Multi-document summarization using A* search and discriminative training

Ahmet Aker **Trevor Cohn** **Robert Gaizauskas**

Abstract

In this paper we address two key challenges for extractive multi-document summarization: the search problem of finding the best scoring summary and the training problem of learning the best model parameters. We propose an A* search algorithm to find the best extractive summary up to a given length, which is both optimal and efficient to run. Further, we propose a discriminative training algorithm which directly maximises the quality of the best summary, rather than assuming a sentence-level decomposition as in earlier work. Our approach leads to significantly better results than earlier techniques across a number of evaluation metrics.

1 Introduction

Multi-document summarization aims to present multiple documents in form of a short summary. This short summary can be used as a replacement for the original documents to reduce, for instance, the time a reader would spend if she were to read the original documents. Following dominant trends in summarization research (Mani, 2001), we focus solely on extractive summarization which simplifies the summarization task to the problem of identifying a subset of units from the document collection (here sentences) which are concatenated to form the summary.

Most multi-document summarization systems define a model which assigns a score to a candidate summary based on the features of the sentences included in the summary. The research challenges are then twofold: 1) the *search* problem of finding the best scoring summary for a given document set, and 2) the *training* problem of learning the model parameters to best describe a training set consisting of pairs of document sets with model or reference summaries – typically human authored extractive or abstractive summaries.

Search is typically performed by a greedy algorithm which selects each sentence in decreasing order of model score until the desired summary length is reached (see, e.g., Saggion (2005)) or using heuristic strategies based on position in document or lexical clues (Edmundson, 1969; Brandow et al., 1995; Hearst, 1997; Ouyang et al., 2010).[1] We show in this paper that the search problem can be solved optimally and efficiently using A* search (Russell et al., 1995). Assuming the model only uses features local to each sentence in the summary, our algorithm finds the best scoring extractive summary up to a given length in words.

Framing summarization as search suggests that many of the popular training techniques are maximising the wrong objective. These approaches train a classifier, regression or ranking model to distinguish between good and bad sentences under an evaluation metric, e.g., ROUGE (Lin, 2004). The model is then used during search to find a summary composed of high scoring ('good') *sentences* (see for a review Ouyang et al. (2010)). However, there is a disconnect between the model used for training and the model used for prediction. In this paper we present a solution to this disconnect in the form of a training algorithm that optimises the full prediction model directly with the search algorithm intact. The training algorithm learns parameters such that

[1] Genetic algorithms have also been devised for solving the search problem (see, e.g., Riedhammer et al. (2008)), however these approaches do not guarantee optimality, nor are they efficient enough to be practicable for large datasets.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 482–491,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

the best scoring *whole summary* under the model has a high score under the evaluation metric. We demonstrate that this leads to significantly better test performance than a competitive baseline, to the tune of 3% absolute increase for ROUGE-1, -2 and -SU4.

The paper is structured as follows. Section 2 presents the summarization model. Next in section 3 we present an A* search algorithm for finding the best scoring (argmax) summary under the model with a constraint on the maximum summary length. We show that this algorithm performs search efficiently, even for very large document sets composed of many sentences. The second contribution of the paper is a new training method which directly optimises the summarization system, and is presented in section 4. This uses the minimum error-rate training (MERT) technique from machine translation (Och, 2003) to optimise the summariser's output to an arbitrary evaluation metric. Section 5 describes our experimental setup and section 6 the results. Finally we conclude in section 7.

2 Summarization Model

Extractive multi-document summarization aims to find the most important sentences from a set of documents, which are then collated and presented to the user in form of a short summary. Following the predominant approach to data-driven summarisation, we define a linear model which scores summaries as the weighted sum of their features,

$$s(\mathbf{y}|\mathbf{x}) = \Phi(\mathbf{x}, \mathbf{y}) \cdot \lambda \quad , \tag{1}$$

where $\mathbf{x}$ is the document set, composed of k sentences, $\mathbf{y} \subseteq \{1 \dots k\}$ are the set of selected sentence indices, $\Phi(\cdot, \cdot)$ is a feature function which returns a vector of features for the candidate summary and λ are the model parameters. We further assume that the features decompose with the sentences in the summary, $\Phi(\mathbf{x}, \mathbf{y}) = \sum_{i \in \mathbf{y}} \phi(x_i)$, and therefore the scoring function also decomposes along the same lines,

$$s(\mathbf{y}|\mathbf{x}) = \sum_{i \in \mathbf{y}} \phi(x_i) \cdot \lambda \quad . \tag{2}$$

While this assumption greatly simplifies inference, it does constrain the representative power of the model by disallowing global features, e.g., those which measure duplication in the summary.[2] Under this model, the search problem is to solve

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} s(\mathbf{y}|\mathbf{x}) \quad , \tag{3}$$

for which we develop a best-first algorithm using A* search, as described in section 3. The training challenge is to find the parameters, λ, to best model the training set. This is achieved by finding λ such that $\hat{\mathbf{y}}$ is similar to the gold standard summary according to an automatic evaluation metric, as described in section 4.

3 A* Search

The prediction problem is to find the best scoring extractive summary (see Equation 3) up to a given length, L. At first glance, this appears to be a simple problem that might be solved efficiently with a greedy algorithm, say by taking the sentences in order of decreasing score and stopping just before the summary exceeds the length threshold. However, the greedy algorithm cannot be guaranteed to find the best summary; to do so requires arbitrary backtracking to revise previous incorrect decisions.

The problem of constructing the summary can be considered a search problem in which we start with an empty summary and incrementally enlarge the summary by concatenating a sentence from our document set. The search graph starts with an empty summary (the starting state) and each outgoing edge adds a sentence to produce a subsequent state, and is assigned a score under the model. A goal state is any state with no more words than the given threshold. The summarisation problem is then equivalent to finding the best scoring path (summed over the edge scores) between the start state and a goal state.

The novel insight in our work is to use A* search (Russell et al., 1995) to solve the prediction problem. A* is a best-first search algorithm which can efficiently find the best scoring path or the n-best paths (unlike the greedy algorithm which is not optimal, and the backtracking variant which is not efficient). The search procedure requires a scoring function for each state, here $s(\mathbf{y}|\mathbf{x})$ from (2), and

[2] Our approach could be adapted to support global features, which would require changes to the heuristic for A* search to bound the score obtainable from the global features. This may incur an additional computational cost over a purely local feature model and perhaps also necessitate using beam search.

a heuristic function which estimates the additional score to get from a given state to a goal state. For the search to be optimal – guaranteed to find the best scoring path as the first solution – the heuristic must be *admissible*, meaning that it bounds from above the score for reaching a goal state. We present three different admissible heuristics later in this section, which bound the score with differing tightness and consequently different search cost.

Algorithm 1 presents A* search for our extractive summarisation model. Given a set of sentences to summary, a scoring and a heuristic function, it finds the best scoring summary. This is achieved by building the search graph incrementally, and storing each frontier state in a priority queue (line 1) which is sorted by the sum of the state's score and its heuristic. These states are popped off the queue (line 3) and expanded by adding a sentence, which is then added to the schedule (lines 8–14). We designate special finishing states using a boolean variable (the last entry in the tuple in lines 1, 7 and 12). Finishing states (with value *T*) denote ceasing to expand the summary, and consequently their scores do not include the heuristic component. Whenever one of these states is popped in line 2, we know that it outscores all competing hypotheses and therefore represents the optimal summary (because the heuristic is guaranteed to never underestimate the cost to a goal state from an unfinished state).[3] Note that in algorithm 1 we create the summary by building a list of sentence indices in sorted order to avoid spurious ambiguity which would unnecessarily expand the search space. The function length$(\mathbf{y}, \mathbf{x}) = \sum_{n \in \mathbf{y}}$ length(x_n) returns the length of sentences specified.

We now return to the problem of defining the heuristic function, $h(\mathbf{y}; \mathbf{x}, l)$ which provides an upper bound on the additional score achievable in reaching a goal state from state $\mathbf{y}$. We present three different variants of increasing fidelity, that is, that bound the cost to a goal state more tightly. Algorithm 2 is the simplest, which simply finds the maximum score per word from the set of unused sentences and then extrapolates this out over the remaining words available to the length threshold. In the algorithm, we use the shorthand $s_n = \phi(x_n) \cdot \lambda$ for sentence n's score, $l_n =$ length(x_n) for its length and $l_{\mathbf{y}} = \sum_{n \in \mathbf{y}} l_n$ for the total length of the current state (unfinished summary).

Algorithm 1 A* search for extractive summarization.

```
Require: set of sentences, $\mathbf{x} = x_1, \ldots, x_k$
Require: scoring function $s(\cdot)$
Require: heuristic function $h(\cdot)$
Require: summary length limit $L$
 1: schedule = [$(0, \emptyset, \mathrm{F})$]          {priority queue of triples}
                        {(A* score, sentence indices, done flag)}
 2: while schedule $\neq$ [] do
 3:     $v, \mathbf{y}, f \leftarrow$ pop(schedule)
 4:     if f = T then
 5:         return $\mathbf{y}$                              {success}
 6:     else
 7:         push(schedule, $(s(\mathbf{y}|\mathbf{x}), \mathbf{y}, \mathrm{T})$)
 8:         for $y \leftarrow [\max(\mathbf{y}) + 1, k]$ do
 9:             $\mathbf{y}' \leftarrow \mathbf{y} \cup y$
10:             if length$(\mathbf{y}', \mathbf{x}) \leq L$ then
11:                 $v' \leftarrow s(\mathbf{y}'|\mathbf{x}) + h(\mathbf{y}'; \mathbf{x}, l)$
12:                 push(schedule, $(v', \mathbf{y}', \mathrm{F})$)
13:             end if
14:         end for
15:     end if
16: end while
```

Algorithm 2 Uniform heuristic, $h_1(\mathbf{y}; \mathbf{x}, L)$

```
Require: $\mathbf{x}$ sorted in order of score/length
$n \leftarrow \max(\mathbf{y}) + 1$
return $(L - l_{\mathbf{y}}) \max\left(\frac{s_n}{l_n}, 0\right)$
```

The h_1 heuristic is overly simple in that it assumes we can 'reuse' a high scoring short sentence many times despite this being disallowed by the model. For this reason we develop an improved bound, h_2, in Algorithm 3. This incrementally adds each sentence in order of its score-per-word until the length limit is reached. If the limit is to be exceeded, the heuristic scales down the final sentence's score based on the fraction of words than can be used to reach the limit.

The fractional usage of the final sentence in h_2 could be considered overly optimistic, especially when the state has length just shy of the limit L. If the next best ranked sentence is a long one, then it will be used in the heuristic to over-estimate of the state. This is complicated to correct, and doing so exactly would require full backtracking which is intractable and would obviate the entire point of using A* search. Instead we use a subtle modification in h_3 (Alg. 4) which is equivalent to h_2 except in the

[3] To improve the efficiency of Algorithm 1 we make a small modification to avoid expanding every possible edge in step 8, of which there are $O(k)$ options. Instead we expand a small number (here, 3) at a time and defer the remaining items until later by inserting a special node into the schedule. These special nodes are represented using a third 'to-be-continued' state into the done flag.

Algorithm 3 Aggregated heuristic, $h_2(\mathbf{y}; \mathbf{x}, L)$

```
Require: $\mathbf{x}$ sorted in order of score/length
$v \leftarrow 0$
$l' \leftarrow l_{\mathbf{y}}$
for $n \in [\max(\mathbf{y}) + 1, k]$ do
    if $s_n \leq 0$ then
        return v
    end if
    if $l' + l_n \leq L$ then
        $l' \leftarrow l' + l_n$
        $v \leftarrow v + s_n$
    else
        return $v + \frac{l_n}{L-l'} s_n$
    end if
end for
return $v$
```

instance where the next best score/word sentence is too long, where it skips over these sentences until it finds the best scoring sentence that does fit. This helps to address the overestimate of h_2 and should therefore lead to a smaller search graph and faster runtime due to its early elimination of dead-ends.

Algorithm 4 Agg.+final heuristic, $h_3(\mathbf{y}; \mathbf{x}, L)$

```
Require: $\mathbf{x}$ sorted in order of score/length
$n \leftarrow \max(\mathbf{y}) + 1$
if $n \leq k \wedge s_n > 0$ then
    if $l_{\mathbf{y}} + l_n \leq L$ then
        return $h_2(\mathbf{y}; \mathbf{x}, L)$
    else
        for $m \in [n + 1, k]$ do
            if $l_{\mathbf{y}} + l_m \leq L$ then
                return $s_m \frac{L-l_{\mathbf{y}}}{l_m}$
            end if
        end for
    end if
end if
return 0
```

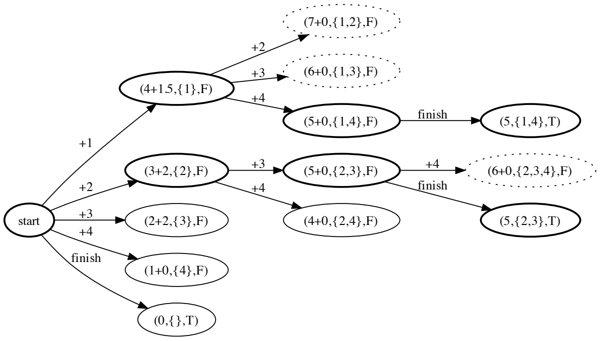

Figure 1: Example of the A* search graph created to find the two top scoring summaries of length ≤ 7 when summarising four sentences with scores of 4, 3, 2 and 1 respectively and lengths of 5, 4, 3 and 1 respectively. The h_1 heuristic was used and the score and heuristic scores are shown separately for clarity. Bold nodes were visited while dashed nodes were visited but found to exceed the length constraint.

The search process is illustrated in figure 1. When a node is visited in the search, if it satisfied the length constraint then the all its child nodes are added to the schedule. These nodes are scored with the score for the summary thus far plus a heuristic term. For example, the value of 4+1.5=5.5 for the $\{1\}$ node arises from a score of 4 plus a heuristic of $(7 - 5) \cdot \frac{3}{4} = 1.5$, reflecting the additional score that would arise if it were to use half of the next sentence to finish the summary. Note that in finding the best two summaries the search process did not need to instantiate the full search graph.

To test the efficacy of A* search with each of the different heuristic functions, we now present empirical runtime results. We used the training data as described in Section 5.2 and for each document set generated the 100-best summaries with word limit $L = 200$. Figure 2 shows the number of nodes and edges visited by A* search, reflecting the space and time cost of the algorithm, as a function of the number of sentences in the document set being summarised. All three heuristics shown an empirical increase in complexity that is roughly linear in the document size, although there are some notable outliers, particularly for the uniform heuristic. Surprisingly the aggregated heuristic, h_2, is not considerably more efficient than the uniform heuristic h_1, despite bounding the cost more precisely. However, the aggregated+final heuristic, h_3, consistently outperforms the other two methods. For this reason we have used h_3 in all subsequent experimentation.

4 Training

We frame the training problem as one of finding model parameters, λ, such that the predicted output, $\hat{\mathbf{y}}$ closely matches the gold standard, $\mathbf{r}$.[4] The quality of the match is measured using an automatic evaluation metric. We adopt the standard machine learning terminology of loss functions, which measure the degree of error in the prediction, $\Delta(\hat{\mathbf{y}}, \mathbf{r})$. In our case the accuracy is measured by the ROUGE

[4] The gold standard is typically an abstractive summary, and as such it is usually impossible for an extractive summarizer to match it exactly.

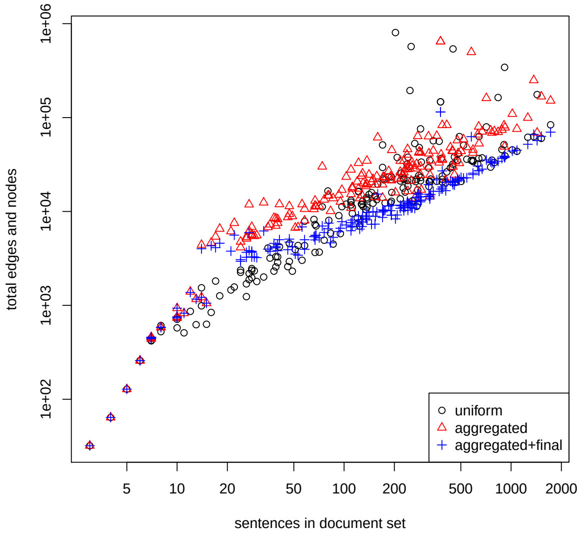

Figure 2: Efficiency of A* search search is roughly linear in the number of sentences in the document set. The y axis measures the search graph size in terms of the number of edges in the schedule and the number of nodes visited. Measured with the final parameters after training to optimise ROUGE-2 with the three different heuristics and expanding five nodes in each step.

score, R, and the loss is simply 1 - R. The training problem is to solve

$$\hat{\lambda} = \arg\min_{\lambda} \Delta(\hat{\mathbf{y}}, \mathbf{r}) \quad , \tag{4}$$

where with a slight abuse of notation, $\hat{\mathbf{y}}$ and $\mathbf{r}$ are taken to range over the corpus of many document-sets and summaries.

To optimise the weights we use the minimum error rate training (MERT) technique (Och, 2003), as used for training statistical machine translation systems. This approach is a first order optimization method using Powell search to find the parameters which minimise the loss on the training data. MERT requires n-best lists which it uses to approximate the full space of possible outcomes. We use the A* search algorithm to construct these n-best lists,[5] and use MERT to optimise the ROUGE score on the training set for the R-1, R-2 and R-SU4 variants of the metric.

5 Experimental settings

In this section we describe the features for which we learn weights. We also describe the input data used in training and testing.

5.1 Summarization system

The summarizer we use is an extractive, query-based multi-document summarization system. It is given two inputs: a query (place name) associated with an image and a set of documents. The summarizer uses the following features, as reported in previous work (Edmundson, 1969; Brandow et al., 1995; Radev et al., 2001; Conroy et al., 2005; Aker and Gaizauskas, 2009; Aker and Gaizauskas, 2010a):

- ***querySimilarity***: Sentence similarity to the query (cosine similarity over the vector representation of the sentence and the query).
- ***centroidSimilarity***: Sentence similarity to the centroid. The centroid is composed of the 100 most frequently occurring non stop words in the document collection (cosine similarity over the vector representation of the sentence and the centroid). For each word/term in the vector we store a value which is the product of the *term frequency* in the document and the *inverse document frequency*, a measurement of the term's distribution over the set of documents (Salton and Buckley, 1988).
- ***sentencePosition***: Position of the sentence within its document. The first sentence in the document gets the score 1 and the last one gets $\frac{1}{n}$ where n is the number of sentences in the document.
- ***inFirst5***: Binary feature indicating whether the sentence occurs is one of the first 5 sentences of the document.
- ***isStarter***: A sentence gets a binary score if it starts with the query term (e.g. *Westminster Abbey*, *The Westminster Abbey*, *The Westminster* or *The Abbey*) or with the object type, e.g. *The church*. We also allow gaps (up to four words) between *the* and the query/object type to capture cases such as *The most magnificent abbey*, etc.
- ***LMProb***: The probability of the sentence under a unigram language model. We trained a separate language model on Wikipedia articles about locations for each object type, e.g.,

[5] We used $n = 100$ in our experiments.

church, *bridge*, etc. When we generate a summary about a location of type church, for instance, then we apply the church language model on the related input documents related to the location.[6]
- ***sentenceCount***: Each sentence gets assigned a value of *1*. This feature is used to learn whether summaries with many sentences are better than summaries with few sentences or vice versa.
- ***wordCount***: Number of words in the summary, to decide whether the model should favor long summaries or short ones.

5.2 Data

For training and testing we use the freely available image description corpus described in Aker and Gaizauskas (2010b). The corpus is based around 289 images of static located objects (e.g *Eiffel Tower*, *Mont Blanc*) each with a manually assigned place name and object type category (e.g. *church*, *mountain*). For each place name there are up to four model summaries that were created manually after reading existing image descriptions taken from the *VirtualTourist* travel community web-site. Each summary contains a minimum of 190 and a maximum of 210 words. We divide this set of 289 place names into training and testing sets. Both sets are described in the following subsections.

Training We use 184 place names from the 289 set for training feature weights. For each training place name we gather all descriptions associated with it from *VirtualTourist*. We compute for each sentence in each description a ROUGE score by comparing the sentence to those included in the model summaries for that particular place name and retaining the highest score. Table 1 gives some details about this training data.

	Max	Min	Avg
Sentences/place	1724	3	260
Words/sentence	37	3	17

Table 1: The training input data contains 184 place names with 42333 sentences in total. The numbers in the columns give detail about the number of sentences for each place and the lengths of the sentences.

	Max	Min	Avg
Documents/place	20	5	12
Sentences/place	1716	15	132
Sentences/document	275	1	10
Words/sentence	211	1	20

Table 2: In domain test data. The numbers in the columns give detail about the number of documents (descriptions) for each place, number of sentences for each place and document (description) and the lengths of the sentences.

We use ROUGE as a metric to maximize because it is also used in DUC[7] and TAC.[8] However, it should be noted that any automatic metric could be used instead of ROUGE. In particular we use ROUGE 1 (R-1), ROUGE 2 (R-2) and ROUGE SU4 (R-SU4). R-1 and R-2 compute the number of uni-gram and bi-gram overlaps, respectively, between the automatic and model summaries. R-SU4 allows bi-grams to be composed of non-contiguous words, with a maximum of four words between the bi-grams.

Testing For testing purposes we use the rest of the place names (105) from the 289 place name set. For each place name we use a set of input documents, generate a summary from these documents using our summarizer and compare the results against model summaries of that place name using ROUGE. We experimented with two different input document types: out of domain and in domain.

The in domain documents are the VirtualTourist original image descriptions from which the model summaries were derived. As with the training set we take all place name descriptions for a particular place and use them as input documents to our summarizer. Table 2 summarizes these input documents.

The out of domain documents are retrieved from the web. Compared to the in domain documents these documents should more challenging to summarize because they will contain different kinds of documents to those seen in training. For each place name we retrieved the top ten related web-documents using the Yahoo! search engine with the place name as a query. The text from these documents is extracted using an HTML parser and passed to the summarizer. Table 3 gives an overview of this data.

[6] For our training and testing sets we manually assigned each location to its corresponding object type (Aker and Gaizauskas, 2009).

6 Results

To evaluate our approach we used two different assessment methods: ROUGE (Lin, 2004) and manual readability. In the following we present the results of each assessment.

6.1 Automatic Evaluation using ROUGE

We report results for training and testing. In both training and testing we distinguish between three different summaries: *wordLimit*, *sentenceLimit* and *regression*. *WordLimit* and *sentenceLimit* summaries are the ones generated using the model trained by MERT. As described in section 4 we trained the summariser using the A* search decoder to maximise the ROUGE score of the best scoring summaries. We used the heuristic function *h3* in A* search because it is the best performing heuristic, and 100-best lists. To experiment with different summary length conditions we differentiate between summaries with a word limit (*wordLimit*, set to 200 words) and summaries containing *N* number of sentences (*sentenceLimit*) as stop condition in A* search. We set *N* so that in both *wordLimit* and *sentenceLimit* summaries we obtain more or less the same number of words (because our training data contains on average 17 words for each word we set *N* to 12, 12*17=194). However, this is only the case in the training. In the testing for both *wordLimit* and *sentenceLimit* we generate summaries with the same word limit constraint which allows us to have a fair comparison between the ROUGE recall scores.

The *regression* summaries are our baseline. In these summaries the sentences are ranked based on the weighted features produced by Support Vector Regression (SVR).[9] Ouyang et al. (2010) use multi-document summarization and linear regression methods to rank sentences in the documents. As regression model they used SVR and showed that it out-performed classification and Learning To Rank methods on the DUC 2005 to 2007 data. For comparison purpose we use SVR as a baseline system for learning feature weights. It should be noted that these weights are learned based on single sentences. However, to have a fair comparison between all our summary types we use these weights to generate summaries using the A* search with the word limit as constraint. We do this for reporting both for training and testing results.

The results for training are shown in Table 4. The table shows ROUGE recall numbers obtained by comparing model summaries against automatically generated summaries on the training data. Because in training we used three different metrics (R-1, R-2, R-SU4) to train weights we report results for each of these three different ROUGE metrics.

In Table 4 we can see that the scores for *wordLimit* and *sentenceLimit* type summaries are always at maximum on the metric they were trained on (this can be observed by following the main diagonal of the result matrix). This confirms that MERT is maximizing the metric for which it was trained. However, this is not the case for regression results. The scores obtained with R-SU4 metric trained weights achieve higher scores on R-1 and R-2 compared to the scores obtained using weights trained on those metrics. This is most likely due to SVR being trained on sentences rather than over entire summaries, and thereby not adequately optimising the metric used for evaluation.

The results for testing are shown in Tables 5 and 6. As with the training setting we report ROUGE recall scores. We use the testing data described in section 5.2 for this setting. However, because we have two different input document sets we report separate results for each of these (Table 5 shows result for in domain data and Table 6 shows result for out

[9] We use the term *regression* to refer to SVR.

Type	metric	R-1	R-2	R-SU4
wordLimit	R-1	**0.3733**	**0.0842**	0.1399
	R-2	0.3731	**0.0842**	**0.1402**
	R-SU4	0.3627	0.0794	0.1340
sentenceLimit	R-1	0.3664	0.0774	0.1321
	R-2	0.3559	0.0717	0.1251
	R-SU4	0.3629	0.0778	0.1312
regression	R-1	0.3431	0.0669	0.1229
	R-2	0.2934	0.0560	0.1043
	R-SU4	0.3417	0.0668	0.1226

Table 5: ROUGE scores obtained on the testing data. The automated summaries are generated using the in domain input documents.

Type	metric	R-1	R-2	R-SU4
wordLimit	R-1	**0.3758**	0.0882	0.1421
	R-2	0.3755	**0.0895**	**0.1423**
	R-SU4	0.369	0.0812	0.137
sentenceLimit	R-1	0.3541	0.0693	0.1226
	R-2	0.3426	0.0638	0.1157
	R-SU4	0.3573	0.073	0.1251
regression	R-1	0.3392	0.0611	0.1179
	R-2	0.3422	0.0606	0.1164
	R-SU4	0.3413	0.0606	0.1176

Table 6: ROUGE scores obtained on the testing data. The automated summaries are generated using the out of domain input documents.

of domain data). Again as with the training setting we report results for the different metrics (R-1, R-2, R-SU4) separately.

From Table 5 we can see that the *wordLimit* summaries score highest compared to the other two types of summaries. This is different from the training results where *sentenceLimit* summary type summaries are the top scoring ones. As mentioned earlier the *sentenceLimit* summaries contain exactly 12 sentences, where on average each sentence in the training data has 17 words. We picked 12 sentences to achieve roughly the same word limit constraint ($12 \times 17 = 204$) so they can be compared to the *wordLimit* and *regression* type summaries. However, these *sentenceLimit* summaries have an average of 221 words, which explains the higher ROUGE recall scores seen in training compared to testing (where a 200 word limit was imposed).

The *wordLimit* summaries are significantly better than the scores from the other summary types irrespective of the evaluation metric.[10] It should be noted that these summaries are the only ones where the training and testing had the same condition in A* search concerning the summary word limit constraint. The scores in *sentenceLimit* type summaries are significantly lower than *wordLimit* summaries, despite using MERT to learn the weights. This shows that training the true model is critical for getting good accuracy. The *regression* type summaries achieved the worst ROUGE metric scores. The weights used to generate these summaries were trained on single sentences using SVR. These results indicate that if the goal is to generate high scoring summaries under a length limit in testing, then the same constraint should also be used in training.

From Table 5 and 6 we can see that the summaries obtained from VirtualTourist captions (in domain data) score roughly the same as the summaries generated using web-documents (out of domain data) as input. A possible explanation is that in many cases the VirtualTourist original captions contain text from Wikipedia articles, which are also returned as results from the web search. Therefore the web-document sets included similar content to the VirtualTourist captions.

6.2 Manual Evaluation

We also evaluated our summaries using a readability assessment as in DUC and TAC. DUC and TAC manually assess the quality of automatically generated summaries by asking human subjects to score each summary using five criteria – *grammaticality, redundancy, clarity, focus* and *coherence* criteria. Each criterion is scored on a five point scale with high scores indicating a better result (Dang, 2005).

For this evaluation we used the best scoring summaries from the *wordLimit* summary type (R-1, R-2 and R-SU4) generated using web-documents (out of domain documents) as input. We also evaluate the *regression* summary types generated using the same input documents to investigate the correlation between high and low ROUGE metric scores to manual evaluation ones. From the *regression* summary type we only use summaries under the *R2* and *RSU4* trained models.

In total we evaluated five different summary types (three from *wordLimit* and two from *regression*). For each type we randomly selected 30 place names and asked three people to assess the summaries for these place names. Each person was shown all 150

[10] Significance is reported at level $p < 0.001$. We used Wilcoxson signed ranked test to perform significance.

Criterion	wordLimit			regression	
	R1	R2	RSU4	R2	RSU4
clarity	4.03	3.92	3.99	3.00	2.92
coherence	3.31	3.06	2.99	2.12	1.88
focus	3.79	3.56	3.54	2.44	2.29
grammaticality	4.21	4.13	4.13	3.93	3.87
redundancy	4.19	4.33	4.41	4.47	4.44

Table 7: Manual evaluation results for the *wordLimit* (R1, R2, RSU4) and *regression* (R2, RSU4) summary types. The numbers in the columns are the average scores.

summaries (30 from each summary type) in a random way and was asked to assess them according to the DUC and TAC manual assessment scheme. The results are shown in Table 7.[11]

From Table 7 we can see that overall the *wordLimit* type summaries perform better than the *regression* ones. For each metric in *regression* summary types (R-2 and R-SU4) we compute the significance of the difference with the same metrics in *wordLimit* summary types.[12] The results for the *clarity*, *coherence* and *focus* criteria in *wordLimit* summaries are significantly better than in *regression* ones (p<0.001) irrespective of the training metric. These results concur with the automatic evaluation results as described in section 6.1. However, this is not the case for the *grammaticality* and *redundancy* criteria. Although in *regression* type summaries the scores for the *grammaticality* criterion are lower than those in *wordLimit* summaries the difference is not significant. Furthermore, we can see that the *redundancy* scores for *regression* summaries are slightly higher than those for *wordLimit* summaries.

One reason for these differences might be the way we trained feature weights for *wordLimit* and *regression* summaries. As mentioned above, feature weights for *wordLimit* summaries are trained using summaries with a specific word limit constraint, whereas the weights for the *regression* summaries are learned using single sentences. Maximizing the ROUGE metrics using "final or output like summaries" will lead to a higher content agreement between the training and the model summaries whereas this is not guaranteed with single sentences. With single sentences we have only a guarantee for high content overlap between single training and model sentences. However, when these sentences are combined into summaries it is not guaranteed that these summaries will also have high content overlap with the entire model ones. Therefore we believe if there is a high content agreement between the training and model summaries this could lead to more readable summaries. However, as we can see from Table 7 this hypothesis does not hold for all criteria. In case of the *redundancy* criterion we have compared to *wordLimit* summary type high scores in *regression* summaries although *wordLimit* summaries are significantly better than *regression* ones when it concerns the ROUGE scores. Thus it is likely that by aggressively optimising the ROUGE metric the model learns to game the metric, which does not penalise redundancy in the summaries. As such it may no longer possible to extrapolate trends from earlier correlation studies against human judgements (Lin, 2004).

To minimize redundancy in summaries it is necessary to also take into consideration global features addressing the linguistic aspects of the summaries. Furthermore, instead of ROUGE recall scores which do not take the repetition of information into consideration, ROUGE precision scores could be used as a metric in order to minimize the redundant content in the summaries.

7 Conclusion

In this paper we have proposed an A* search approach for generating a summary from a ranked list of sentences and learning feature weights for a feature based extractive multi-document summarization system. We developed an algorithm to learn optimize an arbitrary metric and showed that our approach significantly outperforms state of the art techniques. Furthermore, we highlighted the importance of uniformity in training and testing and argued that if the goal is to generate high scoring summaries under a length limit in testing, then the same constraint should also be used in training.

In this paper we experimented with sentence-local features. In the future we plan to expand this feature set with global features, especially ones mea-

[11] We computed the agreement between the users using intra class correlation with Cronbach's Alpha where the correlation coefficient ranges between 0 and 1. Numbers close to 1 indicate high correlation and numbers close to 0 indicate low correlation. For the clarity criterion the assessors' correlation coefficient is 0.547, for coherence 0.687, for focus 0.688, for grammaticality 0.232 and for redundancy 0.453.

[12] We compute significance test for the manual evaluation results using χ square.

suring lexical diversity in the summaries to reduce the redundancy in them. We will investigate various ways of incorporating these global features into our A* search. However this will incur an additional computational cost over a purely local feature model and therefore may necessitate using an approximate beam search. We also plan to investigate using other metrics in training in order to reduce redundant information in the summaries. Finally, we have made our summarizer publicly available as open-source software.[13]

Abstract

Most coreference resolution models determine if two mentions are coreferent using a single function over a set of constraints or features. This approach can lead to incorrect decisions as lower precision features often overwhelm the smaller number of high precision ones. To overcome this problem, we propose a simple coreference architecture based on a sieve that applies tiers of deterministic coreference models one at a time from highest to lowest precision. Each tier builds on the previous tier's entity cluster output. Further, our model propagates global information by sharing attributes (e.g., gender and number) across mentions in the same cluster. This cautious sieve guarantees that stronger features are given precedence over weaker ones and that each decision is made using all of the information available at the time. The framework is highly modular: new coreference modules can be plugged in without any change to the other modules. In spite of its simplicity, our approach outperforms many state-of-the-art supervised and unsupervised models on several standard corpora. This suggests that sieve-based approaches could be applied to other NLP tasks.

1 Introduction

Recent work on coreference resolution has shown that a rich feature space that models lexical, syntactic, semantic, and discourse phenomena is crucial to successfully address the task (Bengston and Roth, 2008; Haghighi and Klein, 2009; Haghighi and Klein, 2010). When such a rich representation is available, even a simple deterministic model can achieve state-of-the-art performance (Haghighi and Klein, 2009).

By and large most approaches decide if two mentions are coreferent using a single function over all these features and information local to the two mentions.[1] This is problematic for two reasons: (1) lower precision features may overwhelm the smaller number of high precision ones, and (2) local information is often insufficient to make an informed decision. Consider this example:

The second attack occurred after some rocket firings aimed, apparently, toward [the israelis], apparently in retaliation. [we]'re checking our facts on that one. ... the president, quoted by ari fleischer, his spokesman, is saying he's concerned the strike will undermine efforts by palestinian authorities to bring an end to terrorist attacks and does not contribute to the security of [israel].

Most state-of-the-art models will incorrectly link *we* to *the israelis* because of their proximity and compatibility of attributes (both *we* and *the israelis* are plural). In contrast, a more cautious approach is to first cluster *the israelis* with *israel* because the demonymy relation is highly precise. This initial clustering step will assign the correct animacy attribute (`inanimate`) to the corresponding geo-political entity, which will prevent the incorrect merging with the mention *we* (`animate`) in later steps.

We propose an unsupervised sieve-like approach to coreference resolution that addresses these is-

[1] As we will discuss below, some approaches use an additional component to infer the overall best mention clusters for a document, but this is still based on confidence scores assigned using local information.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 492–501,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

sues. The approach applies tiers of coreference models one at a time from highest to lowest precision. Each tier builds on the entity clusters constructed by previous models in the sieve, guaranteeing that stronger features are given precedence over weaker ones. Furthermore, each model's decisions are richly informed by sharing attributes across the mentions clustered in earlier tiers. This ensures that each decision uses all of the information available at the time. We implemented all components in our approach using only deterministic models. All our components are unsupervised, in the sense that they do not require training on gold coreference links.

The contributions of this work are the following:

- We show that a simple scaffolding framework that deploys strong features through tiers of models performs significantly better than a single-pass model. Additionally, we propose several simple, yet powerful, new features.
- We demonstrate how far one can get with simple, deterministic coreference systems that do not require machine learning or detailed semantic information. Our approach outperforms most other unsupervised coreference models and several supervised ones on several datasets.
- Our modular framework can be easily extended with arbitrary models, including statistical or supervised models. We believe that our approach also serves as an ideal platform for the development of future coreference systems.

2 Related Work

This work builds upon the recent observation that strong features outweigh complex models for coreference resolution, in both supervised and unsupervised learning setups (Bengston and Roth, 2008; Haghighi and Klein, 2009). Our work reinforces this observation, and extends it by proposing a novel architecture that: (a) allows easy deployment of such features, and (b) infuses global information that can be readily exploited by these features or constraints.

Most coreference resolution approaches perform the task by aggregating local decisions about pairs of mentions (Bengston and Roth, 2008; Finkel and Manning, 2008; Haghighi and Klein, 2009; Stoyanov, 2010). Two recent works that diverge from this pattern are Culotta et al. (2007) and Poon and Domingos (2008). They perform coreference resolution jointly for all mentions in a document, using first-order probabilistic models in either supervised or unsupervised settings. Haghighi and Klein (2010) propose a generative approach that models entity clusters explicitly using a mostly-unsupervised generative model. As previously mentioned, our work is not constrained by first-order or Bayesian formalisms in how it uses cluster information. Additionally, the deterministic models in our tiered model are significantly simpler, yet perform generally better than the complex inference models proposed in these works.

From a high level perspective, this work falls under the theory of shaping, defined as a "method of successive approximations" for learning (Skinner, 1938). This theory is known by different names in many NLP applications: Brown et al. (1993) used simple models as "stepping stones" for more complex word alignment models; Collins (1999) used "cautious" decision list learning for named entity classification; Spitkovsky et al. (2010) used "baby steps" for unsupervised dependency parsing, etc. To the best of our knowledge, we are the first to apply this theory to coreference resolution.

3 Description of the Task

Intra-document coreference resolution clusters together textual mentions within a single document based on the underlying referent entity. Mentions are usually noun phrases (NPs) headed by nominal or pronominal terminals. To facilitate comparison with most of the recent previous work, we report results using gold mention boundaries. However, our approach does not make any assumptions about the underlying mentions, so it is trivial to adapt it to predicted mention boundaries (e.g., see Haghighi and Klein (2010) for a simple mention detection model).

3.1 Corpora

We used the following corpora for development and evaluation:

- **ACE2004-ROTH-DEV**[2] – development split of Bengston and Roth (2008), from the corpus used in the 2004 Automatic Content Extraction (ACE) evaluation. It contains 68 documents and 4,536 mentions.

[2] We use the same corpus names as (Haghighi and Klein, 2009) to facilitate comparison with previous work.

- **ACE2004-CULOTTA-TEST** – partition of ACE 2004 corpus reserved for testing by several previous works (Culotta et al., 2007; Bengston and Roth, 2008; Haghighi and Klein, 2009). It consists of 107 documents and 5,469 mentions.
- **ACE2004-NWIRE** – the newswire subset of the ACE 2004 corpus, utilized by Poon and Domingos (2008) and Haghighi and Klein (2009) for testing. It contains 128 documents and 11,413 mentions.
- **MUC6-TEST** – test corpus from the sixth Message Understanding Conference (MUC-6) evaluation. It contains 30 documents and 2,068 mentions.

We used the first corpus (ACE2004-ROTH-DEV) for development. The other corpora are reserved for testing. We parse all documents using the Stanford parser (Klein and Manning, 2003). The syntactic information is used to identify the mention head words and to define the ordering of mentions in a given sentence (detailed in the next section). For a fair comparison with previous work, we do not use gold named entity labels or mention types but, instead, take the labels provided by the Stanford named entity recognizer (NER) (Finkel et al., 2005).

3.2 Evaluation Metrics

We use three evaluation metrics widely used in the literature: (a) pairwise F1 (Ghosh, 2003) – computed over mention pairs in the same entity cluster; (b) MUC (Vilain et al., 1995) – which measures how many predicted clusters need to be merged to cover the gold clusters; and (c) B^3 (Amit and Baldwin, 1998) – which uses the intersection between predicted and gold clusters for a given mention to mark correct mentions and the sizes of the the predicted and gold clusters as denominators for precision and recall, respectively. We refer the interested reader to (X. Luo, 2005; Finkel and Manning, 2008) for an analysis of these metrics.

4 Description of the Multi-Pass Sieve

Our sieve framework is implemented as a succession of independent coreference models. We first describe how each model selects candidate mentions, and then describe the models themselves.

4.1 Mention Processing

Given a mention m_i, each model may either decline to propose a solution (in the hope that one of the subsequent models will solve it) or deterministically select a single best antecedent from a list of previous mentions $m_1, \ldots, m_{i-1}$. We sort candidate antecedents using syntactic information provided by the Stanford parser, as follows:

Same Sentence – Candidates in the same sentence are sorted using left-to-right breadth-first traversal of syntactic trees (Hobbs, 1977). Figure 1 shows an example of candidate ordering based on this traversal. The left-to-right ordering favors subjects, which tend to appear closer to the beginning of the sentence and are more probable antecedents. The breadth-first traversal promotes syntactic salience by ranking higher noun phrases that are closer to the top of the parse tree (Haghighi and Klein, 2009). If the sentence containing the anaphoric mention contains multiple clauses, we repeat the above heuristic separately in each `S*` constituent, starting with the one containing the mention.

Previous Sentence – For all nominal mentions we sort candidates in the previous sentences using right-to-left breadth-first traversal. This guarantees syntactic salience and also favors document proximity. For pronominal mentions, we sort candidates in previous sentences using left-to-right traversal in order to favor subjects. Subjects are more probable antecedents for pronouns (Kertz et al., 2006). For example, this ordering favors the correct candidate (*pepsi*) for the mention *they*:

> *[pepsi] says it expects to double [quaker]'s snack food growth rate. after a month-long courtship, [they] agreed to buy quaker oats...*

In a significant departure from previous work, each model in our framework gets (possibly incomplete) clustering information for each mention from the earlier coreference models in the multi-pass system. In other words, each mention m_i may already be assigned to a cluster C_j containing a set of mentions: $C_j = \{m_1^j, \ldots, m_k^j\}$; $m_i \in C_j$. Unassigned mentions are unique members of their own cluster. We use this information in several ways:

Attribute sharing – Pronominal coreference resolution (discussed later in this section) is severely af-

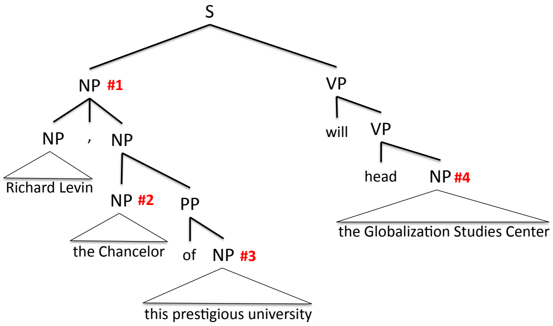

Figure 1: Example of left-to-right breadth-first tree traversal. The numbers indicate the order in which the NPs are visited.

fected by missing attributes (which introduce precision errors because incorrect antecedents are selected due to missing information) and incorrect attributes (which introduce recall errors because correct links are not generated due to attribute mismatch between mention and antecedent). To address this issue, we perform a union of all mention attributes (e.g., number, gender, animacy) in a given cluster and share the result with all cluster mentions. If attributes from different mentions contradict each other we maintain all variants. For example, our naive number detection assigns `singular` to the mention *a group of students* and `plural` to *five students*. When these mentions end up in the same cluster, the resulting number attributes becomes the set {`singular`, `plural`}. Thus this cluster can later be merged with both singular and plural pronouns.

Mention selection – Traditionally, a coreference model attempts to resolve every mention in the text, which increases the likelihood of errors. Instead, in each of our models, we exploit the cluster information received from the previous stages by resolving only mentions that are currently first in textual order in their cluster. For example, given the following ordered list of mentions, $\{m_1^1, m_2^2, m_3^2, m_4^3, m_5^1, m_6^2\}$, where the superscript indicates cluster id, our model will attempt to resolve only m_2^2 and m_4^3. These two are the only mentions that have potential antecedents and are currently marked as the first mentions in their clusters. The intuition behind this heuristic is two-fold. First, early cluster mentions are usually better defined than subsequent ones, which are likely to have fewer modifiers or are pronouns (Fox, 1993). Several of our models use this modifier information. Second, by definition, first mentions appear closer to the beginning of the document, hence there are fewer antecedent candidates to select from, and fewer opportunities to make a mistake.

Search Pruning – Finally, we prune the search space using *discourse salience*. We disable coreference for first cluster mentions that: (a) are or start with indefinite pronouns (e.g., *some*, *other*), or (b) start with indefinite articles (e.g., *a*, *an*). One exception to this rule is the model deployed in the first pass; it only links mentions if their entire extents match exactly. This model is triggered for all nominal mentions regardless of discourse salience, because it is possible that indefinite mentions are repeated in a document when concepts are discussed but not instantiated, e.g., *a sports bar* below:

> *Hanlon, a longtime Broncos fan, thinks it is the perfect place for [a sports bar] and has put up a blue-and-orange sign reading, "Wanted Broncos Sports Bar On This Site." . . . In a Nov. 28 letter, Proper states "while we have no objection to your advertising the property as a location for [a sports bar], using the Broncos' name and colors gives the false impression that the bar is or can be affiliated with the Broncos."*

4.2 The Modules of the Multi-Pass Sieve

We now describe the coreference models implemented in the sieve. For clarity, we summarize them in Table 1 and show the cumulative performance as they are added to the sieve in Table 2.

4.2.1 Pass 1 - Exact Match

This model links two mentions only if they contain exactly the same extent text, including modifiers and determiners, e.g., *the Shahab 3 ground-ground missile*. As expected, this model is extremely precise, with a pairwise precision over 96%.

4.2.2 Pass 2 - Precise Constructs

This model links two mentions if any of the conditions below are satisfied:

Appositive – the two nominal mentions are in an appositive construction, e.g., *[Israel's Deputy Defense Minister], [Ephraim Sneh] , said* . . . We use the same syntactic rules to detect appositions as Haghighi and Klein (2009).

Pass	Type	Features
1	N	exact extent match
2	N,P	appositive | predicate nominative | role appositive | relative pronoun | acronym | demonym
3	N	cluster head match & word inclusion & compatible modifiers only & not i-within-i
4	N	cluster head match & word inclusion & not i-within-i
5	N	cluster head match & compatible modifiers only & not i-within-i
6	N	relaxed cluster head match & word inclusion & not i-within-i
7	P	pronoun match

Table 1: Summary of passes implemented in the sieve. The Type column indicates the type of coreference in each pass: N – nominal or P – pronominal. & and | indicate conjunction and disjunction of features, respectively.

Predicate nominative – the two mentions (nominal or pronominal) are in a copulative subject-object relation, e.g., *[The New York-based College Board] is [a nonprofit organization that administers the SATs and promotes higher education]* (Poon and Domingos, 2008).

Role appositive – the candidate antecedent is headed by a noun and appears as a modifier in an NP whose head is the current mention, e.g., *[[actress] Rebecca Schaeffer]*. This feature is inspired by Haghighi and Klein (2009), who triggered it only if the mention is labeled as a person by the NER. We constrain this heuristic more in our work: we allow this feature to match only if: (a) the mention is labeled as a person, (b) the antecedent is animate (we detail animacy detection in Pass 7), and (c) the antecedent's gender is not neutral.

Relative pronoun – the mention is a relative pronoun that modifies the head of the antecedent NP, e.g., *[the finance street [which] has already formed in the Waitan district]*.

Acronym – both mentions are tagged as NNP and one of them is an acronym of the other, e.g., *[Agence France Presse] . . . [AFP]*. We use a simple acronym detection algorithm, which marks a mention as an acronym of another if its text equals the sequence of upper case characters in the other mention. We will adopt better solutions for acronym detection in future work (Schwartz, 2003).

Demonym – one of the mentions is a demonym of the other, e.g., *[Israel] . . . [Israeli]*. For demonym detection we use a static list of countries and their gentilic forms from Wikipedia.[3]

All the above features are extremely precise. As shown in Table 2 the pairwise precision of the sieve after adding these features is over 95% and recall increases 5 points.

4.2.3 Pass 3 - Strict Head Matching

Linking a mention to an antecedent based on the naive matching of their head words generates a lot of spurious links because it completely ignores possibly incompatible modifiers (Elsner and Charniak, 2010). For example, *Yale University* and *Harvard University* have similar head words, but they are obviously different entities. To address this issue, this pass implements several features that must all be matched in order to yield a link:

Cluster head match – the mention head word matches *any* head word in the antecedent cluster. Note that this feature is actually more relaxed than naive head matching between mention and antecedent candidate because it is satisfied when the mention's head matches the head of any entity in the candidate's cluster. We constrain this feature by enforcing a conjunction with the features below.

Word inclusion – all the non-stop[4] words in the mention cluster are included in the set of non-stop words in the cluster of the antecedent candidate. This heuristic exploits the property of discourse that it is uncommon to introduce novel information in later mentions (Fox, 1993). Typically, mentions of the same entity become shorter and less informative as the narrative progresses. For example, the two mentions in *. . . intervene in the [Florida Supreme Court]'s move . . . does look like very dramatic change made by [the Florida court]* point to the same entity, but the two mentions in the text below belong to different clusters:

The pilot had confirmed . . . he had turned onto

Table 2: Cumulative performance on development (ACE2004-ROTH-DEV) as passes are added to the sieve.

[the correct runway] but pilots behind him say
he turned onto [the wrong runway].

Compatible modifiers only – the mention's modifiers are all included in the modifiers of the antecedent candidate. This feature models the same discourse property as the previous feature, but it focuses on the two individual mentions to be linked, rather than their entire clusters. For this feature we only use modifiers that are nouns or adjectives.

Not i-within-i – the two mentions are not in an i-within-i construct, i.e., one cannot be a child NP in the other's NP constituent (Haghighi and Klein, 2009).

This pass continues to maintain high precision (91% pairwise) while improving recall significantly (over 6 points pairwise and almost 8 points MUC).

4.2.4 Passes 4 and 5 - Variants of Strict Head

Passes 4 and 5 are different relaxations of the feature conjunction introduced in Pass 3, i.e., Pass 4 removes the `compatible modifiers only` feature, while Pass 5 removes the `word inclusion` constraint. All in all, these two passes yield an improvement of 1.7 pairwise F1 points, due to recall improvements. Table 2 shows that the `word inclusion` feature is more precise than `compatible modifiers only`, but the latter has better recall.

4.2.5 Pass 6 - Relaxed Head Matching

This pass relaxes the cluster head match heuristic by allowing the mention head to match any word in the cluster of the candidate antecedent. For example, this heuristic matches the mention *Sanders* to a cluster containing the mentions {*Sauls*, *the judge*, *Circuit Judge N. Sanders Sauls*}. To maintain high precision, this pass requires that both mention and antecedent be labeled as named entities and the types coincide. Furthermore, this pass implements a conjunction of the above features with `word inclusion` and `not i-within-i`. This pass yields less than 1 point improvement in most metrics.

4.2.6 Pass 7 - Pronouns

With one exception (Pass 2), all the previous coreference models focus on nominal coreference resolution. However, it would be incorrect to say that our framework ignores pronominal coreference in the first six passes. In fact, the previous models prepare the stage for pronominal coreference by constructing precise clusters with shared mention attributes. These are crucial factors for pronominal coreference.

Like previous work, we implement pronominal coreference resolution by enforcing agreement constraints between the coreferent mentions. We use the following attributes for these constraints:

Number – we assign number attributes based on: (a) a static list for pronouns; (b) NER labels: mentions marked as a named entity are considered singular with the exception of organizations, which can be both singular or plural; (c) part of speech tags: `NN*S` tags are plural and all other `NN*` tags are singular; and (d) a static dictionary from (Bergsma and Lin, 2006).

Gender – we assign gender attributes from static lexicons from (Bergsma and Lin, 2006; Ji and Lin, 2009).

Person – we assign person attributes only to pronouns. However, we do not enforce this constraint when linking two pronouns if one appears within quotes. This is a simple heuristic for speaker detection, e.g., *I* and *she* point to the same person in

"[I] voted my conscience," [she] said.

Animacy – we set animacy attributes using: (a) a static list for pronouns; (b) NER labels, e.g., PERSON is animate whereas LOCATION is not; and (c) a dictionary boostrapped from the web (Ji and Lin, 2009).

NER label – from the Stanford NER.

If we cannot detect a value, we set attributes to unknown and treat them as wildcards, i.e., they can match any other value.

This final model raises the pairwise recall of our system almost 22 percentage points, with only an 8 point drop in pairwise precision. Table 2 shows that similar behavior is measured for all other metrics. After all passes have run, we take the transitive closure of the generated clusters as the system output.

5 Experimental Results

We present the results of our approach and other relevant prior work in Table 3. We include in the table all recent systems that report results under the same conditions as our experimental setup (i.e., using gold mentions) and use the same corpora. We exclude from this analysis two notable works that report results only on a version of the task that includes finding mentions (Haghighi and Klein, 2010; Stoyanov, 2010). The Haghighi and Klein (2009) numbers have two variants: with semantics (+S) and without (−S). To measure the contribution of our multi-pass system, we also present results from a single-pass variant of our system that uses all applicable features from the multi-pass system (marked as "single pass" in the table).

Our sieve model outperforms all systems on two out of the four evaluation corpora (ACE2004-ROTH-DEV and ACE2004-NWIRE), on all metrics. On the corpora where our model is not best, it ranks a close second. For example, in ACE2004-CULOTTA-TEST our system has a B^3 F1 score only .4 points lower than Bengston and Roth (2008) and it outperforms all unsupervised approaches. In MUC6-TEST, our sieve's B^3 F1 score is 1.8 points lower than Haghighi and Klein (2009) +S, but it outperforms a supervised system that used gold named entity labels. Finally, the multi-pass architecture always beats the equivalent single-pass system with its contribution ranging between 1 and 4 F1 points depending on the corpus and evaluation metric.

Our approach has the highest precision on all corpora, regardless of evaluation metric. We believe this is particularly useful for large-scale NLP applications that use coreference resolution components, e.g., question answering or information extraction. These applications can generally function without coreference information so it is beneficial to provide such information only when it is highly precise.

6 Discussion

6.1 Comparison to Previous Work

The sieve model outperforms all other systems on at least two test sets, even though most of the other models are significantly richer. Amongst the comparisons, several are supervised (Bengston and Roth, 2008; Finkel and Manning, 2008; Culotta et al., 2007). The system of Haghighi and Klein (2009) +S uses a lexicon of semantically-compatible noun pairs acquired transductively, i.e., with knowledge of the mentions in the test set. Our system does not rely on labeled corpora for training (like supervised approaches) nor access to corpora during testing (like Haghighi and Klein (2009)).

The system that is closest to ours is Haghighi and Klein (2009) −S. Like us, they use a rich set of features and deterministic decisions. However, theirs is a single-pass model with a smaller feature set (no cluster-level, acronym, demonym, or animacy information). Table 3 shows that on the two corpora where results for this system are available, we outperform it considerably on all metrics. To understand if the difference is due to the multi-pass architecture or the richer feature set we compared (Haghighi and Klein, 2009) −S against both our multi-pass system and its single-pass variant. The comparison indicates that both these contributions help: our single-pass system outperforms Haghighi and Klein (2009) consistently, and the multi-pass architecture further improves the performance of our single-pass system between 1 and 4 F1 points, depending on the corpus and evaluation metric.

6.2 Semantic Head Matching

Recent unsupervised coreference work from Haghighi and Klein (2009) included a novel semantic component that matched related head words (e.g., *AOL* is a *company*) learned from select

wikipedia articles. They first identified articles relevant to the entity mentions in the test set, and then bootstrapped from known syntactic patterns for apposition and predicate-nominatives in order to learn a database of related head pairs. They show impressive gains by using these learned pairs in coreference decisions. This type of learning using test set mentions is often described as *transductive*.

Our work instead focuses on an approach that does not require access to the dataset beforehand. We thus did not include a similar semantic component in our system, given that running a bootstrapping learner whenever a new data set is encountered is not practical and, ultimately, reduces the usability of this NLP component. However, our results show that our sieve algorithm with minimal semantic information still performs as well as the Haghighi and Klein (2009) system with semantics.

6.3 Flexible Architecture

The sieve architecture offers benefits beyond improved accuracy. Its modular design provides a flexibility for features that is not available in most supervised or unsupervised systems. The sieve allows new features to be seamlessly inserted without affecting (or even understanding) the other components. For instance, once a new high precision feature (or group of features) is inserted as its own stage, it will benefit later stages with more precise clusters, but it will not interfere with their particular algorithmic decisions. This flexibility is in sharp contrast to supervised classifiers that require their models to be retrained on labeled data, and unsupervised systems that do not offer a clear insertion point for new features. It can be difficult to fully understand how a system makes a single decision, but the sieve allows for flexible usage with minimal effort.

6.4 Error Analysis

	Pronominal	Nominal	Proper	Total
Pronominal	49 / 237	116 / 317	104 / 595	269 / 1149
Nominal	79 / 351	129 / 913	61 / 986	269 / 2250
Proper	51 / 518	15 / 730	38 / 595	104 / 1843
Total	179 / 1106	260 / 1960	203 / 2176	642 / 5242

Table 4: Number of pair-wise errors produced by the sieve after transitive closure in the MUC6-TEST corpus. Rows indicate mention types; columns are types of antecedent. Each cell shows the number of precision/recall errors for that configuration. The total number of gold links in MUC6-TEST is 11,236.

Table 4 shows the number of incorrect pair-wise links generated by our system on the MUC6-TEST corpus. The table indicates that most of our errors are for nominal mentions. For example, the combined (precision plus recall) number of errors for proper or common noun mentions is three times larger than the number of errors made for pronominal mentions. The table also highlights that most of our errors are recall errors. There are eight times more recall errors than precision errors in our output. This is a consequence of our decision to prioritize highly precise features in the sieve.

The above analysis illustrates that our next effort should focus on improving recall. In order to understand the limitations of our current system, we randomly selected 60 recall errors (20 for each mention type) and investigated their causes. Not surprisingly, the causes are unique to each type.

For proper nouns, 50% of recall errors are due to *mention lengthening*, mentions that are longer than their earlier mentions. For example, *Washington-based USAir* appears after *USAir* in the text, so our head matching components skip it because their high precision depends on disallowing new modifiers as the discourse proceeds. When the mentions were reversed (as is the usual case), they match.

The common noun recall errors are very different from proper nouns: 17 of the 20 random examples can be classified as *semantic knowledge*. These errors are roughly evenly split between recognizing categories of names (e.g., Gitano is an organization name hence it should match the nominal antecedent *the company*), and understanding hypernym relations like *settlements* and *agreements*.

Pronoun errors come in two forms. Roughly 40% of these errors are attribute mismatches involving sometimes ambiguous uses of gender and number (e.g., *she* with *Pat Carney*). Another 40% are not semantic or attribute-based, but rather simply arise due to the order in which we check potential antecedents. In all these situations, the correct links are missed because the system chooses a closer (incorrect) antecedent.

These four highlighted errors (lengthening, semantics, attributes, ordering) add up to 77% of all recall errors in the selected set. In general, each error type is particular to a specific mention type. This suggests that recall improvements can be made by focusing on one mention type without aversely affecting the others. Our sieve-based approach to coreference uniquely allows for such new models to be seamlessly inserted.

7 Conclusion

We presented a simple deterministic approach to coreference resolution that incorporates document-level information, which is typically exploited only by more complex, joint learning models. Our sieve architecture applies a battery of deterministic coreference models one at a time from highest to lowest precision, where each model builds on the previous model's cluster output. Despite its simplicity, our approach outperforms or performs comparably to the state of the art on several corpora.

An additional benefit of the sieve framework is its modularity: new features or models can be inserted in the system with limited understanding of the other features already deployed. Our code is publicly released[5] and can be used both as a stand-alone coreference system and as a platform for the development of future systems.

[5] http://nlp.stanford.edu/software/dcoref.shtml

The strong performance of our system suggests the use of sieves in other NLP tasks for which a variety of very high-precision features can be designed and non-local features can be shared; likely candidates include relation and event extraction, template slot filling, and author name deduplication.

Abstract

We present a simple, robust generation system which performs content selection and surface realization in a unified, domain-independent framework. In our approach, we break up the end-to-end generation process into a sequence of local decisions, arranged hierarchically and each trained discriminatively. We deployed our system in three different domains—Robocup sportscasting, technical weather forecasts, and common weather forecasts, obtaining results comparable to state-of-the-art domain-specific systems both in terms of BLEU scores and human evaluation.

1 Introduction

In this paper, we focus on the problem of generating descriptive text given a world state represented by a set of database records. While existing generation systems can be engineered to obtain good performance on particular domains (e.g., Dale et al. (2003), Green (2006), Turner et al. (2009), Reiter et al. (2005), *inter alia*), it is often difficult to adapt them across different domains. Furthermore, *content selection* (what to say: see Barzilay and Lee (2004), Foster and White (2004), *inter alia*) and *surface realization* (how to say it: see Ratnaparkhi (2002), Wong and Mooney (2007), Chen and Mooney (2008), Lu et al. (2009), etc.) are typically handled separately. Our goal is to build a simple, flexible system which is domain-independent and performs content selection and surface realization in a unified framework.

We operate in a setting in which we are only given examples consisting of (i) a set of database records (input) and (ii) example human-generated text describing some of those records (output). We use the model of Liang et al. (2009) to automatically induce the correspondences between words in the text and the actual database records mentioned.

We break up the full generation process into a sequence of local decisions, training a log-linear classifier for each type of decision. We use a simple but expressive set of domain-independent features, where each decision is allowed to depend on the entire history of previous decisions, as in the model of Ratnaparkhi (2002). These long-range contextual dependencies turn out to be critical for accurate generation.

More specifically, our model is defined in terms of three types of decisions. The first type chooses records from the database (macro content selection)—for example, wind speed, in the case of generating weather forecasts. The second type chooses a subset of fields from a record (micro content selection)—e.g., the minimum and maximum temperature. The third type chooses a suitable template to render the content (surface realization)—e.g., *winds between* [min] *and* [max] *mph*; templates are automatically extracted from training data.

We tested our approach in three domains: ROBOCUP, for sportscasting (Chen and Mooney, 2008); SUMTIME, for technical weather forecast generation (Reiter et al., 2005); and WEATHERGOV, for common weather forecast generation (Liang et al., 2009). We performed both automatic (BLEU) and human evaluation. On WEATHERGOV, we

achieved a BLEU score of 51.5 on the combined task of content selection and generation, which is more than a two-fold improvement over a model similar to that of Liang et al. (2009). On ROBOCUP and SUMTIME, we achieved results comparable to the state-of-the-art. most importantly, we obtained these results with a general-purpose approach that we believe is simpler than current state-of-the-art systems.

2 Setup and Domains

Our goal is to generate a text given a world state. The *world state*, denoted $\mathbf{s}$, is represented by a set of database records. Define $\mathcal{T}$ to be a set of record types, where each record type $t \in \mathcal{T}$ is associated with a set of fields $\text{FIELDS}(t)$. Each *record* $r \in \mathbf{s}$ has a record type $r.t \in \mathcal{T}$ and a *field value* $r.v[f]$ for each field $f \in \text{FIELDS}(t)$. The *text*, denoted $\mathbf{w}$, is represented by a sequence of tokenized words. We use the term *scenario* to denote a world state $\mathbf{s}$ paired with a text $\mathbf{w}$.

In this paper, we conducted experiments on three domains, which are detailed in the following subsections. Example scenarios for each domain are detailed in Figure 1.

2.1 ROBOCUP: Sportscasting

A world state in the ROBOCUP domain is a set of event records (*meaning representations* in the terminology of Chen and Mooney (2008)) generated by a robot soccer simulator. For example, the record pass(arg1=pink1,arg2=pink5) denotes a passing event; records of this type (pass) have two fields: arg1 (the agent) and arg2 (the recipient). As the game progresses, human commentators talk about some of the events in the game, e.g., *purple3 made a bad pass that was picked off by pink9*.

We used the dataset created by Chen and Mooney (2008), which contains 1919 scenarios from the 2001–2004 Robocup finals. Each scenario consists of a single sentence representing a fragment of a commentary on the game, paired with a set of candidate records, which were recorded within five seconds of the commentary. The records in the ROBOCUP dataset data were aligned by Chen and Mooney (2008). Each scenario contains on average $|\mathbf{s}| = 2.4$ records and 5.7 words. See Figure 1(a) for an example of a scenario. Content selection in this domain is choosing the single record to talk about, and surface realization is talking about it.

2.2 SumTime: Technical Weather Forecasts

Reiter et al. (2005) developed a generation system and created the SumTime-Meteo corpus, which consists of marine wind weather forecasts used by offshore oil rigs, generated by the output of weather simulators. More specifically, these forecasts describe various aspects of the wind at different times during the forecast period.

We used the version of the SumTime-Meteo corpus created by Belz (2008). The dataset consists of 469 scenarios, each containing on average $|\mathbf{s}| = 2.6$ records and 16.2 words. See Figure 1(c) for an example of a scenario. This task requires no content selection, only surface realization: The records are given in some fixed order and the task is to generate from each of these records in turn; of course, due to contextual dependencies, these records cannot be generated independently.

2.3 WeatherGov: Common Weather Forecasts

In the WeatherGov domain, the world state contains detailed information about a local weather forecast (e.g., temperature, rain chance, etc.). The text is a short forecast report based on this information.

We used the dataset created by Liang et al. (2009). The world state is summarized by records which aggregate measurements over selected time intervals. The dataset consists of 29,528 scenarios, each containing on average $|\mathbf{s}| = 36$ records and 28.7 words. See Figure 1(b) for an example of a scenario.

While SumTime and WeatherGov are both weather domains, there are significant differences between the two. SumTime forecasts are intended to be read by trained meteorologists, and thus the text is quite abbreviated. On the other hand, WeatherGov texts are intended to be read by the general public and thus is more English-like. Furthermore, SumTime does not require content selection, whereas content selection is a major focus of WeatherGov. Indeed, on average, only 5 of 36 records are actually mentioned in a WeatherGov scenario. Also, WeatherGov is more complex: The text is more varied, there are multiple record types, and there are about ten times as many records in each world state.

```
Generation Process
for $i = 1, 2, \ldots$ :
  **choose** a record $r_i \in \mathbf{s}$
  if $r_i = \textsc{stop}$: return
  **choose** a field set $F_i \subset \textsc{Fields}(r_i.t)$
  **choose** a template $T_i \in \textsc{Templates}(r_i.t, F_i)$
```

Figure 2: Pseudocode for the generation process. The generated text $\mathbf{w}$ is a deterministic function of the decisions.

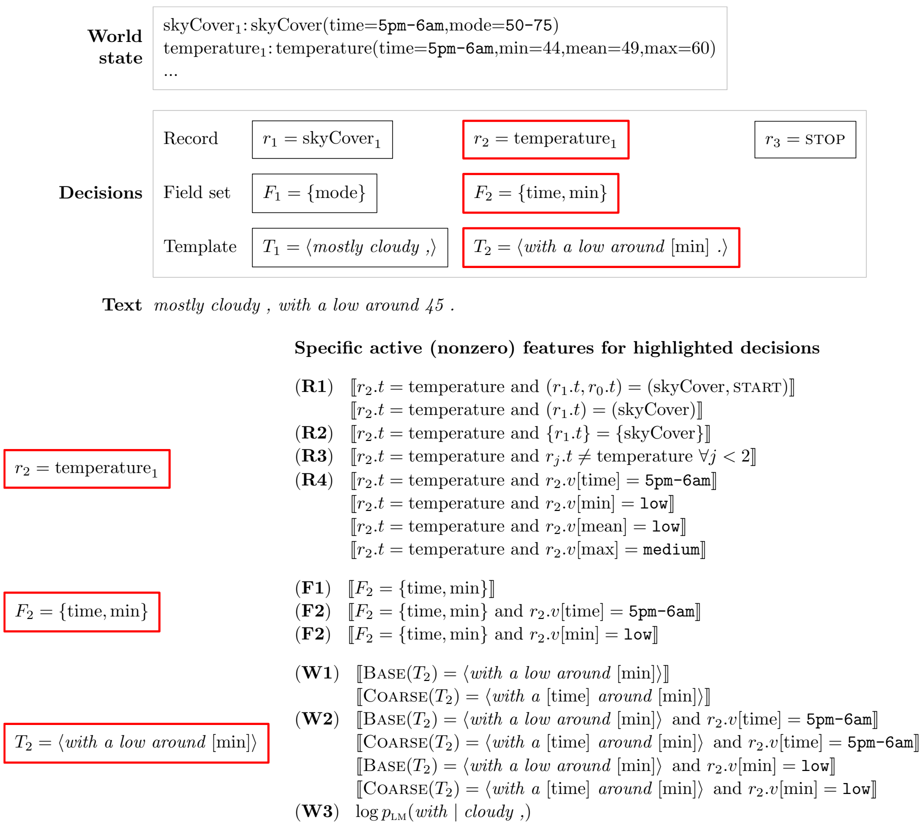
3 The Generation Process

To model the process of generating a text $\mathbf{w}$ from a world state $\mathbf{s}$, we decompose the generation process into a sequence of local decisions. There are two aspects of this decomposition that we need to specify: (i) how the decisions are structured; and (ii) what pieces of information govern the decisions.

The decisions are structured hierarchically into three types of decisions: (i) *record decisions*, which determine which records in the world state to talk about (macro content selection); (ii) *field set decisions*, which determine which fields of those records to mention (micro content selection); and (iii) *template decisions*, which determine the actual words to use to describe the chosen fields (surface realization). Figure 2 shows the pseudocode for the generation process, while Figure 3 depicts an example of the generation process on a WeatherGov scenario.

Each of these decisions is governed by a set of feature templates (see Figure 4), which are represented as functions of the current decision and past decisions. The feature weights are learned from training data (see Section 4.3).

We chose a set of generic domain-independent feature templates, described in the sections below. These features can, in general, depend on the current decision and *all* previous decisions. For example, referring to Figure 4, **R2** features on the record choice depend on all the previous record decisions, and **R5** features depend on the most recent template decision. This is in contrast with most systems for content selection (Barzilay and Lee, 2004) and surface realization (Belz, 2008), where decisions must decompose locally according to either a graph or tree. The ability to use global features in this manner is



World state

$\llbracket \text{BASE}(T_2) = \langle$*with a low around* [min]$\rangle$ and $r_2.v[\text{min}] = \texttt{low} \rrbracket$
$\llbracket \text{COARSE}(T_2) = \langle$*with a* [time] *around* [min]$\rangle$ and $r_2.v[\text{min}] = \texttt{low} \rrbracket$
(W3) $\log p_{\text{LM}}(\textit{with} \mid \textit{cloudy ,})$

Figure 3: The generation process on an example WEATHERGOV scenario. The figure is divided into two parts: The upper part of the figure shows the generation of text from the world state via a sequence of seven decisions (in boxes). Three of these decisions are highlighted and the features that govern these decisions are shown in the lower part of the figure. Note that different decisions in the generation process would result in different features being active (nonzero).

Feature Templates

Record	**R1**†	list of last k record types	$\llbracket r_i.t = * \text{ and } (r_{i-1}.t, \dots, r_{i-k}.t) = * \rrbracket$ for $k \in \{1, 2\}$
	R2	set of previous record types	$\llbracket r_i.t = * \text{ and } \{r_j.t : j < i\} = * \rrbracket$
	R3	record type already generated	$\llbracket r_j.t = r_i.t \text{ for some } j < i \rrbracket$
	R4	field values	$\llbracket r_i.t = * \text{ and } r_i.v[f] = * \rrbracket$ for $f \in \text{FIELDS}(r_i.t)$
	R5†	stop under language model (LM)	$\llbracket r_i.t = \text{STOP} \rrbracket \times \log p_{\text{LM}}(\text{STOP} \mid \text{previous two words generated})$
Field set	**F1**†	field set	$\llbracket F_i = * \rrbracket$
	F2	field values	$\llbracket F_i = * \text{ and } r_i.v[f] = * \rrbracket$ for $f \in F_i$
Template	**W1**†	base/coarse generation template	$\llbracket h(T_i) = * \rrbracket$ for $h \in \{\text{BASE}, \text{COARSE}\}$
	W2	field values	$\llbracket h(T_i) = * \text{ and } r_i.v[f] = * \rrbracket$ for $f \in F_i, h \in \{\text{BASE}, \text{COARSE}\}$
	W3†	first word of template under LM	$\log p_{\text{LM}}(\text{first word in } T_i \mid \text{previous two words})$

Figure 4: Feature templates that govern the record, field set, and template decisions. Each line specifies the name, informal description, and formal description of a set of features, obtained by ranging $*$ over possible values (for example, for $\llbracket r_i.t = * \rrbracket$, $*$ ranges over all record types $\mathcal{T}$). Notation: $\llbracket e \rrbracket$ returns 1 if the expression e is true and 0 if it is false. These feature templates are domain-independent; that is, they are used to create features automatically across domains. Feature templates marked with † are included in our baseline system (Section 5.2).

one of the principal advantages of our approach.

3.1 Record Decisions

Record decisions are responsible for macro content selection. Each record decision chooses a record r_i from the world state s according to features of the following types:

R1 captures the discourse coherence aspect of content selection; for example, we learn that windSpeed tends to follow windDir (but not always). **R2** captures an unordered notion of coherence—simply which sets of record types are preferable; for example, we learn that rainChance is not generated if sleetChance already was mentioned. **R3** is a coarser version of **R2**, capturing how likely it is to propose a record of a type that has already been generated. **R4** captures the important aspect of content selection that the records chosen depend on their field values;[1] for example, we learn that snowChance is not chosen unless there is snow. **R5** allows the language model to indicate whether a STOP record is appropriate; this helps prevent sentences from ending abruptly.

3.2 Field Set Decisions

Field set decisions are responsible for micro content selection, i.e., which fields of a record are mentioned. Each field set decision chooses a subset of fields F_i from the set of fields $\textsc{Fields}(r_i.t)$ of the record r_i that was just generated. These decisions are made based on two types of features:

F1 captures which sets of fields are talked about together; for example, we learn that $\{\text{mean}\}$ and $\{\text{min}, \text{max}\}$ are preferred field sets for the windSpeed record. By defining features on the entire field set, we can capture any correlation structure over the fields; in contrast, Liang et al. (2009) generates a sequence of fields in which a field can only depend on the previous one.

