASH: Learning with Bilingual Names Data

Let (s, t) be a pair of name s and its transliteration equivalent t in a different language/script. We are given the set $T = \{(s, t)\}$ as the training data. Let $\phi(s) \in R^{d_1}$ (and resp. $\psi(t) \in R^{d_2}$) be the feature representation of s (and resp. t). We want to learn a pair of hash functions f, g that map names to d bit codewords: $f : s \mapsto \{-1, 1\}^d$, $g : t \mapsto \{-1, 1\}^d$. We also want the Hamming distance of the codeword of a name to the codeword of its transliteration be small. As in Section 2.1, we want each bit of the codewords to be either 1 or -1 with equal probablity and the successive bits of the codewords to be uncorrelated. Thus we arrive at the following optimization problem:

$$\begin{aligned}
minimize : \quad & \sum_{(s,t) \in T} \| f(s) - g(t) \|^2 \\
s.t. : \quad & \\
& \sum_{s:(s,t) \in T} f(s) = 0 \\
& \sum_{t:(s,t) \in T} g(t) = 0 \\
& \sum_{s:(s,t) \in T} f(s) f(s)^T = \rho^2 I_d \\
& \sum_{t:(s,t) \in S} g(t) g(t)^T = \rho^2 I_d \\
& f(s), g(t) \in \{-1, 1\}^d
\end{aligned}$$

where I_d is an identity matrix of size $d \times d$.

As we want f (and resp. g) to be defined for all s (and resp. t), we relax f (and resp. g) as follows:

$$f_R(s) = A^T \phi(s) \tag{7}$$

$$g_R(t) = B^T \psi(s) \tag{8}$$

where $A = [a_1, \ldots, a_d] \in R^{d_1 \times d}$ and $B = [b_1, \ldots, b_d] \in R^{d_2 \times d}$ are rank d matrices.

As before, we center Φ and Ψ to get $\hat{\Phi}$ and $\hat{\Psi}$ respectively. Thus, we get the following optimization problem:

$$minimize : \quad Tr\ H\left(A, B; \hat{\Phi}, \hat{\Psi}\right) \tag{9}$$

$$s.t. : \tag{10}$$

$$A^T \hat{\Phi} \hat{\Phi}^T A = \rho^2 I_d \tag{11}$$

$$B^T \hat{\Psi} \hat{\Psi}^T B = \rho^2 I_d \tag{12}$$

where $H\left(A, B; \hat{\Phi}, \hat{\Psi}\right) = \left(A^T \hat{\Phi} - B^T \hat{\Psi}\right)\left(A^T \hat{\Phi} - B^T \hat{\Psi}\right)^T$.

The minimization problem can be solved as a generalized Eigenvalue problem:

$$\hat{\Phi} \hat{\Psi}^T B = \hat{\Phi} \hat{\Phi}^T A \Lambda \tag{13}$$

$$\hat{\Psi} \hat{\Phi}^T A = \hat{\Psi} \hat{\Psi}^T B \Lambda \tag{14}$$

where Λ is a $d \times d$ diagonal matrix. Further, Equations 13 and 14 find the canonical coefficients of $\hat{\Phi}$ and $\hat{\Psi}$ (Hardoon et al., 2004).

As with monolingual learning, we get the codeword of s by binarizing the coordinates of $f_R(s)$[6]:

$$f(s) = \left(sgn\left(a_1^T \phi(s)\right), \ldots, sgn\left(a_d^T \phi(s)\right)\right)^T \tag{15}$$

In the reminder of this work, we call the system that uses the hash function learnt from bilingual data as *B-HASH*.

3 Similarity Score

In this section, we develop new techniques for computing the similarity of names at token level as well as a whole. We will use these techniques in the NAME_MATCHING stage of our algorithm (Section 4.2.1).

3.1 Token-level Similarity

We use a logistic function over multiple distance measures to compute the similarity between name tokens s and s':

$$K(s, s') = \frac{1}{1 + e^{-\sum_i \alpha_i d_i(s, s')}}. \tag{16}$$

While a variety of distance measures can be employed in Equation 16, two obvious choices

[6] As a biproduct of bilingual learning, we can hash names in the second language using g:

$$g(t) = \left(sgn\left(b_1^T \psi(t)\right), \ldots, sgn\left(b_d^T \psi(t)\right)\right)^T$$

are the normalized Damerau-Levenshtein edit distance between s and s' and the Hamming distance between the codewords of s and s' $(= \|f(s) - f(s')\|)$. In our experiments, we found that the continuous relaxation $\|f_R(s) - f_R(s')\|$ was better than $\|f(s) - f(s')\|$ and hence we used it with Damerau-Levenshtein edit distance. We estimated α_1 and α_2 using a small held out set.

3.2 Multi-token Name Similarity

Let $Q = s_1 s_2 \ldots s_I$ and $D = s'_1 s'_2 \ldots s'_J$ be two multi-token names. To compute the similarity between Q and D, we first form a weighted bipartite graph with a node for each s_i and a node for each s'_j and set edge weight to $K\left(s_i, s'_j\right)$. We then compute the weight (κ_{max}) of the maximum weighted matching[7] in this graph. The similarity between Q and D is then computed as

$$K(Q, D) = \frac{\kappa_{max}}{|I - J + 1|}. \tag{17}$$

4 Spelling Correction using Hashing

In this section, we describe our algorithm for spelling correction using hashing as a building block.

4.1 Indexing the Name Directory

Given a name directory, we break each name into its constituent tokens and form a set of distinct name tokens. Using the name tokens and the original names, we build an inverted index which, for each name token, lists all the names that have the token as a constituent. Further, we hash each name token into a d bit codeword as described in Equation 6 (and resp. Equation 15) when using the hash function learnt on monolingual data (and resp. bilingual data) and store in a hash table.

4.2 Querying the Name Directory

Querying is done in two stages: NAME_BUCKETING and NAME_MATCHING.

4.2.1 Name Bucketing

Given a query $Q = s_1 s_2 \ldots s_I$, we hash each s_i into a codeword y_i and retrieve all codewords in the hash table that are at a Hamming distance of r or less from y_i. We rank the name tokens thus retrieved using the token level similarity score of Section 3.1 and retain only the top 100. Using the top tokens, we get all names which contain any of the name tokens as a constituent to form the pool of candidates $\mathcal{C}$ for the NAME_MATCHING stage.

4.2.2 Name Matching

First we find the best match for a query Q in the set of candidates $\mathcal{C}$ as follows:

$$D^* = \underset{D \in \mathcal{C}}{\operatorname{argmax}}\, K(Q, D). \tag{18}$$

Next we suggest D^* as the correction for Q if $K(Q, D^*)$ exceeds a certain empirically determined threshold.

5 Experiments and Results

We now discuss the experiments we conducted to study the retrieval performance of the two hashing-based approaches developed in the previous sections. Apart from evaluating the systems on test sets using different name directories, we were interested in comparing our systems with several baselines, understanding the effect of some of the choices we made (e.g. training data size, conjugate language) and comparative analysis of retrieval performance on queries of different complexity.

5.1 Experimental Setup

We tested the proposed hashing-based spelling correction algorithms on two test sets:

- DUMBTIONARY: 1231 misspellings of various names from *Dumbtionary*[8] and a name directory consisting of about $550,000$ names gleaned from the English Wikipedia. Each of the misspellings had a correct spelling in the name directory.

- INTRANET: 200 misspellings of employees taken from the search logs of the intranet of a large organization and a name directory

[7] In practice, a maximal matching computed using a greedy approach suffices since many of the edges in the bipartite graph have low weight.

[8] http://www.dumbtionary.com

consisting of about $150,000$ employee names. Each of the misspellings had a correct spelling in the name directory.

Table 1 shows the average edit distance of a misspelling from the correct name. Compared to DUMBTIONARY, the misspellings in INTRANET are more severe as the relatively high edit distance indicates. Thus, INTRANET represents very hard cases for spelling correction.

Test Set	**Average**	**Std. Dev.**
DUMBTIONARY	1.39	0.76
INTRANET	2.33	1.60

Table 1: Edit distance of a misspelling from the correct name.

5.1.1 Training

For M-HASH, we used 30,000 single token names in English (sampled from the list of names in the Internet Movie Database[9]) as training data and for B-HASH we used 14,941 parallel single token names in English-Hindi [10]. Each name was represented as a feature vector over character bigrams. Thus, the name token *Klein* has the bigrams $\{\cdot k, kl, le, ei, in, n\cdot\}$ as the features.

We learnt the hash functions from the training data by solving the generalized Eigenvalue problems of Sections 2.1 and 2.2. For both M-HASH and B-HASH we used the top 32 Eigenvectors to form the hash function resulting in a 32 bit representation for every name token[11].

5.1.2 Performance Metric

We measured the performance of all the systems using Precision@1, the fraction of names for which a correct spelling was suggested at Rank 1.

5.1.3 Baselines

The baselines are two popular search engines (S1 and S2), Double Metaphone (DM), a widely used phonetic search algorithm (Philips, 2000) and BM25, a very popular Information Retrieval algorithm (Manning et al., 2008). To use BM25 algorithm for spelling correction, we represented each name as a bag of bigrams and set the parameters K and b to 2 and 0.75 respectively.

5.2 Results

5.2.1 DUMBTIONARY

Table 2 compares the results of the hashing-based systems with the baselines on DUMBTIONARY. As the misspellings in DUMBTIONARY are relatively easier to correct, all the systems give reasonably good retrieval results. Nevertheless, the results of M-HASH and B-HASH are substantially better than the baselines. M-HASH reduced the error over the best baseline (S1) by 13.04% whereas B-HASH reduced by 46.17% (Table 6).

M-HASH	**B-HASH**	**S1**	**S2**	**DM**	**BM25**
87.93	**92.53**	86.12	79.33	78.95	84.70

Table 2: Precision@1 of the various systems on DUMBTIONARY.

To get a deeper understanding of the retrieval performance of the various systems, we studied queries of varying complexity of misspelling. Table 3 compares the results of our systems with S1 for queries that are at various edit distances from the correct names. We observe that M-HASH and B-HASH are better than S1 in dealing with relatively less severe misspellings. More interestingly, B-HASH is consistently and significantly better than S1 even when the misspellings are severe.

Distance	**M-HASH**	**B-HASH**	**S1**
1	96.18	**96.55**	89.59
2	81.79	**87.42**	75.76
3	44.07	**67.80**	59.65
4	21.05	**31.58**	29.42
5	0.00	**37.50**	0.00

Table 3: Precision@1 for queries at various edit distances on DUMBTIONARY.

5.2.2 INTRANET

For INTRANET, search engines could not be used as baselines and therefore we compare our systems

[9] http://www.imdb.com

[10] We obtained the names from the organizers of NEWS2009 workshop (http://www.acl-ijcnlp-2009.org/workshops/NEWS2009/pages/sharedtask.html).

[11] We experimented with codewords of various lengths and found that the 32 bit representation gave the best tradeoff between retrieval accuracy and speed.

with Double Metaphone and BM25 in Table 4. We observe that both M-HASH and B-HASH give signficantly better retrieval results than the baselines. M-HASH reduced the error by 36.20% over Double Metaphone whereas B-HASH reduced it by 51.73%. Relative to BM25, M-HASH reduced the error by 31.87% whereas B-HASH reduced it by 48.44%.

M-HASH	B-HASH	DM	BM25
70.65	**77.79**	54.00	56.92

Table 4: Precision@1 of the various systems on INTRANET.

Table 5 shows the results of our systems for queries that are at various edit distances from the correct names. We observe that the retrieval results for each category of queries are consistent with the results on DUMBTIONARY. As before, B-HASH gives signficantly better results than M-HASH.

Distance	M-HASH	B-HASH
1	82.76	**87.93**
2	57.14	**72.86**
3	34.29	**65.71**
4	38.46	**53.85**
5	6.67	**26.67**

Table 5: Precision@1 for queries at various edit distances on INTRANET.

Test Set	M-HASH	B-HASH
DUMBTIONARY	13.04	**46.17**
INTRANET	36.20	**51.73**

Table 6: Percentage error reduction over the best baseline.

5.2.3 Effect of Training Data Size

As both M-HASH and B-HASH are data driven systems, the effect of training data size on retrieval performance is important to study. Table 7 compares the results for systems trained with various amounts of training data on DUMBTIONARY. B-HASH trained with just 1000 name pairs gives 95.5% of the performance of B-HASH trained with 15000 name pairs. Similarly, M-HASH trained with 1000 names gives 98.5% of the performance of M-HASH trained with 30000 name pairs. This is probably because the spelling mistakes in DUMBTIONARY are relatively easy to correct.

Table 8 shows the results on INTRANET. We see that increase in the size of training data brings substantial returns for B-HASH. In contrast, M-HASH gives the best results at 5000 and does not seem to benefit from additional training data.

Size	M-HASH	B-HASH
1000	86.60	**88.34**
5000	87.36	**91.13**
10000	86.96	**92.53**
15000	87.19	**92.20**
30000	87.93	-

Table 7: Precision@1 on DUMBTIONARY as a function of training data size.

Size	M-HASH	B-HASH
1000	**66.04**	66.03
5000	70.65	**72.67**
10000	68.09	**75.26**
15000	68.60	**77.79**
30000	65.40	-

Table 8: Precision@1 on INTRANET as a function of training data size.

5.2.4 Effect of Conjugate Language

In Sections 5.2.1 and 5.2.2, we saw that bilingual data gives substantially better results than monolingual data. In the experiments with bilingual data, we used English-Hindi data for training B-HASH. A natural question to ask is what happens when we use someother language, say Hebrew or Russian or Tamil, instead of Hindi. In other words, does the retrieval performance, on an average, vary substantially with the conjugate language?

Table 9 compares the results on DUMBTIONARY when B-HASH was trained using English-Hindi, English-Hebrew, English-Russian, and English-Tamil data. We see that the retrieval results are good despite the differences in the script and language. Clearly, the source language (English in our experiments) benefits from being paired with any target language. However, some languages seem to give substantially better results than others when used as the conjugate language. For instance, Hindi as a conjugate for English seems to be better than Tamil. At the time of writing this paper, we do not know the reason for this behavior. We believe that a combination of factors including feature representation, training data, and language-specific confusion matrix need to be studied in greater depth to say anything conclusively about conjugate languages.

Conjugate	DUMBTIONARY	INTRANET
Hindi	92.53	77.79
Hebrew	91.30	71.68
Russian	89.42	64.94
Tamil	90.48	69.12

Table 9: Precision@1 of B-HASH for various conjugate languages.

5.2.5 Error Analysis

We looked at cases where either M-HASH or B-HASH (or both) failed to suggest the correct spelling. It turns out that in the DUMBTIONARY test set, for 81 misspelled names, both M-HASH and B-HASH failed to suggest the correct name at rank 1. Similarly, in the case of INTRANET test set, both M-HASH and B-HASH failed to suggest the correct name at rank 1 for 47 queries. This suggests that queries that are difficult for one system are also in general difficult for the other system. However, B-HASH was able to suggest correct names for some of the queries where M-HASH failed. In fact, in the INTRANET test set, whenever B-HASH failed, M-HASH also failed. And interestingly, in the DUMBTIONARY test set, the average edit distance of the query and the correct name for the cases where M-HASH failed to get the correct name in top 10 while B-HASH got it at rank 1 was 2.96. This could be because M-HASH attempts to map names with smaller edit distances to similar codewords.

Table 10 shows some interesting cases we found during error analysis. For the first query, M-HASH suggested the correct name whereas B-HASH did not. For the second query, both M-HASH and B-HASH suggested the correct name. And for the third query, B-HASH suggested the correct name whereas M-HASH did not.

Query	M-HASH	B-HASH

Table 10: Error Analysis.

5.3 Query Response Time

The average query response time is a measure of the speed of a system and is an important factor in real deployments of a Spelling Correction system. Ideally, one would like the average query response time to be as small as possible. However, in practice, average query response time is not only a function of the algorithm's computational complexity but also the computational infrastructure supporting the system. In our expriments, we used a single threaded implementation of M-HASH and B-HASH on an Intel Xeon processor (2.86 GHz). Table 11 shows the average query response time. We note that M-HASH is substantially slower than B-HASH. This is because the number of collisions in the NAME_BUCKETING stage is higher for M-HASH.

We would like to point out that both NAME_BUCKETING and NAME_MATCHING stages can be multi-threaded on a multi-core machine and the query response time can be decreased by an order easily. Further, the memory footprint of the system is very small and the codewords require 4.1 MB for the employees name directory (150,000 names) and 13.8 MB for the Wikipedia name directory (550,000 names).

Test Set	MHASH	BHASH
DUMBTIONARY	190	87
INTRANET	148	75

Table 11: Average response time in milliseconds (single threaded system running on 2.86 GHz Intel Xeon Processor).

6 Related Work

Spelling correction of written text is a well studied problem (Kukich, 1996), (Jurafsky and Martin, 2008). The first approach to spelling correction made use of a lexicon to correct out-of-lexicon terms by finding the closest in-lexicon word (Damerau, 1964). The similarity between a misspelled word and an in-lexicon word was measured using Edit Distance (Jurafsky and Martin, 2008). The next class of approaches applied the noisy channel model to correct single word spelling errors (Kernighan et al., 1990), (Brill and Moore, 2000). A major flaw of single word spelling correction algorithms is they do not make use of the context of the word in correcting the errors. The next stream of approaches explored ways of exploiting the word's context (Golding and Roth, 1996), (Cucerzan and Brill, 2004). Recently, several works have leveraged the Web for improved spelling correction (Chen et al., 2007),(Islam and Inkpen, 2009), (Whitelaw et al., 2009). Spelling correction algorithms targeted for web-search queries have been developed making use of query logs and click-thru data (Cucerzan and Brill, 2004), (Ahmad and Kondrak, 2005), (Sun et al., 2010). None of these approaches focus exclusively on correcting name misspellings.