F2 allows the field set to be chosen based on the values of the fields, analogously to **R4**.

3.3 Template Decisions

Template decisions perform surface realization. A template is a sequence of elements, where each element is either a word (e.g., *around*) or a field (e.g., [min]). Given the record r_i and field set F_i that we are generating from, the goal is to choose a template T_i (Section 4.3.2 describes how we define the set of possible templates). The features that govern the choice of T_i are as follows:

W1 captures a priori preferences for generation templates given field sets. There are two ways to control this preference, BASE and COARSE. $\textsc{Base}(T_i)$ denotes the template T_i itself, thus allowing us to remember exactly which templates were useful. To guard against overfitting, we also use $\textsc{Coarse}(T_i)$, which maps T_i to a coarsened version of T_i, in which more words are replaced with their associated fields (see Figure 5 for an example).

W2 captures a dependence on the values of fields in the field set, and is analogous to **R4** and **F2**. Finally, **W3** contributes a language model probability, to ensure smooth transitions between templates.

After T_i has been chosen, each field in the template is replaced with a word given the corresponding field value in the world state. In particular, a word is chosen from the parameters learned in the model of Liang et al. (2009). In the example in Figure 3, the [min] field in T_2 has value 44, which is rendered to the word *45* (rounding and other noisy deviations are common in the WEATHERGOV domain).

4 Learning a Probabilistic Model

Having described all the features, we now present a conditional probabilistic model over texts $\mathbf{w}$ given world states $\mathbf{s}$ (Section 4.1). Section 4.2 describes how to use the model for generation, and Section 4.3 describes how to learn the model.

4.1 Model

Recall from Section 3 that the generation process generates $r_1, F_1, T_1, r_2, F_2, T_2, \ldots, \textsc{stop}$. To unify notation, denote this sequence of decisions as $\mathbf{d} = (d_1, \ldots, d_{|\mathbf{d}|})$.

Our probability model is defined as follows:

$$p(\mathbf{d} \mid \mathbf{s}; \theta) = \prod_{j=1}^{|\mathbf{d}|} p(d_j \mid \mathbf{d}_{<j}; \theta), \qquad (1)$$

where $\mathbf{d}_{<j} = (d_1, \ldots, d_{j-1})$ is the history of decisions and θ are the model parameters (feature weights). Note that the text $\mathbf{w}$ (the output) is a deterministic function of the decisions $\mathbf{d}$. We use the features described in Section 3 to define a log-linear model for each decision:

$$p(d_j \mid \mathbf{d}_{<j}, \mathbf{s}; \theta) = \frac{\exp\{\phi_j(d_j, \mathbf{d}_{<j}, \mathbf{s})^\top \theta\}}{\sum_{d'_j \in \mathcal{D}_j} \exp\{\phi_j(d'_j, \mathbf{d}_{<j}, \mathbf{s})^\top \theta\}}, \qquad (2)$$

where θ are all the parameters (feature weights), ϕ_j is the feature vector for the j-th decision, and $\mathcal{D}_j$ is

[1] We map a numeric field value onto one of five categories (`very-low`, `low`, `medium`, `high`, or `very-high`) based on its value with respect to the mean and standard deviation of values of that field in the training data.

the domain of the j-th decision (either records, field sets, or templates).

This chaining of log-linear models was used in Ratnaparkhi (1998) for tagging and parsing, and in Ratnaparkhi (2002) for surface realization. The ability to condition on arbitrary histories is a defining property of these models.

4.2 Using the Model for Generation

Suppose we have learned a model with parameters θ (how to obtain θ is discussed in Section 4.3). Given a world state $\mathbf{s}$, we would like to use our model to generate an output text $\mathbf{w}$ via a decision sequence $\mathbf{d}$.

In our experiments, we choose $\mathbf{d}$ by sequentially choosing the best decision in a greedy fashion (until the STOP record is generated):

$$d_j = \operatorname*{argmax}_{d'_j} p(d'_j \mid \mathbf{d}_{<j}, \mathbf{s}; \theta). \qquad (3)$$

Alternatively, instead of choosing the best decision at each point, we can sample from the distribution: $d_j \sim p(d_j \mid \mathbf{d}_{<j}, \mathbf{s}; \theta)$, which provides more diverse generated texts at the expense of a slight degradation in quality.

Both greedy search and sampling are very efficient. Another option is to try to find the Viterbi decision sequence, i.e., the one with the maximum joint probability: $\mathbf{d} = \operatorname{argmax}_{\mathbf{d}'} p(\mathbf{d}' \mid \mathbf{s}; \theta)$. However, this computation is intractable due to features depending arbitrarily on past decisions, making dynamic programming infeasible. We tried using beam search to approximate this optimization, but we actually found that beam search performed worse than greedy. Belz (2008) also found that greedy was more effective than Viterbi for their model.

4.3 Learning

Now we turn our attention to learning the parameters θ of our model. We are given a set of N scenarios $\{(\mathbf{s}^{(i)}, \mathbf{w}^{(i)})\}_{i=1}^{N}$ as training data. Note that our model is defined over the decision sequence $\mathbf{d}$ which contains information not present in $\mathbf{w}$. In Sections 4.3.1 and 4.3.2, we show how we fill in this missing information to obtain $\mathbf{d}^{(i)}$ for each training scenario i.

Assuming this missing information is filled, we end up with a standard supervised learning problem, which can be solved by maximize the (conditional) likelihood of the training data:

$$\max_{\theta \in \mathbb{R}^d} \left(\sum_{i=1}^{N} \sum_{j=1}^{|\mathbf{d}^{(i)}|} \log p(d_j^{(i)} \mid \mathbf{d}_{<j}^{(i)}; \theta) \right) - \lambda ||\theta||^2, \quad (4)$$

where $\lambda > 0$ is a regularization parameter. The objective function in (4) is optimized using the standard L-BFGS algorithm (Liu and Nocedal, 1989).

4.3.1 Latent Alignments

As mentioned previously, our training data includes only the world state $\mathbf{s}$ and generated text $\mathbf{w}$, not the full sequence of decisions $\mathbf{d}$ needed for training. Intuitively, we know *what* was generated but not *why* it was generated.

We use the model of Liang et al. (2009) to impute the decisions $\mathbf{d}$. They introduce a generative model $p(\mathbf{a}, \mathbf{w} | \mathbf{s})$, where the latent *alignment* $\mathbf{a}$ specifies (1) the sequence of records that were chosen, (2) the sequence of fields that were chosen, and (3) which words in the text were spanned by the chosen records and fields. The model is learned in an unsupervised manner using EM to produce $\mathbf{a}$ observing only $\mathbf{w}$ and $\mathbf{s}$.

An example of an alignment is given in the left part of Figure 5. This information specifies the record decisions and a set of fields for each record. Because the induced alignments can be noisy, we need to process them to obtain cleaner template decisions. This is the subject of the next section.

4.3.2 Template Extraction

Given an aligned training scenario (Figure 5), we would like to extract two types of templates.

For each record, an aligned training scenario specifies a sequence of fields and the text that is spanned by each field. We create a template by abstracting fields—that is, replacing the words spanned by a field by the field itself. We call the resulting template COARSE. The problem with using this template directly is that fields can be noisy due to errors from the unsupervised model.

Therefore, we also create a BASE template which only abstracts a subset of the fields. In particular, we define a *trigger pattern* which specifies a simple condition under which a field should be abstracted. For WEATHERGOV, we only abstract fields that

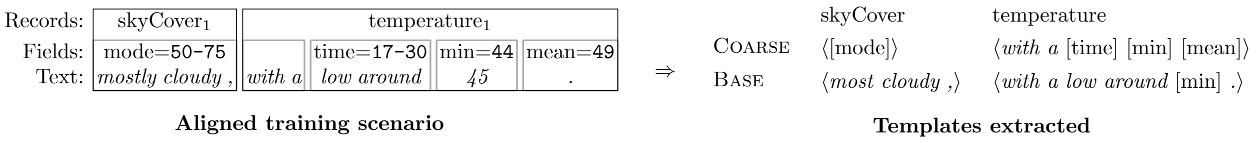

Figure 5: An example of template extraction from an imperfectly aligned training scenario. Note that these alignments are noisy (e.g., [mean] aligns to a period). Therefore, for each record (skyCover and temperature in this case), we extract two templates: (1) a COARSE template, which takes the text spanned by the record and abstracts away all fields in the scenario ([mode], [time], [min], and [mean] in the example); and (2) a BASE template, which only abstracts away fields whose spanned text matches a simple pattern (e.g., numbers in WEATHERGOV, corresponding to [min] in the example).

span numbers; for SUMTIME, fields that span numbers and wind directions; and for ROBOCUP, fields that span words starting with *purple* or *pink*.

For each record r_i, we define T_i so that $\text{BASE}(T_i)$ and $\text{COARSE}(T_i)$ are the corresponding two extracted templates. We restrict F_i to the set of abstracted fields in the COARSE template

5 Experiments

We now present an empirical evaluation of our system on our three domains—ROBOCUP, SUMTIME, and WEATHERGOV.

5.1 Evaluation Metrics

Automatic Evaluation To evaluate surface realization (or, combined content selection and surface realization), we measured the BLEU score (Papineni et al., 2002) (the precision of 4-grams with a brevity penalty) of the system-generated output with respect to the human-generated output.

To evaluate macro content selection, we measured the F_1 score (the harmonic mean of precision and recall) of the set of records chosen with respect to the human-annotated set of records.

Human Evaluation We conducted a human evaluation using Amazon Mechanical Turk. For each domain, we chose 100 scenarios randomly from the test set. We ran each system under consideration on each of these scenarios, and presented each resulting output to 10 evaluators.[2] Evaluators were given instructions to rank an output on the basis of English fluency and semantic correctness on the following scale:

Score	English Fluency	Semantic Correctness
5	Flawless	Perfect
4	Good	Near Perfect
3	Non-native	Minor Errors
2	Disfluent	Major Errors
1	Gibberish	Completely Wrong

Evaluators were also given additional domain-specific information: (1) the background of the domain (e.g., that SUMTIME reports are technical weather reports); (2) general properties of the desired output (e.g., that SUMTIME texts should mention every record whereas WEATHERGOV texts need not); and (3) peculiarities of the text (e.g., the suffix *ly* in SUMTIME should exist as a separate token from its stem, or that *pink goalie* and *pink1* have the same meaning in ROBOCUP).

5.2 Systems

We evaluated the following systems on our three domains:

- HUMAN is the human-generated output.
- OURSYSTEM uses all the features in Figure 4 and is trained according to Section 4.3.
- BASELINE is OURSYSTEM using a subset of the features (those marked with † in Figure 4). In contrast to OURSYSTEM, the included features only depend on a local context of decisions in a manner similar to the generative model of Liang et al. (2009) and the *p*CRU-greedy system of Belz (2008). BASELINE also excludes features that depend on values of the world state.
- The existing state-of-the-art domain-specific system for each domain.

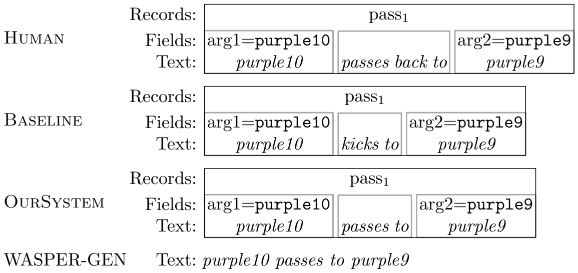
5.3 ROBOCUP Results

Following the evaluation methodology of Chen and Mooney (2008), we trained our system on three

[2] To minimize bias, we evaluated all the systems at once, randomly shuffling the outputs of the systems. The evaluators were not necessarily the same 10 evaluators.

System	F$_1$	BLEU*	English Fluency	Semantic Correctness
BASELINE	78.7	24.8	4.28 ± 0.78	4.15 ± 1.14
OURSYSTEM	79.9	28.8	4.34 ± 0.69	4.17 ± 1.21
WASPER-GEN	72.0	28.7	4.43 ± 0.76	4.27 ± 1.15
HUMAN	—	—	4.43 ± 0.69	4.30 ± 1.07

Table 1: ROBOCUP results. WASPER-GEN is described in Chen and Mooney (2008). The BLEU is reported on systems that use fixed human-annotated records (in other words, we evaluate surface realization given perfect content selection).



HUMAN
Records: pass$_1$
Fields: arg1=purple10 | arg2=purple9
Text: purple10 | passes back to | purple9
BASELINE
Records: pass$_1$
Fields: arg1=purple10 | arg2=purple9
Text: purple10 | kicks to | purple9
OURSYSTEM
Records: pass$_1$
Fields: arg1=purple10 | arg2=purple9
Text: purple10 | passes to | purple9
WASPER-GEN
Text: purple10 passes to purple9

Figure 6: Outputs of systems on an example ROBOCUP scenario. There are some minor differences between the outputs. Recall that OURSYSTEM differs from BASELINE mostly in the addition of feature **W2**, which captures dependencies between field values (e.g., `purple10`) and the template chosen (e.g., [arg1] *passes to* [arg2]). This allows us to capture value-dependent preferences for different realizations (e.g., *passes to* over *kicks to*). Also, HUMAN uses *passes back to*, but this word choice requires knowledge of passing records in previous scenarios, which none of the systems have access to. It would natural, however, to add features that would capture these longer-range dependencies in our framework.

Robocup games and tested on the fourth, averaging over the four train/test splits. We report the average test accuracy weighted by the number of scenarios in a game. First, we evaluated macro content selection. Table 1 shows that OURSYSTEM significantly outperforms BASELINE and WASPER-GEN on F$_1$.

To compare with Chen and Mooney (2008) on surface realization, we fixed each system's record decisions to the ones given by the annotated data and enforced that all the fields of that record are chosen. Table 1 shows that OURSYSTEM significantly outperforms BASELINE and is comparable to WASPER-GEN on BLEU. On human evaluation, OURSYSTEM outperforms BASELINE, but WASPER-GEN outperforms OURSYSTEM. See Figure 6 for example outputs from the various systems.

	BLEU	English Fluency	Semantic Correctness
BASELINE	32.9	4.23 ± 0.71	4.26 ± 0.85
OURSYSTEM	55.1	4.25 ± 0.69	4.27 ± 0.82
OURSYSTEM-CUSTOM	62.3	4.12 ± 0.78	4.33 ± 0.91
*p*CRU-greedy	63.6	4.18 ± 0.71	4.49 ± 0.73
SUMTIME-Hybrid	52.7	—	—
HUMAN	—	4.09 ± 0.83	4.37 ± 0.87

Table 2: SUMTIME results. The SUMTIME-Hybrid system is described in (Reiter et al., 2005); *p*CRU-greedy, in (Belz, 2008).

5.4 SUMTIME Results

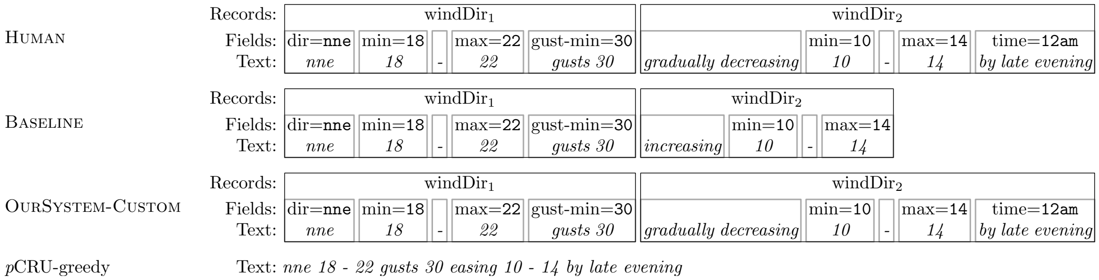
The SUMTIME task only requires micro content selection and surface realization because the sequence of records to be generated is fixed; only these aspects are evaluated. Following the methodology of Belz (2008), we used five-fold cross validation.

We found that using the unsupervised model of Liang et al. (2009) to automatically produce aligned training scenarios (Section 4.3.1) was less effective than it was in the other two domains due to two factors: (i) there are fewer training examples in SUMTIME and unsupervised learning typically works better with a large amount of data; and (ii) the alignment model does not exploit the temporal structure in the SUMTIME world state. Therefore, we used a small set of simple regular expressions to produce aligned training scenarios.

Table 2 shows that OURSYSTEM significantly outperforms BASELINE as well as SUMTIME-Hybrid, a hand-crafted system, on BLEU. Note that OURSYSTEM is domain-independent and has not been specifically tuned to SUMTIME. However, OURSYSTEM is outperformed by the state-of-the-art statistical system *p*CRU-greedy.

Custom Features One of the advantages of our feature-based approach is that it is straightforward to incorporate domain-specific features to capture specific properties of a domain. To this end, we define the following set of feature templates in place of our generic feature templates from Figure 4:

- **F1′**: Value of time
- **F2′**: Existence of gusts/wind direction/wind speeds
- **W1′**: Change in wind direction (clockwise, counterclockwise, or none)



HUMAN
Records: windDir$_1$ windDir$_2$
Fields: dir=nne min=18 max=22 gust-min=30 min=10 max=14 time=12am
Text: nne 18 - 22 gusts 30 gradually decreasing 10 - 14 by late evening
BASELINE
Records: windDir$_1$ windDir$_2$
Fields: dir=nne min=18 max=22 gust-min=30 min=10 max=14
Text: nne 18 - 22 gusts 30 increasing 10 - 14
OURSYSTEM-CUSTOM
Records: windDir$_1$ windDir$_2$
Fields: dir=nne min=18 max=22 gust-min=30 min=10 max=14 time=12am
Text: nne 18 - 22 gusts 30 gradually decreasing 10 - 14 by late evening
pCRU-greedy
Text: nne 18 - 22 gusts 30 easing 10 - 14 by late evening

Figure 7: Outputs of systems on an example SUMTIME scenario. Two notable differences between OURSYSTEM-CUSTOM and BASELINE arise due to OURSYSTEM-CUSTOM's value-dependent features. For example, OURSYSTEM-CUSTOM can choose whether to include the time field (windDir$_2$) or not (windDir$_1$), depending on the value of the time (**F1$'$**), thereby improving content selection. OURSYSTEM-CUSTOM also improves surface realization, choosing *gradually decreasing* over BASELINE's *increasing*. Interestingly, this improvement comes from the joint effort of two features: **W2$'$** prefers *decreasing* over *increasing* in this case, and **W5$'$** adds the modifier *gradually*. An important strength of log-linear models is the ability to combine soft preferences from many features.

- **W2$'$**: Change in wind speed
- **W3$'$**: Change in wind direction and speed
- **W4$'$**: Existence of gust min and/or max
- **W5$'$**: Time elapsed since last record
- **W6$'$**: Whether wind is a cardinal direction (N, E, S, W)

The resulting system, which we call OURSYSTEM-CUSTOM, obtains a BLEU score which is comparable to *p*CRU-greedy.

An important aspect of our system that it is flexible and quick to deploy. According to Belz (2008), SUMTIME-Hybrid took twelve person-months to build, while *p*CRU-greedy took one month. Having developed OURSYSTEM in a domain-independent way, we only needed to do simple reformatting upon receiving the SUMTIME data. Furthermore, it took only a few days to develop the custom features above to create OURSYSTEM-CUSTOM, which has BLEU performance comparable to the state-of-the-art *p*CRU-greedy system.

We also conducted human evaluations on the four systems shown in Table 2. Note that this evaluation is rather difficult for Mechanical Turkers since SUMTIME texts are rather technical compared to those in other domains. Interestingly, all systems outperform HUMAN on English fluency; this result corroborates the findings of Belz (2008). On semantic correctness, all systems perform comparably to HUMAN, except *p*CRU-greedy, which performs slightly better. See Figure 7 for a comparison of the outputs generated by the various systems.

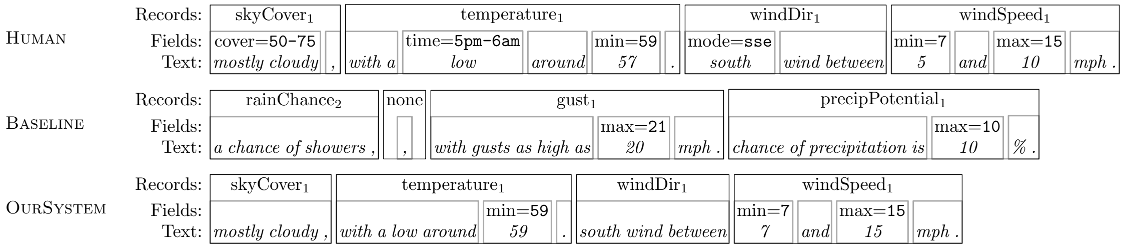
	F$_1$	BLEU*	English Fluency	Semantic Correctness
BASELINE	22.1	22.2	4.07 ± 0.59	3.41 ± 1.16
OURSYSTEM	65.4	51.5	4.12 ± 0.74	4.22 ± 0.89
HUMAN	—	—	4.14 ± 0.71	3.85 ± 0.99

Table 3: WEATHERGOV results. The BLEU score is on joint content selection and surface realization and is modified to not penalize numeric deviations of at most 5.

5.5 WEATHERGOV Results

We evaluate the WEATHERGOV corpus on the joint task of content selection and surface realization. We split our corpus into 25,000 scenarios for training, 1,000 for development, and 3,528 for testing. In WEATHERGOV, numeric field values are often rounded or noisily perturbed, so it is difficult to generate precisely matching numbers. Therefore, we used a modified BLEU score where numbers differing by at most five are treated as equal. Furthermore, WEATHERGOV is evaluated on the joint content selection and surface realization task, unlike ROBOCUP, where content selection and surface realization were treated separately, and SUMTIME, where content selection was not applicable.

Table 3 shows the results. We see that OURSYSTEM substantially outperforms BASELINE, especially on BLEU score and semantic correctness. This difference shows that taking non-local context into account is very important in this domain. This result is not surprising, since WEATHERGOV is the most complicated of the three domains, and this complexity is exactly where non-locality is neces-



HUMAN
Records: skyCover₁ | temperature₁ | windDir₁ | windSpeed₁
Fields: cover=50-75 | time=5pm-6am | min=59 | mode=sse | min=7 | max=15
Text: mostly cloudy , with a low around 57 . south wind between 5 and 10 mph .
BASELINE
Records: rainChance₂ | none | gust₁ | precipPotential₁
Fields: max=21 | max=10
Text: a chance of showers , , with gusts as high as 20 mph . chance of precipitation is 10 % .
OURSYSTEM
Records: skyCover₁ | temperature₁ | windDir₁ | windSpeed₁
Fields: min=59 | min=7 | max=15
Text: mostly cloudy , with a low around 59 . south wind between 7 and 15 mph .

Figure 8: Outputs of systems on an example WEATHERGOV scenario. Most of the gains of OURSYSTEM over BASELINE come from improved content selection. For example, BASELINE chooses rainChance because it happens to be the most common first record type in the training data. However, since OURSYSTEM has features that depend on the value of rainChance (`noChance` in this case), it has learned to disprefer talking about rain when there is no rain. Also, OURSYSTEM has additional features on the entire history of chosen records, which enables it to choose a better sequence of records.

sary. Interestingly, OURSYSTEM even outperforms HUMAN on semantic correctness, perhaps due to generating more straightforward renderings of the world state. Figure 8 describes example outputs for each system.

6 Related Work

There has been a fair amount of work both on content selection and surface realization. In content selection, Barzilay and Lee (2004) use an approach based on local classification with edge-wise scores between local decisions. Our model, on the other hand, can capture higher-order constraints to enforce global coherence.

Liang et al. (2009) introduces a generative model of the text given the world state, and in some ways is similar in spirit to our model. Although that model is capable of generation in principle, it was designed for unsupervised induction of hidden alignments (which is exactly what we use it for). Even if combined with a language model, generated text was much worse than our baseline.

The prominent approach for surface realization is rendering the text from a grammar. Wong and Mooney (2007) and Chen and Mooney (2008) use synchronous grammars that map a logical form, represented as a tree, into a parse of the text. Soricut and Marcu (2006) uses tree structures called WIDL-expressions (the acronym corresponds to four operations akin to the rewrite rules of a grammar) to represent the realization process, and, like our approach, operates in a log-linear framework. Belz (2008) and Belz and Kow (2009) also perform surface realization from a PCFG-like grammar. Lu et al. (2009) uses a conditional random field model over trees. Other authors have performed surface realization using various grammar formalisms, for instance CCG (White et al., 2007), HPSG (Nakanishi et al., 2005), and LFG (Cahill and van Genabith, 2006).

In each of the above cases, the decomposable structure of the tree/grammar enables tractability. However, we saw that it was important to include features that captured long-range dependencies. Our model is also similar in spirit to Ratnaparkhi (2002) in the use of non-local features, but we operate at three levels of hierarchy to include both content selection and surface realization.

One issue that arises with long-range dependencies is the lack of efficient algorithms for finding the optimal text. Koller and Striegnitz (2002) perform surface realization of a flat semantics, which is NP-hard, so they recast the problem as non-projective dependency parsing. Ratnaparkhi (2002) uses beam search to find an approximate solution. We found that a greedy approach obtained better results than beam search; Belz (2008) found greedy approaches to be effective as well.

7 Conclusion

We have developed a simple yet powerful generation system that combines both content selection and surface realization in a domain independent way. Despite our approach being domain-independent, we were able to obtain performance comparable to the state-of-the-art across three domains. Additionally, the feature-based design of our approach makes it easy to incorporate domain-specific knowledge to increase performance even further.

Abstract

The task of selecting information and rendering it appropriately appears in multiple contexts in summarization. In this paper we present a model that simultaneously optimizes selection and rendering preferences. The model operates over a phrase-based representation of the source document which we obtain by merging PCFG parse trees and dependency graphs. Selection preferences for individual phrases are learned discriminatively, while a quasi-synchronous grammar (Smith and Eisner, 2006) captures rendering preferences such as paraphrases and compressions. Based on an integer linear programming formulation, the model learns to generate summaries that satisfy both types of preferences, while ensuring that length, topic coverage and grammar constraints are met. Experiments on headline and image caption generation show that our method obtains state-of-the-art performance using essentially the same model for both tasks without any major modifications.

1 Introduction

Summarization is the process of condensing a source text into a shorter version while preserving its information content. Humans summarize on a daily basis and effortlessly, yet the automatic production of high-quality summaries remains a challenge.

Most work today focuses on *extractive summarization*, where a summary is created by identifying and subsequently concatenating the most important sentences in a document. The advantage of this approach is that it does not require a great deal of linguistic analysis to generate grammatical sentences, assuming the source document was well written. Unfortunately, extracts generated this way are often documents of low readability and text quality, and contain much redundant information. The conciseness can be improved when sentence extraction is interfaced with *sentence compression*, where words and clauses are deleted based on rules typically operating over parsed input (Jing, 2000; Daumé III and Marcu, 2002; Lin, 2003; Daumé III, 2006; Zajic et al., 2007; Martins and Smith, 2009).

An alternative *abstractive* or "bottom-up" approach involves identifying high-interest words and phrases in the source text, and combining them into new sentences guided by a language model (Banko et al., 2000; Soricut and Marcu, 2007). This approach has the potential to work well, breaking out of the single-sentence paradigm. Unfortunately, the resulting summaries are not always coherent — individual constituent phrases are often combined without any semantic constraints — or grammatical beyond the *n*-gram horizon imposed by the language model.

Constituent deletion and recombination are merely two of the many rewrite operations professional editors and abstractors employ when creating summaries (Jing, 2002). Additional operations include truncating sentences, aggregating them, and paraphrasing at word or syntax level. Furthermore, professionals write summaries in a task-specific style. News headlines for example are typically short (three to six words), written in the present tense and active voice, and often leave out forms of the verb *be*. There are also different ways of writing a headline either *directly* by stating what the docu-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 513–523,
MIT, Massachusetts, USA, 9-11 October 2010.

ment is about or *indirectly* by raising a question in the reader's mind, which the document answers.

The automatic generation of summaries similar to those produced by human abstractors is challenging because of the many constraints imposed by the task: the summary must be maximally informative and minimally redundant, grammatical, coherent, adhere to a pre-specified length and stylistic conventions. Importantly, these constraints are conflicting; the deletion of certain phrases may avoid redundancy but result in ungrammatical output and information loss.

In this paper we propose a model for summarization that attempts to capture and optimize these constraints jointly. We learn both how to select the most important information (the content), and how to render it appropriately (the style). Selection preferences are learned discriminatively, while a quasi-synchronous grammar (QG, Smith and Eisner 2006) captures rendering preferences such as paraphrases and compressions. The entire solution space of possible extractions and QG-generated paraphrases is searched efficiently through use of integer linear programming. The ILP framework allows us to model naturally as constraints, additional requirements such as sentence length, overall summary length, topic coverage and, importantly, grammaticality.

We argue that QG is attractive for describing rewrite operations common in summarization. Rather than assuming a strictly synchronous structure over the source and target sentences, QG identifies a "sloppy" alignment of parse trees assuming that the target tree is in some way "inspired by" the source tree. A key insight in our approach is to formulate the summarization problem at the *phrase* level: both QG rules and information extraction operate over individual phrases rather than (as is the norm) sentences. At this smaller unit level, QG rules become more widely applicable and compression falls naturally because only phrases deemed important should appear in the summary.

We evaluate the proposed model on headline generation and the related task of image caption generation. However, there is nothing inherent in our formulation that is specific to those two tasks; it is possible for the model to generate longer or shorter summaries, for a single or multiple documents. Experimental results show that our method obtains state-of-the-art performance, both in terms of grammaticality and informativeness for both tasks using the same summarization model.

2 Related work

Much effort in automatic summarization has been devoted to sentence extraction which is often formalized as a classification task (Kupiec et al., 1995). Given appropriately annotated training data, a binary classifier learns to predict for each document sentence if it is worth extracting. A few previous approaches have attempted to interface sentence compression with summarization. A straightforward way to achieve this is by adopting a two-stage architecture (e.g., Lin 2003) where the sentences are first extracted and then compressed or the other way round.

Other work implements a *joint* model where words are deleted and sentences selected from a document simultaneously (Daumé III and Marcu, 2002; Martins and Smith, 2009; Woodsend and Lapata, 2010). ILP models have also been developed for sentence rather than document compression (Clarke and Lapata, 2008). Dras (1999) discusses the application of ILP to reluctant paraphrasing, i.e., the task of choosing between paraphrases while conforming to length, readability, or style constraints. Again, the aim is to rewrite text without, however, content selection. Rewrite operations other than deletion tend to be hand-crafted and domain specific (Jing and McKeown, 2000). Notable exceptions are Cohn and Lapata (2008) and Zhao et al. (2009) who present a model that can both compress and paraphrase individual sentences without however generating document-level summaries.

Headline generation is a well-studied task within single-document summarization, due to its prominence in the DUC-03 and DUC-04 evaluation competitions.[1] Many approaches identify the most informative sentence in a given document (typically the first sentence for the news genre) and subsequently apply a form of sentence compression such that the headline meets some length requirement (Dorr

[1] Approaches to headline generation are too numerous to list in detail; see the proceedings of DUC-03 and DUC-04 for an overview.

et al., 2003). The compressed sentence may also be "padded" with important content words or phrases to ensure that the topic of the document is covered (Zajic et al., 2004). Other work generates headlines in a bottom-up fashion starting from important, individual words and phrases, that are glued together to create a fluent sentence. For example, Banko et al. (2000) draw inspiration from Machine Translation and generate headlines using statistical models for content selection and sentence realization.

Relatively little work has focused on caption generation, a task related to headline generation. The aim here is to create a short, title-like description of an image embedded in a news article. Like headlines, captions have to be short and informative. In addition, a good caption must clearly identify the subject of the picture and establish its relevance to the article. Feng and Lapata (2010a) develop extractive and abstractive caption generation models that operate over the output of a probabilistic image annotation model that preprocesses the pictures and suggests keywords to describe their content. Their best model is an extension of Banko et al.'s (2000) word-based model for headline generation to phrases.

Our own work develops an ILP-based summarization model with rewrite operations that are not limited to deletion, are defined over phrases, and encoded in quasi-synchronous grammar. The QG formalism has been previously applied to parser adaptation and projection (Smith and Eisner, 2009), paraphrase identification (Das and Smith, 2009), and question answering (Wang et al., 2007); however the use of QG in summarization is novel to our knowledge. Unlike most synchronous grammar formalisms, QG does not posit a strict isomorphism between a source sentence and its target translation; it only loosely links the syntactic structure of the two, and is therefore well suited to describing the relationship between a document and its abstract. We propose an ILP formulation which not only allows to efficiently search through the space of many QG rules but also to incorporate constraints relating to content, style, and the task at hand.

3 Modeling

There are three components to our model. Content selection is performed discriminatively; an SVM learns which information in the source document should be in the summary, and gives a real-valued *salience score* for each phrase. QG rules are used to generate compressions and paraphrases of the source sentences. An ILP model combines the output of these two components into an output summary, while optimizing content selection and surface realization preferences jointly.

3.1 Document Representation

Our model operates on documents annotated with syntactic information which we obtain by parsing every sentence twice, once with a phrase structure parser and once with a dependency parser. The output from the two representations is combined into a single data structure, by mapping the dependencies to the edges of the phrase structure tree. The procedure is described in detail in Woodsend and Lapata (2010). However, we do not merge the leaf nodes into phrases here, but keep the full tree structure, as we will apply compression to phrases through the QG. In our experiments, we obtain this combined representation from the output of the Stanford parser (Klein and Manning, 2003) but any other broadly similar parser could be used instead.

3.2 Quasi-synchronous grammar

Given an input sentence S1 or its parse tree T1, the QG constructs a monolingual grammar for parsing, or generating, the possible translation (or here, paraphrase) trees T2. A grammar node in the target tree T2 is modeled on a subset of nodes in the source tree, with a rather loose alignment between the trees.

In our approach, the process of learning the grammar is unsupervised. Each sentence of the source document is compared to each sentence in the target document — headline or caption, depending on the task. Using the combined PCFG-dependency tree representation described above, we build up a list of leaf node alignments based on lexical identity, after stemming and removing stop words. We align direct parent nodes where more than one child node aligns. A grammar rule is created if the all the nodes in the target tree can be explained using nodes from the

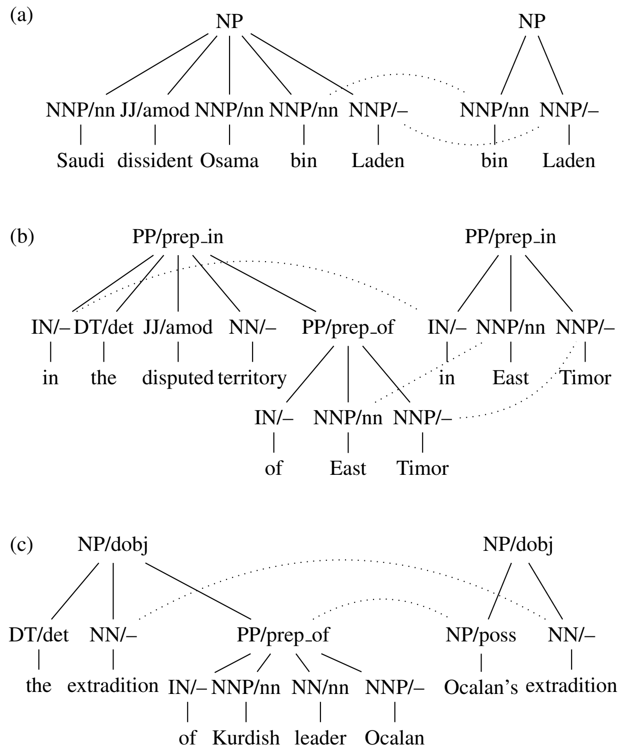

Figure 1: Examples of QG alignments between source node (left) and target node (right). (a) alignment of child nodes, involving compression through deletion; (b) rewriting involving child and grandchild nodes; (c) reordering of child nodes (with further compression through applying other QG rules on children). Nodes bear phrase and dependency labels. Dotted lines show alignments in the grammar between source and target child nodes. Examples are taken from the QG rules discovered in the DUC-03 data set of headlines.

source; this helps to improve the quality in what is inherently a noisy process. Finally, QG rules are created from aligned nodes above the leaf node level, recording the phrase and dependency label of nodes, and the alignment of child nodes.

Unlike previous work involving QG which has used dependency graphs exclusively (e.g., Wang et al. 2007; Das and Smith 2009), our approach operates over a combined PCFG-dependency representation. As a result, some configurations in Smith and Eisner (2006) are not so relevant here — instead, we found that deletions, reorderings, flattening of nodes, and the addition of text elements were important operations for the grammar.

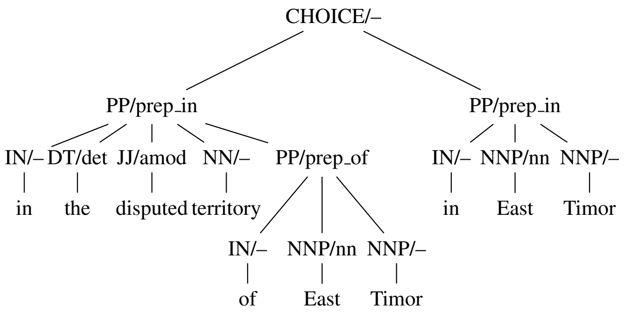

Figure 2: Alternative paraphrases are represented as a CHOICE sub-tree.

Figure 1 shows some example alignments that are captured by the QG, with the source node on the left and the target node on the right. Leaf nodes have their original text, while other nodes have a combined phrase and dependency label that they obtain in the merged representation described in Section 3.1 above (e.g., NP/dobj is a noun phrase and a direct object, NNP/nn is a proper noun and a nominal modifier, whereas NN/– is a head noun). Alignments between the children are shown by dotted lines. In Figure 1(a), some child nodes are aligned while others are not present in the target tree. This type of rule is common in our training data, and typically arises from the compression of names in noun phrases. Another frequent compression, shown in Figure 1(b), is flattening the tree structure by incorporating grand-child elements at the child level. Figure 1(c) shows a rule involving the reordering of child nodes, and where additional rules are applied recursively to achieve further compression and a transformation in the phrase constituency.

Paraphrases are created from source sentence parse trees by applying suitable rules recursively. Suitable rules have matching structure in terms of phrase and dependency label, for both the parent and child nodes. Additionally, the proposed paraphrase sub-tree must be suitable for the target tree being created (i.e., the root node of the paraphrase must match the phrase and dependency label of the corresponding node in the target tree). Where more than one paraphrase is possible, the alternatives are incorporated into the target parse tree under a *CHOICE* node, as is shown in Figure 2. Note that unlike previous QG approaches, we do not use the probability model proposed by Smith and Eisner (2006); instead the QG is used to represent rewrite operations, and we simply record a frequency count for how often each rule is encountered in the training data.

3.3 ILP model

The objective of our model is to create the most informative text possible, subject to constraints which can be tailored to the specific task. These relate to sentence length, overall summary length, the inclusion of specific topics, and grammaticality. These constraints are *global* in their scope, and cannot be adequately satisfied by optimizing each one of them individually. Our approach therefore uses an ILP formulation which will provide a globally optimal solution, and which can be efficiently solved using standard optimization tools. Specifically, the model selects phrases and paraphrases from which to form the output sentence. Here, we focus on a single sentence as this is most appropriate for title generation. However, multi-sentence output can be easily generated by setting a summary length constraint. The model operates over the merged phrase structure trees described in Section 3.1, augmented with paraphrase choice nodes such as shown in Figure 2 rather than raw text.

Let $\mathcal{S}$ be the set of sentences in a document, $\mathcal{P}$ be the set of phrases, and $\mathcal{P}_s \subset \mathcal{P}$ be the set of phrases in each sentence $s \in \mathcal{S}$. Let the sets $\mathcal{D}_i \subset \mathcal{P}, \forall i \in \mathcal{P}$ capture the phrase dependency information for each phrase i, where each set $\mathcal{D}_i$ contains the phrases that depend on the presence of i. In a similar fashion, $\mathcal{C} \subset \mathcal{P}$ is the set of choice nodes throughout the document, which represent nodes in the tree where more than one QG rule can be applied; $\mathcal{C}_i \subset \mathcal{P}, i \in \mathcal{C}$ are the sets of phrases that are direct children of each choice node, in other words they are the individual alternative paraphrases. Let l_i be the length of each phrase i, in tokens.

For caption generation, the model has as additional input a list of tags (keywords drawn from the source document) that correspond to the image, and we refer to this set of tags as $\mathcal{T}$. $\mathcal{P}_t \subset \mathcal{P}$ is the set of phrases containing the tag $t \in \mathcal{T}$. We use the probabilistic image annotation model of Feng and Lapata (2010a) to generate the list of keywords. The latter highlight the objects depicted in the image and should be in all likelihood included in the caption.

The model is cast as an integer linear program:

$$\begin{aligned}
\max_{x} \quad & \sum_{i \in \mathcal{P}} (f_i + \lambda g_i) x_i && && \text{(1a)}\\
\text{s.t.} \quad & \sum_{i \in \mathcal{P}} l_i x_i \leq L_{max} && && \text{(1b)}\\
& \sum_{i \in \mathcal{P}} l_i x_i \geq L_{min} && && \text{(1c)}\\
& \sum_{i \in \mathcal{P}_t, t \in \mathcal{T}} x_i \geq T_{min} && && \text{(1d)}\\
& x_j \rightarrow x_i && \forall i \in \mathcal{P}, j \in \mathcal{D}_i && \text{(1e)}\\
& \sum_{j \in \mathcal{C}_i} x_j = x_i && \forall i \in \mathcal{C}, j \in \mathcal{C}_i && \text{(1f)}\\
& x_i \rightarrow y_s && \forall s \in \mathcal{S}, i \in \mathcal{P}_s && \text{(1g)}\\
& \sum_{s \in \mathcal{S}} y_s \leq N_S && && \text{(1h)}\\
& x_i \in \{0,1\} && \forall i \in \mathcal{P} && \text{(1i)}\\
& y_s \in \{0,1\} && \forall s \in \mathcal{S}. && \text{(1j)}
\end{aligned}$$

A vector of binary variables $x \in \{0,1\}^{|\mathcal{P}|}$ indicates if each phrase is to be part of the output. The vector of auxiliary binary variables $y \in \{0,1\}^{|\mathcal{S}|}$ indicates from which sentences the chosen phrases come, see Equation (1g).

Our objective function (1a) is the weighted sum of two components for each phrase: a salience score, and a measure of how frequently the QG rule was seen in the training data. Let f_i denote the salience score for phrase i, determined by the machine learning algorithm. We apply a paraphrase penalty g_i to each phrase,

$$g_i = \log\left(\frac{n_r}{N_r}\right),$$

where n_r is a count of the number of times this particular QG rule r was seen in the training data, and N_r is the number of times all suitable rules for this phrase node were seen. If no suitable rules exist, we set $g_i = 0$. The intuition here is that common paraphrases should be more trustworthy, and thus are given a smaller penalty than rare ones. Paraphrase penalties are weighted by the constant parameter λ. which controls the amount of paraphrasing we allow in the output. The objective function is the sum of the salience scores and paraphrase penalties of all the phrases chosen to form the output of a given document, subject to the constraints in Equations (1b)–(1j). The latter provide a natural way of describing the requirements the output must meet.

Constraints (1b) and (1c) ensure that the generated output stays within the acceptable length range of (L_{min}, L_{max}) tokens. Equation (1d) is a set-covering constraint, requiring that at least T_{min} words in $\mathcal{T}$ appear in the output. This is important where we want to focus on some aspect of the source document, for instance on the subject of an image.

Constraint (1e) ensures that the phrase dependencies are respected and thus enforces grammatical correctness. Phrases that depend on phrase i are contained in the set $\mathcal{D}_i$. Variable x_i is true, and therefore phrase i will be included, if any of its dependents $x_j \in \mathcal{D}_i$ are true. The phrase dependency constraints, contained in the set $\mathcal{D}_i$ and enforced by (1e), are the result of three principles based on the typed dependency information:

1. Where the QG provides alternative paraphrases, it makes sense of course to select only one. This is controlled by constraint (1f), and by placing all paraphrases in the set $\mathcal{D}_i$ for the choice node i.

2. Where there are no applicable QG rules to guide the model, in general we require all child nodes j of the current node i to be included in the summary if node i is included. As exceptions, we allow the subtree represented by node j to be deleted if the dependency label for the connecting edge $i \rightarrow j$ is of type *advcl* (adverbial clause) or some form of *conj* (conjunction).

3. In general, we force the parent node p of the current node i to be included in the output if i is, resulting in all ancestors up to the root node being included. We allow a break, and the subtree at i to be used as a stand-alone sentence, if the PCFG parser has marked i with an S (sentence) label.

Constraint (1g) tells the ILP to output a sentence if one of its constituent phrases is chosen. Finally, (1h) limits the output to a maximum of N_S sentences.

4 Experimental Set-up

As mentioned earlier we evaluated the performance of our model on two title generation tasks, namely headline and caption generation. In this section we give details on the corpora and grammars we used, model parameters and features. We also describe the baselines used for comparison with our approach, and explain how system output was evaluated.

Training We obtained phrase-based salience scores using a supervised machine learning algorithm. For the headline generation task, the full DUC-03 (Task 1) corpus was used for training; it contains 500 documents and 4 headline-style summaries per document. For the captions, training data was gathered from the CNN news website.[2] We used 200 documents and their corresponding captions. Sentences were first tokenized to separate words and punctuation, and then parsed to obtain phrases and dependencies as described in Section 3 using the Stanford parser (Klein and Manning, 2003). Document phrases were marked as positive or negative automatically. If there was a unigram overlap (excluding stop words) between the phrase and any of the original title or caption, we marked this phrase with a positive label. Non-overlapping phrases were given negative labels.

Our feature set comprised surface features such as sentence and paragraph position information, POS tags, and whether high-scoring tf.idf words were present in the phrase. Additionally, the caption training set contained features for unigram and bigram overlap with the title. We learned the feature weights with a linear SVM, using the software SVM-OOPS (Woodsend and Gondzio, 2009). This tool gave us directly the feature weights as well as support vector values, and it allowed different penalties to be applied to positive and negative misclassifications, enabling us to compensate for the unbalanced data set. The penalty hyper-parameters chosen were the ones that gave the best F-scores, using 10-fold validation.

For each of the two tasks, QG rules were extracted from the same data used to train the SVM, resulting in 2,910 distinct rules for headlines and 2,757 rules for the captions. Table 1 shows that for both tasks, the majority of rules apply to PP and NP phrases. Both tasks involve considerable compression, but the proportions of the rewrite operations involved indicate differences in style between them. Compared

(b) Captions

Table 1: QG rules generated for (a) headline and (b) caption tasks (top 4 labels shown). The columns show label of root node, proportion of the full ruleset, then the proportions of rules for this label involving no modification, deletions, insertions and re-orderings.

to headlines, captions involve slightly less deletion and a higher proportion of the phrases are unmodified. The QG learning mechanism also discovers more alignments between source sentences and captions than it does for the headline task.

Title generation For the headline generation task, we evaluated our model on a testing partition from the DUC-04 corpus (75 documents, Task 1). For the caption task, we used the test set (240 documents) described in Feng and Lapata (2010a). Their corpus was downloaded from the BBC news site and contains documents, images, and their captions.[3]

We created and solved an ILP for each document. For each phrase, features were extracted and salience scores calculated from the feature weights determined through SVM training. The distance from the SVM hyperplane represents the salience score. Parameters for the ILP models for the two tasks are shown in Table 2. The λ parameter was set to 0.2 to ensure that paraphrases were included; other parameters were chosen to capture the properties seen in the majority of the training set. Note the maximum number of sentences allowed to form a headline is set to 5 as some of the headlines in the DUC dataset contained multiple sentences.

Parameter		Headlines	Captions
Min length	L_{min}	8	8
Max length	L_{max}	16	20
Min keywords	T_{min}	0	2
Max sentences	N_S	5	1
Paraphrase	λ	0.2	0.1

Table 2: ILP model parameters for the two tasks.

To solve the ILP model we used the ZIB Optimization Suite software (Achterberg, 2007; Koch, 2004). The solution was converted into a sentence by removing nodes not chosen from the tree representation, then concatenating the remaining leaf nodes in order.

Model Comparison For the headline task, we compared our model to the DUC-04 standard baseline of the first sentence, truncated at the first word boundary after 75 characters; and the output of the Topiary system (Zajic et al., 2004), which came top in almost all measures in the DUC-04 evaluation. In order to generate a headline, Topiary first compresses the lead sentence using linguistically motivated heuristics and then enhances it with topic keywords. For the captions, we compared our model against the highest-scoring document sentence according to the SVM and against the probabilistic model presented in Feng and Lapata (2010a). The latter estimates the probability of a phrase appearing in the caption given the same phrase appearing in the corresponding document and uses a language model to select among many different surface realizations. The language model is adapted with probabilities from an image annotation model (Feng and Lapata, 2010b).

Evaluation We evaluated the quality of the headlines using ROUGE (Lin and Hovy, 2003). The DUC-04 dataset provides four reference headlines per document. We report unigram overlap (ROUGE-1) and bigram overlap (ROUGE-2) as a means of assessing informativeness, and the longest common subsequence (ROUGE-L) as a means of as-

[3] Available from `http://homepages.inf.ed.ac.uk/s0677528/data.html`.

sessing fluency. Original DUC-04 ROUGE parameters were used. We also use ROUGE to evaluate the automatic captions with the original BBC captions as reference.

In addition, we evaluated the generated headlines by eliciting human judgments. Participants were presented with a news article and its corresponding headline and were asked to rate the latter along two dimensions: informativeness (does the headline capture the article's most important information?), and grammaticality (is it fluent and easy to understand?). The subjects used a seven point rating scale; an ideal system would receive high numbers for both measures. We randomly selected twelve documents from the test set and generated headlines with our model. We also included the output of Topiary and the human written DUC-04 headlines as a gold standard. We thus obtained ratings for 48 (12 × 4) document-highlights pairs.

We elicited judgments for the generated captions in a similar fashion. Participants were presented with a document, an associated image, and its caption, and asked to rate the latter (using a 1–7 rating scale) with respect to grammaticality and informativeness (does it describe succinctly the content of the image and document?). Again, we randomly selected 12 document-image pairs from the test set and generated captions for them using the highest scoring document sentence according to the SVM, our ILP-based model, and the output of Feng and Lapata's (2010a) system. We also included the original BBC captions as an upper bound. Both studies were conducted over the Internet using WebExp (Keller et al., 2009). 80 unpaid volunteers rated the headlines and 65 the captions, all self reported native English speakers.

5 Results

We report results on the headline generation task in Figure 3, with ROUGE-1, ROUGE-2 and ROUGE-L. In ROUGE-1 and ROUGE-L measures, the best scores are obtained by the Topiary system, slightly better than the lead sentence baseline, while for ROUGE-2 the ordering is reversed. Our model does not outperform the lead sentence or Topiary. Note that the 95% confidence level intervals reported by ROUGE are so large that no results are statistically

significant. We also investigated using an ILP model with just the QG rules or just dependency label information (see constraint (1e) in Section 3.3). Both settings gave less compressed output, and the resulting ROUGE scores were lower on all measures. The ROUGE results for the caption generation task follow a similar pattern (see Figure 4). Our model is slightly better than the best sentence baseline but performs worse than Feng and Lapata (2010a). Tables 3 and 4 show example output for the ILP model and the baselines on the headline and caption tasks respectively. In the tables, *Source* refers to the sentence chosen by the ILP, but before any paraphrasing is applied. We can see that deletion rules dominate, and a more compressive style of paraphrasing has been learned for the headline task.

The results of our human evaluation study for the DUC-04 headlines are summarized in Table 5. Means differences were compared using a Post-hoc Tukey test. The headlines created by our model were considered significantly more important and more grammatical than those of the Topiary system ($\alpha < 0.01$), despite the better overlap of Topiary with the reference headlines as indicated in the Rouge results above. Compared to the lead sentence of the article (the DUC-04 baseline), our model was also rated significantly higher in terms of importance ($\alpha < 0.01$) but not grammaticality.

Table 6 summarizes the results of our second judgment elicitation study. The captions generated by our model are significantly more grammatical than those of Feng and Lapata (2010a) ($\alpha < 0.01$). The SVM, ILP model and reference captions do not differ significantly in terms of grammaticality. In terms of importance, the ILP model is significantly better than the SVM ($\alpha < 0.01$) and Feng and Lapata ($\alpha < 0.01$) and comparable to the reference.

The human ratings are more favorable to our model than ROUGE for both tasks. There are two reasons for this. Firstly, the model is not biased towards selecting the lead sentence as a headline/caption and is disadvantaged in ROUGE evaluations as professional abstractors often reuse the lead or parts of it to create a title. Secondly, the model often generates an appropriate title that is lexically distinct from the reference even though it expresses similar meaning.

6 Conclusions

In this paper we proposed a joint content selection and surface realization model for single-document summarization. The model operates over a syntax-rich representation of the source document and learns which phrases should be in the summary. Content selection preferences are coupled with a quasi-synchronous grammar whose rules encode surface realization preferences (e.g., paraphrases and compressions). Both types of preferences are optimized simultaneously in an integer linear program subject to grammaticality, length and coverage constraints. Importantly, the QG allows the model to adapt to the writing and stylistic conventions of different tasks. The results of our human studies show that our system creates grammatical and informative summaries whilst outperforming several competitive baselines.

The model itself is relatively simple and achieves good performance without any task-specific modification. One potential stumbling block may be the availability of parallel data for acquiring the QG. The Internet provides a large repository of news documents with headlines, images and captions. In some cases news articles are even accompanied with "story highlights" which could be used as training data for longer summaries.[4] For other domains obtaining such data may be more difficult. However, our experiments have shown that relatively small parallel corpora (in the range of 200–500 pairs) suffice to learn many of the writing conventions for a given task.

In the future, we plan to explore how to integrate more sophisticated QG rules in the generation process. Currently we consider deletions, reorderings and insertions. Ideally, we would also like to model arbitrary substitutions between words but also larger constituents (e.g., subclauses, sentence aggregation). Beyond summarization, we would also like to apply our model to other generation tasks, such as paraphrasing and text simplification.

Acknowledgments We are grateful to David Chiang and Noah Smith for their input on earlier versions of this work. We would also like to thank Andreas Grothey and members of ICCS at the School of Informatics for valuable discussions and comments. Abstract

We employ statistical methods to analyze, generate, and translate rhythmic poetry. We first apply unsupervised learning to reveal word-stress patterns in a corpus of raw poetry. We then use these word-stress patterns, in addition to rhyme and discourse models, to generate English love poetry. Finally, we translate Italian poetry into English, choosing target realizations that conform to desired rhythmic patterns.

1 Introduction

When it comes to generating creative language (poems, stories, jokes, etc), people have massive advantages over machines:

- people can construct grammatical, sensible utterances,
- people have a wide range of topics to talk about, and
- people experience joy and heart-break.

On the other hand, machines have some minor advantages:

- a machine can easily come up with a five-syllable word that starts with *p* and rhymes with *early*, and
- a machine can analyze very large online text repositories of human works and maintain these in memory.

In this paper we concentrate on statistical methods applied to the analysis, generation, and translation of poetry. By analysis, we mean extracting patterns from existing online poetry corpora. We use these patterns to generate new poems and translate existing poems. When translating, we render target text in a rhythmic scheme determined by the user.

Poetry generation has received research attention in the past (Manurung et al., 2000; Gervas, 2001; Diaz-Agudo et al., 2002; Manurung, 2003; Wong and Chun, 2008; Tosa et al., 2008; Jiang and Zhou, 2008; Netzer et al., 2009), including the use of statistical methods, although there is a long way to go. One difficulty has been the evaluation of machine-generated poetry—this continues to be a difficulty in the present paper. Less research effort has been spent on poetry analysis and poetry translation, which we tackle here.

2 Terms

Meter refers to the rhythmic beat of poetic text when read aloud. Iambic is a common meter that sounds like *da-DUM da-DUM da-DUM*, etc. Each *da-DUM* is called a foot. Anapest meter sounds like *da-da-DUM da-da-DUM da-da-DUM*, etc.

Trimeter refers to a line with three feet, pentameter to a line with five feet, etc. Examples include:

- a VE-ry NAS-ty CUT (iambic trimeter)
- shall I com-PARE thee TO a SUM-mer's DAY? (iambic pentameter)
- twas the NIGHT before CHRIST-mas and ALL through the HOUSE (anapest tetrameter)

Classical English sonnets are poems most often composed of 14 lines of iambic pentameter.

3 Analysis

We focus on English rhythmic poetry. We define the following analysis task: *given poetic lines in a known meter (such as sonnets written in iambic pentameter), assign a syllable-stress pattern to each word in each line*. Making such decisions is part of the larger task of reading poetry aloud. Later in the paper, we will employ the concrete statistical tables from analysis to the problems of poetry generation and translation.

We create a test set consisting of 70 lines from Shakespeare's sonnets, which are written in iambic pentameter. Here is an input line annotated with gold output.

```
shall i compare thee to a summers day
|     |    /\    |    |  |   /\     |
S     S*  S  S* S    S* S  S* S    S*
```

S refers to an unstressed syllable, and S* refers to a stressed syllable. One of the authors created gold-standard output by listening to Internet recordings of the 70 lines and marking words according to the speaker's stress. The task evaluation consists of *per-word accuracy* (how many words are assigned the correct stress pattern) and *per-line accuracy* (how many lines have all words analyzed perfectly).

This would seem simple enough, if we are armed with something like the CMU pronunciation dictionary: we look up syllable-stress patterns for each word token and lay these down on top of the sequence S S* S S* S S* S S* S S*. However, there are difficulties:

- The test data contains many words that are unknown to the CMU dictionary.
- Even when all words are known, many lines do not seem to contain 10 syllables. Some lines contain eleven words.
- Spoken recordings include stress reversals, such as poin-TING instead of POIN-ting.
- Archaic pronunciations abound, such as PROV-ed (two syllables) instead of PROVED (one syllable).
- In usage, syllables are often subtracted (PRIS-ner instead of PRIS-o-ner), added (SOV-e-reign instead of SOV-reign), or merged.
- Some one-syllable words are mostly stressed, and others mostly unstressed, but the dictionary provides no guidance. When we generate rhythmic text, it is important to use one-syllable words properly. For example, we would be happy for an iambic generator to output *big thoughts are not quite here*, but not *quite big thoughts are not here*.

$$\text{e} \rightarrow \boxed{\text{P}(m|e)} \rightarrow \text{m}$$

Figure 1: Finite-state transducer (FST) for mapping sequences of English words (e) onto sequences of S* and S symbols (m), representing stressed and unstressed syllables.

Therefore, we take a different tack and apply unsupervised learning to acquire word-stress patterns directly from raw poetry, without relying on a dictionary. This method easily ports to other languages, where dictionaries may not exist and where morphology is a severe complication. It may also be used for dead languages.

For raw data, we start with all Shakespeare sonnets (17,134 word tokens). Because our learning is unsupervised, we do not mind including our 70-line test set in this data (*open testing*).

Figures 1 and 2 show a finite-state transducer (FST) that converts sequences of English words to sequences of S* and S symbols. The FST's transitions initially map each English word onto all output sub-sequences of lengths 1 to 4 (i.e., S, S*, S-S, S-S*, S*-S, S*-S*, S-S-S, . . .) plus the sequences S-S*-S-S*-S and S*-S-S*-S-S*. Initial probabilities are set to 1/32. The FST's main loop allows it to process a sequence of word tokens. If the same word appears twice in a sequence, then it may receive two different pronunciations, since the mapping is probabilistic. However, a token's syllable/stress pattern is chosen independently of other tokens in the sequence; we look at relaxing this assumption later.

We next use finite-state EM training[1] to train the machine on input/output sequences such as these:

```
from fairest creatures we desire increase
S S* S S* S S* S S* S S*

but thou contracted to thine own bright eyes
S S* S S* S S* S S* S S*
```

[1] All operations in this paper are carried out with the generic finite-state toolkit Carmel (Graehl, 1997). For example, the *train-cascade* command uses EM to learn probabilities in an arbitrary FST cascade from end-to-end input/output string pairs.

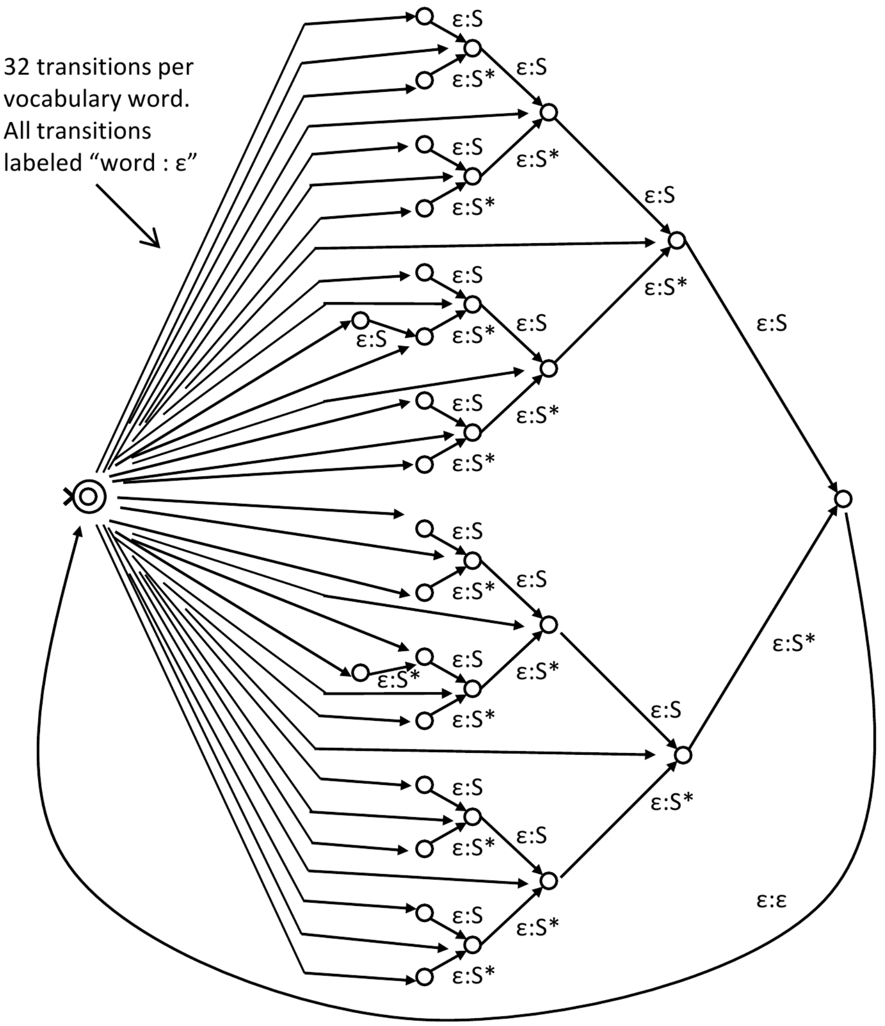

Figure 2: An efficient FST implementing P($m|e$). This machine maps sequences of English words onto sequences of S* and S symbols, representing stressed and unstressed syllables. Initially every vocabulary word has 32 transitions, each with probability 1/32. After EM training, far fewer transitions remain.

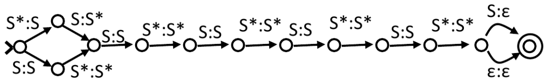

Figure 3: An FST that accepts any of four input meters and deterministically normalizes its input to strict iambic pentameter. We call this FST *norm*.

$$e \rightarrow \boxed{\mathrm{P}(m|e)} \rightarrow \mathrm{m} \rightarrow \boxed{norm} \rightarrow \mathrm{m}$$

Figure 4: FST cascade that encodes a loose interpretation of iambic pentameter. The *norm* FST accepts any of four near-iambic-pentameter sequences and normalizes them into strict iambic pentameter.

Note that the output sequences are all the same, representing our belief that each line should be read as iambic pentameter.[2] After we train the FST, we can use Viterbi decoding to recover the highest-probability alignments, e.g.:

```
from fairest creatures we desire increase
 |     |       /| \    |    /\      /\
 S     S*     S S* S   S*  S  S*   S  S*

but thou contracted to thine own bright eyes
 |    |    /| \     |    |    |    |     |
 S    S*  S S* S    S*   S    S*   S     S*
```

Note that the first example contains an error—the words *fairest* and *creatures* should each be read with two syllables. There are many such errors. We next improve the system in two ways: more data and better modeling.

First, we augment the Shakespeare sonnets with data from the website *sonnets.org*, increasing the number of word tokens from 17,134 to 235,463. The *sonnets.org* data is noisier, because it contains some non-iambic-pentameter poetry, but overall we find that alignments improve, e.g.:

```
from fairest creatures we desire increase
 |     /\       /\     |    /\      /\
 S    S* S     S* S    S*  S  S*   S  S*
```

Second, we loosen our model. When we listen to recordings, we discover that not all lines are read S S* S S* S S* S S* S S*. Indeed, some lines in our data contain eleven words—these are unexplainable by the EM training system. We also observe that poets often use the word *mother* (S* S) at the beginnings and ends of lines, where it theoretically should not appear.

Training data	Training tokens	Test token accuracy	Test line accuracy
Shakespeare	17,134	82.3%	55.7%
sonnets.org	235,463	94.2%	81.4%

Figure 5: Analysis task accuracy.

Two well-known variations explain these facts. One is optional *inversion* of the first foot (S S* → S* S). Second is the optional addition of an eleventh unstressed syllable (the *feminine ending*). These variations yield four possible syllable-stress sequences:

```
S  S* S S* S S* S S* S S*
S* S  S S* S S* S S* S S*
S  S* S S* S S* S S* S S* S
S* S  S S* S S* S S* S S* S
```

We want to offer EM the freedom to analyze lines into any of these four variations. We therefore construct a second FST (Figure 3), $norm$, which maps all four sequences onto the canonical pattern S S* S S* S S* S S* S S*. We then arrange both FSTs in a cascade (Figure 4), and we train the whole cascade on the same input/output sequences as before. Because $norm$ has no trainable parameters, we wind up training only the lexical mapping parameters. Viterbi decoding through the two-step cascade now reveals EM's proposed internal meter analysis as well as token mappings, e.g.:

```
to be or not to be that is the question
|  |  |   |  |  |    |  |   |     /\
S  S* S   S* S  S*   S  S*  S    S* S
|  |  |   |  |  |    |  |   |    |
S  S* S   S* S  S*   S  S*  S    S*
```

Figure 5 shows accuracy results on the 70-line test corpus mentioned at the beginning of this section. Over 94% of word tokens are assigned a syllable-stress pattern that matches the pattern transcribed from audio. Over 81% of whole lines are also scanned correctly. The upper limit for whole-line scanning under our constraints is 88.6%, because 11.4% of gold outputs do not match any of the four patterns we allow.

We further obtain a probabilistic table of word mappings that we can use for generation and trans-

[2] We can augment the data with lines of poetry written in meters other than iambic pentameter, so long as we supply the desired output pattern for each input line.

```
P(S* S S* | altitude) = 1.00

P(S* S | creatures)   = 1.00

P(S* S  | pointed)    = 0.95
P(S  S* | pointed)    = 0.05

P(S* S    | prisoner) = 0.74
P(S* S S* | prisoner) = 0.26

P(S* S  | mother)     = 0.95
P(S*    | mother)     = 0.03
P(S  S* | mother)     = 0.02
```

Figure 6: Sample learned mappings between words and syllable-stress patterns.

word	P(S* | word)	P(S | word)
a	0.04	0.96
the	0.06	0.94
their	0.09	0.91
mens	0.10	0.90
thy	0.10	0.90
be	0.48	0.52
me	0.49	0.51
quick	0.50	0.50
split	0.50	0.50
just	0.51	0.49
food	0.90	0.10
near	0.90	0.10
raised	0.91	0.09
dog	0.93	0.07
thought	0.95	0.05

Figure 7: Sample mappings for one-syllable words.

lation tasks. Figure 6 shows a portion of this table. Note that P(S S* | mother) has a very small probability of 0.02. We would incorrectly learn a much higher value if we did not loosen the iambic pentameter model, as many *mother* tokens occur line-initial and line-final.

Figure 7 shows which one-syllable words are more often stressed (or unstressed) in iambic pentameter poetry. Function words and possessives tend to be unstressed, while content words tend to be stressed, though many words are used both ways. This useful information is not available in typical pronunciation dictionaries.

$$\boxed{\mathrm{P}(m)} \rightarrow \mathrm{m} \rightarrow \boxed{\mathrm{P}(e|m)} \rightarrow \mathrm{e} \rightarrow \boxed{\mathrm{P}(e)} \rightarrow \mathrm{e}$$

Figure 8: Finite-state cascade for poetry generation.

Alignment errors still occur, especially in noisy portions of the data that are not actually written in iambic pentameter, but also in clean portions, e.g.:

```
the perfect ceremony of loves rite
 |     /\      /|\    |   |    /\
 S    S* S    S* S S*  S   S*  S  S*
```

The word *ceremony* only occurs this once in the data, so it is willing to accept any stress pattern. While *rite* is correctly analyzed elsewhere as a one-syllable word, *loves* prefers S*, and this overwhelms the one-syllable preference for *rite*. We can blame our tokenizer for this, as it conflates *loves* and *love's*, despite the fact that these words have different stress probabilities.

4 Generation

Figure 8 shows our concept of generation as a cascade of weighted FSTs.

P(m) is a user-supplied model of desired meters—normally it deterministically generates a single string of S* and S symbols. (The user also supplies a rhyme scheme—see below).

P($e|m$) is the reverse of Section 3's P($m|e$), being a model of word selection. Its generative story is: (1) probabilistically select n tokens (n = 1 to 5) from the input, (2) probabilistically select a word w that realizes that n-token sequence, and (3) recurse until the input is consumed. Instead of asking how a given word is likely to be pronounced (e.g., S or S*), we now ask how a given stress-pattern (e.g., S or S*) is likely to be realized. This model is trained with the same method described in Section 3 and is augmented with the CMU pronunciation dictionary.

Finally, P(e) is a word-trigram model built from a 10,000-line corpus of 105 English love poems.

We select the first line of our poem from the FST cascade's 100,000-best list, or by hand. To generate each subsequent line, we modify the cascade and run it again. The first modification is to incorporate a discourse model. From our poetry corpus, we estimate a word's unigram probability given the words on the previous line, via IBM Model 1 (Brown et al., 1993). We modify P(e) by interpolating in these probabilities. Second, we check if any previous line

```
The women of the night
Again and all the way
Like a mouse in the white
Not the heart of the day.
  - - -
Of the bed to trust me
Around her twists the string
But i will not tell thee
Fire changes everything.
  - - -
A son of the right hand confines
His uncle could have broken in
Towards the high bank and the pines
Upon the eyes and i have been
  - - -
Into one of her hundred year old
Or the house in a house in a cold
The first time she met him
Like a mouse in the dim
For me to the moon and when i told
  - - -
Into one of them some years before
His own man or the house in a more
The moon and when the day
Into one of the way
With the breath from the first time
  she swore
```

Figure 9: Sample poems generated with a weighted FST cascade.

$w_1, w_2, ...w_n$ needs to be rhymed with, according to the user-supplied scheme. If so, we build an additional FST that accepts only strings whose final word rhymes with w_n. This is a reasonable approach, though it will not, for example, rhyme *...tar me* with *...army*. We say two non-identical words rhyme if their phoneme strings share a common suffix that includes the last stressed vowel.

Figure 9 shows several poems that we automatically generate with this scheme.

5 Translation

Automatically generated poetry can sound good when read aloud, but it often has a "nonsense" feel to it. According to (Gervas, 2010), creative-language researchers interested in realization and surface language statistics ("how to say") have tended to gravitate to poetry generation, while researchers interested in characters, goals, and story-line ("what to say") have tended to gravitate to prose story generation.

Translation provides one way to tie things together. The source language provides the input ("what to say"), and the target language can be shaped to desired specifications ("how to say"). For example, we may want to translate Italian sonnets into fluent English iambic pentameter. This is certainly a difficult task for people, and one which is generally assumed to be impossible for computers.

$$\mathrm{i} \rightarrow \boxed{\mathrm{P}(e|i)} \rightarrow \mathrm{e} \rightarrow \boxed{\mathrm{P}(m|e)} \rightarrow \mathrm{m} \rightarrow \boxed{\mathrm{P}(m)} \rightarrow \mathrm{m}$$

Figure 10: Finite-state cascade for poetry translation.

Here we investigate translating Dante's *Divine Comedy* (DC) from Italian into English by machine. The poem begins:

```
nel mezzo del cammin di nostra vita
mi ritrovai per una selva oscura
che la via diritta era smarrita.
```

DC is a long sequence of such three-line stanzas (*tercets*). The meter in Italian is hendecasyllabic, which has ten syllables and ensures three beats. Dante's Italian rhyme scheme is: **ABA**, **BCB**, **CDC**, etc, meaning that lines 2, 4, and 6 rhyme with each other; lines 5, 7, and 9 rhyme with each other, and so forth. There is also internal rhyme (e.g., *diritta/smarrita*).

Because DC has been translated many times into English, we have examples of good outputs. Some translations target iambic pentameter, but even the most respected translations give up on rhyme, since English is much harder to rhyme than Italian. Longfellow's translation begins:

```
midway upon the journey of our life
i found myself within a forest dark
for the straightforward pathway had
  been lost.
```

We arrange the translation problem as a cascade of WFSTs, as shown in Figure 10. We call our Italian input i. In lieu of the first WFST, we use the statistical phrase-based machine translation (PBMT) system Moses (Koehn et al., 2007), which generates a target-language lattice with paths scored by P($e|i$). We send this lattice through the same P($m|e$) device we trained in Section 3. Finally, we filter the resulting syllable sequences with a strict, single-path, deterministic iambic pentameter acceptor, P(m).[3] Our

[3] It is also possible to use a looser iambic P(m) model, as described in Section 3.

DC-test	2,861

Figure 11: Data for Italian/English statistical translation.

finite-state toolkit's top-k paths represent the translations with the highest product of scores P($e|i$) · P($m|e$) · P(m).

In general, the P($e|i$) and P($m|e$) models fight each other in ranking candidate outputs. In experiments, we find that the P($e|i$) preference is sometimes so strong that the P($m|e$) model is pushed into using a low-probability word-to-stress mapping. This creates output lines that do not scan easily. We solve this problem by assigning a higher weight to the P($m|e$) model.[4]

Figure 11 shows the data we used to train the PBMT system. The vast majority of parallel Italian/English poetry is DC itself, for which we have four English translations. We break DC up into DC-train, DC-tune, and DC-test. We augment our target language model with English poetry collected from many sources. We also add Europarl data, which is out of domain, but which reduces the unknown word-token rate in DC-test from 9% to 6%, and the unknown word-type rate from 22% to 13%.

Original: nel mezzo del cammin di nostra vita mi ritrovai per una selva oscura che la via diritta era smarrita.
Phrase-based translation (PBMT): midway in the journey of our life i found myself within a forest dark for the straight way was lost.
PBMT + meter model: midway upon the journey of our life i found myself within a forest dark for the straightforward pathway had been lost.

Figure 12: Automatic translation of lines from Dante's *Divine Comedy*. In this test-on-train scenario, the machine reproduces lines from human translations it has seen.

We first experiment in a test-on-train scenario, where we translate parts of DC that are in our training set. This is a normal scenario in human poetry translation, where people have access to previous translations.

Figure 12 shows how we translate the first lines of DC, first using only PBMT, then using the full system. When we use the full system, we not only get an output string, but also the system's intended scan, e.g.:

```
midway upon the journey of our life
 /\     /\   |    /\    |   |   |
S  S*  S  S* S   S* S   S*  S   S*
```

The machine's translation here is the same as Longfellow's, which is in the training data. In other cases, we observe the machine combining existing translations, e.g.:

```
i:  bedi la bestia per cu io mi volsi
I5: behold the beast that made me turn aside

H1: BEHOLD THE BEAST for which i have turned back
H2: you see the beast THAT MADE ME TURN ASIDE
H3: see the beast that forced me to turn back
H4: look at the beast that drove me to turn back
```

I5 refs to the machine's iambic pentameter transla-

[4] We set this weight manually to 3.0, i.e., we raise all probabilities in the P($m|e$) model to the power of 3.0. Setting the weight too high results in lines that scan very well, but whose translation quality is low.

tion, while H1-4 refer to human translations. The machine also creates new translations:

```
i:  diro' de laltre cose chi vho scorte
I5: i shall explain the other things i saw

H1: speak will i of the other things i saw there
H2: ill also tell THE OTHER THINGS I SAW
H3: i will recount the other things i saw
H4: i here will tell the other things i saw
```

We can further change the target meter to anything we desire. To obtain iambic tetrameter (4-beat) translations, we delete the last two transitions of the P(m) model. We then get:

```
I4: in our life the journey way
    i found myself deep on dark wood
    that lost straightforward pathway had.

    ah how to say the what is hard
    this forest savage rough and stern
    the very thought renews the fear.
```

Translations and scans are uneven, but we have significant flexibility. We can even request translations that avoid the English letter A, by adding a filter to the end of the FST cascade, obtaining:

```
I5: in midst upon the journey of our life
    i found myself within the wood obscure
    <fail>
```

To steer clear of the adjective *dark* in the second line, the system switches from *forest* to *wood*, so obtain a proper scan. The third line fails because all paths through the translation lattice contain an A somewhere.

Translating blind-test data proves to be more difficult. We hold out Canto XXXI of DC's Paradiso section for testing. Figure 13 shows a portion of the translation results. The MT system handles unknown Italian words by passing them through to the output. The P($m|e$) meter model cannot process those words, accounting for the I5 failure rate.

Here, we get a first look at statistical MT translating poetry into rhythmic structures—as with all MT, there are successes and problems, and certainly more to do.

Original:

in forma dunque di candida rosa
mi si mostrava la milizia santa
che nel suo sangue cristo fece sposa

ma laltra che volando vede e canta
la gloria di colui che la nnamora
e la bonta‘ che la fece cotanta

Human translation:

in fashion then as of a snow white rose
displayed itself to me the saintly host
whom christ in his own blood had made his bride

but the other host that flying sees and sings
the glory of him who doth enamour it
and the goodness that created it so noble

Phrase-based translation (PBMT):

in the form so rose candida
i now was shown the militia holy
that in his blood christ did bride

but the other that flying sees and sings
the glory of him that the nnamora
and the goodness that the made cotanta

PBMT + meter model:

<fail>
i now was shown the holy soldiery
that in his blood he married jesus christ

but flying sees and sings the other which
<fail>
<fail>

Figure 13: Automatic translation of blind-test data from Dante's *Divine Comedy*.

6 Future Work

We plan to release all our of data in useful, processed form. Below we list directions for future research. In general, we see many interesting paths to pursue.

Analysis. Proper use of one-syllable words remains tricky. Lines coming out of generation and translation do not always scan naturally when read aloud by a person. We trace such errors to the fact that our lexical probabilities are context-independent. For example, we have:

```
P(S  | off) = 0.39
P(S* | off) = 0.61
```

When we look at Viterbi alignments from the analysis task, we see that when *off* is preceded by the word *far*, the probabilities reverse dramatically:

```
P(S  | off, after far) = 0.95
P(S* | off, after far) = 0.05
```

Similarly, the probability of stressing *at* is 40% in general, but this increases to 91% when the next word is *the*. Developing a model with context-dependent probabilities may be useful not only for improving generation and translation, but also for improving poetry analysis itself, as measured by anlaysis task accuracy.

Other potential improvements include the use of prior knowledge, for example, taking word length and spelling into account, and exploiting incomplete pronunciation dictionary information.

Generation. Evaluation is a big open problem for automatic poetry generation—even evaluating human poetry is difficult. Previous suggestions for automatic generation include acceptance for publication in some established venue, or passing the Turing test, i.e., confounding judges attempts to distinguish machine poetry from human poetry. The Turing test is currently difficult to pass with medium-sized Western poetry.

Translation. The advantage of translation over generation is that the source text provides a coherent sequence of propositions and images, allowing the machine to focus on "how to say" instead of "what to say." However, translation output lattices offer limited material to work with, and as we dig deeper into those lattices, we encounter increasingly disfluent ways to string together renderings of the source substrings.

An appealing future direction is to combine translation and generation. Rather than translating the source text, a program may instead use the source text for inspiration. Such a hybrid translation/generation program would not be bound to translate every word, but rather it could more freely combine lexical material from its translation tables with other grammatical and lexical resources. Interestingly, human translators sometimes work this way when they translate poetry—many excellent works have been produced by people with very little knowledge of the source language.

Paraphrasing. Recently, e→f translation tables have been composed with f→e tables, to make e→e tables that can paraphrase English into English (Bannard and Callison-Burch, 2005). This makes it possible to consider statistical translation of English prose into English poetry.

Abstract

We address the modeling, parameter estimation and search challenges that arise from the introduction of reordering models that capture non-local reordering in alignment modeling. In particular, we introduce several reordering models that utilize (pairs of) function words as contexts for alignment reordering. To address the parameter estimation challenge, we propose to estimate these reordering models from a relatively small amount of manually-aligned corpora. To address the search challenge, we devise an iterative local search algorithm that stochastically explores reordering possibilities. By capturing non-local reordering phenomena, our proposed alignment model bears a closer resemblance to state-of-the-art translation model. Empirical results show significant improvements in alignment quality as well as in translation performance over baselines in a large-scale Chinese-English translation task.

1 Introduction

In many Statistical Machine Translation (SMT) systems, alignment represents an important piece of information, from which translation rules are learnt. However, while translation models have evolved from word-based to syntax-based modeling, the *de facto* alignment model remains word-based (Brown et al., 1993; Vogel et al., 1996). This gap between alignment modeling and translation modeling is clearly undesirable as it often generates tensions that would prevent the extraction of many useful translation rules (DeNero and Klein, 2007). Recent work, e.g. by Blunsom et al. (2009) and Haghihi et al. (2009) just to name a few, show that alignment models that bear closer resemblance to state-of-the-art translation model consistently yields not only a better alignment quality but also an improved translation quality.

In this paper, we follow this recent effort to narrow the gap between alignment model and translation model to improve translation quality. More concretely, we focus on the reordering component since we observe that the treatment of reordering remains significantly different when comparing alignment versus translation: the reordering component in state-of-the-art translation models has focused on long-distance reordering, but its counterpart in alignment models has remained focused on local reordering, typically modeling distortion based entirely on positional information. This leaves most alignment decisions to association-based scores.

Why is employing stronger reordering models more challenging in alignment than in translation? One answer can be attributed to the fact that alignment points are unobserved in parallel text, thus so are their reorderings. As such, introducing stronger reordering often further exacerbates the computational complexity to do inference over the model. Some recent alignment models appeal to external linguistic knowledge, mostly by using monolingual syntactic parses (Cherry and Lin, 2006; Pauls et al., 2010), which at the same time, provides an approximation of the bilingual syntactic divergences that drive the reordering. To our knowledge, however, this approach has been used mainly to constrain reordering possibilities, or to add to the generalization ability of association-based scores, not to directly model reordering in the context of alignment.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 534–544,
MIT, Massachusetts, USA, 9-11 October 2010.

In this paper, we introduce a new approach to improving the modeling of reordering in alignment. Instead of relying on monolingual parses, we condition our reordering model on the behavior of *function words* and the phrases that surround them. Function words are the “syntactic glue” of sentences, and in fact many syntacticians believe that functional categories, as opposed to substantive categories like noun and verb, are primarily responsible for cross-language syntactic variation (Ouhalla, 1991). Our reordering model can be seen as offering a reasonable approximation to more fully elaborated bilingual syntactic modeling, and this approximation is also highly practical, as it demands no external knowledge (other than a list of function words) and avoids the practical issues associated with the use of monolingual parses, e.g. whether the monolingual parser is robust enough to produce reliable output for every sentence in training data.

At a glance, our reordering model enumerates the function words on both source and target sides, modeling their reordering relative to their neighboring phrases, their neighboring function words, and the sentence boundaries. Because the frequency of function words is high, we find that by predicting the reordering of function words accurately, the reordering of the remaining words improves in accuracy as well. In total, we introduce six sub-models involving function words, and these serve as features in a log linear model. We train model weights discriminatively using Minimum Error Rate Training (MERT) (Och, 2003), optimizing F-measure.

The parameters of our sub-models are estimated from manually-aligned corpora, leading the reordering model more directly toward reproducing human alignments, rather than maximizing the likelihood of unaligned training data. This use of manual data for parameter estimation is a reasonable choice because these models depend on a small, fixed number of lexical items that occur frequently in language, hence only small training corpora are required. In addition, the availability of manually-aligned corpora has been growing steadily.

The remainder of the paper proceeds as follows. In Section 2, we provide empirical motivation for our approach. In Section 3, we discuss six submodels based on function word relationships and how their parameters are estimated; these are combined with additional features in Section 4 to produce a single discriminative alignment model. Section 5 describes a simple decoding algorithm to find the most probable alignment under the combined model, Section 6 describes the training of our discriminative model and Section 7 presents experimental results for the model using this algorithm. We wrap up in Sections 8 and 9 with a discussion of related work and a summary of our conclusions.

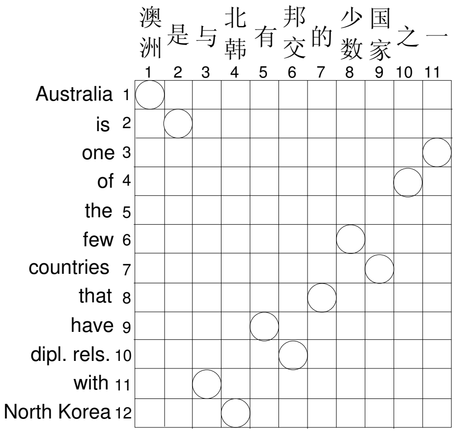

Figure 1: An aligned Chinese-English sentence pair.

2 Empirical Motivation

Fig. 1 shows an example of a Chinese-English sentence pair together with correct alignment points. Predicting the alignment for this particular Chinese-English sentence pair is challenging, since the significantly different syntactic structures of these two languages lead to non-monotone reordering. For example, an accurate alignment model should account for the fact that prepositional phrases in Chinese appear in a different order than in English, as illustrated by the movement of the phrase “与北韩/with North Korea” from the beginning of the Chinese noun phrase to the end of the corresponding English.

The central question that concerns us here is how to define and infer regularities that can be useful to predict alignment reorderings. The approach we take here is supported by empirical results from a pilot study, conducted as an inquiry into the idea of focusing on function words to model alignment reordering, which we briefly describe.

We took a Chinese-English manually-aligned corpus of approximately 21 thousand sentence pairs,

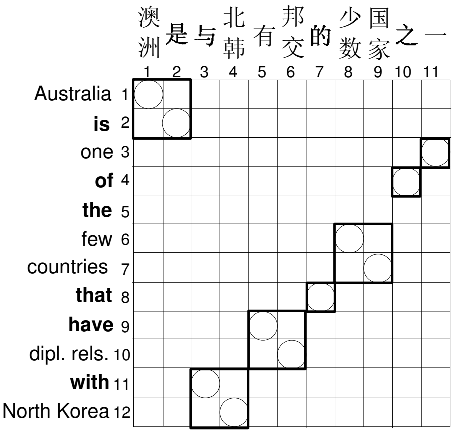

Figure 2: The all-monotone phrase pairs, indicated as rectangular areas in **bold**, that can be extracted from the Fig. 1 example.

and divided each sentence pair into *all-monotone phrase pairs*. Visually, an all-monotone phrase pair corresponds to a maximal block in the alignment matrix for which internal alignment points appear in monotone order from the top-left corner to the bottom-right corner. Fig. 2 illustrates seven such pairs that can be extracted from the example in Fig. 1. In total, there are 154,517 such phrase pairs in our manually-aligned corpus.

The alignment configuration internal to all-monotone phrase pair blocks is, obviously, monotonic, which is a configuration that is effectively modeled by traditional alignments models. On the other hand, the reordering between two adjacent blocks is the focus of our efforts since existing models are less effective at modeling non-monotonic alignment configurations. To measure the function words' potential to predict non-monotone reorderings, we examined the *border* words where two adjacent blocks meet. In particular, we are interested in how many adjacent blocks whose border words are function words.

The results of this pilot study were quite encouraging. If we consider only the Chinese side of the phrase pairs, 88.35% adjacent blocks have function words as their boundary words. If we consider only the English side, function words appear at the borders of 93.91% adjacent blocks. If we consider both the Chinese and English sides, the percentage increases to 95.53%. Notice that in Fig. 2, function words appear at the borders of *all* adjacent all-monotone phrase pairs, if both Chinese and English sides are considered. Clearly with such high coverage, function words are central in predicting non-monotone reordering in alignment.

3 Reordering with Function Words

The reordering models we describe follow our previous work using function word models for translation (Setiawan et al., 2007; Setiawan et al., 2009). The core hypothesis in this work is that function words provide robust clues to the reordering patterns of the phrases surrounding them. To make this insight useful for alignment, we develop features that score the alignment configuration of the neighboring phrases of a function word (which functions as an anchor) using two kinds of information: 1) the relative ordering of the phrases with respect to the function word anchor; and 2) the span of the phrases. This section provides a high level overview of our reordering model, which attempts to leverage this information.

To facilitate subsequent discussions, we introduce the notion of *monolingual* function word phrase FW_i, which consists of the tuple (Y_i, L_i, R_i), where Y_i is the i-th function word and L_i,R_i are its left and right neighboring phrases, respectively. Note that this notion of "phrase" is defined only for reordering purposes in our model, and does not necessarily correspond to a linguistic phrase. We define such phrases on both sides to cover as many non-monotone reorderings as possible, as suggested by the pilot study. To denote the side, we append a subscript: $FW_{i,S} = (Y_{i,S}, L_{i,S}, R_{i,S})$ refers to a function word phrase on the source side, and $FW_{i,T} = (Y_{i,T}, L_{i,T}, R_{i,T})$ to one on the target side. In our subsequent discussion, we will mainly use $FW_{i,S}$, and we will omit subscripts S or T if they are clear from context.

The primary objective of our reordering model is to predict the projection of monolingual function word phrases from one language to the other, inferring *bilingual* function word phrase pairs $FW_{i,S\rightarrow T} = (Y_{i,S\rightarrow T}, L_{i,S\rightarrow T}, R_{i,S\rightarrow T})$, which encode the two aforementioned pieces of information.[1] To infer these phrases, we take a probabilis-

[1] The subscript $S \rightarrow T$ denotes the projection direction from source to target. The subscript for the other direction is $T \rightarrow S$.

tic approach. For instance, to estimate the spans of $L_{i,S\rightarrow T}, R_{i,S\rightarrow T}$, our reordering model assumes that any span to the left of $Y_{i,S}$ is a possible $L_{i,S}$ and any span to the right of $Y_{i,S}$ is a possible $R_{i,S}$, deciding which is most probable via features, rather than committing to particular spans (e.g. as defined by a monolingual text chunker or parser). We only enforce one criterion on $L_{i,S\rightarrow T}$ and $R_{i,S\rightarrow T}$: they have to be the *maximal* alignment blocks satisfying the consistent heuristic (Och and Ney, 2004) that end or start with $Y_{i,S\rightarrow T}$ on the source S side respectively.[2]

To infer these phrases, we decompose $L_{i,S\rightarrow T}$ into $(o(L_{i,S\rightarrow T}),\ d(FW_{i-1,S\rightarrow T}),\ b(\langle s\rangle))$; similarly, $R_{i,S\rightarrow T}$ into $(o(R_{i,S\rightarrow T}),d(FW_{i+1,S\rightarrow T}),$ $b(\langle /s\rangle)$)). Taking the decomposition of $L_{i,S\rightarrow T}$ as a case in point, here $o(L_{i,S\rightarrow T})$ describes the reordering of the left neighbor $L_{i,S\rightarrow T}$ with respect to the function word $Y_{i,S\rightarrow T}$, while $d(FW_{i-1,S\rightarrow T})$ and $b(\langle s\rangle))$ probe the span of $L_{i,S\rightarrow T}$, i.e. whether it goes beyond the preceding function word phrase pairs $FW_{i-1,S\rightarrow T}$ and up to the beginning-of-sentence marker $\langle s\rangle$ respectively. The same definition applies to the decomposition of $R_{i,S\rightarrow T}$, where $FW_{i+1,S\rightarrow T}$ is the succeeding function word phrase pair and $\langle /s\rangle$ is the end-of-sentence marker.

3.1 Six (Sub-)Models

To model $o(L_{i,S\rightarrow T})$, $o(R_{i,S\rightarrow T})$, i.e. the reordering of the neighboring phrases of a function word, we employ the *orientation* model introduced by Setiawan et al. (2007). Formally, this model takes the form of probability distribution $P_{ori}(o(L_{i,S\rightarrow T}), o(R_{i,S\rightarrow T})|Y_{i,S\rightarrow T})$, which conditions the reordering on the lexical identity of the function word alignment (but independent of the lexical identity of its neighboring phrases). In particular, o maps the reordering into one of the following four orientation values (borrowed from Nagata et al. (2006)) with respect to the function word: Monotone Adjacent (MA), Monotone Gap (MG), Reverse Adjacent (RA) and Reverse Gap (RG). The Monotone/Reverse distinction indicates whether the projected order follows the original order, while the Adjacent/Gap distinction indicates whether the projections of the function word and the neighboring phrase are adjacent or separated by an intervening phrase.

To model $d(FW_{i-1,S\rightarrow T})$, $d(FW_{i+1,S\rightarrow T})$, i.e. whether $L_{i,S\rightarrow T}$ and $R_{i,S\rightarrow T}$ extend beyond the neighboring function word phrase pairs, we utilize the *pairwise dominance* model of Setiawan et al. (2009). Taking $d(FW_{i-1,S\rightarrow T})$ as a case in point, this model takes the form $P_{dom}(d(FW_{i-1,S\rightarrow T})|Y_{i-1,S\rightarrow T}, Y_{i,S\rightarrow T})$, where d takes one of the following four dominance values: leftFirst, rightFirst, dontCare, or neither. We will detail the exact formulation of these values in the next subsection. However, to provide intuition, the value of either leftFirst or neither for $d(FW_{i-1,S\rightarrow T})$ would suggest that the span of $L_{i,S\rightarrow T}$ doesn't extend to $Y_{i-1,S\rightarrow T}$; the further distinction between leftFirst and neither concerns with whether the span of $R_{i-1,S\rightarrow T}$ extends to $FW_{i,S\rightarrow T}$.

To model $b(\langle s\rangle)$, $b(\langle /s\rangle)$, i.e. whether the span of $L_{i,S\rightarrow T}$ and $R_{i,S\rightarrow T}$ extends up to sentence markers, we introduce the *borderwise dominance* model. Formally, this model is similar to the pairwise dominance model, except that we use the sentence boundaries as the anchors instead of the neighboring phrase pairs. This model captures longer distance dependencies compared to the previous two models; in the Chinese-English case, in particular, it is useful to discourage word alignments from crossing clause or sentence boundaries. The sentence boundary issue is especially important in machine translation (MT) experimentation, since the Chinese side of English-Chinese parallel text often includes long sentences that are composed of several independent clauses joined together; in such cases, words from one clause should be discouraged from aligning to words from other clauses. In Fig. 1, this model is potentially useful to discourage words from crossing the copula "是/is".

We define each model for all (pairs of) function word phrase pairs, forming features over a set of word alignments (A) between source (S) and target

[2] This heuristic is commonly used in learning phrase pairs from parallel text. The maximality ensures the uniqueness of L and R.

(T) sentence pair, as follows:

$$f_{ori} = \prod_{i=1}^{N} P_{ori}(o(L_i), o(R_i)|Y_i) \tag{1}$$

$$f_{dom} = \prod_{i=2}^{N} P_{dom}(d(FW_{i-1})|Y_{i-1}, Y_i) \tag{2}$$

$$f_{bdom} = \prod_{i=1}^{N} P_{bdom}(b(\langle s \rangle)|\langle s \rangle, Y_i) \cdot P_{bdom}(b(\langle /s \rangle)|Y_i, \langle /s \rangle) \tag{3}$$

where N is the number of function words (of the source side, in the $S \to T$ case). As the bilingual function word phrase pairs are uni-directional, we employ these three models in both directions, i.e. $T \to S$ as well as $S \to T$. As a result, there are six reordering models based on function words.

3.2 Prediction and Parameter Estimation

Given $FW_{i-1,S\to T}$ (and all other $FW_{\forall i'/i,S\to T}$), our reordering model has to decompose $L_{i,S\to T}$ into $(o(L_{i,S\to T}),\ d(FW_{i-1,S\to T}),\ b(\langle s \rangle))$; and $R_{i,S\to T}$ into $(o(R_{i,S\to T}), d(FW_{i+1,S\to T}),\ b(\langle /s \rangle)\ )$ during prediction and parameter estimation. In prediction mode (described in Section 5), it has to make the decomposition on the current state of alignment, while during parameter estimation, it has to make the same decomposition on the manually-aligned corpora. Since the process is identical, we proceed with the discussion in the context of parameter estimation, where the decomposition is performed to collect counts to estimate the parameters of our models.

Orientation model. Using $L_{i,S\to T}$ as a case in point and given ($Y_{i,S\to T}{=}s_l^l/t_m^m$, $L_{i,S\to T}{=}s_{l_1}^{l_2}/t_{m_1}^{m_2}$, $R_{i,S\to T}{=}s_{l_3}^{l_4}/t_{m_3}^{m_4}$)[3], the value of $o(L_{i,S\to T})$ in terms of Monotone/Reverse is:

$$\text{Monotone/Reverse} = \begin{cases} M, & m_2 < m, \\ R, & m < m_1. \end{cases} \tag{4}$$

while its value in terms of Adjacent/Gap values is:

$$\text{Adjacent/Gap} = \begin{cases} A, & |m - m_1| \vee |m - m_2| = 1, \\ G, & \text{otherwise.} \end{cases} \tag{5}$$

By adjusting the indices, the computation of $o(R_{i,S\to T})$ follows similarly to the procedure above.

Suppose we want to estimate the probability of $L_{i,S\to T}{=}MA$ for a particular Y_i. Note that here, we are interested in the lexical identity of Y_i, thus the index i is irrelevant. We first gather the counts of the orientation value for all $L_{i,S\to T}$ of Y_i in the corpus: $c(o(L_{i,S\to T}) \in \{MA, RA, MG, RG\}, Y_i)$. Then $P_{ori}(MA|Y_i)$ is estimated as follows:

$$P_{ori}(MA|Y_i) = \frac{c(MA, Y_i)}{c(Y_i)} \tag{6}$$

where $c(Y_i)$ is the frequency of Y_i in the corpus. The estimation of other orientation values as well as the $T \to S$ version of the model, follows the same procedure.

Pairwise and Borderwise dominance models. Given $R_{i,S\to T} = s_{l_1}^{l_2}/t_{m_1}^{m_2}$ and $L_{i+1,S\to T} = s_{l_3}^{l_4}/t_{m_3}^{m_4}$, i.e. the spans of the neighbors of a pair of neighboring function word phrase pairs ($Y_i = s_{l_5}^{l_5}/t_{m_5}^{m_5}, Y_{i+1} = s_{l_6}^{l_6}/t_{m_6}^{m_6}$), the value of $d(FW_{i+1,S\to T})$ is:

$$= \begin{cases} \textsf{leftFirst}, & l_2 \geq l_6 \bigwedge l_3 > l_5 \\ \textsf{rightFirst}, & l_2 < l_6 \bigwedge l_3 \leq l_5 \\ \textsf{dontCare}, & l_2 \geq l_6 \bigwedge l_3 \leq l_5 \\ \textsf{neither}, & l_2 < l_6 \bigwedge l_3 > l_5 \end{cases} \tag{7}$$

Note that the neighbors of the sentence markers for the borderwise models span the whole sentence, thus value of neither is impossible for these models.

Suppose we want to estimate the probability of Y_i and Y_{i+1} having a dontCare dominance value. Note that here we are interested in the lexical identity of Y_i and Y_{i+1}, thus the models are insensitive to the indices. We first gather the counts of the Y_i and Y_{i+1} having the dontCare value $c(\textsf{dontCare}, Y_i, Y_{i+1})$; then $P_{dom}(\textsf{dontCare}|Y_i, Y_{i+1})$ is estimated as follows:

$$P_{dom}(\textsf{dontCare}|Y_i, Y_{i+1}) = \frac{c(\textsf{dontCare}, Y_i, Y_{i+1})}{c(Y_i, Y_{i+1})} \tag{8}$$

where $c(Y_i, Y_{i+1})$ is the count of Y_i appears after Y_{i+1} in the training corpus without any other function word comes in between.

[3] We use subscripts to indicate the starting index, and superscripts the ending index.

4 Alignment Model

To use the function word alignment features described in the previous section to predict alignments, we use a linear model of the following form:

$$\hat{A} = \arg \max_{A \in \mathcal{A}(S,T)} \boldsymbol{\theta} \cdot \mathbf{f}(A, S, T) \qquad (9)$$

where $\mathcal{A}(S, T)$ is the set of all possible alignments of a source sentence S and target sentence T, and $\mathbf{f}(A, S, T)$ is a vector of feature functions on A, S, and T, and $\boldsymbol{\theta}$ is a parameter vector.

In addition to the six reordering models, our model employs several association-based scores that look at alignments in isolation. These features include:

1. Normalized log-likelihood ratio (LLR). This feature represents an association score, derived from statistical testing statistics. LLR (Dunning, 1993) has been widely used especially to measure lexical association. Since the values of LLR are unnormalized, we normalize them on a per-sentence basis, so that the normalized LLRs of, say, a particular source word to the target words in a particular sentence sum up to one.

2. Translation table from IBM model 4. This feature represents another association score, derived from a generative model, in particular the word-based IBM model 4. The use of this feature is widespread in recent alignment models, since it provides a relatively accurate initial prediction.

3. Translation table from manually-aligned corpora. This feature represents a gold-standard association score, based on human annotation. While attractive, this feature suffers from data sparseness issues since the lexical coverage of manually-aligned corpora, especially over content words, is very low. To overcome this issue, we design this feature to have two levels of granularity; as such, a fine-grained one is applied for function words and the coarse-grained one for content words.

4. Grow-diag-final alignments bonus. This feature encourages our alignment model to reuse alignment points that are part of the alignments created by the grow-diag-final heuristic, which we used as the baseline of our machine translation experiments.

5. Fertility model from IBM model 4. This feature, which is another by-product of IBM model 4, measures the probability of a certain word aligning to zero, one, or two or more words.

6. Null-alignment probability. This binomial feature models preference towards not aligning words, i.e. aligning to the NULL token. The intuition is to penalize NULL alignments depending on word class, by assigning lower probability mass to unaligned content words than to unaligned function words. In our experiment, we assign feature value 10^{-3} for a function word aligning to NULL, and 10^{-5} for a content word aligning to NULL.

Note that with the exception of the alignment bonus feature (4), all features are uni-directional, and therefore we employ these features in both directions just as was done for the reordering models.

5 Search

To find $\hat{A}$ using the model in Eq. 9, it is necessary to search $2^{|S|\times|T|}$ different alignment configurations, and, because of the non-local dependencies in some of our features, it is not possible to use dynamic programming to perform this search efficiently. We therefore employ an approximate search for the best alignment. We use a local search procedure which starts from some alignment (in our case, a symmetrized Model 4 alignment) and make local changes to it. Rather than taking a pure hill-climbing approach which greedily moves to locally better configurations (Brown et al., 1993), we use a stochastic search procedure which can move into lower-scoring states with some probability, similar to the Monte Carlo techniques used to draw samples from analytically intractable probability distributions.

5.1 Algorithm

To find $\hat{A}$, our search algorithm starts with an initial alignment $A^{(1)}$ and iteratively draws a new set by making a few small changes to the current set. For each step $i = [1, n]$, with alignment $A^{(i)}$, a set of neighboring alignments $\mathcal{N}(A^{(i)})$ is induced by applying small transformations (discussed below) to the current alignment. The next alignment $A^{(i+1)}$

is sampled from the following distribution:

$$p(A^{(i+1)}|S,T,A^{(i)}) = \frac{\exp \boldsymbol{\theta} \cdot \mathbf{f}(A^{(i+1)},S,T)}{Z(A^{(i)},S,T)}$$

where $Z(A^{(i)},S,T) = \sum_{A' \in \mathcal{N}(A^{(i)})} \exp \boldsymbol{\theta} \cdot \mathbf{f}(A',S,T)$

In addition to the current 'active' alignment configuration $A^{(i)}$, the algorithm keeps track of the highest scoring alignment observed so far, $A^{\max}$. After n steps, the algorithm returns $A^{\max}$ as its approximation of $\hat{A}$. In the experiments reported below, we initialized $A^{(1)}$ with the Model 4 alignments symmetrized by using the *grow-diag-final-and* heuristic (Koehn et al., 2003).

5.2 Alignment Neighborhoods

We now turn to a discussion of how the alignment neighborhoods used by our stochastic search algorithm are generated. We define three local transformation operations that apply to single columns of the alignment grid (which represent all of the alignments to the l^{th} source word), rows, or existing alignment points (l,m). Our three neighborhood generating operators are ALIGN, ALIGNEXCLUSIVE, and SWAP. The ALIGN operator applies to the l^{th} column of A and can either add an alignment point (l,m') or move an existing one (including to *null*, thus deleting it). ALIGNEXCLUSIVE adds an alignment point (l,m) and deletes all other points from row m. Finally, the SWAP operator swaps (l,m) and (l',m'), resulting in new alignment points (l,m') and (l',m). We increase the decoder's mobility by traversing the target side and applying the same steps above for each target word. Fig. 3 illustrates the three operators. By iterating over all columns l and rows m, the full alignment space $\mathcal{A}(S,T)$ can be explored.[4]

To further reduce the search space, an alignment point (l,m) is only admitted into a neighborhood if it is found in the high-recall alignment set $\mathcal{R}(S,T)$, which we define to be the model 4 union alignments (bidirectional model 4 symmetrized via union) plus the 5 best alignments according to the log-likelihood ratio.

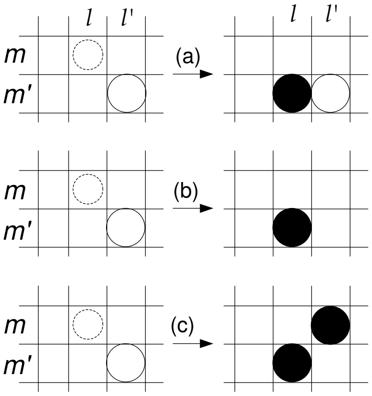

Figure 3: Illustrations for (a) ALIGN, (b) ALIGNEXCLUSIVE, and (c) SWAP operators, as applied to align the dotted, smaller circle (l,m) to (l,m'). The left hand side represents $\mathcal{A}^{(i)}$, while the right hand side represents a candidate for $\mathcal{A}^{(i+1)}$. The solid circles represent the new alignment points added to $\mathcal{A}^{(i+1)}$.

6 Discriminative Training

To set the model parameters $\boldsymbol{\theta}$, we used the minimum error rate training (MERT) algorithm (Och, 2003) to maximize the F-measure of the 1-best alignment of the model on a development set consisting of sentence pairs with manually generated alignments. The candidate set used by MERT to approximate the model is simply the set of alignments $\{A^{(1)}, A^{(2)}, \ldots, A^{(n)}\}$ encountered in the stochastic search.

While MERT does not scale to large numbers of features, the scarcity of manually aligned training data also means that models with large numbers of sparse features would be difficult to learn discriminatively, so this limitation is somewhat inherent in the problem space. Additionally, MERT has several advantages that make it particularly useful for our task. First, we can optimize F-measure of the alignments directly, which has been shown to correlate with translation quality in a downstream system (Fraser and Marcu, 2007b). Second, we are optimizing the quality of the 1-best alignments under the model. Since translation pipelines typically use only a single word alignment, this criterion is appropriate. Finally, and very importantly for us, MERT requires only an approximation of the model's hypothesis space to carry out optimization. Since we are using a stochastic search, this is crucial, since sub-

[4] Using only the ALIGN operator, it is possible to explore the full alignment space; however, using all three operators increases mobility.

sequent evaluations of the same sentence pair (even with the same weights) may result in a different candidate set.

Although MERT is a non-probabilistic optimizer, we explore the alignment space stochastically. This is necessary to make sure that the weights we use correspond to a probability distribution that is not overly peaked (which would result in a greedy hill-climbing search) or flat (which would explore the model space without information from the model). We found that normalizing the weights by the Euclidean norm resulted in a distribution that was well-balanced between the two extremes.

7 Experiments

We evaluated our proposed alignment model intrinsically on an alignment task and extrinsically on a large-scale translation task, focusing on Chinese-English as the language pair. Our training data consists of manually aligned corpora available from LDC (LDC2006E93 and LDC2008E57) and unaligned corpora, which include FBIS, ISI, HKNews and Xinhua. In total, the manually aligned corpora consist of more than 21 thousand sentence pairs, while the unaligned corpora consist of more than 710 thousand sentence pairs. The manually-aligned corpora are primarily used for training the reordering models and for discriminative training purposes. For translation experiments, we used cdec (Dyer et al., 2010), a fast implementation of hierarchical phrase-based translation models (Chiang, 2005), which represents a state-of-the-art translation system.

We constructed the list of function words in English manually and in Chinese from (Howard, 2002). Punctuation marks were added to the list, resulting in 883 and 359 tokens in the Chinese and English lists, respectively. For the alignment experiments, we took the first 500 sentence pairs from the newswire genre of the manually-aligned corpora and used the first 250 sentences as the development set, with the remaining 250 as the test set. To ensure blind experimentation, we excluded these sentence pairs from the training of the features, including the reordering models.

7.1 Alignment Quality

We used GIZA++, the implementation of the *de-facto* standard IBM alignment model, as our baseline alignment model. In particular, we used GIZA++ to align the concatenation of the development set, the test set, and the unaligned corpora, with 5, 5, 3 and 3 iterations of model 1, HMM, model 3, and model 4 respectively. Since the IBM model is asymmetric, we followed the standard practice of running GIZA++ twice, once in each direction, and combining the resulting outputs heuristically. We chose to use the grow-diag-final-and heuristic as it worked well for hierarchical phrase-based translation in our early experiments. We recorded the alignment quality of the test set as our baseline performance.

For our alignment model, we used the same set of training data. To align the test set, we first tuned the weights of the features in our discriminative alignment model using minimum error rate training (MERT) (Och, 2003) with $F_{\alpha=0.1}$ as the optimization criterion. At each iteration, our aligner outputs k-best alignments under current set of weights, from which MERT proceeds to compute the next set of weights. MERT terminates once the improvement over the previous iteration is lower than a predefined value. Once tuned, we ran our aligner on the test set and measured the quality of the resulting alignment as the performance of our model.

Model	P	R	$F_{0.5}$	$F_{0.1}$
gdfa	70.97	63.83	67.21	64.48
association	73.70	76.85	75.24	76.52
+ori	74.09	78.29	76.13	77.85
+dom	75.06	78.98	76.97	78.57
+bdom	**75.41**	**80.53**	**77.89**	**79.99**

Table 1: Alignment quality results ($F_{0.1}$) for our discriminative reordering models with various features (lines 2-5) versus the baseline IBM word-based Model 4 symmetrized using the grow-diag-final-and heuristic. The balanced $F_{0.5}$ measure is reported for reference. The best scores are **bolded**.

Table 1 reports the results of our experiments, which are conducted in an incremental fashion primarily to highlight the role of reordering modeling. The first line (gdfa) reports the baseline performance. In the first experiment (association), we employed only the association-based features described in Section 4. As shown, we obtain a significant improvement over baseline. This result is consistent with recent literature (Fraser and Marcu, 2007a) that shows that a discriminatively trained model outperforms baseline unsupervised models like GIZA++. In the second set of experiments, we added the reordering models into our discriminative model one by one, starting with the orientation models, then the pairwise dominance model and finally the borderwise dominance model, reported in lines +ori, +dom and +bdom respectively. As shown, each additional reordering model provides a significant additional improvement. The best result is obtained by employing all reordering models. These results empirically confirm our hypothesis that we can improve alignment quality by employing reordering models that capture non-local reordering phenomena.

7.2 Translation Quality

For translation experiments, we used the products from our intrinsic experiments to learn translation rules for the hierarchical phrase-based decoder, i.e. the features weights of the +bdom experiment to align the MT training data using our discriminative model. For our translation model, we used the standard features based on the relative frequency counts, including a 5-gram language model feature trained on the English portion of the whole training data plus portions of the Gigaword v2 corpus. Specifically, we tuned the weights of these features via MERT on the NIST MT06 set and we report the result on the NIST MT02, MT03, MT04 and MT05 sets.

	MT02	MT03	MT04	MT05
gdfa	25.61	32.05	31.80	29.34
this work	**26.56**	**33.79**	**32.61**	**30.47**

Table 2: The translation performance (BLEU) of hierarchical phrase-based translation trained on training data aligned by IBM model 4 symmetrized with the grow-diag-final-and heuristic, versus being trained on alignments by our discriminative alignment model. **Bolded** scores indicate that the improvement is statistically significant.

Table 2 shows the result of our translation experiments. In our alignment model, we employed the whole set of reordering models, i.e. the one reported in the +bdom line in Table 1. As shown, our discriminative alignment model produces a consistent and significant improvement over the baseline IBM model 4 ($p < 0.01$), ranging between 0.81 and 1.71 BLEU points.

8 Related Work

The focus of our work is to strengthen the reordering component of alignment modeling. Although the *de facto* standard, the IBM models do not generalize well in practice: the IBM approach employs a series of reordering models based on the word's position, but reordering depends on syntactic context rather than absolute position in the sentence. Over the years, there have been many proposals to improve these reordering models, most notably Vogel et al. (1996), which adds a first-order dependency. Nevertheless, the use of these distortion-based models remains widespread (Marcu and Wong, 2002; Moore, 2004).

Alignment modeling is challenging because it often has to consider a prohibitively large alignment space. Efforts to constrain the space generally comes from the use of Inversion Transduction Grammar (ITG) (Wu, 1997). Recent proposals that use ITG constraints include (Haghighi et al., 2009; Blunsom et al., 2009) just to name a few. More recent models have begun to use linguistically-motivated constraints, often in combination with ITG, primarily exploiting monolingual syntactic information (Burkett et al., 2010; Pauls et al., 2010).

Our reordering model is closely related to the model proposed by Zhang and Gildea (2005; 2006; 2007a), with respect to conditioning the reordering predictions on lexical items. These related models treat their lexical items as latent variables to be estimated from training data, while our model uses a fixed set of lexical items that correspond to the class of function words. With respect to the focus on function words, our reordering model is closely related to the UALIGN system (Hermjakob, 2009). However, UALIGN uses deep syntactic analysis and hand-crafted heuristics in its model.

9 Conclusions

Languages exhibit regularities of word order that are preserved when projected to another language. We use the notion of function words to infer such regularities, resulting in several reordering models that are employed as features in a discriminative alignment model. In particular, our models predict the reordering of function words by looking at their dependencies with respect to their neighboring phrases, their neighboring function words, and the sentence boundaries. By capturing such long-distance dependencies, our proposed alignment model contributes to the effort to unify alignment and translation. Our experiments demonstrate that our alignment approach achieves both its intrinsic and extrinsic goals.

Abstract

We report on investigations into hierarchical phrase-based translation grammars based on rules extracted from posterior distributions over alignments of the parallel text. Rather than restrict rule extraction to a single alignment, such as Viterbi, we instead extract rules based on posterior distributions provided by the HMM word-to-word alignment model. We define translation grammars progressively by adding classes of rules to a basic phrase-based system. We assess these grammars in terms of their expressive power, measured by their ability to align the parallel text from which their rules are extracted, and the quality of the translations they yield. In Chinese-to-English translation, we find that rule extraction from posteriors gives translation improvements. We also find that grammars with rules with only one nonterminal, when extracted from posteriors, can outperform more complex grammars extracted from Viterbi alignments. Finally, we show that the best way to exploit source-to-target and target-to-source alignment models is to build two separate systems and combine their output translation lattices.

1 Introduction

Current practice in hierarchical phrase-based translation extracts regular phrases and hierarchical rules from word-aligned parallel text. Alignment models estimated over the parallel text are used to generate these alignments, but these models are then typically used no further in rule extraction. This is less than ideal because these alignment models, even if they are not suitable for direct use in translation, can still provide a great deal of useful information beyond a single best estimate of the alignment of the parallel text. Our aim is to use alignment models to generate the statistics needed to build translation grammars. The challenge in doing so is to extend the current procedures, which are geared towards the use of a single alignment, to make more of what can be provided by alignment models. The goal is to extract a richer and more robust set of translation rules.

There are two aspects to hierarchical phrase-based translation grammars which concern us. The first is expressive power, which we take as the ability to generate known reference translations from sentences in the source language. This is determined by the degree of phrase movements and the translations allowed by the rules of the grammar. For a grammar with given types of rules, larger rule sets will yield greater expressive power. This motivates studies of grammars based on the rules which are extracted and the movement the grammar allows. The second aspect is of course translation accuracy. If the expressive power is adequate, then the desire is that the grammar assigns a high score to a correct translation.

We use posterior probabilities over parallel data to address both of these aspects. These posteriors allow us to build larger rule sets with improved translation accuracy. Ideally, for a sentence pair we wish to consider all possible alignments between all possible source and target phrases within these sentences. Given a grammar allowing certain types of movement, we would then extract all possible parses that are consistent with any alignments of these phrases.

To make this approach feasible, we consider only phrase-to-phrase alignments with a high posterior probability under the alignment models. In this way, the alignment model probabilities guide rule extraction.

The paper is organized as follows. Section 2 reviews related work on using posteriors to extract phrases, as well as other approaches that tightly integrate word alignment and rule extraction. Section 3 describes rule extraction based on word and phrase posterior distributions provided by the HMM word-to-word alignment model. In Section 4 we define translation grammars progressively by adding classes of rules to a basic phrase-based system, motivating each rule type by the phrase movement it is intended to achieve. In Section 5 we assess these grammars in terms of their expressive power and the quality of the translations they yield in Chinese-to-English, showing that rule extraction from posteriors gives translation improvements. We also find that the best way to exploit source-to-target and target-to-source alignment models is to build two separate systems and combine their output translation lattices. Section 6 presents the main conclusions of this work.

2 Related Work

Some authors have previously addressed the limitation caused by decoupling word alignment models from grammar extraction. For instance Venugopal et al. (2008) extract rules from n-best lists of alignments for a syntax-augmented hierarchical system. Alignment n-best lists are also used in Liu et al. (2009) to create a structure called weighted alignment matrices that approximates word-to-word link posterior probabilities, from which phrases are extracted for a phrase-based system. Alignment posteriors have been used before for extracting phrases in non-hierarchical phrase-based translation (Venugopal et al., 2003; Kumar et al., 2007; Deng and Byrne, 2008).

In order to simplify hierarchical phrase-based grammars and make translation feasible with relatively large parallel corpora, some authors discuss the need for various filters during rule extraction (Chiang, 2007). In particular Lopez (2008) enforces a minimum span of two words per nonterminal, Zollmann et al. (2008) use a minimum count threshold for all rules, and Iglesias et al. (2009) propose a finer-grained filtering strategy based on rule patterns. Other approaches include insisting that target-side rules are well-formed dependency trees (Shen et al., 2008).

We also note approaches to tighter coupling between translation grammars and alignments. Marcu and Wong (2002) describe a joint-probability phrase-based model for alignment, but the approach is limited due to excessive complexity as Viterbi inference becomes NP-hard (DeNero and Klein, 2008). More recently, Saers et al. (2009) report improvement on a phrase-based system where word alignment has been trained with an inversion transduction grammar (ITG) rather than IBM models. Pauls et al. (2010) also use an ITG to directly align phrases to nodes in a string-to-tree model. Bayesian methods have been recently developed to induce a grammar directly from an unaligned parallel corpus (Blunsom et al., 2008; Blunsom et al., 2009). Finally, Cmejrek et al. (2009) extract rules directly from bilingual chart parses of the parallel corpus without using word alignments. We take a different approach in that we aim to start with very strong word alignment models and use them to guide grammar extraction.

3 Rule Extraction from Alignment Posteriors

The goal of rule extraction is to generate a set of good-quality translation rules from a parallel corpus. Rules are of the form $X{\rightarrow}\langle\gamma,\alpha,\sim\rangle$, where $\gamma, \alpha \in \{X \cup \mathbf{T}\}^+$ are the source and target sides of the rule, $\mathbf{T}$ denotes the set of terminals (words) and $\sim$ is a bijective function[1] relating source and target nonterminals X of each rule (Chiang, 2007). For each γ, the probability over translations α is set by relative frequency over the extracted examples from the corpus.

We take a general approach to rule extraction, as described by the following procedure. For simplicity we discuss the extraction of regular phrases, that is, rules of the form $X{\rightarrow}\langle w,w\rangle$, where $w \in \{\mathbf{T}\}^+$. Section 3.3 extends this procedure to rules with non-

[1] This function is defined if there are at least two nonterminals, and for clarity of presentation will be omitted in this paper

terminal symbols.

Given a sentence pair (f_1^J, e_1^I), the extraction algorithm traverses the source sentence and, for each sequence of terminals $f_{j_1}^{j_2}$, it considers all possible target-side sequences $e_{i_1}^{i_2}$ as translation candidates. Each target-side sequence that satisfies the alignment constraints $\mathcal{C}_A$ is ranked by the function f_R. For practical reasons, a set of selection criteria $\mathcal{C}_S$ is then applied to these ranked candidates and defines the set of translations of the source sequence that are extracted as rules. Each extracted rule is assigned a count f_C.

In this section we will explore variations of this rule extraction procedure involving alternative definitions of the ranking and counting functions, f_R and f_C, based on probabilities over alignment models.

Common practice (Koehn et al., 2003) takes a set of word alignment links $\mathbf{L}$ and defines the alignment constraints $\mathcal{C}_A$ so that there is a *consistency* between the links in the $(f_{j_1}^{j_2}, e_{i_1}^{i_2})$ phrase pair. This is expressed by $\forall (j,i) \in \mathbf{L} : (j \in [j_1, j_2] \wedge i \in [i_1, i_2]) \vee (j \notin [j_1, j_2] \;\wedge\; i \notin [i_1, i_2])$. If these constraints are met, then alignment probabilities are ignored and $f_R = f_C = 1$. We call this extraction Viterbi-based, as the set of alignment links is generally obtained after applying a symmetrization heuristic to source-to-target and target-to-source Viterbi alignments.

In the following section we depart from this approach and apply novel functions to rank and count target-side translations according to their quality in the context of each parallel sentence, as defined by the word alignment models. We also depart from common practice in that we do not use a set of links as alignment constraints. We thus find an increase in the number of extracted rules, and consequently better relative frequency estimates over translations.

3.1 Ranking and Counting Functions

We describe two alternative approaches to modify the functions f_R and f_C so that they incorporate the probabilities provided by the alignment models.

3.1.1 Word-to-word Alignment Posterior Probabilities

Word-to-word alignment posterior probabilities $p(l_{ji}|f_1^J, e_1^I)$ express how likely it is that the words in source position j and target position i are aligned given a sentence pair. These posteriors can be efficiently computed for Model 1, Model 2 and HMM, as described in (Brown et al., 1993; Venugopal et al., 2003; Deng and Byrne, 2008).

We will use these posteriors in functions to score phrase pairs. For a simple non-disjoint case $(f_{j_1}^{j_2}, e_{i_1}^{i_2})$ we use:

$$f_R(f_{j_1}^{j_2}, e_{i_1}^{i_2}) = \prod_{j=j_1}^{j_2} \sum_{i=i_1}^{i_2} \frac{p(l_{ji}|f_1^J, e_1^I)}{i_2 - i_1 + 1} \qquad (1)$$

which is very similar to the score used for lexical features in many systems (Koehn, 2010), with the link posteriors for the sentence pair playing the role of the Model 1 translation table.

For a particular source phrase, Equation 1 is not a proper conditional probability distribution over all phrases in the target sentence. Therefore it cannot be used as such without further normalization. Indeed we find that this distribution is too sharp and overemphasises short phrases, so we use $f_C = 1$. However, it does allow us to rank target phrases as possible translations. In contrast to the common extraction procedure described in the previous section, the ranking approach described here can lead to a much more exhaustive extraction unless selection criteria are applied. These we describe in Section 3.2.

We note that Equation 1 can be computed using link posteriors provided by alignment models trained on either source-to-target or target-to-source translation directions.

3.1.2 Phrase-to-phrase Alignment Posterior Probabilities

Rather than limit ourselves to word-to-word link posteriors we can define alignment probability distributions over phrase alignments. We do this by defining the set of alignments A as $A(j_1, j_2; i_1, i_2) = \{a_1^J : a_j \in [i_1, i_2] \text{ iff } j \in [j_1, j_2]\}$, where a_j is the random process that describes word-to-word alignments. These are the alignments from which the phrase pair $(f_{j_1}^{j_2}, e_{i_1}^{i_2})$ would be extracted.

The posterior probability of these alignments given the sentence pair is defined as follows:

$$p(A|e_1^I, f_1^J) = \frac{\sum_{a_1^J \in A} p(f_1^J, a_1^J|e_1^I)}{\sum_{a_1^J} p(f_1^J, a_1^J|e_1^I)} \qquad (2)$$

G_0	G_1	G_2	G_3
$S\rightarrow\langle X,X\rangle$ $S\rightarrow\langle S\ X,S\ X\rangle$ $X\rightarrow\langle w,w\rangle$	$X\rightarrow\langle w\ X,X\ w\rangle$ $X\rightarrow\langle X\ w,w\ X\rangle$	$X\rightarrow\langle w\ X,X\ w\rangle$ $X\rightarrow\langle X\ w,w\ X\rangle$ $X\rightarrow\langle w\ X,w\ X\rangle$	$X\rightarrow\langle w\ X,X\ w\rangle$ $X\rightarrow\langle X\ w,w\ X\rangle$ $X\rightarrow\langle w\ X,w\ X\rangle$ $X\rightarrow\langle w\ X\ w,w\ X\ w\rangle$

Table 1: Hierarchical phrase-based grammars containing different types of rules. The grammar expressivity is greater as more types of rules are included. In addition to the rules shown in the respective columns, G_1, G_2 and G_3 also contain the rules of G_0.

With IBM models 1 and 2, the numerator and denominator in Equation 2 can be computed in terms of posterior link probabilities (Deng, 2005). With the HMM model, the denominator is computed using the forward algorithm while the numerator can be computed using a modified forward algorithm (Deng, 2005).

These phrase posteriors directly define a probability distribution over the alignments of translation candidates, so we use them both for ranking and scoring extracted rules, that is $f_R = f_C = p$. This approach assigns a fractional count to each extracted rule, which allows finer estimation of the forward and backward translation probability distributions.

3.2 Alignment Constraints and Selection Criteria

In order to keep this process computationally tractable, some extraction constraints are needed. In order to extract a phrase pair $(f_{j_1}^{j_2}, e_{i_1}^{i_2})$, we define the following:

- $\mathcal{C}_A$ requires at least one pair of positions (j,i) : $(j \in [j_1,j_2] \wedge i \in [i_1,i_2])$ with word-to-word link posterior probability $p(l_{ji}|f_1^J, e_1^I) > 0.5$, and that there is no pair of positions (j,i) : $(j \in [j_1,j_2] \wedge i \notin [i_1,i_2]) \vee (j \notin [j_1,j_2] \wedge i \in [i_1,i_2])$ with $p(l_{ji}|f_1^J, e_1^I) > 0.5$

- $\mathcal{C}_S$ allows only the k best translation candidates to be extracted. We use $k = 3$ for regular phrases, and $k = 2$ for hierarchical rules.

Note that we do not discard rules according to their scores f_C at this point (unlike Liu et al. (2009)), since we prefer to add all phrases from all sentence pairs before carrying out such filtering steps.

Once all rules over the entire collection of parallel sentences have been extracted, we require each rule to occur at least n_{obs} times and with a forward translation probability $p(\alpha|\gamma) > 0.01$ to be used for translation.

3.3 Extraction of Rules with Nonterminals

Extending the procedure previously described to the case of more complex hierarchical rules including one or even two nonterminals is conceptually straightforward. It merely requires that we traverse the source and target sentences and consider possibly disjoint phrase pairs. Optionally, the alignment constraints can also be extended to apply on the nonterminal X.

Equation 1 is then only modified in the limits of the product and summation, whereas Equation 2 remains unchanged, as long as the set of valid alignments A is redefined. For example, for a rule of the form $X\rightarrow\langle w\ X\ w,w\ X\ w\rangle$, we use $A \equiv A(j_1, j_2; j_3, j_4; i_1, i_2; i_3, i_4)$.

4 Hierarchical Translation Grammar Definition

In this section we define the hierarchical phrase-based synchronous grammars we use for translation experiments. Each grammar is defined by the type of hierarchical rules it contains. The rule type can be obtained by replacing every sequence of terminals by a single symbol 'w', thus ignoring the identity of the words, but capturing its generalized structure and the kind of reordering it encodes (this was defined as rule pattern in Iglesias et al. (2009)).

A monotonic phrase-based translation grammar G_0 can be defined as shown in the left-most column of Table 1; it includes all regular phrases, represented by the rule type $X\rightarrow\langle w,w\rangle$, and the two glue

(G_0) R^1: $S\rightarrow\langle X,X\rangle$
(G_0) R^2: $X\rightarrow\langle \mathrm{s}_2\ \mathrm{s}_3,\mathrm{t}_2\rangle$
(G_1) R^3: $X\rightarrow\langle \mathrm{s}_1\ X,X\ \mathrm{t}_3\rangle$
(G_1) R^4: $X\rightarrow\langle X\ \mathrm{s}_4,\mathrm{t}_1\ X\rangle$
(G_2) R^5: $X\rightarrow\langle \mathrm{s}_1\ X,\mathrm{t}_7\ X\rangle$
(G_3) R^6: $X\rightarrow\langle \mathrm{s}_1\ X\ \mathrm{s}_4,\mathrm{t}_5\ X\ \mathrm{t}_6\rangle$

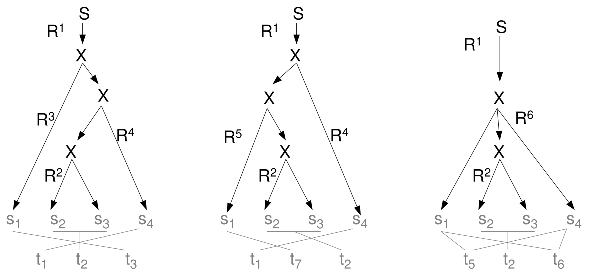

Figure 1: Example of a hierarchical translation grammar and two parsing trees following alternative rule derivations for the input sentence $s_1 s_2 s_3 s_4$.

rules that allow concatenation. Our approach is now simple: we extend this grammar by successively incorporating sets of hierarchical rules. The goal is to obtain a grammar with few rule types but which is capable of generating a rich set of translation candidates for a given input sentence.

With this in mind, we define the following three grammars, also summarized in Table 1:

- $G_1 := G_0 \bigcup \{\ X\rightarrow\langle w\ X,X\ w\rangle\ ,\ X\rightarrow\langle X\ w,w\ X\rangle\ \}$. This incorporates reordering capabilities with two rule types that place the unique nonterminal in an opposite position in each language; we call these 'phrase swap rules'. Since all nonterminals are of the same category X, nested reordering is possible. However, this needs to happen consecutively, *i.e.* a swap must apply after a swap, or the rule is concatenated with the glue rule.

- $G_2\ :=\ G_1 \bigcup \{\ X\rightarrow\langle w\ \ X,w\ \ X\rangle\ \}$. This adds monotonic concatenation capabilities to the previous translation grammar. The glue rule already allows rule concatenation. However, it does so at the S category, that is, it concatenates phrases and rules *after* they have been reordered, in order to complete a sentence. With this new rule type, G_2 allows phrase/rule concatenation *before* reordering with another hierarchical rule. Therefore, nested reordering does not require successive swaps anymore.

- $G_3\ :=\ G_2 \bigcup \{\ X\rightarrow\langle w\ X\ w,w\ X\ w\rangle\ \}$. This adds single nonterminal rules with disjoint terminal sequences, which can encode a monotonic or reordered relationship between them, depending on what their alignment was in the parallel corpus. Although one could expect the movement captured by this phrase-disjoint rule type to be also present in G_2 (via two swaps or one concatenation plus one swap), the terminal sequences w may differ.

Figure 1 shows an example set of rules indicating to which of the previous grammars each rule belongs, and shows three translation candidates as generated by grammars G_1 (left-most tree), G_2 (middle tree) and G_3 (right-most tree). Note that the middle tree cannot be generated with G_1 as it requires monotonic concatenation before reordering with rule R^4.

The more rule types a hierarchical grammar contains, the more different rule derivations and the greater the search space of alternative translation candidates. This is also connected to how many rules are extracted per rule type. Ideally we would like the grammar to be able to generate the correct translation of a given input sentence, without overgenerating too many other candidates, as that makes the translation task more difficult.

We will make use of the parallel data in measuring the ability of a grammar to generate correct translations. By extracting rules from a parallel sentence, we translate them and observe whether the translation grammar is able to produce the parallel target translation. In Section 5.1 we evaluate this for a Chinese-to-English task.

4.1 Reducing Grammar Redundancy

Let us discuss grammar G_2 in more detail. As described in the previous section, the motivation for including rule type $X \rightarrow \langle w\ X, w\ X \rangle$ is that the grammar be able to carry out monotonic concatenation *before* applying another hierarchical rule with reordering. This movement is permitted by this rule type, but the use of a single nonterminal category X also allows the grammar to apply the concatenation *after* reordering, that is, immediately before the glue rule is applied. This creates significant redundancy in rule derivations, as this rule type is allowed to act as a glue rule. For example, given an input sentence $s_1 s_2$ and the following simple grammar:

R^0: $S \rightarrow \langle X, X \rangle$
R^1: $S \rightarrow \langle S\ X, S\ X \rangle$
R^2: $X \rightarrow \langle \mathrm{s}_1, \mathrm{t}_1 \rangle$
R^3: $X \rightarrow \langle \mathrm{s}_2, \mathrm{t}_2 \rangle$
R^4: $X \rightarrow \langle \mathrm{s}_1\ X, \mathrm{t}_1\ X \rangle$

two derivations are possible: R^2,R^0,R^3,R^1 and R^3,R^4,R^0, and the translation result is identical.

To avoid this situation we introduce a nonterminal M in the left-hand side of monotonic concatenation rules of G_2. All rules are allowed to use nonterminals X and M in their right-hand side, except the glue rules, which can only take X. In the context of our example, R^4 is substituted by:

R^{4a}: $M \rightarrow \langle \mathrm{s}_1\ X, \mathrm{t}_1\ X \rangle$
R^{4b}: $M \rightarrow \langle \mathrm{s}_1\ M, \mathrm{t}_1\ M \rangle$

so that only the first derivation is possible: R^2,R^0,R^3,R^1, because applying R^3,R^{4a} yields a nonterminal M that cannot be taken by the glue rule R^0.

5 Experiments

We report experiments in Chinese-to-English translation. Our system is trained on a subset of the GALE 2008 evaluation parallel text;[2] this is approximately 50M words per language. We report translation results on a development set *tune-nw* and a test set *test-nw1*. These contain translations produced by the GALE program and portions of the newswire sections of MT02 through MT06. They contain 1,755 sentences and 1,671 sentences respectively. Results are also reported on a smaller held-out test set *test-nw2*, containing 60% of the NIST newswire portion of MT06, that is, 369 sentences.

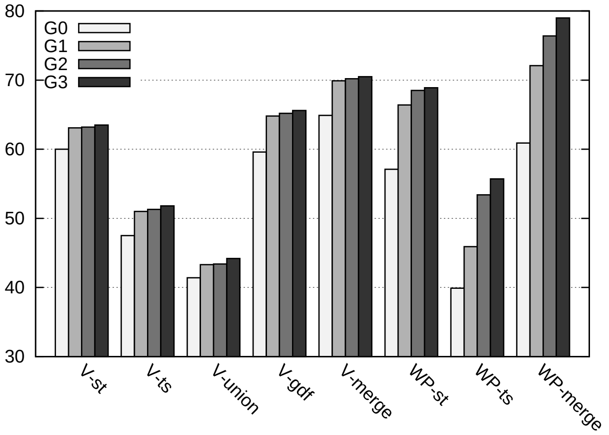

Figure 2: Percentage of parallel sentences successfully aligned for various extraction methods and grammars.

The parallel texts for both language pairs are aligned using MTTK (Deng and Byrne, 2008). For decoding we use HiFST, a lattice-based decoder implemented with Weighted Finite State Transducers (de Gispert et al., 2010). Likelihood-based search pruning is applied if the number of states in the lattice associated with each CYK grid cell exceeds 10,000, otherwise the entire search space is explored. The language model is a 4-gram language model estimated over the English side of the parallel text and the AFP and Xinhua portions of the English Gigaword Fourth Edition (LDC2009T13), interpolated with a zero-cutoff stupid-backoff (Brants et al., 2007) 5-gram estimated using 6.6B words of English newswire text. In tuning the systems, standard MERT (Och, 2003) iterative parameter estimation under IBM BLEU[3] is performed on the development sets.

5.1 Measuring Expressive Power

We measure the expressive power of the grammars described in the previous section by running the translation system in alignment mode (de Gispert et al., 2010) over the parallel corpus. Conceptually, this is equivalent to replacing the language model by the target sentence and seeing if the system is able to find any candidate. Here the weights assigned to the

Table 2: Chinese-to-English translation results with alternative grammars and extraction methods (lower-cased BLEU shown). Time (secs/word) and prune (times/word) measurements done on *tune-nw* set.

rules are irrelevant, as only the ability of the grammar to create a desired hypothesis is important.

We compare the percentage of target sentences that can be successfully produced by grammars G_0, G_1, G_2 and G_3 for the following extraction methods:

- **Viterbi (V)**. This is the standard extraction method based on a set of alignment links. We distinguish four cases, depending on the model used to obtain the set of links: source-to-target (**V-st**), target-to-source (**V-ts**), and two common symmetrization strategies: union (**V-union**) and grow-diag-final (**V-gdf**), described in (Koehn et al., 2003).

- **Word Posteriors (WP)**. The extraction method is based on word alignment posteriors described in Section 3.1.1. These rules can be obtained either from the posteriors of the source-to-target (**WP-st**) or the target-to-source (**WP-ts**) alignment models. We apply the alignment constraints and selection criteria described in Section 3.2. We do not report alignment percentages when using phrase posteriors (as described in Section 3.1.2) as they are roughly identical to the **WP** case.

- Finally, in both cases, we also report results when merging the extracted rules in both directions into a single rule set (**V-merge** and **WP-merge**).

Figure 2 shows the results obtained for a random selection of 10,000 parallel corpus sentences. As expected, we can see that for any extraction method, the percentage of aligned sentences increases when switching from G_0 to G_1, G_2 and G_3. Posterior-based extraction is shown to outperform standard methods based on a Viterbi set of alignments for nearly all grammars. The highest alignment percentages are obtained when merging rules obtained under models trained in each direction (**WP-merge**), approximately reaching 80% for grammar G_3.

The maximum rule span in alignment was allowed to be 15 words, so as to be similar to translation, where the maximum rule span is 10 words. Relaxing this in alignment to 30 words yields approximately 90% coverage for **WP-merge** under G_3.

We note that if alignment constraints $\mathcal{C}_A$ and selection criteria $\mathcal{C}_S$ were not applied, that is $k = \infty$, then alignment percentages would be 100% even for G_0, but the extracted grammar would include many noisy rules with poor generalization power and would suffer from overgeneration.

5.2 Translation Results

In this section we investigate the translation performance of each hierarchical grammar, as defined by rules obtained from three rule extraction methods:

- **Viterbi union (V-union)**. Standard rule extraction from the union of the source-to-target and target-to-source alignment link sets.

- **Word Posteriors (WP-st)**. Extraction based on word posteriors as described in Section 3.1.1. The posteriors are provided by the source-to-target alignment model. Alignment constraints and selection criteria of Section 3.2 are applied, with $n_{obs} = 2$.

- **Phrase Posteriors (PP-st)**. Extraction based on phrase alignment posteriors, as described in Section 3.1.2, with fractional counts proportional to the phrase probability under the source-to-target alignment model. Alignment constraints and selection criteria of Section 3.2 are applied, with $n_{obs} = 0.2$.

Table 2 reports the translation results, as well as the number of extracted rules in each case. It also shows the following decoding statistics as measured on the *tune-nw* set: decoding time in seconds per input word, and number of instances of search pruning (described in Section 5) per input word.

As a contrast, we extract rules according to the heuristics introduced in (Chiang, 2007) and apply the filters described in (Iglesias et al., 2009) to generate a standard hierarchical phrase-based grammar G_H. This uses rules with up to two nonadjacent nonterminals, but excludes identical rule types such as $X \rightarrow \langle w\ X, w\ X \rangle$ or $X \rightarrow \langle w\ X_1\ w\ X_2, w\ X_1\ w\ X_2 \rangle$, which were reported to cause computational difficulties without a clear improvement in translation (Iglesias et al., 2009).

Grammar expressivity. As expected, for the standard extraction method (see rows entitled **V-union**), grammar G_1 is shown to underperform all other grammars due to its structural limitations. On the other hand, grammar G_2 obtains much better scores, nearly generating the same translation quality as the baseline grammar G_H. Finally, G_3 does not prove able to outperform G_2, which suggests that the phrase-disjoint rules with one nonterminal are redundant for the translation grammar.

Rule extraction method. For all grammars, we find that the proposed extraction methods based on alignment posteriors outperform standard Viterbi-based extraction, with improvements ranging from 0.5 to 1.1 BLEU points for *test-nw1* (depending on the grammar) and from 1.0 to 1.5 for *test-nw2*. In all cases, the use of phrase posteriors **PP** is the best option. Interestingly, we find that G_2 extracted with **WP** and **PP** methods outperforms the more complex G_H grammar as obtained from Viterbi alignments.

Rule set statistics. For grammar G_2 evaluated on the *tune-nw* set, standard Viterbi-based extraction produces 0.7M rules, whereas the WP and PP extraction methods yield 1.1M and 1.2M rules respectively. We further analyse the sets of rules $X \rightarrow \langle \gamma, \alpha, \sim \rangle$ in terms of the number of distinct source and target sequences γ and α which are extracted. Viterbi extraction yields 82k distinct source sequences whereas the WP and PP methods yield 116k and 146k sequences, respectively. In terms of the average number of target sequences for each source sequence, Viterbi extraction yields an average of 8.7 while WP and PP yield 9.7 and 8.4 rules on average. This shows that method **PP** yields wider coverage but with sharper forward rule translation probability distributions than method **WP**, as the average number of translations per rule is determined by the $p(\alpha|\gamma) > 0.01$ threshold mentioned in Section 3.2.

Decoding time and pruning in search. In connection to the previous comments, we find an increased need for search pruning, and subsequently slower decoding speed, as the search space grows larger with methods **WP** and **PP**. A larger search space is created by the larger rule sets, which allows the system to generate new hypotheses of better quality.

5.3 Rule Concatenation in Grammar G_2

In Section 4.1 we described a strategy to reduce grammar redundancy by introducing an additional nonterminal M for monotonic concatenation rules. We find that without this distinction among nonterminals, search pruning and decoding time are increased by a factor of 1.5, and there is a slight degradation in BLEU ($\sim$0.2) as more search errors are introduced.

Another relevant aspect of this grammar is the actual rule type selected for monotonic concatenation. We described using type $X \rightarrow \langle w\ X, w\ X \rangle$ (concatenation on the right), but one could also include $X \rightarrow \langle X\ w, X\ w \rangle$ (concatenation on the left), or both, for the same purpose. We evaluated the three alternatives and found that scores are identical when either including right or left concatenation types, but including both is harmful for performance, as the need to prune and decoding time increase by a factor of 5 and 4, respectively, and we observe again a slight degradation in performance.

Rule Extraction	*tune-nw*	*test-nw1*	*test-nw2*
V-st	34.7	35.6	37.5
V-ts	34.0	34.8	36.6
V-union	34.5	35.4	37.2
V-gdf	34.4	35.3	37.1
WP-st	35.1	36.0	37.7
WP-ts	34.5	35.0	37.0
PP-st	35.5	36.4	38.2
PP-ts	34.8	35.3	37.2
PP-merge	35.5	36.4	38.4
PP-merge-MERT	35.5	36.4	38.3
LMBR(**V-st)**	35.0	35.8	38.4
LMBR(**V-st,V-ts)**	35.5	36.3	38.9
LMBR(**PP-st)**	36.1	36.8	38.8
LMBR(**PP-st,PP-ts)**	36.4	36.9	39.3

Table 3: Translation results under grammar G_2 with individual rule sets, merged rule sets, and rescoring and system combination with lattice-based MBR (lower-cased BLEU shown)

5.4 Symmetrizing Alignments of Parallel Text

In this section we investigate extraction from alignments (and posterior distributions) over parallel text which are generated using alignment models trained in the source-to-target (**st**) and target-to-source (**ts**) directions. Our motivation is that symmetrization strategies have been reported to be beneficial for Viterbi extraction methods (Och and Ney, 2003; Koehn et al., 2003).

Results are shown in Table 3 for grammar G_2. We find that rules extracted under the source-to-target alignment models (**V-st**, **WP-st** and **PP-st**) consistently perform better than the **V-ts**, **WP-ts** and **PP-ts** cases. Also, for Viterbi extraction we find that the source-to-target **V-st** case performs better than any of the symmetrization strategies, which contradicts previous findings for non-hierarchical phrase-based systems(Koehn et al., 2003).

We use the **PP** rule extraction method to extract two sets of rules, under the **st** and **ts** alignment models respectively. We now investigate two ways of merging these sets into a single grammar for translation. The first strategy is **PP-merge** and merges both rule sets by assigning to each rule the maximum count assigned by either alignment model. We then extend the previous strategy by adding three binary feature functions to the system, indicating whether the rule was extracted under the '**st**' model, the '**ts**' model or both. The motivation is that MERT can weight rules differently according to the alignment model they were extracted from. However, we do not find any improvement with either strategy.

Finally, we use linearised lattice minimum Bayes-risk decoding (Tromble et al., 2008; Blackwood et al., 2010) to combine translation lattices (de Gispert et al., 2010) as produced by rules extracted under each alignment direction (see rows named LMBR(**V-st,V-ts)**) and LMBR(**PP-st,PP-ts)**). Gains are consistent when comparing this to applying LMBR to each of the best individual systems (rows named LMBR(**V-st)** and LMBR(**PP-st)**). Overall, the best-performing strategy is to extract two sets of translation rules under the phrase pair posteriors in each translation direction, and then to perform translation twice and merge the results.

6 Conclusion

Rule extraction based on alignment posterior probabilities can generate larger rule sets. This results in grammars with more expressive power, as measured by the ability to align parallel sentences. Assigning counts equal to phrase posteriors produces better estimation of rule translation probabilities. This results in improved translation scores as the search space grows.

This more exhaustive rule extraction method permits a grammar simplification, as expressed by the phrase movement allowed by its rules. In particular a simple grammar with rules of only one nonterminal is shown to outperform a more complex grammar built on rules extracted from Viterbi alignments. Finally, we find that the best way to exploit alignment models trained in each translation direction is to extract two rule sets based on alignment posteriors, translate the input independently with each rule set and combine translation output lattices.