Name matching techniques have been studied in the context of database record deduplication, text mining, and information retrieval (Christen, 2006), (Pfeifer et al., 1996). Most techniques use one or more measures of phonetic similarity and/or string similarity. The popular phonetic similarity-based techniques are Soundex, Phonix, and Metaphone (Pfeifer et al., 1996). Some of the string similarity-based techniques employ Damerau-Levenshtein edit distance, Jaro distance or Winkler distance (Christen, 2006). Data driven approaches for learning edit distance have also been proposed (Ristad and Yianilos, 1996). Most of these techniques either give poor retrieval performance on large name directories or do not scale.

Hashing techniques for similarity search is also a well studied problem (Shakhnarovich et al., 2008). Locality Sensitive Hashing (LSH) is a theoretically grounded data-oblivious approach for using random projections to define the hash functions for data objects with a single view (Charikar, 2002), (Andoni and Indyk, 2006). Although LSH guarantees that asymptotically the Hamming distance between the codewords approaches the Euclidean distance between the data objects, it is known to produce long codewords making it practically inefficient. Recently data-aware approaches that employ Machine Learning techniques to learn hash functions have been proposed and shown to be a lot more effective than LSH on both synthetic and real data. Semantic Hashing employs Restricted Boltzmann Machine to produce more compact codes than LSH (Salakhutdinov and Hinton, 2009). Spectral Hashing formalizes the requirements for a good code and relates them to the problem of balanced graph partitioning which is known to be NP hard (Weiss et al., 2008). To give a practical algorithm for hashing, Spectral Hashing assumes that the data are sampled from a multidimensional uniform distribution and solves a relaxed partitioning problem.

7 Conclusions

We developed two hashing-based techniques for spelling correction of person names in People Search applications.To the best of our knowledge, these are the first techniques that focus exclusively on correcting spelling mistakes in person names. Our approach has several advantages over other spelling correction techniques. Firstly, we do not suggest incorrect suggestions for valid queries unlike (Cucerzan and Brill, 2004). Further, as we suggest spellings from only authoritative name directories, the suggestions are always well formed and coherent. Secondly, we do not require query logs and other resources that are not easily available unlike (Cucerzan and Brill, 2004), (Ahmad and Kondrak, 2005). Neither do we require pairs of misspelled names and their correct spellings for learning the error model unlike (Brill and Moore, 2000) or large-coverage general purpose lexicon for unlike (Cucerzan and Brill, 2004) or pronunciation dictionaries unlike (Toutanova and Moore, 2002). Thirdly, we correct the query as a whole unlike (Ahmad and Kondrak, 2005) and can handle word order changes unlike (Cucerzan and Brill, 2004). Fourthly, we do not iteratively process misspelled name unlike (Cucerzan and Brill, 2004). Fifthly, we handle large name directories efficiently unlike the spectrum of name matching techniques discussed in (Pfeifer et al., 1996). Finally, our training data requirement is relatively small.

As future work, we would like to explore the possibility of learning hash functions using 1) bilingual and monolingual data together and 2) multiple conjugate languages.

Identifying Functional Relations in Web Text

Thomas Lin, Mausam, Oren Etzioni
Turing Center
University of Washington
Seattle, WA 98195, USA
{tlin,mausam,etzioni}@cs.washington.edu

Abstract

Determining whether a textual phrase denotes a functional relation (*i.e.*, a relation that maps each domain element to a unique range element) is useful for numerous NLP tasks such as synonym resolution and contradiction detection. Previous work on this problem has relied on either counting methods or lexico-syntactic patterns. However, determining whether a relation is functional, by analyzing mentions of the relation in a corpus, is challenging due to ambiguity, synonymy, anaphora, and other linguistic phenomena.

We present the LEIBNIZ system that overcomes these challenges by exploiting the synergy between the Web corpus and freely-available knowledge resources such as Freebase. It first computes multiple *typed functionality* scores, representing functionality of the relation phrase when its arguments are constrained to specific types. It then aggregates these scores to predict the global functionality for the phrase. LEIBNIZ outperforms previous work, increasing area under the precision-recall curve from 0.61 to 0.88. We utilize LEIBNIZ to generate the first public repository of automatically-identified functional relations.

1 Introduction

The paradigm of Open Information Extraction (IE) (Banko et al., 2007; Banko and Etzioni, 2008) has scaled extraction technology to the massive set of relations expressed in Web text. However, additional work is needed to better understand these relations, and to place them in richer semantic structures. A step in that direction is identifying the properties of these relations, *e.g.*, symmetry, transitivity and our focus in this paper – functionality. We refer to this problem as *functionality identification*.

A binary relation is functional if, for a given arg1, there is exactly one unique value for arg2. Examples of functional relations are *father, death_date, birth_city*, *etc.* We define a *relation phrase* to be functional if all semantic relations commonly expressed by that phrase are functional. For example, we say that the phrase *'was born in'* denotes a functional relation, because the different semantic relations expressed by the phrase (*e.g.*, *birth_city, birth_year, etc.*) are all functional.

Knowing that a relation is functional is helpful for numerous NLP inference tasks. Previous work has used functionality for the tasks of contradiction detection (Ritter et al., 2008), quantifier scope disambiguation (Srinivasan and Yates, 2009), and synonym resolution (Yates and Etzioni, 2009). It could also aid in other tasks such as ontology generation and information extraction. For example, consider two sentences from a contradiction detection task:
(1) "George Washington *was born in* Virginia." and
(2) "George Washington *was born in* Texas."
As Ritter *et al.* (2008) points out, we can only determine that the two sentences are contradictory if we know that the semantic relation referred to by the phrase *'was born in'* is functional, and that both Virginia and Texas are distinct states.

Automatic functionality identification is essential when dealing with a large number of relations as in Open IE, or in complex domains where expert help

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1266–1276,
MIT, Massachusetts, USA, 9-11 October 2010.

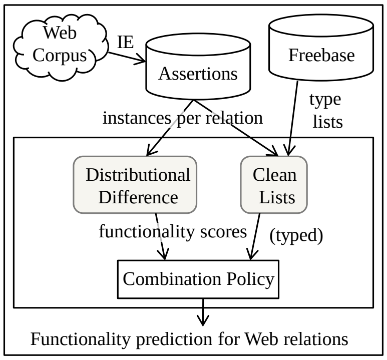

Figure 1: Our system, LEIBNIZ, uses the Web and Freebase to determine functionality of Web relations.

is scarce or expensive (*e.g.*, biomedical texts). This paper tackles automatic functionality identification using Web text. While functionality identification has been utilized as a module in various NLP systems, this is the first paper to focus exclusively on functionality identification as a *bona fide* NLP inference task.

It is natural to identify functions based on triples extracted from text instead of analyzing sentences directly. Thus, as our input, we utilize tuples extracted by TEXTRUNNER (Banko and Etzioni, 2008) when run over a corpus of 500 million webpages. TEXTRUNNER maps sentences to tuples of the form <arg1, *relation phrase*, arg2> and enables our LEIBNIZ system to focus on the problem of deciding whether the relation phrase is a function.

The naive approach, which classifies a relation phrase as non-functional if several arg1s have multiple arg2s in our extraction set, fails due to several reasons: synonymy – a unique entity may be referred by multiple strings, polysemy of both entities and relations – a unique string may refer to multiple entities/relations, metaphorical usage, extraction errors and more. These phenomena conspire to make the functionality determination task inherently statistical and surprisingly challenging.

In addition, a functional relation phrase may appear non-functional until we consider the types of its arguments. In our *'was born in'* example, <George Washington, *was born in*, 1732> does not contradict <George Washington, *was born in*, Virginia> even though we see two distinct arg2s for the same arg1. To solve functionality identification, we need to consider *typed relations* where the relations analyzed are constrained to have specific argument types.

We develop several approaches to overcome these challenges. Our first scheme employs approximate argument merging to overcome the synonymy and anaphora problems. Our second approach, DISTRDIFF, takes a statistical view of the problem and learns a separator for the typical count distributions of functional versus non-functional relations. Finally, our third and most successful scheme, CLEANLISTS, identifies and processes a cleaner subset of the data by intersecting the corpus with entities in a secondary knowledge-base (in our case, Freebase (Metaweb Technologies, 2009)). Utilizing pre-defined types, CLEANLISTS first identifies typed functionality for suitable types for that relation phrase, and then combines them to output a final functionality label. LEIBNIZ, a hybrid of CLEANLISTS and DISTRDIFF, returns state-of-the-art results for our task.

Our work makes the following contributions:

1. We identify several linguistic phenomena that make the problem of corpus-based functionality identification surprisingly difficult.

2. We designed and implemented three novel techniques for identifying functionality based on instance-based counting, distributional differences, and use of external knowledge bases.

3. Our best method, LEIBNIZ, outperforms the existing approaches by wide margins, increasing area under the precision-recall curve from 0.61 to 0.88. It is also capable of distinguishing functionality of typed relation phrases, when the arguments are restricted to specific types.

4. Utilizing LEIBNIZ, we created the first public repository of functional relations.[1]

2 Related Work

There is a recent surge in large knowledge bases constructed by human collaboration such as Freebase (Metaweb Technologies, 2009) and VerbNet (Kipper-Schuler, 2005). VerbNet annotates its verbs with several properties but not functionality. Freebase does annotate some relations with an 'is unique' property, which is similar to functionality, but the number of relations in Freebase is still much

[1] available at http://www.cs.washington.edu/research/leibniz

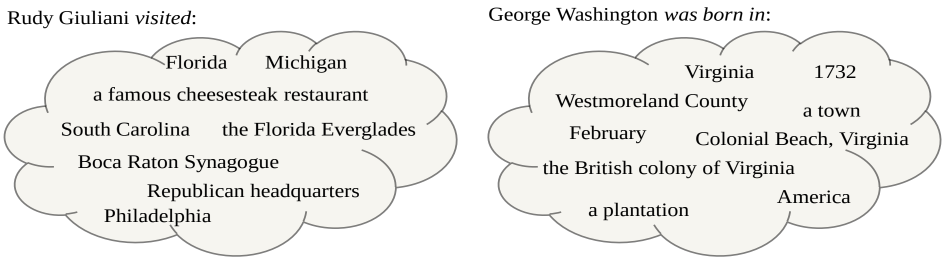

Figure 2: Sample arg2 values for a non-functional relation (*visited*) *vs.* a functional relation (*was born in*) illustrate the challenge in discriminating functionality from Web text.

smaller than the hundreds of thousands of relations existing on the Web, necessitating automatic approaches to functionality identification.

Discovering functional dependencies has been recognized as an important database analysis technique (Huhtala et al., 1999; Yao and Hamilton, 2008), but the database community does not address any of the linguistic phenomena which make this a challenging problem in NLP. Three groups of researchers have studied functionality identification in the context of natural language.

AuContraire (Ritter et al., 2008) is a contradiction detection system that also learns relation functionality. Their approach combines a probabilistic model based on (Downey et al., 2005) with estimates on whether each arg1 is ambiguous. The estimates are used to weight each arg1's contribution to an overall functionality score for each relation. Both argument-ambiguity and relation-functionality are jointly estimated using an EM-like method. While elegant, AuContraire requires substantial hand-engineered knowledge, which limits the scalability of their approach.

Lexico-syntactic patterns: Srinivasan and Yates (2009) disambiguate a quantifier's scope by first making judgments about relation functionality. For functionality, they look for *numeric phrases* following the relation. For example, the presence of the numeric term 'four' in the sentence "the fire *destroyed* four shops" suggests that *destroyed* is not functional, since the same arg1 can destroy multiple things.

The key problem with this approach is that it often assigns different functionality labels for the present tense and past tense phrases of the same semantic relation. For example, it will consider *'lived in'* to be non-functional, but *'lives in'* to be functional, since we rarely say "someone lives in many cities". Since both these phrases refer to the same semantic relation this approach has low precision. Moreover, it performs poorly for relation phrases that naturally expect numbers as the target argument (*e.g.*, *'has an atomic number of'*).

While these lexico-syntactic patterns do not perform as well for our task, they are well-suited for identifying whether a verb phrase can take multiple objects or not. This can be understood as a functionality property of the verb phrase within a sentence, as opposed to functionality of the semantic relation the phrase represents.

WIE: In a preliminary study, Popescu (2007) applies an instance based counting approach, but her relations require manually annotated type restrictions, which makes the approach less scalable.

Finally, functionality is just one property of relations that can be learned from text. A number of other studies (Guarino and Welty, 2004; Volker et al., 2005; Culotta et al., 2006) have examined detecting other relation properties from text and applying them to tasks such as ontology cleaning.

3 Challenges for Functionality Identification

A functional binary relation r is formally defined as one such that $\forall x, y_1, y_2 : r(x, y_1) \wedge r(x, y_2) \Rightarrow y_1 = y_2$. We define a relation string to be functional if all semantic relations commonly expressed by the relation string are individually functional. Thus, under our definition, *'was born in'* and *'died in'* are functional, even though they can take different arg2s for the same arg1, *e.g.*, year, city, state, country, *etc.*

The definition of a functional relation suggests a naive instance-based counting algorithm for identifying functionality. "Look for the number of arg2s for each arg1. If all (or most) arg1s have exactly one arg2, label the relation phrase functional, else, non-functional." Unfortunately, this naive algorithm fails for our task exposing several linguistic phenomena that make our problem hard (see Figure 2):

Synonymy: Various arg2s for the same arg1 may refer to the same entity. This makes many functional relations seem non-functional. For instance, <George Washington, *was born in*, Virginia> and <George Washington, *was born in*, the British colony of Virginia> are not in conflict. Other examples of synonyms include 'Windy City' and 'Chicago'; '3rd March' and '03/03', *etc.*

Anaphora: An entity can be referred to by using several phrases. For instance, <George Washington, *was born in*, a town> does not conflict with his being born in 'Colonial Beach, Virginia', since 'town' is an anaphora for his city of birth. Other examples include 'The US President' for 'George W. Bush', and 'the superpower' to refer to 'United States'. The effect is similar to that of synonyms – many relations incorrectly appear non-functional.

Argument Ambiguity: <George Washington, *was born in*, 'Kortrijk, Belgium'> in addition to his being born in 'Virginia' suggests that *'was born in'* is non-functional. However, the real cause is that 'George Washington' is ambiguous and refers to different people. This ambiguity gets more pronounced if the person is referred to just by their first (or last name), *e.g.*, 'Clinton' is commonly used to refer to both Hillary and Bill Clinton.

Relation Phrase Ambiguity: A relation phrase can have several senses. For instance '*weighs* 80 kilos' is a different *weighs* than '*weighs* his options'.

Type Restrictions: A closely related problem is type-variations in the argument. *E.g.*, <George Washington, *was born in*, America> *vs.* <George Washington, *born in*, Virginia> both use the same sense of *'was born in'* but refer to different semantic relations – one that takes a country in arg2, and the other that takes a state. Moreover, different argument types may result in different functionality labels. For example, *'published in'* is functional if the arg2 is a year, but non-functional if it is a language, since a book could be published in many languages. We refer to this finer notion of functionality as *typed functionality*.

Data Sparsity: There is limited data for more obscure relations instances and non-functional relation phrases appear functional due to lack of evidence.

Textually Functional Relations: Last but not least, some relations that are not functional may appear functional in text. An example is *'collects'*. We collect many things, but rarely mention it in text. Usually, someone's collection is mentioned in text only when it makes the news. We name such relations *textually functional*. Even though we could build techniques to reduce the impact of other phenomena, no instance based counting scheme could overcome the challenge posed by textually functional relations.

Finally, we note that our functionality predictor operates over tuples generated by an Open IE system. The extractors are not perfect and their errors can also complicate our analysis.

4 Algorithms

To overcome these challenges, we design three algorithms. Our first algorithm, IBC, applies several rules to determine whether two arg2s are equal. Our second algorithm, DISTRDIFF, takes a statistical approach, and tries to learn a discriminator between typical count distributions for functional and non-functional relations. Our final approach, CLEANLISTS, applies counting over a cleaner subset of the corpus, which is generated based on entities present in a secondary KB such as Freebase.

From this section onwards, we gloss over the distinction between a semantic relation and a relation phrase, since our algorithms do not have access to relations and operate only at the phrase level. We use 'relation' to refer to the phrases.

4.1 Instance Based Counting (IBC)

For each relation, IBC computes a global functionality score by aggregating local functionality scores for each arg1. The local functionality for each arg1 computes the fraction of arg2 pairs that refer to the same entity. To operationalize this computation we need to identify which arg2s co-refer. Moreover, we also need to pick an aggregation strategy to combine local functionality scores.

Data Cleaning: Common nouns in arg1s are often anaphoras for other entities. For example, <the company, *was headquartered in*, ...> refers to different companies in different extractions. To combat this, IBC restricts arg1s to proper nouns. Secondly, to counter extraction errors and data bias, it retains

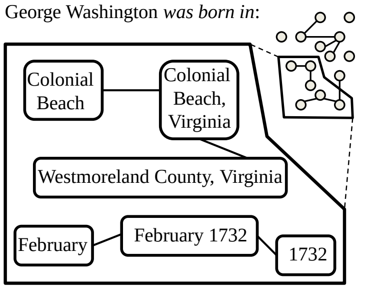

Figure 3: IBC judges that *Colonial Beach* and *Westmoreland County, Virginia* refer to the same entity.

an extraction only once per unique sentence. This reduces the disproportionately large frequencies of some assertions that are generated from a single article published at multiple websites. Similarly, it allows an extraction only once per website url. Moreover, it filters out any arg1 that does not appear at least 10 times with that relation.