Abstract

Hierarchical phrase-based (HPB) translation provides a powerful mechanism to capture both short and long distance phrase reorderings. However, the phrase reorderings lack of contextual information in conventional HPB systems. This paper proposes a context-dependent phrase reordering approach that uses the maximum entropy (MaxEnt) model to help the HPB decoder select appropriate reordering patterns. We classify translation rules into several reordering patterns, and build a MaxEnt model for each pattern based on various contextual features. We integrate the MaxEnt models into the HPB model. Experimental results show that our approach achieves significant improvements over a standard HPB system on large-scale translation tasks. On Chinese-to-English translation, the absolute improvements in BLEU (case-insensitive) range from 1.2 to 2.1.

1 Introduction

The hierarchical phrase-based (HPB) model (Chiang, 2005; Chiang, 2007) has been widely adopted in statistical machine translation (SMT). It utilizes synchronous context free grammar (SCFG) rules to perform translation. Typically, there are three types of rules (see Table 1): *phrasal* rule, a phrase pair consisting of consecutive words; *hierarchical* rule, a hierarchical phrase pair consisting of both words and variables; and *glue* rule, which is used to merge phrases serially. Phrasal rule captures short distance reorderings within phrases, while hierarchical rule captures long distance reorderings between phrases. Therefore, the HPB model outperforms conventional phrase-based models on phrase reorderings.

Type	Constituent		Examples
	Word	Variable	
PR	√	-	$X \rightarrow \langle$之一, one of$\rangle$
HR	√	√	$X \rightarrow \langle X$的$, \text{of}X\rangle$
GR	-	√	$S \rightarrow \langle SX, SX\rangle$

Table 1: A classification of grammar rules for the HPB model. PR = phrasal rule, HR = hierarchical rule, GR = glue rule.

However, HPB translation suffers from a limitation, in that the phrase reorderings lack of contextual information, such as the surrounding words of a phrase and the content of sub-phrases that represented by variables. Consider the following two hierarchical rules in translating a Chinese sentence into English:

$$X \rightarrow \langle X_1 \text{ 的 } X_2,\ X_1 \text{ 's } X_2\rangle \quad (1)$$

$$X \rightarrow \langle X_1 \text{ 的 } X_2,\ X_2 X_1\rangle \quad (2)$$

和 俄罗斯 的 谈判
with Russia 's talks
talks with Russia

Both pattern-match the source sentence, but produce quite different phrase reorderings. The first rule generates a monotone translation, while the second rule swaps the source phrases covered by X_1 and X_2 on the target side. During decoding, the first

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 555–563,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

rule is more likely to be used, as it occurs more frequently in a training corpus. However, the example is not a noun possessive case because the subphrase covered by X_1 is not a noun but a prepositional phrase. Thus, without considering information of sub-phrases, the decoder may make errors on phrase reordering.

Contextual information has been widely used to improve translation performance. It is helpful to reduce ambiguity, thus guide the decoder to choose correct translation for a source text. Several researchers observed that word sense disambiguation improves translation quality on lexical translation (Carpuat and Wu, 2007; Chan et al., 2007). These methods utilized contextual features to determine the correct meaning of a source word, thus help an SMT system choose an appropriate target translation.

Zens and Ney (2006) and Xiong et al. (2006) utilized contextual information to improve phrase reordering. They addressed phrase reordering as a two-class classification problem that translating neighboring phrases serially or inversely. They built a maximum entropy (MaxEnt) classifier based on boundary words to predict the order of neighboring phrases.

He et al. (2008) presented a lexicalized rule selection model to improve both lexical translation and phrase reordering for HPB translation. They built a MaxEnt model for each ambiguous source side based on contextual features. The method was also successfully applied to improve syntax-based SMT translation (Liu et al., 2008), using more sophisticated syntactical features. Shen et al. (2008) integrated various contextual and linguistic features into an HPB system, using surrounding words and dependency information for building context and dependency language models, respectively.

In this paper, we focus on improving phrase reordering for HPB translation. We classify SCFG rules into several reordering patterns consisting of two variables X and F (or E) [1], such as X_1FX_2 and X_2EX_1. We treat phrase reordering as a classification problem and build a MaxEnt model for each source reordering pattern based on various contextual features. We propose a method to integrate the MaxEnt models into an HPB system. Specifically:

- For hierarchical rules, we classify the source-side and the target-side into 7 and 17 reordering patterns, respectively. Target reordering patterns are treated as possible labels. We then build a classifier for each source pattern to predict phrase reorderings. This is different from He et al. (2008), in which they built a classifier for each ambiguous hierarchical source-side. Therefore, the training examples for each MaxEnt model is small and the model maybe unstable. Here, we classify source hierarchical phrases into 7 reordering patterns according to the arrangement of words and variables. We can obtain sufficient samples for each MaxEnt model from large-scale bilingual corpus.

- For glue rules, we extend the HPB model by using bracketing transduction grammar (BTG) (Wu, 1996) instead of the monotone glue rule. By doing this, there are two options for the decoder to merge phrases: serial or inverse. We then build a classifier for glue rules to predict reorderings of neighboring phrases, analogous to Xiong et al. (2006).

- We integrate the MaxEnt based phrase reordering models as features into the HPB model (Chiang, 2005). The feature weights can be tuned together with other feature functions by MERT algorithm (Och, 2003).

Experimental results show that the presented method achieves significant improvement over the baseline. On Chinese-to-English translation tasks of NIST evluation, improvements in BLEU (case-insensitive) are 1.2 on MT06 GALE set, 1.8 on MT06 NIST set, and 2.1 on MT08.

The rest of the paper is structured as follows: Section 2 describes the MaxEnt based phrase reordering method. Section 3 integrates the MaxEnt models into the translation model. In Section 4, we report experimental results. We analyze the presented method and experimental results in Section 5 and conclude in Section 6.

[1] We use F and E to represent source and target words, respectively.

	X and
X 和	with X
	between X and

Figure 1: A source hierarchical phrase and its corresponding target translation.

2 MaxEnt based Phrase Reordering

We regard phrase reordering as a pattern classification problem. A reordering pattern indicates an arrangement of words and variables. Although there are a large amount of hierarchical rules may be extracted from bilingual corpus, these rules can be classified into several reordering patterns (Section 2.1). In addition, we extend the HPB model with BTG, that adding an inverted glue rule to merge phrases inversely (Section 2.2). Therefore, the glue rules are classified into two patterns: serial or inverse. We then build a MaxEnt phrase reordering (MEPR) classifier for each source reordering pattern (Section 2.3). In Section 2.4, we describe contextual features.

2.1 Reordering Pattern Classification for Hierarchical Rule

Hierarchical rule, consisting of both words and variables, is of great importance for the HPB model. During decoding, words are used for lexical translation, and variables capture phrase reordering. We may learn millions of hierarchical rules from a bilingual corpus. Although these rules are different from each other, they can be classified into several reordering patterns according to the arrangement of variables and words.

In this paper, we follow the constraint as described in (Chiang, 2005) that a hierarchical rule can have at most two variables and they cannot be adjacent on the source side. We use "X" to represent the variable, and "F" and "E" to represent word strings in source and target language, respectively. Therefore, in a hierarchical rule, E is the lexical translation of F, while the order of X and E contains phrase reordering information.

For the hierarchical rule that contains one variable (see Figure 1 for example), both the source and the target phrases can be classified into three patterns (Table 2). To reduce the complexity of classification, we do not distinguish the order of word strings. For example, we consider "e_1Xe_2" and "e_2Xe_1" as the same pattern "EXE", because the target words are determined by lexical translation of source words. Our focus is the order between X and E. During decoding the phrases covered by X are dynamically changed and the contextual information of these phrases is ignored for pattern-matching of hierarchical rules.

Source pattern	Target pattern
XF	XE
FX	EX
FXF	EXE

Table 2: A classification of the source side and the target side for the hierarchical rule that contains one variable.

Source pattern	Target pattern
	X_1EX_2
	X_2EX_1
	X_1X_2E
	X_2X_1E
	EX_1X_2
X_1FX_2	EX_2X_1
X_1FX_2F	X_1EX_2E
FX_1FX_2	X_2EX_1E
FX_1FX_2F	EX_1X_2E
	EX_2X_1E
	EX_1EX_2
	EX_2EX_1
	EX_1EX_2E
	EX_2EX_1E

Table 3: A classification of the source side and the target side for the hierarchical rule that contains two variables.

Analogously, for the hierarchical rule that contains two variables, the source phrases are classified into 4 patterns, while the target phrases are classified into 14 patterns, as shown in Table 3. The pattern number on the source side is less than that on the target side, because on the source side, "X_1" always appears before "X_2", and they cannot be adjacent.

2.2 Reordering Pattern Classification for Glue Rule

The HPB model used glue rule to combine phrases serially. The reason is that in some cases, there are no valid translation rules that cover a source span. Therefore, the glue rule provides a default monotone combination of phrases in order to complete a translation. This is not sufficient because in certain cases, the order of phrases may be inverted on the target-side.

In this paper, we extend the glue rule with BTG (Wu, 1996), which consists of three types of rules:

$$X \rightarrow \langle \tilde{f}, \tilde{e} \rangle \tag{3}$$

$$X \rightarrow \langle X_1 X_2, X_1 X_2 \rangle \tag{4}$$

$$X \rightarrow \langle X_1 X_2, X_2 X_1 \rangle \tag{5}$$

Rule 3 is a phrasal rule that translates a source phrase $\tilde{f}$ into a target phrase $\tilde{e}$. Rule 4 merges two consecutive phrases in monotone order, while Rule 5 merges them in inverted order. During decoding, the decoder first uses Rule 3 to produce phrase translation, and then iteratively uses Rule 4 and 5 to merge two neighboring phrases into a larger phrase until the whole sentence is covered.

We replace the original glue rules in the HPB model with BTG rules (see Table 4). We believe that the extended HPB model can benefit from BTG in the following aspects:

- In the HPB model, as we mentioned, hierarchical rules are constrained in that nonterminals cannot be adjacent on the source side, i.e., the source side cannot contain "$X_1 X_2$". One reason is that it will heavily increase the rule table size. The other reason is that it can cause a spurious ambiguity problem (Chiang, 2005). The inverted glue rule in BTG, however, can solve this problem.

- In the HPB model, only a monotone glue rule is provided to merge phrases serially. In the extended HPB model, the combination of phrases is classified into two types: monotone and inverse.

Analogous to Xiong et al. (2006), to perform context-dependent phrase reordering, we build a MaxEnt based classifier for glue rules to predict the order of two neighboring phrases. In this paper, we utilize more contextual features.

Glue Rule	Extended Glue Rule
$S \rightarrow \langle X, X \rangle$	$S \rightarrow \langle X, X \rangle$
$S \rightarrow \langle SX, SX \rangle$	$X \rightarrow \langle X_1 X_2, X_1 X_2 \rangle$
-	$X \rightarrow \langle X_1 X_2, X_2 X_1 \rangle$

Table 4: Extending the glue rules in the HPB model with BTG.

2.3 The MaxEnt based Phrase Reordering Classifier

As described above, we classified phrase reorderings into several patterns. Therefore, phrase reordering can be regarded as a classification problem: for each source reordering pattern, we treat the corresponding target reordering patterns as labels.

We build a general classification model within the MaxEnt framework:

$$P_{me}(T_\gamma | T_\alpha, \alpha, \gamma) = \frac{exp(\sum_i \lambda_i h_i(\gamma, \alpha, f(X), e(X))}{\sum_{T_\gamma} exp(\sum_i \lambda_i h_i(\gamma, \alpha, f(X), e(X))} \tag{6}$$

where, α and γ are the source and target side, respectively. T_α/T_γ is the reordering pattern of α/γ. $f(X)$ and $e(X)$ are the phrases that covered by X one the source and target side, respectively. Given a source phrase, the model predicts a target reordering pattern, considering various contextual features (Section 2.4).

According to the classification of reordering patterns, there are 3 kinds of classifiers:

- P_{me}^{hr1} includes 3 classifiers for the hierarchical rules that contain 1 variable. Each of the classifier has 3 labels;

- P_{me}^{hr2} includes 4 classifiers for the hierarchical rules that contain 2 variables. Each of the classifier has 14 labels;

- P_{me}^{gr} includes 1 classifier for the glue rules. The classifier has 2 labels that predict a monotone or inverse order for two neighboring phrases. This classifier is analogous to (Xiong et al., 2006).

There are 8 classifiers in total. This is much fewer than the classifiers in He et al. (2008), in which a classifier was built for each ambiguous hierarchical source side. In this way, a classifier may face the risk that there are not enough samples for training a stable MaxEnt model. While our approach is more generic, rather than training a MaxEnt model for a specific hierarchical source side, we train a model for a source reordering pattern. Thus, we reduce the number of classifiers and can extract large training examples for each classifier.

2.4 Feature definition

For a reordering pattern pair $\langle T_\alpha, T_\gamma \rangle$, we design three feature functions for phrase reordering classifiers:

- Source lexical feature, including boundary words and neighboring words. Boundary words are the left and right word of the source phrases covered by $f(X)$, while neighboring words are the words that immediately to the left and right of a source phrase $f(\alpha)$;
- Part-of-Speech (POS) feature, POS tags of the boundary and neighboring words on the source side.
- Target lexical feature, the boundary words of the target phrases covered by $e(X)$.

These features can be extracted together with translation rules from bilingual corpus. However, since the hierarchical rule does not allow for adjacent variables on the source side, we extract features for P_{me}^{gr} by using the method described in Xiong et al. (2006). We train the classifiers with a MaxEnt trainer (Zhang, 2004).

3 Integrating the MEPR Classifier into the HPB Model

The HPB model is built within the standard log-linear framework (Och and Ney, 2002):

$$Pr(e|f) \propto \sum_i \lambda_i h_i(\alpha, \gamma) \tag{7}$$

where $h_i(\alpha, \gamma)$ is a feature function and λ_i is the weight of h_i. The HPB model has the following features: translation probabilities $p(\gamma|\alpha)$ and $p(\alpha|\gamma)$, lexical weights $p_w(\gamma|\alpha)$ and $p_w(\alpha|\gamma)$, word penalty, phrase penalty, glue rule penalty, and a target n-gram language model.

To integrate the MEPR classifiers into the translation model, the features of the log-linear model are changed as follows:

- We add the MEPR classifier as a feature function to predict reordering pattern:

  $$h_{me}(T_\gamma|T_\alpha) = \sum P_{me}(T_\gamma|T_\alpha, \alpha, \gamma) \tag{8}$$

  During decoding, we first classify each source phrase into one of the 8 source reordering patterns and then use the corresponding MEPR classifier to predict the possible target reordering pattern. Therefore, the contextual information guides the decoder to perform phrase reordering.

- We split the "glue rule penalty" into two features: monotone glue rule number and inverted glue rule number. These features reflect preference of the decoder for using monotone or inverted glue rules.

The advantage of our extension method is that the weights of the new features can be tuned together with the other features by MERT algorithm (Och, 2003).

We utilize a standard CKY algorithm for decoding. Given a source sentence, the decoder searches the best derivation from the bottom to top. For a source span $[j_1, j_2]$, the decoder uses three kinds of rules: translation rules produce lexical translation and phrase reordering (for hierarchical rules), monotone rule merges any neighboring sub-spans $[j_1, k]$ and $[k+1, j_2]$ serially, and inverted rule swap them. Note that when the decoder uses the monotone and inverted glue rule to combine sub-spans, it merges phrases that do not contain variables. Because the CKY algorithm guarantees that the sub spans $[j_1, k]$ and $[k+1, j_2]$ have been translated before $[j_1, j_2]$.

4 Experiments

We carried out experiments on four systems:

- HPB: replication of the Hiero system (Chiang, 2005);
- HPB+MEHR: HPB with MaxEnt based classifier for hierarchical rules, as described in Section 2.1;
- HPB+MEGR: HPB with MaxEnt based classifier for glue rules, as described in Section 2.2;
- HPB+MER: HPB with MaxEnt based classifier for both hierarchical and glue rules.

All systems were tuned on NIST MT03 and tested on MT06 and MT08. The evaluation metric was BLEU (Papineni et al., 2002) with case-insensitive matching of n-grams, where $n = 4$.

We evaluated our approach on Chinese-to-English translation. The training data contained 77M Chinese words and 81M English words. These data come from 17 corpora: LDC2002E18, LDC2002L27, LDC2002T01, LDC2003E07, LDC2003E14, LDC2004T07, LDC2005E83, LDC2005T06, LDC2005T10, LDC2005T34, LDC2006E24, LDC2006E26, LDC2006E34, LDC2006E86, LDC2006E92, LDC2006E93, LDC2004T08 (HK_News, HK_Hansards).

To obtain word alignments, we first ran GIZA++ (Och and Ney, 2000) in both translation directions and then refined the results using the "grow-diag-final" method (Koehn et al., 2003). For the language model, we used the SRI Language Modeling Toolkit (Stolcke, 2002) to train two 4-gram models on the Xinhua portion of the GigaWord corpus and the English side of the training corpus.

4.1 Statistical Information of Rules

Hierarchical Rules

We extracted 162M translation rules from the training corpus. Among them, there were 127M hierarchical rules, which contained 85M hierarchical source phrases. We classified these source phrases into 7 patterns as described in Section 2.1. Table 5 shows the statistical information. We observed that the most frequent source pattern is "FXF", which accounted for 46.1% of the total. Interestingly, "X_1FX_2", accounting for 3.7%, was the least frequent pattern. Table 6 and Table 7 show the distributions of reordering patterns for hierarchical source phrases that contain one and two variables, respectively. From both the tables, we observed that for Chinese-to-English translation, the most frequent "reordering" pattern for a source phrase is monotone translation (bold font in the tables).

Source Pattern	Percentage (%)
XF	9.7
FX	9.7
FXF	46.1
X_1FX_2	3.7
X_1FX_2F	11.9
FX_1FX_2	11.8
FX_1FX_2F	7.1

Table 5: Statistical information of reordering pattern classification for hierarchical source phrases.

#	Source		
Target (%)	FX	XF	FXF
EX	**82.8**	7	4.6
XE	6.4	**82.4**	2.9
EXE	10.8	10.6	**92.5**

Table 6: Percentage of target reordering pattern for each source pattern containing one variable.

Glue Rules

To train a MaxEnt classifier for glue rules, we extracted 65.8M reordering (monotone and inverse) instances from the training data, using the algorithm described in Xiong et al. (2006). There were 63M monotone instances, accounting for 95.7%. Although instances of inverse reordering accounted for 4.3%, they are important for phrase reordering.

4.2 Results

Table 8 shows the BLEU scores and decoding speed of the four systems on MT06 (GALE set and NIST set) and MT08. From the table, we made the following observations:

#	Source			
Target (%)	FX_1FX_2	FX_1FX_2F	X_1FX_2	X_1FX_2F
EX_1EX_2	**78.1**	3.6	4.6	1.2
EX_1EX_2E	2.1	**75.9**	0.1	1.6
EX_1X_2	6.8	0.1	2.8	0.1
EX_1X_2E	1.8	11.2	0.1	2
EX_2EX_1	2.8	1.4	2	1.2
EX_2EX_1E	1.4	2.3	0.7	1.1
EX_2X_1	0.9	0.1	2.2	0.2
EX_2X_1E	1	1.1	0.9	1.0
X_1EX_2	1.9	0.1	**71.2**	3.3
X_1EX_2E	0.7	2.1	6	**78.4**
X_1X_2E	0.1	0.1	2.8	5.9
X_2EX_1	0.9	0.4	1.6	0.7
X_2EX_1E	1.5	1.5	2.6	2.4
X_2X_1E	0.1	0.04	2.2	0.8

Table 7: Percentage of target reordering pattern for each source pattern containing two variables.

System	Test Data			Speed
	06G	06N	08	
HPB	14.19	33.93	25.85	8.7
HPB+MEHR	14.76	34.95	26.56	3.2
HPB+MEGR	15.09	35.72	27.34	2.7
HPB+MER	15.42	35.80	27.94	1.7

Table 8: BLEU percentage scores and translation speed (words/second) on test data. G=GALE set, N=NIST set. All improvements are statistically significant ($p < 0.01$). Note that MT06G has one reference for each source sentence, while the MT06N and MT08 have four references.

- The HPB+MEHR system achieved significant improvements on all test sets compared to the HPB system. The absolute increases in BLEU scores ranging from 0.6 (on 06G) to 1.0 (on 06N) percentage points. This indicates that the ME based reordering for hierarchical rules improves translation performance.

- The HPB+MEGR system achieved significant improvements over the HPB system. The absolute increases in BLEU scores ranging from 0.9 (on 06G) to 1.8 (on 06N) percentage points. The HPB+MEGR system overcomes the shortcoming of the HPB system by using both monotone glue rule and inverted glue rule, which merging phrases serially and inversely, respectively. Furthermore, the HPB+MEGR system outperformed the HPB+MEHR system.

- The HPB+MER system achieved the best performances on all test sets, with absolute increases of BLEU scores ranging from 1.2 (on 06G) to 2.1 (on 08). The system combining with ME based reordering for both hierarchical and glue rules, outperformed both the HPB+MEHR and HPB+MEGR systems.

- In addition, we found that the decoder takes more time after adding the MEPR models (the *speed* column of Table 8). The average translation speed of HPB+MER (1.7 words/second) is about 5 times slower than the HPB system (8.7 words/second). One reason is that the MEPR models utilized contextual information to compute classification scores. Another reason is that adding inverted glue rules increases search space.

5 Analysis

Experiments showed that the presented approach achieved significant gains on BLEU scores. Furthermore, we sought to explore what would happen after integrating the MEPR classifiers into the translation model. We compared the outputs of HPB and HPB+MER and observed that the translation performance are improved on phrase reordering. For example, the translations of a source sentence in MT08 are as follows [2]:

- **Src:** 韩国$_1$ 政府$_2$ 上个月$_3$ 底$_4$ 开始$_5$ 启动$_6$ 对$_7$ 朝鲜$_8$ 提供$_9$ 40万$_{10}$ 吨$_{11}$ 大米$_{12}$ 的$_{13}$ 援助$_{14}$ 计划$_{15}$

- **Ref:** At the end$_4$ of last$_3$ month$_3$, the South$_1$ Korean$_1$ government$_2$ began$_5$ a plan$_{15}$ to provide$_9$ 400,000$_{10}$ tonnes$_{11}$ of rice$_{12}$ as aid$_{14}$ to North$_8$ Korea$_8$

- **HPB:** South Korean government late last month to start with 400,000 tons of rice aid to the DPRK

- **HPB+MER**: Start at the end of last month, South Korean government plans to provide 400,000 tons of rice in aid to the DPRK

The most obvious error that the baseline system makes is the order of the time expression "*上个月底, the end of last month*", which should be either at the beginning or the end on target side. However, the baseline produced a monotone translation by using the rule "*韩国 政府* X_1, *South Korean government* X_1". The HPB+MER system, however, moved the time expression to the beginning of the sentence by using the rule "*韩国 政府* X_1, X_1 *South Korean government*'. The reason is that the MaxEnt phrase reordering classifier uses the contextual features (e.g. the boundary words) of the phrase covered by X_1 to predict the phrase reordering as X_1E for the source phrase FX_1.

6 Conclusions and Future Work

In this paper, we have proposed a MaxEnt based phrase reordering approach to help the HPB decoder select reordering patterns. We classified hierarchical rules into 7 reordering patterns on the source side and 17 reordering patterns on the target side. In addition, we introduced BTG to enhance the reordering of neighboring phrases and classified the glue rules into two patterns. We trained a MaxEnt classifier for each reordering pattern and integrated it into a standard HPB system. Experimental results showed that the proposed approach achieved significant improvements over the baseline. The absolute improvements in BLEU range from 1.2 to 2.1.

MaxEnt based phrase reordering provides a mechanism to incorporate various features into the translation model. In this paper, we only use a few feature sets based on standard contextual word and POS tags. We believe that additional features will further improve translation performance. Such features could include syntactical features (Chiang et al., 2009). In the future, we will carry out experiments on deeper features and evaluate the effects of different feature sets.

Abstract

We present the first evaluation of the utility of automatic evaluation metrics on surface realizations of Penn Treebank data. Using outputs of the OpenCCG and XLE realizers, along with ranked WordNet synonym substitutions, we collected a corpus of generated surface realizations. These outputs were then rated and post-edited by human annotators. We evaluated the realizations using seven automatic metrics, and analyzed correlations obtained between the human judgments and the automatic scores. In contrast to previous NLG meta-evaluations, we find that several of the metrics correlate moderately well with human judgments of both adequacy and fluency, with the TER family performing best overall. We also find that all of the metrics correctly predict more than half of the significant system-level differences, though none are correct in all cases. We conclude with a discussion of the implications for the utility of such metrics in evaluating generation in the presence of variation. A further result of our research is a corpus of post-edited realizations, which will be made available to the research community.

1 Introduction and Background

In building surface-realization systems for natural language generation, there is a need for reliable automated metrics to evaluate the output. Unlike in parsing, where there is usually a single gold-standard parse for a sentence, in surface realization there are usually many grammatically-acceptable ways to express the same concept. This parallels the task of evaluating machine-translation (MT) systems: for a given segment in the source language, there are usually several acceptable translations into the target language. As human evaluation of translation quality is time-consuming and expensive, a number of automated metrics have been developed to evaluate the quality of MT outputs. In this study, we investigate whether the metrics developed for MT evaluation tasks can be used to reliably evaluate the outputs of surface realizers, and which of these metrics are best suited to this task.

A number of surface realizers have been developed using the Penn Treebank (PTB), and BLEU scores are often reported in the evaluations of these systems. But how useful is BLEU in this context? The original BLEU study (Papineni et al., 2001) scored MT outputs, which are of generally lower quality than grammar-based surface realizations. Furthermore, even for MT systems, the usefulness of BLEU has been called into question (Callison-Burch et al., 2006). BLEU is designed to work with multiple reference sentences, but in treebank realization, there is only a single reference sentence available for comparison.

A few other studies have investigated the use of such metrics in evaluating the output of NLG systems, notably (Reiter and Belz, 2009) and (Stent et al., 2005). The former examined the performance of BLEU and ROUGE with computer-generated weather reports, finding a moderate correlation with human fluency judgments. The latter study applied several MT metrics to paraphrase data from Barzilay and Lee's corpus-based system (Barzilay and Lee, 2003), and found moderate correlations with human adequacy judgments, but little correlation with fluency judgments. Cahill (2009) examined the performance of six MT metrics (including BLEU) in evaluating the output of a LFG-based surface realizer for

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 564–574,
MIT, Massachusetts, USA, 9-11 October 2010.

German, also finding only weak correlations with the human judgments.

To study the usefulness of evaluation metrics such as BLEU on the output of grammar-based surface realizers used with the PTB, we assembled a corpus of surface realizations from three different realizers operating on Section 00 of the PTB. Two human judges evaluated the adequacy and fluency of each of the realizations with respect to the reference sentence. The realizations were then scored with a number of automated evaluation metrics developed for machine translation. In order to investigate the correlation of targeted metrics with human evaluations, and gather other acceptable realizations for future evaluations, the judges manually repaired each unacceptable realization during the rating task. In contrast to previous NLG meta-evaluations, we found that several of the metrics correlate moderately well with human judgments of both adequacy and fluency, with the TER family performing best. However, when looking at statistically significant system-level differences in human judgments, we found that some of the metrics get some of the rankings correct, but none get them all correct, with different metrics making different ranking errors. This suggests that multiple metrics should be routinely consulted when comparing realizer systems.

Overall, our methodology is similar to that of previous MT meta-evaluations, in that we collected human judgments of system outputs, and compared these scores with those assigned by automatic metrics. A recent alternative approach to paraphrase evaluation is ParaMetric (Callison-Burch et al., 2008); however, it requires a corpus of annotated (aligned) paraphrases (which does not yet exist for PTB data), and is arguably focused more on paraphrase analysis than paraphrase generation.

The plan of the paper is as follows: Section 2 discusses the preparation of the corpus of surface realizations. Section 3 describes the human evaluation task and the automated metrics applied. Sections 4 and 5 present and discuss the results of these evaluations. We conclude with some general observations about automatic evaluation of surface realizers, and some directions for further research.

2 Data Preparation

We collected realizations of the sentences in Section 00 of the WSJ corpus from the following three sources:

1. OpenCCG, a CCG-based chart realizer (White, 2006)
2. The XLE Generator, a LFG-based system developed by Xerox PARC (Crouch et al., 2008)
3. WordNet synonym substitutions, to investigate how differences in lexical choice compare to grammar-based variation.[1]

Although all three systems used Section 00 of the PTB, they were applied with various parameters (e.g., language models, multiple-output versus single-output) and on different input structures. Accordingly, our study does not compare OpenCCG to XLE, or either of these to the WordNet system.

2.1 OpenCCG realizations

OpenCCG is an open source parsing/realization library with multimodal extensions to CCG (Baldridge, 2002). The OpenCCG chart realizer takes logical forms as input and produces strings by combining signs for lexical items. Alternative realizations are scored using integrated n-gram and perceptron models. For robustness, fragments are greedily assembled when necessary. Realizations were generated from 1,895 gold standard logical forms, created by constrained parsing of development-section derivations. The following OpenCCG models (which differ essentially in the way the output is ranked) were used:

1. Baseline 1: Output ranked by a trigram word model
2. Baseline 2: Output ranked using three language models (3-gram words + 3-gram words with named entity class replacement + factored language model of words, POS tags and CCG supertags)

[1] Not strictly surface realizations, since they do not involve an abstract input specification, but for simplicity we refer to them as realizations throughout.

3. Baseline 3: Perceptron with syntax features and the three LMs mentioned above

4. Perceptron full-model: n-best realizations ranked using perceptron with syntax features and the three n-gram models, as well as discriminative n-grams

The perceptron model was trained on sections 02-21 of the CCGbank, while a grammar extracted from section 00-21 was used for realization. In addition, oracle supertags were inserted into the chart during realization. The purpose of such a non-blind testing strategy was to evaluate the quality of the output produced by the statistical ranking models in isolation, rather than focusing on grammar coverage, and avoid the problems associated with lexical smoothing, i.e. lexical categories in the development section not being present in the training section.

To enrich the variation in the generated realizations, dative-alternation was enforced during realization by ensuring alternate lexical categories of the verb in question, as in the following example:

(1) the executives gave [the chefs] [a standing ovation]

(2) the executives gave [a standing ovation] [to the chefs]

2.2 XLE realizations

The corpus of realizations generated by the XLE system contained 42,527 surface realizations of approximately 1,421 section 00 sentences (an average of 30 per sentence), initially unranked. The LFG f-structures used as input to the XLE generator were derived from automatic parses, as described in (Riezler et al., 2002). The realizations were first tokenized using Penn Treebank conventions, then ranked using perplexities calculated from the same trigram word model used with OpenCCG. For each sentence, the top 4 realizations were selected. The XLE generator provides an interesting point of comparison to OpenCCG as it uses a manually-developed grammar with inputs that are less abstract but potentially noisier, as they are derived from automatic parses rather than gold-standard ones.

2.3 WordNet synonymizer

To produce an additional source of variation, the nouns and verbs of the sentences in section 00 of the PTB were replaced with all of their WordNet synonyms. Verb forms were generated using verb stems, part-of-speech tags, and the *morphg* tool.[2] These substituted outputs were then filtered using the n-gram data which Google Inc. has made available.[3] Those without any 5-gram matches centered on the substituted word (or 3-gram matches, in the case of short sentences) were eliminated.

3 Evaluation

From the data sources described in the previous section, a corpus of realizations to be evaluated by the human judges was constructed by randomly choosing 305 sentences from section 00, then selecting surface realizations of these sentences using the following algorithm:

1. Add OpenCCG's best-scored realization.

2. Add other OpenCCG realizations until all four models are represented, to a maximum of 4.

3. Add up to 4 realizations from either the XLE system or the WordNet pool, chosen randomly.

The intent was to give reasonable coverage of all realizer systems discussed in Section 2 without overloading the human judges. "System" here means any instantiation that emits surface realizations, including various configurations of OpenCCG (using different language models or ranking systems), and these can be multiple-output, such as an n-best list, or single-output (best-only, worst-only, etc.). Accordingly, more realizations were selected from the OpenCCG realizer because 5 different systems were being represented. Realizations were chosen randomly, rather than according to sentence types or other criteria, in order to produce a representative sample of the corpus. In total, 2,114 realizations were selected for evaluation.

[2] http://www.informatics.sussex.ac.uk/research/groups/nlp/carroll/morph.html

[3] http://www.ldc.upenn.edu/Catalog/docs/LDC2006T13/readme.txt

3.1 Human judgments

Two human judges evaluated each surface realization on two criteria: *adequacy*, which represents the extent to which the output conveys all and only the meaning of the reference sentence; and *fluency*, the extent to which it is grammatically acceptable. The realizations were presented to the judges in sets containing a reference sentence and the 1-8 outputs selected for that sentence. To aid in the evaluation of adequacy, one sentence each of leading and trailing context were displayed. Judges used the guidelines given in Figure 1, based on the scales developed by the NIST Machine Translation Evaluation Workshop.

In addition to rating each realization on the two five-point scales, each judge also repaired each output which he or she did not judge to be fully adequate and fluent. An example is shown in Figure 2. These repairs resulted in new reference sentences for a substantial number of sentences. These repaired realizations were later used to calculate *targeted* versions of the evaluation metrics, i.e., using the repaired sentence as the reference sentence. Although targeted metrics are not fully automatic, they are of interest because they allow the evaluation algorithm to focus on what is actually wrong with the input, rather than all textual differences. Notably, targeted TER (HTER) has been shown to be more consistent with human judgments than human annotators are with one another (Snover et al., 2006).

3.2 Automatic evaluation

The realizations were also evaluated using seven automatic metrics:

- IBM's BLEU, which scores a hypothesis by counting n-gram matches with the reference sentence (Papineni et al., 2001), with smoothing as described in (Lin and Och, 2004)
- The NIST n-gram evaluation metric, similar to BLEU, but rewarding rarer n-gram matches, and using a different length penalty
- METEOR, which measures the harmonic mean of unigram precision and recall, with a higher weight for recall (Banerjee and Lavie, 2005)
- TER (Translation Edit Rate), a measure of the number of edits required to transform a hypothesis sentence into the reference sentence (Snover et al., 2006)
- TERP, an augmented version of TER which performs phrasal substitutions, stemming, and checks for synonyms, among other improvements (Snover et al., 2009)
- TERPA, an instantiation of TERP with edit weights optimized for correlation with adequacy in MT evaluations
- GTM (General Text Matcher), a generalization of the F-measure that rewards contiguous matching spans (Turian et al., 2003)

Additionally, targeted versions of BLEU, METEOR, TER, and GTM were computed by using the human-repaired outputs as the reference set. The human repair was different from the reference sentence in 193 cases (about 9% of the total), and we expected this to result in better scores and correlations with the human judgments overall.

4 Results

4.1 Human judgments

Table 1 summarizes the dataset, as well as the mean adequacy and fluency scores garnered from the human evaluation. Overall adequacy and fluency judgments were high (4.16, 3.63) for the realizer systems on average, and the best-rated realizer systems achieved mean fluency scores above 4.

4.2 Inter-annotator agreement

Inter-annotator agreement was measured using the κ-coefficient, which is commonly used to measure the extent to which annotators agree in category judgment tasks. κ is defined as $\frac{P(A)-P(E)}{1-P(E)}$, where $P(A)$ is the observed agreement between annotators and $P(E)$ is the probability of agreement due to chance (Carletta, 1996). Chance agreement for this data is calculated by the method discussed in Carletta's squib. However, in previous work in MT meta-evaluation, Callison-Burch et al. (2007), assume the less strict criterion of uniform chance agreement, i.e. $\frac{1}{5}$ for a five-point scale. They also

Score	*Adequacy*	*Fluency*
5	All the meaning of the reference	Perfectly grammatical
4	Most of the meaning	Awkward or non-native; punctuation errors
3	Much of the meaning	Agreement errors or minor syntactic problems

introduce the notion of "relative" κ, which measures how often two or more judges agreed that $A > B$, $A = B$, or $A < B$ for two outputs A and B, irrespective of the specific values given on the five-point scale; here, uniform chance agreement is taken to be $\frac{1}{3}$. We report both absolute and relative κ in Table 2, using actual chance agreement rather than uniform chance agreement.

The κ scores of 0.60 for adequacy and 0.63 for fluency across the entire dataset represent "substantial" agreement, according to the guidelines discussed in (Landis and Koch, 1977), better than is typically reported for machine translation evaluation tasks; for example, Callison-Burch et al. (2007) reported "fair" agreement, with κ = 0.281 for fluency and κ = 0.307 for adequacy (relative). Assuming the uniform chance agreement that the previously cited work adopts, our inter-annotator agreements (both absolute and relative) are still higher. This is likely due to the generally high quality of the realizations evaluated, leading to easier judgments.

4.3 Correlation with automatic evaluation

To determine how well the automatic evaluation methods described in Section 3 correlate with the human judgments, we averaged the human judgments for adequacy and fluency, respectively, for each of the rated realizations, and then computed both Pearson's correlation coefficient and Spearman's rank correlation coefficient between these scores and each of the metrics. Spearman's correlation makes fewer assumptions about the distribution of the data, but may not reflect a linear relationship that is actually present. Both are frequently reported in the literature. Due to space constraints, we show only Spearman's correlation, although the TER family scored slightly better on Pearson's coefficient, relatively.

The results for Spearman's correlation are given in Table 3. Additionally, the average scores for adequacy and fluency were themselves averaged into a single score, following (Snover et al., 2009), and the Spearman's correlation of each of the automatic metrics with these scores are given in Table 4. All reported correlations are significant at $p < 0.001$.

4.4 Bootstrap sampling of correlations

For each of the sub-corpora shown in Table 1, we computed confidence intervals for the correlations between adequacy and fluency human scores with selected automatic metrics (BLEU, HBLEU, TER, TERP, and HTER) as described in (Koenh, 2004). We sampled each sub-corpus 1000 times with replacement, and calculated correlations between the rankings induced by the human scores and those induced by the metrics for each reference sentence. We then used these coefficients to estimate the confidence interval, after excluding the top 25 and bottom 25 coefficients, following (Lin and Och, 2004). The results of this for the BLEU metric are shown in Table 5. We determined which correlations lay within the 95% confidence interval of the best performing metric in each row of Table Table 3; these figures are italicized.

5 Discussion

5.1 Human judgments of systems

The results for the four OpenCCG perceptron models mostly confirm those reported in (White and Rajkumar, 2009), with one exception: the B-3 model was below B-2, though the P-B (perceptron-best) model still scored highest. This may have been due to differences in the testing scenario. None of the differences in adequacy scores among the individual systems are significant, with the exception of the WordNet system. In this case, the lack of word-sense disambiguation for the substituted words results in a poor overall adequacy score (e.g., *wage floor* → *wage story*). Conversely, it scores highest for fluency, as substituting a noun or verb with a synonym does not usually introduce ungrammaticality.

5.2 Correlations of human judgments with MT metrics

Of the non-human-targeted metrics evaluated, BLEU and TER/TERP demonstrate the highest correlations with the human judgments of fluency ($r = 0.62, 0.64$). The TER family of evaluation metrics have been observed to perform very well in MT-evaluation tasks, and although the data evaluated here differs from typical MT data in some important ways, the correlation of TERP with the human judgments is substantial. In contrast with previous MT evaluations where TERP performs considerably better than TER, these scored close to equal on our data, possibly because TERP's stem, synonym, and paraphrase matching are less useful when most of the variation is syntactic.

The correlations with BLEU and METEOR are lower than those reported in (Callison-Burch et al., 2007); in that study, BLEU achieved adequacy and fluency correlations of 0.690 and 0.722, respectively, and METEOR achieved 0.701 and 0.719. The correlations for these metrics might be expected to be lower for our data, since overall quality is higher, making the metrics' task more difficult as the outputs involve subtler differences between acceptable and unacceptable variation.

The human-targeted metrics (represented by the prefixed *H* in the data tables) correlated even more strongly with the human judgments, compared to the non-targeted versions. HTER demonstrated the best correlation with realizer fluency ($r = 0.75$).

For several kinds of acceptable variation involving the rearrangement of constituents (such as dative shift), TERP gives a more reasonable score than BLEU, due to its ability to directly evaluate phrasal shifts. The following realization was rated 4.5 for fluency, and was more correctly ranked by TERP than BLEU:

(3) *Ref:* The deal also gave Mitsui access to a high-tech medical product.

(4) *Realiz.:* The deal also gave access to a high-tech medical product to Mitsui.

For each reference sentence, we compared the ranking of its realizations induced from the human scores to the ranking induced from the TERP score, and counted the rank errors by the latter, informally categorizing them by error type (see Table 7). In the 50 sentences with the highest numbers of rank errors, 17 were affected by punctuation differences, typically involving variation in comma placement. Human fluency judgments of outputs with only punctuation problems were generally high, and many realizations with commas inserted or removed were rated fully fluent by the annotators. However, TERP penalizes such insertions or deletions. Agreement errors are another frequent source of ranking errors for TERP. The human judges tended to harshly penalize sentences with number-agreement or tense errors, whereas TERP applies only a single substitution penalty for each such error. We expect that with suitable optimization of edit weights to avoid over-penalizing punctuation shifts and under-penalizing agreement errors, TERP would exhibit an even stronger correlation with human fluency judgments.

None of the evaluation metrics can distinguish an acceptable movement of a word or constituent from an unacceptable movement, with only one reference sentence. A substantial source of error for both TERP and BLEU is variation in adverbial placement, as shown in (7).

Similar errors are seen with prepositional phrases and some commonly-occurring temporal adverbs, which typically admit a number of variations in placement. Another important example of acceptable variation which these metrics do not generally rank correctly is dative alternation:

(7) *Ref.* We need to clarify what exactly is wrong with it.

(5) *Ref.* When test booklets were passed out 48 hours ahead of time, she says she copied questions in the social studies section and gave the answers to students.

(6) *Realiz.* When test booklets were passed out 48 hours ahead of time , she says she copied questions in the social studies section and gave students the answers.

The correlations of each of the metrics with the human judgments of fluency for the realizer systems indicate at least a moderate relationship, in contrast with the results reported in (Stent et al., 2005) for paraphrase data, which found an inverse correlation for fluency, and (Cahill, 2009) for the output of a surface realizer for German, which found only a weak correlation. However, the former study employed a corpus-based paraphrase generation system rather than grammar-driven surface realizers, and the resulting paraphrases exhibited much broader variation. In Cahill's study, the outputs of the realizer were almost always grammatically correct, and the automated evaluation metrics were ranking markedness instead of grammatical acceptability.

5.3 System-level comparisons

In order to investigate the efficacy of the metrics in ranking different realizer systems, or competing realizations from the same system generated using different ranking models, we considered seven different "systems" from the whole dataset of realizations. These consisted of five OpenCCG-based realizations (the best realization from three baseline models, and the best and the worst realization from the full perceptron model), and two XLE-based systems (the best and the worst realization, after ranking the outputs of the XLE realizer with an n-gram model). The mean of the combined adequacy and fluency scores of each of these seven systems was compared with that of every other system, resulting in 21 pairwise comparisons. Then Tukey's HSD test was performed to determine the systems which differed significantly in terms of the average adequacy and fluency rating they received.[4] The test revealed five pairwise comparisons where the scores were significantly different.

Subsequently, for each of these systems, an overall system-level score for each of the MT metrics was calculated. For the five pairwise comparisons where the adequacy-fluency group means differed significantly, we checked whether the metric ranked the systems correctly. Table 8 shows the results of a pairwise comparison between the ranking induced by each evaluation metric, and the ranking induced by the human judgments. Five of the seven non-targeted metrics correctly rank more than half of the systems. NIST, METEOR, and GTM get the most comparisons right, but neither NIST nor GTM correctly rank the OpenCCG-baseline model 1 with respect to the XLE-best model. TER and TERP get two of the five comparisons correct, and they incorrectly rank two of the five OpenCCG model comparisons, as well as the comparison between the XLE-worst and OpenCCG-best systems.

For the targeted metrics, HNIST is correct for all five comparisons, while neither HBLEU nor HMETEOR correctly rank all the OpenCCG models. On the other hand, HTER and HGTM incorrectly rank the XLE-best system versus OpenCCG-based models.

In summary, some of the metrics get some of the rankings correct, but none of the non-targeted metrics get all of them correct. Moreover, different metrics make different ranking errors. This argues for

[4] This particular test was chosen since it corrects for multiple post-hoc analyses conducted on the same data-set.

the use of multiple metrics in comparing realizer systems.

6 Conclusion

Our study suggests that although the task of evaluating the output from realizer systems differs from the task of evaluating machine translations, the automatic metrics used to evaluate MT outputs deliver moderate correlations with combined human fluency and adequacy scores when used on surface realizations. We also found that the MT-evaluation metrics are useful in evaluating different versions of the same realizer system (e.g., the various OpenCCG realization ranking models), and finding cases where a system is performing poorly. As in MT-evaluation tasks, human-targeted metrics have the highest correlations with human judgments overall. These results suggest that the MT-evaluation metrics are useful for developing surface realizers. However, the correlations are lower than those reported for MT data, suggesting that they should be used with caution, especially for cross-system evaluation, where consulting multiple metrics may yield more reliable comparisons. In our study, the targeted version of TERP correlated most strongly with human judgments of fluency.

In future work, the performance of the TER family of metrics on this data might be improved by optimizing the edit weights used in computing its scores, so as to avoid over-penalizing punctuation movements or under-penalizing agreement errors, both of which were significant sources of ranking errors. Multiple reference sentences may also help mitigate these problems, and the corpus of human-repaired realizations that has resulted from our study is a step in this direction, as it provides multiple references for some cases. We expect the corpus to also prove useful for feature engineering and error analysis in developing better realization models.[5]

Acknowledgements

We thank Aoife Cahill and Tracy King for providing us with the output of the XLE generator. We also thank Chris Callison-Burch and the anonymous reviewers for their helpful comments and suggestions.

Abstract

Part-of-speech (POS) induction is one of the most popular tasks in research on unsupervised NLP. Many different methods have been proposed, yet comparisons are difficult to make since there is little consensus on evaluation framework, and many papers evaluate against only one or two competitor systems. Here we evaluate seven different POS induction systems spanning nearly 20 years of work, using a variety of measures. We show that some of the oldest (and simplest) systems stand up surprisingly well against more recent approaches. Since most of these systems were developed and tested using data from the WSJ corpus, we compare their generalization abilities by testing on both WSJ and the multilingual Multext-East corpus. Finally, we introduce the idea of evaluating systems based on their ability to produce cluster prototypes that are useful as input to a prototype-driven learner. In most cases, the prototype-driven learner outperforms the unsupervised system used to initialize it, yielding state-of-the-art results on WSJ and improvements on non-English corpora.

1 Introduction

In recent years, unsupervised learning has become a hot area in NLP, in large part due to the use of sophisticated machine learning approaches which promise to deliver better results than more traditional methods. Often the new approaches are tested using part-of-speech (POS) tagging as an example application, and usually they are shown to perform better than one or another comparison system. However, it is difficult to draw overall conclusions about the relative performance of unsupervised POS tagging systems because of differences in evaluation measures, and the fact that no paper includes direct comparisons against more than a few other systems. In this paper, we attempt to remedy that situation by providing a comprehensive evaluation of seven different POS induction systems spanning nearly 20 years of research. We focus specifically on POS *induction* systems, where no prior knowledge is available, in contrast to POS *disambiguation* systems (Merialdo, 1994; Toutanova and Johnson, 2007; Naseem et al., 2009; Ravi and Knight, 2009; Smith and Eisner, 2005), which use a dictionary to provide possible tags for some or all of the words in the corpus, or *prototype-driven* systems (Haghighi and Klein, 2006), which use a small set of prototypes for each tag class, but no dictionary. Our motivation stems from another part of our own research, in which we are trying to use NLP systems on over 50 low-density languages (some of them dead) where both tagged corpora and language speakers are mostly unavailable. We therefore desire to use these systems straight out of the box and to know how well we can expect them to work.

One difficulty in evaluating POS induction systems is that there is no straightforward way to map the clusters found by the algorithm onto the gold standard tags; moreover, some systems are designed to induce the number of clusters as well as their contents, so the number of found clusters may not match either the gold standard or that of another system. Nevertheless, most recent papers have used mapping-based performance measures (either *one-to-one* or *many-to-one* accuracy). Here, we argue that the entropy-based V-Measure (Rosenberg and

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 575–584,
MIT, Massachusetts, USA, 9-11 October 2010.

Hirschberg, 2007) is more useful in many cases, being more stable across different numbers of found and true clusters, and avoiding several of the problems with another commonly used entropy-based measure, Variation of Information (Meilă, 2003).

Using V-Measure along with several other evaluation measures, we compare the performance of the different induction systems on both WSJ (the data on which most systems were developed and tested) and Multext East, a corpus of parallel texts in eight different languages. We find that for virtually all measures and datasets, older systems using relatively simple models and algorithms (Brown et al., 1992; Clark, 2003) work as well or better than systems using newer and often far more sophisticated and time-consuming machine learning methods (Goldwater and Griffiths, 2007; Johnson, 2007; Graca et al., 2009; Berg-Kirkpatrick et al., 2010). Thus, although these newer methods have introduced potentially useful machine learning techniques, they should not be assumed to provide the best performance for unsupervised POS induction.

In addition to our review and comparison, we introduce a new way to both evaluate and potentially improve a POS induction system. Our method is based on the prototype-driven learning system of Haghighi and Klein (2006), which achieves very good performance by using a hand-selected list of prototypes for each syntactic cluster. We instead use the existing POS induction systems to induce prototypes automatically, and evaluate the systems based on the quality of their prototypes. We find that the oldest system tested (Brown et al., 1992) produces the best prototypes, and that using these prototypes as input to Haghighi and Klein's system yields state-of-the-art performance on WSJ and improvements on seven of the eight non-English corpora.

2 POS Induction Systems

We describe each system only briefly; for details, see the respective papers, cited below. Each system outputs a set of syntactic clusters C; except where noted, the target number of clusters $|C|$ must be specified as an input parameter. Since we are interested in out-of-the-box performance, we use the default parameter settings for each system, except for $|C|$, which is varied in some of our experiments. The systems are as follows:[1]

[brown]: Class-based n-grams (Brown et al., 1992). This is the oldest and one of the simplest systems we tested. It uses a bigram model where each word type is assigned to a latent class (a hard assignment), and the probability of the corpus $w_1 \dots w_n$ is computed as $P(w_1|c_1) \prod_{i=2}^{n} P(w_i|c_i)P(c_i|c_{i-1})$, where c_i is the class of w_i. The goal is to optimize the probability of the corpus under this model. The authors use an approximate search procedure: greedy agglomerative hierarchical clustering followed by a step in which individual word types are considered for movement to a different class if this improves the corpus probability.

[clark]: Class-based n-grams with morphology (Clark, 2003). This system uses a similar model to the previous one, and also clusters word types (rather than tokens, as the rest of the systems do). The main differences between the systems are that clark uses a slightly different approximate search procedure, and that he augments the probabilistic model with a prior that prefers clusterings where morphologically similar words are clustered together. The morphology component is implemented as a single-order letter HMM.

[cw]: Chinese Whispers graph clustering (Biemann, 2006). Unlike the other systems we consider, this one induces the value of $|C|$ rather than taking it as an input parameter.[2] The system uses a graph clustering algorithm called *Chinese Whispers* that is based on contextual similarity. The algorithm works in two stages. The first clusters the most frequent 10,000 words (*target words*) based on their context statistics, with contexts formed from the most frequent 150-250 words (*feature words*) that appear ei-

bhmm, **vbhmm**, **pr**, **feat**: by request from the authors of the respective papers.

[2] Another recent model that induces $|C|$ is the Infinite HMM (Van Gael et al., 2009). Unfortunately, we were unable to obtain code for the IHMM in time to include it in our analysis. Van Gael et al. (2009) report results of around 59% V-Measure on WSJ, with 194 induced clusters, which is not as good as the best system scores in Section 4.

ther to the left or right of a target word. The second stage deals with medium and low frequency words and uses pairwise similarity scores calculated by the number of shared neighbors between two words in a 4-word context window. The final clustering is a combination of the clusters obtained in the two stages. While the number of target words, feature words, and window size are in principle parameters of the algorithm, they are hard-coded in the implementation we used and we did not change them.

[bhmm]: Bayesian HMM with Gibbs sampling (Goldwater and Griffiths, 2007). This system is based on a standard HMM for POS tagging. It differs from the standard model by placing Dirichlet priors over the multinomial parameters defining the state-state and state-emission distributions, and uses a collapsed Gibbs sampler to infer the hidden tags. The Dirichlet hyperparameters α (which controls the sparsity of the transition probabilities) and β (which controls the sparsity of the emission probabilities) can be fixed or inferred. We used a bigram version of this model with hyperparameter inference.

[vbhmm]: Bayesian HMM with variational Bayes (Johnson, 2007). This system uses the same bigram model as **bhmm**, but uses variational Bayesian EM for inference. We fixed the α and β parameters to 0.1, values that appeared to be reasonable based on Johnson (2007), and which were also used by Graca et al. (2009).

[pr]: Sparsity posterior-regularization HMM (Graca et al., 2009). The Bayesian approaches described above encourage sparse state-state and state-emission distributions only indirectly through the Dirichlet priors. This system, while utilizing the same bigram HMM, encourages sparsity directly by constraining the *posterior* distributions using the posterior regularization framework (Ganchev et al., 2009). A parameter σ controls the strengths of the constraints (default = 25). Following Graca et al. (2009), we set $\alpha = \beta = 0.1$.

[feat]: Feature-based HMM (Berg-Kirkpatrick et al., 2010). This system uses a model that has the structure of a standard HMM, but assumes that the state-state and state-emission distributions are logistic, rather than multinomial. The logistic distributions allow the model to incorporate local features of the sort often used in discriminative models. The default features are morphological, such as character trigrams and capitalization.

3 Evaluation Measures

One difficulty in comparing POS induction methods is in finding an appropriate evaluation measure. Many different measures have been proposed over the years, but there is still no consensus on which is best. In addition, some measures with supposed theoretical advantages, such as Variation of Information (VI) (Meilă, 2003) have had little empirical analysis. Our goal in this section is to determine which of these measures is most sensible for evaluating the systems presented above. We first describe each measure before presenting empirical results. Except for VI, all measures range from 0 to 1, with higher scores indicating better performance.

[many-to-1]: Many-to-one mapping accuracy (also known as *cluster purity*) maps each cluster to the gold standard tag that is most common for the words in that cluster (henceforth, the *preferred tag*), and then computes the proportion of words tagged correctly. More than one cluster may be mapped to the same gold standard tag. This is the most commonly used metric across the literature as it is intuitive and creates a meaningful POS sequence out of the cluster identifiers. However, it tends to yield higher scores as $|C|$ increases, making comparisons difficult when $|C|$ can vary.

[crossval]: Cross-validation accuracy (Gao and Johnson, 2008) is intended to address the problem with many-to-one accuracy which is that assigning each word to its own class yields a perfect score. In this measure, the first half of the corpus is used to obtain the many-to-one mapping of clusters to tags, and this mapping is used to compute the accuracy of the clustering on the second half of the corpus.

[1-to-1]: One-to-one mapping accuracy (Haghighi and Klein, 2006) constrains the mapping from clusters to tags, so that at most one cluster can be mapped to any tag. The mapping is performed greedily. In general, as the number of clusters increases, fewer clusters will be mapped to their preferred tag and scores will decrease (especially if the number of clusters is larger than the number of tags, so that some clusters are unassigned and receive zero credit). Again, this makes it difficult to compare solutions with different values of $|C|$.

[vi]: Variation of Information (Meilă, 2003) is an information-theoretic measure that regards the system output C and the gold standard tags T as two separate clusterings, and evaluates the amount of information lost in going from C to T and the amount of information gained, i.e., the sum of the conditional entropy of each clustering conditioned on the other. More formally, $VI(C,T) = H(T|C) + H(C|T) = H(C) + H(T) - 2I(C,T)$, where $H(.)$ is the entropy function and $I(.)$ is the mutual information. VI and other entropy-based measures have been argued to be superior to accuracy-based measures such as those above, because they consider not only the majority tag in each cluster, but also whether the remainder of the cluster is more or less homogeneous. Unlike the other measures we consider, lower scores are better (since VI measures the difference between clusterings in bits).

[vm]: V-Measure (Rosenberg and Hirschberg, 2007) is another entropy-based measure that is designed to be analogous to F-measure, in that it is defined as the weighted harmonic mean of two values, homogeneity (h, the precision analogue) and completeness (c, the recall analogue):

$$h = 1 - \frac{H(T|C)}{H(T)} \quad (1)$$

$$c = 1 - \frac{H(C|T)}{H(C)} \quad (2)$$

$$VM = \frac{(1+\beta)hc}{(\beta h) + c} \quad (3)$$

As with F-measure, β is normally set to 1.

[vmb]: V-beta is an extension to V-Measure, proposed by (Vlachos et al., 2009). They noted that V-Measure favors clusterings where the number of clusters $|C|$ is larger than the number of POS tags $|T|$. To address this issue the parameter β in equation 3 is set to $|C|/|T|$ in order adjust the balance between homogeneity and completeness.

[s-fscore]: Substitutable F-score (Frank et al., 2009). One potential issue with all of the above measures is that they require a gold standard tagging to compute. This is normally available during development of a system, but if the system is deployed on a novel language a gold standard may not be available. In addition, there is the question of whether the gold standard itself is "correct". Recently, Frank et al. (2009) proposed this novel evaluation measure that requires no gold standard, instead using the concept of substitutability to evaluate performance. Instead of comparing the system's clusters C to gold standard clusters T, they are compared to a set of clusters S created from *substitutable frames*, i.e., clusters of words that occur in the same syntactic environment. Ideally a substitutable frame would be created by sentences differing in only one word (e.g. "I want the blue ball." and "I want the red ball.") and the resulting cluster would contain the words that change (e.g. [blue, red]). However since it is almost impossible to find these types of sentences in real-world corpora, the authors use frames created by two words appearing in the corpus with exactly one word between (e.g. the — ball). Once the substitutable clusters have been created, they can be used to calculate the Precision (SP), Recall (SR) and F-score (SF) of the system's clustering:

$$SP = \frac{\sum_{s\in S}\sum_{c\in C}|s\cap c|(|s\cap c|-1)}{\sum_{c\in C}|c|(|c|-1)} \quad (4)$$

$$SR = \frac{\sum_{s\in S}\sum_{c\in C}|s\cap c|(|s\cap c|-1)}{\sum_{s\in S}|s|(|s|-1)} \quad (5)$$

$$SF = \frac{2\cdot SP\cdot SR}{SP+SR} \quad (6)$$

3.1 Empirical results

We mentioned a few strengths and weaknesses of each evaluation method above; in this section we present some empirical results to expand on these claims. First, we examine the effects of varying $|C|$ on the behavior of the evaluation measures, while keeping the number of gold standard tags the same ($|T| = 45$). Results were obtained by training and evaluating each system on the full WSJ portion of the Penn Treebank corpus (Marcus et al., 1993). Figure 1 shows the results from the Brown system for $|C|$ ranging from 1 to 200; the same trends were observed for all other systems.[3] In addition, Table 1 provides results for the two extremes of $|C| = 1$ (**all** words assigned to the same cluster) and $|C|$ equal to the size of the corpus (a **single** word per cluster), as

[3] The results reported in this paper are only a fraction of the total from our experiments; given the number of parameters, models and measures tested, we obtained over 15000 results. The full set of results can be found at `http://homepages.inf.ed.ac.uk/s0787820/pos/`.

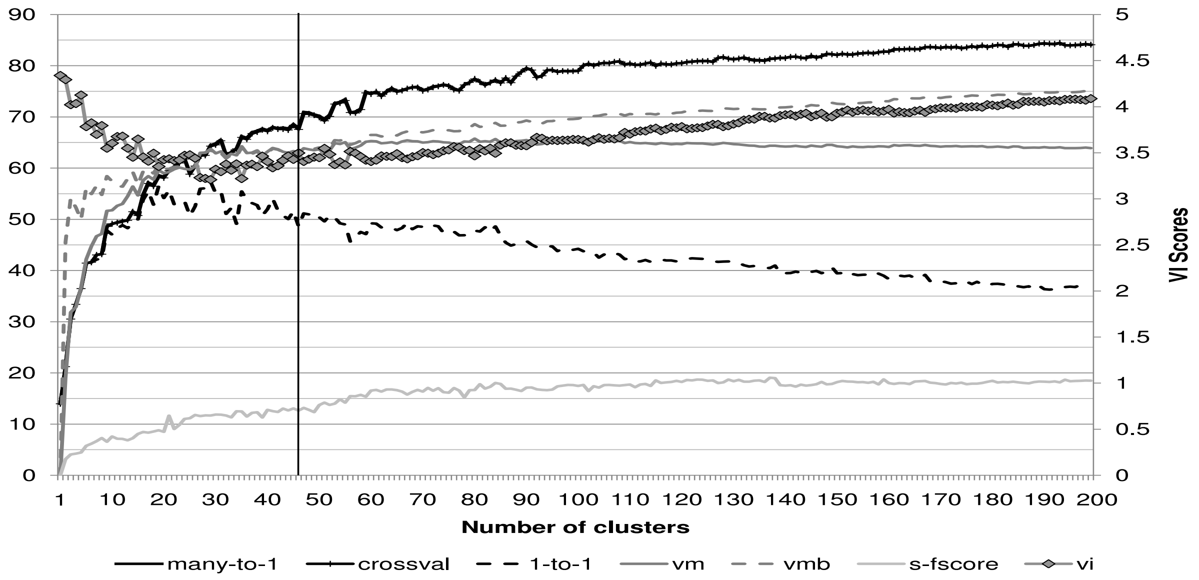

Figure 1: Scores for all evaluation measures as a function of the number of clusters returned [model:brown, corpus:wsj, $|C|$:{1-200}, $|T|$:45]. The right-hand y-axis shows VI scores (lower is better); the left-hand y-axis shows percentage scores for all other measures. The vertical line indicates $|T|$. Many-to-1 is invisible as it tracks crossval so closely.

measure	super	random	all	single
many-to-1	97.85	13.97	13.97	100
crossval	97.59	13.98	13.98	0
1-to-1	97.86	2.42	13.97	0.01
vi	0.35	9.81	4.33	15.82
vm	95.98	0.02	0	35.42
vmb	95.98	0	0	99.99
s-fscore	7.53	0.50	0	0

Table 1: Baseline scores for the different evaluation measures on the WSJ corpus. For all measures except VI higher is better.

well as two other baselines (a **super**vised tagging[4] and a **random** clustering with $|C| = 45$).

These empirical results confirm that certain measures favor solutions with many clusters, while others prefer fewer clusters. As expected, **many-to-1** correlates positively with $|C|$, rising to almost 85% with $|C| = 200$ and reaching 100% when the number of clusters is maximal (i.e., **single**). Recall that **crossval** was proposed as a possible solution to this problem, and it does solve the extreme case of **single**, yielding 0% accuracy rather than 100%. However, it patterns just like **many-to-1** for up to 200 clusters, suggesting that there is very little difference between the two for any reasonable number of clusters, and we should be wary of using either one when $|C|$ may vary.

In contrast to these measures are **1-to-1** and **vi**: for the most part, they yield worse performance (lower **1-to-1**, higher **vi**) as $|C|$ increases. However, in this case the trend is not monotonic: there is an initial improvement in performance before the decrease begins. One might hope that the peak in performance would occur when the number of clusters is approximately equal to the number of gold standard tags; however, the best performance for both **1-to-1** and **vi** occurs with approximately 25-30 clusters, many fewer than the gold standard 45.

Next we consider **vm** and **vmb**. Interestingly, although **vmb** was proposed as a way to correct for the supposed tendency of **vm** to increase with increasing $|C|$, we find that **vm** is actually more stable than **vmb** over different values of $|C|$. Thus, if the goal is to compare systems producing different numbers of clusters (especially important for systems that induce the number of clusters), then **vm** seems more appropriate than any of the above measures, which are more standard in the literature.

Finally, we analyze the behavior of the gold-standard-independent measure, **s-fscore**. On the positive side, this measure assigns scores of 0 to the

[4] We used the Stanford Tagger trained on the WSJ corpus: `http://nlp.stanford.edu/software/tagger.shtml`.

two extreme cases of **all** and **single**, and is relatively stable across different values of $|C|$ after an initial increase. It assigns a lower score to the supervised system than to **brown**, indicating that words in the supervised clusters (which are very close to the gold standard) are actually less substitutable than words in the unsupervised clusters. This is probably due to the fact that the gold standard encodes “pure” syntactic classes, while substitutability also depends on semantic characteristics (which tend to be picked up by unsupervised clustering systems as well). Another potential problem with this measure is that it has a very small dynamic range – while scores as high as 1 are theoretically possible, in practice they will never be achieved, and we see that the actual range of scores observed are all under 20%.

We conclude that there is probably no single evaluation measure that is best for all purposes. If a gold standard is available, then **many-to-1** and **1-to-1** are the most intuitive measures, but should not be used when $|C|$ is variable, and do not account for differences in the errors made. While **vi** has been popular as an entropy-based alternative to address the latter problem, its scores are not easy to interpret (being on a scale of bits) and it still has the problem of incomparability across different $|C|$. Overall, **vm** seems to be the best general-purpose measure that combines an entropy-based score with an intuitive 0-1 scale and stability over a wide range of $|C|$.

4 System comparison

Having provided some intuitions about the behavior of different evaluation methods, we move on to evaluating the various systems presented in Section 2. We first present results for the same WSJ corpus used above. However, because most of the systems were initially developed on this corpus, and often evaluated only on it, there is a question of whether their methods and/or hyperparameters are overly specific to the domain or to the English language. This is a particularly pertinent question since a primary argument in favor of unsupervised systems is that they are easier to port to a new language or domain than supervised systems. To address this question, we evaluate all the systems as well on the multilingual Multext East corpus (Erjavec, 2004), without changing any of the parameter settings. $|C|$ was set to 45 for all of the experiments reported in this section. Based on our assessment of evaluation measures above, we report VM scores as the most reliable measure across different systems and cluster set sizes; to facilitate comparisons with previous papers, we also report many-to-one and one-to-one accuracy.

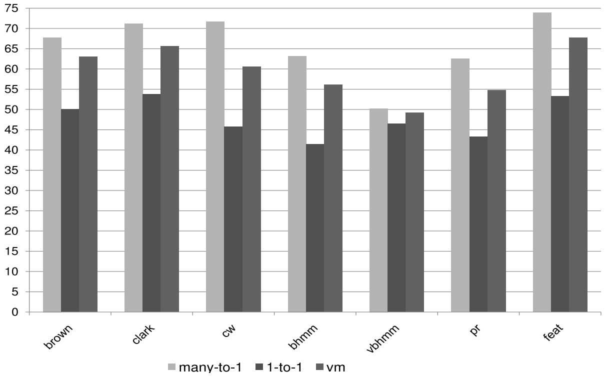

Figure 2: Performance of the different systems on WSJ, using three different measures [$|C|$:45, $|T|$:45]

system	runtime
brown	~10 min.
clark	~40 min.
cw	~10 min.
bhmm	~4 hrs.
vbhmm	~10 hrs.
pr	~10 hrs.*
feat	~40 hrs.*

Table 2: Runtimes for the different systems on WSJ [$|C|$:45]. ***pr** and **feat** have multithreading implementations and ran on 16 cores.

4.1 Results on WSJ

Figure 2 presents results for all seven systems, with approximate runtimes shown in Table 2. While these algorithms have not necessarily been optimized for speed, there is a fairly clear distinction between the older type-clustering models (**brown**, **clark**) and the graph-based algorithm (**cw**) on the one hand, and the newer machine-learning approaches (**bhmm**, **vbhmm**, **pr**, **feat**) on the other, with the former being much faster to run. Despite their faster runtimes and less sophisticated methods, however, these systems perform surprisingly well in comparison to the latter group. Even the oldest and perhaps simplest method (**brown**) outperforms the two BHMMs and posterior regularization on all measures. Only

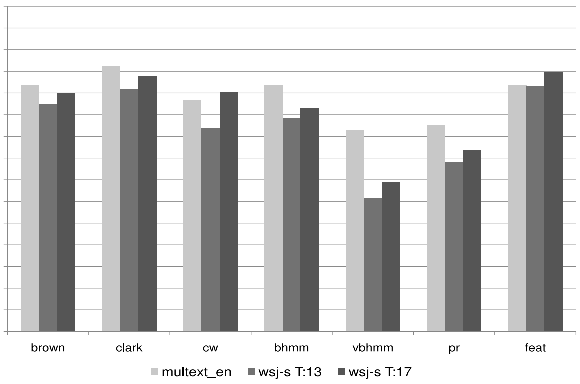

Figure 3: VM scores for the different systems on English Multext-East and WSJ-S corpora [$|C|$:45, $|T|$:{14,17}]

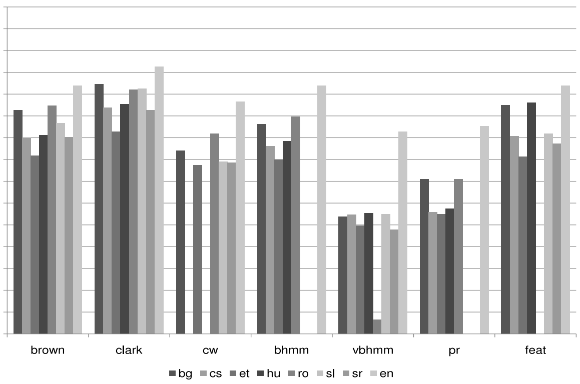

Figure 4: VM scores for the different systems on the eight Multext-East corpora [$|C|$:45, $|T|$:14]

the very latest approach (**feat**) rivals **clark**, showing slightly better performance on two of the three measures (**clark**: 71.2, 53.8, 65.5 on many-to-one, one-to-one, VM; **feat**: 73.9, 53.3, 67.7). The **cw** system returns a total of 568 clusters on this data set, so the many-to-one and one-to-one measures are not strictly comparable to the other systems; on VM this system achieves middling performance.

We note that the two best-performing systems, **clark** and **feat**, are also the only two to use morphological information. Since the clustering algorithms used by **brown** and **clark** are quite similar, the difference in performance between the two can probably be attributed to the extra information provided by the morphology. This supports the (unsurprising) conclusion that incorporating morphological features is generally helpful for POS induction.

4.2 Results on other corpora

We now examine whether either the relative or absolute performance of the different systems holds up when tested on a variety of different languages. For these experiments, we used the 1984 portion of the Multext-East corpus (~7k sentences), which contains parallel translations of Orwell's *1984* in 8 different languages: Bulgarian[**bg**], Czech[**cs**], Estonian[**et**], Hungarian[**hu**], Romanian[**ro**], Slovene[**sl**], Serbian[**sr**] and English[**en**]. We also included a 7k sentence version of the WSJ corpus [**wsj-s**] to help differentiate effects of corpus size from those of domain/language. For the WSJ corpora we experimented with two standardly used tagsets: the original PTB 45-tag gold standard and a coarser set of 17 tags previously used by several researchers working on unsupervised POS tagging (Smith and Eisner, 2005; Goldwater and Griffiths, 2007; Johnson, 2007). For the Multext-East corpus only a coarse 14-tag tagset was available.[5] Finally, to facilitate direct comparisons of genre while controlling for the size of both the corpus and the tag set, we also created a further collapsed 13-tag set for WSJ.[6]

Figure 3 illustrates the abilities of the different systems to generalize across different genres of English text. Comparing the results for the Multext-East English corpus and the small WSJ corpus with 13 tags (i.e., controlling as much as possible for corpus size and number of gold standard tags), we see that despite being developed on WSJ, the systems actually perform better on Multext-East. This is encouraging, since it suggests that the methods and hyperparameters of the algorithms are not strongly tied to WSJ. It also suggests that Multext-East is in some sense an easier corpus than WSJ. Indeed, the distribution of vocabulary items supports this view: the 100 most frequent words account for 48% of the WSJ corpus, but 57% of the 1984 novel. It is also worth pointing out that, although previous researchers have reduced the 45-tag WSJ set to 17 tags in order to create an easier task for unsupervised learning (and to decrease training time), reducing the tag set further to 13 tags actually decreases performance, since some distinctions found by the sys-

[5] Out of the 14 tags only 11 are shared across all languages. For details c.f. Appendix B in (Naseem et al., 2009).

[6] We tried to make the meanings of the tags as similar as possible between the two corpora; we had to create 13 rather than 14 WSJ tags for this reason. Our 13-tag set can be found at `http://homepages.inf.ed.ac.uk/s0787820/pos/`.

tems (e.g., between different types of punctuation) are collapsed in the gold standard.

Figure 4 gives the results of the different systems on the various languages.[7] Not surprisingly, all the algorithms perform best on English, often by a wide margin, suggesting that they are indeed tuned better towards English syntax and/or morphology. One might expect that the two systems with morphological features (**clark** and **feat**) would show less difference between English and some of the other languages (all of which have complex morphology) than the other systems. However, although **clark** and **feat** (along with Brown) are the best performing systems overall, they don't show any particular benefit for the morphologically complex languages.[8]

One difference between the Multext-East results and the WSJ results is that on Multext-East, **clark** clearly outperforms all the other systems. This is true for both the English and non-English corpora, despite the similar performance of **clark** and **feat** on (English) WSJ. This suggests that **feat** benefits more from the larger corpus size of WSJ. For the other languages **clark** may be benefiting from somewhat more general morphological features; **feat** currently contains suffix features but no prefix features (although these could be added).

Overall, our experiments on multiple languages support our earlier claim that many of the newer POS induction systems are not as successful as the older methods. Moreover, these experiments underscore the importance of testing unsupervised systems on multiple languages and domains, since both the absolute and relative performance of systems may change on different data sets. Ideally, some of the corpora should be held out as unseen test data if an effective argument is to be made regarding the language- or domain-generality of the system.

5 Learning from induced prototypes

We now introduce a final novel method of evaluating POS induction systems and potentially improving their performance as well. Our idea is based on the prototype-driven learning model of Haghighi and Klein (2006). This model is unsupervised, but requires as input a handful of *prototypes* (canonical examples) for each word class. The system uses a log-linear model with features that include the prototype lists as well as morphological features (the same ones used in **feat**). Using the most frequent words in each gold standard class as prototypes, the authors report 80.5% accuracy (both many-to-one and one-to-one) on WSJ, considerably higher than any of the induction systems seen here. This raises two questions: If we wish to induce prototypes without a tagged corpus or language-specific knowledge, which induction system will provide the best prototypes (i.e., most similar to the gold standard prototypes)? And, can we use the induced prototypes as input to the prototype-driven model (**h&k**) to achieve better performance than the system the prototypes were extracted from?

To explore these questions, we implemented a simple heuristic method for inducing prototypes from the output C of a POS induction system by selecting a few frequent words in each cluster that are the most similar to other words in the cluster and also the most dissimilar to the words in other clusters. For each cluster $c_i \in C$, we retain as candidate prototypes the words whose frequency in c_i is at least 90% as high as the word with the highest frequency (in c_i). This yields about 20-30 candidates from each cluster. For each of these, we compute its average similarity $\mathcal{S}$ to the other candidates in its cluster, and the average dissimilarity $\mathcal{D}$ to the candidates in other clusters. Similarity is computed using the method described by Haghighi and Klein (2006), which uses SVD on word context vectors and cosine similarity. Dissimilarity between a pair of words is computed as one minus the similarity. Finally we compute the average $\mathcal{M} = 0.5(\mathcal{S} + \mathcal{D})$, sort the words by their $\mathcal{M}$ scores, and keep as prototypes the top ten words with $\mathcal{M} > 0.25 * \max_{c_i}(\mathcal{M})$. The cutoff threshold results in some clusters having less than ten prototypes, which is appropriate since some gold standard categories have very few members (e.g., punctuation, determiners).

Using this method, we first tested the various base+proto systems on the WSJ corpus. Results in Table 3 show that the **brown** system produces the best prototypes. Although not as good as using prototypes from the gold standard (**h&k**),

[7] Some results are missing because not all of the corpora were successfully processed by all of the systems.

[8] It can be argued that lemmatization would have given a significant gain to the performance of the systems in these languages. Although lemmatization information was included in the corpus we chose not to use it, maintaining the fully unsupervised nature of this task.

system	many-to-1	1-to-1	vm
brown	**76.1**(8.3)	60.7(10.6)	**68.8**(5.8)
clark	74.5(3.3)	62.1(8.3)	68.6(3.0)

sr	48.0(2.8)	46.4(-4.9)

Table 4: VM scores for **brown+proto** and **clark+proto** on all corpora. Numbers in parentheses indicate improvement over the base systems.

brown+proto yields a large improvement over **brown**, and the highest performance of any system tested so far. In fact, the **brown+proto** scores are, to our knowledge, the best reported results for an unsupervised POS induction system on WSJ.

Next, we evaluated the two best-performing **+proto** systems on Multext-East, as shown in Table 4. We see that **brown** again yields the best prototypes, and again yields improvements when used as **brown+proto** (although the improvements are not as large as those on WSJ). Interestingly, **clark+proto** actually performs worse than **clark** on the multilingual data, showing that although induced prototypes can in principle improve the performance of a system, not all systems will benefit in all situations. This suggests a need for additional investigation to determine what properties of an existing induction system allow it to produce useful prototypes with the current method and/or to develop a specialized system specifically targeted towards inducing useful prototypes.

6 Conclusion

In this paper, we have attempted to provide a more comprehensive review and comparison of evaluation measures and systems for POS induction than has been done before. We pointed out that most of the commonly used evaluation measures are sensitive to the number of induced clusters, and suggested that V-measure (which is less sensitive) should be used as an alternative or in conjunction with the standard measures. With regard to the systems themselves, we found that many of the newer approaches actually perform worse than older methods that are both simpler and faster. The newer systems have introduced potentially important machine learning tools, but are not necessarily better suited to the POS induction task specifically.

Since portability is a distinguishing feature for unsupervised models, we have stressed the importance of testing the systems on corpora that were not used in their development, and especially on different languages. We found that on non-English languages, Clark's (2003) system performed best.

Finally, we introduced the idea of evaluating induction systems based on their ability to produce useful cluster prototypes. We found that the oldest system (Brown et al., 1992) yielded the best prototypes, and that using these prototypes gave state-of-the-art performance on WSJ, as well as improvements on nearly all of the non-English corpora. These promising results suggest a new direction for future research: improving POS induction by developing methods targeted towards extracting better prototypes, rather than focusing on improving clustering of the entire data set.

Acknowledgments

We thank Mark Johnson, Kuzman Ganchev, and Taylor Berg-Kirkpatrick for providing the implementations of their models, as well as Stella Frank, Tom Kwiatkowski, Luke Zettlemoyer and the anonymous reviewers for their comments and suggestions. Abstract

Domain adaptation, the problem of adapting a natural language processing system trained in one domain to perform well in a different domain, has received significant attention. This paper addresses an important problem for deployed systems that has received little attention – detecting when such adaptation is needed by a system operating in the wild, i.e., performing classification over a stream of unlabeled examples. Our method uses $\mathcal{A}$-distance, a metric for detecting shifts in data streams, combined with classification margins to detect domain shifts. We empirically show effective domain shift detection on a variety of data sets and shift conditions.

1 Introduction

Consider a named entity recognition system trained on newswire stories. Given annotated documents containing sentences like "*Tony Hayward* has faced fresh criticism for taking time off to go sailing ..." we would like to learn a model that will allow us to recognize that "Obama" and "BP" are named entities in a sentence like "Obama summoned BP executives ...". When all of the documents come from one data distribution, like newswire articles, this tends to work well. However, the sentence "OBAMA SUMMONED BP EXECUTIVES ..." from transcribed broadcast news, and others like it, will probably lead to poor results because the features it relies on have changed. For example, capitalization patterns are no longer a good indicator of the presence of a named entity and appositives are not indicated by punctuation. This problem of *domain shift* is a pervasive problem in NLP in which any kind of model – a parser, a POS tagger, a sentiment classifier – is tested on data that do not match the training data.

Given a model and a stream of unlabeled instances, we are interested in automatically *detecting* changes in the feature distribution that negatively impact classification accuracy. For example, a sentiment classification model trained on book reviews may heavily weight n-grams features like "uplifting" and "page turner". Those features may never occur in reviews of kitchen appliances that get mixed in at test time, and useful features in this new domain like "efficient" and "noisy compressor" will have never been seen during training and therefore not be in the model. Furthermore, we do not assume labeled instances are available to help detect these harmful changes. Other tasks related to changes in data distributions, like detecting concept drift in which the labeling function changes, may require labeled instances, but that is not the focus of this paper.

There is significant work on the related problem of adapting a classifier for a known domain shift. Versions of this problem include adapting using only unlabeled target domain data (Blitzer et al., 2006; Blitzer et al., 2007; Jiang and Zhai, 2007), adapting using a limited amount of target domain labeled data (Daumé, 2007; Finkel and Manning, 2009), and learning across multiple domains simultaneously in an online setting (Dredze and Crammer, 2008b). However, in practical settings, we do not know *if* the data distribution will change, and certainly not when. Additionally, we will not know to *what* do-

main the shift will happen. A discussion forum devoted to science fiction books may change over time to focus more on fantasy and then narrow to discussions of vampire fiction. Maybe this shift is harmless and it is possible to identify the sentiment of the discussants with the original model with no loss in accuracy. If not, we seek methods that detect this shift and trigger the use of an adaptation method.

Our domain shift detection problem can be decomposed into two subproblems: detecting distributional changes in streams of real numbers, and representing a stream of examples as a stream of real numbers informative for distribution change detection. We select the $\mathcal{A}$-distance metric (Kifer et al., 2004) to solve the first subproblem since it has been previously used in other domain adaptation work (Blitzer et al., 2006; Blitzer et al., 2007). Our main contribution is towards the second problem, representing examples as real numbers for this task. We demonstrate that classification margins, which incorporate information about features that most impact system accuracy, can effectively solve the second subproblem. Furthermore, we show that the previously proposed Confidence Weighted learning algorithm (Dredze et al., 2008) can provide a more informative measure than a simple margin for this task. Our experiments include evaluations on commonly used domain adaptation data and false change scenarios, as well as comparisons to *supervised* detection methods that observe label values, or have knowledge of the target domain.

We begin with a description of our task and previous applications to language data. After describing the data used in this paper, we discuss the $\mathcal{A}$-distance metric and how it has previously been used for adaptation. We then show that margin based methods effectively capture information to detect domain shifts, and propose an alternate way of generating informative margin values. Finally, we compare our results to settings with supervised knowledge, and close with a survey of related work.

2 Domain Shifts in Language Data

The study of domain shifts in language data has been the purview of domain adaptation and transfer learning, which seek to adapt or transfer a model learned on one source domain with labeled data to another target domain with few or no labeled examples. Formally, errors from such transfers have two sources: differences in feature distributions and changes to labeling functions (annotation standards) (Ben-David et al., 2006; Ben-David et al., 2009). Empirical work on NLP domain shifts has focused on the former. For example, Blitzer et al. (2007) learned correspondences between features across domains and Jiang and Zhai (2007) weighted source domain examples by their similarity to the target distribution.

We continue in this tradition by making two assumptions about our setting. First, a change in domain will be signaled by a change in the feature distributions. That is, new words, phrases, syntactic structures, etc. signal that the system has shifted to a new domain. Second, while there may be a change in the labeling function, i.e., features have a different meaning in each domain, this will be a secondary concern. For example, both Daumé (2007) and Dredze and Crammer (2008b) assume that domains are more similar than different.

A similar problem to the one we consider is that of concept drift, where a stream of examples are labeled with a shifting labeling function (concept) (Nishida and Yamauchi, 2007; Widmer and Kubat, 1996). While concept drift is similar there are two important differences. First, concept drift can be measured using a stream of *labeled* examples, so system accuracy is directly measured. For example, Klinkenberg and Joachims (2000) detect concept drift with support vector machines, using estimates of leave-one-out performance to adaptively adjust and maintain a training window that minimizes estimated generalization error. This is possible only because class labels arrive with the examples in the stream. Another concept drift detection algorithm, STEPD, uses a statistical test to continually monitor the possibly changing stream, measuring system accuracy directly, again using the labels it receives for each example (Nishida, 2008). Obviously, no such labels are available in our unsupervised setting. Second, concept drift assumes only changes in the labeling function, whereas domain adaptation relies on feature distribution changes.

Several properties of detecting domain shifts in natural language streams distinguish it from traditional domain adaptation, concept drift, and other related tasks:

- **No Target Distribution Examples** Blitzer et al. (2007) estimate the loss in accuracy from domain shift by discriminating between two data distributions. In our setting, we have no knowledge of the target distribution.

- **No Labeled Target Data** Some approaches to domain adaptation assume a limited number of labeled examples (Daumé, 2007; Dredze and Crammer, 2008b; Finkel and Manning, 2009). We assume no labels in our setting.

- **Online Setting** Domain adaptation typically assumes a batch transfer between two domains. We consider a purely stream (online) setting.

- **Computationally Constrained** Our approach must be fast, as we expect to run our domain shift detector alongside a deployed NLP system. This limits both computation and storage.

- **Unknown Adaptation** A critical assumption of previous work is that a domain change has occurred. We must ascertain this ourselves.

Despite these challenges, we show unsupervised stream-based methods that effectively identify shifts in domain in language data. Furthermore, our methods are tied directly to the learning task so are sensitive to changes in actual task accuracy. Our methods have low false positive rates of change detection, which is important since examples within a single domain display a large amount of variance, which could be mistaken for a domain change.

Once a change is detected, any number of actions may be appropriate. The maintainer of the system may be notified that performance is suffering, labels can be obtained for a sample of instances from the stream for retraining, or large volumes of unlabeled instances can be used for instance reweighting (Jiang and Zhai, 2007).

3 Datasets

We begin the presentation of our methods by describing the data used in our experiments. We selected three data sets commonly used in domain adaptation: spam (Jiang and Zhai, 2007), ACE 2005 named entity recognition (Jiang and Zhai, 2007), and sentiment (Blitzer et al., 2007). Sentiment and spam are binary and ACE is multi-class. Note that in all experiments, a shift in the domain yields a decrease in system accuracy.

The goal of the spam data is to classify an email (bag-of-words) as either spam or ham (not-spam). Each email user may have different preferences and features. We used unigram and bigram features, following Dredze and Crammer (2008b) for feature extraction, and used the three task A users as three domains. The ACE 2005 named entity recognition dataset includes 7 named entity class labels (person, organization, location, geopolitical entity, facility, vehicle, weapon) for 5 text genres (newswire, broadcast news, broadcast conversations, conversational telephone speech, weblogs). We use 4000 examples from each genre and used Jiang and Zhai's feature-extracted data.[1] The sentiment data contains reviews from Amazon for four product types: books, dvds, electronics, and kitchen. We include an additional two types (music and video from Dredze and Crammer) in our false shift experiments and use unigram and bigram features, following Blitzer et al.

4 The $\mathcal{A}$-Distance

Our approach to detecting domain shifts in data streams that negatively impact system accuracy is based on the ability to (1) detect distributional changes in streams of real numbers and (2) convert document streams to streams of informative real numbers. This section describes how we achieve the former, and the next section describes the latter.

Theoretical work on domain adaptation showed that the $\mathcal{A}$-distance (Kifer et al., 2004), a stream based measure of difference between two arbitrary probability distributions P and P', can be used to evaluate the difference between two domain distributions (Ben-David et al., 2006). In a batch setting this corresponds to learning a linear classifier to discriminate the domains, and Blitzer et al. (2007) showed correlations with the error from domain adaptation. Given our interest in streaming data we return to the original stream formulation of $\mathcal{A}$-distance.

The $\mathcal{A}$-distance detects differences between two arbitrary probability distributions by dividing the range of a random variable into a set of (possibly

[1] We thank Jing Jiang for the feature-extracted ACE data.

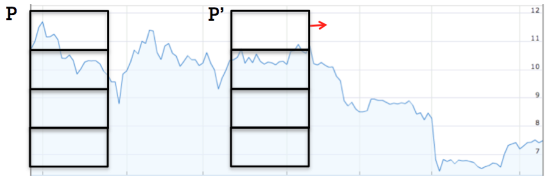

Figure 1: The $\mathcal{A}$-distance is computed between two windows (P and P' in a stream of real-valued data. The samples in each window are divided into intervals, and the $\mathcal{A}$-distance measures the change in the distributions over these intervals between the two windows.

overlapping) intervals, and then measures changes in the probability that a value drawn for that variable falls into any one of the intervals. If such a change is large, a change in the underlying distribution is declared. Let $\mathcal{A}$ be a set of real intervals and let $A \in \mathcal{A}$ be one such interval. For that interval, $P(A)$ is the probability that a value drawn from some unknown distribution falls in A. The $\mathcal{A}$-distance between P and P', i.e. the difference between two distributions over the intervals, is defined as follows:

$$d_{\mathcal{A}}(P, P') = 2 \sup {}_{A \in \mathcal{A}} |P(A) - P'(A)|.$$

Two distributions are said to be different when, for a user-specified threshold ϵ, $d_{\mathcal{A}}(P, P') > \epsilon$. The $\mathcal{A}$-distance is distribution independent. That is, it makes no assumptions about the form of the underlying distribution nor about the form of the change that might occur, either algorithmically or in the underlying theory. Unlike the L_1 norm, the $\mathcal{A}$-distance can be shown to require finitely many samples to detect distribution differences, a property that is crucial for streaming, sample-based approaches.

Since the $\mathcal{A}$-distance processes a stream of real numbers, we need to represent an example using a real number, such as the classification margin for that example. The first n of these numbers in the stream are a sample from P, and the most recent n are a sample from P'. We signal a domain shift when the $\mathcal{A}$-distance between P and P' is large (greater than ϵ). Larger values of n result in more accurate estimates of $P(A)$ and slower detection of changes.

The two windows of samples of size n are shown graphically in Fig. 1. Each increment on the horizontal axis represents the arrival of a new document. The vertical axis is some value computed from each document, such as its classification margin. To compute P and P', one needs to specify $\mathcal{A}$ and n, which are shown as two stacks of boxes that are identical except for their position. The width of each box is n, the number of examples used to estimate $P(A)$ and $P(A')$ for $A \in \mathcal{A}$, where the real interval A corresponds to the vertical span of the box. The value $P(A)$ is simply the number of documents whose real value falls inside that interval A divided by n. Note that the first n documents in the stream are used to compute P, and as each new document arrives the location of the stack of boxes used to compute P' is shifted to the right by one.

In Fig. 1, the number of examples whose real value falls in the top two intervals for P is approximately the same, with no example's value falling in the lower two intervals. For P', almost every one of the n document values falls in the second interval from the top, virtually assuring that $d_{\mathcal{A}}(P, P')$ will be large. Though the intervals in the figure do not overlap, they typically do.

Given n and intervals $\mathcal{A}$, the value of ϵ is chosen by randomization testing. Because the $\mathcal{A}$-distance is distribution independent, a sample of size $m \gg n$ is drawn from any distribution that spans $\mathcal{A}$. This sample is treated as a stream as described above, and the largest value of $d_{\mathcal{A}}(P, P')$ is stored. The sample is permuted and this process is repeated l times. Note that any change detection would be a false positive because all values were sampled from the same distribution. The values $d_{\mathcal{A}}(P, P')$ are sorted from largest to smallest, and ϵ is chosen to be the $\lfloor \alpha l \rfloor^{th}$ such value where parameter α is a user specified false positive probability.

Both the time and space complexity of our approach based on the $\mathcal{A}$-distance are small. Given n and $\mathcal{A}$, n instances must be stored in the sliding window and $2|\mathcal{A}|$ counters are required to represent P and P'. Note that both values are constants based on user specified parameters, not on the size of the stream. Processing a new instance involves computing its margin and updating P and P', all of which can occur in constant time.

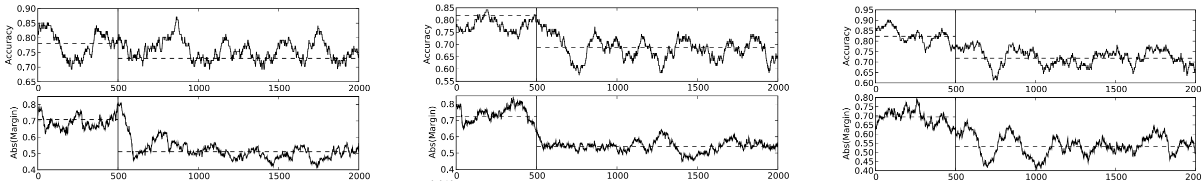

Figure 2: Each column of plots is a representative result using an SVM on a single run over a sentiment data shift: dvds → electronics, electronics → books, and kitchen → books, from left to right. The horizontal axis is the number of instances from the stream processed by the classifier. The top plot is the accuracy of the classifier on the last 100 instances. The bottom plot is the absolute value of the SVM classification margin. The vertical line at 500 instances marks the point of domain shift. Horizontal dotted lines indicate the mean of the accuracy/margin before and after the domain shift. Note that in all cases, the mean accuracy drops, as do the mean margin values, demonstrating that both can indicate domain shifts.

5 $\mathcal{A}$-Distance Over Margins

Since shifts in domains correlate with changes in distributions, it is natural to begin by considering the observed features in each example. When we shift from a source domain (e.g., book reviews) to a target domain (e.g., dvd reviews) we expect a change in the distribution for common source words (“author” and “plot” become less common). Since the $\mathcal{A}$-distance assumes a stream of single values, we can apply an $\mathcal{A}$-distance detector to each feature (e.g., unigram and bigram count) individually. However, our extensive experiments with this approach (omitted here) show that it suffers from a number of flaws, such as a high false positive rate if all features are tracked, the difficult problem of identifying an informative subset of features for tracking, and deciding how many such features need to change before a shift has occurred, which turns out to be highly variable between shifts.

Therefore, our goal is to use a single $\mathcal{A}$-distance tracker by collapsing each example to a single value. One way of doing this is to consider the *classification margin* produced by the classifier. The margin weighs features by their importance in classification. When more important features disappear, we expect the magnitude of the margin to decrease. Additionally, features that change but do not influence system performance are effectively ignored since they do not influence the margin. This approach has the advantage of task sensitivity, only tracking changes that impact task accuracy. Initial experiments showed effectiveness with the unsigned (absolute value of the) margin, which we use in all experiments.

We begin by examining visually the information content of the margin with regards to predicting a domain shift. The caption of Fig. 2 describes the setup, and the first row of the figure illustrates the effects of the shift on the source domain classifier’s empirical accuracy, measured on a window of the previous 100 examples. The horizontal dashed lines indicate the average accuracy before and after the shift. Note that in each case, average classification accuracy drops after the shift. However, at any one point the accuracy displays considerable variance. Thus, while classification accuracy clearly suffers, it is difficult to measure this even in a supervised setting with labeled examples when considering a small portion of the stream.

The second row of Fig. 2 shows the average unsigned margin value of an SVM classifier computed over the previous 100 examples in the stream. The two dashed horizontal lines indicate the average margin value over source and target examples. There is a clear drop in the average margin value after the shift. This difference suggests that the margin can be examined directly to detect a domain shift. However, these values vary considerably so extracting useful information is not trivial.

We evaluated the ability of $\mathcal{A}$-distance trackers to detect such changes in margin values by simulating domain shifts using each domain pair in a task (books to dvds, weblogs to newswire, etc.). For each domain shift setting, we first trained a classifier on 1000 source domain instances. In our experiments, we used three different classification algorithms: Support Vector Machines (SVM) (Chang

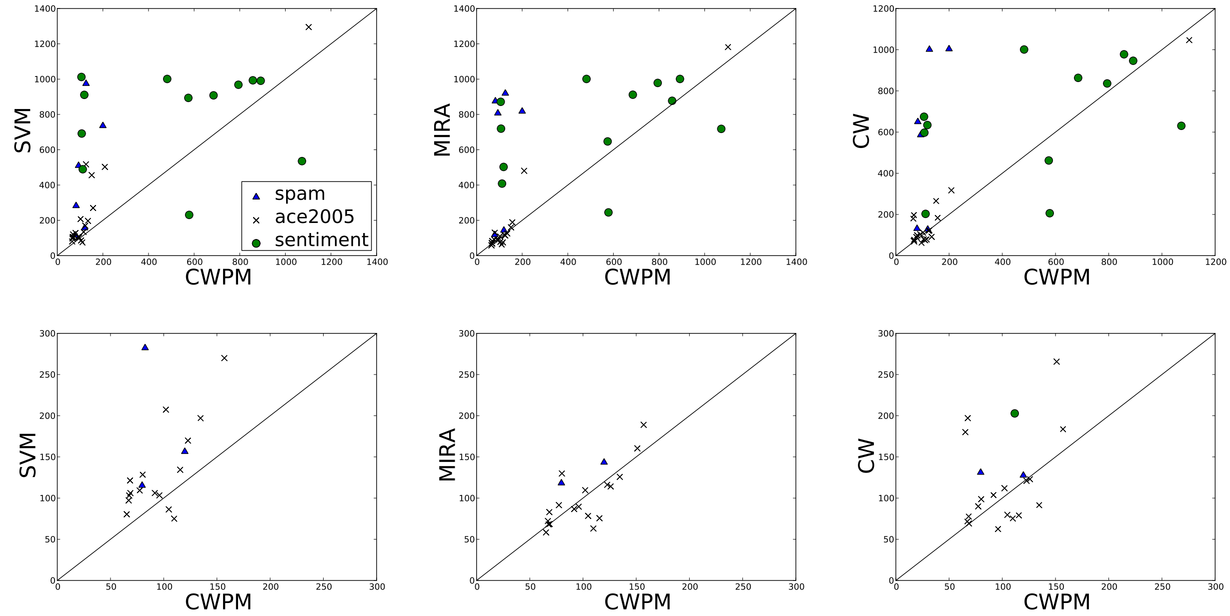

Figure 3: The mean number of instances after a domain change at which the $\mathcal{A}$-distance tracker detects a change. Each point represents the mean number of instances for CWPM (x-axis) and the SVM, MIRA and CW methods (y-axis). Datasets are indicated by different markers. The second row zooms each plot to the bottom left corner of the first row. Points above the diagonal indicate SVM, MIRA or CW took longer to detect a change than CWPM.

and Lin, 2001), MIRA (Crammer et al., 2006) and Confidence Weighted (CW) learning (Dredze et al., 2008). We evaluated each trained classifier on 500 test examples to measure accuracy on the source domain, and then used it to label examples in a stream. The first 500 examples in the stream were used for calibrating our change detection methods. The next 500 examples were from the source domain, followed by 1500 examples from the target domain. Over these 2000 examples we ran each of our detection methods. Experiments were repeated over 10 fixed random data permutations.

We automatically select $\mathcal{A}$-distance intervals as follows. First, we computed the mean and variance of the 500 calibration margins and then added intervals for .5 standard deviations away from the mean in each direction, .5 to 1 standard deviation in each direction, and intervals for 1 standard deviation to $\pm\infty$. We also added three evenly spaced overlapping intervals. To calibrate a FP rate of 0.05 we sampled from a Gaussian with the above mean and variance and used $n = 200$, $m = 10000$ and $l = 50$.

The results for each experiment (38 shifts repeated averaged over 10 runs each) are shown in Fig. 3.[2] Each plot represents one of the three classifiers (SVM, MIRA, CW) plotted on the vertical axis, where each point's y-value indicates the number of examples observed after a shift occurred before the $\mathcal{A}$-distance detector registered a change. Smaller values (lower points) are preferred. The second row of plots highlights the 0 to 300 region of the first row. (The x-axis will be discussed in the next section.) Notice that in many cases, a change was registered within 300 examples, showing that domain shifts can be reasonably detected using the margin values alone.

Equally important to detecting changes is robustness to false changes. We evaluated the margin detector for false positives in two ways. First, we logged any incorrectly detected changes before the shift. For all three algorithms, there were very few false positives (Table 1). The highest false positive rate was about 1% (CW), while for the SVM experiments, not a single detector fired prematurely in any experiment.

[2] The method plotted on the x-axis will be introduced in the next section. To evaluate the three methods in this section (SVM, MIRA, CW) compare the y-values.

Second, we sought to test the robustness of the method over a long stream of examples where no change occurred. In this experiment, we selected 11 domains that had a sufficient number of examples to consider a long stream of source domain examples.[3] Rather than use 500 source domain examples followed by 1500 target domain examples, all 2000 examples were from the source domain. All other settings were the same. For the SVM detector, out of 110 runs we detected 6 false positives, 3 of which were for the same data set (kitchen) (see Table 1.)

6 Confidence Weighted Margins

In the previous section, we showed that margin values could be used to detect domain shifts. We now explore ways to reduce the number of target domain examples needed to detect domain shift by improving the margin values.

Margin values are often taken as a measure of prediction confidence. From this perspective, the $\mathcal{A}$-distance margin tracker identifies when prediction confidence drops. Another task that relies on margins as measures of confidence is active learning, where uncertainty sampling for margin based systems is determined based on the magnitude of the predicted margin. Dredze and Crammer (2008a) showed how Confidence Weighted (CW) learning could be used to generate a more informative measure of confidence for active learning.

CW is an online algorithm inspired by the MIRA update (Crammer et al., 2006), which ensures a positive margin while minimizing parameter change. CW replaces the Euclidean distance used in the MIRA update with the KL divergence over Gaussian distributions. CW learning maintains a Gaussian distribution over linear weight vectors with mean $\boldsymbol{\mu} \in \mathbb{R}^N$ and diagonal covariance $\Sigma \in \mathbb{R}^{N \times N}$.

Maintaining a distribution over prediction functions is appropriate for our task where we consider margin values as confidence. We replace the margin $|\boldsymbol{w} \cdot \boldsymbol{x}|$, where $\boldsymbol{w}$ is a standard linear classifier, with a probabilistic margin $|\left(\Pr_{\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}_i, \Sigma_i)} \left[\text{sign}(\boldsymbol{w} \cdot \boldsymbol{z}) = 1\right]\right) - \frac{1}{2}|$. Dredze and Crammer showed that this probabilistic margin can be translated into a *corrected* geometric margin, which is computed as the normalized margin as $\bar{\text{M}} = M/\sqrt{V}$, where M is the mean $M = \boldsymbol{\mu} \cdot \boldsymbol{x}$ and V the variance $V = \boldsymbol{x}^\top \Sigma \boldsymbol{x}$ of a univariate Gaussian distribution over the unsigned-margin $\text{M} = \boldsymbol{w} \cdot \boldsymbol{x}$. We call this method CWPM, for Confidence Weighted Probabilistic Margin.

We compared using CWPM to the standard margins produced by an SVM, MIRA and CW classifier in the last section. Fig. 3 shows the results of these comparisons. In each plot, CWPM (normalized margin) is plotted on the x-axis, indicating how many examples from the target domain were observed before the detector identified a change. The y-axis in each plot is the number of instances observed for the SVM, MIRA and CW methods. As before, each point is the average of the 10 randomized runs used above (assuming that detectors that did not fire do so at the end of the stream.) Points above the diagonal indicate that CWPM detected a change sooner than the comparative method. Of the 38 shifts, CWPM detected domain shifts faster than an SVM 34 times, MIRA 26 times and CW 27 times.

We repeated the experiments to detect false positives for each margin based method. Table 1 shows the false positives for the 38 domain shifts considered as well as the 11 false shift domain shifts. The false positive rates are among the lowest for CWPM. This shows that CWPM is a more useful indicator for detecting domain changes.

7 Gradual Shifts

We have shown detection of sudden shifts between the source and target domains. However, some shifts may happen gradually over time. We evaluate this by modifying the stream as follows: the first 500 instances come from the source domain, and the remaining 1500 are sampled randomly from the source and target domains. The probability of an instance being drawn from the target domain at time i is $p_i(\boldsymbol{x} = \text{target}) = \frac{i}{1500}$, where i counts from the start of the shift at index 500. The probability of sampling target domain data increases uniformly over the stream. At index 750 after the start of the shift each domain is equally likely. The ACE and Sentiment datasets had sufficient data to be evaluated in this setting. Fig. 4 shows CWPM still performs best, but results are close (SVM: 22 of 32, MIRA &

[3] ACE: bc, bn, cts, nw, wl; Sentiment: books, dvd, electronics, kitchen, music, video

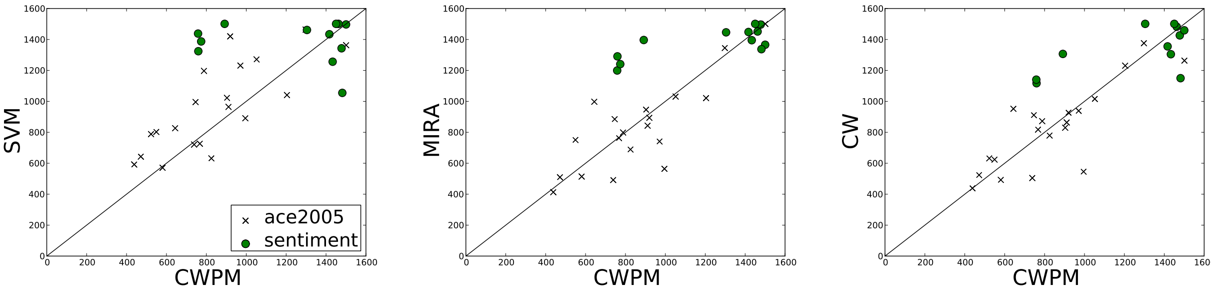

Figure 4: Gradual shift detection with SVM, MIRA or CW vs. CWPM. There were no false positives.

	Domain Shift FPs	
Algorithm	*True Shift*	*False Shift*
Sec. 5: SVM	0	6
Sec. 6: MIRA	2	13
Sec. 6: CW	5	10
Sec. 6: CWPM	1	6
Total tests	380	110

Table 1: False positives (FPs) observed in true domain shift and false domain shift experiments for methods in corresponding sections. Each setting was run 10 times, resulting in 380 true domain shifts and 110 false shifts.

CW: 17 of 32). As expected, detections happen later in the stream. The closer results are likely due to the increased difficulty of the task. With less clear information, there it is more difficult for all the algorithms to recognize a change, and performance across the methods begins to equalize. Even in this more difficult setting, CWPM is the best performer.

8 Comparison to Supervised Information

So far we have considered applying $\mathcal{A}$-distance tracking to information freely available in a real world system: the classification margins. As a useful baseline for comparison, we can measure using *supervised* sources of information, where additional information is provided that is not normally available. In particular, we investigate two types of supervised knowledge: the labels of examples in the stream and knowledge of the target domain. In each case, we compare using the $\mathcal{A}$-distance and CWPM versus applying the $\mathcal{A}$-distance to supervised information.

8.1 Classifier Accuracy

In Sec. 4 we showed that both the margin and recent classifier accuracy indicate when shifts in domains occur (Fig. 2). We developed techniques based on the margin, which is available at test time. We now consider knowledge of the true labels for these test examples, which allows for tracking classifier accuracy. We can use the $\mathcal{A}$-distance to detect when unexpected changes in accuracy occur.

For each test example classified by the system, we evaluated whether the system was correct in its prediction by examining the label. If the classifier was correct, we output a 1; otherwise, we output a 0. Over this 1/0 stream produced by checking classifier accuracy we ran an $\mathcal{A}$-distance detector, with intervals set for 1s and 0s (10,000 uniform samples to calibrate the threshold for a false positive rate of 0.05.) If an unusual number of 0s or 1s occur – more or less mistakes than on the source domain – a change is detected.[4] Results on this accuracy stream are compared to CWPM (Fig. 5.) Despite this supervised information, CWPM still detects domain changes faster than with labeled examples. Consider again Fig. 2, which shows both accuracy and margin values over time. While the average accuracy drops, the instantaneous value is very noisy, suggesting that even this additional information may not yield better domain shift detection. This will be interesting to explore in future work.

[4] An alternate approach would be to measure accuracy directly as a real valued number. However, our experiments showed the discrete approach to be more effective.

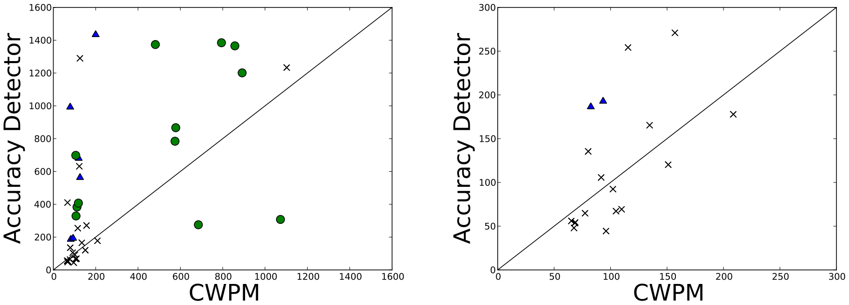

Figure 5: An $\mathcal{A}$-distance accuracy detector, run over a stream of 1s and 0s indicating correct and incorrect predictions of the classifier on examples in a stream. The bulk of points above the line indicate that CWPM is more effective at detecting domain change. CWPM had a single false positive and the accuracy detector had no false positives.

8.2 Domain Classification

Next, we consider another source of supervision: a selection of examples known to be from the target domain. In this setting, we know that a shift will occur and we know to which domain it will occur. This requires a sample of (unlabeled) target domain examples when the target domain is not known ahead of time. Using a common approach to detecting domain differences when data is available from both domains (Ben-David et al., 2009; Blitzer et al., 2007; Rai et al., 2010), we train a binary classifier to differentiate between the source and target domain. We learn a CW classifier on 1000 examples (500 from each domain) that do not appear in the test stream. We then label each example as either "source" or "target" and output a 1 or 0 accordingly. Over this 0/1 stream, we run an $\mathcal{A}$-distance detector with two intervals, one for 1s and one for 0s. The remaining setup is identical to the $\mathcal{A}$-distance experiments above.

Fig. 6 shows the detection rate of CWPM versus $\mathcal{A}$-distance over the domain classifier stream. As expected, the detection rate for the domain classifier is very fast, in almost every case (save 1) less than 400 examples after the shift happens. When CWPM is slow to detect a change (over 400 examples), the domain classifier is the clear winner. However, in the majority of experiments, especially for ACE and spam data, both detectors register a change quickly. These results suggest that while a sample of target domain examples is very helpful, our CWPM approach can also be effective when such samples are not available.

9 Related Work

Early NLP work in the *unsupervised* setting monitored classification confidence values, setting a confidence threshold based on a break-even heuristic, monitoring the rate of (presumed) irrelevant examples based on this threshold, and signaling a change when this rate increased (Lanquillon, 1999).

Confidence estimation has been used for specific NLP components such as information extraction. The correctness of fields extracted via a conditional random field extractor has been shown to correlate well to an estimate obtained by a constrained forward-backward technique (Culotta and McCallum, 2004). EM-based confidence estimation has been used to estimate the confidence of patterns derived from partially supervised relation extraction (Agichtein, 2006). Confidence estimation has also been used to improve the overall effectiveness of NLP systems. Confidence estimates obtained via neural networks have shown gains for speech recognition, spoken language understanding, and machine translation (Gandrabur et al., 2006). Pipeline models using confidence estimates at one stage as weights for further downstream stages improve over baseline dependency parsing and named entity recognition pipeline models (Bunescu, 2008).

An alternative formulation of domain adaptation trains on different corpora from many different domains, then uses linear combinations of models trained on the different corpora(McClosky et al., 2010).

Work in novelty detection is relevant to the task of detecting domain shifts (Scholkopf et al., 2000),

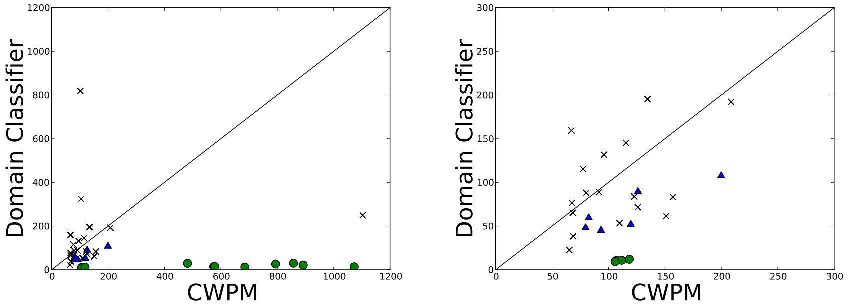

Figure 6: $\mathcal{A}$-distance over a stream of 1s and 0s produced by a supervised classifier trained to differentiate between the source and target domain. Samples from the unseen target domain is very effective. However, for many shifts, the margin based $\mathcal{A}$-distance detector is still competitive. CWPM had a single false positive while the domain classifier stream had 2 false positives in these experiments.

though the rate of occurrence of novel instances is more informative in our setting than the mere fact that novel instances are observed.

We are also motivated by the problem of detecting *genre shift* in addition to domain shift, as in the ACE 2005 data set shifts from newswire to transcripts and blogs. Different text genres occur in traditional settings, such as broadcast news transcripts and newswire, and have begun to proliferate with the variety of social media technologies now available including weblogs. Static genre classification has been explored using a variety of techniques, including exploiting punctuation (Kessler et al., 1997; Dewdney et al., 2001), TF-IDF statistics (Lee and Myaeng, 2002), and part-of-speech statistics and histograms (Finn and Kushmerick, 2006; Feldman et al., 2009).

Finally, statistical estimation in a streaming context has been considered in data mining applications (Muthukrishnan, 2005). Change detection via sequential hypothesis testing has been effective for streaming applications such as network intrusion detection (Muthukrishnan et al., 2007). Detecting new events in a stream of Twitter posts can be done using constant time and space similarity measures based on a modification of locality sensitive hashing (Petrović et al., 2010).

10 Conclusion

While there are a number of methods for domain adaptation, a system first needs to determine that a domain shift has occurred. We have presented methods for automatically detecting such domain shifts from a stream of (unlabeled) examples that require limited computation and memory by virtue of operating on fixed-size windows of data. Our methods were evaluated empirically on a variety of domain shifts using NLP data sets and are shown to be sensitive to shifts while maintaining a low rate of false positives. Additionally, we showed improved detection results using a probabilistic margin based on Confidence Weighted learning. Comparisons to detection with supervised information show that our results are effective even in unlabeled settings. Our methods are promising as tools to accompany the deployment of domain adaptation algorithms, so that a complete system can first identify when a domain shift has occurred before automatically adapting to the new domain.

A Fast Fertility Hidden Markov Model for Word Alignment Using MCMC

Shaojun Zhao and **Daniel Gildea**
Department of Computer Science
University of Rochester

Abstract

A word in one language can be translated to zero, one, or several words in other languages. Using word fertility features has been shown to be useful in building word alignment models for statistical machine translation. We built a fertility hidden Markov model by adding fertility to the hidden Markov model. This model not only achieves lower alignment error rate than the hidden Markov model, but also runs faster. It is similar in some ways to IBM Model 4, but is much easier to understand. We use Gibbs sampling for parameter estimation, which is more principled than the neighborhood method used in IBM Model 4.

1 Introduction

IBM models and the hidden Markov model (HMM) for word alignment are the most influential statistical word alignment models (Brown et al., 1993; Vogel et al., 1996; Och and Ney, 2003). There are three kinds of important information for word alignment models: **lexicality**, **locality** and **fertility**. IBM Model 1 uses only lexical information; IBM Model 2 and the hidden Markov model take advantage of both lexical and locality information; IBM Models 4 and 5 use all three kinds of information, and they remain the state of the art despite the fact that they were developed almost two decades ago.

Recent experiments on large datasets have shown that the performance of the hidden Markov model is very close to IBM Model 4. Nevertheless, we believe that IBM Model 4 is essentially a better model because it exploits the fertility of words in the target language. However, IBM Model 4 is so complex that most researches use the GIZA++ software package (Och and Ney, 2003), and IBM Model 4 itself is treated as a black box. The complexity in IBM Model 4 makes it hard to understand and to improve. Our goal is to build a model that includes lexicality, locality, and fertility; and, at the same time, to make it easy to understand. We also want it to be accurate and computationally efficient.

There have been many years of research on word alignment. Our work is different from others in essential ways. Most other researchers take either the HMM alignments (Liang et al., 2006) or IBM Model 4 alignments (Cherry and Lin, 2003) as input and perform post-processing, whereas our model is a potential replacement for the HMM and IBM Model 4. Directly modeling fertility makes our model fundamentally different from others. Most models have limited ability to model fertility. Liang et al. (2006) learn the alignment in both translation directions jointly, essentially pushing the fertility towards 1. ITG models (Wu, 1997) assume the fertility to be either zero or one. It can model phrases, but the phrase has to be contiguous. There have been works that try to simulate fertility using the hidden Markov model (Toutanova et al., 2002; Deng and Byrne, 2005), but we prefer to model fertility directly.

Our model is a coherent generative model that combines the HMM and IBM Model 4. It is easier to understand than IBM Model 4 (see Section 3). Our model also removes several undesired properties in IBM Model 4. We use Gibbs sampling instead of a heuristic-based neighborhood method for parameter

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 596–605,
MIT, Massachusetts, USA, 9-11 October 2010.

estimation. Our distortion parameters are similar to IBM Model 2 and the HMM, while IBM Model 4 uses inverse distortion (Brown et al., 1993). Our model assumes that fertility follows a Poisson distribution, while IBM Model 4 assumes a multinomial distribution, and has to learn a much larger number of parameters, which makes it slower and less reliable. Our model is much faster than IBM Model 4. In fact, we will show that it is also faster than the HMM, and has lower alignment error rate than the HMM.

Parameter estimation for word alignment models that model fertility is more difficult than for models without fertility. Brown et al. (1993) and Och and Ney (2003) first compute the Viterbi alignments for simpler models, then consider only some neighbors of the Viterbi alignments for modeling fertility. If the optimal alignment is not in those neighbors, this method will not be able find the optimal alignment. We use the Markov Chain Monte Carlo (MCMC) method for training and decoding, which has nice probabilistic guarantees. DeNero et al. (2008) applied the Markov Chain Monte Carlo method to word alignment for machine translation; they do not model word fertility.

2 Statistical Word Alignment Models

2.1 Alignment and Fertility

Given a source sentence $\mathbf{f}_1^J = f_1, f_2, \ldots, f_J$ and a target sentence $\mathbf{e}_1^I = e_1, e_2, \ldots, e_I$, we define the alignments between the two sentences as a subset of the Cartesian product of the word positions. Following Brown et al. (1993), we assume that each source word is aligned to exactly one target word. We denote as $\mathbf{a}_1^J = a_1, a_2, \ldots, a_J$ the alignments between $\mathbf{f}_1^J$ and $\mathbf{e}_1^I$. When a word f_j is not aligned with any word e, a_j is 0. For convenience, we add an empty word ϵ to the target sentence at position 0 (i.e., $e_0 = \epsilon$). However, as we will see, we have to add more than one empty word for the HMM. In order to compute the "jump probability" in the HMM model, we need to know the position of the aligned target word for the previous source word. If the previous source word aligns to an empty word, we could use the position of the empty word to indicate the nearest previous source word that does not align to an empty word. For this reason, we use a total of $I + 1$ empty words for the HMM model[1]. Moore (2004) also suggested adding multiple empty words to the target sentence for IBM Model 1. After we add $I + 1$ empty words to the target sentence, the alignment is a mapping from source to target word positions:

$$a : j \rightarrow i, i = a_j$$

where $j = 1, 2, \ldots, J$ and $i = 1, 2, \ldots, 2I + 1$. Words from position $I + 1$ to $2I + 1$ in the target sentence are all empty words.

We allow each source word to align with exactly one target word, but each target word may align with multiple source words.

The fertility ϕ_i of a word e_i at position i is defined as the number of aligned source words:

$$\phi_i = \sum_{j=1}^{J} \delta(a_j, i)$$

where δ is the Kronecker delta function:

$$\delta(x, y) = \begin{cases} 1 & \text{if } x = y \\ 0 & \text{otherwise} \end{cases}$$

In particular, the fertility of all empty words in the target sentence is $\sum_{i=I+1}^{2I+1} \phi_i$. We define $\phi_\epsilon \equiv \sum_{i=I+1}^{2I+1} \phi_i$. For a bilingual sentence pair $\mathbf{e}_1^{2I+1}$ and $\mathbf{f}_1^J$, we have $\sum_{i=1}^{I} \phi_i + \phi_\epsilon = J$.

The inverted alignments for position i in the target sentence are a set B_i, such that each element in B_i is aligned with i, and all alignments of i are in B_i. Inverted alignments are explicitly used in IBM Models 3, 4 and 5, but not in our model, which is one reason that our model is easier to understand.

2.2 IBM Model 1 and HMM

IBM Model 1 and the HMM are both generative models, and both start by defining the probability of alignments and source sentence given the target sentence: $P(\mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$; the data likelihood can be computed by summing over alignments:

[1] If f_{j-1} does not align with an empty word and f_j aligns with an empty word, we want to record the position of the target word that f_{j-1} aligns with. There are $I + 1$ possibilities: f_j is the first word in the source sentence, or f_{j-1} aligns with one of the target word.

$P(\mathbf{f}_1^J|\mathbf{e}_1^{2I+1}) = \sum_{\mathbf{a}_1^J} P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})$. The alignments $\mathbf{a}_1^J$ are the hidden variables. The expectation maximization algorithm is used to learn the parameters such that the data likelihood is maximized.

Without loss of generality, $P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})$ can be decomposed into **length probabilities**, **distortion probabilities** (also called alignment probabilities), and **lexical probabilities** (also called translation probabilities):

$$\begin{aligned} & P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1}) \\ & = P(J|\mathbf{e}_1^{2I+1}) \prod_{j=1}^{J} P(a_j, f_j|f_1^{j-1}, a_1^{j-1}, \mathbf{e}_1^{2I+1}) \\ & = P(J|\mathbf{e}_1^{2I+1}) \prod_{j=1}^{J} \Big(P(a_j|f_1^{j-1}, a_1^{j-1}, \mathbf{e}_1^{2I+1}) \times \\ & \qquad P(f_j|f_1^{j-1}, a_1^{j}, \mathbf{e}_1^{2I+1}) \Big) \end{aligned}$$

where $P(J|\mathbf{e}_1^{2I+1})$ is a length probability, $P(a_j|f_1^{j-1}, a_1^{j-1}, \mathbf{e}_1^{2I+1})$ is a distortion probability and $P(f_j|f_1^{j-1}, a_1^{j}, \mathbf{e}_1^{2I+1})$ is a lexical probability.

IBM Model 1 assumes a uniform distortion probability, a length probability that depends only on the length of the target sentence, and a lexical probability that depends only on the aligned target word:

$$P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1}) = \frac{P(J|I)}{(2I+1)^J} \prod_{j=1}^{J} P(f_j|e_{a_j})$$

The hidden Markov model assumes a length probability that depends only on the length of the target sentence, a distortion probability that depends only on the previous alignment and the length of the target sentence, and a lexical probability that depends only on the aligned target word:

$$P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1}) = \\ P(J|I) \prod_{j=1}^{J} P(a_j|a_{j-1}, I) P(f_j|e_{a_j})$$

In order to make the HMM work correctly, we enforce the following constraints (Och and Ney, 2003):

$$\begin{aligned} P(i+I+1|i', I) &= p_0 \delta(i, i') \\ P(i+I+1|i'+I+1, I) &= p_0 \delta(i, i') \\ P(i|i'+I+1, I) &= P(i|i', I) \end{aligned}$$

where the first two equations imply that the probability of jumping to an empty word is either 0 or p_0, and the third equation implies that the probability of jumping from a non-empty word is the same as the probability of jumping from the corespondent empty word.

The absolute position in the HMM is not important, because we re-parametrize the distortion probability in terms of the distance between adjacent alignment points (Vogel et al., 1996; Och and Ney, 2003):

$$P(i|i', I) = \frac{c(i - i')}{\sum_{i''} c(i'' - i')}$$

where $c(\,)$ is the count of jumps of a given distance.

In IBM Model 1, the word order does not matter. The HMM is more likely to align a source word to a target word that is adjacent to the previous aligned target word, which is more suitable than IBM Model 1 because adjacent words tend to form phrases.

For these two models, in theory, the fertility for a target word can be as large as the length of the source sentence. In practice, the fertility for a target word in IBM Model 1 is not very big except for rare target words, which can become a garbage collector, and align to many source words (Brown et al., 1993; Och and Ney, 2003; Moore, 2004). The HMM is less likely to have this garbage collector problem because of the alignment probability constraint. However, fertility is an inherent cross-language property and these two models cannot assign consistent fertility to words. This is our motivation for adding fertility to these two models, and we expect that the resulting models will perform better than the baseline models. Because the HMM performs much better than IBM Model 1, we expect that the fertility hidden Markov model will perform much better than the fertility IBM Model 1. Throughout the paper, “our model” refers to the fertility hidden Markov model.

Due to space constraints, we are unable to provide details for IBM Models 3, 4 and 5; see Brown et al. (1993) and Och and Ney (2003). But we want to point out that the locality property modeled in the HMM is missing in IBM Model 3, and is modeled invertedly in IBM Model 4. IBM Model 5 removes deficiency (Brown et al., 1993; Och and Ney, 2003) from IBM Model 4, but it is computationally very expensive due to the larger number of parameters than IBM Model 4, and IBM Model 5 often provides no improvement on alignment accuracy.

3 Fertility Hidden Markov Model

Our fertility IBM Model 1 and fertility HMM are both generative models and start by defining the probability of fertilities (for each non-empty target word and all empty words), alignments, and the source sentence given the target sentence: $P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$; the data likelihood can be computed by summing over fertilities and alignments: $P(\mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) = \sum_{\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J} P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$.

The fertility for a non-empty word e_i is a random variable ϕ_i, and we assume ϕ_i follows a Poisson distribution $\mathrm{Poisson}(\phi_i; \lambda(e_i))$. The sum of the fertilities of all the empty words (ϕ_ϵ) grows with the length of the target sentence. Therefore, we assume that ϕ_ϵ follows a Poisson distribution with parameter $I\lambda(\epsilon)$.

Now $P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$ can be decomposed in the following way:

$$\begin{aligned}
&P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\
&\quad = P(\phi_1^I | \mathbf{e}_1^{2I+1}) P(\phi_\epsilon | \phi_1^I, \mathbf{e}_1^{2I+1}) \times \\
&\qquad \prod_{j=1}^{J} P(a_j, f_j | f_1^{j-1}, a_1^{j-1}, \mathbf{e}_1^{2I+1}, \phi_1^I, \phi_\epsilon) \\
&\quad = \prod_{i=1}^{I} \frac{\lambda(e_i)^{\phi_i} e^{-\lambda(e_i)}}{\phi_i!} \times \\
&\qquad \frac{(I\lambda(\epsilon))^{\phi_\epsilon} e^{-I\lambda(\epsilon)}}{\phi_\epsilon!} \times \\
&\qquad \prod_{j=1}^{J} \Big(P(a_j | f_1^{j-1}, a_1^{j-1}, \mathbf{e}_1^{2I+1}, \phi_1^I, \phi_\epsilon) \times \\
&\qquad\quad P(f_j | f_1^{j-1}, a_1^{j}, \mathbf{e}_1^{2I+1}, \phi_1^I, \phi_\epsilon) \Big)
\end{aligned}$$

Superficially, we only try to model the length probability more accurately. However, we also enforce the fertility for the same target word across the corpus to be consistent. The expected fertility for a non-empty word e_i is $\lambda(e_i)$, and the expected fertility for all empty words is $I\lambda(\epsilon)$. Any fertility value has a non-zero probability, but fertility values that are further away from the mean have low probability. IBM Models 3, 4, and 5 use a multinomial distribution for fertility, which has a much larger number of parameters to learn. Our model has only one parameter for each target word, which can be learned more reliably.

In the fertility IBM Model 1, we assume that the distortion probability is uniform, and the lexical probability depends only on the aligned target word:

$$\begin{aligned}
&P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\
&\quad = \prod_{i=1}^{I} \frac{\lambda(e_i)^{\phi_i} e^{-\lambda(e_i)}}{\phi_i!} \times \\
&\qquad \frac{(I\lambda(\epsilon))^{\phi_\epsilon} e^{-(I\lambda(\epsilon))}}{\phi_\epsilon!} \times \\
&\qquad \frac{1}{(2I+1)^J} \prod_{j=1}^{J} P(f_j | e_{a_j}) \qquad (1)
\end{aligned}$$

In the fertility HMM, we assume that the distortion probability depends only on the previous alignment and the length of the target sentence, and that the lexical probability depends only on the aligned target word:

$$\begin{aligned}
&P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\
&\quad = \prod_{i=1}^{I} \frac{\lambda(e_i)^{\phi_i} e^{-\lambda(e_i)}}{\phi_i!} \times \\
&\qquad \frac{(I\lambda(\epsilon))^{\phi_\epsilon} e^{-(I\lambda(\epsilon))}}{\phi_\epsilon!} \times \\
&\qquad \prod_{j=1}^{J} P(a_j | a_{j-1}, I) P(f_j | e_{a_j}) \qquad (2)
\end{aligned}$$

When we compute $P(\mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$, we only sum over fertilities that agree with the alignments:

$$P(\mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \quad = \quad \sum_{\mathbf{a}_1^J} P(\mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$$

where

$$\begin{aligned} & P(\mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\ &= \sum_{\phi_1^I, \phi_\epsilon} P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\ &\approx P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \times \\ &\quad \prod_{i=1}^{I} \delta\left(\sum_{j=1}^{J} \delta(a_j, i), \phi_i\right) \times \\ &\quad \delta\left(\sum_{i=I+1}^{2I+1} \sum_{j=1}^{J} \delta(a_j, i), \phi_\epsilon\right) \qquad (3) \end{aligned}$$

In the last two lines of Equation 3, ϕ_ϵ and each ϕ_i are not free variables, but are determined by the alignments. Because we only sum over fertilities that are consistent with the alignments, we have $\sum_{\mathbf{f}_1^J} P(\mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) < 1$, and our model is deficient, similar to IBM Models 3 and 4 (Brown et al., 1993). We can remove the deficiency for fertility IBM Model 1 by assuming a different distortion probability: the distortion probability is 0 if fertility is not consistent with alignments, and uniform otherwise. The total number of consistent fertility and alignments is $\frac{J!}{\phi_\epsilon! \prod_{j=1}^{J} \phi_i!}$. Replacing $\frac{1}{(2I+1)^J}$ with $\frac{\phi_\epsilon! \prod_{j=1}^{J} \phi_i!}{J!}$, we have:

$$\begin{aligned} & P(\phi_1^I, \phi_\epsilon, \mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\ &= \prod_{i=1}^{I} \lambda(e_i)^{\phi_i} e^{-\lambda(e_i)} \times \\ &\quad (I\lambda(\epsilon))^{\phi_\epsilon} e^{-(I\lambda(\epsilon))} \times \\ &\quad \frac{1}{J!} \prod_{j=1}^{J} P(f_j | e_{a_j}) \end{aligned}$$

In our experiments, we did not find a noticeable change in terms of alignment accuracy by removing the deficiency.

4 Expectation Maximization Algorithm

We estimate the parameters by maximizing $P(\mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$ using the expectation maximization (EM) algorithm (Dempster et al., 1977). The auxiliary function is:

$$\begin{aligned} & L(P(f|e), P(a|a'), \lambda(e), \xi_1(e), \xi_2(a')) \\ &= \sum_{\mathbf{a}_1^J} \tilde{P}(\mathbf{a}_1^J | \mathbf{e}_1^{2I+1}, \mathbf{f}_1^J) \log P(\mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1}) \\ &\quad - \sum_{e} \xi_1(e)(\sum_{f} P(f|e) - 1) \\ &\quad - \sum_{a'} \xi_2(a')(\sum_{a} P(a|a') - 1) \end{aligned}$$

Because $P(\mathbf{a}_1^J, \mathbf{f}_1^J | \mathbf{e}_1^{2I+1})$ is in the exponential family, we get a closed form for the parameters from expected counts:

$$P(f|e) = \frac{\sum_s c(f|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}{\sum_f \sum_s c(f|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})} \qquad (4)$$

$$P(a|a') = \frac{\sum_s c(a|a'; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}{\sum_a \sum_s c(a|a'; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})} \qquad (5)$$

$$\lambda(e) = \frac{\sum_s c(\phi|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}{\sum_s c(k|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})} \qquad (6)$$

where s is the number of bilingual sentences, and

$$\begin{aligned} c(f|e; \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) &= \sum_{\mathbf{a}_1^J} \tilde{P}(\mathbf{a}_1^J | \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) \times \\ &\quad \sum_j \delta(f_j, f) \delta(e_i, e) \\ c(a|a'; \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) &= \sum_{\mathbf{a}_1^J} \tilde{P}(\mathbf{a}_1^J | \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) \times \\ &\quad \sum_j \delta(a_j, a) \delta(a_{j-1}, a') \\ c(\phi|e; \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) &= \sum_{\mathbf{a}_1^J} \tilde{P}(\mathbf{a}_1^J | \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) \times \\ &\quad \sum_i \phi_i \delta(e_i, e) \\ c(k|e; \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) &= \sum_i k(e_i) \delta(e_i, e) \end{aligned}$$

These equations are for the fertility hidden Markov model. For the fertility IBM Model 1, we do not need to estimate the distortion probability.

5 Gibbs Sampling for Fertility HMM

Although we can estimate the parameters by using the EM algorithm, in order to compute the expected counts, we have to sum over all possible alignments $\mathbf{a}_1^J$, which is, unfortunately, exponential. We developed a Gibbs sampling algorithm (Geman and Geman, 1984) to compute the expected counts.

For each target sentence $\mathbf{e}_1^{2I+1}$ and source sentence $\mathbf{f}_1^J$, we initialize the alignment a_j for each source word f_j using the Viterbi alignments from IBM Model 1. During the training stage, we try all $2I + 1$ possible alignments for a_j but fix all other alignments.[2] We choose alignment a_j with probability $P(a_j|a_1, \cdots a_{j-1}, a_{j+1} \cdots a_J, \mathbf{f}_1^J, \mathbf{e}_1^{2I+1})$, which can be computed in the following way:

$$P(a_j|a_1, \cdots, a_{j-1}, a_{j+1}, \cdots, a_J, \mathbf{f}_1^J, \mathbf{e}_1^{2I+1}) = \frac{P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})}{\sum_{a_j} P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})} \quad (7)$$

For each alignment variable a_j, we choose t samples. We scan through the corpus many times until we are satisfied with the parameters we learned using Equations 4, 5, and 6. This Gibbs sampling method updates parameters constantly, so it is an “online learning” algorithm. However, this sampling method needs a large amount of communication between machines in order to keep the parameters up to date if we compute the expected counts in parallel. Instead, we do “batch learning”: we fix the parameters, scan through the entire corpus and compute expected counts in parallel (E-step); then combine all the counts together and update the parameters (M-step). This is analogous to what IBM models and the HMM do in the EM algorithms. The algorithm for the E-step on one machine (all machines are independent) is in Algorithm 1.

For the fertility hidden Markov model, updating $P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})$ whenever we change the alignment a_j can be done in constant time, so the complexity of choosing t samples for all a_j $(j = 1, 2, \ldots, J)$ is $O(tIJ)$. This is the same complexity as the HMM if t is $O(I)$, and it has lower complexity if t is a constant. Surprisingly, we can achieve better results than the HMM by computing as few as 1 sample for each alignment, so the fertility hidden Markov model is much faster than the HMM. Even when choosing t such that our model is 5 times faster than the HMM, we achieve better results.

Algorithm 1: One iteration of E-step: draw t samples for each a_j for each sentence pair $(\mathbf{f}_1^J, \mathbf{e}_1^{2I+1})$ in the corpus

```
for $(\mathbf{f}_1^J, \mathbf{e}_1^{2I+1})$ in the corpus do
    Initialize $\mathbf{a}_1^J$ with IBM Model 1;
    for $t$ do
        for $j$ do
            for $i$ do
                $a_j = i$;
                Compute $P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})$;
            end
            Draw a sample for $a_j$ using
            Equation 7;
            Update counts;
        end
    end
end
```

We also consider initializing the alignments using the HMM Viterbi algorithm in the E-step. In this case, the fertility hidden Markov model is not faster than the HMM. Fortunately, initializing using IBM Model 1 Viterbi does not decrease the accuracy in any noticeable way, and reduces the complexity of the Gibbs sampling algorithm.

In the testing stage, the sampling algorithm is the same as above except that we keep the alignments $\mathbf{a}_1^J$ that maximize $P(\mathbf{a}_1^J, \mathbf{f}_1^J|\mathbf{e}_1^{2I+1})$. We need more samples in the testing stage because it is unlikely to get to the optimal alignments by sampling a few times for each alignment. On the contrary, in the above training stage, although the samples are not accurate enough to represent the distribution defined by Equation 7 for each alignment a_j, it is accurate enough for computing the expected counts, which are defined at the corpus level. Interestingly, we found that throwing away the fertility and using the HMM Viterbi decoding achieves same results as the sampling approach (we can ignore the difference because it is tiny), but is faster. Therefore, we use Gibbs sampling for learning and the HMM Viterbi decoder for testing.

Gibbs sampling for the fertility IBM Model 1 is similar but simpler. We omit the details here.

[2] For fertility IBM Model 1, we only need to compute $I + 1$ values because e_{I+1}^{2I+1} are identical empty words.

Table 1: AER results. IBM1F refers to the fertility IBM1 and HMMF refers to the fertility HMM. We choose $t = 1$, 5, and 30 for the fertility HMM.

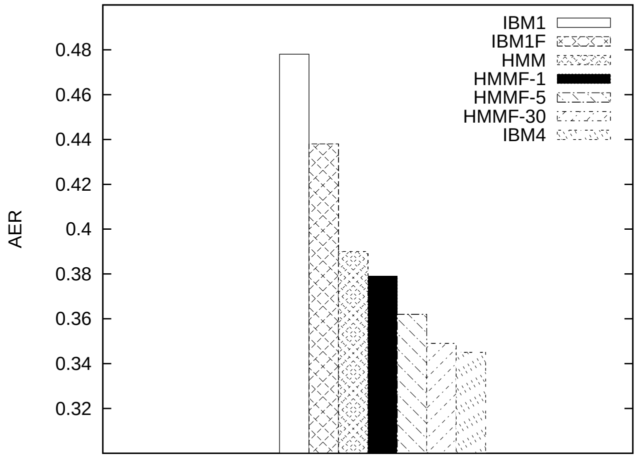

Figure 1: AER comparison (en→cn)

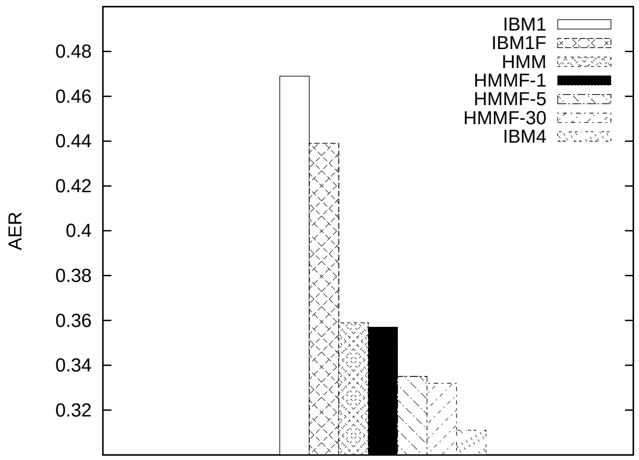

Figure 2: AER comparison (cn →en)

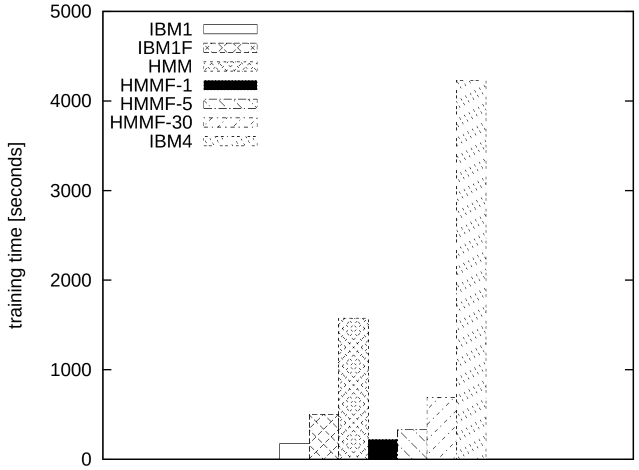

Figure 3: Training time comparison. The training time for each model is calculated from scratch. For example, the training time of IBM Model 4 includes the training time of IBM Model 1, the HMM, and IBM Model 3.

6 Experiments

We evaluated our model by computing the word alignment and machine translation quality. We use the alignment error rate (AER) as the word alignment evaluation criterion. Let A be the alignments output by word alignment system, P be a set of possible alignments, and S be a set of sure alignments both labeled by human beings. S is a subset of P.

Precision, recall, and AER are defined as follows:

$$\begin{aligned} \text{recall} &= \frac{|A \cap S|}{|S|} \\ \text{precision} &= \frac{|A \cap P|}{|A|} \\ \text{AER}(S, P, A) &= 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|} \end{aligned}$$

AER is an extension to F-score. Lower AER is better.

We evaluate our fertility models on a Chinese-English corpus. The Chinese-English data taken from FBIS newswire data, and has 380K sentence pairs, and we use the first 100K sentence pairs as our training data. We used hand-aligned data as reference. The Chinese-English data has 491 sentence pairs.

We initialize IBM Model 1 and the fertility IBM Model 1 with a uniform distribution. We smooth all parameters ($\lambda(e)$ and $P(f|e)$) by adding a small value (10^{-8}), so they never become too small. We run both models for 5 iterations. AER results are computed using the IBM Model 1 Viterbi alignments, and the Viterbi alignments obtained from the Gibbs sampling algorithm.

We initialize the HMM and the fertility HMM with the parameters learned in the 5th iteration of IBM Model 1. We smooth all parameters ($\lambda(e)$, $P(a|a')$ and $P(f|e)$) by adding a small value (10^{-8}). We run both models for 5 iterations. AER results are computed using traditional HMM Viterbi decoding for both models.

It is always difficult to determine how many samples are enough for sampling algorithms. However, both fertility models achieve better results than their baseline models using a small amount of samples. For the fertility IBM Model 1, we sample 10 times for each a_j, and restart 3 times in the training stage; we sample 100 times and restart 12 times in the testing stage. For the fertility HMM, we sample 30 times for each a_j with no restarting in the training stage; no sampling in the testing stage because we use traditional HMM Viterbi decoding for testing. More samples give no further improvement.

Initially, the fertility IBM Model 1 and fertility HMM did not perform well. If a target word e only appeared a few times in the training corpus, our model cannot reliably estimate the parameter $\lambda(e)$. Hence, smoothing is needed. One may try to solve it by forcing all these words to share a same parameter $\lambda(e_{\text{infrequent}})$. Unfortunately, this does not solve the problem because all infrequent words tend to have larger fertility than they should. We solve the problem in the following way: estimate the parameter $\lambda(e_{\text{non\_empty}})$ for all non-empty words, all infrequent words share this parameter. We consider words that appear less than 10 times as infrequent words.

Table 1, Figure 1, and Figure 2 shows the AER results for different models. We can see that the fertility IBM Model 1 consistently outperforms IBM Model 1, and the fertility HMM consistently outperforms the HMM.

The fertility HMM not only has lower AER than the HMM, it also runs faster than the HMM. Figure 3 show the training time for different models. In fact, with just 1 sample for each alignment, our model archives lower AER than the HMM, and runs more than 5 times faster than the HMM. It is possible to use sampling instead of dynamic programming in the HMM to reduce the training time with no decrease in AER (often an increase). We conclude that the fertility HMM not only has better AER results, but also runs faster than the hidden Markov model.

We also evaluate our model by computing the machine translation BLEU score (Papineni et al., 2002) using the Moses system (Koehn et al., 2007). The training data is the same as the above word alignment evaluation bitexts, with alignments for each model symmetrized using the grow-diag-final heuristic. Our test is 633 sentences of up to length 50, with four references. Results are shown in Table 2; we see that better word alignment results do not lead to better translations.

Model	BLEU
HMM	19.55
HMMF-30	19.26
IBM4	18.77

Table 2: BLEU results

7 Conclusion

We developed a fertility hidden Markov model that runs faster and has lower AER than the HMM. Our model is thus much faster than IBM Model 4. Our model is also easier to understand than IBM Model 4. The Markov Chain Monte Carlo method used in our model is more principled than the heuristic-based neighborhood method in IBM Model 4. While better word alignment results do not necessarily correspond to better translation quality, our translation results are comparable in translation quality to both the HMM and IBM Model 4.

Abstract

Minimum Error Rate Training is the algorithm for log-linear model parameter training most used in state-of-the-art Statistical Machine Translation systems. In its original formulation, the algorithm uses N-best lists output by the decoder to grow the *Translation Pool* that shapes the surface on which the actual optimization is performed. Recent work has been done to extend the algorithm to use the entire translation lattice built by the decoder, instead of N-best lists. We propose here a third, intermediate way, consisting in growing the translation pool using samples randomly drawn from the translation lattice. We empirically measure a systematic improvement in the BLEU scores compared to training using N-best lists, without suffering the increase in computational complexity associated with operating with the whole lattice.

1 Introduction

Most state-of-the-art Statistical Machine Translation (SMT) systems are based on a log-linear model of the conditional probability of generating a certain translation given a specific source sentence. More specifically, the conditional probability of a translation **e** and a word alignment **a** given a source sentence **f** is modeled as:

$$P(\mathbf{e},\mathbf{a}|\mathbf{f}) \propto \exp\left(\sum_{k=1}^{K} \lambda_k h_k\left(\mathbf{e},\mathbf{a},\mathbf{f}\right)\right) \qquad (1)$$

where the $h_k(\mathbf{e},\mathbf{a},\mathbf{f})$ are *feature functions* providing complementary sources of information on the quality of the produced translation (and alignment). Once such a model is known: the *decoder* (i.e. the actual translation program), which builds a translation by searching in the space of all possible translations the one that maximizes the conditional probability:

$$(\mathbf{e}^*,\mathbf{a}^*) = \arg\max_{\mathbf{e},\mathbf{a}} \sum_{k=1}^{K} \lambda_k h_K(\mathbf{e},\mathbf{a},\mathbf{f}) \qquad (2)$$

where we have taken into account that the exponential is monotonic.

The parameters λ_k determine the relative importance of the different feature functions in the global score. Best results are typically obtained by searching in the space of all possible parameter vectors $\bar{\lambda}$ for the one that minimizes the error on a held-out development dataset for which one or more reference human translations are available, as measured by some automatic measure. This procedure is referred to as *Minimum Error Rate Training (MERT)*.

1.1 Minimum Error Rate Training on N-best Lists

The most widespread MERT algorithm is the one described in (Och, 2003). This algorithm starts by initializing the parameter vector $\bar{\lambda}$. For each source sentence in the development set, the decoder

[*] The work behind this paper was done during an internship at the Xerox Research Centre Europe. The author was partially supported by NSF through Grant CCF-0643593 and the AFOSR Young Investigator Research Program.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 606–615,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

is used to initialize a translation pool with a list of N-best scoring candidate translations according to the model. Using this pool and the corresponding reference translations then, an optimization procedure is run to update the parameter vector to a $\bar{\lambda}'$ with reduced error. The decoder is then invoked again, the new output N-best list is merged into the translation pool, and the procedure is iterated. The algorithm stops either after a predefined number of iterations or upon convergence, which is reached when no new element is added to the translation pool of any sentence, or when the size of the update in the parameter vector is below a threshold.

The error measure minimized at each iteration is usually BLEU (Papineni et al., 2002). BLEU essentially measures the precision with which the translation produced by a system recovers n-grams of different orders from the available reference translation(s), used as a gold standard.