Equality Checking: This key component judges if two arg2s refer to the same entity. It first employs weak typing by disallowing equality checks across common nouns, proper nouns, dates and numbers. This mitigates the relation ambiguity problem, since we never compare *'born in*(1732)' and *'born in*(Virginia)'. Within the same category it judges two arg2s to co-refer if they share a content word. It also performs a connected component analysis (Hopcraft and Tarjan, 1973) to take a transitive closure of arg2s judged equal (see Figure 3).

For example, for the relation *'was named after'* and arg1='Bluetooth' our corpus has three arg2s: 'Harald Bluetooth', 'Harald Bluetooth, the King of Denmark' and 'the King of Denmark'. Our equality method judges all three as referring to the same entity. Note that this is a heuristic approach, which could make mistakes. But for an error, there needs to be extractions with the same arg1, relation and similar arg2s. Such cases exist, but are not common. Our equality checking mitigates the problems of anaphora, synonymy as well as some typing.

Aggregation: We try several methods to aggregate local functionality scores for each arg1 into a global score for the relation. These include, a simple average, a weighted average weighted by frequency of each arg1, a weighted average weighted by log of frequency of each arg1, and a Bayesian approach that estimates the probability that a relation is functional using statistics over a small development set. Overall, the log-weighting works the best: it assigns a higher score for popular arguments, but not so high that it drowns out all the other evidence.

4.2 DISTRDIFF

Our second algorithm, DISTRDIFF, takes a purely statistical, discriminative view of the problem. It recognizes that, due to aforementioned reasons, whether a relation is functional or not, there are bound to be several arg1s that look locally functional and several that look locally non-functional. The difference is in the *number* of such arg1s – a functional relation will have more of the former type.

DISTRDIFF studies the count distributions for a small development set of functional relations (and similarly for non-functional) and attempts to build a separator between the two. As an illustration, Figure 4(a) plots the arg2 counts for various arg1s for a functional relation (*'is headquartered in'*). Each curve represents a unique arg1. For an arg1, the x-axis represents the rank (based on frequency) of arg2s and y-axis represents the normalized frequency of the arg2. For example, if an arg1 is found with just one arg2, then x=1 will match with y=1 (the first point has all the mass) and x=2 will match with y=0. If, on the other hand, an arg1 is found with five arg2s, say, appearing ten times each, then the first five x-points will map to 0.2 and the sixth point will map to 0.

We illustrate the same plot for a non-functional relation (*'visited'*) in Figure 4(b). It is evident from the two figures that, as one would expect, curves for most arg1s die early in case of a functional relation, whereas the lower ranked arg2s are more densely populated in case of a non-functional relation.

We aggregate this information using *slope* of the best-fit line for each arg1 curve. For functional relations, the best-fit lines have steep slopes, whereas for non-functional the lines are flatter. We bucket the slopes in integer bins and count the fraction of arg1s appearing in each bin. This lets us aggregate the information into a single slope-distribution for each relation. Bold lines in Figure 4(c) illustrate the average slope-distributions, averaged over ten sample relations of each kind – dashed for non-functional and solid for functional. Most non-functional relations have a much higher probability of arg1s with low magnitude slopes, whereas functional relations are

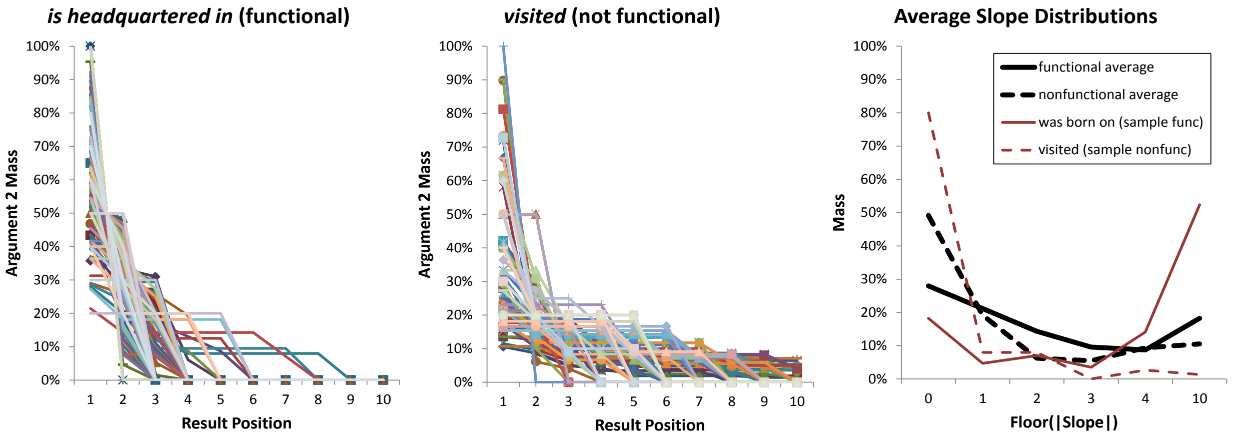

Figure 4: DISTRDIFF: Arg2 count distributions fall more sharply for (a) a sample functional relation, than (b) a sample non-functional relation. (c) The distance of aggregated slope-distributions from average slope-distributions can be used to predict the functionality.

the opposite. Notice that the aggregated curve for *'visited'* in the figure is closer to the average curve for non-functional than to functional and vice-versa for *'was born on'*.

We plot the aggregated slope-distributions for each relation and use the distance from average distributions as a means to predict the functionality. We use KL divergence (Kullback and Leibler, 1951) to compute the distance between two distributions. We score a relation's functionality in three ways using: (1) KLFUNC, its distance from average functional slope-distribution F_{avg}, (2) KLDIFF, its distance from average functional minus its distance from average non-functional N_{avg}, and (3) average of these two scores. For a relation with slope distribution R, the scores are computed as:

$$\text{KLFUNC} = \sum_i R(i) ln \frac{R(i)}{F_{avg}(i)}$$
$$\text{KLDIFF} = \text{KLFUNC} - (\sum_i R(i) ln \frac{R(i)}{N_{avg}(i)})$$

Section 5.2 compares the three scoring functions. A purely statistical approach is resilient to noisy data, and does not need to explicitly account for the various issues we detailed earlier. A disadvantage is that it cannot handle relation ambiguity and type restrictions. Moreover, we may need to relearn the separator if applying DISTRDIFF to a corpus with very different count distributions.

4.3 CLEANLISTS

Our third algorithm, CLEANLISTS, is based on the intuition that for identifying functionality we need not reason over all the data in our corpus; instead, a small but cleaner subset of the data may work best. This clean subset should ideally be free of synonyms, ambiguities and anaphora, and be typed.

Several knowledge-bases such as Wordnet, Wikipedia, and Freebase (Fellbaum, 1998; Wikipedia, 2004; Metaweb Technologies, 2009), are readily and freely available and they all provide clean typed lists of entities. In our experiments CLEANLISTS employs Freebase as a source of clean lists, but we could use any of these or other domain-specific ontologies such as SNOMED (Price and Spackman, 2000) as well.

CLEANLISTS takes the intersection of Freebase entities with our corpus to generate a clean subset for functionality analysis. Freebase currently has over 12 million entities in over 1,000 typed lists. Thus, this intersection retains significant portions of the useful data, and gets rid of most of anaphora and synonymy issues. Moreover, by matching against typed lists, many relation ambiguities are separated as well, since ambiguous relations often take different types in the arguments (*e.g.*, *'ran*(Distance)' *vs.* *'ran*(Company)'). To mitigate the effect of argument ambiguity, we additionally get rid of instances in which arg1s match multiple names in the Freebase list of names.

As an example, consider the *'was born in'* relation. CLEANLISTS will remove instances with only 'Clinton' in arg1, since it matches multiple people in Freebase. It will treat the different types, *e.g.*, cities, states, countries, months separately and analyze the functionality for each of these individually.

By intersecting the relation data with argument lists for these types, we will be left with a smaller, but much cleaner, subset of relation data, one for each type. CLEANLISTS analyzes each subset using simple, instance based counting and computes a typed functionality score for each type. Thus, it first computes typed functionality for each relation.

There are two subtleties in applying this algorithm. First, we need to identify the set of types to consider for each relation. Our algorithm currently picks the types that occur most in each relation's observed data. In the future, we could also use a selectional preferences system (Ritter et al., 2010; Kozareva and Hovy, 2010). Note that we remove Freebase types such as *Written Work* from consideration for containing many entities whose primary senses are not that type. For example, both 'Al Gore' and 'William Clinton' are also names of books, but references in text to these are rarely a reference to the written work sense.

Secondly, an argument could belong to multiple Freebase lists. For example, 'California' is both a city and a state. We apply a simple heuristic: if a string appears in multiple lists under consideration, we assign it to the smallest of the lists (the list of cities is much larger than states). This simple heuristic usually assigns an argument to its intended type. On a development set, the error rate of this heuristic is <4%, though it varies a bit depending on the types involved.

CLEANLISTS determines the overall functionality of a relation string by aggregating the scores for each type. It outputs functional if a majority of typed senses for the relation are functional. For example, CLEANLISTS judges *'was born in'* to be functional, since all relevant type restrictions are individually typed functional – everyone is born in exactly one country, city, state, month, *etc.*

CLEANLISTS has a much higher precision due to the intersection with clean lists, though at some cost of recall. The reason for lower recall is that the approach has a bias towards types that are easy to enumerate. It does not have different distances (*e.g.*, 50 kms, 20 miles, *etc.*) in its lists. Moreover, arguments that do not correspond to a noun cannot be handled. For example, in the sentence, "He *weighed* eating a cheeseburger against eating a salad", the arg2 of *'weighed'* can't be matched to a Freebase list. To increase the recall we back off to DISTRDIFF in the cases when CLEANLISTS is unable to make a prediction. This combination gives the best balance of precision and recall for our task. We name our final system LEIBNIZ.

One current limitation is that using only those arg2s that exactly match clean lists leaves out some good data (*e.g.*, a tuple with an arg2 of 'Univ of Wash' will not match against a list of universities that spells it as 'University of Washington'). Because we have access to entity types, using typed equality checkers (Prager et al., 2007) with the clean lists would allow us to recapture much of this useful data. Moreover, the knowledge of functions could apply to building new type nanotheories and reduce considerable manual effort. We wish to study this in the future.

5 Evaluation

In our evaluation, we wish to answer three questions: (1) How do our three approaches, *Instance Based Counting* (IBC), DISTRDIFF, and CLEANLISTS, compare on the functionality identification task? (2) How does our final system, LEIBNIZ, compare against the existing state of the art techniques? (3) How well is LEIBNIZ able to identify typed functionality for different types in the same relation phrase?

5.1 Dataset

For our experiments we test on the set of 887 relations used by Ritter *et al.* (2008) in their experiments. We use the Open IE corpus generated by running TEXTRUNNER on 500 million high quality Webpages (Banko and Etzioni, 2008) as the source of instance data for these relations. Extractor and corpus differences lead to some relations not occurring (or not occurring with sufficient frequency to properly analyze, *i.e.*, ≥ 5 arg1 with ≥ 10 evidence), leaving a dataset of 629 relations on which to test.

Two human experts tagged these relations for functionality. Tagging the functionality of relation phrases can be a bit subjective, as it requires the experts to imagine the various senses of a phrase and judge functionality over all those senses. The inter-annotator agreement between the experts was 95.5%. We limit ourselves to the subset of the data

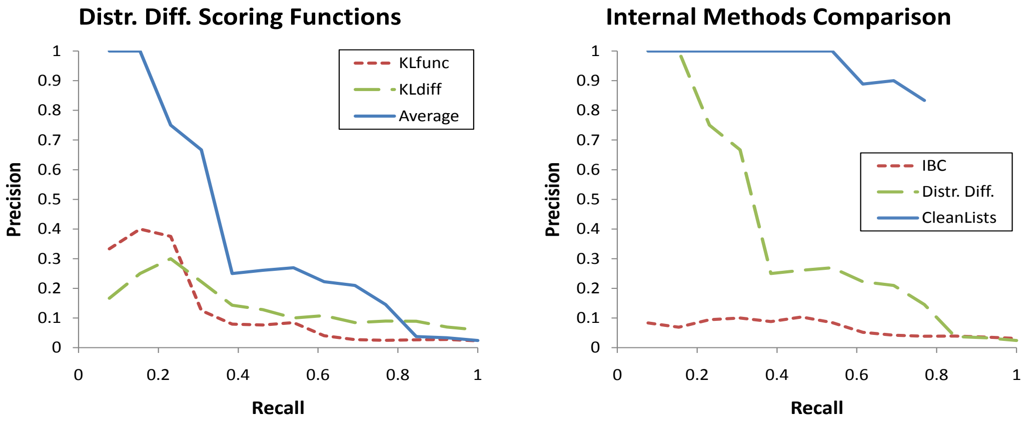

Figure 5: (a) The best scoring method for DistrDiff averages KLfunc and KLdiff. (b) CleanLists performs significantly better than DistrDiff, which performs significantly better than IBC.

on which the two experts agreed (a subset of 601 relation phrases).

5.2 Internal Comparisons

First, we compare the three scoring functions for DistrDiff. We vary the score thresholds to generate the different points on the precision-recall curves for each of the three. Figure 5(a) plots these curves. It is evident that the hybrid scoring function, *i.e.*, one which is an average of KLfunc (distance from average functional) and KLdiff (distance from average functional minus distance from average non-functional) performs the best. We use this scoring in the further experiments involving DistrDiff.

Next, we compare our three algorithms on the dataset. Figure 5(b) reports the results. CleanLists outperforms DistrDiff by vast margins, covering a 33.5% additional area under the precision-recall curve. Overall, CleanLists finds the very high precision points, because of its use of clean data. However, it is unable to make 23.1% of the predictions, primarily because the intersection between the corpus and Freebase entities results in very little data for those relations. DistrDiff performs better than IBC, due to its statistical nature, but the issues described in Section 3 plague both these systems much more than CleanLists.

To increase the recall Leibniz uses a combination of DistrDiff and CleanLists, in which the algorithm backs off to DistrDiff if CleanLists is unable to output a prediction.

5.3 External Comparisons

We next compare Leibniz against the existing state of the art approaches. Our competitors are AuContraire and NumericTerms (Ritter et al., 2008; Srinivasan and Yates, 2009). Because we use the AuContraire dataset, we report the results from their best performing system. We reimplement a version of NumericTerms using their list of numeric quantifiers and extraction patterns that best correspond to our relation format. We run our implementation of NumericTerms on a dataset of 100 million English sentences from a crawl of high quality Webpages to generate the functionality labels.

Figure 6(a) reports the results of this experiment. We find that Leibniz outperforms AuContraire by vast margins covering an additional 44% area in the precision-recall curve. AuContraire's AUC is 0.61 whereas Leibniz covers 0.88. A Bootstrap Percentile Test (Keller et al., 2005) on F_1 score found the improvement of our techniques over AuContraire to be statistically significant at $\alpha = 0.05$. NumericTerms does not perform well, because it makes decisions based only on the local evidence in a sentence, and does not integrate the knowledge from different occurrences of the same relation. It returns many false positives, such as *'lives in'*, which appear functional to the lexico-syntactic pattern, but are clearly non-functional, *e.g.*, one could live in many places over a lifetime.

An example of a Leibniz error is the *'represented'* relation. Leibniz classifies this as functional, because it finds several strongly functional senses (*e.g.*, when a person represents a country),

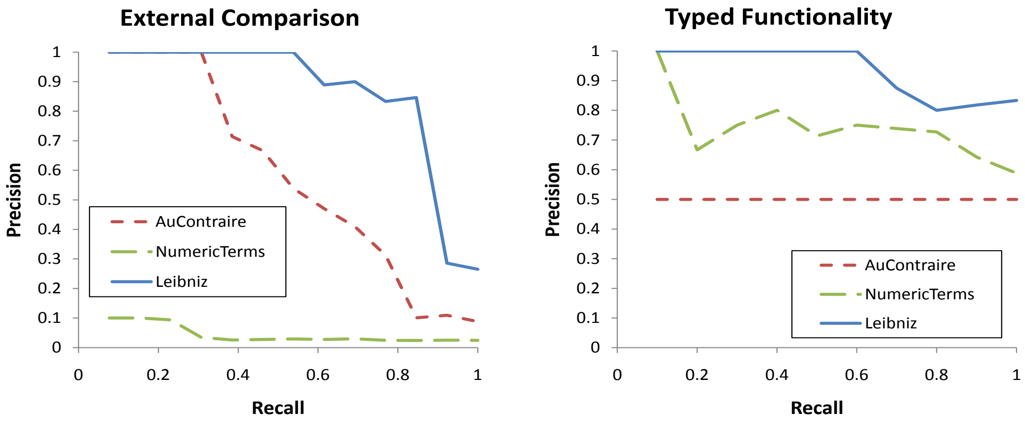

Figure 6: (a) LEIBNIZ, which is a hybrid of CLEANLISTS and DISTRDIFF, achieves 0.88 AUC and outperforms the 0.61 AUC from AuContraire (Ritter et al., 2008) and the 0.05 AUC from NumericTerms (Srinivasan and Yates, 2009). (b) LEIBNIZ is able to tease apart different senses of polysemous relations much better than other systems.

but the human experts might have had some non-functional senses in mind while labeling.

5.4 Typed Functionality

Next, we conduct a study of the typed functionality task. We test on ten common polysemous relations, each having both a functional and a non-functional sense. An example is the *'was published in'* relation. If arg2 is a year it is functional, *e.g.* <Harry Potter 5, *was published in*, 2003>. However, *'was published in*(Language)' is not functional, *e.g.* <Harry Potter 5, *was published in*, [French / Spanish / English]>. Similarly, *'will become*(Company)' is functional because when a company is renamed, it transitions away from the old name exactly once, *e.g.* <Cingular, *will become*, AT&T Wireless>. However, *'will become*(government title)' is not functional, because people can hold different offices in their life, *e.g.*, <Obama, *will become*, [Senator / President]>.

In this experiment, a simple baseline of predicting the same label for the two types of each relation achieves a precision of 0.5. Figure 6(b) presents the results of this study. AuContraire achieves a flat 0.5, since it cannot distinguish between types. NumericTerms can be modified to distinguish between basic types – check the word just after the numeric term to see whether it matches the type name. For example, the modified NumericTerms will search the Web for instances of *"was published in* [numeric term] *years" vs. "was published in* [numeric term] *languages"*. This scheme works better when the type name is simple (*e.g.*, languages) rather than complex (*e.g.*, government titles).

LEIBNIZ performs the best and is able to tease apart the functionality of various types very well. When LEIBNIZ did not work, it was generally because of textual functionality, which is a larger issue for typed functionality than general functionality. Of course, these results are merely suggestive – we perform a larger-scale experiment and generate a repository of typed functions next.

6 A Repository of Functional Relations

We now report on a repository of typed functional relations generated automatically by applying LEIBNIZ to a large collection of relation phrases. Instead of starting with the most frequent relations from TEXTRUNNER, we use OCCAM's relations (Fader et al., 2010) because they are more specific. For instance, where TEXTRUNNER outputs an underspecified tuple, <Gold, *has*, an atomic number of 79>, OCCAM extracts <Gold, *has an atomic number of*, 79>. OCCAM enables LEIBNIZ to identify far more functional relations than TEXTRUNNER.

6.1 Addressing Evidence Sparsity

Scaling up to a large collection of typed relations requires us to consider the size of our data sets. For example, consider which relation is more likely to be functional—a relation with 10 instances all of which indicate functionality versus a relation with 100 instances where 95 behave functionally.

To address this problem, we adapt the likelihood ratio approach from Schoenmackers *et al.* (2010).

For a typed relation with *n* instances, *f* of which indicate functionality, the G-test (Dunning, 1993), $G = 2*(f*\ln(f/k)+(n-f)*\ln((n-f)/(n-k)))$, provides a measure for the likelihood that the relation is not functional. Here *k* denotes the evidence indicating functionality for the case where the relation is not functional. Setting $k = n*0.25$ worked well for us. This G-score replaces our previous metric for scoring functional relations.

6.2 Evaluation of the Repository

In CLEANLISTS a factor that affects the quality of the results is the exact set of lists that is used. If the lists are not clean, results get noisy. For example, Freebase's list of *films* contains 73,000 entries, many of which (*e.g.*, "*Egg*") are not films in their primary senses. Even with heuristics such as assigning terms to their smallest lists and disqualifying dictionary words that occur from large type lists, there is still significant noise left.

Using LEIBNIZ with a set of 35 clean lists on OCCAM's extraction corpus, we generated a repository of 5,520 typed functional relations. To evaluate this resource a human expert tagged a random subset of the top 1,000 relations. Of these relations 22% were either ill-formed or had non-sensical type constraints. From the well-formed typed relations the precision was estimated to be 0.8. About half the errors were due to textual functionality and the rest were LEIBNIZ errors. Some examples of good functions found include *isTheSequelTo(videogame)* and *areTheBirthstoneFor(month)*. An example of a textually functional relation found is *wasTheFounderOf(company).*

This is the first public repository of automatically-identified functional relations. Scaling up our data set forced us to confront new sources of noise including extractor errors, errors due to mismatched types, and errors due to sparse evidence. Still, our initial results are encouraging and we hope that our resource will be valuable as a baseline for future work.

7 Conclusions

Functionality identification is an important subtask for Web-scale information extraction and other machine reading tasks. We study the problem of predicting the functionality of a relation phrase automatically from Web text. We presented three algorithms for this task: (1) instance-based counting, (2) DISTRDIFF, which takes a statistical approach and discriminatively classifies the relations using average arg-distributions, and (3) CLEANLISTS, which performs instance based counting on a subset of clean data generated by intersection of the corpus with a knowledge-base like Freebase.

Our best approach, LEIBNIZ, is a hybrid of DISTRDIFF and CLEANLISTS, and outperforms the existing state-of-the-art approaches by covering 44% more area under the precision-recall curve. We also observe that an important sub-component of identifying a functional relation phrase is identifying typed functionality, *i.e.*, functionality when the arguments of the relation phrase are type-constrained. Because CLEANLISTS is able to use typed lists, it can successfully identify typed functionality.

We run our techniques on a large set of relations to output a first repository of typed functional relations. We release this list for further use by the research community.[2]

Future Work: Functionality is one of the several properties a relation can possess. Others include selectional preferences, transitivity (Schoenmackers et al., 2008), mutual exclusion, symmetry, *etc.* These properties are very useful in increasing our understanding about these Open IE relation strings. We believe that the general principles developed in this work, for example, connecting the Open IE knowledge with an existing knowledge resource, will come in very handy in identifying these other properties.

Acknowledgements

We would like to thank Alan Ritter, Alex Yates and Anthony Fader for access to their data sets. We would like to thank Stephen Soderland, Yoav Artzi, and the anonymous reviewers for helpful comments on previous drafts. A Latent Variable Model for Geographic Lexical Variation

Abstract

The rapid growth of geotagged social media raises new computational possibilities for investigating geographic linguistic variation. In this paper, we present a multi-level generative model that reasons jointly about latent topics and geographical regions. High-level topics such as "sports" or "entertainment" are rendered differently in each geographic region, revealing topic-specific regional distinctions. Applied to a new dataset of geotagged microblogs, our model recovers coherent topics and their regional variants, while identifying geographic areas of linguistic consistency. The model also enables prediction of an author's geographic location from raw text, outperforming both text regression and supervised topic models.

1 Introduction

Sociolinguistics and dialectology study how language varies across social and regional contexts. Quantitative research in these fields generally proceeds by counting the frequency of a handful of previously-identified linguistic *variables*: pairs of phonological, lexical, or morphosyntactic features that are semantically equivalent, but whose frequency depends on social, geographical, or other factors (Paolillo, 2002; Chambers, 2009). It is left to the experimenter to determine which variables will be considered, and there is no obvious procedure for drawing inferences from the distribution of multiple variables. In this paper, we present a method for identifying geographically-aligned lexical variation directly from raw text. Our approach takes the form of a probabilistic graphical model capable of identifying both geographically-salient terms and coherent linguistic communities.

One challenge in the study of lexical variation is that term frequencies are influenced by a variety of factors, such as the topic of discourse. We address this issue by adding latent variables that allow us to model topical variation explicitly. We hypothesize that geography and topic interact, as "pure" topical lexical distributions are corrupted by geographical factors; for example, a sports-related topic will be rendered differently in New York and California. Each author is imbued with a latent "region" indicator, which both selects the regional variant of each topic, and generates the author's observed geographical location. The regional corruption of topics is modeled through a cascade of logistic normal priors—a general modeling approach which we call *cascading* topic models. The resulting system has multiple capabilities, including: (i) analyzing lexical variation by both topic and geography; (ii) segmenting geographical space into coherent linguistic communities; (iii) predicting author location based on text alone.

This research is only possible due to the rapid growth of social media. Our dataset is derived from the microblogging website Twitter,[1] which permits users to post short messages to the public. Many users of Twitter also supply exact geographical coordinates from GPS-enabled devices (e.g., mobile phones),[2] yielding *geotagged* text data. Text in computer-mediated communication is often more vernacular (Tagliamonte and Denis, 2008), and as such it is more likely to reveal the influence of geographic factors than text written in a more formal genre, such as news text (Labov, 1966).

We evaluate our approach both qualitatively and quantitatively. We investigate the topics and regions

[1] http://www.twitter.com

[2] User profiles also contain self-reported location names, but we do not use that information in this work.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1277–1287,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

that the model obtains, showing both common-sense results (place names and sports teams are grouped appropriately), as well as less-obvious insights about slang. Quantitatively, we apply our model to predict the location of unlabeled authors, using text alone. On this task, our model outperforms several alternatives, including both discriminative text regression and related latent-variable approaches.

2 Data

The main dataset in this research is gathered from the microblog website Twitter, via its official API. We use an archive of messages collected over the first week of March 2010 from the "Gardenhose" sample stream,[3] which then consisted of 15% of all public messages, totaling millions per day. We aggressively filter this stream, using only messages that are tagged with physical (latitude, longitude) coordinate pairs from a mobile client, and whose authors wrote at least 20 messages over this period. We also filter to include only authors who follow fewer than 1,000 other people, and have fewer than 1,000 followers. Kwak et al. (2010) find dramatic shifts in behavior among users with social graph connectivity outside of that range; such users may be marketers, celebrities with professional publicists, news media sources, etc. We also remove messages containing URLs to eliminate bots posting information such as advertising or weather conditions. For interpretability, we restrict our attention to authors inside a bounding box around the contiguous U.S. states, yielding a final sample of about 9,500 users and 380,000 messages, totaling 4.7 million word tokens. We have made this dataset available online.[4]

Informal text from mobile phones is challenging to tokenize; we adapt a publicly available tokenizer[5] originally developed for Twitter (O'Connor et al., 2010), which preserves emoticons and blocks of punctuation and other symbols as tokens. For each user's Twitter feed, we combine all messages into a single "document." We remove word types that appear in fewer than 40 feeds, yielding a vocabulary of 5,216 words. Of these, 1,332 do not appear in the English, French, or Spanish dictionaries of the spell-checking program `aspell`.

Every message is tagged with a location, but most messages from a single individual tend to come from nearby locations (as they go about their day); for modeling purposes we use only a single geographic location for each author, simply taking the location of the first message in the sample.

The authors in our dataset are fairly heavy Twitter users, posting an average of 40 messages per day (although we see only 15% of this total). We have little information about their demographics, though from the text it seems likely that this user set skews towards teens and young adults. The dataset covers each of the 48 contiguous United States and the District of Columbia.

3 Model

We develop a model that incorporates two sources of lexical variation: topic and geographical region. We treat the text and geographic locations as outputs from a generative process that incorporates both topics and regions as latent variables.[6] During inference, we seek to recover the topics and regions that best explain the observed data.

At the base level of model are "pure" topics (such as "**sports**", "**weather**", or "**slang**"); these topics are rendered differently in each region. We call this general modeling approach a *cascading* topic model; we describe it first in general terms before moving to the specific application to geographical variation.

3.1 Cascading Topic Models

Cascading topic models generate text from a chain of random variables. Each element in the chain defines a distribution over words, and acts as the mean of the distribution over the subsequent element in the chain. Thus, each element in the chain can be thought of as introducing some additional corruption. All words are drawn from the final distribution in the chain.

At the beginning of the chain are the priors, followed by unadulerated base topics, which may then be corrupted by other factors (such as geography or time). For example, consider a base "**food**" topic

[3] `http://dev.twitter.com/pages/streaming_api`

[4] `http://www.ark.cs.cmu.edu/GeoTwitter`

[5] `http://tweetmotif.com`

[6] The region could be observed by using a predefined geographical decomposition, e.g., political boundaries. However, such regions may not correspond well to linguistic variation.

that emphasizes words like *dinner* and *delicious*; the corrupted "**food-California**" topic would place weight on these words, but might place extra emphasis on other words like *sprouts*.

The path through the cascade is determined by a set of indexing variables, which may be hidden or observed. As in standard latent Dirichlet allocation (Blei et al., 2003), the base topics are selected by a per-token hidden variable z. In the geographical topic model, the next level corresponds to regions, which are selected by a per-author latent variable r.

Formally, we draw each level of the cascade from a normal distribution centered on the previous level; the final multinomial distribution over words is obtained by exponentiating and normalizing. To ensure tractable inference, we assume that all covariance matrices are uniform diagonal, i.e., $a\mathbf{I}$ with $a > 0$; this means we do not model interactions between words.

3.2 The Geographic Topic Model

The application of cascading topic models to geographical variation is straightforward. Each document corresponds to the entire Twitter feed of a given author during the time period covered by our corpus. For each author, the latent variable r corresponds to the geographical region of the author, which is not observed. As described above, r selects a corrupted version of each topic: the kth basic topic has mean $\boldsymbol{\mu}_k$, with uniform diagonal covariance σ_k^2; for region j, we can draw the regionally-corrupted topic from the normal distribution, $\boldsymbol{\eta}_{jk} \sim \mathcal{N}(\boldsymbol{\mu}_k, \sigma_k^2\mathbf{I})$.

Because $\boldsymbol{\eta}$ is normally-distributed, it lies not in the simplex but in $\mathbb{R}^W$. We deterministically compute multinomial parameters $\boldsymbol{\beta}$ by exponentiating and normalizing: $\boldsymbol{\beta}_{jk} = \exp(\boldsymbol{\eta}_{jk}) / \sum_i \exp(\eta_{jk}^{(i)})$. This normalization could introduce identifiability problems, as there are multiple settings for $\boldsymbol{\eta}$ that maximize $P(\boldsymbol{w}|\boldsymbol{\eta})$ (Blei and Lafferty, 2006a). However, this difficulty is obviated by the priors: given $\boldsymbol{\mu}$ and σ^2, there is only a single $\boldsymbol{\eta}$ that maximizes $P(\boldsymbol{w}|\boldsymbol{\eta})P(\boldsymbol{\eta}|\boldsymbol{\mu}, \sigma^2)$; similarly, only a single $\boldsymbol{\mu}$ maximizes $P(\boldsymbol{\eta}|\boldsymbol{\mu})P(\boldsymbol{\mu}|\boldsymbol{a}, b^2)$.

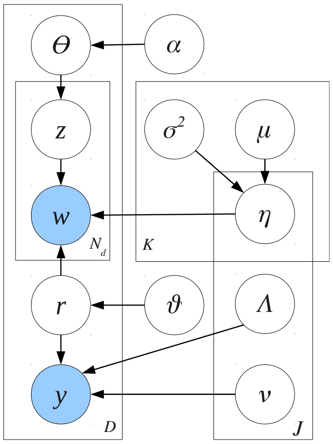
The observed latitude and longitude, denoted $\boldsymbol{y}$, are normally distributed and conditioned on the region, with mean $\boldsymbol{\nu}_r$ and precision matrix Λ_r indexed by the region r. The region index r is itself drawn from a single shared multinomial $\boldsymbol{\vartheta}$. The model is shown as a plate diagram in Figure 1.

Given a vocabulary size W, the generative story is as follows:

- **Generate base topics**: for each topic $k < K$
  - Draw the base topic from a normal distribution with uniform diagonal covariance: $\boldsymbol{\mu}_k \sim \mathcal{N}(\boldsymbol{a}, b^2\mathbf{I})$,
  - Draw the regional variance from a Gamma distribution: $\sigma_k^2 \sim \mathcal{G}(c, d)$.
  - **Generate regional variants**: for each region $j < J$,
    - * Draw the region-topic $\boldsymbol{\eta}_{jk}$ from a normal distribution with uniform diagonal covariance: $\boldsymbol{\eta}_{jk} \sim \mathcal{N}(\boldsymbol{\mu}_k, \sigma_k^2\mathbf{I})$.
    - * Convert $\boldsymbol{\eta}_{jk}$ into a multinomial distribution over words by exponentiating and normalizing: $\boldsymbol{\beta}_{jk} = \exp\left(\boldsymbol{\eta}_{jk}\right) / \sum_i^W \exp(\eta_{jk}^{(i)})$, where the denominator sums over the vocabulary.
- **Generate regions**: for each region $j < J$,
  - Draw the spatial mean $\boldsymbol{\nu}_j$ from a normal distribution.
  - Draw the precision matrix Λ_j from a Wishart distribution.
- Draw the distribution over regions $\boldsymbol{\vartheta}$ from a symmetric Dirichlet prior, $\boldsymbol{\vartheta} \sim \text{Dir}(\alpha_{\vartheta}\mathbf{1})$.
- **Generate text and locations**: for each document d,
  - Draw topic proportions from a symmetric Dirichlet prior, $\boldsymbol{\theta} \sim \text{Dir}(\alpha\mathbf{1})$.
  - Draw the region r from the multinomial distribution $\boldsymbol{\vartheta}$.
  - Draw the location $\boldsymbol{y}$ from the bivariate Gaussian, $\boldsymbol{y} \sim \mathcal{N}(\boldsymbol{\nu}_r, \Lambda_r)$.
  - For each word token,
    - * Draw the topic indicator $z \sim \boldsymbol{\theta}$.
    - * Draw the word token $w \sim \boldsymbol{\beta}_{rz}$.

4 Inference

We apply mean-field variational inference: a fully-factored variational distribution Q is chosen to minimize the Kullback-Leibler divergence from the true distribution. Mean-field variational inference with conjugate priors is described in detail elsewhere (Bishop, 2006; Wainwright and Jordan, 2008); we restrict our focus to the issues that are unique to the geographic topic model.