The optimization procedure that is run within each iteration on the growing translation pools is based on the key observation that BLEU only depends on the single translation receiving the highest score by the translation model (which would be the one shown to the receipient) in the translation pool. This in turn means that, for any given sentence, its contribution to BLEU changes only when the value of the parameters change in such a way that the sentence ranking first according to the model switches from one to another. This situation does not change when one considers all the sentences in a development set instead of just one: while varying the $\bar{\lambda}$ vector, the BLEU score changes only when there is a change at the top of the ranking of the alternatives for at least one sentence in the set. In other words, BLEU is piece-wise constant in $\bar{\lambda}$. MERT then proceeds by performing an iterative line search by fixing each time the value of all components of $\bar{\lambda}$ but one[1]: for such a free parameter a global optimum can be identified by enumerating all the points that cause a change in BLEU. The value of the component is then fixed at the middle of an interval with maximum BLEU, and the procedure is iterated until convergence. Since the error function is highly irregular, and the iterative line search is not guaranteed to converge to a global optimum, the procedure is repeated many times with different initializations, and the best convergence point is retained.

The MERT algorithm suffers from the following problem: it assumes at each iteration that the set of candidates with a chance to make it to the top (for some value of the parameter vector) is well represented in the translation pool. If the translation pool is formed in the standard way by merging N-best lists, this assumption is easily violated in practice. Indeed, the N-best list often contains only candidates displaying minor differences, and represents only a very small sample of alternative possible translations, strongly biased by the current parameter setting.

Recognizing this shortcoming, Macherey et al. (2008) extended the MERT algorithm so as to use the whole set of candidate translations compactly represented in the search lattice produced by the decoder, instead of only a N-best list of candidates extracted from it. This is achieved via an elegant but relatively heavy dynamic programming algorithm that propagates sufficient statistics (called *envelopes*) throughout the whole search graph. The reported theoretical worst-case complexity of this algorithm is $O(|V||\mathcal{E}|\log|\mathcal{E}|)$, where V and $\mathcal{E}$ are the vertex set and the edge set of the lattice respectively.

We propose here an alternative method consisting in sampling a list of candidate translations from the probability distribution induced by the translation lattice. This simple method produces a list of candidates more representative of the complete distribution than an N-best list, side-stepping the intricacies of propagating envelopes throughout the lattice. Computational complexity increases only marginally over the N-best list approach, while still yielding significant improvements in final translation quality.

1.2 The translation lattice

Finding the optimal translation according to Equation 1 is NP-complete (Knight, 1999). Most phrase-based SMT systems resort then to beam-search heuristic algorithms for solving the problem approximately. In their most widespread version, PBSMT decoders proceed by progressively extending translation prefixes by adding one new phrase at a time, and correspondingly "consuming" portions of the

[1] More generally, one can select each time a combination of coordinates identifying a line in the parameter space, and is not restricted to a coordinate direction.

source sentence. Each prefix is associated with a node in a graph, and receives a score according to the model. Whenever two prefixes having exactly the same possible extensions are detected, the lower-scoring one is *merged* into the other, thus creating a re-entrancy in the directed graph, which has then the characteristics of a *lattice* (Figure 1). Edges in the lattice are labelled with the phrase-pair that was used to perform the corresponding extension, the source word positions that were covered in doing the extension, and the corresponding increment in model score.

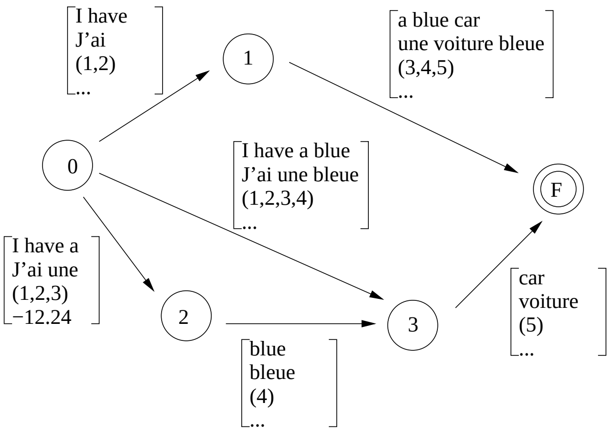

Figure 1: A lattice showing some possible translations of the English sentence: *I have a blue car*. The state with ID 0 is the start state and the one with F is the final state.

2 Related Work

Since its introduction, (Och, 2003) there has been various suggestions for optimizing the MERT criterion. Zens et al. (2007) use the MERT criterion to optimize the N-best lists using the Downhill Simplex Algorithm (Press, 2007). But the Downhill Simplex Algorithm loses its robustness as the dimension goes up by more than 10 (Macherey et al., 2008). Deterministic Annealing was suggested by Smith and Eisner (2006) where the authors propose to minimize the *expected loss* or *risk*. They define the expectation using a probability distribution over hypotheses that they gradually anneal to focus on the 1-best hypothesis. Different search strategies were investigated by Cer et al. (2008). Work has been done to investigate a perceptron-like online margin training for statisitical machine translation (Watanabe et al., 2007). Building on this paper, the most recent work to our knowledge has been done by Chiang et al. (2008). They explore the use of the Margin Infused Relaxed Algorithm (MIRA) (Crammer and Singer, 2003; Crammer et al., 2006) algorithm instead of MERT. Macherey et al. (2008) propose a new variation of MERT where the algorithm is tuned to work on the whole phrase lattice instead of N-best list only. The new algorithm constructs the error surface of all translations that are encoded in the phrase lattice. They report significant convergence improvements and BLEU score gains over N-best MERT when trained on NIST 2008 translation tasks. More recently, this algorithm was extended to work with hypergraphs encoding a huge number of translations produced by MT systems based on Synchronous Context Free Grammars (Kumar et al., 2009). All the methods cited here work on either N-best lists or from whole translation lattices built by the decoder. To our knowledge, none of them proposes sampling translations from the lattice.

3 Sampling candidate translations from the lattice

In this section we first start by providing an intuition of why we believe it is a good idea to sample from the translation lattice, and then describe in detail how we do it.

3.1 An intuitive explanation

The limited scope of n-best lists rules out many alternative translations that would receive the highest score for some values of the parameter vector. The complete set of translations that can be produced using a fixed phrase table (also called *reachable* translations) for a given source sentence can be represented as a set of vectors in the space spanned by the feature functions (Fig. 2). Not all such translations stand a chance to receive the highest score for any value of the parameter vector, though. Indeed, if translations **h**, **h'**and **h"** are such that $h_k \leq h'_k \leq h''_k$ for all feature k, then there is no value of $\bar{\lambda}$ that will give to **h'** a score higher than both **h** and **h"**. The candidates that would rank first for some value of the $\bar{\lambda}$ parameter vector are those on the convex envelope of the overall candidate set. We know of no effective way to generate this convex envelope in polynomial time. The set of candidates represented by the decoder lattice is a subset (enclosed in the larger dashed polygon in the figure) of this set. This subset is biased to contain translations ranking high according to the values of the parameter vector (the direction labelled with λ) used to produce it, because of the pruning strategies that guide the construction of the translation lattice. Both the N-best list and our proposed random sample are further subsets of the set of translations encoded in the lattice. The N-best list is very biased towards translations that score high with the current choice of parameters: its convex envelope (the smaller dashed polygon) is very different from the one of the complete set of translations, and also from that of the translations in the lattice. The convex envelope of a random sample from the translation lattice (the dotted polygon in the figure), will generally be somewhat closer to the envelope of the whole lattice itself.

The curves in the figure indicate regions of constant loss (e.g. iso-BLEU score, much more irregularly shaped in reality than in the drawing). For this sentence, then, the optimal choice of the parameters would be around λ^*. Performing an optimization step based on the random sample envelope would result in a more marked update (λ'_{sample}) in the direction of the best parameter vector than if an N-best list is used ($\lambda'_{\text{N-best}}$).

Notice that Figure 2 portraits a situation with only two features, for obvious reasons. In practice the number of features will be substantially larger, with values between five and twenty being common practice. In real cases, then, a substantially larger fraction of reachable translations will tend to lie on the convex envelope of the set, and not inside the convex hull.

3.2 The sampling procedure

We propose to modify the standard MERT algorithm and sample N candidates from the translation lattice according to the probability distribution over paths induced by the model, given the current setting of the $\bar{\lambda}$ parameters, instead of using an N-best list. The sampling procedes from the root node of the lattice, corresponding to an empty translation candidate covering no words of the source, by chosing step by step the next edge to follow. The probability distribution for each possible follow-up is the posterior probability of following the edge given the path prefix derived from the lattice: it is obtained via a preliminary backward sweep.

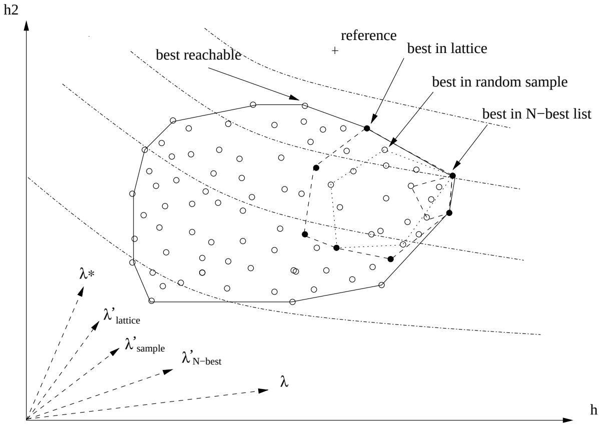

Figure 2: Envelope of the set of reachable translations where the model has two feature functions h_1 and h_2. The envelope of the lattice is the outer dashed polygon, while the envelope of the N-best list is the inner one. Using the whole lattice as translation pool will result in a more marked update towards the optimal parameters. The random sample from the lattice is enclosed by the dotted line. If we use it, we can intuitively expect updates towards the optimum of intermediate effectiveness between those of the N-best list method and those of the lattice method.

Since feature functions are incremental over the edges by design, the non-normalized probability of a path is given by:

$$P(e_1, \ldots, e_m) = e^{\sum_{i=1}^{m} \sigma(e_i)} \qquad (3)$$

where

$$\sigma(e_i) = \sum_{k=1}^{K} \lambda_k h_k(e_i) \qquad (4)$$

is the *score* of edge e_i. With a small abuse of notation we will also denote it as $\sigma(n_{j,k})$, where it is intended that e_i goes from node n_j to node n_k. Let's denote with $\sigma(n_i)$ the score of node n_i, i.e. the logarithm of the cumulative unnormalized probability of all the paths in the lattice that go from node n_i to a final node. The unnormalized probability of selecting node n_j starting from n_i can then be expressed recursively as follows:

$$S(n_j|n_i) \approx e^{(\sigma(n_j)+\sigma(n_{i,j}))} \quad (5)$$

The scores required to compute this sampling probabilities can be obtained by a simple backward pass in the lattice. Let P_i be the set of successors of n_i. So the total unnormalized log-probability of reaching a final state (i.e. with a complete translation) from n_i is given by the equation below.

$$\sigma(n_i) = \log(\sum_{n_j \in P_i} e^{(\sigma(n_j)+\sigma(n_{i,j}))}) \quad (6)$$

where we set $\sigma(n_i) = 0$ if $P_i = \emptyset$, that is if n_i is a final node. At the end of the backward sweep, $\sigma(n_0)$ contains the unnormalized cumulative probability of all paths, i.e. the partition function. Notice that this normalising constant cancels out when computing local sampling probabilities for traversed nodes in the lattice.

Once we know the transition probability (Eq. 5) for each node, we sample by starting in the root node of the lattice and at each step randomly selecting among its successors, until we end in the final node. The whole sampling procedure is repeated as many times as the number of samples sought. After collecting samples for each sentence, the whole list is used to grow the translation pool.

Notice that when using this sampling method it is no longer possible to use the stability of the translation pool as a stopping criterion. The MERT algorithm must thus be run either for a fixed number of iterations, or until the norm of the update to the parameter vector goes below a threshold.

3.3 Time Complexity Analysis

For each line search in the inner loop of the MERT algorithm, all methods considered here need to compute the projection of the convex envelope that can be scanned by leaving all components unchanged but one[2]. If we use either N-best lists or random samples to form the translation pool, and M is the size of the translation pool, then computing the envelope can be done in time $O(M \log M)$ using the *SweepLine* algorithm reproduced as Algorithm 1 in (Macherey et al., 2008). As shown in the same article, the lattice method for computing the envelope is $O(|V||\mathcal{E}| \log |\mathcal{E}|)$, where V is the vertex set of the lattice, and $\mathcal{E}$ is its edge set. In standard decoders there is a maximum limit D to the allowed distortion, and lattice vertices are organized in J priority queues [3] of size at most a, where J is the length of the source sentence and a is a parameter of the decoder set by the user. Also, there is a limit K to the maximum number of source words spanned by a phrase, and only up to c alternative translations for a same source phrase are kept in the phrase table. Under these standard conditions, the number of outgoing edges E' from each lattice vertex can be bounded by a constant. A way to see this is by considering that if an hypothesis is extended with a phrase, then the extended hypothesis must end up in a stack at most K stacks to the right of the original one. There are only aK places in these stacks, so it must be $|E'| \leq aK$.

Since the number of edges leaving each node is bounded by a constant, it is $|E| = \Theta(|V|)$, and the lattice method is $O(|V|^2 \log(|V|))$. The maximum number of vertices in the lattice is limited by the capacity of the stacks: $|V| \leq aJ$. This eventually leads to a complexity of $O(J^2 \log J)$ for the inner loop of the lattice method.

It is interesting to observe that the complexity is driven by the length of the source sentence in the case of the lattice method, and by the size of the translation pool in the case of both the N-best list method and the random sampling method. The latter two methods are asymptotically more effective as long as the size of the sample/N-best list grows subquadratically in the length of the sentence. In most of our experiments we keep the size of the sample constant, independent of the length of the sentence, but other choices can be considered. Since the number of reachable translations grows with the length of the source sentence, length-independent samples explore a smaller fraction of the reachable space. Generating samples (or n-best lists) of size increasing with the length of the source sentence could thus lead to more homogeneous sampling, and possibly a better use of CPU time.

We have so far compared methods in term of the complexity of the innermost loop: the search for a global optimum along a line in the parameter space.

[2] In general, moving along a 1-dimensional subspace of the parameter space.

[3] Traditionally referred to as *stacks*.

This is indeed the most important analysis, since the line search is repeated many times. In order to complete the analysis, we also compare the different methods in terms of the operations that need be performed as part of the outer iteration, that is upon redecoding the development set with a new parameter vector.

The N-best list method requires simply constructing an N-best list from the lattice. This can be done in time linear in the size J of the sentence and in N with a backward sweep in the lattice.

The sampling method requires sampling N times the lattice according to the probability distribution induced by the weights on its edges. We use a dynamic programming approach for computing the posterior probabilities of traversing edges. In this phase we visit each edge of the lattice exactly once, hence this phase is linear in the number of edges in the lattice, hence under the standard assumptions above in the length J of the sentence. Once posterior probabilities are computed for the lattice, we need to sample N paths from it, each of which is composed of at most J edges[4]. Under standard assumptions, randomly selecting the next edge to follow at each lattice node can be done in constant time, so the whole sampling is also $O(NJ)$, like extracting the N-best list.

No operation at all is required by the lattice method in the outer loop, since the whole lattice is passed over for envelope propagation to the inner loop.

4 Experimental Results

Experiments were conducted on the Europarl corpus with the split used for the WMT-08 shared task (Europarl training and test condition) for the language pairs English-French (En-Fr), English-Spanish (En-Es) and English-German (En-De), each in both directions. Training corpora contain between 1.2 and 1.3 million sentence pairs each, development and test datasets are of size 2,000. Detailed token and type statistics can be found in Callison-Burch et al. (2008). The Moses decoder (Koehn et al., 2007) was used for generating lattices and n-best lists. The maximum number of decoding iterations was set to twelve. Since Moses was run with its lexicalised distortion model, there were 14 features. Moses L1-normalises the parameter vector: parameter scaling only marginally affects n-best list construction (via threshold pruning during decoding), while it substantially impacts sampling.

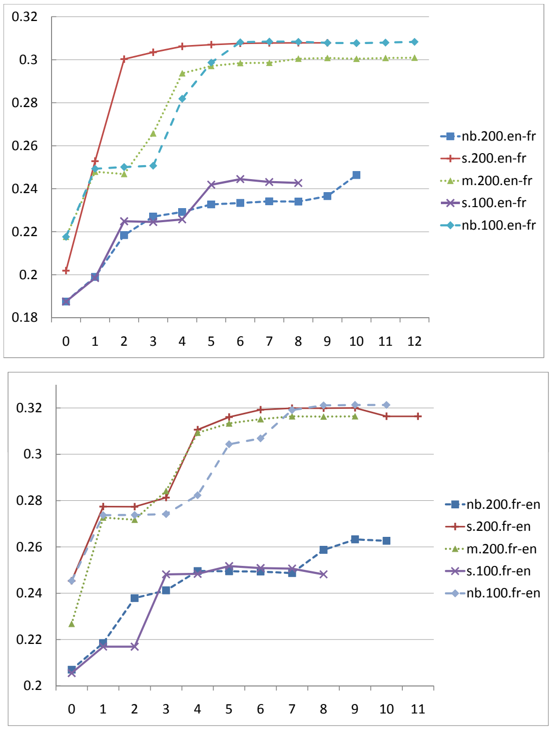

Figure 3: Learning curves (BLEU on the development set) for different tested conditions for English to French (top) and French to English (bottom).

For each of the six configurations, we compared the BLEU score on the test data when optimizing feature weights with MERT using n-best and random samples of size 100 and 200. In all cases we used 20 random restarts for MERT. Results are presented in Table 1. We also ran non systematic experiments on some of the configurations with larger samples and n-best lists, with results changing very little from the respective 200 cases: we do not report them here.

Learning curves (BLEU on the development set) are shown in Figure 3. Learning curves for the other tested language pairs follow a similar pattern.

[4] We assume all phrase pairs cover at least one source word.

5 Analysis of results

All differences of the test scores between optimizing the parameters using nbest-200 lists and from randomly sampled lists of size 200 were found to be statisitically significant at 0.05 level at least. We used Approximate Randomization Test (Riezler and Maxwell, 2005) for the purpose, random sampling being done 1000 times.

S-T	NB-100	RS-100	NB-200	RS-200
En-Fr	32.47	31.36	32.32	**32.76**
Fr-En	32.43	31.77	32.46	**32.91**
En-Es	29.21	28.98	29.65	**30.19**
Es-En	30.97	30.41	31.22	**31.66**
En-De	20.36	19.92	20.55	**20.93**
De-En	27.48	26.98	27.30	**27.62**

Table 1: Test set BLEU Scores for six different “Source-Target” Pairs

Somewhat surprisingly, while random sampling with sample size of 200 yields overall the best results, random sampling with size 100 give systematically worse results than n-best lists of the same size. We conjectured that n-best lists and random samples could have complementary advantages. Indeed, it seems intuitive that a good translation pool should be sufficiently varied, as argued in Section 3.1. However it should also stand high chances to contain the best reachable translation, or translations close to the best. It might thus be that 100-best lists are unable to provide diversity, and random samples of size 100 to guarantee sufficient quality.

In order to test this conjecture we repeated our experiments, but at each iteration we used the union of a 100 random sample and a 100 n-best list. Results for this experiments are in Table 2. The corresponding results with random samples of size 200 are also repeated to ease comparison. Depending on the language pair, improvements over random sampling range from 0.17 (En-Es) to 0.44 (Fr-En) BLEU points. Improvements over 200-best lists range from 0.68 (De-En) to 0.89 (Fr-En) BLEU points. These results indicate quite clearly that N-best lists and random samples contribute complementary information to the translation pool: indeed, in most cases there is very little or no overlap between the two.

Source-Target	Mixed 100 + 100	RS-200
En-Fr	33.17	32.76
Fr-En	33.35	32.91
En-Es	30.37	30.19
Es-En	32.04	31.66
En-De	21.31	20.93
De-En	27.98	27.62

Table 2: Test set BLEU Scores for the same ’‘Source-Target” pairs using a mixed strategy combining a 100 N-best list and a random sample of size 100 after each round of decoding.

Convergence curves show that RS-200, NB-100 and M-200 (i.e. the hybrid combination) systematically converge to higher BLEU scores, on the development set and on their respective translation pools, than RS-100 and NB-200. Notice however that it is misleading to compare scores across different translation pools, especially if these have substantially different sizes. On the one hand adding more candidates increases the chances of adding one with high contribution to the corpus BLEU, and can thus increase the achievable value of the objective function. On the other hand, adding more candidates reduces the freedom MERT has to find parameter values selecting high-BLEU candidates for all sentences. To see this, consider the extreme case when the translation pools are all of size one and are provided by an oracle that gives the highest-BLEU reachable translation for each sentence: the objective surface is uninformatively flat, all values of the parameters are equally good, and the BLEU score on the devset is the highest achievable one. If now we add to each translation pool the second-best BLEU-scoring candidate, BLEU will be maximized in a half-space for each sentence in the development set: MERT will try to select λ in the intersection of all the half-spaces, if this is not empty, but will have to settle for a lower-scoring compromise otherwise. The larger the translation pools, the more difficult it becomes for MERT to “make all sentences happy”. A special case of this is when adding more candidates extends the convex envelopes in such a way that the best candidates fall in the interior of the convex hull. It is difficult to tell which of the two opposing effects (the one that tends to increase the value of the objective function or the one that tends to depress it) is stronger in any given case, but from the convergence curves it would seem that the first prevails in the case of random samples, whereas the second wins in the case of n-best lists. In the case of random samples going from size 100 to 200 systematically leads to higher BLEU score on the devsets, as more high-BLEU candidates are drawn. In the case of n-best lists, conversely, this leads to lower BLEU scores, as lower-BLEU (in average) candidates are added to translation pools providing a sharper representation of the BLEU surface and growing MERT out of the "delusion" that a given high BLEU score is actually achieveable.

In the light of this discussion, it is interesting to observe that the value achieved by the objective function on the development set is only a weak predictor of performance on the test set, e.g. M-200 never converges to values above those of NB-100, but is systematically superior on the test data.

In Macherey et al. (2008) the authors observe a dip in the value of the objective function at the first iteration when training using n-best lists. We did not observe this behaviour in our experiments. A possible explanation for this resides in the larger size of the n-best lists we use (100 or 200, compared to 50 in the cited work) and in the smaller number of dimensions (14 instead of 20-30).

We hinted in Section 3.3 that it would seem reasonable to use samples/nbest-list of size increasing with the length of the source sentence, so as to sample reachable translations with a more uniform density across development sentences. We tested this idea on the French to English condition, making samples size depend linearly on the length of the sentence, and in such a way that the average sample size is either 100 or 200. For average sample size 100 we obtained a BLEU of 31.55 (compared to 31.77 with the constant-size 100 random sample) and for average size 200 31.84 (32.46 in the corresponding constant-size condition). While partial, these results are not particularly encouraging w.r.t. using variable size samples.

Finally, in order to assess the stability of the proposed training procedure across variations in development datasets, we experimented with extracting five distinct devsets of size 2,000 each for the French to English RS-200 condition, keeping the test set fixed: the maximum difference we observed was of 0.33 BLEU points.

6 Conclusions

We introduced a novel variant to the well-known MERT method for performing parameter estimation in Statistical Machine Translation systems based on log-linear models. This method, of straightforward implementation, is based on sampling candidates from the posterior distribution as approximated by an existing translation lattice in order to progressively expand the *translation pool* that shapes the optimization surface. This method compares favorably against existing methods on different accounts. Compared to the standard method by which N-best lists are used to grow the translation pool, it yields empirically better results as shown in our experiments, without significant penalties in terms of computational complexity. These results are in agreement with the intuition that the sampling method introduces more variety in the translation pool, and thus allows to perform more effective parameter updates towards the optimum. A hybrid strategy, consisting in combining N-best lists and random samples, brings about further significant improvements, indicating that both quality and variety are desireable in the translation pool that defines the optimization surface. A possible direction to investigate in the future consists in generalizing this hybrid strategy and combining random samples where the probability distribution induced on the lattice by the current parameters is scaled by a further temperature parameter β:

$$P'(\mathbf{e}, \mathbf{a}|\mathbf{f}) \propto P(\mathbf{e}, \mathbf{a}|\mathbf{f})^{\beta} \tag{7}$$

where for $\beta = 1$ the random samples used in this paper are obtained, for β tending to infinite the distribution becomes peaked around the single best path, thus producing samples similar to N-best lists, and samples from other real values of the temperature can be combined.

Compared to the method using the whole lattice, the proposed approaches have a substantially lower computational complexity under very broad and common assumptions, and yet yield translation quality improvements of comparable magnitude over the baseline N-best list method.

While the method presented in this paper operates on the translation lattices generated by Phrase-Based SMT decoders, the extension to translation forests generated by hierarchical decoders (Chiang, 2007) seems straightforward. In that case, the backward sweep for propagating unnormalized posterior probabilities is replaced by a bottom-up sweep, and the sampling now concerns (binary) trees instead of paths, but the rest of the procedure is substantially unchanged. We conjecture however that the extension to translation forests would be less competitive compared to working with the whole packed forest (as in (Kumar et al., 2009)) than lattice sampling is compared to working with the whole lattice. The reason we believe this is that hierarchical models lead to much more spurious ambiguity than phrase-based models, so that both the N-best method and the sampling method explore a smaller portion of the candidate space compared to the compact representation of all the candidate translations in a beam.

Abstract

In modern machine translation practice, a statistical phrasal or hierarchical translation system usually relies on a huge set of translation rules extracted from bi-lingual training data. This approach not only results in space and efficiency issues, but also suffers from the sparse data problem. In this paper, we propose to use factorized grammars, an idea widely accepted in the field of linguistic grammar construction, to generalize translation rules, so as to solve these two problems. We designed a method to take advantage of the XTAG English Grammar to facilitate the extraction of factorized rules. We experimented on various setups of low-resource language translation, and showed consistent significant improvement in BLEU over state-of-the-art string-to-dependency baseline systems with 200K words of bi-lingual training data.

1 Introduction

A statistical phrasal (Koehn et al., 2003; Och and Ney, 2004) or hierarchical (Chiang, 2005; Marcu et al., 2006) machine translation system usually relies on a very large set of translation rules extracted from bi-lingual training data with heuristic methods on word alignment results. According to our own experience, we obtain about 200GB of rules from training data of about 50M words on each side. This immediately becomes an engineering challenge on space and search efficiency.

A common practice to circumvent this problem is to filter the rules based on development sets in the step of rule extraction or before the decoding phrase, instead of building a real distributed system. However, this strategy only works for research systems, for which the segments for translation are always fixed.

However, do we really need such a large rule set to represent information from the training data of much smaller size? Linguists in the grammar construction field already showed us a perfect solution to a similar problem. The answer is to use a factorized grammar. Linguists decompose lexicalized linguistic structures into two parts, (unlexicalized) templates and lexical items. Templates are further organized into families. Each family is associated with a set of lexical items which can be used to lexicalize all the templates in this family. For example, the XTAG English Grammar (XTAG-Group, 2001), a hand-crafted grammar based on the Tree Adjoining Grammar (TAG) (Joshi and Schabes, 1997) formalism, is a grammar of this kind, which employs factorization with LTAG e-tree templates and lexical items.

Factorized grammars not only relieve the burden on space and search, but also alleviate the sparse data problem, especially for low-resource language translation with few training data. With a factored model, we do not need to observe exact "template – lexical item" occurrences in training. New rules can be generated from template families and lexical items either offline or on the fly, explicitly or implicitly. In fact, the factorization approach has been successfully applied on the morphological level in previous study on MT (Koehn and Hoang, 2007). In this work, we will go further to investigate factorization of rule structures by exploiting the rich XTAG English Grammar.

We evaluate the effect of using factorized translation grammars on various setups of low-resource language translation, since low-resource MT suffers greatly on poor generalization capability of trans-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 616–625,

lation rules. With the help of high-level linguistic knowledge for generalization, factorized grammars provide consistent significant improvement in BLEU (Papineni et al., 2001) over string-to-dependency baseline systems with 200K words of bi-lingual training data.

This work also closes the gap between compact hand-crafted translation rules and large-scale unorganized automatic rules. This may lead to a more effective and efficient statistical translation model that could better leverage generic linguistic knowledge in MT.

In the rest of this paper, we will first provide a short description of our baseline system in Section 2. Then, we will introduce factorized translation grammars in Section 3. We will illustrate the use of the XTAG English Grammar to facilitate the extraction of factorized rules in Section 4. Implementation details are provided in Section 5. Experimental results are reported in Section 6.

2 A Baseline String-to-Tree Model

As the baseline of our new algorithm, we use a string-to-dependency system as described in (Shen et al., 2008). There are several reasons why we take this model as our baseline. First, it uses syntactic tree structures on the target side, which makes it easy to exploit linguistic information. Second, dependency structures are relatively easier to implement, as compared to phrase structure grammars. Third, a string-to-dependency system provides state-of-the-art performance on translation accuracy, so that improvement over such a system will be more convincing.

Here, we provide a brief description of the baseline string-to-dependency system, for the sake of completeness. Readers can refer to (Shen et al., 2008; Shen et al., 2009) for related information.

In the baseline string-to-dependency model, each translation rule is composed of two parts, source and target. The source sides is a string rewriting rule, and the target side is a tree rewriting rule. Both sides can contain non-terminals, and source and target non-terminals are one-to-one aligned. Thus, in the decoding phase, non-terminal replacement for both sides are synchronized.

Decoding is solved with a generic chart parsing algorithm. The source side of a translation rule is used to detect when this rule can be applied. The target side of the rule provides a hypothesis tree structure for the matched span. Mono-lingual parsing can be viewed as a special case of this generic algorithm, for which the source string is a projection of the target tree structure.

Figure 1 shows three examples of string-to-dependency translation rules. For the sake of convenience, we use English for both source and target. Upper-cased words represent source, while lower-cased words represent target. X is used for non-terminals for both sides, and non-terminal alignment is represented with subscripts.

In Figure 1, the top boxes mean the source side, and the bottom boxes mean the target side. As for the third rule, *FUN_Q* stands for a function word in the source language that represents a question.

3 Translation with a Factorized Grammar

We continue with the example rules in Figure 1. Suppose, we have "... *HATE* ... *FUN_Q*" in a given test segment. There is no rule having both *HATE* and *FUN_Q* on its source side. Therefore, we have to translate these two source words separately. For example, we may use the second rule in Figure 1. Thus, *HATE* will be translated into *hates*, which is wrong.

Intuitively, we would like to have translation rule that tell us how to translate *X1 HATE X2 FUN_Q* as in Figure 2. It is not available directly from the training data. However, if we obtain the three rules in Figure 1, we are able to predict this missing rule. Furthermore, if we know *like* and *hate* are in the same syntactic/semantic class in the source or target language, we will be very confident on the validity of this hypothesis rule.

Now, we propose a factorized grammar to solve this generalization problem. In addition, translation rules represented with the new formalism will be more compact.

3.1 Factorized Rules

We decompose a translation rule into two parts, a pair of **lexical items** and an unlexicalized **template**. It is similar to the solution in the XTAG English Grammar (XTAG-Group, 2001), while here we

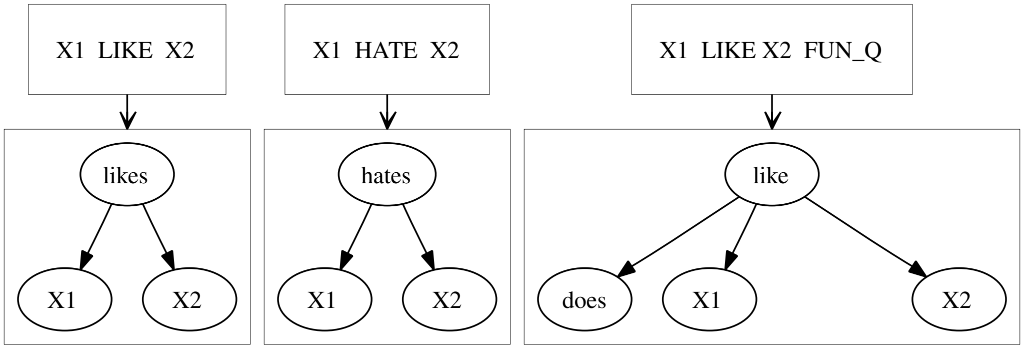

Figure 1: Three examples of string-to-dependency translation rules.

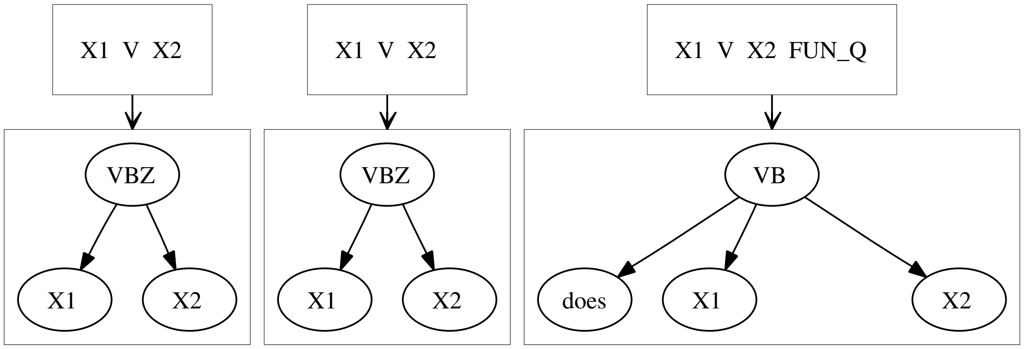

Figure 3: Templates for rules in Figure 1.

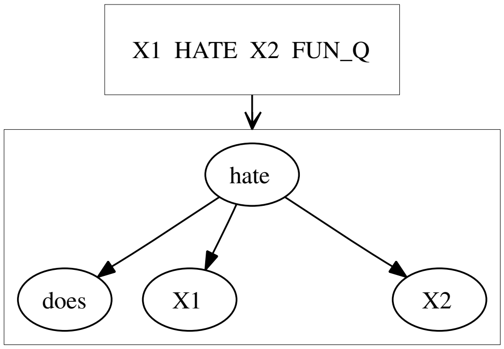

Figure 2: An example of a missing rule.

work on two languages at the same time.

For each rule, we first detect a pair of aligned head words. Then, we extract the stems of this word pair as lexical items, and replace them with their POS tags in the rule. Thus, the original rule becomes an unlexicalized rule template.

As for the three example rules in Figure 1, we will extract lexical items (*LIKE, like*), (*HATE, hate*) and (*LIKE, like*) respectively. We obtain the same lexical items from the first and the third rules.

The resultant templates are shown in Figure 3. Here, *V* represents a verb on the source side, VB stands for a verb in the base form, and *VBZ* means a verb in the third person singular present form as in the Penn Treebank representation (Marcus et al., 1994).

In the XTAG English Grammar, tree templates for transitive verbs are grouped into a family. All transitive verbs are associated with this family. Here, we assume that the rule templates representing structural variations of the same word class can also be organized into a template **family**. For example, as shown in Figure 4, templates and lexical items are associated with families. It should be noted that a template or a lexical item can be associated with more than one family.

Another level of indirection like this provides more generalization capability. As for the missing

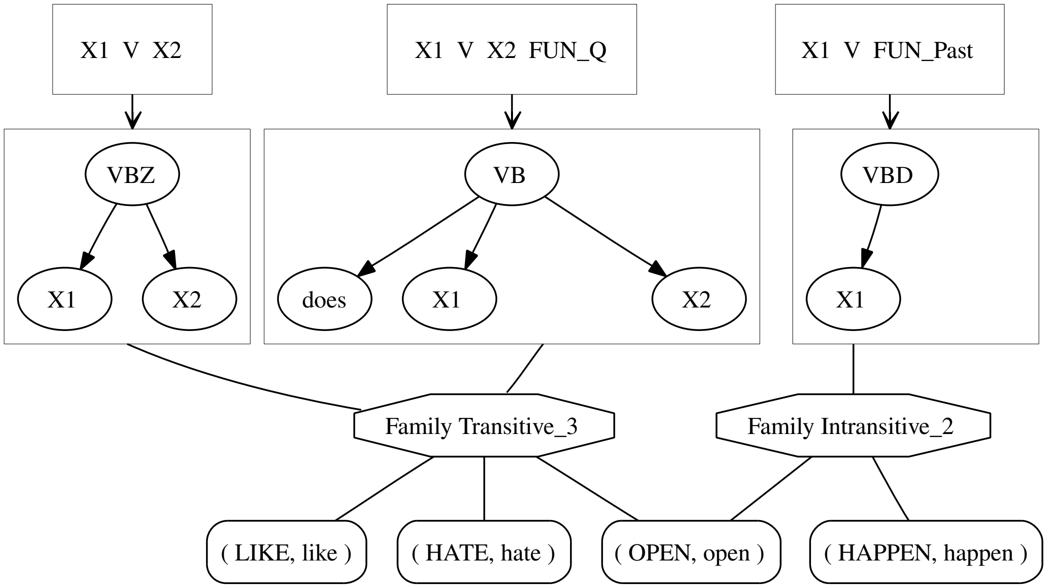

Figure 4: Templates and lexical items are associated with families.

rule in Figure 2, we can now generate it by replacing the POS tags in the second template of Figure 4 with lexical items (*HATE, hate*) with their correct inflections. Both the template and the lexical items here are associated with the family Transitive_3..

3.2 Statistical Models

Another level of indirection also leads to a desirable back-off model. We decompose a rule R into to two parts, its template P_R and its lexical items L_R. Assuming they are independent, then we can compute $Pr(R)$ as

$$Pr(R) = Pr(P_R)Pr(L_R), \text{ or}$$
$$Pr(R) = \textstyle\sum_F Pr(P_R|F)Pr(L_R|F)Pr(F), \quad (1)$$

if they are conditionally independent for each family F. In this way, we can have a good estimate for rules that do not appear in the training data. The second generative model will also be useful for unsupervised learning of families and related probabilities.

In this paper, we approximate families by using target (English) side linguistic knowledge as what we will explain in Section 4, so this changes the definition of the task. In short, we will be given a list of families. We will also be given an association table $B(L, F)$ for lexical items L and families F, such that $B(L, F) = true$ if and only L is associated with F, but we do not know the distributions.

Let S be the source side of a rule or a rule template, T the target side of a rule of a rule template. We define Pr_b, the back-off conditional model of templates, as follows.

$$Pr_b(P_S|P_T, L) = \frac{\sum_{F:B(L,F)} \#(P_S, P_T, F)}{\sum_{F:B(L,F)} \#(P_T, F)}, \quad (2)$$

where # stands for the count of events.

Let P and L be the template and lexical items of R respectively. Let Pr_t be the MLE model obtained from the training data. The smoothed probability is then defined as follows.

$$\begin{aligned} Pr(R_S|R_T) &= (1-\alpha)Pr_t(R_S|R_T) \\ &\quad +\alpha Pr_b(P_S|P_T, L), \quad (3) \end{aligned}$$

where α is a parameter. We fix it to 0.1 in later experiments. Conditional probability $Pr(R_T|R_S)$ is defined in a similar way.

3.3 Discussion

The factorized models discussed in the previous section can greatly alleviate the sparse data problem, especially for low-resource translation tasks. However, when the training data is small, it is not easy to learn families. Therefore, to use unsupervised learning with a model like (1) somehow reduces a hard translation problem to another one of the same difficulty, when the training data is small.

However, in many cases, we do have extra information that we can take advantage of. For example, if the target language has rich resources, although the source language is a low-density one, we can exploit the linguistic knowledge on the target side, and carry it over to bi-lingual structures of the translation model. The setup of X-to-English translation tasks is just like this. This will be the topic of the next section. We leave unsupervised learning of factorized translation grammars for future research.

4 Using A Mono-Lingual Grammar

In this section, we will focus on X-to-English translation, and explain how to use English resources to build a factorized translation grammar. Although we use English as an example, this approach can be applied to any language pairs that have certain linguistic resources on one side.

As shown in Figure 4, intuitively, the families are intersection of the word families of the two languages involved, which means that they are refinement of the English word families. For example, a sub-set of the English transitive families may be translated in the same way, so they share the same set of templates. This is why we named the two families Transitive_3 and Intransitive_2 in Figure 4.

Therefore, we approximate bi-lingual families with English families first. In future, we can use them as the initial values for unsupervised learning.

In order to learn English families, we need to take away the source side information in Figure 4, and we end up with a template–family–word graph as shown in Figure 5. We can learn this model on large mono-lingual data if necessary.

What is very interesting is that there already exists a hand-crafted solution for this model. This is the XTAG English Grammar (XTAG-Group, 2001).

The XTAG English Grammar is a large-scale English grammar based on the TAG formalism extended with lexicalization and unification-based feature structures. It consists of morphological, syntactic, and tree databases. The syntactic database contains the information that we have represented in Figure 5 and many other useful linguistic annotations, e.g. features.

The XTAG English grammar contains 1,004 templates, organized in 53 families, and 221 individual templates. About 30,000 lexical items are associated with these families and individual templates [1]. In addition, it also has the richest English morphological lexicon with 317,000 inflected items derived from 90,000 stems. We use this resource to predict POS tags and inflections of lexical items.

In our applications, we select all the verb families plus one each for nouns, adjectives and adverbs. We use the families of the English word as the families of bi-lingual lexical items. Therefore, we have a list of about 20 families and an association table as described in Section 3.2. Of course, one can use other linguistic resources if similar family information is provided, e.g. VerbNet (Kipper et al., 2006) or WordNet (Fellbaum, 1998).

5 Implementation

Nowadays, machine translation systems become more and more complicated. It takes time to write a decoder from scratch and hook it with various modules, so it is not the best solution for research purpose. A common practice is to reduce a new translation model to an old one, so that we can use an existing system, and see the effect of the new model quickly. For example, the tree-based model proposed in (Carreras and Collins, 2009) used a phrasal decoder for sub-clause translation, and recently, DeNeefe and Knight (2009) reduced a TAG-based translation model to a CFG-based model by applying all possible adjunction operations offline and stored the results as rules, which were then used by an existing syntax-based decoder.

Here, we use a similar method. Instead of building a new decoder that uses factorized grammars, we reduce factorized rules to baseline string-to-dependency rules by performing combination of templates and lexical items in an offline mode. This is similar to the rule generation method in (DeNeefe and Knight, 2009). The procedure is as follows.

In the rule extraction phase, we first extract all the string-to-dependency rules with the baseline system.

[1] More information about XTAG is available online at http://www.cis.upenn.edu/˜xtag .

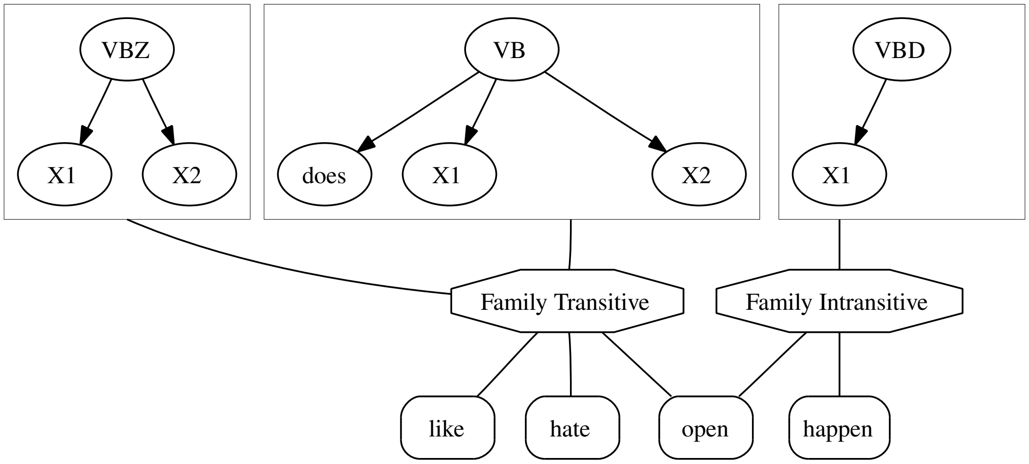

Figure 5: Templates, families, and words in the XTAG English Grammar.

For each extracted rule, we try to split it into various "template–lexical item" pairs by choosing different aligned words for delexicalization, which turns rules in Figure 1 into lexical items and templates in Figure 3. Events of templates and lexical items are counted according to the family of the target English word. If an English word is associated with more than one family, the count is distributed uniformly among these families. In this way, we collect sufficient statistics for the back-off model in (2).

For each family, we keep the top 200 most frequent templates. Then, we apply them to all the lexical items in this families, and save the generated rules. We merge the new rules with the original one. The conditional probabilities for the rules in the combined set is smoothed according to (2) and (3).

Obviously, using only the 200 most frequent templates for each family is just a rough approximation. An exact implementation of a new decoder for factorized grammars can make better use of all the templates. However, the experiments will show that even an approximation like this can already provide significant improvement on small training data sets, i.e. with no more than 2M words.

Since we implement template application in an offline mode, we can use exactly the same decoding and optimization algorithms as the baseline. The decoder is a generic chart parsing algorithm that generates target dependency trees from source string input. The optimizer is an L-BFGS algorithm that maximizes expected BLEU scores on n-best hypotheses (Devlin, 2009).

6 Experiments on Low-Resource Setups

We tested the performance of using factorized grammars on low-resource MT setups. As what we noted above, the sparse data problem is a major issue when there is not enough training data. This is one of the cases that a factorized grammar would help.

We did not tested on real low-resource languages. Instead, we mimic the low-resource setup with two of the most frequently used language pairs, Arabic-to-English and Chinese-to-English, on newswire and web genres. Experiments on these setups will be reported in Section 6.1. Working on a language which actually has more resources allows us to study the effect of training data size. This will be reported in Section 6.2. In Section 6.3, we will show examples of templates learned from the Arabic-to-English training data.

6.1 Languages and Genres

The Arabic-to-English training data contains about 200K (target) words randomly selected from an LDC corpus, LDC2006G05 A2E set, plus an Arabic-English dictionary with about 89K items. We build our development sets from GALE P4 sets. There are one tune set and two test sets for the MT systems [2]. TEST-1 has about 5000 segments and TEST-2 has about 3000 segments.

[2] One of the two test sets will later be used to tune an MT combination system.

MODEL	TUNE			TEST-1			TEST-2		
	BLEU	**%BL**	**MET**	**BLEU**	**%BL**	**MET**	**BLEU**	**%BL**	**MET**
Arabic-to-English newswire									
baseline	21.07	12.41	43.77	19.96	11.42	42.79	21.09	11.03	43.74
factorized	21.70	13.17	44.85	20.52	11.70	43.83	21.36	11.77	44.72
Arabic-to-English web

factorized	10.67	5.34	33.83	9.74	5.20	32.52	14.66	7.69	37.11
Chinese-to-English newswire									
baseline	13.17	8.04	44.70	19.62	9.32	48.60	14.53	6.82	45.34
factorized	13.91	8.09	45.03	20.48	9.70	48.61	15.16	7.37	45.31
Chinese-to-English web									
baseline	11.52	5.96	42.18	11.44	6.07	41.90	9.83	4.66	39.71
factorized	11.98	6.31	42.84	11.72	5.88	42.55	10.25	5.34	40.34

Table 1: Experimental results on Arabic-to-English / Chinese-to-English newswire and web data. **%BL** stands for BLEU scores for documents whose BLEU scores are in the bottom 75% to 90% range of all documents. **MET** stands for METEOR scores.

The Chinese-to-English training data contains about 200K (target) words randomly selected from LDC2006G05 C2E set, plus a Chinese-English dictionary (LDC2002L27) with about 68K items. The development data setup is similar to that of Arabic-to-English experiments.

Chinese-to-English translation is from a morphology poor language to a morphology rich language, while Arabic-to-English translation is in the opposite direction. It will be interesting to see if factorized grammars help on both cases. Furthermore, we also test on two genres, newswire and web, for both languages.

Table 1 lists the experimental results of all the four conditions. The tuning metric is expected BLEU. We are also interested in the BLEU scores for documents whose BLEU scores are in the bottom 75% to 90% range of all documents. We mark it as %BL in the table. This metric represents how a system performances on difficult documents. It is important to certain percentile evaluations. We also measure METEOR (Banerjee and Lavie, 2005) scores for all systems.

The system using factorized grammars shows BLEU improvement in all conditions. We measure the significance of BLEU improvement with paired bootstrap resampling as described by (Koehn, 2004). All the BLEU improvements are over 95% confidence level. The new system also improves %BL and METEOR in most of the cases.

6.2 Training Data Size

The experiments to be presented in this section are designed to measure the effect of training data size. We select Arabic web for this set of experiments. Since the original Arabic-to-English training data LDC2006G05 is a small one, we switch to LDC2006E25, which has about 3.5M target words in total. We randomly select 125K, 250K, 500K, 1M and 2M sub-sets from the whole data set. A larger one always includes a smaller one. We still tune on expected BLEU, and test on BLEU, %BL and METEOR.

The average BLEU improvement on test sets is about 0.6 on the 125K set, but it gradually diminishes. For better observation, we draw the curves of BLEU improvement along with significance test results for each training set. As shown in Figure 6 and 7, more improvement is observed with fewer training data. This fits well with fact that the baseline MT model suffers more on the sparse data problem with smaller training data. The reason why the improvement diminishes on the full data set could be that the rough approximation with 200 most frequent templates cannot fully take advantage of this paradigm, which will be discussed in the next section.

MODEL	SIZE	TUNE			TEST-1			TEST-2		
		BLEU	%BL	MET	BLEU	%BL	MET	BLEU	%BL	MET
Arabic-to-English web										
baseline	125K	8.54	2.96	28.87	7.41	2.82	26.95	11.29	5.06	31.37

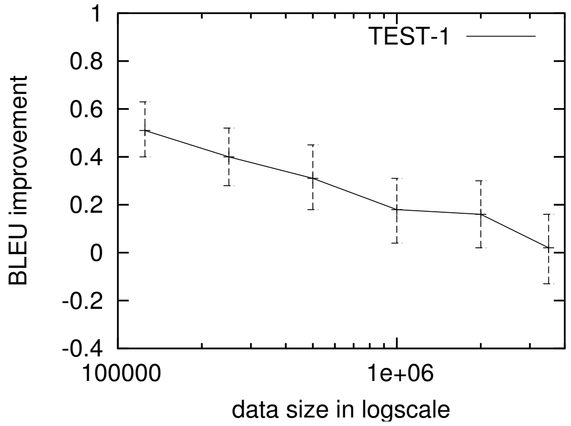

Figure 6: BLEU Improvement with 95% confidence range by using factorized grammars on TEST-1.

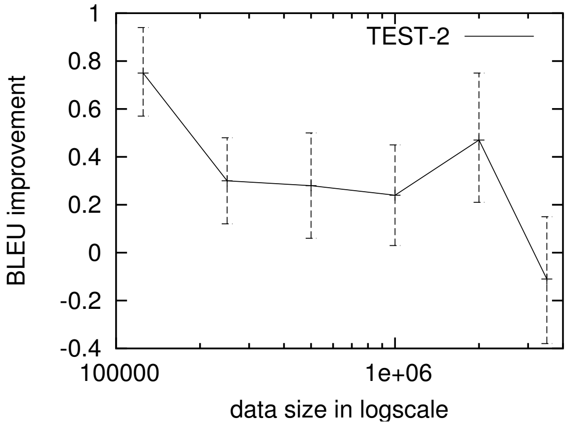

Figure 7: BLEU Improvement with 95% confidence range by using factorized grammars on TEST-2.

6.3 Example Templates

Figure 8 lists seven Arabic-to-English templates randomly selected from the transitive verb family. TMPL_151 is an interesting one. It helps to alleviate the pronoun dropping problem in Arabic. However, we notice that most of the templates in the 200 lists are rather simple. More sophisticated solutions are needed to go deep into the list to find out better templates in future.

It will be interesting to find an automatic or semi-automatic way to discover source counterparts of target treelets in the XTAG English Grammar. Generic rules like this will be very close to handcraft translate rules that people have accumulated for rule-based MT systems.

7 Conclusions and Future Work

In this paper, we proposed a novel statistical machine translation model using a factorized structure-based translation grammar. This model not only alleviates the sparse data problem but only relieves the burden on space and search, both of which are imminent issues for the popular phrasal and/or hierarchical MT systems.

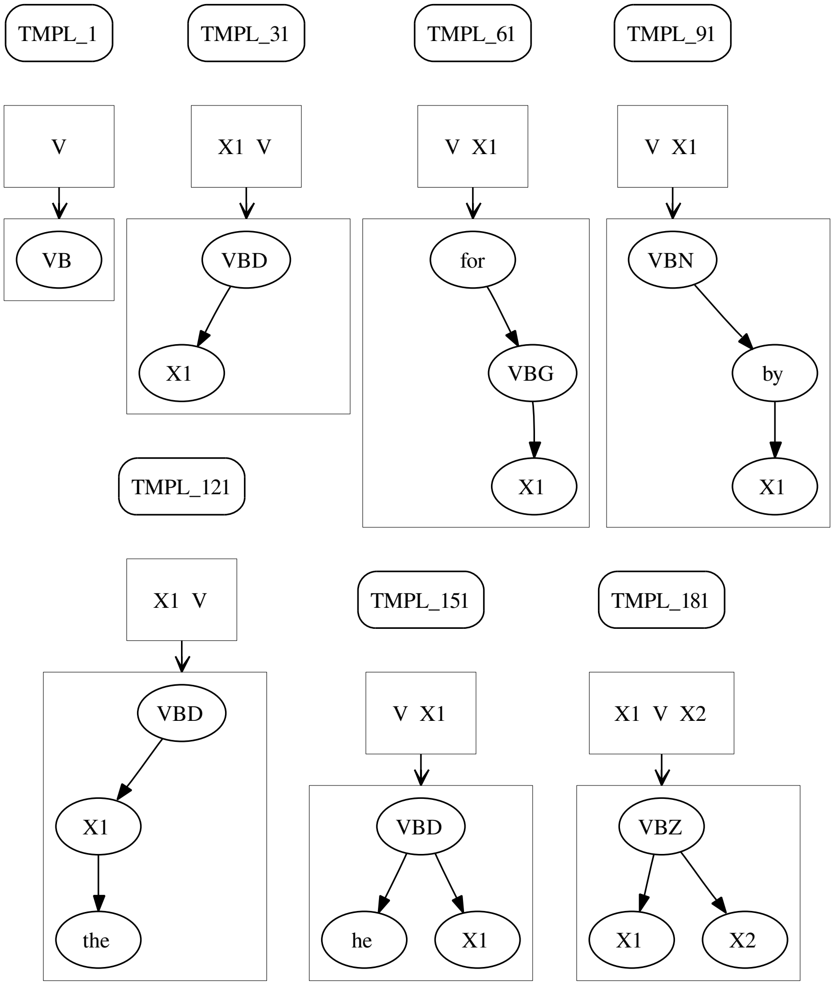

Figure 8: Randomly selected Arabic-to-English templates from the transitive verb family.

We took low-resource language translation, especially X-to-English translation tasks, for case study. We designed a method to exploit family information in the XTAG English Grammar to facilitate the extraction of factorized rules. We tested the new model on low-resource translation, and the use of factorized models showed significant improvement in BLEU on systems with 200K words of bi-lingual training data of various language pairs and genres.

The factorized translation grammar proposed here shows an interesting way of using richer syntactic resources, with high potential for future research.

In future, we will explore various learning methods for better estimation of families, templates and lexical items. The target linguistic knowledge that we used in this paper will provide a nice starting point for unsupervised learning algorithms.

We will also try to further exploit the factorized representation with discriminative learning. Features defined on templates and families will have good generalization capability.

Abstract

Production of parallel training corpora for the development of statistical machine translation (SMT) systems for resource-poor languages usually requires extensive manual effort. Active sample selection aims to reduce the labor, time, and expense incurred in producing such resources, attaining a given performance benchmark with the smallest possible training corpus by choosing informative, non-redundant source sentences from an available candidate pool for manual translation. We present a novel, discriminative sample selection strategy that preferentially selects batches of candidate sentences with constructs that lead to erroneous translations on a held-out development set. The proposed strategy supports a built-in diversity mechanism that reduces redundancy in the selected batches. Simulation experiments on English-to-Pashto and Spanish-to-English translation tasks demonstrate the superiority of the proposed approach to a number of competing techniques, such as random selection, dissimilarity-based selection, as well as a recently proposed semi-supervised active learning strategy.

1 Introduction

Resource-poor language pairs present a significant challenge to the development of statistical machine translation (SMT) systems due to the latter's dependence on large parallel texts for training. Bilingual human experts capable of producing the requisite data resources are often in short supply, and the task of preparing high-quality parallel corpora is laborious and expensive. In light of these constraints, an attractive strategy is to construct the smallest possible parallel training corpus with which a desired performance benchmark may be achieved.

Such a corpus may be constructed by selecting the most informative instances from a large collection of source sentences for translation by a human expert, a technique often referred to as *active learning*. A SMT system trained with sentence pairs thus generated is expected to perform significantly better than if the source sentences were chosen using, say, a naïve random sampling strategy.

Previously, Eck et al. (2005) described a selection strategy that attempts to maximize coverage by choosing sentences with the highest proportion of previously unseen n-grams. Depending on the composition of the candidate pool with respect to the domain, this strategy may select irrelevant outliers. They also described a technique based on TF-IDF to de-emphasize sentences similar to those that have already been selected, thereby encouraging diversity. However, this strategy is bootstrapped by random initial choices that do not necessarily favor sentences that are difficult to translate. Finally, they worked exclusively with the source language and did not use any SMT-derived features to guide selection.

Haffari et al. (2009) proposed a number of features, such as similarity to the seed corpus, translation probability, n-gram and phrase coverage, etc., that drive data selection. They also proposed a model in which these features combine linearly to predict a rank for each candidate sentence. The

top-ranked sentences are chosen for manual translation. However, this approach requires that the pool have the same distributional characteristics as the development sets used to train the ranking model. Additionally, batches are chosen atomically. Since similar or identical sentences in the pool will typically meet the selection criteria simultaneously, this can have the undesired effect of choosing redundant batches with low diversity.

The semi-supervised active learning strategy proposed by Ananthakrishnan et al. (2010) uses multilayer perceptrons (MLPs) to rank candidate sentences based on various features, including domain representativeness, translation difficulty, and batch diversity. A greedy, incremental batch construction technique encourages diversity. While this strategy was shown to be superior to random as well as n-gram based dissimilarity selection, its coarse granularity (reducing a candidate sentence to a low-dimensional feature vector for ranking) makes it unsuitable for many situations. In particular, it is seen to have little or no benefit over random selection when there is no logical separation of the candidate pool into "in-domain" and "out-of-domain" subsets.

This paper introduces a novel, active sample selection technique that identifies translation errors on a held-out development set, and preferentially selects candidate sentences with constructs that are incorrectly translated in the former. A discriminative pairwise comparator function, trained on the ranked development set, is used to order candidate sentences and pick sentences that provide maximum potential reduction in translation error. The feature functions that power the comparator are updated after each selection to encourage batch diversity. In the following sections, we provide details of the proposed sample selection approach, and describe simulation experiments that demonstrate its superiority over a number of competing strategies.

2 Error-Driven Active Learning

Traditionally, unsupervised selection strategies have dominated the active learning literature for natural language processing (Hwa, 2004; Tang et al., 2002; Shen et al., 2004). Sample selection for SMT has followed a similar trend. The work of Eck et al. (2005) and most of the techniques proposed by Haffari et al. (2009) fall in this category. Notable exceptions include the linear ranking model of Haffari et al. (2009) and the semi-supervised selection technique of Ananthakrishnan et al. (2010), both of which use one or more held-out development sets to train and tune the sample selector. However, while the former uses the posterior translation probability and the latter, a sentence-level confidence score as part of the overall selection strategy, current active learning techniques for SMT do not explicitly target the sources of error.

Error-driven active learning attempts to choose candidate instances that potentially maximize error reduction on a reference set (Cohn et al., 1996; Meng and Lee, 2008). In the context of SMT, this involves decoding a held-out development set with an existing baseline (seed) SMT system. The selection algorithm is then trained to choose, from the candidate pool, sentences containing constructs that give rise to translation errors on this set. Assuming perfect reference translations and word alignment in subsequent SMT training, these sentences provide maximum potential reduction in translation error with respect to the seed SMT system. It is a *supervised* approach to sample selection. We assume the following are available.

- A seed parallel corpus $\mathbf{S}$ for training the initial SMT system.
- A candidate pool of monolingual source sentences $\mathbf{P}$ from which samples must be selected.
- A held-out development set $\mathbf{D}$ for training the selection algorithm and for tuning the SMT.
- A test set $\mathbf{T}$ for evaluating SMT performance.

We further make the following reasonable assumptions: (a) the development set $\mathbf{D}$ and the test set $\mathbf{T}$ are drawn from the same distribution and (b) the candidate pool $\mathbf{P}$ consists of both in- and out-of-domain source sentences, as well as an allowable level of redundancy (similar or identical sentences).

Using translation errors on the development set to drive sample selection has the following advantages over previously proposed active learning strategies for SMT.

- The seed training corpus $\mathbf{S}$ need not be derived from the same distribution as $\mathbf{D}$ and $\mathbf{T}$. The seed SMT system can be trained with any available parallel corpus for the specified language pair. This is very useful if, as is often the case, little or no in-domain training data is available to bootstrap the SMT system. This removes a critical restriction present in the semi-supervised approach of Ananthakrishnan et al. (2010).

- Sentences chosen are guaranteed to be relevant to the domain, because selection is based on n-grams derived from the development set. This alleviates potential problems with approaches suggested by Eck et al. (2005) and several techniques used by Haffari et al. (2009), where irrelevant outliers may be chosen simply because they contain previously unseen n-grams, or are deemed difficult to translate.
- The proposed technique seeks to minimize held-out translation error rather than maximize training-set coverage. This is the more intuitive, direct approach to sample selection for SMT.
- Diversity can be encouraged by preventing n-grams that appear in previously selected sentences from playing a role in choosing subsequent sentences. This provides an efficient alternative to the cumbersome "batch diversity" feature proposed by Ananthakrishnan et al. (2010).

The proposed implementation of error-driven active learning for SMT, discriminative sample selection, is described in the following section.

3 Discriminative Sample Selection

The goal of active sample selection is to induce an ordering of the candidate instances that satisfies an objective criterion. Eck et al. (2005) ordered candidate sentences based on the frequency of unseen n-grams. Haffari et al. (2009) induced a ranking based on unseen n-grams, translation difficulty, etc., as well as one that attempted to incrementally maximize BLEU using two held-out development sets. Ananthakrishnan et al. (2010) attempted to order the candidate pool to incrementally maximize source n-gram coverage on a held-out development set, subject to difficulty and diversity constraints.

In the case of error-driven active learning, we attempt to learn an ordering model based on errors observed on the held-out development set $\mathbf{D}$. We achieve this in an innovative fashion by casting the ranking problem as a pairwise sentence comparison problem. This approach, inspired by Ailon and Mohri (2008), involves the construction of a binary classifier functioning as a relational operator that can be used to order the candidate sentences. The pairwise comparator is trained on an ordering of $\mathbf{D}$ that ranks constituent sentences in decreasing order of the number of translation errors. The comparator is then used to rank the candidate pool in decreasing order of potential translation error reduction.

3.1 Maximum-Entropy Pairwise Comparator

Given a pair of source sentences (u, v), we define, adopting the notation of Ailon and Mohri (2008), the pairwise comparator $h(u, v)$ as follows:

$$h(u,v) = \begin{cases} 1, & u < v \\ 0, & u >= v \end{cases} \qquad (1)$$

In Equation 1, the binary comparator $h(u, v)$ plays the role of the "less than" ("$<$") relational operator, returning 1 if u is preferred to v in an ordered list, and 0 otherwise. As detailed in Ailon and Mohri (2008), the comparator must satisfy the constraint that $h(u, v)$ and $h(v, u)$ be complementary, i.e. $h(u, v) + h(v, u) = 1$ to avoid ambiguity. However, it need not satisfy the triangle inequality.

We implement $h(u, v)$ as a combination of discriminative maximum entropy classifiers triggered by feature functions drawn from n-grams of u and v. We define $p(u, v)$ as the conditional posterior probability of the Bernoulli event $u < v$ given (u, v) as shown in Equation 2.

$$p(u,v) = Pr(u < v \mid u, v) \qquad (2)$$

In our implementation, $p(u, v)$ is the output of a binary maximum-entropy classifier trained on the development set. However, this implementation poses two problems.

First, if we use constituent n-grams of u and v as feature functions to trigger the classifier, there is no way to distinguish between (u, v) and (v, u) as they will trigger the same feature functions. This will result in identical values for $p(u, v)$ and $p(v, u)$, a contradiction. We resolve this issue by introducing a set of "complementary" feature functions, which are formed by simply appending a recognizable identifier to the existing n-gram feature func-

u: `how are you`
v: `i am going`

$\mathbf{f}(u) = \{$`how:1, are:1, you:1, how*are:2, are*you:2, how*are*you:3`$\}$
$\mathbf{f}(v) = \{$`i:1, am:1, going:1, i*am:2, am*going:2, i*am*going:3`$\}$

$\mathbf{f}'(u) = \{$`!how:1, !are:1, !you:1, !how*are:2, !are*you:2, !how*are*you:3`$\}$
$\mathbf{f}'(v) = \{$`!i:1, !am:1, !going:1, !i*am:2, !am*going:2, !i*am*going:3`$\}$

Table 1: Standard and complementary trigram feature functions for a source pair (u, v).

tions. Then, to evaluate $p(u, v)$, for instance, we invoke the classifier with standard feature functions for u and complementary feature functions for v. Similarly, $p(v, u)$ is evaluated by triggering complementary feature functions for u and standard feature functions for v. Table 1 illustrates this with a simple example.

Note that each feature function is associated with a real value, whose magnitude is an indicator of its importance. In our implementation, an n-gram feature function (standard or complementary) receives a value equal to its length. This is based on our intuition that longer n-grams play a more important role in dictating SMT performance.

Second, the introduction of complementary triggers implies that evaluation of $p(u, v)$ and $p(v, u)$ now involves disjoint sets of feature functions. Thus, $p(u, v)$ is not guaranteed to satisfy the complementarity condition imposed on $h(u, v)$, and therefore cannot directly be used as the binary pairwise comparator. We resolve this by normalizing across the two possible permutations, as follows:

$$h'(u, v) = \frac{p(u, v)}{p(u, v) + p(v, u)} \qquad (3)$$

$$h'(v, u) = \frac{p(v, u)}{p(u, v) + p(v, u)} \qquad (4)$$

Since $h'(u, v) + h'(v, u) = 1$, the complementarity constraint is now satisfied, and $h(u, v)$ is just a binarized (thresholded) version of $h'(u, v)$. Thus, the binary pairwise comparator can be constructed from the permuted classifier outputs.

3.2 Training the Pairwise Comparator

Training the maximum-entropy classifier for the pairwise comparator requires a set of target labels and input feature functions, both of which are derived from the held-out development set $\mathbf{D}$. We begin by decoding the source sentences in $\mathbf{D}$ with the seed SMT system, followed by error analysis using the Translation Edit Rate (TER) measure (Snover et al., 2006). TER measures translation quality by computing the number of edits (insertions, substitutions, and deletions) and shifts required to transform a translation hypothesis to its corresponding reference. We then rank $\mathbf{D}$ in decreasing order of the number of post-shift edits, i.e. the number of insertions, substitutions, and deletions after the shift operation is completed. Since shifts are often due to word re-ordering issues within the SMT decoder (especially for phrase-based systems), we do not consider them as errors for the purpose of ranking $\mathbf{D}$. Sentences at the top of the ordered list $\mathbf{D}'$ contain the maximum number of translation errors.

For each pair of sentences $(u, v) : u < v$ in $\mathbf{D}'$, we generate two training entries. The first, signifying that u appears before v in $\mathbf{D}'$, assigns the label *true* to a trigger list consisting of standard feature functions derived from u, and complementary feature functions derived from v. The second, reinforcing this observation, assigns the label *false* to a trigger list consisting of complementary feature functions from u, and standard feature functions from v. The labeled training set (feature:label pairs) for the comparator can be expressed as follows:

$$\begin{aligned} \forall (u, v) \quad \in \quad & \mathbf{D}' : u < v, \\ & \{\mathbf{f}(u) \quad \mathbf{f}'(v)\} : true \\ & \{\mathbf{f}'(u) \quad \mathbf{f}(v)\} : false \end{aligned}$$

Thus, if there are d sentences in $\mathbf{D}'$, we obtain a total of $d(d - 1)$ labeled examples to train the comparator. We use the standard L-BFGS optimization algorithm (Liu and Nocedal, 1989) to estimate the parameters of the maximum entropy model.

3.3 Greedy Discriminative Selection

The discriminatively-trained pairwise comparator can be used as a relational operator to sort the candidate pool $\mathbf{P}$ in decreasing order of potential translation error reduction. A batch of pre-determined size K can then be selected from the top of this list to augment the existing SMT training corpus. Assuming the pool contains N candidate sentences, and given a fast sorting algorithm such as Quicksort, the complexity of this strategy is $O(N \log N)$. Batches can be selected iteratively until a specified performance threshold is achieved.

A potential downside of this approach reveals itself when there is redundancy in the candidate pool. Since the batch is selected in a single atomic operation from the sorted candidates, and because similar or identical sentences will typically occupy the same range in the ordered list, it is likely that this approach will result in batches with low diversity. Whereas we desire diverse batches for better coverage and efficient use of manual translation resources. This issue was previously addressed in Shen et al. (2004) in the context of named-entity recognition, where they used a two-step procedure to first select the most informative and representative samples, followed by a diversity filter. Ananthakrishnan et al. (2010) used a greedy, incremental batch construction strategy with an integrated, explicit batch diversity feature as part of the ranking model. Based on these ideas, we design a greedy selection strategy using the discriminative relational operator.

Rather than perform a full sort on $\mathbf{P}$, we simply invoke the $min_{h(u,v)}(\cdots)$ function to find the sentence that potentially minimizes translation error. The subscript indicates that our implementation of this function utilizes the discriminative relational operator trained on the development set $\mathbf{D}$. The best choice sentence s is then added to our batch at the current position (we begin with an empty batch). We then remove the standard and complementary feature functions $\mathbf{f}(s)$ and $\mathbf{f}'(s)$ triggered by s from the global pool of feature functions obtained from $\mathbf{D}$, so that they do not play a role in the selection of subsequent sentences for the batch. Subsequently, a candidate sentence that is similar or identical to s will not be preferred, because the feature functions that previously caused it to rank highly will no longer trigger. Algorithm 1 summarizes our selection strategy in pseudocode. Since each call to $min_{h(u,v)}(\cdots)$ is $O(N)$, the overall complexity of greedy discriminative selection is $O(K \cdot N)$.

Algorithm 1 Greedy Discriminative Selection

```
$\mathbf{B} \leftarrow ()$
for $k = 1$ to $K$ do
    $s \leftarrow min_{h(u,v)}(\mathbf{P})$
    $B(k) \leftarrow s$
    $\mathbf{P} \leftarrow \mathbf{P} - \{s\}$
    $\mathbf{f}(\mathbf{D}) \leftarrow \mathbf{f}(\mathbf{D}) - \mathbf{f}(s)$
    $\mathbf{f}'(\mathbf{D}) \leftarrow \mathbf{f}'(\mathbf{D}) - \mathbf{f}'(s)$
end for
return $\mathbf{B}$
```

4 Experiments and Results

We conduct a variety of simulation experiments with multiple language pairs (English-Pashto and Spanish-English) and different data configurations in order to demonstrate the utility of discriminative sample selection in the context of resource-poor SMT. We also compare the performance of the proposed strategy to numerous competing active and passive selection methods as follows:

- *Random*: Source sentences are uniformly sampled from the candidate pool $\mathbf{P}$.
- *Similarity*: Choose sentences from $\mathbf{P}$ with the highest fraction of n-gram overlap with the seed corpus $\mathbf{S}$.
- *Dissimilarity*: Select sentences from $\mathbf{P}$ with the highest proportion of n-grams not seen in the seed corpus $\mathbf{S}$ (Eck et al., 2005; Haffari et al., 2009).
- *Longest*: Pick the longest sentences from the candidate pool $\mathbf{P}$.
- *Semi-supervised*: Semi-supervised active learning with greedy incremental selection (Ananthakrishnan et al., 2010).
- *Discriminative*: Choose sentences that potentially minimize translation error using a maximum-entropy pairwise comparator (proposed method).

Identical low-resource initial conditions are applied to each selection strategy so that they may be objectively compared. A very small seed corpus $\mathbf{S}$ is sampled from the available parallel training data; the remainder serves as the candidate pool. Following the literature on active learning for SMT, our simulation experiments are iterative. A fixed-size batch of source sentences is constructed from the candidate pool using one of the above selection strategies. We then look up the corresponding translations from the candidate targets (simulating an expert human translator), augment the seed corpus with the selected data, and update the SMT system with the expanded training corpus. The selected data are removed from the candidate pool. This select-update cycle is then repeated for either a fixed number of iterations or until a specified performance benchmark is attained. At each iteration, we decode the unseen test set $\mathbf{T}$ with the most current SMT configuration and evaluate translation performance in terms of BLEU as well as coverage (defined as the fraction of untranslatable source words in the target hypotheses).

We use a phrase-based SMT framework similar to Koehn et al. (2003) for all experiments.

4.1 English-Pashto Simulation

Our English-Pashto (E2P) data originates from a two-way collection of spoken dialogues, and consists of two parallel sub-corpora: a directional E2P corpus and a directional Pashto-English (P2E) corpus. Each sub-corpus has its own independent training, development, and test partitions. The directional E2P training, development, and test sets consist of 33.9k, 2.4k, and 1.1k sentence pairs, respectively. The directional P2E training set consists of 76.5k sentence pairs. The corpus was used as-is, i.e. no length-based filtering or redundancy-reduction (i.e. removal of duplicates, if any) was performed. The test-set BLEU score with the baseline E2P SMT system trained from all of the above data was 9.5%.