$\boldsymbol{\mu}_k$	log of base topic k's distribution over word types
σ_k^2	variance parameter for regional variants of topic k
$\boldsymbol{\eta}_{jk}$	region j's variant of base topic $\boldsymbol{\mu}_k$
$\boldsymbol{\theta}_d$	author d's topic proportions
r_d	author d's latent region
$\boldsymbol{y}_d$	author d's observed GPS location
$\boldsymbol{\nu}_j$	region j's spatial center
Λ_j	region j's spatial precision
z_n	token n's topic assignment
w_n	token n's observed word type
$\boldsymbol{\alpha}$	global prior over author-topic proportions
$\boldsymbol{\vartheta}$	global prior over region classes

Figure 1: Plate diagram for the geographic topic model, with a table of all random variables. Priors (besides α) are omitted for clarity, and the document indices on z and w are implicit.

We place variational distributions over all latent variables of interest: $\boldsymbol{\theta}, \boldsymbol{z}, \boldsymbol{r}, \boldsymbol{\vartheta}, \boldsymbol{\eta}, \boldsymbol{\mu}, \sigma^2, \boldsymbol{\nu}$, and Λ, updating each of these distributions in turn, until convergence. The variational distributions over $\boldsymbol{\theta}$ and $\boldsymbol{\vartheta}$ are Dirichlet, and have closed form updates: each can be set to the sum of the expected counts, plus a term from the prior (Blei et al., 2003). The variational distributions $q(z)$ and $q(r)$ are categorical, and can be set proportional to the expected joint likelihood—to set $q(z)$ we marginalize over r, and vice versa.[7] The updates for the multivariate Gaussian spatial parameters $\boldsymbol{\nu}$ and Λ are described by Penny (2001).

4.1 Regional Word Distributions

The variational region-topic distribution $\boldsymbol{\eta}_{jk}$ is normal, with uniform diagonal covariance for tractability. Throughout we will write $\langle x \rangle$ to indicate the expectation of x under the variational distribution Q. Thus, the vector mean of the distribution $q(\boldsymbol{\eta}_{jk})$ is written $\langle \boldsymbol{\eta}_{jk} \rangle$, while the variance (uniform across i) of $q(\boldsymbol{\eta})$ is written $\mathcal{V}(\boldsymbol{\eta}_{jk})$.

To update the mean parameter $\langle \boldsymbol{\eta}_{jk} \rangle$, we maximize the contribution to the variational bound L from the relevant terms:

$$L_{[\langle \eta_{jk}^{(i)} \rangle]} = \langle \log p(\boldsymbol{w}|\boldsymbol{\beta}, \boldsymbol{z}, \boldsymbol{r}) \rangle + \langle \log p(\eta_{jk}^{(i)} | \mu_k^{(i)}, \sigma_k^2) \rangle, \tag{1}$$

with the first term representing the likelihood of the observed words (recall that β is computed deterministically from η) and the second term corresponding to the prior. The likelihood term requires the expectation $\langle \log \boldsymbol{\beta} \rangle$, but this is somewhat complicated by the normalizer $\sum_i^W \exp(\eta^{(i)})$, which sums over all terms in the vocabulary. As in previous work on logistic normal topic models, we use a Taylor approximation for this term (Blei and Lafferty, 2006a).

The prior on $\boldsymbol{\eta}$ is normal, so the contribution from the second term of the objective (Equation 1) is $-\frac{1}{2\langle \sigma_k^2 \rangle} \langle (\eta_{jk}^{(i)} - \mu_k^{(i)})^2 \rangle$. We introduce the following notation for expected counts: $N(i, j, k)$ indicates the expected count of term i in region j and topic k, and $N(j, k) = \sum_i N(i, j, k)$. After some calculus, we can write the gradient $\partial L / \partial \langle \eta_{jk}^{((i))} \rangle$ as

$$N(i, j, k) - N(j, k) \langle \beta_{jk}^{(i)} \rangle - \langle \sigma_k^{-2} \rangle (\langle \eta_{jk}^{(i)} \rangle - \langle \mu_k^{(i)} \rangle), \tag{2}$$

which has an intuitive interpretation. The first two terms represent the difference in expected counts for term i under the variational distributions $q(z, r)$ and $q(z, r, \beta)$: this difference goes to zero when $\beta_{jk}^{(i)}$ perfectly matches $N(i, j, k)/N(j, k)$. The third term penalizes $\eta_{jk}^{(i)}$ for deviating from its prior $\mu_k^{(i)}$, but this penalty is proportional to the expected inverse variance $\langle \sigma_k^{-2} \rangle$. We apply gradient ascent to maximize the objective L. A similar set of calculations gives the gradient for the variance of $\boldsymbol{\eta}$; these are described in an forthcoming appendix.

[7] Thanks to the naïve mean field assumption, we can marginalize over $\boldsymbol{z}$ by first decomposing across all N_d words and then summing over $q(z)$.

4.2 Base Topics

The base topic parameters are $\boldsymbol{\mu}_k$ and σ_k^2; in the variational distribution, $q(\boldsymbol{\mu}_k)$ is normally distributed and $q(\sigma_k^2)$ is Gamma distributed. Note that $\boldsymbol{\mu}_k$ and σ_k^2 affect only the regional word distributions $\boldsymbol{\eta}_{jk}$. An advantage of the logistic normal is that the variational parameters over $\boldsymbol{\mu}_k$ are available in closed form,

$$\langle \mu_k^{(i)} \rangle = \frac{b^2 \sum_j^J \langle \eta_{jk}^{(i)} \rangle + \langle \sigma_k^2 \rangle a^{(i)}}{b^2 J + \langle \sigma_k^2 \rangle}$$
$$\mathcal{V}(\boldsymbol{\mu}_k) = (b^{-2} + J \langle \sigma_k^{-2} \rangle)^{-1},$$

where J indicates the number of regions. The expectation of the base topic μ incorporates the prior and the average of the generated region-topics—these two components are weighted respectively by the expected variance of the region-topics $\langle \sigma_k^2 \rangle$ and the prior topical variance b^2. The posterior variance $\mathcal{V}(\boldsymbol{\mu})$ is a harmonic combination of the prior variance b^2 and the expected variance of the region topics.

The variational distribution over the region-topic variance σ_k^2 has Gamma parameters. These parameters cannot be updated in closed form, so gradient optimization is again required. The derivation of these updates is more involved, and is left for a forthcoming appendix.

5 Implementation

Variational scheduling and initialization are important aspects of any hierarchical generative model, and are often under-discussed. In our implementation, the variational updates are scheduled as follows: given expected counts, we iteratively update the variational parameters on the region-topics $\boldsymbol{\eta}$ and the base topics $\boldsymbol{\mu}$, until convergence. We then update the geographical parameters $\boldsymbol{\nu}$ and Λ, as well as the distribution over regions $\boldsymbol{\vartheta}$. Finally, for each document we iteratively update the variational parameters over $\boldsymbol{\theta}, \boldsymbol{z}$, and r until convergence, obtaining expected counts that are used in the next iteration of updates for the topics and their regional variants. We iterate an outer loop over the entire set of updates until convergence.

We initialize the model in a piecewise fashion. First we train a Dirichlet process mixture model on the locations $\boldsymbol{y}$, using variational inference on the truncated stick-breaking approximation (Blei and Jordan, 2006). This automatically selects the number of regions J, and gives a distribution over each region indicator r_d from geographical information alone. We then run standard latent Dirichlet allocation to obtain estimates of $\boldsymbol{z}$ for each token (ignoring the locations). From this initialization we can compute the first set of expected counts, which are used to obtain initial estimates of all parameters needed to begin variational inference in the full model.

The prior $\boldsymbol{a}$ is the expected mean of each topic $\boldsymbol{\mu}$; for each term i, we set $a^{(i)} = \log N(i) - \log N$, where $N(i)$ is the total count of i in the corpus and $N = \sum_i N(i)$. The variance prior b^2 is set to 1, and the prior on σ^2 is the Gamma distribution $\mathcal{G}(2, 200)$, encouraging minimal deviation from the base topics. The symmetric Dirichlet prior on $\boldsymbol{\theta}$ is set to $\frac{1}{2}$, and the symmetric Dirichlet parameter on ϑ is updated from weak hyperpriors (Minka, 2003). Finally, the geographical model takes priors that are linked to the data: for each region, the mean is very weakly encouraged to be near the overall mean, and the covariance prior is set by the average covariance of clusters obtained by running K-means.

6 Evaluation

For a quantitative evaluation of the estimated relationship between text and geography, we assess our model's ability to predict the geographic location of unlabeled authors based on their text alone.[8] This task may also be practically relevant as a step toward applications for recommending local businesses or social connections. A randomly-chosen 60% of authors are used for training, 20% for development, and the remaining 20% for final evaluation.

6.1 Systems

We compare several approaches for predicting author location; we divide these into latent variable generative models and discriminative approaches.

[8] Alternatively, one might evaluate the attributed regional memberships of the words themselves. While the Dictionary of American Regional English (Cassidy and Hall, 1985) attempts a comprehensive list of all regionally-affiliated terms, it is based on interviews conducted from 1965-1970, and the final volume (covering Si–Z) is not yet complete.

6.1.1 Latent Variable Models

Geographic Topic Model This is the full version of our system, as described in this paper. To predict the unseen location $\boldsymbol{y}_d$, we iterate until convergence on the variational updates for the hidden topics $\boldsymbol{z}_d$, the topic proportions $\boldsymbol{\theta}_d$, and the region r_d. From r_d, the location can be estimated as $\hat{\boldsymbol{y}}_d = \arg\max_{\boldsymbol{y}} \sum_j^J p(\boldsymbol{y}|\boldsymbol{\nu}_j, \Lambda_j) q(r_d = j)$. The development set is used to tune the number of topics and to select the best of multiple random initializations.

Mixture of Unigrams A core premise of our approach is that modeling topical variation will improve our ability to understand geographical variation. We test this idea by fixing $K = 1$, running our system with only a single topic. This is equivalent to a Bayesian mixture of unigrams in which each author is assigned a single, regional unigram language model that generates all of his or her text. The development set is used to select the best of multiple random initializations.

Supervised Latent Dirichlet Allocation In a more subtle version of the mixture-of-unigrams model, we model each author as an admixture of regions. Thus, the latent variable attached to each author is no longer an index, but rather a vector on the simplex. This model is equivalent to supervised latent Dirichlet allocation (Blei and McAuliffe, 2007): each topic is associated with equivariant Gaussian distributions over the latitude and longitude, and these topics must explain both the text and the observed geographical locations. For unlabeled authors, we estimate latitude and longitude by estimating the topic proportions and then applying the learned geographical distributions. This is a linear prediction

$$f(\bar{\boldsymbol{z}}_d; \boldsymbol{a}) = (\bar{\boldsymbol{z}}_d^{\mathsf{T}} \boldsymbol{a}^{\text{lat}},\ \bar{\boldsymbol{z}}_d^{\mathsf{T}} \boldsymbol{a}^{\text{lon}})$$

for an author's topic proportions $\bar{\boldsymbol{z}}_d$ and topic-geography weights $\boldsymbol{a} \in \mathbb{R}^{2K}$.

6.1.2 Baseline Approaches

Text Regression We perform linear regression to discriminatively learn the relationship between words and locations. Using term frequency features $\boldsymbol{x}_d$ for each author, we predict locations with word-geography weights $\boldsymbol{a} \in \mathbb{R}^{2W}$:

$$f(\boldsymbol{x}_d; \boldsymbol{a}) = (\boldsymbol{x}_d^{\mathsf{T}} \boldsymbol{a}^{\text{lat}},\ \boldsymbol{x}_d^{\mathsf{T}} \boldsymbol{a}^{\text{lon}})$$

Weights are trained to minimize the sum of squared Euclidean distances, subject to L_1 regularization:

$$\sum_d (\boldsymbol{x}_d^{\mathsf{T}} \boldsymbol{a}^{\text{lat}} - y_d^{\text{lat}})^2 + (\boldsymbol{x}_d^{\mathsf{T}} \boldsymbol{a}^{\text{lon}} - y_d^{\text{lon}})^2$$
$$+ \lambda_{\text{lat}} ||\boldsymbol{a}^{\text{lat}}||_1 + \lambda_{\text{lon}} ||\boldsymbol{a}^{\text{lon}}||_1$$

The minimization problem decouples into two separate latitude and longitude models, which we fit using the `glmnet` elastic net regularized regression package (Friedman et al., 2010), which obtained good results on other text-based prediction tasks (Joshi et al., 2010). Regularization parameters were tuned on the development set. The L_1 penalty outperformed L_2 and mixtures of L_1 and L_2.

Note that for both word-level linear regression here, and the topic-level linear regression in SLDA, the choice of squared Euclidean distance dovetails with our use of spatial Gaussian likelihoods in the geographic topic models, since optimizing $\boldsymbol{a}$ is equivalent to maximum likelihood estimation under the assumption that locations are drawn from equivariant circular Gaussians centered around each $f(\boldsymbol{x}_d; \boldsymbol{a})$ linear prediction. We experimented with decorrelating the location dimensions by projecting $\boldsymbol{y}_d$ into the principal component space, but this did not help text regression.

***K*-Nearest Neighbors** Linear regression is a poor model for the multimodal density of human populations. As an alternative baseline, we applied supervised K-nearest neighbors to predict the location $\boldsymbol{y}_d$ as the average of the positions of the K most similar authors in the training set. We computed term-frequency inverse-document frequency features and applied cosine similarity over their first 30 principal components to find the neighbors. The choices of principal components, IDF weighting, and neighborhood size $K = 20$ were tuned on the development set.

6.2 Metrics

Our principle error metrics are the mean and median distance between the predicted and true location in kilometers.[9] Because the distance error may be difficult to interpret, we also report accuracy of classi-

[9] For convenience, model training and prediction use latitude and longitude as an unprojected 2D Euclidean space. However, properly measuring the physical distance between points on the

System	Regression		Classification accuracy (%)	
	Mean Dist. (km)	Median Dist. (km)	Region (4-way)	State (49-way)
Geographic topic model	**900**	**494**	**58**	24
Mixture of unigrams	947	644	53	19
Supervised LDA	1055	728	39	4
Text regression	948	712	41	4
K-nearest neighbors	1077	853	37	2
Mean location	1148	1018		
Most common class			37	**27**

Table 1: Location prediction results; lower scores are better on the regression task, higher scores are better on the classification task. Distances are in kilometers. Mean location and most common class are computed from the test set. Both the geographic topic model and supervised LDA use the best number of topics from the development set (10 and 5, respectively).

fication by state and by region of the United States. Our data includes the 48 contiguous states plus the District of Columbia; the U.S. Census Bureau divides these states into four regions: West, Midwest, Northeast, and South.[10] Note that while major population centers straddle several state lines, most region boundaries are far from the largest cities, resulting in a clearer analysis.

6.3 Results

As shown in Table 1, the geographic topic model achieves the strongest performance on all metrics. All differences in performance between systems are statistically significant ($p < .01$) using the Wilcoxon-Mann-Whitney test for regression error and the χ^2 test for classification accuracy. Figure 2 shows how performance changes as the number of topics varies.

Note that the geographic topic model and the mixture of unigrams use identical code and parametrization – the only difference is that the geographic topic model accounts for topical variation, while the mixture of unigrams sets $K = 1$. These results validate our basic premise that it is important to model the interaction between topical and geographical variation.

Text regression and supervised LDA perform especially poorly on the classification metric. Both methods make predictions that are averaged across each word in the document: in text regression, each word is directly multiplied by a feature weight; in supervised LDA the word is associated with a latent topic first, and then multiplied by a weight. For these models, all words exert an influence on the predicted location, so uninformative words will draw the prediction towards the center of the map. This yields reasonable distance errors but poor classification accuracy. We had hoped that K-nearest neighbors would be a better fit for this metric, but its performance is poor at all values of K. Of course it is always possible to optimize classification accuracy directly, but such an approach would be incapable of predicting the exact geographical location, which is the focus of our evaluation (given that the desired geographical partition is unknown). Note that the geographic topic model is also not trained to optimize classification accuracy.

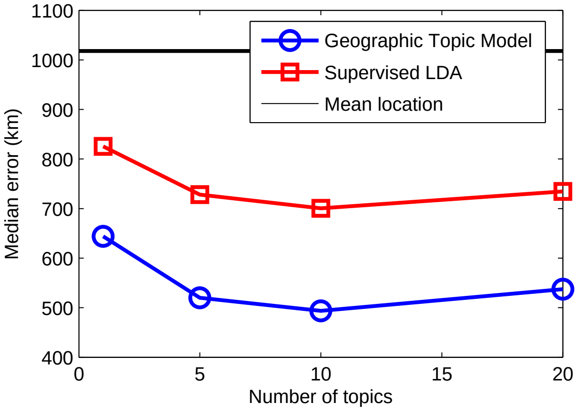


Figure 2: The effect of varying the number of topics on the median regression error (lower is better).

Earth's surface requires computing or approximating the great circle distance – we use the Haversine formula (Sinnott, 1984). For the continental U.S., the relationship between degrees and kilometers is nearly linear, but extending the model to a continental scale would require a more sophisticated approach.

Table 2: Example base topics (top line) and regional variants. For the base topics, terms are ranked by log-odds compared to the background distribution. The regional variants show words that are strong compared to both the base topic and the background. Foreign-language words are shown in *italics*, while terms that are usually in proper nouns are shown in SMALL CAPS. See Table 3 for definitions of slang terms; see Section 7 for more explanation and details on the methodology.

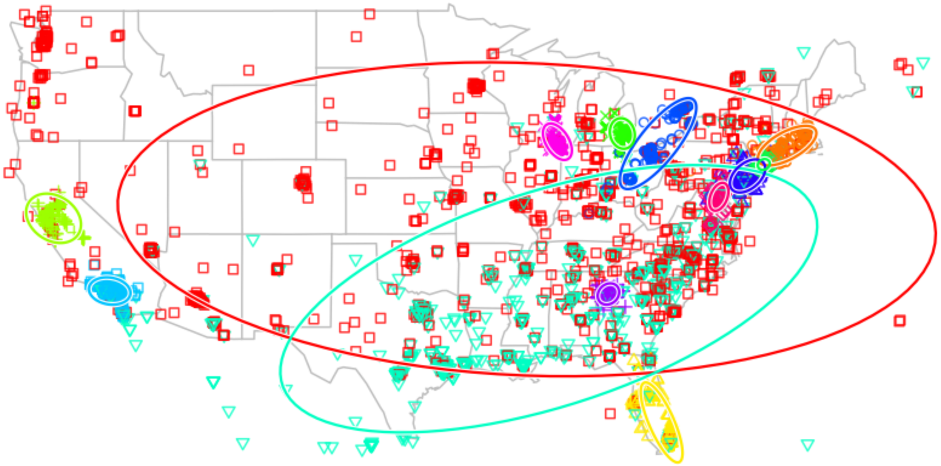

Figure 3: Regional clustering of the training set obtained by one randomly-initialized run of the geographical topic model. Each point represents one author, and each shape/color combination represents the most likely cluster assignment. Ellipses represent the regions' spatial means and covariances. The same model and coloring are shown in Table 2.

7 Analysis

Our model permits analysis of geographical variation in the context of topics that help to clarify the significance of geographically-salient terms. Table 2 shows a subset of the results of one randomly-initialized run, including five hand-chosen topics (of 50 total) and five regions (of 13, as chosen automatically during initialization). Terms were selected by log-odds comparison. For the base topics we show the ten strongest terms in each topic as compared to the background word distribution. For the regional variants, we show terms that are strong both regionally and topically: specifically, we select terms that are in the top 100 compared to both the background distribution and to the base topic. The names for the topics and regions were chosen by the authors.

Nearly all of the terms in column 1 ("**basketball**") refer to sports teams, athletes, and place names—encouragingly, terms tend to appear in the regions where their referents reside. Column 2 contains several proper nouns, mostly referring to popular music figures (including PEARL from the band Pearl Jam).[11] Columns 3–5 are more conversational. Spanish-language terms (*papi, pues, nada, ese*) tend to appear in regions with large Spanish-speaking populations—it is also telling that these terms appear in topics with emoticons and slang abbreviations, which may transcend linguistic barriers. Other terms refer to people or subjects that may be especially relevant in certain regions: *tacos* appears in the southern California region and *cab* in the New York region; TUPAC refers to a rap musician from Los Angeles, and WIZ refers to a rap musician from Pittsburgh, not far from the center of the "Lake Erie" region.

A large number of slang terms are found to have strong regional biases, suggesting that slang may depend on geography more than standard English does. The terms *af* and *hella* display especially strong regional affinities, appearing in the regional variants of multiple topics (see Table 3 for definitions). Northern and Southern California use variant spellings *koo* and *coo* to express the same meaning.

term	definition	term	definition
af	as fuck (very)	jk	just kidding

iam	I am	omw	on my way
ima	I'm going to	smh	shake my head
imm	I'm	suttin	something
iono	I don't know	wassup	what's up
lames	lame (not cool) people	wyd	what are you doing?

Table 3: A glossary of non-standard terms from Table 2. Definitions are obtained by manually inspecting the context in which the terms appear, and by consulting `www.urbandictionary.com`.

While research in perceptual dialectology does confirm the link of *hella* to Northern California (Bucholtz et al., 2007), we caution that our findings are merely suggestive, and a more rigorous analysis must be undertaken before making definitive statements about the regional membership of individual terms. We view the geographic topic model as an exploratory tool that may be used to facilitate such investigations.

Figure 3 shows the regional clustering on the training set obtained by one run of the model. Each point represents an author, and the ellipses represent the bivariate Gaussians for each region. There are nine compact regions for major metropolitan areas, two slightly larger regions that encompass Florida and the area around Lake Erie, and two large regions that partition the country roughly into north and south.

8 Related Work

The relationship between language and geography has been a topic of interest to linguists since the nineteenth century (Johnstone, 2010). An early work of particular relevance is Kurath's *Word Geography of the Eastern United States* (1949), in which he conducted interviews and then mapped the occurrence of equivalent word pairs such as *stoop* and *porch*. The essence of this approach—identifying variable pairs and measuring their frequencies—remains a dominant methodology in both dialec-

[11] This analysis is from an earlier version of our dataset that contained some Twitterbots, including one from a Boston-area radio station. The bots were purged for the evaluation in Section 6, though the numerical results are nearly identical.

tology (Labov et al., 2006) and sociolinguistics (Tagliamonte, 2006). Within this paradigm, computational techniques are often applied to post hoc analysis: logistic regression (Sankoff et al., 2005) and mixed-effects models (Johnson, 2009) are used to measure the contribution of individual variables, while hierarchical clustering and multidimensional scaling enable aggregated inference across multiple variables (Nerbonne, 2009). However, in all such work it is assumed that the relevant linguistic variables have already been identified—a time-consuming process involving considerable linguistic expertise. We view our work as complementary to this tradition: we work directly from raw text, identifying both the relevant features and coherent linguistic communities.

An active recent literature concerns geotagged information on the web, such as search queries (Backstrom et al., 2008) and tagged images (Crandall et al., 2009). This research identifies the geographic distribution of individual queries and tags, but does not attempt to induce any structural organization of either the text or geographical space, which is the focus of our research. More relevant is the work of Mei et al. (2006), in which the distribution over latent topics in blog posts is conditioned on the geographical location of the author. This is somewhat similar to the supervised LDA model that we consider, but their approach assumes that a partitioning of geographical space into regions is already given.

Methodologically, our cascading topic model is designed to capture multiple dimensions of variability: topics and geography. Mei et al. (2007) include sentiment as a second dimension in a topic model, using a switching variable so that individual word tokens may be selected from either the topic or the sentiment. However, our hypothesis is that individual word tokens reflect both the topic and the geographical aspect. Sharing this intuition, Paul and Girju (2010) build topic-aspect models for the cross product of topics and aspects. They do not impose any regularity across multiple aspects of the same topic, so this approach may not scale when the number of aspects is large (they consider only two aspects). We address this issue using cascading distributions; when the observed data for a given region-topic pair is low, the model falls back to the base topic. The use of cascading logistic normal distributions in topic models follows earlier work on dynamic topic models (Blei and Lafferty, 2006b; Xing, 2005).

9 Conclusion

This paper presents a model that jointly identifies words with high regional affinity, geographically-coherent linguistic regions, and the relationship between regional and topic variation. The key modeling assumption is that regions and topics interact to shape observed lexical frequencies. We validate this assumption on a prediction task in which our model outperforms strong alternatives that do not distinguish regional and topical variation.

We see this work as a first step towards a unsupervised methodology for modeling linguistic variation using raw text. Indeed, in a study of morphosyntactic variation, Szmrecsanyi (2010) finds that by the most generous measure, geographical factors account for only 33% of the observed variation. Our analysis might well improve if non-geographical factors were considered, including age, race, gender, income and whether a location is urban or rural. In some regions, estimates of many of these factors may be obtained by cross-referencing geography with demographic data. We hope to explore this possibility in future work.

Dual Decomposition for Parsing with Non-Projective Head Automata

Terry Koo Alexander M. Rush Michael Collins Tommi Jaakkola David Sontag

{maestro,srush,mcollins,tommi,dsontag}@csail.mit.edu

Abstract

This paper introduces algorithms for non-projective parsing based on *dual decomposition*. We focus on parsing algorithms for *non-projective head automata*, a generalization of head-automata models to non-projective structures. The dual decomposition algorithms are simple and efficient, relying on standard dynamic programming and minimum spanning tree algorithms. They provably solve an LP relaxation of the non-projective parsing problem. Empirically the LP relaxation is very often tight: for many languages, exact solutions are achieved on over 98% of test sentences. The accuracy of our models is higher than previous work on a broad range of datasets.

1 Introduction

Non-projective dependency parsing is useful for many languages that exhibit non-projective syntactic structures. Unfortunately, the non-projective parsing problem is known to be NP-hard for all but the simplest models (McDonald and Satta, 2007). There has been a long history in combinatorial optimization of methods that exploit structure in complex problems, using methods such as *dual decomposition* or *Lagrangian relaxation* (Lemaréchal, 2001). Thus far, however, these methods are not widely used in NLP.

This paper introduces algorithms for non-projective parsing based on dual decomposition. We focus on parsing algorithms for *non-projective head automata*, a generalization of the head-automata models of Eisner (2000) and Alshawi (1996) to non-projective structures. These models include non-projective dependency parsing models with higher-order (e.g., sibling and/or grandparent) dependency relations as a special case. Although decoding of full parse structures with non-projective head automata is intractable, we leverage the observation that key components of the decoding *can* be efficiently computed using combinatorial algorithms. In particular,

1. Decoding for individual head-words can be accomplished using dynamic programming.
2. Decoding for arc-factored models can be accomplished using directed minimum-weight spanning tree (MST) algorithms.

The resulting parsing algorithms have the following properties:

- They are efficient and easy to implement, relying on standard dynamic programming and MST algorithms.
- They provably solve a linear programming (LP) relaxation of the original decoding problem.
- Empirically the algorithms very often give an exact solution to the decoding problem, in which case they also provide a certificate of optimality.

In this paper we first give the definition for non-projective head automata, and describe the parsing algorithm. The algorithm can be viewed as an instance of Lagrangian relaxation; we describe this connection, and give convergence guarantees for the method. We describe a generalization to models that include grandparent dependencies. We then introduce a perceptron-driven training algorithm that makes use of point 1 above.

We describe experiments on non-projective parsing for a number of languages, and in particular compare the dual decomposition algorithm to approaches based on general-purpose linear programming (LP) or integer linear programming (ILP) solvers (Martins et al., 2009). The accuracy of our models is higher than previous work on a broad range of datasets. The method gives exact solutions to the decoding problem, together with a certificate of optimality, on over 98% of test examples for many of the test languages, with parsing times ranging between 0.021 seconds/sentence for the most simple languages/models, to 0.295 seconds/sentence for the

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1288–1298,
MIT, Massachusetts, USA, 9-11 October 2010.

most complex settings. The method compares favorably to previous work using LP/ILP formulations, both in terms of efficiency, and also in terms of the percentage of exact solutions returned.

While the focus of the current paper is on non-projective dependency parsing, the approach opens up new ways of thinking about parsing algorithms for lexicalized formalisms such as TAG (Joshi and Schabes, 1997), CCG (Steedman, 2000), and projective head automata.

2 Related Work

McDonald et al. (2005) describe MST-based parsing for non-projective dependency parsing models with arc-factored decompositions; McDonald and Pereira (2006) make use of an approximate (hill-climbing) algorithm for parsing with more complex models. McDonald and Pereira (2006) and McDonald and Satta (2007) describe complexity results for non-projective parsing, showing that parsing for a variety of models is NP-hard. Riedel and Clarke (2006) describe ILP methods for the problem; Martins et al. (2009) recently introduced alternative LP and ILP formulations. Our algorithm differs in that we do not use general-purpose LP or ILP solvers, instead using an MST solver in combination with dynamic programming; thus we leverage the underlying structure of the problem, thereby deriving more efficient decoding algorithms.

Both dual decomposition and Lagrangian relaxation have a long history in combinatorial optimization. Our work was originally inspired by recent work on dual decomposition for inference in graphical models (Wainwright et al., 2005; Komodakis et al., 2007). However, the non-projective parsing problem has a very different structure from these models, and the decomposition we use is very different in nature from those used in graphical models. Other work has made extensive use of decomposition approaches for efficiently solving LP relaxations for graphical models (e.g., Sontag et al. (2008)). Methods that incorporate combinatorial solvers within loopy belief propagation (LBP) (Duchi et al., 2007; Smith and Eisner, 2008) are also closely related to our approach. Unlike LBP, our method has strong theoretical guarantees, such as guaranteed convergence and the possibility of a certificate of optimality.

Finally, in other recent work, Rush et al. (2010) describe dual decomposition approaches for other NLP problems.

3 Sibling Models

This section describes a particular class of models, *sibling models*; the next section describes a dual-decomposition algorithm for decoding these models.

Consider the dependency parsing problem for a sentence with n words. We define the *index set* for dependency parsing to be $\mathcal{I} = \{(i,j) : i \in \{0 \dots n\}, j \in \{1 \dots n\}, i \neq j\}$. A dependency parse is a vector $y = \{y(i,j) : (i,j) \in \mathcal{I}\}$, where $y(i,j) = 1$ if a dependency with head word i and modifier j is in the parse, 0 otherwise. We use $i = 0$ for the root symbol. We define $\mathcal{Y}$ to be the set of all well-formed non-projective dependency parses (i.e., the set of directed spanning trees rooted at node 0). Given a function $f : \mathcal{Y} \mapsto \mathbb{R}$ that assigns scores to parse trees, the optimal parse is

$$y^* = \operatorname*{argmax}_{y \in \mathcal{Y}} f(y) \qquad (1)$$

A particularly simple definition of $f(y)$ is $f(y) = \sum_{(i,j) \in \mathcal{I}} y(i,j)\theta(i,j)$ where $\theta(i,j)$ is the score for dependency (i,j). Models with this form are often referred to as *arc-factored models*. In this case the optimal parse tree y^* can be found efficiently using MST algorithms (McDonald et al., 2005).

This paper describes algorithms that compute y^* for more complex definitions of $f(y)$; in this section, we focus on algorithms for models that capture interactions between sibling dependencies. To this end, we will find it convenient to define the following notation. Given a vector y, define

$$y_{|i} = \{y(i,j) : j = 1 \dots n, j \neq i\}$$

Hence $y_{|i}$ specifies the set of modifiers to word i; note that the vectors $y_{|i}$ for $i = 0 \dots n$ form a partition of the full set of variables.

We then assume that $f(y)$ takes the form

$$f(y) = \sum_{i=0}^{n} f_i(y_{|i}) \qquad (2)$$

Thus $f(y)$ decomposes into a sum of terms, where each f_i considers modifiers to the i'th word alone.

In the general case, finding $y^* = \operatorname{argmax}_{y \in \mathcal{Y}} f(y)$ under this definition of $f(y)$ is an NP-hard problem. However for certain definitions of f_i, it is possible to efficiently compute $\operatorname{argmax}_{y_{|i} \in \mathcal{Z}_i} f_i(y_{|i})$ for any value of i, typically using dynamic programming. (Here we use $\mathcal{Z}_i$ to refer to the set of all possible values for $y_{|i}$: specifically, $\mathcal{Z}_0 = \{0,1\}^n$ and for $i \neq 0$, $\mathcal{Z}_i = \{0,1\}^{n-1}$.) In these cases we can efficiently compute

$$z^* = \operatorname*{argmax}_{z \in \mathcal{Z}} f(z) = \operatorname*{argmax}_{z \in \mathcal{Z}} \sum_i f_i(z_{|i}) \qquad (3)$$

where $\mathcal{Z} = \{z : z_{|i} \in \mathcal{Z}_i \quad \text{for } i = 0 \ldots n\}$ by simply computing $z^*_{|i} = \operatorname{argmax}_{z_{|i} \in \mathcal{Z}_i} f_i(z_{|i})$ for $i = 0 \ldots n$. Eq. 3 can be considered to be an approximation to Eq. 1, where we have replaced $\mathcal{Y}$ with $\mathcal{Z}$. We will make direct use of this approximation in the dual decomposition parsing algorithm. Note that $\mathcal{Y} \subseteq \mathcal{Z}$, and in all but trivial cases, $\mathcal{Y}$ is a strict subset of $\mathcal{Z}$. For example, a structure $z \in \mathcal{Z}$ could have $z(i,j) = z(j,i) = 1$ for some (i,j); it could contain longer cycles; or it could contain words that do not modify exactly one head. Nevertheless, with suitably powerful functions f_i—for example functions based on discriminative models—z^* may be a good approximation to y^*. Later we will see that dual decomposition can effectively use MST inference to rule out ill-formed structures.

We now give the main assumption underlying sibling models:

Assumption 1 (Sibling Decompositions) *A model $f(y)$ satisfies the sibling-decomposition assumption if: 1) $f(y) = \sum_{i=0}^{n} f_i(y_{|i})$ for some set of functions $f_0 \ldots f_n$. 2) For any $i \in \{0 \ldots n\}$, for any value of the variables $u(i,j) \in \mathbb{R}$ for $j = 1 \ldots n$, it is possible to compute*

$$\operatorname*{argmax}_{y_{|i} \in \mathcal{Z}_i} \left(f_i(y_{|i}) - \sum_j u(i,j) y(i,j) \right)$$

in polynomial time.

The second condition includes additional terms involving $u(i,j)$ variables that modify the scores of individual dependencies. These terms are benign for most definitions of f_i, in that they do not alter decoding complexity. They will be of direct use in the dual decomposition parsing algorithm.