We obtained a seed training corpus by randomly sampling 1,000 sentence pairs from the directional E2P training partition. The remainder of this set, and the entire reversed P2E training partition were combined to create the pool (109.4k sentence pairs). In the past, we have observed that the reversed directional P2E data gives very little performance gain in the E2P direction even though its vocabulary is similar, and can be considered "out-of-domain" as far as the E2P translation task is concerned. Thus, our pool consists of 30% in-domain and 70% out-of-domain sentence pairs, making for a challenging active learning problem. A pool training set of 10k source sentences is sampled from this collection for the semi-supervised selection strategy, leaving us with 99.4k candidate sentences, which we use for all competing techniques. The data configuration used in this simulation is identical to Ananthakrishnan et al. (2010), allowing us to compare various strategies under the same conditions. We simulated a total of 20 iterations with batches of 200 sentences each; the original 1,000 sample seed corpus grows to 5,000 sentence pairs and the end of our simulation.

Figure 1(a) illustrates the variation in BLEU scores across iterations for each selection strategy. The proposed discriminative sample selection technique performs significantly better at every iteration than random, similarity, dissimilarity, longest, and semi-supervised active selection. At the end of 20 iterations, the BLEU score gained 3.21 points, a relative improvement of 59.3%. This was followed by semi-supervised active learning, which improved by 2.66 BLEU points, a 49.2% relative improvement. Table 2 summarizes the total number of words selected by each strategy, as well as the total area under the BLEU curve with respect to the baseline. The latter, labeled $\text{BLEU}_{\text{area}}$ and expressed in *percent-iterations*, is a better measure of the overall performance of each strategy across all iterations than comparing BLEU scores at the final iteration.

Figure 1(b) shows the variation in coverage (percentage of untranslatable source words in target hypotheses) for each selection technique. Here, discriminative sample selection was better than all other approaches except longest-sentence selection.

4.2 Spanish-English Simulation

The Spanish-English (S2E) training corpus was drawn from the Europarl collection (Koehn, 2005). To prevent length bias in selection, the corpus was filtered to only retain sentence pairs whose source ranged between 7 and 15 words (excluding punctuation). Additionally, redundancy was reduced by removing all duplicate sentence pairs. After these steps, we obtained approximately 253k sentence pairs for training. The WMT10 held-out develop-

Method	**E2P size**	**E2P BLEU$_{\text{area}}$**	**S2E size**	**S2E BLEU$_{\text{area}}$**
Random	58.1k	26.4	26.5k	45.0
Similarity	30.7k	21.9	24.7k	13.2
Dissimilarity	39.2k	12.4	24.2k	54.9
Longest	173.0k	27.5	39.6k	48.3
Semi-supervised	80.0k	34.1	27.6k	45.6
Discriminative	109.1k	49.6	31.0k	64.5

Table 2: Source corpus size (in words) and BLEU$_{\text{area}}$ after 20 sample selection iterations.

ment and test sets (2k and 2.5k sentence pairs, respectively) were used to tune our system and evaluate performance. Note that this data configuration is different from that of the E2P simulation in that there is no logical separation of the training data into "in-domain" and "out-of-domain" sets. The baseline S2E SMT system trained with all available data gave a test-set BLEU score of 17.2%.

We randomly sampled 500 sentence pairs from the S2E training partition to obtain a seed training corpus. The remainder, after setting aside another 10k source sentences for training the semi-supervised strategy, serves as the candidate pool. We again simulated a total of 20 iterations, except in this case, we used batches of 100 sentences in an attempt to obtain smoother performance trajectories. The training corpus grows from 500 sentence pairs to 2,500 as the simulation progresses.

Variation in BLEU scores and coverage for the S2E simulation are illustrated in Figures 2(a) and 2(b), respectively. Discriminative sample selection outperformed all other selection techniques across all iterations of the simulation. After 20 iterations, we obtained a 4.51 point gain in BLEU, a relative improvement of 142.3%. The closest competitor was dissimilarity-based selection, which improved by 4.38 BLEU points, a 138.1% relative improvement. The proposed method also outperformed other selection strategies in improving coverage, with significantly better results especially in the early iterations. Table 2 summarizes the number of words chosen, and BLEU$_{\text{area}}$, for each strategy.

5 Conclusion and Future Directions

Building SMT systems for resource-poor language pairs requires significant investment of labor, time, and money for the development of parallel training corpora. We proposed a novel, discriminative sample selection strategy that can help lower these costs by choosing batches of source sentences from a large candidate pool. The chosen sentences, in conjunction with their manual translations, provide significantly better SMT performance than numerous competing active and passive selection techniques.

Our approach hinges on a maximum-entropy pairwise comparator that serves as a relational operator for comparing two source sentences. This allows us to rank the candidate pool in decreasing order of potential reduction in translation error with respect to an existing seed SMT system. The discriminative comparator is coupled with a greedy, incremental selection technique that discourages redundancy in the chosen batches. The proposed technique diverges from existing work on active sample selection for SMT in that it uses machine learning techniques in an attempt to explicitly reduce translation error by choosing sentences whose constituents were incorrectly translated in a held-out development set.

While the performance of competing strategies varied across language pairs and data configurations, discriminative sample selection proved consistently superior under all test conditions. It provides a powerful, flexible, data selection front-end for rapid development of SMT systems. Unlike some selection techniques, it is also platform-independent, and can be used as-is with a phrase-based, hierarchical, syntactic, or other SMT framework.

We have so far restricted our experiments to simulations, obtaining expert human translations directly from the sequestered parallel corpus. We are now actively exploring the possibility of linking the sample selection front-end to a crowd-sourcing backend, in order to obtain "non-expert" translations using a platform such as the Amazon Mechanical Turk.

Effects of Empty Categories on Machine Translation

Abstract

We examine effects that empty categories have on machine translation. Empty categories are elements in parse trees that lack corresponding overt surface forms (words) such as dropped pronouns and markers for control constructions. We start by training machine translation systems with manually inserted empty elements. We find that inclusion of some empty categories in training data improves the translation result. We expand the experiment by automatically inserting these elements into a larger data set using various methods and training on the modified corpus. We show that even when automatic prediction of null elements is not highly accurate, it nevertheless improves the end translation result.

1 Introduction

An empty category is an element in a parse tree that does not have a corresponding surface word. They include traces such as Wh-traces which indicate movement operations in interrogative sentences and dropped pronouns which indicate omission of pronouns in places where pronouns are normally expected. Many treebanks include empty nodes in parse trees to represent non-local dependencies or dropped elements. Examples of the former include traces such as relative clause markers in the Penn Treebank (Bies et al., 1995). An example of the latter include dropped pronouns in the Korean Treebank (Han and Ryu, 2005) and the Chinese Treebank (Xue and Xia, 2000).

In languages such as Chinese, Japanese, and Korean, pronouns are frequently or regularly dropped when they are pragmatically inferable. These languages are called *pro-drop* languages. Dropped pronouns are quite a common phenomenon in these languages. In the Chinese Treebank, they occur once in every four sentences on average. In Korean the Treebank, they are even more frequent, occurring in almost every sentence on average. Translating these pro-drop languages into languages such as English where pronouns are regularly retained could be problematic because English pronouns have to be generated from nothing.

There are several different strategies to counter this problem. A special NULL word is typically used when learning word alignment (Brown et al., 1993). Words that have non-existent counterparts can be aligned to the NULL word. In phrase-based translation, the phrase learning system may be able to learn pronouns as a part of larger phrases. If the learned phrases include pronouns on the target side that are dropped from source side, the system may be able to insert pronouns even when they are missing from the source language. This is an often observed phenomenon in phrase-based translation systems. Explicit insertion of missing words can also be included in syntax-based translation models (Yamada and Knight, 2001). For the closely related problem of inserting grammatical function particles in English-to-Korean and English-to-Japanese machine translation, Hong et al. (2009) and Isozaki et al. (2010) employ preprocessing techniques to add special symbols to the English source text.

In this paper, we examine a strategy of automatically inserting two types of empty elements from the Korean and Chinese treebanks as a preprocess-

ing step. We first describe our experiments with data that have been annotated with empty categories, focusing on zero pronouns and traces such as those used in control constructions. We use these annotations to insert empty elements in a corpus and train a machine translation system to see if they improve translation results. Then, we illustrate different methods we have devised to automatically insert empty elements to corpus. Finally, we describe our experiments with training machine translation systems with corpora that are automatically augmented with empty elements. We conclude this paper by discussing possible improvements to the different methods we describe in this paper.

2 Initial experiments

2.1 Setup

We start by testing the plausibility of our idea of preprocessing corpus to insert empty categories with ideal datasets. The Chinese Treebank (LDC2005T01U01) is annotated with null elements and a portion of the Chinese Treebank has been translated into English (LDC2007T02). The Korean Treebank version 1.0 (LDC2002T26) is also annotated with null elements and includes an English translation. We extract null elements along with tree terminals (words) and train a simple phrase-based machine translation system. Both datasets have about 5K sentences and 80% of the data was used for training, 10% for development, and 10% for testing.

We used Moses (Koehn et al., 2007) to train machine translation systems. Default parameters were used for all experiments. The same number of GIZA++ (Och and Ney, 2003) iterations were used for all experiments. Minimum error rate training (Och, 2003) was run on each system afterwards, and the BLEU score (Papineni et al., 2002) was calculated on the test sets.

There are several different empty categories in the different treebanks. We have experimented with leaving in and out different empty categories for different experiments to see their effect. We hypothesized that nominal phrasal empty categories such as dropped pronouns may be more useful than other ones, since they are the ones that may be missing in the source language (Chinese and Korean) but have counterparts in the target (English). Table 1 summarizes empty categories in Chinese and Korean treebank and their frequencies in the training data.

2.2 Results

Table 2 summarizes our findings. It is clear that not all elements improve translation results when included in the training data. For the Chinese to English experiment, empty categories that mark control structures (*PRO*), which serve as the subject of a dependent clause, and dropped pronouns (*pro*), which mark omission of pragmatically in-

word	$P(e \mid *\text{pro}*)$	word	$P(e \mid *\text{PRO}*)$
the	0.18	to	0.45
i	0.13	NULL	0.10
it	0.08	the	0.02
to	0.08	of	0.02
they	0.05	as	0.02

Table 3: A lexical translation table from the Korean-English translation system (left) and a lexical translation from the Chinese-English translation system (right). For the Korean-English lexical translation table, the left column is English words that are aligned to a dropped pronoun (*pro*) and the right column is the conditional probability of $P(e \mid *\text{pro}*)$. For the Chinese-English lexical translation table, the left column is English words that are aligned to a control construction marker (*PRO*) and the right column is the conditional probability of $P(e \mid *\text{PRO}*)$.

ferable pronouns, helped to improve translation results the most. For the Korean to English experiment, the dropped pronoun is the only empty category that seems to improve translation.

For the Korean to English experiment, we also tried annotating whether the dropped pronouns are a subject, an object, or a complement using information from the Treebank's function tags, since English pronouns are inflected according to case. However, this did not yield a very different result and in fact was slightly worse. This is possibly due to data sparsity created when dropped pronouns are annotated. Dropped pronouns in subject position were the overwhelming majority (91%), and there were too few dropped pronouns in object position to learn good parameters.

2.3 Analysis

Table 3 and Table 4 give us a glimpse of why having these empty categories may lead to better translation. Table 3 is the lexical translation table for the dropped pronoun (*pro*) from the Korean to English experiment and the marker for control constructions (*PRO*) from the Chinese to English experiment. For the dropped pronoun in the Korean to English experiment, although there are errors, the table largely reflects expected translations of a dropped pronoun. It is possible that the system is inserting pronouns in right places that would be missing otherwise. For the control construction marker in the Chinese to English experiment, the top translation for *PRO* is the English word *to*, which is expected since Chinese clauses that have control construction markers often translate to English as to-infinitives. However, as we discuss in the next paragraph, the presence of control construction markers may affect translation results in more subtle ways when combined with phrase learning.

Table 4 shows how translations from the system trained with null elements and the system trained without null elements differ. The results are taken from the test set and show extracts from larger sentences. Chinese verbs that follow the empty node for control constructions (*PRO*) are generally translated to English as a verb in to-infinitive form, a gerund, or a nominalized verb. The translation results show that the system trained with this null element (*PRO*) translates verbs that follow the null element largely in such a manner. However, it may not be always closest to the reference. It is exemplified by the translation of one phrase.

Experiments in this section showed that preprocessing the corpus to include some empty elements can improve translation results. We also identified which empty categories maybe helpful for improving translation for different language pairs. In the next section, we focus on how we add these elements automatically to a corpus that is not annotated with empty elements for the purpose of preprocessing corpus for machine translation.

3 Recovering empty nodes

There are a few previous works that have attempted restore empty nodes for parse trees using the Penn English Treebank. Johnson (2002) uses rather simple pattern matching to restore empty categories as well as their co-indexed antecedents with surprisingly good accuracy. Gabbard et al. (2006) present a more sophisticated algorithm that tries to recover empty categories in several steps. In each step, one or more empty categories are restored using patterns or classifiers (five maximum-entropy and two perceptron-based classifiers to be exact).

What we are trying to achieve has obvious similarity to these previous works. However, there are several differences. First, we deal with different languages. Second, we are only trying to recover

Chinese	English Reference	System trained w/ nulls	System trained w/o nulls
PRO 贯彻	implementing	implementation	implemented
PRO 逐步 形成	have gradually formed	to gradually form	gradually formed
PRO 吸引 外资 作为	attracting foreign investment	attracting foreign investment	attract foreign capital

Table 4: The first column is a Chinese word or a phrase that immediately follows empty node marker for Chinese control constructions. The second column is the English reference translation. The third column is the translation output from the system that is trained with the empty categories added in. The fourth column is the translation output from the system trained without the empty categories added, which was given the test set without the empty categories. Words or phrases and their translations presented in the table are part of larger sentences.

a couple of empty categories that would help machine translation. Third, we are not interested in recovering antecedents. The linguistic differences and the empty categories we are interested in recovering made the task much harder than it is for English. We will discuss this in more detail later.

From this section on, we will discuss only Chinese-English translation because Chinese presents a much more interesting case, since we need to recover two different empty categories that are very similarly distributed. Data availability was also a consideration since much larger datasets (bilingual and monolingual) are available for Chinese. The Korean Treebank has only about 5K sentences, whereas the version of Chinese Treebank we used includes 28K sentences.

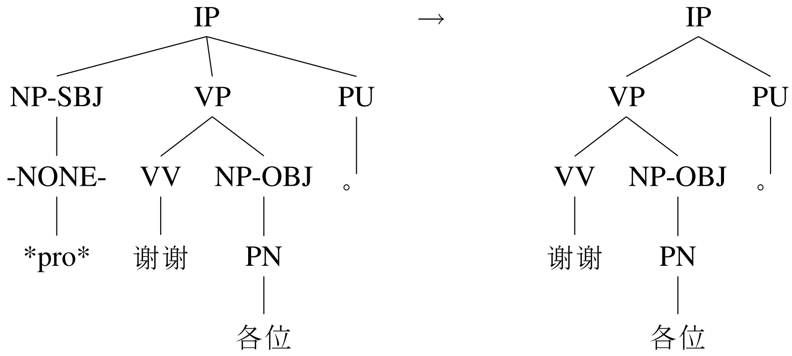
The Chinese Treebank was used for all experiments that are mentioned in the rest of this Section. Roughly 90% of the data was used for the training set, and the rest was used for the test set. As we have discussed in Section 2, we are interested in recovering dropped pronouns (*pro*) and control construction markers (*PRO*). We have tried three different relatively simple methods so that recovering empty elements would not require any special infrastructure.

3.1 Pattern matching

Johnson (2002) defines a pattern for empty node recovery to be a minimally connected tree fragment containing an empty node and all nodes co-indexed with it. Figure 1 shows an example of a pattern. We extracted patterns according this definition, and it became immediately clear that the same definition that worked for English will not work for Chinese. Table 5 shows the top five patterns that match control constructions (*PRO*) and dropped pronouns (*pro*). The top pattern that matches *pro* and *PRO* are both exactly the same, since the pattern will be matched against parse trees where empty nodes have been deleted.

When it became apparent that we cannot use the same definition of patterns to successfully restore empty categories, we added more context to the patterns. Patterns needed more context for them to be able to disambiguate between sites that need to be inserted with *pro*s and sites that need to be inserted with *PRO*s. Instead of using minimal tree fragments that matched empty categories, we included the parent and siblings of the minimal tree fragment in the pattern (pattern matching method 1). This way, we gained more context. However, as can be seen in Table 5, there is still a lot of overlap between patterns for the two empty categories. However, it is more apparent that at least we can choose the pattern that will maximize matches for one empty category and then discard that pattern for the other empty category.

We also tried giving patterns even more context by including terminals if preterminals are present in the pattern (pattern matching method 2). In this way, we are able have more context for patterns such as (VP VV (IP (NP (-NONE- *PRO*)) VP)) by knowing what the verb that precedes the empty category is. Instead of the original pattern, we would have patterns such as (VP (VV 决 定) (IP (NP (-NONE- *PRO*)) VP)). We are able to gain more context because some verbs select for a control construction. The Chinese verb 决定 generally translates to English as *to decide* and is more often followed by a control construction than by a dropped pronoun. Whereas the pattern (VP (VV 决定) (IP (NP (-NONE- *PRO*)) VP)) occurred 154 times in the training data, the pattern (VP (VV 决定) (IP (NP (-NONE- *pro*)) VP)) occurred only 8 times in the



(IP (NP-SBJ (-NONE- *pro*)) VP PU) (IP VP PU)

Figure 1: An example of a tree with an empty node (left), the tree stripped of an empty node (right), and a pattern that matches the example. Sentences are parsed without empty nodes and if a tree fragment (IP VP PU) is encountered in a parse tree, the empty node may be inserted according to the learned pattern (IP (NP-SBJ (-NONE- *pro*)) VP PU).

	PRO		*pro*
Count	Pattern	Count	Pattern
12269	(IP (NP (-NONE- *PRO*)) VP)	10073	(IP (NP (-NONE- *pro*)) VP)
102	(IP PU (NP (-NONE- *PRO*)) VP PU)	657	(IP (NP (-NONE- *pro*)) VP PU)
14	(IP (NP (-NONE- *PRO*)) VP PRN)	415	(IP ADVP (NP (-NONE- *pro*)) VP)
13	(IP NP (NP (-NONE- *PRO*)) VP)	322	(IP NP (NP (-NONE- *pro*)) VP)
12	(CP (NP (-NONE- *PRO*)) CP)	164	(IP PP PU (NP (-NONE- *pro*)) VP)

	PRO		*pro*
Count	Pattern	Count	Pattern
2991	(VP VV NP (IP (NP (-NONE- *PRO*)) VP))	1782	(CP (IP (NP (-NONE- *pro*)) VP) DEC)
2955	(VP VV (IP (NP (-NONE- *PRO*)) VP))	1007	(VP VV (IP (NP (-NONE- *pro*)) VP))
850	(CP (IP (NP (-NONE- *PRO*)) VP) DEC)	702	(LCP (IP (NP (-NONE- *pro*)) VP) LC)
765	(PP P (IP (NP (-NONE- *PRO*)) VP))	684	(IP IP PU (IP (NP (-NONE- *pro*)) VP) PU)
654	(LCP (IP (NP (-NONE- *PRO*)) VP) LC)	654	(TOP (IP (NP (-NONE- *pro*)) VP PU))

Table 5: Top five minimally connected patterns that match *pro* and *PRO* (top). Patterns that match both *pro* and *PRO* are shaded with the same color. The table on the bottom show more refined patterns that are given added context by including the parent and siblings to minimally connected patterns. Many patterns still match both *pro* and *PRO* but there is a lesser degree of overlap.

training data.

After the patterns are extracted, we performed pruning similar to the pruning that was done by Johnson (2002). The patterns that have less than 50% chance of matching are discarded. For example, if (IP VP) occurs one hundred times in a treebank that is stripped of empty nodes and if pattern (IP (NP (-NONE- *PRO*)) VP) occurs less than fifty times in the same treebank that is annotated with empty nodes, it is discarded.[1] We also found that we can discard patterns that occur very rarely (that occur only once) without losing much accuracy. In cases where there was an overlap between two empty categories, the pattern was chosen for either *pro* or *PRO*, whichever that maximized the number of matchings and then discarded for the other.

3.2 Conditional random field

We tried building a simple conditional random field (Lafferty et al., 2001) to predict null elements. The model examines each and every word boundary and decides whether to leave it as it is, insert *pro*, or insert *PRO*. The obvious disadvantage of this method is that if there are two consecutive null elements, it will miss at least one of them. Although there were some cases like this in the treebank, they were rare enough that we decided to ignore them. We first tried using only differently sized local windows of words as features (CRF model 1). We also experimented with adding the part-of-speech tags of words as features (CRF model 2). Finally, we experimented with a variation where the model is given each word and its part-of-speech tag and its immediate parent node as features (CRF model 3).

We experimented with using different regularizations and different values for regularizations but it did not make much difference in the final results. The numbers we report later used L_2 regularization.

3.3 Parsing

In this approach, we annotated nonterminal symbols in the treebank to include information about empty categories and then extracted a context free grammar from the modified treebank. We parsed with the modified grammar, and then deterministically recovered the empty categories from the trees. Figure 2 illustrates how the trees were modified. For every empty node, the most immediate ancestor of the empty node that has more than one child was annotated with information about the empty node, and the empty node was deleted. We annotated whether the deleted empty node was *pro* or *PRO* and where it was deleted. Adding where the child was necessary because, even though most empty nodes are the first child, there are many exceptions.

	PRO			*pro*		
Cycle	Prec.	Rec.	F1	Prec	Rec.	F1
1	0.38	0.08	0.13	0.38	0.08	0.12
2	0.52	0.23	0.31	0.37	0.18	0.24
3	0.59	0.46	0.52	0.43	0.24	0.31
4	**0.62**	0.50	0.56	**0.47**	0.25	0.33
5	0.61	0.52	**0.56**	0.47	0.33	0.39
6	0.60	**0.53**	0.56	0.46	0.39	**0.42**
7	0.58	0.52	0.55	0.43	**0.40**	0.41

Table 6: Result using the grammars output by the Berkeley state-splitting grammar trainer to predict empty categories

We first extracted a plain context free grammar after modifying the trees and used the modified grammar to parse the test set and then tried to recover the empty elements. This approach did not work well. We then applied the latent annotation learning procedures of Petrov et al. (2006)[2] to refine the nonterminals in the modified grammar. This has been shown to help parsing in many different situations. Although the state splitting procedure is designed to maximize the likelihood of of the parse trees, rather than specifically to predict the empty nodes, learning a refined grammar over modified trees was also effective in helping to predict empty nodes. Table 6 shows the dramatic improvement after each split, merge, and smoothing cycle. The gains leveled off after the sixth iteration and the sixth order grammar was used to run later experiments.

3.4 Results

Table 7 shows the results of our experiments. The numbers are very low when compared to accuracy reported in other works that were mentioned in the beginning of this Section, which dealt with the Penn English Treebank. Dropped pronouns are especially

Table 7: Result of recovering empty nodes

hard to recover. However, we are dealing with a different language and different kinds of empty categories. Empty categories recovered this way may still help translation. In the next section, we take the best variation of the each method use it to add empty categories to a training corpus and train machine translation systems to see whether having empty categories can help improve translation in more realistic situations.

3.5 Analysis

The results reveal many interesting aspects about recovering empty categories. The results suggest that tree structures are important features for finding sites where markers for control constructions (*PRO*) have been deleted. The method utilizing patterns that have more information about tree structure of these sites performed better than other methods. The fact that the method using parsing was better at predicting *PRO*s than the methods that used the conditional random fields also corroborates this finding. For predicting dropped pronouns, the method using the CRFs did better than the others. This suggests that rather than tree structure, local context of words and part-of-speech tags maybe more important features for predicting dropped pronouns. It may also suggest that methods using robust machine learning techniques are better outfitted for predicting dropped pronouns.

It is interesting to note how effective the parser was at predicting empty categories. The method using the parser requires the least amount of supervision. The method using CRFs requires feature design, and the method that uses patterns needs human decisions on what the patterns should be and pruning criteria. There is also room for improvement. The split-merge cycles learn grammars that produce better parse trees rather than grammars that predict empty categories more accurately. By modifying this learning process, we may be able to learn grammars that are better suited for predicting empty categories.

4 Experiments

4.1 Setup

For Chinese-English, we used a subset of FBIS newswire data consisting of about 2M words and 60K sentences on the English side. For our development set and test set, we had about 1000 sentences each with 10 reference translations taken from the NIST 2002 MT evaluation. All Chinese data was re-segmented with the CRF-based Stanford Chinese segmenter (Chang et al., 2008) that is trained on the segmentation of the Chinese Treebank for consistency. The parser used in Section 3 was used to parse the training data so that null elements could be recovered from the trees. The same method for recovering null elements was applied to the train-

	BLEU	BP	*PRO*	*pro*

ing, development, and test sets to insert empty nodes for each experiment. The baseline system was also trained using the raw data.

We used Moses (Koehn et al., 2007) to train machine translation systems. Default parameters were used for all experiments. The same number of GIZA++ (Och and Ney, 2003) iterations were used for all experiments. Minimum error rate training (Och, 2003) was run on each system afterwards and the BLEU score (Papineni et al., 2002) was calculated on the test set.

4.2 Results

Table 8 summarizes our results. Generally, all systems produced BLEU scores that are better than the baseline, but the best BLEU score came from the system that used the CRF for null element insertion. The machine translation system that used training data from the method that was overall the best in predicting empty elements performed the best. The improvement is 0.96 points in BLEU score, which represents statistical significance at $p < 0.002$ based on 1000 iterations of paired bootstrap resampling (Koehn, 2004). Brevity penalties applied for calculating BLEU scores are presented to demonstrate that the baseline system is not penalized for producing shorter sentences compared other systems.[3]

The BLEU scores presented in Table 8 represent the best variations of each method we have tried for recovering empty elements. Although the difference was small, when the F1 score were same for two variations of a method, it seemed that we could get slightly better BLEU score with the variation that had higher recall for recovering empty elements rather the variation with higher precision.

We tried a variation of the experiment where the CRF method is used to recover *pro* and the pattern matching is used to recover *PRO*, since these represent the best methods for recovering the respective empty categories. However, it was not as successful as we thought would be. The resulting BLEU score from the experiment was 24.24, which is lower than the one that used the CRF method to recover both *pro* and *PRO*. The problem was we used a very naïve method of resolving conflict between two different methods. The CRF method identified 17463 sites in the training data where *pro* should be added. Of these sites, the pattern matching method guessed 2695 sites should be inserted with *PRO* rather than *pro*, which represent more than 15% of total sites that the CRF method decided to insert *pro*. In the aforementioned experiment, wherever there was a conflict, both *pro* and *PRO* were inserted. This probably lead the experiment to have worse result than using only the one best method. This experiment suggest that more sophisticated methods should be considered when resolving conflicts created by using heterogeneous methods to recover different empty categories.

Table 9 shows five example translations of source sentences in the test set that have one of the empty categories. Since empty categories have been automatically inserted, they are not always in the correct places. The table includes the translation results from the baseline system where the training and test sets did not have empty categories and the translation results from the system (the one that used the CRF) that is trained on an automatically augmented corpus and given the automatically augmented test set.

5 Conclusion

In this paper, we have showed that adding some empty elements can help building machine translation systems. We showed that we can still benefit from augmenting the training corpus with empty elements even when empty element prediction is less than what would be conventionally considered robust.

We have also shown that there is a lot of room for improvement. More comprehensive and sophisti-

cated methods, perhaps resembling the work of Gabbard et al. (2006) may be necessary for more accurate recovery of empty elements. We can also consider simpler methods where different algorithms are used for recovering different empty elements, in which case, we need to be careful about how recovering different empty elements could interact with each other as exemplified by our discussion of the pattern matching algorithm in Section 3 and our experiment presented in Section 4.2.

There are several other issues we may consider when recovering empty categories that are missing in the target language. We only considered empty categories that are present in treebanks. However, there might be some empty elements which are not annotated but nevertheless helpful for improving machine translation. As always, preprocessing the corpus to address a certain problem in machine translation is less principled than tackling the problem head on by integrating it into the machine translation system itself. It may be beneficial to include consideration for empty elements in the decoding process, so that it can benefit from interacting with other elements of the machine translation system.

SCFG Decoding Without Binarization

Abstract

Conventional wisdom dictates that synchronous context-free grammars (SCFGs) must be converted to Chomsky Normal Form (CNF) to ensure cubic time decoding. For arbitrary SCFGs, this is typically accomplished via the synchronous binarization technique of (Zhang et al., 2006). A drawback to this approach is that it inflates the constant factors associated with decoding, and thus the practical running time. (DeNero et al., 2009) tackle this problem by defining a superset of CNF called Lexical Normal Form (LNF), which also supports cubic time decoding under certain implicit assumptions. In this paper, we make these assumptions explicit, and in doing so, show that LNF can be further expanded to a broader class of grammars (called "scope-3") that also supports cubic-time decoding. By simply pruning non-scope-3 rules from a GHKM-extracted grammar, we obtain better translation performance than synchronous binarization.

1 Introduction

At the heart of bottom-up chart parsing (Younger, 1967) is the following combinatorial problem. We have a context-free grammar (CFG) rule (for instance, S → NP VP PP) and an input sentence of length n (for instance, "on the fast jet ski of mr smith"). During chart parsing, we need to apply the rule to all relevant subspans of the input sentence. See Figure 1. For this particular rule, there are $\binom{n+1}{4}$ *application contexts*, i.e. ways to choose the subspans. Since the asymptotic running time of chart parsing is at least linear in this quantity, it will take at least $O(\binom{n+1}{4}) = O(n^4)$ time if we include this rule in our grammar.

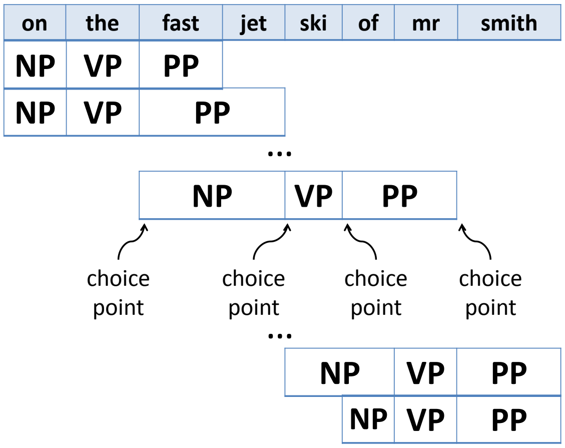

Figure 1: A demonstration of application contexts. There are $\binom{n+1}{4}$ application contexts for the CFG rule "S → NP VP PP", where n is the length of the input sentence.

Fortunately, we can take advantage of the fact that any CFG has an equivalent representation in Chomsky Normal Form (CNF). In CNF, all rules have the form X → Y Z or X → x, where x is a terminal and X, Y, Z are nonterminals. If a rule has the form X → Y Z, then there are only $\binom{n+1}{3}$ application contexts, thus the running time of chart parsing is $O(\binom{n+1}{3}) = O(n^3)$ when applied to CNF grammars.

A disadvantage to CNF conversion is that it increases both the overall number of rules and the overall number of nonterminals. This inflation of the "grammar constant" does not affect the asymptotic runtime, but can have a significant impact on the performance in practice. For this reason, (DeN-

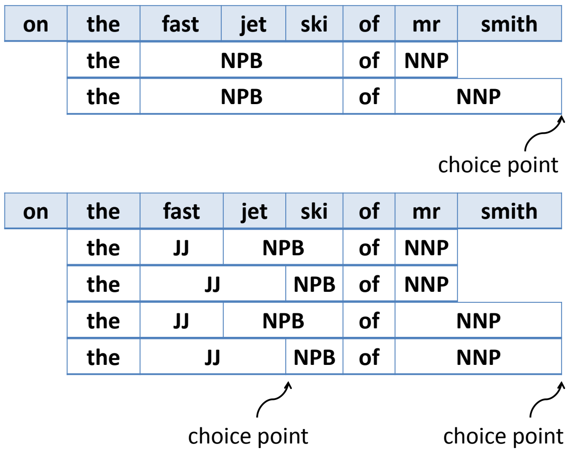

Figure 2: A demonstration of application contexts for rules with lexical anchors. There are $O(n)$ application contexts for CFG rule “S → the NPB of NNP”, and $O(n^2)$ application contexts for CFG rule “S → the JJ NPB of NNP”, if we assume that the input sentence has length n and contains no repeated words.

ero et al., 2009) provide a relaxation of CNF called Lexical Normal Form (LNF). LNF is a superclass of CNF that also allows rules whose right-hand sides have no consecutive nonterminals. The intuition is that the terminals provide anchors that limit the applicability of a given rule. For instance, consider the rule NP → the NPB of NNP. See Figure 2. Because the terminals constrain our choices, there are only two different application contexts. The implicit assumption is that input sentences will not repeat the same word more than a small constant number of times. If we make the explicit assumption that all words of an input sentence are unique, then there are $O(n^2)$ application contexts for a “no consecutive nonterminals” rule. Thus under this assumption, the running time of chart parsing is still $O(n^3)$ when applied to LNF grammars.

But once we make this assumption explicit, it becomes clear that we can go even further than LNF and still maintain the cubic bound on the runtime. Consider the rule NP → the JJ NPB of NNP. This rule is not LNF, but there are still only $O(n^2)$ application contexts, due to the anchoring effect of the terminals. In general, for a rule of the form X → γ, there are at most $O(n^p)$ application contexts, where p is the number of consecutive nonterminal pairs in the string X $\cdot\gamma\cdot$ X (where X is an arbitrary nonterminal). We refer to p as the *scope* of a rule. Thus chart parsing runs in time $O(n^{\mathsf{scope}(G)})$, where $\mathsf{scope}(G)$ is the maximum scope of any of the rules in CFG G. Specifically, any scope-3 grammar can be decoded in cubic time.

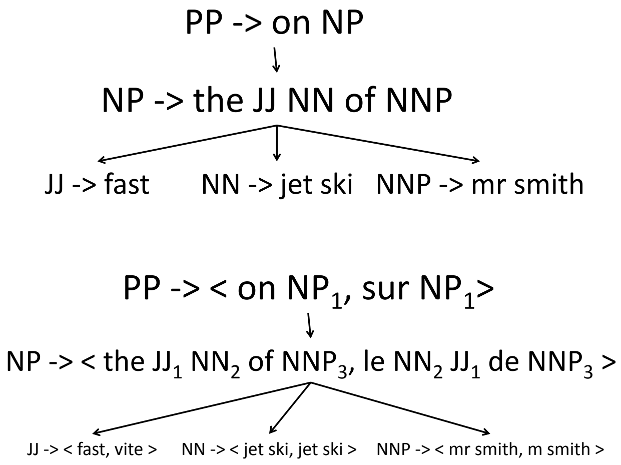
Like (DeNero et al., 2009), the target of our interest is synchronous context-free grammar (SCFG) decoding with rules extracted using the GHKM algorithm (Galley et al., 2004). In practice, it turns out that only a small percentage of the lexical rules in our system have scope greater than 3. By simply removing these rules from the grammar, we can maintain the cubic running time of chart parsing without any kind of binarization. This has three advantages. First, we do not inflate the grammar constant. Second, unlike (DeNero et al., 2009), we maintain the *synchronous* property of the grammar, and thus can integrate language model scoring into chart parsing. Finally, a system without binarized rules is considerably simpler to build and maintain. We show that this approach gives us better practical performance than a mature system that binarizes using the technique of (Zhang et al., 2006).

2 Preliminaries

Assume we have a global vocabulary of *symbols*, containing the reserved *substitution symbol* $\Diamond$. Define a *sentence* as a sequence of symbols. We will typically use space-delimited quotations to represent example sentences, e.g. “the fast jet ski” rather than $\langle$the, fast, jet, ski$\rangle$. We will use the dot operator to represent the concatenation of sentences, e.g. “the fast” · “jet ski” = “the fast jet ski”.

Define the *rank* of a sentence as the count of its $\Diamond$ symbols. We will use the notation $\textsc{sub}(s, s_1, ..., s_k)$ to denote the substitution of k sentences $s_1, ..., s_k$ into a k-rank sentence s. For instance, if s = “the $\Diamond$ $\Diamond$ of $\Diamond$”, then $\textsc{sub}(s, \text{“fast”}, \text{“jet ski”}, \text{“mr smith”})$ = “the fast jet ski of mr smith”.

To refer to a subsentence, define a *span* as a pair $[a, b]$ of nonnegative integers such that $a < b$. For a sentence $s = \langle s_1, s_2, ..., s_n\rangle$ and a span $[a, b]$ such that $b \leq n$, define $s_{[a,b]} = \langle s_{a+1}, ..., s_b\rangle$.



PP -> on NP
NP -> the JJ NN of NNP
JJ -> fast
NN -> jet ski
NNP -> mr smith
PP -> < on NP$_1$, sur NP$_1$>
NP -> < the JJ$_1$ NN$_2$ of NNP$_3$, le NN$_2$ JJ$_1$ de NNP$_3$ >
JJ -> < fast, vite >
NN -> < jet ski, jet ski >
NNP -> < mr smith, m smith >

Figure 3: An example CFG derivation (above) and an example SCFG derivation (below). Both derive the sentence SUB("on ◊", SUB("the ◊ ◊ of ◊", "fast", "jet ski", "mr smith")) = "on the fast jet ski of mr smith". The SCFG derivation simultaneously derives the auxiliary sentence "sur le jet ski vite de m smith".

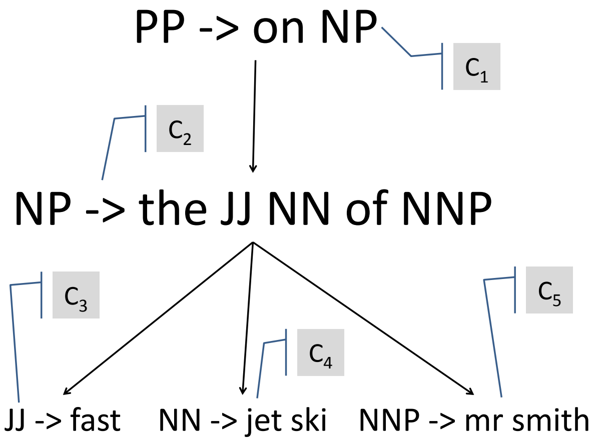


Figure 4: The cost of the CFG derivation in Figure 3 is $C_1 + C_2 + C_3 + C_4 + C_5$, where C_1 is the base cost of rule "PP → on NP", etc. Notice that this cost can be distributed locally to the nodes of the derivation.

3 Minimum Derivation Cost

Chart parsing solves a problem which we will refer to as Minimum Derivation Cost. Because we want our results to be applicable to both CFG decoding and SCFG decoding with an integrated language model, we will provide a somewhat more abstract formulation of chart parsing than usual.

In Figure 3, we show an example of a CFG derivation. A derivation is a tree of CFG rules, constructed so that the *preconditions* (the RHS nonterminals) of any rule match the *postconditions* (the LHS nonterminal) of its child rules. The purpose of a derivation is to *derive* a sentence, which is obtained through recursive substitution. In the example, we substitute "fast", "jet ski", and "mr smith" into the lexical *pattern* "the ◊ ◊ of ◊" to obtain "the fast jet ski of mr smith". Then we substitute this result into the lexical pattern "on ◊" to obtain "on the fast jet ski of mr smith".

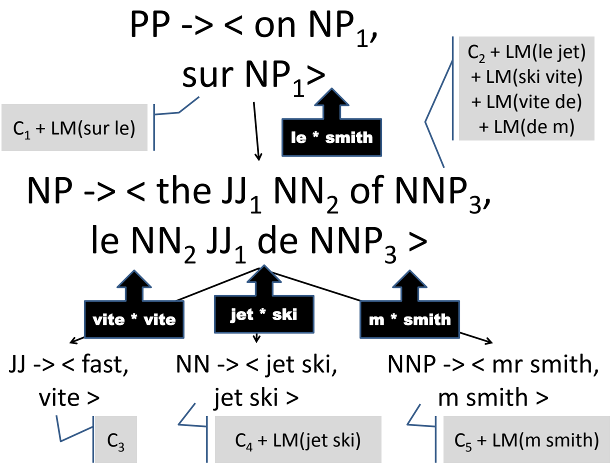
The cost of a derivation is simply the sum of the base costs of its rules. Thus the cost of the CFG derivation in Figure 3 is $C_1 + C_2 + C_3 + C_4 + C_5$, where C_1 is the base cost of rule "PP → on NP", etc. Notice that this cost can be distributed locally to the nodes of the derivation (Figure 4).

An SCFG derivation is similar to a CFG derivation, except that it simultaneously derives two sentences. For instance, the SCFG derivation in Figure 3 derives the sentence pair ⟨ "on the fast jet ski of mr smith", "sur le jet ski vite de m smith" ⟩. In machine translation, often we want the cost of the SCFG derivation to include a language model cost for this second sentence. For example, the cost of the SCFG derivation in Figure 3 might be $C_1+C_2+C_3+C_4+C_5+LM(\text{sur le})+LM(\text{le jet})+LM(\text{jet ski})+LM(\text{ski de}) + LM(\text{de m}) + LM(\text{m smith})$, where LM is the negative log of a 2-gram language model. This new cost function can also be distributed locally to the nodes of the derivation, as shown in Figure 5. However, in order to perform the local computations, we need to pass information (in this case, the LM boundary words) up the tree. We refer to this extra information as *carries*. Formally, define a *carry* as a sentence of rank 0.

In order to provide a chart parsing formulation that applies to both CFG decoding and SCFG decoding with an integrated language model, we need abstract definitions of rule and derivation that capture the above concepts of *pattern*, *postcondition*, *preconditions*, *cost*, and *carries*.

3.1 Rules

Define a *rule* as a tuple $\langle k, s^*, X, \pi, \Gamma, c \rangle$, where k is a nonnegative integer called the *rank*, s^* is a rank-k



PP -> < on NP1, sur NP1>
C1 + LM(sur le)
le * smith
C2 + LM(le jet) + LM(ski vite) + LM(vite de) + LM(de m)
NP -> < the JJ1 NN2 of NNP3, le NN2 JJ1 de NNP3 >
vite * vite
jet * ski
m * smith
JJ -> < fast, vite >
NN -> < jet ski, jet ski >
NNP -> < mr smith, m smith >
C3
C4 + LM(jet ski)
C5 + LM(m smith)

Figure 5: The cost of the SCFG derivation in Figure 3 (with an integrated language model score) can also be distributed to the nodes of the derivation, but to perform the local computations, information must be passed up the tree. We refer to this extra information as a *carry*.

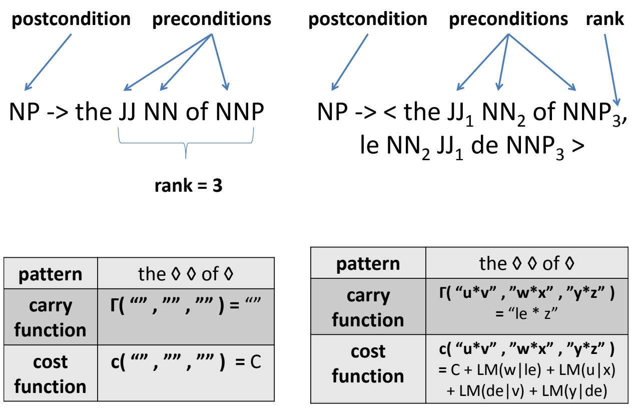


Figure 6: Deconstruction of a CFG rule (left) and SCFG rule (right) according to the definition of rule in Section 3.1. The carry function of the SCFG rule computes boundary words for a 2-gram language model. In the cost functions, C is a real number and LM returns the negative log of a language model query.

sentence called the *pattern* [1], X is a symbol called the *postcondition*, π is a k-length sentence called the *preconditions*, Γ is a function (called the *carry function*) that maps a k-length list of carries to a carry, and c is a function (called the *cost function*) that maps a k-length list of carries to a real number. Figure 6 shows a CFG and an SCFG rule, deconstructed according to this definition. [2] Note that the CFG rule has trivial cost and carry functions that map everything to a constant. We refer to such rules as *simple*.

We will use $\mathsf{post}(r)$ to refer to the postcondition of rule r, and $\mathsf{pre}(r, i)$ to refer to the i^{th} precondition of rule r.

Finally, define a *grammar* as a finite set of rules. A grammar is *simple* if all its rules are simple.

3.2 Derivations

For a grammar R, define $\mathsf{deriv}(R)$ as the smallest set that contains every tuple $\langle r, \delta_1, ..., \delta_k \rangle$ satisfying the following conditions:

- $r \in R$ is a k-rank rule
- $\delta_i \in \mathsf{deriv}(R)$ for all $1 \leq i \leq k$
- $\mathsf{pre}(r, i) = \mathsf{post}(r_i)$ for all $1 \leq i \leq k$, where r_i is the first element of tuple δ_i.

An *R–derivation* is an element of $\mathsf{deriv}(R)$. Consider a derivation $\delta = \langle r, \delta_1, ..., \delta_k \rangle$, where rule $r = \langle k, s^*, X, \pi, \Gamma, c \rangle$. Define the following properties:

$$\mathsf{post}(\delta) = \mathsf{post}(r)$$
$$\mathsf{sent}(\delta) = \textsc{sub}(s^*, \mathsf{sent}(\delta_1), ..., \mathsf{sent}(\delta_k))$$
$$\mathsf{carry}(\delta) = \Gamma(\mathsf{carry}(\delta_1), ..., \mathsf{carry}(\delta_k))$$
$$\mathsf{cost}(\delta) = c(\mathsf{carry}(\delta_1), ..., \mathsf{carry}(\delta_k)) + \sum_{j=1}^{k} \mathsf{cost}(\delta_j)$$

In words, we say that derivation δ *derives* sentence $\mathsf{sent}(\delta)$. If for some span σ of a particular sentence s, it holds that $\mathsf{sent}(\delta) = s_\sigma$, then we will say that δ is a derivation *over* span σ.

3.3 Problem Statement

The Minimum Derivation Cost problem is the following. Given a set R of rules and an input sentence

[1] For simplicity, we also impose the condition that “◊” is not a valid pattern. This is tantamount to disallowing unary rules.

[2] One possible point of confusion is why the pattern of the SCFG rule refers only to the primary sentence, and not the auxiliary sentence. To reconstruct the auxiliary sentence from an SCFG derivation in practice, one would need to augment the abstract definition of rule with an auxiliary pattern. However this is not required for our theoretical results.

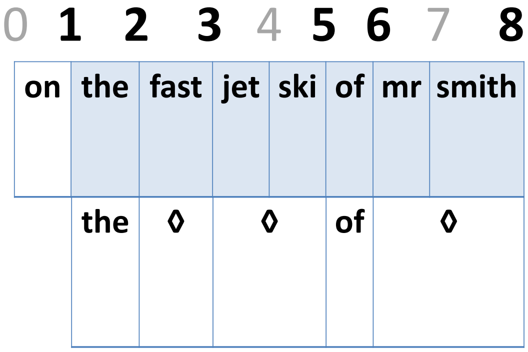

Figure 7: An application context for the pattern "the ◊ ◊ of ◊" and the sentence "on the fast jet ski of mr smith".

s, find the minimum cost of any R–derivation that derives s. In other words, compute:

$$\mathsf{MinDCost}(R, s) \triangleq \min_{\delta \in \mathsf{deriv}(R) | \mathsf{sent}(\delta) = s} \mathsf{cost}(\delta)$$

4 Application Contexts

Chart parsing solves Minimum Derivation Cost via dynamic programming. It works by building derivations over increasingly larger spans of the input sentence s. Consider just one of these spans σ. How do we build a derivation over that span?

Recall that a derivation takes the form $\langle r, \delta_1, ..., \delta_k \rangle$. Given the rule r and its pattern s^*, we need to choose the subderivations δ_i such that $\text{SUB}(s^*, \mathsf{sent}(\delta_1), ..., \mathsf{sent}(\delta_k)) = s_\sigma$. To do so, we must match the pattern to the span, so that we know which subspans we need to build the subderivations over. Figure 7 shows a matching of the pattern "the ◊ ◊ of ◊" to span $[1, 8]$ of the sentence "on the fast jet ski of mr smith". It tells us that we can build a derivation over span $[1, 8]$ by choosing this rule and subderivations over subspans $[2, 3]$, $[3, 5]$, and $[6, 8]$.

We refer to these matchings as *application contexts*. Formally, given two sentences s^* and s of respective lengths m and n, define an $\langle s^*, s \rangle$–*context* as an monotonically increasing sequence $\langle x_0, x_1, ..., x_m \rangle$ of integers between 0 and n such that for all i:

$$s^*_{[i-1,i]} \neq \lozenge \text{ implies that } s^*_{[i-1,i]} = s_{[x_{i-1}, x_i]}$$

The context shown in Figure 7 is $\langle 1, 2, 3, 5, 6, 8 \rangle$. Use $\mathsf{cxt}(s^*, s)$ to denote the set of all $\langle s^*, s \rangle$–contexts.

An $\langle s^*, s \rangle$–context $x = \langle x_0, x_1, ..., x_m \rangle$ has the following properties:

$$\mathsf{span}(x; s^*, s) = [x_0, x_m]$$
$$\mathsf{subspans}(x; s^*, s) = \langle [x_0, x_1], ..., [x_{m-1}, x_m] \rangle$$

Moreover, define $\mathsf{varspans}(x; s^*, s)$ as the subsequence of $\mathsf{subspans}(x; s^*, s)$ including only $[x_{i-1}, x_i]$ such that $s^*_{[i-1,i]} = \lozenge$. For the context x shown in Figure 7:

$$\mathsf{span}(x; s^*, s) = [1, 8]$$
$$\mathsf{subspans}(x; s^*, s) = \langle [1, 2], [2, 3], [3, 5], [5, 6], [6, 8] \rangle$$
$$\mathsf{varspans}(x; s^*, s) = \langle [2, 3], [3, 5], [6, 8] \rangle$$

An application context $x \in \mathsf{cxt}(s^*, s)$ tells us that we can build a derivation over $\mathsf{span}(x)$ by choosing a rule with pattern s^* and subderivations over each span in $\mathsf{varspans}(x; s^*, s)$.

5 Chart Parsing Algorithm

We are now ready to describe the chart parsing algorithm. Consider a span σ of our input sentence s and assume that we have computed and stored all derivations over any subspan of σ. A naive way to compute the minimum cost derivation over span σ is to consider every possible derivation:

1. Choose a rule $r = \langle k, s^*, X, \pi, \Gamma, c \rangle$.
2. Choose an application context $x \in \mathsf{cxt}(s^*, s)$ such that $\mathsf{span}(x; s^*, s) = \sigma$.
3. For each subspan $\sigma_i \in \mathsf{varspans}(x; s^*, s)$, choose a subderivation δ_i such that $\mathsf{post}(\delta_i) = \mathsf{pre}(r, i)$.

The key observation here is the following. In order to score such a derivation, we did not actually need to know each subderivation in its entirety. We merely needed to know the following information about it: (a) the subspan that it derives, (b) its postcondition, (c) its carry.

Chart parsing takes advantage of the above observation to avoid building all possible derivations. Instead it groups together derivations that share a common subspan, postcondition, and carry, and records only the minimum cost for each equivalence class. It records this cost in an associative map referred to as the *chart*.

Specifically, assume that we have computed and stored the minimum cost of every derivation class $\langle \sigma', X', \gamma' \rangle$, where X' is a postcondition, γ' is a carry, and σ' is a proper subspan of σ. Chart parsing computes the minimum cost of every derivation class $\langle \sigma, X, \gamma \rangle$ by adapting the above naive method as follows:

1. Choose a rule $r = \langle k, s^*, X, \pi, \Gamma, c \rangle$.

2. Choose an application context $x \in \mathsf{cxt}(s^*, s)$ such that $\mathsf{span}(x; s^*, s) = \sigma$.

3. For each subspan $\sigma_i \in \mathsf{varspans}(x; s^*, s)$, **choose a derivation class** $\langle \sigma_i, X_i, \gamma_i \rangle$ **from the chart** such that $X_i = \mathsf{pre}(r, i)$.

4. **Update**[3] **the cost of derivation class** $\langle \sigma, \mathsf{post}(r), \Gamma(\gamma_1, ..., \gamma_k) \rangle$ **with:**

$$c(\gamma_1, ..., \gamma_k) + \sum_{i=1}^{k} \mathsf{chart}[\sigma_i, X_i, \gamma_i]$$

where $\mathsf{chart}[\sigma_i, X_i, \gamma_i]$ **refers to the stored cost of derivation class** $\langle \sigma_i, X_i, \gamma_i \rangle$.

By iteratively applying the above method to all subspans of size 1, 2, etc., chart parsing provides an efficient solution for the Minimum Derivation Cost problem.

6 Runtime Analysis

At the heart of chart parsing is a single operation: the updating of a value in the chart. The running time is linear in the number of these chart updates. [4] The typical analysis counts the number of chart updates *per span*. Here we provide an alternative analysis that counts the number of chart updates *per rule*. This provides us with a finer bound with practical implications.

Let r be a rule with rank k and pattern s^*. Consider the chart updates involving rule r. There is (potentially) an update for every choice of (a) span, (b) application context, and (c) list of k derivation classes. If we let $\mathfrak{C}$ be the set of possible carries, then this means there are at most $|\mathsf{cxt}(s^*, s)| \cdot |\mathfrak{C}|^k$ updates involving rule r. [5] If we are doing beam decoding (i.e. after processing a span, the chart keeps only the B items of lowest cost), then there are at most $|\mathsf{cxt}(s^*, s)| \cdot B^k$ updates.

We can simplify the above by providing an upper bound for $|\mathsf{cxt}(s^*, s)|$. Define an *ambiguity* as the sentence "$\Diamond$ $\Diamond$", and define $\mathsf{scope}(s^*)$ as the number of ambiguities in the sentence "$\Diamond$" $\cdot s^* \cdot$ "$\Diamond$". The following bound holds:

Lemma 1. *Assume that a zero-rank sentence s does not contain the same symbol more than once. Then* $|\mathsf{cxt}(s^*, s)| \leq |s|^{\mathsf{scope}(s^*)}$.

Proof. Suppose s^* and s have respective lengths m and n. Consider $\langle x_0, x_1, ..., x_m \rangle \in \mathsf{cxt}(s^*, s)$. Let I be the set of integers i between 1 and m such that $s^*_i \neq \Diamond$ and let I^+ be the set of integers i between 0 and $m-1$ such that $s^*_{i+1} \neq \Diamond$. If $i \in I$, then we know the value of x_i, namely it is the unique integer j such that $s_j = s^*_i$. Similarly, if $i \in I^+$, then the value of x_i must be the unique integer j such that $s_j = s^*_{i+1}$. Thus the only nondetermined elements of context x_i are those for which $i \notin I \cup I^+$. Hence $|\mathsf{cxt}(s^*, s)| \leq |s|^{\{0,1,...,m\} - I - I^+} = |s|^{\mathsf{scope}(s^*)}$. □

Hence, under the assumption that the input sentence s does not contain the same symbol more than once, then there are at most $|s|^{\mathsf{scope}(s^*)} \cdot |\mathfrak{C}|^k$ chart updates involving a rule with pattern s^*.

For a rule r with pattern s^*, define $\mathsf{scope}(r) = \mathsf{scope}(s^*)$. For a grammar R, define $\mathsf{scope}(R) = \max_{r \in R} \mathsf{scope}(r)$ and $\mathsf{rank}(R) = \max_{r \in R} \mathsf{rank}(r)$.

Given a grammar R and an input sentence s, the above lemma tells us that chart parsing makes

[3] Here, *update* means "replace the cost associated with the class if the new cost is lower."

[4] This assumes that you can linearly enumerate the relevant updates. One convenient way to do this is to frame the enumeration problem as a search space, e.g. (Hopkins and Langmead, 2009)

[5] For instance, in SCFG decoding with an integrated j-gram language model, a carry consists of $2(j-1)$ boundary words. Generally it is assumed that there are $O(n)$ possible choices for a boundary word, and hence $O(n^{2(j-1)})$ possible carries.

$O(|s|^{\mathsf{scope}(R)} \cdot |\mathfrak{C}|^{\mathsf{rank}(R)})$ chart updates. If we restrict ourselves to beam search, than chart parsing makes $O(|s|^{\mathsf{scope}(R)})$ chart updates. [6]

6.1 On the Uniqueness Assumption

In practice, it will not be true that each input sentence contains only unique symbols, but it is not too far removed from the practical reality of many use cases, for which relatively few symbols repeat themselves in a given sentence. The above lemma can also be relaxed to assume only that there is a constant upper bound on the multiplicity of a symbol in the input sentence. This does not affect the O-bound on the number of chart updates, as long as we further assume a constant limit on the length of rule patterns.

7 Scope Reduction

From this point of view, CNF binarization can be viewed as a specific example of *scope reduction*. Suppose we have a grammar R of scope p. See Figure 8. If we can find a grammar $\hat{R}$ of scope $\hat{p} < p$ which is "similar" to grammar R, then we can decode in $O(n^{\hat{p}})$ rather than $O(n^p)$ time.

We can frame the problem by assuming the following parameters:

- a grammar R
- a desired scope p
- a loss function Λ that returns a (non-negative real-valued) score for any two grammars R and $\hat{R}$; if $\Lambda(R, \hat{R}) = 0$, then the grammars are considered to be equivalent

A *scope reduction method with loss* λ finds a grammar $\hat{R}$ such that $\mathsf{scope}(\hat{R}) \leq p$ and $\Lambda(R, \hat{R}) = \lambda$. A scope reduction method is *lossless* when its loss is 0.

In the following sections, we will use the loss function:

$$\Lambda(R, \hat{R}) = |\mathsf{MinDCost}(R, s) - \mathsf{MinDCost}(\hat{R}, s)|$$

where s is a fixed input sentence. Observe that if $\Lambda(R, \hat{R}) = 0$, then the solution to the Minimum Derivation Cost problem is the same for both R and $\hat{R}$. [7]

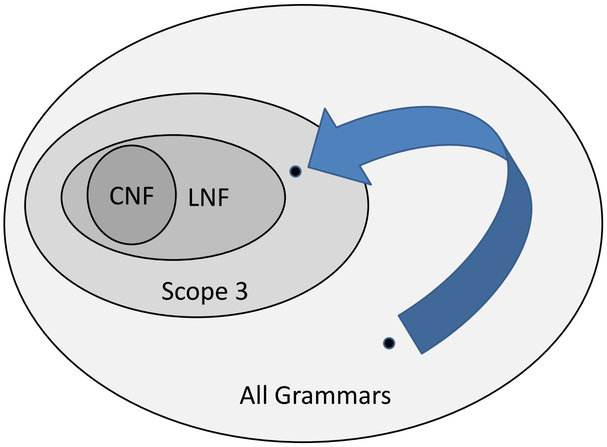

Figure 8: The "scope reduction" problem. Given a grammar of large scope, find a similar grammar of reduced scope.

7.1 CNF Binarization

A rule r is *CNF* if its pattern is "$\Diamond\ \Diamond$" or "x", where x is any non-substitution symbol. A grammar is *CNF* if all of its rules are CNF. Note that the maximum scope of a CNF grammar is 3.

CNF binarization is a deterministic process that maps a simple grammar to a CNF grammar. Since binarization takes subcubic time, we can decode with any grammar R in $O(n^3)$ time by converting R to CNF grammar $\hat{R}$, and then decoding with $\hat{R}$. This is a lossless scope reduction method.

What if grammar R is not simple? For SCFG grammars, (Zhang et al., 2006) provide a scope reduction method called *synchronous binarization* with quantifiable loss. Synchronous binarization selects a "binarizable" subgrammar R' of grammar R, and then converts R' into a CNF grammar $\hat{R}$. The cost and carry functions of these new rules are constructed such that the conversion from R' to $\hat{R}$ is a lossless scope reduction. Thus the total loss of the method is $|\mathsf{MinDCost}(R, s) - \mathsf{MinDCost}(R', s)|$. Fortunately, they find in practice that R' usually contains the great majority of the rules of R, thus they

[6] Assuming $\mathsf{rank}(R)$ is bounded by a constant.

[7] Note that if we want the actual derivation and not just its cost, then we need to specify a more finely grained loss function. This is omitted for clarity and left as an exercise.

assert that this loss is negligable.

A drawback of their technique is that the resulting CNF grammar contains many more rules and postconditions than the original grammar. These constant factors do not impact asymptotic performance, but do impact practical performance.

7.2 Lexical Normal Form

Concerned about this inflation of the grammar constant, (DeNero et al., 2009) consider a superset of CNF called Lexical Normal Form (LNF). A rule is *LNF* if its pattern does not contain an ambiguity as a proper subsentence (recall that an ambiguity was defined to be the sentence "◊ ◊"). Like CNF, the maximum scope of an LNF grammar is 3. In the worst case, the pattern s^* is "◊ ◊", in which case there are three ambiguities in the sentence "◊" $\cdot s^* \cdot$ "◊".

(DeNero et al., 2009) provide a lossless scope reduction method that maps a simple grammar to an LNF grammar, thus enabling cubic-time decoding. Their principal objective is to provide a scope reduction method for SCFG that introduces fewer postconditions than (Zhang et al., 2006). However unlike (Zhang et al., 2006), their method *only* addresses simple grammars. Thus they cannot integrate LM scoring into their decoding, requiring them to rescore the decoder output with a variant of cube growing (Huang and Chiang, 2007).

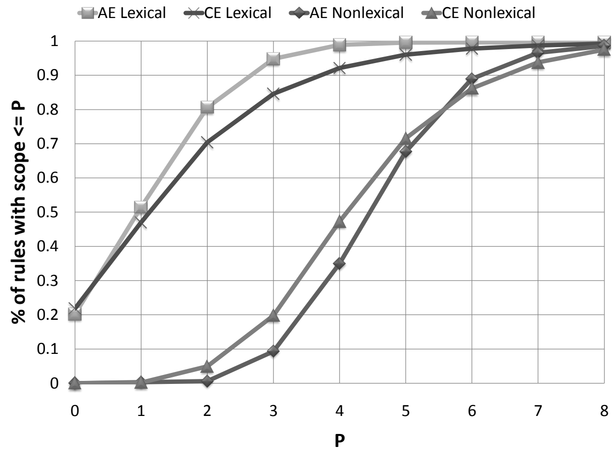

Figure 10: Breakdown of rules by scope (average per sentence in our test sets). In practice, most of the lexical rules applicable to a given sentence (95% for Arabic-English and 85% for Chinese-English) are scope 3 or less.

7.3 Scope Pruning

To exercise the power of the ideas presented in this paper, we experimented with a third (and very easy) scope reduction method called *scope pruning*. If we consider the entire space of scope-3 grammars, we see that it contains a much richer set of rules than those permitted by CNF or LNF. See Figure 9 for examples. Scope pruning is a lossy scope reduction method that simply takes an arbitrary grammar and prunes all rules with scope greater than 3. By not modifying any rules, we preserve their cost and carry functions (enabling integrated LM decoding), without increasing the grammar constant. The practical question is: how many rules are we typically pruning from the original grammar?

We experimented with two pretrained syntax-based machine translation systems with rules extracted via the GHKM algorithm (Galley et al., 2004). The first was an Arabic-English system, with rules extracted from 200 million words of parallel data from the NIST 2008 data collection, and with a 4-gram language model trained on 1 billion words of monolingual English data from the LDC Gigaword corpus. We evaluated this system's performance on the NIST 2008 test corpus, which consists of 1357 Arabic sentences from a mixture of newswire and web domains, with four English reference translations. The second system was a Chinese-

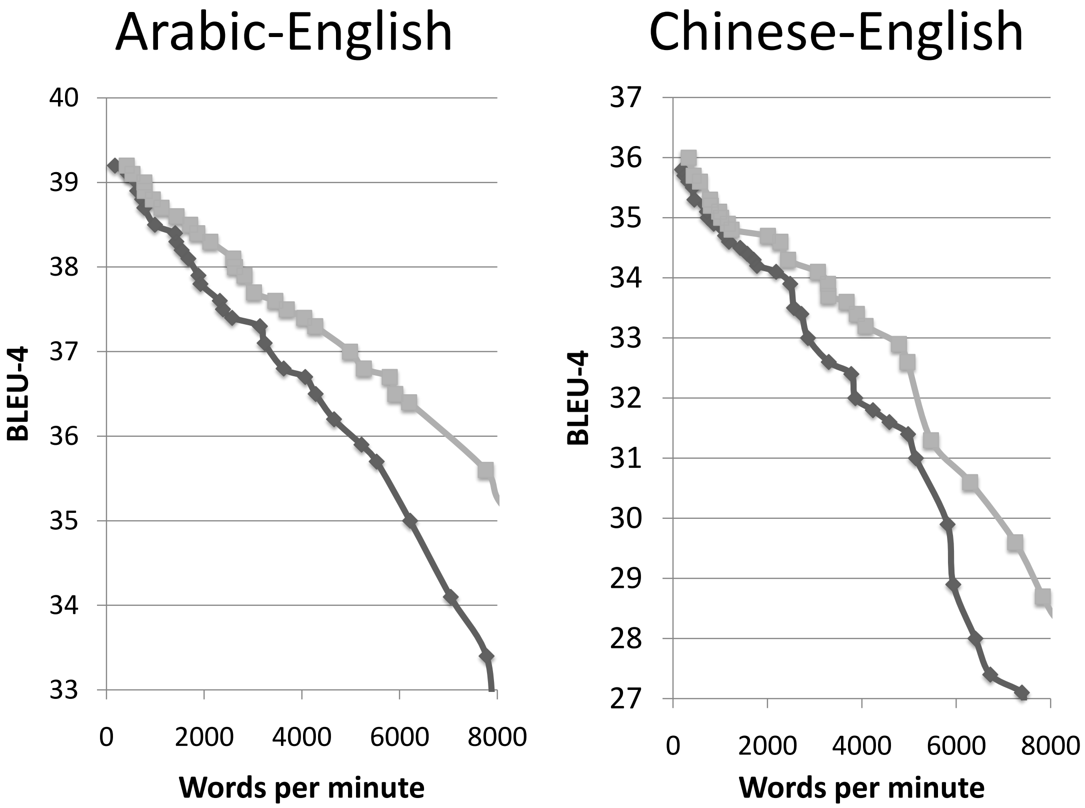

Figure 11: Speed-quality tradeoff curves comparing the baseline scope reduction method of synchronous binarization (dark gray diamonds) with scope-3 pruning (light gray squares).

English system, with rules extracted from 16 million words of parallel data from the mainland-news domain of the LDC corpora, and with a 4-gram language model trained on monolingual English data from the AFP and Xinhua portions of the LDC Gigaword corpus. We evaluated this system's performance on the NIST 2003 test corpus, which consists of 919 Chinese sentences, with four English reference translations. For both systems, we report BLEU scores (Papineni et al., 2002) on untokenized, recapitalized output.

In practice, how many rules have scope greater than 3? To answer this question, it is useful to distinguish between *lexical* rules (i.e. rules whose patterns contain at least one non-substitution symbol) and *non-lexical* rules. Only a subset of lexical rules are potentially applicable to a given input sentence. Figure 10 shows the scope profile of these applicable rules (averaged over all sentences in our test sets). Most of the lexical rules applicable to a given sentence (95% for Arabic-English, 85% for Chinese-English) are scope 3 or less. [8] Note, however, that scope pruning also prunes a large percentage of non-lexical rules.

Figure 11 compares scope pruning with the baseline technique of synchronous binarization. To generate these speed-quality tradeoff curves, we decoded the test sets with 380 different beam settings. We then plotted the hull of these 380 points, by eliminating any points that were dominated by another (i.e. had better speed and quality). We found that this simple approach to scope reduction produced a better speed-quality tradeoff than the much more complex synchronous binarization. [9]

[8] For contrast, the corresponding numbers for LNF are 64% and 53%, respectively.

[9] We also tried a hybrid approach in which we scope-pruned

8 Conclusion

In this paper, we made the following contributions:

- We provided an abstract formulation of chart parsing that generalizes CFG decoding and SCFG decoding with an integrated LM.
- We framed *scope reduction* as a first-class abstract problem, and showed that CNF binarization and LNF binarization are two specific solutions to this problem, each with their respective advantages and disadvantages.
- We proposed a third scope reduction technique called *scope pruning*, and we showed that it can outperform synchronous CNF binarization for particular use cases.

Moreover, this work gives formal expression to the extraction heuristics of hierarchical phrase-based translation (Chiang, 2007), whose directive not to extract SCFG rules with adjacent nonterminals can be viewed as a preemptive pruning of rules with scope greater than 2 (more specifically, the pruning of non-LNF lexical rules). In general, this work provides a framework in which different approaches to *tractability-focused* grammar construction can be compared and discussed.

the lexical rules and synchronously binarized the non-lexical rules. This had a similar performance to scope-pruning all rules. The opposite approach of scope-pruning the lexical rules and synchronously binarizing the non-lexical rules had a similar performance to synchronous binarization.

Example-based Paraphrasing for Improved Phrase-Based Statistical Machine Translation

Abstract

In this article, an original view on how to improve phrase translation estimates is proposed. This proposal is grounded on two main ideas: first, that appropriate examples of a given phrase should participate more in building its translation distribution; second, that paraphrases can be used to better estimate this distribution. Initial experiments provide evidence of the potential of our approach and its implementation for effectively improving translation performance.

1 Introduction

Phrase translation estimation in Statistical Phrase-based Translation (Koehn et al., 2003) is hampered by the availability of both too many and too few training instances. Recent results on tera-scale SMT (Lopez, 2008) show that access to many training examples[1] can lead to significant improvements in translation quality. Also, providing indirect training instances via synonyms or paraphrases for previously unseen phrases can result in gains in translation quality, which are more apparent when little training data is originally available (Callison-Burch et al., 2006; Marton et al., 2009; Mirkin et al., 2009; Aziz et al., 2010). Although there is a consensus on the importance of using more parallel data in SMT, it has never been formally shown that all additional training instances are actually useful in predicting contextually appropriate translation hypotheses.

Attempts at limiting training parallel sentences to those resembling test data through thematic adaptation (Hildebrand et al., 2005) indeed confirm that large quantities of training data cannot compensate for the requirement for contextually appropriate training instances. In fact, it is important that phrase translation models adequatly reflect contextual preferences for each phrase occurrence in a text. A variety of recent works have used dynamically adapted translation models, where each phrase occurrence has its own translation distribution (Carpuat and Wu, 2007; Stroppa et al., 2007; Max et al., 2008; Gimpel and Smith, 2008; Haque et al., 2009) derived from local contextual information in the training examples.[2] These approaches are supported by the study of (Wisniewski et al., 2010) which shows that phrase-based SMT systems are expressive enough to achieve very high translation performance and therefore suggests a better scoring of phrases.

The apparent tradeoff between the number of training examples and their appropriateness in each indivual context naturally asks for means of increasing the number of appropriate examples. Exploiting comparable corpora for acquiring translation equivalents (Munteanu and Marcu, 2005; Abdul-Rauf and Schwenk, 2009) offers interesting prospects to this issue, but so far focus has not been so much on context appropriateness as on globally increasing the number of biphrase examples.

[1] To be more accurate, works such as that of (Lopez, 2008) have recourse to random sampling to build models of a manageable size in a reasonable amount of time.

[2] The study of (Carpuat, 2009) shows that the one translation per discourse hypothesis holds in some cases, but to our knowledge no SMT systems have attempted to exploit it yet. However, in our view, this finding does not contradict the need for estimating translation distributions at the individual phrase level, but they should be integrated as additional information.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 656–666,
MIT, Massachusetts, USA, 9-11 October 2010.

The approach we take in this article is motivated by the fact that natural language allows for multiple text views on a given content, and that if two phrases are good paraphrases in context, then considering appropriate training examples of one of the phrases could provide larger quantities of training data for translating the other. In other words, we hypothesize that there may be more training data to learn a phrase's translations in a bilingual corpus than what SMT approaches typically use.

In contrast to previous attempts at using paraphrases to improve Statistical Machine Translation, which require external data in the form of additional parallel bilingual corpora (Callison-Burch et al., 2006), monolingual corpora (Marton et al., 2009), lexico-semantic resources (Mirkin et al., 2009; Aziz et al., 2010), or sub-sentential (Resnik et al., 2010) or sentential paraphrases of the input (Schroeder et al., 2009), the approach we take here can be endogenous with respect to the original training data. It also significantly departs from previous work in that paraphrasing is not simply considered as a way of finding alternative wordings that can be translated given the original training data for out-of-vocabulary phrases only (Callison-Burch et al., 2006; Marton et al., 2009; Mirkin et al., 2009; Aziz et al., 2010), but as a means to better estimate translations for *any* possible phrase. Also, as opposed to the work by (Schroeder et al., 2009; Onishi et al., 2010; Du et al., 2010), we do not encode paraphrases into input lattices to have them compete against each other to belong to the source sentential paraphrase that will lead to the highest scoring output sentence[3]. Instead, we make use of all contextually appropriate paraphrases of a source phrase, which *collectively evaluate the quality of each translation for that phrase*.

This work can thus be seen as a contribution towards shifting from global phrase translation distributions to contextual translation distributions for contextually equivalent source units. The remainder of this paper is organized as followed. In section 2 we review relevant previous works and discuss how they differ from our approach. Section 3 provides a description of the details of our approach. We describe an experimental setup in section 4 and comment on our results. Finally, we discuss our future work in section 5.

2 Relation to previous work

2.1 Contextual estimation of phrase translations

In standard approaches to phrase-based SMT, evidence of a translation is accumulated uniformely every time it is found associated with a source phrase in the training corpus. In addition to the fact that errors in automatic word alignment and non literal translations often produce useless biphrases, this results in rare but appropriate translations being very unlikely to be considered during decoding. Some approaches on source context modelling (Carpuat and Wu, 2007; Stroppa et al., 2007; Max et al., 2008; Haque et al., 2009) build classifiers offline for the phrases in a test set, so that context similarity can for example reinforce scores associated with rare but appropriate translations. However, heavy offline computation makes scaling to larger corpora an issue. Other approaches (Callison-Burch et al., 2005; Lopez, 2008) instead focus on accessing very large corpora. Indexing by suffix arrays is used to allow fast access to phrase instances in the corpus, and random sampling to avoid collecting the full set of examples has been shown to perform well. However, these approaches consider all instances of a phrase as equivalent for the estimation of its translations.