Example 1: Bigram Sibling Models. Recall that $y_{|i}$ is a binary vector specifying which words are modifiers to the head-word i. Define $l_1 \ldots l_p$ to be the sequence of left modifiers to word i under $y_{|i}$, and $r_1 \ldots r_q$ to be the set of right modifiers (e.g., consider the case where $n = 5$, $i = 3$, and we have $y(3,1) = y(3,5) = 0$, and $y(3,2) = y(3,4) = 1$: in this case $p = 1$, $l_1 = 2$, and $q = 1$, $r_1 = 4$). In *bigram sibling models*, we have

$$f_i(y_{|i}) = \sum_{k=1}^{p+1} g_L(i, l_{k-1}, l_k) + \sum_{k=1}^{q+1} g_R(i, r_{k-1}, r_k)$$

where $l_0 = r_0 = \text{START}$ is the initial state, and $l_{p+1} = r_{q+1} = \text{END}$ is the end state. The functions g_L and g_R assign scores to bigram dependencies to the left and right of the head. Under this model calculating $\operatorname{argmax}_{y_{|i} \in \mathcal{Z}_i} \left(f_i(y_{|i}) - \sum_j u(i,j) y(i,j) \right)$ takes $O(n^2)$ time using dynamic programming, hence the model satisfies Assumption 1. □

Example 2: Head Automata Head-automata models constitute a second important model type that satisfy the sibling-decomposition assumption (bigram sibling models are a special case of head automata). These models make use of functions $g_R(i, s, s', r)$ where $s \in S, s' \in S$ are variables in a set of possible states S, and r is an index of a word in the sentence such that $i < r \leq n$. The function g_R returns a cost for taking word r as the next dependency, and transitioning from state s to s'. A similar function g_L is defined for left modifiers. We define

$$f_i(y_{|i}, s_0 \ldots s_q, t_0 \ldots t_p) =$$
$$\sum_{k=1}^{q} g_R(i, s_{k-1}, s_k, r_k) + \sum_{k=1}^{p} g_L(i, t_{k-1}, t_k, l_l)$$

to be the joint score for dependencies $y_{|i}$, and left and right state sequences $s_0 \ldots s_q$ and $t_0 \ldots t_p$. We specify that $s_0 = t_0 = \text{START}$ and $s_q = t_p = \text{END}$. In this case we define

$$f_i(y_{|i}) = \max_{s_0 \ldots s_q, t_0 \ldots t_p} f_i(y_{|i}, s_0 \ldots s_q, t_0 \ldots t_p)$$

and it follows that $\operatorname{argmax}_{y_{|i} \in \mathcal{Z}_i} f_i(y_{|i})$ can be computed in $O(n|S|^2)$ time using a variant of the Viterbi algorithm, hence the model satisfies the sibling-decomposition assumption. □

4 The Parsing Algorithm

We now describe the dual decomposition parsing algorithm for models that satisfy Assumption 1. Consider the following generalization of the decoding

```
Set $u^{(1)}(i,j) \leftarrow 0$ for all $(i,j) \in \mathcal{I}$
for $k = 1$ to $K$ do
    $y^{(k)} \leftarrow \operatorname*{argmax}_{y \in \mathcal{Y}} \sum_{(i,j) \in \mathcal{I}} \big(\gamma(i,j) + u^{(k)}(i,j)\big) y(i,j)$
    for $i \in \{0 \dots n\}$,
        $z^{(k)}_{|i} \leftarrow \operatorname*{argmax}_{z_{|i} \in \mathcal{Z}_i} \; (f_i(z_{|i}) - \sum_j u^{(k)}(i,j) z(i,j))$
    if $y^{(k)}(i,j) = z^{(k)}(i,j)$ for all $(i,j) \in \mathcal{I}$ then
        return $(y^{(k)}, z^{(k)})$
    for all $(i,j) \in \mathcal{I}$,
        $u^{(k+1)}(i,j) \leftarrow u^{(k)}(i,j) + \alpha_k (z^{(k)}(i,j) - y^{(k)}(i,j))$
return $(y^{(K)}, z^{(K)})$
```

Figure 1: The parsing algorithm for sibling decomposable models. $\alpha_k \geq 0$ for $k = 1 \dots K$ are step sizes, see Appendix A for details.

problem from Eq. 1, where $f(y) = \sum_i f_i(y_{|i})$, $h(y) = \sum_{(i,j) \in \mathcal{I}} \gamma(i,j) y(i,j)$, and $\gamma(i,j) \in \mathbb{R}$ for all (i,j):[1]

$$\operatorname*{argmax}_{z \in \mathcal{Z}, y \in \mathcal{Y}} \quad f(z) + h(y) \tag{4}$$

$$\text{such that} \quad z(i,j) = y(i,j) \text{ for all } (i,j) \in \mathcal{I} \tag{5}$$

Although the maximization w.r.t. z is taken over the set $\mathcal{Z}$, the constraints in Eq. 5 ensure that $z = y$ for some $y \in \mathcal{Y}$, and hence that $z \in \mathcal{Y}$.

Without the $z(i,j) = y(i,j)$ constraints, the objective would decompose into the separate maximizations $z^* = \operatorname{argmax}_{z \in \mathcal{Z}} f(z)$, and $y^* = \operatorname{argmax}_{y \in \mathcal{Y}} h(y)$, which can be easily solved using dynamic programming and MST, respectively. Thus, it is these constraints that complicate the optimization. Our approach gets around this difficulty by introducing new variables, $u(i,j)$, that serve to enforce agreement between the $y(i,j)$ and $z(i,j)$ variables. In the next section we will show that these $u(i,j)$ variables are actually Lagrange multipliers for the $z(i,j) = y(i,j)$ constraints.

Our parsing algorithm is shown in Figure 1. At each iteration k, the algorithm finds $y^{(k)} \in \mathcal{Y}$ using an MST algorithm, and $z^{(k)} \in \mathcal{Z}$ through separate decoding of the $(n+1)$ sibling models. The $u^{(k)}$ variables are updated if $y^{(k)}(i,j) \neq z^{(k)}(i,j)$ for some (i,j); these updates modify the objective functions for the two decoding steps, and intuitively encourage the $y^{(k)}$ and $z^{(k)}$ variables to be equal.

4.1 Lagrangian Relaxation

Recall that the main difficulty in solving Eq. 4 was the $z = y$ constraints. We deal with these constraints using *Lagrangian relaxation* (Lemaréchal, 2001). We first introduce Lagrange multipliers $u = \{u(i,j) : (i,j) \in \mathcal{I}\}$, and define the Lagrangian

$$\begin{aligned} L(u,y,z) \; &= \\ & f(z) + h(y) + \sum_{(i,j) \in \mathcal{I}} u(i,j) \Big(y(i,j) - z(i,j) \Big) \end{aligned} \tag{6}$$

If L^* is the optimal value of Eq. 4 subject to the constraints in Eq. 5, then for any value of u,

$$L^* = \max_{z \in \mathcal{Z}, y \in \mathcal{Y}, y = z} L(u,y,z) \tag{7}$$

This follows because if $y = z$, the right term in Eq. 6 is zero for any value of u. The dual objective $L(u)$ is obtained by omitting the $y = z$ constraint:

$$\begin{aligned} L(u) \; &= \; \max_{z \in \mathcal{Z}, y \in \mathcal{Y}} L(u,y,z) \\ &= \; \max_{z \in \mathcal{Z}} \Big(f(z) - \sum_{i,j} u(i,j) z(i,j) \Big) \\ & \quad + \max_{y \in \mathcal{Y}} \Big(h(y) + \sum_{i,j} u(i,j) y(i,j) \Big). \end{aligned}$$

Since $L(u)$ maximizes over a larger space (y may not equal z), we have that $L^* \leq L(u)$ (compare this to Eq. 7). The *dual problem*, which our algorithm optimizes, is to obtain the tightest such upper bound,

$$\text{(Dual problem)} \qquad \min_{u \in \mathbb{R}^{|\mathcal{I}|}} L(u). \tag{8}$$

The dual objective $L(u)$ is convex, but not differentiable. However, we can use a subgradient method to derive an algorithm that is similar to gradient descent, and which minimizes $L(u)$. A subgradient of a convex function $L(u)$ at u is a vector d_u such that for all $v \in \mathbb{R}^{|\mathcal{I}|}$, $L(v) \geq L(u) + d_u \cdot (v - u)$. By standard results,

$$d_{u^{(k)}} = y^{(k)} - z^{(k)}$$

is a subgradient for $L(u)$ at $u = u^{(k)}$, where $z^{(k)} = \operatorname{argmax}_{z \in \mathcal{Z}} f(z) - \sum_{i,j} u^{(k)}(i,j) z(i,j)$ and $y^{(k)} =$

[1] This is equivalent to Eq. 1 when $\gamma(i,j) = 0$ for all (i,j). In some cases, however, it is convenient to have a model with non-zero values for the γ variables; see the Appendix. Note that this definition of $h(y)$ allows $\operatorname{argmax}_{y \in \mathcal{Y}} h(y)$ to be calculated efficiently, using MST inference.

$\text{argmax}_{y \in \mathcal{Y}} h(y) + \sum_{i,j} u^{(k)}(i,j)y(i,j)$. Subgradient optimization methods are iterative algorithms with updates that are similar to gradient descent:

$$u^{(k+1)} = u^{(k)} - \alpha_k d_{u^{(k)}} = u^{(k)} - \alpha_k(y^{(k)} - z^{(k)}),$$

where α_k is a step size. It is easily verified that the algorithm in Figure 1 uses precisely these updates.

4.2 Formal Guarantees

With an appropriate choice of the step sizes α_k, the subgradient method can be shown to solve the dual problem, i.e.

$$\lim_{k \to \infty} L(u^{(k)}) = \min_u L(u).$$

See Korte and Vygen (2008), page 120, for details.

As mentioned before, the dual provides an upper bound on the optimum of the primal problem (Eq. 4),

$$\max_{z \in \mathcal{Z}, y \in \mathcal{Y}, y=z} f(z) + h(y) \leq \min_{u \in \mathbb{R}^{|\mathcal{I}|}} L(u). \quad (9)$$

However, we do not necessarily have strong duality—i.e., equality in the above equation—because the sets $\mathcal{Z}$ and $\mathcal{Y}$ are discrete sets. That said, for some functions $h(y)$ and $f(z)$ strong duality does hold, as stated in the following:

Theorem 1 *If for some $k \in \{1 \ldots K\}$ in the algorithm in Figure 1, $y^{(k)}(i,j) = z^{(k)}(i,j)$ for all $(i,j) \in \mathcal{I}$, then $(y^{(k)}, z^{(k)})$ is a solution to the maximization problem in Eq. 4.*

Proof. We have that $f(z^{(k)}) + h(y^{(k)}) = L(u^{(k)}, z^{(k)}, y^{(k)}) = L(u^{(k)})$, where the last equality is because $y^{(k)}$, $z^{(k)}$ are defined as the respective argmax's. Thus, the inequality in Eq. 9 is tight, and ($y^{(k)}$, $z^{(k)}$) and $u^{(k)}$ are primal and dual optimal. □

Although the algorithm is not guaranteed to satisfy $y^{(k)} = z^{(k)}$ for some k, by Theorem 1 if it does reach such a state, then we have the guarantee of an *exact* solution to Eq. 4, with the dual solution u providing a certificate of optimality. We show in the experiments that this occurs very frequently, in spite of the parsing problem being NP-hard.

It can be shown that Eq. 8 is the dual of an LP relaxation of the original problem. When the conditions of Theorem 1 are satisfied, it means that the LP relaxation is *tight* for this instance. For brevity we omit the details, except to note that when the LP relaxation is *not* tight, the optimal primal solution to the LP relaxation could be recovered by averaging methods (Nedić and Ozdaglar, 2009).

5 Grandparent Dependency Models

In this section we extend the approach to consider grandparent relations. In grandparent models each parse tree y is represented as a vector

$$y = \{y(i,j) : (i,j) \in \mathcal{I}\} \cup \{y_\uparrow(i,j) : (i,j) \in \mathcal{I}\}$$

where we have added a second set of duplicate variables, $y_\uparrow(i,j)$ for all $(i,j) \in \mathcal{I}$. The set of all valid parse trees is then defined as

$$\begin{aligned} \mathcal{Y} = \{y \ : \ & y(i,j) \text{ variables form a directed tree,} \\ & y_\uparrow(i,j) = y(i,j) \text{ for all } (i,j) \in \mathcal{I}\} \end{aligned}$$

We again partition the variables into $n+1$ subsets, $y_{|0} \ldots y_{|n}$, by (re)defining

$$\begin{aligned} y_{|i} \ = \ & \{y(i,j) : j = 1 \ldots n, j \neq i\} \\ & \cup \{y_\uparrow(k,i) : k = 0 \ldots n, k \neq i\} \end{aligned}$$

So as before $y_{|i}$ contains variables $y(i,j)$ which indicate which words modify the i'th word. In addition, $y_{|i}$ includes $y_\uparrow(k,i)$ variables that indicate the word that word i itself modifies.

The set of all possible values of $y_{|i}$ is now

$$\begin{aligned} \mathcal{Z}_i = \{y_{|i} : \ & y(i,j) \in \{0,1\} \text{ for } j = 1 \ldots n, j \neq i; \\ & y_\uparrow(k,i) \in \{0,1\} \text{ for } k = 0 \ldots n, k \neq i; \\ & \sum_k y_\uparrow(k,i) = 1\} \end{aligned}$$

Hence the $y(i,j)$ variables can take any values, but only one of the $y_\uparrow(k,i)$ variables can be equal to 1 (as only one word can be a parent of word i). As before, we define $\mathcal{Z} = \{y : y_{|i} \in \mathcal{Z}_i \text{ for } i = 0 \ldots n\}$.

We introduce the following assumption:

Assumption 2 (GS Decompositions)
A model $f(y)$ satisfies the grandparent/sibling-decomposition (GSD) assumption if: 1) $f(z) = \sum_{i=0}^n f_i(z_{|i})$ for some set of functions $f_0 \ldots f_n$. 2) For any $i \in \{0 \ldots n\}$, for any value of the variables $u(i,j) \in \mathbb{R}$ for $j = 1 \ldots n$, and $v(k,i) \in \mathbb{R}$ for $k = 0 \ldots n$, it is possible to compute

$$\underset{z_{|i} \in \mathcal{Z}_i}{\text{argmax}} (f_i(z_{|i}) - \sum_j u(i,j)z(i,j) - \sum_k v(k,i)z_\uparrow(k,i))$$

in polynomial time.

Again, it follows that we can approximate $y^* = \text{argmax}_{y\in\mathcal{Y}} \sum_{i=0}^{n} f_i(y_{|i})$ by $z^* = \text{argmax}_{z\in\mathcal{Z}} \sum_{i=0}^{n} f_i(z_{|i})$, by defining $z^*_{|i} = \text{argmax}_{z_{|i}\in\mathcal{Z}_i} f_i(z_{|i})$ for $i = 0\ldots n$. The resulting vector z^* may be deficient in two respects. First, the variables $z^*(i,j)$ may not form a well-formed directed spanning tree. Second, we may have $z^*_{\uparrow}(i,j) \neq z^*(i,j)$ for some values of (i,j).

Example 3: Grandparent/Sibling Models An important class of models that satisfy Assumption 2 are defined as follows. Again, for a vector $y_{|i}$ define $l_1 \ldots l_p$ to be the sequence of left modifiers to word i under $y_{|i}$, and $r_1 \ldots r_q$ to be the set of right modifiers. Define k^* to the value for k such that $y_{\uparrow}(k,i) = 1$. Then the model is defined as follows:

$$f_i(y_{|i}) = \sum_{j=1}^{p+1} g_L(i, k^*, l_{j-1}, l_j) + \sum_{j=1}^{q+1} g_R(i, k^*, r_{j-1}, r_j)$$

This is very similar to the bigram-sibling model, but with the modification that the g_L and g_R functions depend in addition on the value for k^*. This allows these functions to model grandparent dependencies such as (k^*, i, l_j) and sibling dependencies such as (i, l_{j-1}, l_j). Finding $z^*_{|i}$ under the definition can be accomplished in $O(n^3)$ time, by decoding the model using dynamic programming separately for each of the $O(n)$ possible values of k^*, and picking the value for k^* that gives the maximum value under these decodings. □

A dual-decomposition algorithm for models that satisfy the GSD assumption is shown in Figure 2. The algorithm can be justified as an instance of Lagrangian relaxation applied to the problem

$$\underset{z\in\mathcal{Z}, y\in\mathcal{Y}}{\text{argmax}} \quad f(z) + h(y) \tag{10}$$

with constraints

$$z(i,j) = y(i,j) \;\text{ for all } (i,j) \in \mathcal{I} \tag{11}$$

$$z_{\uparrow}(i,j) = y(i,j) \;\text{ for all } (i,j) \in \mathcal{I} \tag{12}$$

The algorithm employs two sets of Lagrange multipliers, $u(i,j)$ and $v(i,j)$, corresponding to constraints in Eqs. 11 and 12. As in Theorem 1, if at any point in the algorithm $z^{(k)} = y^{(k)}$, then $(z^{(k)}, y^{(k)})$ is an exact solution to the problem in Eq. 10.

```
Set $u^{(1)}(i,j) \leftarrow 0$, $v^{(1)}(i,j) \leftarrow 0$ for all $(i,j) \in \mathcal{I}$
for $k = 1$ to $K$ do
    $y^{(k)} \leftarrow \text{argmax}_{y\in\mathcal{Y}} \sum_{(i,j)\in\mathcal{I}} y(i,j)\theta(i,j)$
    where $\theta(i,j) = \gamma(i,j) + u^{(k)}(i,j) + v^{(k)}(i,j)$.
    for $i \in \{0 \ldots n\}$,
        $z^{(k)}_{|i} \leftarrow \text{argmax}_{z_{|i}\in\mathcal{Z}_i} (f_i(z_{|i}) - \sum_j u^{(k)}(i,j)z(i,j)$
                                    $- \sum_j v^{(k)}(j,i)z_{\uparrow}(j,i))$
    if $y^{(k)}(i,j) = z^{(k)}(i,j) = z^{(k)}_{\uparrow}(i,j)$ for all $(i,j) \in \mathcal{I}$
    then
        return $(y^{(k)}, z^{(k)})$
    for all $(i,j) \in \mathcal{I}$,
        $u^{(k+1)}(i,j) \leftarrow u^{(k)}(i,j) + \alpha_k(z^{(k)}(i,j) - y^{(k)}(i,j))$
        $v^{(k+1)}(i,j) \leftarrow v^{(k)}(i,j) + \alpha_k(z^{(k)}_{\uparrow}(i,j) - y^{(k)}(i,j))$
return $(y^{(K)}, z^{(K)})$
```

Figure 2: The parsing algorithm for grandparent/sibling-decomposable models.

6 The Training Algorithm

In our experiments we make use of discriminative linear models, where for an input sentence x, the score for a parse y is $f(y) = w \cdot \phi(x,y)$ where $w \in \mathbb{R}^d$ is a parameter vector, and $\phi(x,y) \in \mathbb{R}^d$ is a feature-vector representing parse tree y in conjunction with sentence x. We will assume that the features decompose in the same way as the sibling-decomposable or grandparent/sibling-decomposable models, that is $\phi(x,y) = \sum_{i=0}^{n} \phi(x, y_{|i})$ for some feature vector definition $\phi(x, y_{|i})$. In the *bigram sibling* models in our experiments, we assume that

$$\phi(x, y_{|i}) = \sum_{k=1}^{p+1} \phi_L(x, i, l_{k-1}, l_k) + \sum_{k=1}^{q+1} \phi_R(x, i, r_{k-1}, r_k)$$

where as before $l_1 \ldots l_p$ and $r_1 \ldots r_q$ are left and right modifiers under $y_{|i}$, and where ϕ_L and ϕ_R are feature vector definitions. In the *grandparent models* in our experiments, we use a similar definition with feature vectors $\phi_L(x, i, k^*, l_{k-1}, l_k)$ and $\phi_R(x, i, k^*, r_{k-1}, r_k)$, where k^* is the parent for word i under $y_{|i}$.

We train the model using the averaged perceptron for structured problems (Collins, 2002). Given the i'th example in the training set, $(x^{(i)}, y^{(i)})$, the perceptron updates are as follows:

- $z^* = \text{argmax}_{y\in\mathcal{Z}}\, w \cdot \phi(x^{(i)}, y)$
- If $z^* \neq y^{(i)}$, $w = w + \phi(x^{(i)}, y^{(i)}) - \phi(x^{(i)}, z^*)$

The first step involves inference over the set $\mathcal{Z}$, rather than $\mathcal{Y}$ as would be standard in the perceptron. Thus, decoding during training can be achieved by dynamic programming over head automata alone, which is very efficient.

Our training approach is closely related to *local training methods* (Punyakanok et al., 2005). We have found this method to be effective, very likely because $\mathcal{Z}$ is a superset of $\mathcal{Y}$. Our training algorithm is also related to recent work on training using *outer bounds* (see, e.g., (Taskar et al., 2003; Finley and Joachims, 2008; Kulesza and Pereira, 2008; Martins et al., 2009)). Note, however, that the LP relaxation optimized by dual decomposition is significantly tighter than $\mathcal{Z}$. Thus, an alternative approach would be to use the dual decomposition algorithm for inference during training.

7 Experiments

We report results on a number of data sets. For comparison to Martins et al. (2009), we perform experiments for Danish, Dutch, Portuguese, Slovene, Swedish and Turkish data from the CoNLL-X shared task (Buchholz and Marsi, 2006), and English data from the CoNLL-2008 shared task (Surdeanu et al., 2008). We use the official training/test splits for these data sets, and the same evaluation methodology as Martins et al. (2009). For comparison to Smith and Eisner (2008), we also report results on Danish and Dutch using their alternate training/test split. Finally, we report results on the English WSJ treebank, and the Prague treebank. We use feature sets that are very similar to those described in Carreras (2007). We use marginal-based pruning, using marginals calculated from an arc-factored spanning tree model using the matrix-tree theorem (McDonald and Satta, 2007; Smith and Smith, 2007; Koo et al., 2007).

In all of our experiments we set the value K, the maximum number of iterations of dual decomposition in Figures 1 and 2, to be 5,000. If the algorithm does not terminate—i.e., it does not return $(y^{(k)}, z^{(k)})$ within 5,000 iterations—we simply take the parse $y^{(k)}$ with the maximum value of $f(y^{(k)})$ as the output from the algorithm. At first sight 5,000 might appear to be a large number, but decoding is still fast—see Sections 7.3 and 7.4 for discussion.[2] The strategy for choosing step sizes α_k is described in Appendix A, along with other details.

We first discuss performance in terms of *accuracy*, *success in recovering an exact solution*, and *parsing speed*. We then describe additional experiments examining various aspects of the algorithm.

7.1 Accuracy

Table 1 shows results for previous work on the various data sets, and results for an arc-factored model with pure MST decoding with our features. (We use the acronym UAS (unlabeled attachment score) for dependency accuracy.) We also show results for the bigram-sibling and grandparent/sibling (G+S) models under dual decomposition. Both the bigram-sibling and G+S models show large improvements over the arc-factored approach; they also compare favorably to previous work—for example the G+S model gives better results than all results reported in the CoNLL-X shared task, on all languages. Note that we use different feature sets from both Martins et al. (2009) and Smith and Eisner (2008).

7.2 Success in Recovering Exact Solutions

Next, we consider how often our algorithms return an exact solution to the original optimization problem, with a certificate—i.e., how often the algorithms in Figures 1 and 2 terminate with $y^{(k)} = z^{(k)}$ for some value of $k < 5000$ (and are thus optimal, by Theorem 1). The CertS and CertG columns in Table 1 give the results for the sibling and G+S models respectively. For all but one setting[3] over 95% of the test sentences are decoded exactly, with 99% exactness in many cases.

For comparison, we also ran both the single-commodity flow and multiple-commodity flow LP relaxations of Martins et al. (2009) with our models and features. We measure how often these relaxations terminate with an exact solution. The results in Table 2 show that our method gives exact solutions more often than both of these relaxations.[4] In computing the accuracy figures for Martins et al.

[2] Note also that the feature vectors ϕ and inner products $w \cdot \phi$ only need to be computed once, thus saving computation.

[3] The exception is Slovene, which has the smallest training set at only 1534 sentences.

[4] Note, however, that it is possible that the Martins et al. relaxations would have given a higher proportion of integral solutions if their relaxation was used during training.

Table 1: A comparison of non-projective automaton-based parsers with results from previous work. MST: Our first-order baseline. Sib/G+S: Non-projective head automata with sibling or grandparent/sibling interactions, decoded via dual decomposition. Ma09: The best UAS of the LP/ILP-based parsers introduced in Martins et al. (2009). Sm08: The best UAS of any LBP-based parser in Smith and Eisner (2008). Mc06: The best UAS reported by McDonald and Pereira (2006). Best: For the CoNLL-X languages only, the best UAS for any parser in the original shared task (Buchholz and Marsi, 2006) or in any column of Martins et al. (2009, Table 1); note that the latter includes McDonald and Pereira (2006), Nivre and McDonald (2008), and Martins et al. (2008). CertS/CertG: Percent of test examples for which dual decomposition produced a certificate of optimality, for Sib/G+S. TimeS/TimeG: Seconds/sentence for test decoding, for Sib/G+S. TrainS/TrainG: Seconds/sentence during training, for Sib/G+S. For consistency of timing, test decoding was carried out on identical machines with zero additional load; however, training was conducted on machines with varying hardware and load. We ran two tests on the CoNLL-08 corpus. Eng^1: UAS when testing on the CoNLL-08 validation set, following Martins et al. (2009). Eng^2: UAS when testing on the CoNLL-08 test set.

(2009), we project fractional solutions to a well-formed spanning tree, as described in that paper.

Finally, to better compare the tightness of our LP relaxation to that of earlier work, we consider randomly-generated instances. Table 2 gives results for our model and the LP relaxations of Martins et al. (2009) with randomly generated scores on automata transitions. We again recover exact solutions more often than the Martins et al. relaxations. Note that with random parameters the percentage of exact solutions is significantly lower, suggesting that the exactness of decoding of the trained models is a special case. We speculate that this is due to the high performance of approximate decoding with $\mathcal{Z}$ in place of $\mathcal{Y}$ under the trained models for f_i; the training algorithm described in section 6 may have the tendency to make the LP relaxation tight.

7.3 Speed

Table 1, columns TimeS and TimeG, shows decoding times for the dual decomposition algorithms. Table 2 gives speed comparisons to Martins et al. (2009). Our method gives significant speed-ups over the Martins et al. (2009) method, presumably because it leverages the underlying structure of the problem, rather than using a generic solver.

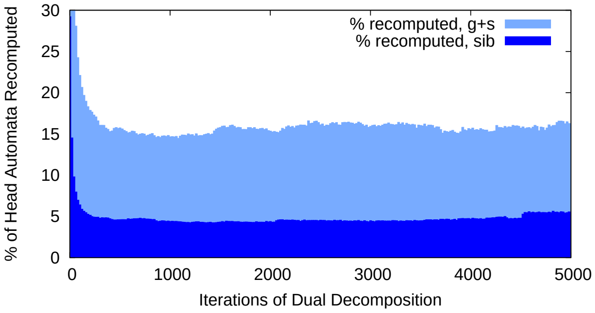

Figure 3: The average percentage of head automata that must be recomputed on each iteration of dual decomposition on the PTB validation set.

7.4 Lazy Decoding

Here we describe an important optimization in the dual decomposition algorithms. Consider the algorithm in Figure 1. At each iteration we must find

$$z_{|i}^{(k)} = \operatorname*{argmax}_{z_{|i} \in \mathcal{Z}_i} (f_i(z_{|i}) - \sum_j u^{(k)}(i,j) z(i,j))$$

DD-250	92.66	85.47	0.12	0.0

Table 2: A comparison of dual decomposition with linear programs described by Martins et al. (2009). LP(S): Linear Program relaxation based on single-commodity flow. LP(M): Linear Program relaxation based on multi-commodity flow. ILP: Exact Integer Linear Program. DD-5000/DD-250: Dual decomposition with non-projective head automata, with $K = 5000/250$. Upper results are for the sibling model, lower results are G+S. Columns give scores for UAS accuracy, percentage of solutions which are integral, and solution speed in seconds per sentence. These results are for Section 22 of the PTB. The last column is the percentage of integral solutions on a random problem of length 10 words. The (I)LP experiments were carried out using Gurobi, a high-performance commercial-grade solver.

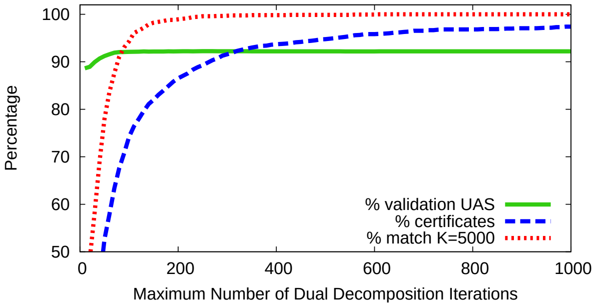

Figure 4: The behavior of the dual-decomposition parser with sibling automata as the value of K is varied.

	Sib	P-Sib	G+S	P-G+S
PTB	92.19	92.34	92.71	92.70
PDT	86.41	85.67	87.40	86.43

Table 3: UAS of projective and non-projective decoding for the English (PTB) and Czech (PDT) validation sets. Sib/G+S: as in Table 1. P-Sib/P-G+S: Projective versions of Sib/G+S, where the MST component has been replaced with the Eisner (2000) first-order projective parser.

for $i = 0 \ldots n$. However, if for some i, $u^{(k)}(i,j) = u^{(k-1)}(i,j)$ for all j, then $z^{(k)}_{|i} = z^{(k-1)}_{|i}$. In *lazy decoding* we immediately set $z^{(k)}_{|i} = z^{(k-1)}_{|i}$ if $u^{(k)}(i,j) = u^{(k-1)}(i,j)$ for all j; this check takes $O(n)$ time, and saves us from decoding with the i'th automaton. In practice, the updates to u are very sparse, and this condition occurs very often in practice. Figure 3 demonstrates the utility of this method for both sibling automata and G+S automata.

7.5 Early Stopping

We also ran experiments varying the value of K—the maximum number of iterations—in the dual decomposition algorithms. As before, if we do not find $y^{(k)} = z^{(k)}$ for some value of $k \leq K$, we choose the $y^{(k)}$ with optimal value for $f(y^{(k)})$ as the final solution. Figure 4 shows three graphs: 1) the accuracy of the parser on PTB validation data versus the value for K; 2) the percentage of examples where $y^{(k)} = z^{(k)}$ at some point during the algorithm, hence the algorithm returns a certificate of optimality; 3) the percentage of examples where the solution returned is the same as the solution for the algorithm with $K = 5000$ (our original setting). It can be seen for K as small as 250 we get very similar accuracy to $K = 5000$ (see Table 2). In fact, for this setting the algorithm returns the same solution as for $K = 5000$ on 99.59% of the examples. However only 89.29% of these solutions are produced with a certificate of optimality ($y^{(k)} = z^{(k)}$).

7.6 How Good is the Approximation z^*?

We ran experiments measuring the quality of $z^* = \text{argmax}_{z \in \mathcal{Z}} f(z)$, where $f(z)$ is given by the perceptron-trained bigram-sibling model. Because z^* may not be a well-formed tree with n dependencies, we report precision and recall rather than conventional dependency accuracy. Results on the PTB validation set were 91.11%/88.95% precision/recall, which is accurate considering the unconstrained nature of the predictions. Thus the z^* approximation is clearly a good one; we suspect that this is one reason for the good convergence results for the method.

7.7 Importance of Non-Projective Decoding

It is simple to adapt the dual-decomposition algorithms in figures 1 and 2 to give *projective* dependency structures: the set $\mathcal{Y}$ is redefined to be the set of all projective structures, with the $\arg\max$ over $\mathcal{Y}$ being calculated using a projective first-order parser (Eisner, 2000). Table 3 shows results for projective and non-projective parsing using the dual decomposition approach. For Czech data, where non-projective structures are common, non-projective decoding has clear benefits. In contrast, there is little difference in accuracy between projective and non-projective decoding on English.

8 Conclusions

We have described dual decomposition algorithms for non-projective parsing, which leverage existing dynamic programming and MST algorithms. There are a number of possible areas for future work. As described in section 7.7, the algorithms can be easily modified to consider projective structures by replacing $\mathcal{Y}$ with the set of projective trees, and then using first-order dependency parsing algorithms in place of MST decoding. This method could be used to derive parsing algorithms that include higher-order features, as an alternative to specialized dynamic programming algorithms. Eisner (2000) describes extensions of head automata to include word senses; we have not discussed this issue in the current paper, but it is simple to develop dual decomposition algorithms for this case, using similar methods to those used for the grandparent models. The general approach should be applicable to other lexicalized syntactic formalisms, and potentially also to decoding in syntax-driven translation. In addition, our dual decomposition approach is well-suited to parallelization. For example, each of the head-automata could be optimized independently in a multi-core or GPU architecture. Finally, our approach could be used with other structured learning algorithms, e.g. Meshi et al. (2010).

A Implementation Details

This appendix describes details of the algorithm, specifically choice of the step sizes α_k, and use of the $\gamma(i,j)$ parameters.

A.1 Choice of Step Sizes

We have found the following method to be effective. First, define $\delta = f(z^{(1)}) - f(y^{(1)})$, where $(z^{(1)}, y^{(1)})$ is the output of the algorithm on the first iteration (note that we always have $\delta \geq 0$ since $f(z^{(1)}) = L(u^{(1)})$). Then define $\alpha_k = \delta/(1 + \eta_k)$, where η_k is the number of times that $L(u^{(k')}) > L(u^{(k'-1)})$ for $k' \leq k$. Hence the learning rate drops at a rate of $1/(1+t)$, where t is the number of times that the dual increases from one iteration to the next.

A.2 Use of the $\gamma(i,j)$ Parameters

The parsing algorithms both consider a generalized problem that includes $\gamma(i,j)$ parameters. We now describe how these can be useful. Recall that the optimization problem is to solve $\mathrm{argmax}_{z\in\mathcal{Z},y\in\mathcal{Y}}\, f(z) + h(y)$, subject to a set of agreement constraints. In our models, $f(z)$ can be written as $f'(z) + \sum_{i,j} \alpha(i,j)z(i,j)$ where $f'(z)$ includes only terms depending on higher-order (non arc-factored features), and $\alpha(i,j)$ are weights that consider the dependency between i and j alone. For any value of $0 \leq \beta \leq 1$, the problem $\mathrm{argmax}_{z\in\mathcal{Z},y\in\mathcal{Y}}\, f_2(z) + h_2(y)$ is equivalent to the original problem, if $f_2(z) = f'(z) + (1-\beta)\sum_{i,j} \alpha(i,j)z(i,j)$ and $h_2(y) = \beta\sum_{i,j} \alpha(i,j)y(i,j)$. We have simply shifted the $\alpha(i,j)$ weights from one model to the other. While the optimization problem remains the same, the algorithms in Figure 1 and 2 will converge at different rates depending on the value for β. In our experiments we set $\beta = 0.001$, which puts almost all the weight in the head-automata models, but allows weights on spanning tree edges to break ties in MST inference in a sensible way. We suspect this is important in early iterations of the algorithm, when many values for $u(i,j)$ or $v(i,j)$ will be zero, and where with $\beta = 0$ many spanning tree solutions $y^{(k)}$ would be essentially random, leading to very noisy updates to the $u(i,j)$ and $v(i,j)$ values. We have not tested other values for β.