These works converge on the need for accessing a sufficient number of examples that are relevant for any source phrase in context, fast enough to permit on-the-fly phrase table building. This paper proposes an intermediate step: the full set of phrase examples is found efficiently, and a measure of the adequacy of each example with a phrase in context provides evidence for its translation that depends on this value of adequacy. In this way, the translation associated with an example for a different sense of a polysemous word would in the best scenario only be considered marginally when computing the translation distribution. As in most previous works, adequacy can be approximated by context similarity between phrase occurrences and training examples.

Ideally, one would stop extracting examples when enough appropriate examples have been found to estimate a reliable translation distribution. (Callison-

[3] This highly depends on how well estimated translations for each independent paraphrase are.

sample size	100	500	1K	5K	10k	50k	unlim.
BLEU score	28.8	28.8	28.8	28.9	29.1	28.9	29.0

Figure 1: Effect of number of samples on translation quality (measured on German to English translation on Europarl data) reported by (Callison-Burch et al., 2005)

Burch et al., 2005) measured the impact on translation quality of the sample size in random sampling of source phrase examples in the training corpus to estimate a phrase's translation probabilities. As Table 1 shows, quality (in terms of BLEU scores) almost remains constant for samples of size 100 or more. This apparent confirmation of the efficiency of random sampling is backed up by the authors with the following possible explanations: 1) the most probable translations remain the same for different sample sizes; 2) misestimated probabilities are ruled out by the target language model; and 3) longer or less frequent phrases, which are not affected by sampling, are preferred. However, as said previously, random sampling cannot guarantee that contextually-appropriate examples are selected. In fact, (Lopez, 2008) points out to using discriminatively trained models with contextual features of source phrases in conjunction with phrase sampling as an open problem. This work does not attempt to directly address it, but instead resorts to complete analysis of the training data to guarantee that all contextually-appropriate examples are considered.

2.2 Using paraphrases for translating

For some phrases, not enough examples can be found in the training corpus to estimate reliable translation probabilities in context. In such cases, one might be interested in finding more appropriate examples, which seems at first impossible using the sole original bilingual corpus. We can in fact consider the set of source phrases that have similar translations in context. This set is roughly made up of a subset of what can be referred to as *paraphrases*. One possible approach to extract local (i.e. phrasal) paraphrases precisely exploits similarity *on the target side* in another language by extracting source phrases that share common translations (Bannard and Callison-Burch, 2005), but recent approaches have combined this approach with similarity computation in the "source" (i.e. original) language (Callison-Burch, 2008; Max, 2008; Kok and Brockett, 2010). Figure 2 provides examples of English paraphrases obtained by automatically pivoting via French. As can be seen, some examples would be clearly useful to better estimate translations of the original source phrase: (*Balkan War* ↔ *war in the Balkans*) are syntactic variants that can generally substitute with each other, (*Balkan War* ↔ *Balkans war*) are character-level variants[4]. Other examples, however, clearly illustrate the need for validation in context: (*Dalai Lama's* ↔ *of the Dalai Lama*) require different syntactic contexts, and (*I don't see* ↔ *I do not believe*) are only interchangeable in specific semantic contexts.

Source phrase	**Paraphrases**
Balkan War	*Balkan war* (0.25) *Balkans War* (0.125) *Balkans* (0.125) *Balkans war* (0.125) *war in the Balkans* (0.125) *Balkan conflict* (0.125)
British forces	*British troops* (0.29) *British armed_forces* (0.19)
Czech president	*President of the Czech Republic* (0.5)
Dalai Lama's	*of the Dalai Lama* (0.27)
I don't see	*I do not believe* (0.18) *I do not think* (0.18) *I do not see* (0.15)

Figure 2: Examples of paraphrases obtained by pivoting via French; values indicate *paraphrase probability* as defined in (Bannard and Callison-Burch, 2005).

Previous attempts at exploiting paraphrases in SMT have first concentrated on obtaining translations for phrases absent from the training corpus (Callison-Burch et al., 2006; Marton et al., 2009; Mirkin et al., 2009)[5], with modest gains in translation performance as measured by automatic metrics. (Callison-Burch et al., 2006) obtain paraphrases by pivoting via additional bilingual corpora and use the translations of known paraphrases to translate unseen phrases, which requires that the additional bilingual corpora contain the unseen source phrases and that some of the extracted paraphrases be present in the original corpus. (Marton et al.,

[4] To our knowledge, most implementations of SMT decoders do not integrate flexible matching of phrases.

[5] The work by (Mirkin et al., 2009) in fact considers both paraphrases and entailed texts to increase the number of properly translated texts.

2009) proceed similarly but obtain their paraphrases from comparatively much larger monolingual corpora by following the *distributionality hypothesis*. In both cases, gains are only obtained in very specific conditions where very few training data are available and where useful additional knowledge can be brought in from external resources. Furthermore, the described implementations do not consider acceptability of the paraphrases in context, as their underlying hypothesis is that it might be more desirable to translate some paraphrase than not to translate a given phrase.[6] In contrast, the work by (Mirkin et al., 2009) attempts to model context when using replacements for words (synonyms or hypernyms).

The natural next step that we take here is to exploit the complementarity of the original bilingual training corpus for finding paraphrases and the monolingual (source) side of the same corpus for validating them in context. Furthermore, our focus here is not on paraphrasing unseen phrases[7], but possibly any phrase, or any phrase seen less than a given number of times, or any types of difficult-to-translate phrases (Mohit and Hwa, 2007).

The recent work of (Resnik et al., 2010) uses crowdsourcing to obtain paraphrases for source phrases corresponding to mistranslated target phrases. The spotting of the incorrect target phrases and the paraphrasing of the source phrases can be automated. Promising oracle figures are obtained, validating the claim that some variations of the input sentence might be more easily translated than others by a given system. Paraphrases have also been used to represent alternative inputs encoded in lattices using existing (Schroeder et al., 2009) or automatically built paraphrases (Onishi et al., 2010; Du et al., 2010). In this scenario, paraphrases are in fact competing with each other, whereas in our proposal paraphrases *collectively participate in evaluating the quality of each translation for a source phrase*. We believe that if two phrases are indeed paraphrases in context, then their respective set of translations are both relevant to translate the two phrases. The target language model nevertheless still has an important role to play to select appropriate translations among semantically-compatible translations (i.e., target side paraphrases) in the specific context of a generated target hypothesis.

Lastly, automatic sentential paraphrasing has also been used in SMT to build alternative reference translations for parameter optimization (Madnani et al., 2008) and to build alternative training corpora (Bond et al., 2008).

3 Towards better exploitation of training corpora in phrase-based SMT

In typical phrase-based SMT settings (Koehn et al., 2003), words from the source side of the corpus are first aligned to words on the target side and biphrases are extracted from each training sentence using some heuristics on the word alignments. A source phrase f in a sentence being translated may therefore be aligned to a variety of target phrases. In the example on Figure 3, f is aligned some number of times in the training corpus to target phrases e_1, e_2, e_3 and e_5. Using the number of times f is paired with some target phrase e_i, $count(f, e_i)$, relative frequency estimation can be used to compute the probability of translation e_i given source phrase f:

$$p_{rel}(e_i|f) = \frac{count(f, e_i)}{\sum_j count(f, e_j)} \qquad (1)$$

This value, together with other estimates of how appropriate a translation pair (f, e_i) is, are recorded in a phrase table, which typically discards all contextual information.[8] Therefore, the translation distribution of some phrase is globally estimated from a training corpus independently of the actual context of that phrase.[9] On Figure 3, phrase f has at least two distinct senses: one represented by set $\mathcal{E}$, which in our example corresponds to the appropriate sense for a particular occurrence of f in a test sentence; and one which corresponds to translation e_5. A typical problem, due to the lack of context modeling,

[6] The default strategy for most decoders is to copy out-of-vocabulary tokens into the final text.

[7] Doing it in conjunction with our approach for improving the translation of known phrases is part of our future work.

[8] See (Carpuat and Wu, 2007; Stroppa et al., 2007; Max et al., 2008; Gimpel and Smith, 2008; Haque et al., 2009) for notable exceptions.

[9] Context is in fact taken into account to some extent by the target language model, which should score higher translations that are more appropriate given a target translation hypothesis being built. In fact, in this work we consider the target language model as the main source of information for selecting among acceptable target phrases (target language paraphrases).

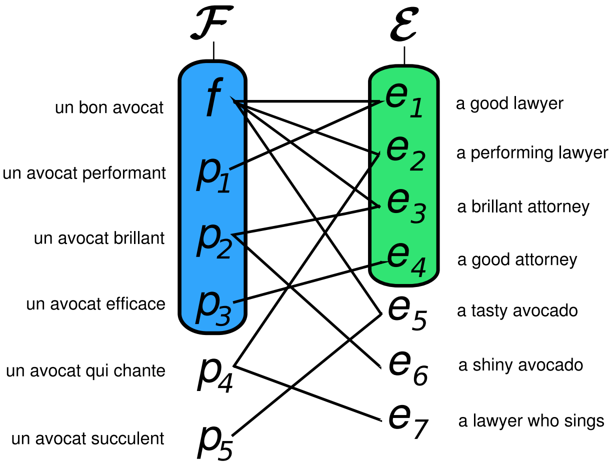

Figure 3: Example of possible source equivalents and translations for phrase occurrence f "*un bon avocat*" in the sentence "*L'embauche d'un bon avocat est cruciale quelle que soit l'activité*" ("*Hiring a good lawyer is crucial to any business"*). Set $\mathcal{E}$ represents target phrase types that are acceptable translations given the particular context of f, and set $\mathcal{F}$ represents source phrase types that can be in a paraphrasing relation to f depending on the context they appear in.

is that in situations such as $\forall e_i \in \mathcal{E}, count(f, e_5) \gg count(f, e_i)$, it is very unlikely that a correct translation will be selected during decoding against the incorrect but much more frequent one. Taking an extreme view on this issue, it is in fact desirable that when estimating phrase translation probabilities for a phrase f, translations of incompatible senses be not considered.[10] Of course, this raises the difficult issue of sense clustering of phrases. We propose here an intermediary solution, which consists in considering each occurrence in the training corpus as counting a number of times that depends on its contextual similarity with the occurrence of f from the test file, through the following additional translation model :

$$p_{cont}(e_i|f) = \frac{\sum_{\langle f_k, e_i \rangle} sim_{cont}(C(f), C(f_k))}{\sum_{\langle f_k, e_j \rangle} sim_{cont}(C(f), C(f_k))} \tag{2}$$

where f is some source phrase to translate and f_k an example of f in the training corpus, $\langle f_k, e_i \rangle$ is a biphrase from the training corpus, $C(f)$ the context of some source phrase, $C(f_k)$ the context of a particular example of f in the training corpus, sim_{phr} a function indicating the contextual similarity between two phrase contexts, and e_j is any possible translation of f.

The problem of modeling phrase translation is however not limited to inappropriate training examples. For various reasons, legitimate occurrences of source phrases may not be considered when building a phrase's translation distribution. We describe those cases by considering the possible source phrases p_i from Figure 3:

- p_1's only translation, e_1, is a common translation with f; each contextually-appropriate example of p_1 should reinforce the probability of e_1 being a translation for f.

- Contextually-appropriate examples of p_2 can reinforce e_3. Translation e_6 should correspond to contextually-inappropriate examples of p_2, so e_6 should not be considered as a new potential translation for f.

- Contrarily to the examples of p_2 translating as e_6, examples of p_3 translating as e_4 are much more likely of being contextually-appropriate with f, meaning that f could be substituted with most p_3 examples. Therefore, e_4, which was not initially considered as a possible translation of f, could now be considered as such.

- p_4 shares a translation with f, e_2, but this is due to the polysemous nature of this translation. Again, all examples of p_4 should be found contextually-inappropriate with f, and their translations should not be considered when estimating the translations of f.

- Lastly, the case of the common translation e_5 between f and p_5 illustrates a consequence of the polysemous nature of the source phrase corresponding to word sequence f: translations corresponding to other senses of f should not get reinforced by paraphrase examples such as those of p_5 as these examples should be found contextually-inappropriate with f.

[10] Put differently, is it more acceptable to copy a source word in the target hypothesis or to incorrectly translate it when the confidence about its being incorrect is high?

We build a separate translation model for translations estimated through paraphrases, defined as follows:

$$p_{para}(e_i|f) = \frac{\sum_{\langle p_k,e_i \rangle} sim_{para}(C(f), C(p_k))}{\sum_{\langle p_k,e_j \rangle} sim_{para}(C(f), C(p_k))} \quad (3)$$

where p_k is a paraphrase of f, $\langle p_k, e_i \rangle$ is a biphrase from the training corpus such that e_i is also a translation of f, $C(f)$ the context of a given source phrase for which we are estimating the translation distribution, $C(p_k)$ the context of a particular example of p_k in the training corpus, sim_{para} a function indicating the contextual similarity between a phrase context and a paraphrase context, and e_j is any possible translation of f.

Several requirements can be drawn from the previous description:

1. **List of potential paraphrases**: some mechanism for finding potential paraphrases for source phrases is required, and several such mechanisms could be combined. Pivoting via bilingual corpora, a natural strategy given the issue at hand, is just one among many different proposed strategies (Madnani and Dorr, 2010).

2. **Contextual similarity measure**: a similarity measure between the contexts of two phrases or two potential local paraphrases is required. This automatic measure should ideally be able to model not only syntactic but also semantic and pragmatic information.

3. **Robust translation evaluation**: our approach is designed to reinforce estimates for any contextually-appropriate translations of a phrase, as shown by set $\mathcal{E}$ on Figure 3. It is therefore important to have some means of accepting them as subparts of valid translations. Robustness in Machine Translation evaluation is an active domain, and potential candidates include using BLEU-like metrics with multiple references, Human-targeted Translation Error Rate (Snover et al., 2006) and the use of paraphrases for reference translations (Kauchak and Barzilay, 2006).

Figure 4: Statistics of the corpora used.

In this paper, we want to evaluate whether an endogenous approach for finding paraphrases can lead to some improvement in translation performance. Note that we will not consider in this initial work the possibility of adding new translations to phrases (such as e_4 for f on Figure 3) as it adds complexity and should be investigated when the other simpler cases can be handled successfully.

In the following section, we describe experiments in which the original bilingual corpus is the only resource used to find potential paraphrases and to estimate phrase translations in context. We chose a very simple measure of similarity, and let to our future work the task of improving context modeling. As regards evaluation, we will resort to various ways to measure the impact of our implementation on translation performance.

4 Experiments and results

4.1 Data and baseline SMT systems

We have conducted our experiments using the MOSES[11] package to build state-of-the-art phrase-based SMT systems for phrases of up to 5 tokens, using standard parameters and MERT for optimizing model weights. We used a subpart of the Europarl corpus[12] in French and English as our training corpus and built baseline MOSES systems (**bsl**) in both directions. The target side of the training corpus was used to train 3-gram target language model with modified Kneser-Ney smoothing. Held-out datasets were used for development and testing. The characteristics of all corpora are described in Figure 4.

4.2 Example-based Paraphrasing SMT systems

We also built systems that exploit phrase and paraphrase context under the form of two additional models p_{cont} and p_{para} described in section 3. These

Figure 5: Statistics on the size and the number of entries of the phrase tables filtered on the development set.

models are added to the list of models used to evaluate the various translations of a phrase in the appropriate phrase tables, and are optimized with the other models by standard MERT.

In order to model context, we modified the source texts so that each phrase becomes unique in the phrase table, i.e. it has its own translation distribution. This is done (as in other works (Carpuat and Wu, 2007; Stroppa et al., 2007)) by transforming each token into a unique token, e.g. *token* → *token@337*. This therefore leads to a significant increase in the size of the phrase table, as illustrated on Figure 5, as all occurrences for the same phrase are not factored anymore.[13]

We chose a very simple initial definition of context similarity based on the presence of common *n*-grams in the immediate vicinity of two phrases. Let $length_{left}$ (resp. $length_{right}$) be the length of the longest common *n*-gram in the immediate vicinity on the left (resp. right) of two phrases in context ($C(f)$ and $C(f_i)$). For instance, given the two following contexts (phrases under focus are in bold and common *n*-grams are underlined):

1. *the commission accepts the substance of the* ***amendments@11257 proposed@11258 by@11259*** *the committee on fisheries ...*

2. *this is why we shall support all of the* ***amendments put forward by*** *the committee on agriculture and rural development ...*

$length_{left} = 2$ and $length_{right} = 3$. We further define $length$ as:

$$length = \begin{cases} length_{left} + length_{right} \\ \quad \text{if } length_{left} > 0 \\ \quad \text{and } length_{right} > 0 \\ 0 \text{ otherwise} \end{cases} \qquad (4)$$

We can now define the two similarity functions used in Equations 2 and 3 that we used for our experiments:

$$sim_{cont}(C(f), C(f_i)) \;=\; (1 + length)^{\alpha} \qquad (5)$$
$$sim_{para}(C(f), C(p_i)) \;=\; (length)^{\beta} \qquad (6)$$

The rationale for these functions is the following. Exact phrase examples add at least a translation count of 1, i.e. their translation is always taken into account to estimate p_{cont}. Paraphrase examples add a translation count of 0 if $length = 0$, i.e. their translation is not taken into account at all if surrounding *n*-gram similarity is too low. We used $\alpha = \beta = 1.5$. Algorithm 1 describes how the two models are estimated from the training data.

```
foreach phrase $f$ in training file do
    extract $C(f)$;
    /* phrase count */
    foreach unique phrase $f_i$ in $test(f)$) do
        extract $C(f_i)$;
        compute $sim_{cont}(C(f), C(f_i))$;
    end
    /* paraphrase count */
    foreach phrase $p_i$ in $para(f)$ do
        foreach unique phrase $f_j$ in $test(p_i)$ do
            extract $C(f_j)$;
            compute $sim_{para}(C(f), C(f_j))$;
        end
    end
end
estimate $p_{cont}$ and $_{para}$;
```

Algorithm 1: Model estimation for p_{cont} and p_{para}. Function $test(f)$ returns all unique phrases corresponding to phrase f from the test file. Function $para(f)$ return all phrases for which f is a known paraphrase.

We implemented the following strategy to find paraphrases for phrases in the test file. We extract all

[13] These volumes of data and our available hardware facilities for these experiments led us to initially limit the size of our data sets. We will discuss in section 5 how we intend to address this limitation in our future work.

Figure 6: Examples of paraphrases in context from the development file. The input sentence (IS) contains a source phrase of interest (in bold), the paraphrase example (PE) contains a paraphrase of that source phrase (in bold) for which a paraphrase translation (PT) is known.

paraphrases p for a phrase f by pivot: all target language phrases e aligned to f are first extracted, and all source language phrases p aligned to e are extracted. The following constraints are then applied to define which paraphrases are kept:

- string p is not included in string f and vice versa (in order to minimize the impact of alignment errors in the training corpus);
- the paraphrasing probability is greater than a fixed threshold: $para(f,p) \geq 10^{-2}$, where $para(f,p) = \sum_e p(e|f)p(p|e)$ (Bannard and Callison-Burch, 2005);
- the number of occurrences of phrase f and paraphrase p are equal or less than independent thresholds: $numOccs(f) \leq 100$ and $numOccs(p) \leq 1000$.[14]

Figure 6 shows examples of paraphrases in context with high similarity with some original phrase, and Figure 7 provides various statistics on the paraphrases extracted on the test file.

4.3 Results and analysis

Automatic evaluation results are reported in Table 8 for various configurations. We also wanted to focus our measures on content words, which are known to be important as regards information content in translation. We applied the contrastive lexical evaluation (CLE) methodology described in (Max et al., 2010), which indicates how many times source words grouped into user-defined classes were correctly translated or not across systems. These additional results are reported on Figure 9.

phrase	**# phrases**		**# paraphrased**		**# paraphrases**	
length	en	fr	en	fr	en	fr
1	13,620	15,707	458	725	1,824	2,684

Figure 7: Statistics on numbers of phrases, numbers of paraphrased phrases and numbers of paraphrases per phrase length.

On English to French translation, both additional features lead to improvements over the baseline with all metrics, including CLE, and their combination shows a strong improvement in TER (-1.55). CLE on content words reveals that the **para** feature seems particularly effective in reducing the number of words in all categories that only the baseline system translated correctly.

Results on French to English translation are less positive: neither **cont** nor **para** alone improve over the baseline with any metrics. However, their combination improves over the baseline with all metrics except BLEU, including a reduction of -1.07 in TER. Detailed analysis of CLE results shows that the translation of adjectives and nouns benefited

[14] The first threshold value was chosen as (Callison-Burch et al., 2005) report it to be an optimal sample size for estimating phrase translation probabilities. The relatively low value for the second threshold was selected to reduce computation time.

more from using our two additional models. Verbs, whose translation improved slightly, are strongly inflected in French, so finding examples for a given form is more difficult than for less inflected word categories, as is finding paraphrases with the appropriate inflection. Also, pivoting via English is one reason why paraphrases obtained via a low-inflected language can be of varying quality. Furthermore, the simplicity of our context modeling may have been ineffective in filtering out some bad examples. Overall, **para** was more effective with the low-inflected English as the source language, improving over the baseline with all metrics.

These results confirm that translation performance can be improved by exploiting context and paraphrases in the original training corpus only. We next attempted to measure whether some improvement in the quality of the paraphrases used would have some measurable impact on translation performance. To this end, we devised a semi-oracle experiment in the following way: the source and target test files were automatically aligned, and for each source phrase possible target phrases (i.e., reference translations) were extracted, and used as pivots to extract potential paraphrases, which were then filtered with the same constraints as previously. In this way, we exploit the information that paraphrases can at least produce the desired translation, but they may also propose other incorrect translations and/or be present in very few examples. Results appear in the **inf** rows of Tables 8 and 9. We obtain the most important improvement over the baseline in BLEU for the two language pairs (resp. +0.99 and +0.44), though the results for the other metrics for French to English translation are more difficult to interpret. For this language pair, possible reasons include again that the pivot language may not be appropriate, and also that the limitation to a single pivot[15] may not have produced more monolingual variation that might have proved useful. CLE on English to French, however, reveals significant gains with a relative improvement over the baseline of +116 content words. Under this condition, this result shows that the higher the quality of the paraphrases used, the more translation quality can be improved, which is in line with works that make use of human-made paraphrases to improve translation quality (Schroeder et al., 2009; Resnik et al., 2010).

5 Conclusion and future work

We have introduced an original way of exploiting both context and paraphrasing for the estimation of phrase translations in phrase-based SMT. To our knowledge, this is the first time that paraphrases acquired in an endogenous manner have been shown to improve translation performance, which shows that bilingual corpora can be better exploited than they typically are. Our experiments further showed the promises of our approach when paraphrases of higher quality are available.

In the light of our results and our initial typology of paraphrases presented on Figure 10, as well as previous work on paraphrasing for SMT, the difficult question of what units should be paraphrased for what success should be addressed, taking into account parameters such as language pairs, quantity of training data and availability of external resources.

Our future work includes three main areas: first, we want to improve the modeling of context, by notably working on techniques inspired from Information Retrieval to quickly access contextually-similar examples of source phrases in bilingual corpora. Such *contextual sampling* on large bilingual corpora for phrases and their paraphrases, which could integrate more complex linguistic information, will allow us to assess our approach on more challenging conditions. This would also allow us to build contextual models on-the-fly, and experiment with using lattices to encode contextually estimated paraphrases. Second, we will combine paraphrases obtained via different techniques and resources, which will allow us to also learn translation distributions for phrases absent from the original corpus. Lastly, we want to also exploit paraphrases for the *additional* translations that they propose (such as e_4 on Figure 3) and that would be contextually similar in the target language to other existing translations of a given phrase or that could even represent a new sense of the original phrase.

Combining Unsupervised and Supervised Alignments for MT: An Empirical Study

Jinxi Xu and **Antti-Veikko I. Rosti**

{jxu,arosti}@bbn.com

Abstract

Word alignment plays a central role in statistical MT (SMT) since almost all SMT systems extract translation rules from word aligned parallel training data. While most SMT systems use unsupervised algorithms (e.g. GIZA++) for training word alignment, supervised methods, which exploit a small amount of human-aligned data, have become increasingly popular recently. This work empirically studies the performance of these two classes of alignment algorithms and explores strategies to combine them to improve overall system performance. We used two unsupervised aligners, GIZA++ and HMM, and one supervised aligner, ITG, in this study. To avoid language and genre specific conclusions, we ran experiments on test sets consisting of two language pairs (Chinese-to-English and Arabic-to-English) and two genres (newswire and weblog). Results show that the two classes of algorithms achieve the same level of MT performance. Modest improvements were achieved by taking the union of the translation grammars extracted from different alignments. Significant improvements (around 1.0 in BLEU) were achieved by combining outputs of different systems trained with different alignments. The improvements are consistent across languages and genres.

1 Introduction

Word alignment plays a central role in training statistical machine translation (SMT) systems since almost all SMT systems extract translation rules from word aligned parallel training data. Until recently, most SMT systems used GIZA++ (Och and Ney, 2003), an unsupervised algorithm, for aligning parallel training data. In recent years, with the availability of human aligned training data, supervised methods (e.g. the ITG aligner (Haghighi et al., 2009)) have become increasingly popular.

The main objective of this work is to show the two classes (unsupervised and supervised) of algorithms are complementary and combining them will improve overall system performance. The use of human aligned training data allows supervised methods such as ITG to more accurately align frequent words, such as the alignments of Chinese particles (e.g. “bei”, “de”, etc) to their English equivalents (e.g. “is/are/was/..”, “of”, etc). On the other hand, supervised methods can be affected by suboptimal alignments in hand-aligned data. For example, the hand-aligned data used in our experiments contain some coarse-grained alignments (e.g. “lianhe guo” to “United Nations”) although fine-grained alignments (“lian-he” to “United” and “guo” to “Nations”) are usually more appropriate for SMT. Unsupervised methods are less likely to be affected by this problem. We used two well studied unsupervised aligners, GIZA++ (Och and Ney, 2003) and HMM (Liang et al., 2006) and one supervised aligner, ITG (Haghighi et al., 2009) as representatives in this work.

We explored two techniques to combine different alignment algorithms. One is to take the union of the translation rules extracted from alignments produced by different aligners. This is motivated by studies that showed that the coverage of translation rules is critical to SMT (DeNeefe et al., 2007). The

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 667–673,
MIT, Massachusetts, USA, 9-11 October 2010.

other method is to combine the outputs of different MT systems trained using different aligners. Assuming different systems make independent errors, system combination can generate a better translation than those of individual systems through voting (Rosti et al., 2007).

Our work differs from previous work in two ways. Past studies of combining alternative alignments focused on minimizing alignment errors, usually by merging alternative alignments for a sentence pair into a single alignment with the fewest number of incorrect alignment links (Ayan and Dorr, 2006). In contrast, our work is based on the assumption that perfect word alignment is impossible due to the intrinsic difficulty of the problem, and it is more effective to resolve translation ambiguities at later stages of the MT pipeline. A main focus of much previous work on word alignments is on theoretical aspects of the proposed algorithms. In contrast, the nature of this work is purely empirical. Our system was trained on a large amount of training data and evaluated on multiple languages (Chinese-to-English and Arabic-to-English) and multiple genres (newswire and weblog). Furthermore, we used a state of the art string-to-tree decoder (Shen et al., 2008) to establish the strongest possible baseline. In comparison, experiments in previous studies typically used one language pair and one genre (usually newswire), a reduced amount of training data and a phrase based decoder.

This paper is organized as follows. Section 2 describes the three alignment algorithms. Section 3 describes the two methods used to combine these aligners to improve MT. The experimental setup used to compare these methods is presented in Section 4. Section 5 shows the results including a discussion. Section 6 discusses related work. Section 7 concludes the paper.

2 Alignment Algorithms

We used three aligners in this work: GIZA++ (Och and Ney, 2003), jointly trained HMM (Liang et al., 2006), and ITG (Haghighi et al., 2009). GIZA++ is an unsupervised method based on models 1-5 of Brown et al. (1993). Given a sentence pair $e - f$, it seeks the alignment a that maximizes the probability $P(f, a|e)$. As in most previous studies using GIZA++, we ran GIZA++ in both directions, from e to f and from f to e, and symmetrized the bidirectional alignments into one, using a method similar to the grow-diagonal-final method described in Och and Ney (2003). We ran GIZA++ up to model 4.

The jointly trained HMM aligner, or HMM for short, is also unsupervised but it uses a small amount of hand-aligned data to tweak a few high level parameters. Low level parameters are estimated in an unsupervised manner like GIZA++.

The ITG aligner is a supervised method whose parameters are tuned to optimize alignment accuracy on hand-aligned data. It uses the inversion transduction grammar (ITG) (Wu, 1997) to narrow the space of possible alignments. Since the ITG aligner uses features extracted from HMM alignments, HMM was run as a prepossessing step in our experiments. Both the HMM and ITG aligners are publicly available[1].

3 Methods of Combining Alternative Alignments for MT

We explored two methods of combining alternative alignments for MT. One is to extract translation rules from the three alternative alignments and take the union of the three sets of rules as the single translation grammar. Procedurally, this is done by concatenating the alignment files before extracting translation rules. We call this method *unioned grammar*. This method greatly increases the coverage of the rules, as the unioned translation grammar has about 80% more rules than the ones extracted from the individual alignment in our experiments. As such, decoding is also slower.

The other is to use system combination to combine outputs of systems trained using different aligners. Due to differences in the alignment algorithms, these systems would produce different hypotheses with independent errors. Combining a diverse set of hypotheses could improve overall system performance. While system combination is a well-known technique, to our knowledge this work is the first to apply it to explicitly exploit complementary alignment algorithms on a large scale.

Since system combination is an established technique, here we only briefly discuss our system com-

[1] http://code.google.com/p/berkeleyaligner/

bination setup. The basic algorithm was described in Rosti et al. (2007). In this work, we use incremental hypothesis alignment with flexible matching (Rosti et al., 2009) to produce the confusion networks. 10-best lists from all systems are collected first. All 1-best hypotheses for each segment are used as confusion network skeletons, the remaining hypotheses are aligned to the confusion networks, and the resulting networks are connected in parallel into a joint lattice with skeleton specific prior probabilities estimated from the alignment statistics on the initial arcs. This lattice is expanded with an unpruned bigram language model and the system combination weights are tuned directly to maximize the BLEU score of the 1-best decoding outputs. Given the tuned system combination weights, a 300-best list is extracted from the lattice, the hypotheses are rescored using an unpruned 5-gram language model, and a second set of system combination weights is tuned to maximize the BLEU score of the 1-best hypothesis of the re-scored 300-best list. The same rescoring step is also applied to the outputs of individual systems.

4 Experiment Setup

To establish strong baselines, we used a string-to-tree SMT system (Shen et al., 2008), one of the top performing systems in the NIST 2009 MT evaluation, and trained it with very large amounts of parallel and language model data. The system used large sets of discriminatively tuned features (up to 55,000 on Arabic) inspired by the work of Chiang et al. (2009). To avoid drawing language, genre, and metric specific conclusions, we experimented with two language pairs, Arabic-English and Chinese-English, and two genres, newswire and weblog, and report both BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) scores. Systems were tuned to maximize BLEU on the tuning set using a procedure described in Devlin (2009).

The sizes of the parallel training corpora are 238M words (target side) for Arabic-English MT and 265M words for Chinese-English. While the majority of the data is publicly available from the Linguistic Data Consortium (LDC), some of the data is available under the DARPA GALE program. Due to the size of the parallel corpora, we divided them into five chunks and aligned them in parallel to save time. Due to its running complexity, we ran ITG only on sentences with 60 or fewer words. For longer sentences, we used HMM alignments instead, which were conveniently generated in the preprocessing step of ITG aligner. For language model training, we used about 9 billion words of English text, most of which are from English Gigaword corpus and GoogleNews. Each system used a 3-gram LM for decoding and a 5-gram LM for re-scoring. The same 5-gram LM was also used for re-scoring system combination results.

For each combination of language pair and genre, we used three development sets:

- `Tune`, which was used to tune parameters of individual MT systems. Each system was tuned ten iterations based on BLEU.
- `SysCombTune`, which was used to tune parameters of system combination. A subset of it was also used as validation for determining the best iteration in tuning individual systems.
- `Test`, which was the blind test corpus for measuring performances of both individual systems and system combination.

Test materials were drawn from two sources: NIST MT evaluations 2004 to 2008, and development and evaluation data for the DARPA GALE program. Due to the mixing of different data sources, some test sentences have four reference translations while the rest have only one. The average number of references per test sentence varies across test sets. For this reason, MT scores are not comparable across test sets. Table 1 shows the size and the average number of references per sentence of the test sets.

Two hand-aligned corpora were used to train the ITG aligner: LDC2009E82 (Arabic-English) and LDC2009E83 (Chinese-English). We re-tokenized the corpora using our tokenizers and projected the LDC alignments to our tokenization heuristically. The projection was not perfect and sometimes created very coarse-grained alignments. We used a set of filters to remove such problematic data. We ended up with 3,667 Arabic-English and 879 Chinese-English hand-aligned sentence pairs with sufficient quality for training automatic aligners.

language and genre	Tune	SysCombTune	Test
Arabic newswire	2963 (2.9)	3223 (2.7)	2242 (2.7)
Arabic web	4597 (1.5)	4526 (1.4)	2703 (2.7)
Chinese newswire	3085 (2.6)	3001 (2.7)	2055 (1.4)
Chinese web	4221 (1.3)	4285 (1.3)	3092 (1.2)

5 Results

Three baseline systems were trained using the three different aligners. Case insensitive BLEU and TER scores for Arabic newswire, Arabic weblog, Chinese newswire, and Chinese weblog are shown in Tables 2, 3, 4, and 5, respectively[2]. The BLEU scores on the `Test` set are fairly similar but the ordering between different alignment algorithms is mixed between different languages and genres. To compare the two alignment combination strategies, we trained a system using the union of the rules extracted from the alternative alignments (`union` in the tables) and a combination of the three baseline system outputs (`3 syscomb` in the tables). The system with the unioned grammar was also added as an additional system in the combination marked by `4 syscomb`.

As seen in the tables, unioned grammar and system combination improve MT on both languages (Arabic and Chinese) and both genres (newswire and weblog). While there are improvements on both `SysCombTune` and `Test`, the results on `SysCombTune` are not totally fair since it was used for tuning system combination weights and as validation for optimizing weights of the MT systems. Therefore our discussion will focus on results on `Test`. (We did not show scores on `Tune` because systems were directly tuned on it.) Statistical significance is determined at 95% confidence level using the bootstrap method described in Koehn (2004), and is only applied on results obtained on the blind `Test` set.

For unioned grammar, the overall improvement in BLEU is modest, ranging from 0.1 to 0.6 point compared with the best baseline system, with little change in TER score. The improvements in BLEU score are statistically significant for Arabic (both genres), but not for Chinese. The improvements in TER are not significant for either language.

System combination produces bigger improvements in performance. Compared with the best baseline system, the improvement in BLEU ranges from 0.8 to 1.6 point. There are also noticeable improvements in TER, around 1.0 point. The TER improvements are mostly explained by the hypothesis alignment algorithm which is closely related to TER scoring (Rosti et al., 2009). The results are interesting because all three baseline systems (GIZA++, HMM and ITG) are identical except for the word alignments used in rule extraction. The results confirm that the aligners are indeed complementary, as we conjectured earlier. Also, the four-system combination yields consistent gains over the three-system combination, suggesting that the system using the unioned grammar is somewhat complementary to the three baseline systems. The statistical test indicates that both the three and four system combinations are significantly better than the single best alignment system for all languages and genres in BLEU and TER. In most cases, they are also significantly better than unioned grammar.

Somewhat surprisingly, the GIZA++ trained system is slightly better than the ITG trained system on all genres but Chinese weblog. However, we should point out that such a comparison is not entirely fair. First, we only ran ITG on short sentences. (For long sentences, we had to settle for HMM alignments for computing reasons.) Second, the hand-aligned data used for ITG training are not very clean, as we said before. The ITG results could be improved if these problems were not present.

[2] Dagger (†) indicates statistically better results than the best individual alignment system. Double dagger (‡) indicates statistically better results than both best individual alignment and unioned grammar. Bold indicates best Test set performance among individual alignment systems.

5.1 Discussion

Inter-aligner agreements provide additional evidence about the differences between the aligners. Suppose on a common data set, the sets of alignment links produced by two aligners are A and B, we compute their agreement as $(|A \bigcap B|/|A| + |A \bigcap B|/|B|)/2$. (This is the average of recall and precision of one set by treating the other set as reference.) The agreement between GIZA++ and ITG is around 78% on a subset of the Arabic-English parallel data. The agreements between GIZA++ and HMM, and between HMM and ITG are slightly higher, around 83%. Since ITG could not align long sentences, we only used short sentences (at most 60 words in length) in our calculation.

Due to the large differences between the aligners, significantly more rules were extracted with the unioned grammar method in our experiments. On average, the size of the grammar (number of rules) was increased by about 80% compared with the baseline systems. The larger grammar results in more combinations of partial theories in decoding. However, for computing reasons, we kept the beam size of the decoder constant despite the increase in grammar size, potentially pruning out good theories. Performance could be improved further if larger beam sizes were used. We will leave this to future work.

6 Related Work

Ayan and Dorr (2006) described a method to minimize alignment errors by combining alternative alignments into a single alignment for each sentence pair. Deng and Zhou (2009) used the number of extractable translation pairs as the objective function for alignment combination. Och and Ney (2003) and Koehn et al. (2003) used heuristics to merge the bidirectional GIZA++ alignments into a single alignment. Despite differences in algorithms and objective functions in these studies, they all attempted to produce a single final alignment for each sentence pair. In comparison, all alternative alignments are directly used by the translation system in this work.

The unioned grammar method in this work is very similar to Giménez and Màrquez (2005), which combined phrase pairs extracted from different alignments into a single phrase table. The difference from that work is that our focus is to leverage complementary alignment algorithms, while theirs was to leverage alignments of different lexical units produced by the same aligner.

Some studies leveraged other types of differences between systems to improve MT. For example, de Gispert et al. (2009) combined systems trained with different tokenizations.

The theory behind the GIZA++ aligner was due to Brown et al. (1993). The theory of Inversion Transduction Grammars (ITG) was due to Wu (1997). The ITG aligner (Haghighi et al., 2009) used in this work extended the original ITG to handle blocks of words in addition to single words. The use of HMM for word alignment can be traced as far back as to Vogel et al. (1996). The HMM aligner used in this work was due to Liang et al. (2006). It refined the original HMM alignment algorithm by jointly training two HMMs, one in each direction. Furthermore, it used a small amount of supervised data to tweak some high level parameters, although it did not directly use the supervised data in training.

7 Conclusions

We explored two methods to exploit complementary alignment algorithms. One is to extract translation rules from all alternative alignments. The other is to combine outputs of different MT systems trained using different aligners. Experiments on two language pairs and two genres show consistent improvements over the baseline systems.

Top-Down Nearly-Context-Sensitive Parsing

ec@cs.brown.edu

Abstract

We present a new syntactic parser that works left-to-right and top down, thus maintaining a fully-connected parse tree for a few alternative parse hypotheses. All of the commonly used statistical parsers use context-free dynamic programming algorithms and as such work bottom up on the entire sentence. Thus they only find a complete fully connected parse at the very end. In contrast, both subjective and experimental evidence show that people understand a sentence word-to-word as they go along, or close to it. The constraint that the parser keeps one or more fully connected syntactic trees is intended to operationalize this cognitive fact. Our parser achieves a new best result for top-down parsers of 89.4%,a 20% error reduction over the previous single-parser best result for parsers of this type of 86.8% (Roark, 2001). The improved performance is due to embracing the very large feature set available in exchange for giving up dynamic programming.

1 Introduction

We present a new syntactic parser that works top-down and left-to-right, maintaining a fully-connected parse tree for a few alternative parse hypotheses. It is a Penn treebank (Marcus et al., 1993) parser in that it is capable of parsing the Penn treebank test sets, and is trained on the now standard training set. It achieves a new best result for this parser type.

All of the commonly used statistical parsers available on the web such as the Collins(/Bikel) (Collins, 2003) Charniak-Johnson(Charniak and Johnson, 2005), and Petrov-Klein (Petrov et al., 2006), parsers use context-free dynamic programming algorithms so they work bottom up on the entire sentence. Thus they only find a complete fully-connected parse at the very end.

In contrast human syntactic parsing must be fully connected (or close to it) as people are able to apply vast amounts of real-world knowledge to the process as it proceeds from word-to-word(van Gompel and Pickering, 2007). Thus any parser claiming cognitive plausibility must, to a first approximation, work in this left-to-right top-down fashion.

Our parser obtains a new best result for top-down parsers of 89.4% (on section 23 of the Penn Treebank). This is a 20% error reduction over the previous best single-parser result of 86.8%, achieved by Rork(Roark, 2001).

Our model is in the tradition of this latter parser. The current work's superior performance is not due to any innovation in architecture but in how probability distributions are computed. It differs from Roark in its explicit recognition that by giving up context-free dynamic programming we may embrace near context sensitivity and condition on many diverse pieces of information. (It is only "near" because we still only condition on a finite amount of information.) This is made possible by use of random-forests (Amit and Geman, 1997; Breiman, 2004; Xu and Jelinek, 2004) to choose features, provide smoothing, and finally do the probability computation. To the best of our knowledge ours is the first application of random-forests to parsing.

MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

Section two describes previous work on this type of parser, and in particular gives details on the Roark architecture we use. Section three describes how random forests allow us to integrate the diverse information sources that context-sensitive parsing allows. Section four gives implementation details. Section five is devoted to the main experimental finding of the paper along with subsidiary results showing the effects of the large feature set we now may use. Finally, section six suggests that because this parser type is comparatively little explored one may hope for further substantial improvements, and proposes avenues to be explored.

2 Previous Work on Top-Down Parsing and the Roark Model

We care about top-down incremental parsing because it automatically satisfies the criteria we have established for cognitive plausibility. Before looking at previous work on this type model we briefly discuss work that does *not* meet the criteria we have set out, but which people often assume does so.

We are using the terms "top-down" and "left-to-right" following e.g., (Abney and Johnson, 1991; Roark, 2001). In particular

> In top-down strategies a node is enumerated before any of its descendents.(Abney and Johnson, 1991)

In this era of statistical parsers it is useful to think in terms of possible conditioning information. In typical bottom up CKY parsing when creating, say, a constituent X from positions i to j we may not condition on its parent. That the grammar is "context-free" means that this constituent may be used anywhere.

Using our definition, the Earley parsing algorithm(Earley, 1970), which is often cited as "top-down," is no such thing. In fact, it is long been noted that the Earley algorithm is "almost identical"(Graham et al., 1980) to CKY. Again, when Earley posits an X it may not condition on the parent.

Similarly, consider the more recent work of Nivre(Nivre, 2003) and Henderson(Henderson, 2003). The reason these are not fully-connected is the same. While they are incremental parsers, they are not top down — both are shift-reduce parsers. Consider a constituency shift-reduce mechanism. Suppose we have a context-free rule S → NP VP. As we go left-to-right various terminal and non-terminals are added to and removed from the stack until at some point the top two items are NP and VP. Then a reduce operation replaces them with S. Note that this means that *none* of the words or sub-constituents of either the NP or VP are integrated into a single overall tree until the very end. This is clearly not fully connected. Since Nivre's parser is a dependency parser this exact case does not apply (as it does not use CFG rules), but similar situations arise. In particular, whenever a word is dependent on a word that appears later in the string, it remains unconnected on the stack until the second word appears. Naturally this is transitive so that the parser can, and presumably does, process an unbounded number of words before connecting them all together.

```
parse ($w_{0,n-1}$)
$C[0](= h =< q, r, t >) \leftarrow < 1, 1, ROOT >$
for $i = 0, n$
    do while ABOVE-THRESHOLD $(h, C, N)$
        remove $h$ from $C$
        for all $x$ such that $p(x \mid t) > 0$
            let $h' =< q', r', t' >$
            where $q' = q * p(x \mid t)$,
                  $r' = \text{LAP}(t', w')$,
                  and $t' = t \circ x$
            if$(x = w)$ then $w' = w_{i+1}$
                  insert $h'$ in $N$
            else $w' = w$
                insert $h'$ in $C$
    empty $C$
    exchange $C$ and $N$
output $t(C[0])$.
```

Figure 1: Roark's Fully-Connected Parsing Algorithm

Here we follow the work of Roark (Roark, 2001) which *is* fully-connected. The basic al-

	Current hypotheses	Prob of next tree element
1	$< 1.4 * 10^{-3}, 5 * 10^{-2}$,(S (NP (NNS Terms)>	p(x=")" | t)=.64
2	$< 7 * 10^{-5}, 5 * 10^{-2}$,(S (S (NP (NNS Terms)>	
3	$< 9 * 10^{-4}, 8 * 10^{-2}$,(S (NP (NNS Terms))>	p(x=VP | t) =.88
4		p(x=S | t)= $2 * 10^{-4}$
5	$< 7 * 10^{-5}, 5 * 10^{-2}$,(S (S (NP (NNS Terms)>	
6	$< 9 * 10^{-4}, 9 * 10^{-2}$,(S (NP (NNS Terms)) (VP>	p(x=AUX | t)= .38
7	$< 7 * 10^{-5}, 5 * 10^{-2}$,(S (S (NP (NNS Terms)>	
8	$< 2 * 10^{-8}, 9 * 10^{-2}$,(S (NP (NNS Terms)) (S>	
9	$< 3 * 10^{-4}, 2 * 10^{-1}$,(S (NP (NNS Terms)) (VP (AUX >	p(x="were" | t)= .21
10	$< 7 * 10^{-5}, 5 * 10^{-2}$,(S (S (NP (NNS Terms)>	
11	$< 2 * 10^{-8}, 9 * 10^{-2}$,(S (NP (NNS Terms)) (S>	
12	$< 7 * 10^{-5}, 3 * 10^{-1}$,(S (NP (NNS Terms)) (VP (AUX were)>	

Figure 2: Parsing the second word of "Terms were not disclosed."

gorithm is given in Figure 1. (Note we have simplified the algorithm in several ways.) The input to the parser is a string of n words $w_{0,n-1}$. We pad the end of the string with an end-of-sentence marker $w_n = \triangleleft$. This has the special property that $p(\triangleleft \mid t) = 1$ for a complete tree t of $w_{0,n-1}$, zero otherwise.

There are two priority queues of hypotheses, C (current), and N (next). A hypothesis h is a three-tuple $< q, r, t >$ where q is the probability assigned to the current tree t. In Figure 1 h always denotes $C[0]$ the top-most element of C. While we call t the "tree", it is a vector representation of a tree. For example, the tree (ROOT) would be a vector of two elements, ROOT and ")", the latter indicating that the constituent labeled root is completed. Thus elements of the vector are the terminals, non-terminals, and ")" — the close parenthesis element. Lastly r is the "look-ahead probability" or LAP. LAP(w,h) is (a crude estimate of) the probability that the next word is w given h. We explain its purpose below.

We go through the words one at a time. At the start of our processing of w_i we have hypotheses on C ordered by $p \cdot q$ — the probability of the hypothesis so far times an estimate q of the probability cost we encounter when trying to now integrate w_i. We remove each h from C and integrate a new tree symbol x. If $x = w_i$ it means that we have successfully added the new word to the tree and this hypothesis goes into the queue for the next word N. Otherwise h does not yet represent an extension to w_i and we put it back on C to compete with the other hypotheses waiting to be extended. The look-ahead probability LAP(h) = q is intended to keep a level playing field. If we put h back onto C it's probability p is lowered by the factor $p(x \mid h)$. On the other hand, if x is the correct symbol, q should go up, so the two should offset and h is still competitive.

We stop processing a word and move onto the next when ABOVE-THRESHOLD returns false. Without going into details, we have adopted exactly the decision criteria and associated parameters used by Roark so that the accuracy numbers presumably reflect the same amount of search. (The more liberal ABOVE-THRESHOLD, the more search, and presumably the more accurate results, everything else being equal.)

Figure 2 shows a few points in the processing of the second word of "Terms were not disclosed." Lines one and two show the current queue at the start of processing. Line one has the ultimately correct partial tree (S (NP (NNS Terms). Note that the NP is not closed off as the parser defers closing constituents until necessary. On the right of line 1 we show the possible next tree pieces that could be added. Here we simply have one, namely a right parenthesis to close off the NP. (In reality there would be many such x's.) The result is that the hypothesis of line 1 is removed from the queue, and a new hypothesis is added back on C as this new hypothesis does not incorporate the second word.

Lines 3 and 5 now show the new state of C. Again we remove the top candidate from C. The right-hand side of lines 3 and 4 show two possible continuations for the h of line 3, start a new VP or a new S. With line 3 removed from the queue, and its two extensions added, we get the new queue state shown in lines 6,7 and 8. Line 6 shows the top-most hypothesis extended by an AUX. This still has not yet incorporated the next word into the parse, so this extension is inserted in the current queue giving us the queue state shown in 9,10,11. Finally line 9 is extended with the word "were." This addition incorporates the current word, and the resulting extension, shown in line 12 is inserted in N, not C, ending this example.

3 Random Forests

The Roark model we emulate requires the estimation of two probability distributions: one for the next tree element (non-terminals,terminals, and ")") in the grammar, and one for the look-ahead probability of the yet-to-be-incorporated next word. In this section we use the first of these for illustration.

We first consider how to construct a single (non-random) decision tree for estimating this distribution. A tree is a fully-connected directed acyclic graph where each node has one input arc (except for the root) and, for reasons we go into later, either zero or two output arcs — the tree is binary. A node is a four-tuple $< d, s, p, q >$, where d is a set of training instances, p, a probability distribution of the correct decisions for all of the examples in d, and q a binary question about the conditioning information for the examples in d. The 0/1 answer to this question causes the decision-tree program to follow the left/right arc out of the node to the children nodes. If q is null, the node is a leaf node. s is a strict subset of the domain of the q for the parent of h.

Decision tree construction starts with the root node n where d consists of the several million situations in the training data where the next tree element needs to be guessed (according to our probability distribution) based upon previous words and the analysis so far. At each iteration one node is selected from a queue of unprocessed nodes. A question q is selected, and based upon its answers two descendents n_1 and n_2 are created with d_1 and d_2 respectively, $d_1 \cup d_2 = d$. These are inserted in the queue of unprocessed nodes and the process repeats. Termination can be handled in multiple ways. We have chosen to simply pick the number of nodes we create. Nodes left on the queue are the leaf nodes of the decision tree. We pick nodes from the heap based upon how much they increased the probability of the data.

Still open is the selection of q at each iteration. First pick a query type qt from a user supplied set. In our case there are 27 types. Examples include the parent of the non-terminal to be created, its predecessor, 2 previous, etc. A complete list is given in Figure 4. Note that the answers to these queries are *not* binary.

Secondly we turn our qt into a binary question by creating two disjoint sets s_1 and s_2 $s_1 \cup s_2 = s$ where s is the domain of qt. If a particular history $h \in d$ is such that $qt(h) = x$ and $x \in s_1$ then h is put in d_1. Similarly for s_2. For example, if qt is the parent relation, and the parent in h is NP, then h goes in d_1 iff NP $\in s_1$. We create the sets s_i by initializing them randomly, and then for each $x \in s$ try moving x to the opposite set s_i. If this results in a higher data probability we keep it in its new s_i, otherwise it reverts to it's original s_i. This is repeated until no switch lowers probability. (Or were the a's are individual words, until no more than two words switch.)

We illustrate with a concrete example. One important fact quickly impressed on the cre-

No.	Q	S	p(“of”)	p(“in”)
0	1			
1	1	NN,IN	0.05	0.03
4	1	NNS,IN	0.09	0.06
12	2	RB,IN	0.17	0.11
16	3	PP,WHPP	0.27	0.18
39	20	NP,NX	0.51	0.16
40	20	S,VP	0.0004	0.19

Figure 3: Some nodes in a decision tree for $p(w_i \mid t)$

ator of parsers is the propensity of prepositional phrases (PP) headed by “of” to attach to noun phrases (NP) rather than verb phrases (VP). Here we illustrate how a decision tree for $p(w_i \mid t)$ captures this. Some of the top nodes in this decision tree are shown in Figure 3. Each line gives a node number, Q — the question asked at that node, examples of answers, and probabilities for “of” and “in”. Questions are specified by the question type numbers given in Figure 4 in the next section. Looking at node 0 we see that the first question type is 1 — parent of the proposed word. The children trees are 1 and 2. We see that prepositions (IN) have been put in node 1. Since this is a binary choice, about half the preterminals are covered in this node. To get a feel for who is sharing this node with prepositions each line gives two examples. For node 1 this includes a lot of very different types, including NN (common singular noun).

Node 1 again asks about the preterminal, leading to node 4. At this point NN has split off, but NNS (common plural noun) is still there. Node 4 again asks about the preterminal, leading to node 12. By this point IN is only grouped with things that are much closer, e.g. RB (adverb).

Also note that at each node we give the probability of both “of” and “to” given the questions and answers leading to that node. We can see that the probability of “of” goes up from 0.05 at node 1 to 0.27 at node 16. The probabilities for “to” go in lockstep. By node 16 we are concentrating on prepositions heading prepositional phrases, but nothing has been asked that would distinguish between these two prepositions. However, at node 16 we ask the question “who is the grandparent” leading to nodes 39 and 40. Node 39 is restricted to the answer “noun phrase” and things that look very much like noun phrases — e.g., NX, a catchall for abnormal noun phrases, while 40 is restricted to PP’s attaching to VP’s and S’s. At this point note how the probability of “of” dramatically increases for node 39, and decreases for 40.

That the tree is binary forces the decision tree to use information about words and nonterminals one bit at a time. In particular, we can now ask for a little information about many different previous words in the sentence.

We go from a single decision tree to a random forest by creating many trees, randomly changing the questions used at every node. First note that in our greedy selection of s_i’s the outcome depends on the initial random assignment of a’s. Secondly, each qt produces its own binary version q. Rather than picking the one that raises the data probability the most, we choose it with probability m. With probability $1 - m$ we repeat this procedure on the list of q’s minus the best. Given a forest of f trees we compute the final probability by taking the average over all the trees:

$$p(x \mid t) = \frac{1}{f} \sum_{j=1,f} p^j(x \mid t)$$

where p^j denotes the probability computed by tree j.

4 Implementation Details

We have twenty seven basic query types as shown in Figure 4. Each entry first gives identification numbers for the query types followed by a description of types. The description is from the point of view of the tree entry x to be added to the tree. So the first line of Figure 4 specifies six query types, the most local of which is the label of the parent of x. For example, if we have the local context “(S (NP (DT the)” and we are assigning a probability to the preterminal after DT, (e.g., NN) then the parent of x is NP. Similarly one of the query types from line two is one-previous, which is DT. Two previous is ϵ, signifying nothing in this position.

1-6 The non-terminal of the parent, grandparent, parent^3, up to parent^6

7-10 The previous non-terminal, 2-previous, up to 4-previous

11-14 The non-terminal just prior to the parent, 2-prior, up to 4 prior

15-16 The non-terminal and terminals of the head of the previous constituent

17-18 Same, but 2 previous

19-20 Same but previous to the parent

21-22 Same but 2 previous to the parent

23-24 The non-terminal and terminal symbols just prior to the start of the current parent constituent

25 The non-terminal prior to the grandparent

26 Depth in tree, binned logarithmically

27 Is a conjoined phrase prior to parent.

Figure 4: Question types

Random forests, at least in obvious implementations, are somewhat time intensive. Thus we have restricted their use to the distribution $p(x \mid t)$. The forest size we picked is 4400 nodes. For the look-ahead probability, LAP, we use a single decision tree with greedy optimal questions and 1600 nodes.

We smooth our random forest probabilities by successively backing off to distributions three earlier in the decision tree. We use linear interpolation so

$$p_l(x \mid t) = \lambda(c_l) * \hat{p}_l(x \mid t) + (1 - \lambda(c_l)) * p_{l-3}(x \mid t)$$

Here p_l is the smoothed distribution for level l of the tree and $\hat{p}_l$ is the maximum likelihood (unsmoothed) distribution. We use Chen smoothing so the linear interpolation parameters λ are functions of the Chen number of the level l node. See (Chen and Goodman, 1996). We could back off to $l - 1$, but this would slow the algorithm, and seemed unnecessary.

Following (Klein and Manning, 2003) we handle unknown and rare words by replacing them with one of about twenty unknown word types. For example, “barricading” would be replaced by UNK-ING, denoting an unknown word ending in “ing.” Any word that occurs less than twenty times in the training corpus is considered rare. The only information that is retained about it is the parts of speech with which it has appeared. Future uses are restricted to these pre-terminals.

Because random forests have so much latitude in picking combinations of words for specific situations we have the impression that it can overfit the training data, although we have not done an explicit study to confirm this. As a mild corrective we only allow verbs appearing 75 times or more, and all other words appearing 250 times or more, to be conditioned upon in question types 16, 18, 20, 22, and 27. Because the inner loop of random-forest training involves moving a conditioning event to the other decedent node to see if this raises training data probability, this also substantially speeds up training time.

Lastly Roark obtained the results we quote here with selective use of left-corner transforms (Demers, 1977; Johnson and Roark, 2000). We also use this technique but the details differ. Roark uses left-corner transforms only for immediately recursive NP's, the most common situation by far. As it was less trouble to do so, we use them for any immediately recursive constituent. However, we are also aware that in some respects left-corner transforms work against the fully-connected tree rule as operationalizing the “understand as you go along” cognitive constraint. For example, the normal sentence initial NP serves as the subject of the sentence. However in Penn-treebank grammar style an initial NP could also be a possessive NP as in (S (NP (NP (DT The) (NN dog) (POS 's)))) Clearly this NP is *not* the subject. Thus using left corner transforms on all NP's allows the parser to conflate differing semantic situations into a single tree. To avoid this we have added the additional restriction that we only allow left-corner treatment when the head words (and thus presumably the meaning) are

	Precision	Recall	F

Figure 5: Precision/Recall measurements, Penn Treebank Section 23, Sentence length ≤ 100

the same. (Generally head-word rules dictate that the POS is the head of the possessive NP.)

5 Results and Analysis

We trained the parser on the standard sections 2-21 of the Penn Tree-bank, and tested on all sentences of length ≤ 100 of section 23. We used section 24 for development.

Figure 5 shows the performance of our model (last line, in bold) along with the performance of other parsers. The first group of results show the performance of standard parsers now in use. While our performance of 89.4% f-measure needs improvement before it would be worth-while using this parser for routine work, it has moved past the accuracy of the Collins-Bikel (Collins, 2003; Bikel, 2004) parser and is not statistically distinguishable from (Charniak, 2000).

The middle group of results in Figure 5 show a very significant improvement over the original Roark parser, (89.4% vs.86.8%). Although we have not discussed it to this point, (Collins and Roark, 2004) present a perceptron algorithm for use with the Roark architecture. As seen above (C/R Perceptron), this does not give any improvement over the original Roark model. As is invariably the case, when combined the two models perform much better than either by itself (C/R Combined — 88.8%). However we still achieve a 0.6% improvement over that result. Naturally, a new combination using our parser would almost surely register another significant gain.

Conditioning Non-terminals	Conditioning Terminals	F-measure
8	1	86.6
10	2	88.0
13	3	88.3
17	4	88.8
21	6	89.0

Figure 6: Labeled precision-recall results on section 24 of the Penn Tree-bank. All but one sentence of length ≤ 100. (Last one not parsed).

In Figure 6 we show results illustrating how parser performance improves as the probability distributions are conditioned on more diverse information from the partial trees. The first line has results when we condition on only the "closest" eight non-terminal and the previous word. We successively add more distant conditioning events. The last line (89.0% F-measure) corresponds to our complete model but since we are experimenting here on the development set the result is not the same as in Figure 5. (The result is consistent with the parsing community's observation that the test set is slightly easier than the development set — e.g., average sentence length is less.)

One other illustrative result: if we keep all system settings constant and replace the random forest mechanism by a single greedy optimal decision tree for probability computation, performance is reduced to 86.3% f-measure. While this almost certainly overstates the performance improvement due to many random trees (the system parameters could be better adjusted to the one-tree case), it strongly suggests that nothing like our performance could have been obtained without the forests in random forests.

6 Conclusions and Future Work

We have presented a new top-down left-to-right parsing model. Its performance of 89.4% is a 20% error reduction over the previous single-parser performance, and indeed is a small improvement (0.6%) over the best combination-parser result. The code is publically available.[1]

[1] http://bllip.cs.brown.edu/resources.shtml#software

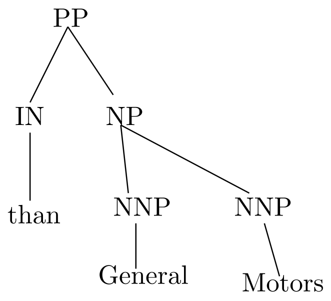

Figure 7: The start of an incorrect analysis for "than General Motors is worth"

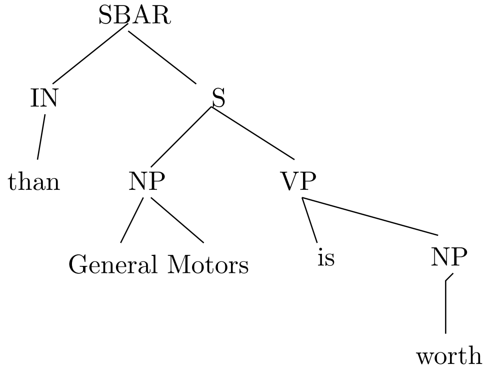

Figure 8: The correct analysis for "than General Motors is worth"

Furthermore, as models of this sort have received comparatively little attention, it seems reasonable to think that significant further improvements may be found.

One particular topic in need of more study is search errors. Consider the following example:

> The government had to spend more than General Motors is worth.

which is difficult for our parser. The problem is integrating the words starting with "than General Motors." Initially the parser believes that this is a prepositional phrase as shown in Figure 7. However, the correct tree-bank parse incorporates a subordinate sentential clause"than General Motors is worth", as in Figure 8. Unfortunately, before it gets to "is" which disambiguates the two alternatives, the subordinate clause version has fallen out of the parser's beam (unless, of course, one sets the beam-width to an unacceptably high level). Furthermore, it does not seem that there is any information available when one starts working on "than" to allow a person to immediately pick the correct continuation. It is also the case that the parsing model gives the correct parse a higher probability if it is available, showing that this is a search error, not a model error.

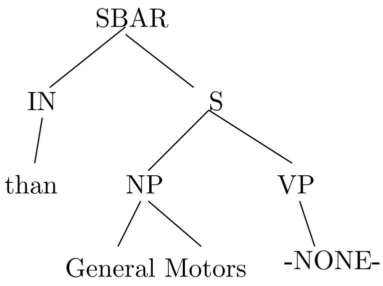

Figure 9: Alternative analysis for "than General Motors"

If there is no information that would allow a person to make the correct decision in time, perhaps people do not need to make this decision. Rather the problem could be in the treebank representation itself. Suppose we reanalyzed "than General Motors" in this context as in Figure 9. Here we would not need to guess anything in advance of the (missing) VP. Furthermore, we can make this change without loosing the great benefit of the treebank for training and testing. The change is local and deterministic. We can tree-transform the training data and then untransform before scoring. It is our impression that a few examples like this would remove a large set of current search errors.

Three other kinds of information are often added as additional annotations to syntactic trees: Penn-Treebank form-function tags, trace elements, and semantic roles. Most research on such annotation takes the parsing process as fixed and is solely concerned with improving the retrieval of the annotation in question. When they have been integrated with parsing, finding the parse and the further annotation jointly has not improved the parse. While it is certainly possible that this would prove to be the same for this new model, the use of random forests to integrate more diverse information sources might help us to reverse this state of affairs.

Finally there is no reason why we even need to stop our collection of features at sentence boundaries — information from previous sentences is there for our perusal. There are many known intra-sentence correlations, for example "sentences" that are actually fragments are much more common if the previous sentence is a question. The tense of sequential sentences main verbs are correlated. Main clause subjects are more likely to be co-referent. Certainly the "understanding" humans pick up helps them assign structure to subsequent phrases. How much, if any, of this meaning we can glean given our current (lack-of) understanding of semantics and pragmatics is an interesting question.

Abstract

We introduce a novel training algorithm for unsupervised grammar induction, called *Zoomed Learning*. Given a training set T and a test set S, the goal of our algorithm is to identify subset pairs T_i, S_i of T and S such that when the unsupervised parser is trained on a training subset T_i its results on its paired test subset S_i are better than when it is trained on the entire training set T. A successful application of zoomed learning improves overall performance on the full test set S.
We study our algorithm's effect on the leading algorithm for the task of fully unsupervised parsing (Seginer, 2007) in three different English domains, WSJ, BROWN and GENIA, and show that it improves the parser F-score by up to 4.47%.

1 Introduction

Grammar induction is the task of learning grammatical structure from plain text without human supervision. The task is of great importance both for the understanding of human language acquisition and since its output can be used by NLP applications, avoiding the costly and error prone creation of manually annotated corpora. Many recent works have addressed the task (e.g. (Klein and Manning, 2004; Seginer, 2007; Cohen and Smith, 2009; Headden et al., 2009)) and its importance has increased due to the recent availability of huge corpora.

A basic challenge to this research direction is how to utilize training data in the best possible way. Klein and Manning (2004) report results for their dependency model with valence (DMV) for unsupervised dependency parsing when it is trained and tested on the same corpus (both when sentence length restriction is imposed, such as for WSJ10, and when it is not, such as for the entire WSJ). Today's best unsupervised dependency parsers, which are rooted in this model, train on short sentences only: both Headen et al., (2009) and Cohen and Smith (2009) train on WSJ10 even when the test set includes longer sentences.

Recently, Spitkovsky et al., (2010) demonstrated that training the DMV model on sentences of up to 15 words length yields better results on the entire section 23 of WSJ (with no sentence length restriction) than training with the entire WSJ corpus.

In contrast to these dependency models, the Seginer constituency parser achieves its best performance when trained on the entire WSJ corpus either if sentence length restriction is imposed on the test corpus or not. The sentence length restriction training protocol of (Spitkovsky et al., 2010), harms this parser. When the parser is trained with the entire WSJ corpus its F-score performance on the WSJ10, WSJ20 and the entire WSJ corpora are 76, 64.8 and 56.7 respectively. When training is done with WSJ10 (WSJ20) performance degrades to 60 (72.2), 37.4 (61.9) and 29.7 (48) respectively.

In this paper we introduce the *Zoomed Learning* (ZL) technique for unsupervised parser training: given a training set T and a test set S, it identifies subset pairs T_i, S_i of T and S such that when the unsupervised parser is trained on a training subset T_i its results on its paired test subset S_i are better than when it is trained on the entire training set T. A

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 684–693,
MIT, Massachusetts, USA, 9-11 October 2010.

successful application of zoomed learning improves performance on the full test set S.

We describe ZL algorithms of increasing sophistication. In the simplest algorithm the subsets are randomly selected while in the more sophisticated versions subset selection is done using a fully unsupervised measure of constituency parse tree quality.

We apply ZL to the Seginer parser, the best algorithm for fully unsupervised constituency parsing. The input is a plain text corpus without any annotation, not even POS tagging[1], and the output is an unlabeled bracketing for each sentence.

We experiment in three different English domains: WSJ (economic newspaper), GENIA (biological articles) and BROWN (heterogeneous domains), and show that ZL improves the parser F-score by as much as 4.47%.

2 Related Work

Unsupervised parsing has attracted researchers for over a quarter of a century (see (Clark, 2001; Klein, 2005) for reviews). In recent years efforts have been made to evaluate the algorithms on manually annotated corpora such as the WSJ PennTreebank. Recent works on unlabeled bracketing or dependencies induction include (Klein and Manning, 2002; Klein and Manning, 2004; Dennis, 2005; Bod, 2006a; Bod, 2006b; Bod, 2007; Smith and Eisner, 2006; Seginer, 2007; Cohen et al., 2008; Cohen and Smith, 2009; Headden et al., 2009). Most of the works above use POS tag sequences, created either manually or by a supervised algorithm, as input. The only exception is Seginer's parser, which induces bracketing from plain text.

Our confidence-based ZL algorithms use the PUPA unsupervised parsing quality score (Reichart and Rappoport, 2009b). As far as we know, PUPA is the only unsupervised quality assessment algorithm for syntactic parsers that has been proposed. Combining PUPA with Seginer's parser thus preserves the fully unsupervised nature of the task.

Quality assessment of a learning algorithm's output has been addressed for supervised algorithms (see (Caruana and Niculescu-Mizil, 2006) for a survey) and specifically for supervised syntactic parsing (Yates et al., 2006; Reichart and Rappoport, 2007; Ravi et al., 2008; Kawahara and Uchimoto, 2008). All these algorithms are based on manually annotated data and thus do not preserve the unsupervised nature of the task addressed in this paper.

We experiment with the Seginer parser for two reasons. First, this is the best algorithm for the task of fully unsupervised parsing which motivates us to improve its performance. Second, this is the only publicly available unsupervised parser that induces constituency trees. The PUPA score we use in our confidence-based algorithms is applicable for constituency trees only. When additional constituency parsers will be made available, we will test ZL with them as well. Interestingly, the results reported for other constituency models (the CCM model (Klein and Manning, 2002) and the U-DOP model (Bod, 2006a; Bod, 2006b)) are reported when the parser is trained on its test corpus even if the sentences is that corpus are of bounded length (e.g. WSJ10). This raises the question if using more training data (e.g. the entire WSJ) wisely can enhance these models.

Recently, Spitkovsky et al., (2010) proposed three approaches for improvement of unsupervised grammar induction by considering the complexity of the training data. The approaches have been applied to the DMV unsupervised dependency parser (Klein and Manning, 2004) and improved its performance. One of these approaches is to train the model with sentences whose length is up to 15 words. As noted above, such a training protocol fails to improve the performance of the Seginer parser.

The other approaches in that paper, bootstrapping via iterated learning of increasingly longer sentences and a combination of the bootstrapping and the short sentences approaches, are not directly applicable to the Seginer parser since its training method cannot be trivially bootstrapped with parses created in former steps (Seginer, 2007).

Related machine learning methods. ZL is related to ensemble methods. Both ZL and such methods produce multiple learners, each of them trained on a different subset of the training data, and decide which learner to use for a particular test instance. Bagging (Breiman, 1996) and boosting (Freund and Schapire, 1996), where the experts utilize the same

[1] For clarity of exposition, we still refer to this corpus as our *training corpus*. In the algorithms presented in this paper, the test set is included in the training set which is a common practice in unsupervised parsing.

learning algorithm and differ in the sample of the training data they use for its training, were applied to supervised parsing (Henderson and Brill, 2000; Becker and Osborne, 2005). In Section 3 we discuss the connection of ZL to boosting.

Owing to the fact that ZL produces different learners, it is natural to use it in conjunction with an ensemble method, which is what we do in this paper with our EZL model (Section 3).

ZL is also related to active learning (AL) (Cohn and Ladner, 1994). AL also uses training subset selection, with the goal of obtaining a faster learning curve for an algorithm. AL is done in supervised settings, usually in order to minimize human annotation costs. AL algorithms providing faster learning than random subset selection for parsing have been proposed (Reichart and Rappoport, 2009a; Hwa, 2004). However, we are not aware of AL applications in which the *overall* performance on the test set has been improved. In addition, our application here is to an unsupervised problem.

Algorithms that utilize unsupervised clustering for class decomposition in order to improve classifiers' performance (e.g. (Vilalta and Rish, 2003)) are related to ZL. In such methods, examples that belong to the same class are clustered, and the induced clusters are considered as separate classes. These methods, however, have been applied only to supervised classification in contrast to our work that addresses unsupervised structured learning. Moreover, after class decomposition a classifier is trained with the entire training data while the subsets identified by a ZL algorithm are parsed by a parser trained only with the sentences they contain.

3 Zoomed Learning Algorithms

Zoomed Learning proposes that performance on a particular test instance might improve if training is done on a proper *subset* of the training set. The ZL view is clearly applicable when the training data is comprised of subsets originating from different sources having different natures. If the test data is also similarly composed, performance on any particular test instance might improve if training is done on a training subset coming from the same source. However, even when the training and test data are from the same source, a ZL algorithm may capture fine differences between subsets.

The ZL idea is therefore related to the notions of *in-domain* and *out-of-domain* (domain adaptation). In the former, the training and test data are assumed to originate from the same domain. In the latter, the test data comes from a different domain, and therefore has different statistics from the training data. Indeed, the performance of NLP algorithms in domain adaptation scenarios is markedly lower than in in-domain ones (McClosky et al., 2006).

ZL takes this observation to the extreme, assuming that a similar situation might exist *even in in-domain scenarios.* After all, a 'domain' is only a coarse qualification of the nature of a data set. In NLP, a domain is usually specified as the genre of the text involved (e.g., 'newspapers'). However, there are additional axes that might influence the statistics obtained from training data, e.g., the syntactic nature of sentences.

This section presents our ZL algorithms. We start with the simplest possible ZL algorithm where the subsets are randomly selected. We then describe ZL algorithms based on quality-based parse selection. We first detail a basic version and then an extended version consisting of another level of parse selection. Finally, we briefly discuss the PUPA quality measure that we use to evaluate the quality of a parse tree.

In all versions of the algorithm the input consists of a set T of N training sentences, a set $S \subseteq T$ of test sentences, and an integer number $N_H \leq N$.

Zoomed Learning with Random Selection (RZL). The simplest ZL algorithm randomly assigns each of the training sentences to one of n sets ($n = 2$ in this paper). More explicitly, the set number is drawn from a uniform distribution on $\{1, 2, \ldots n\}$. Each set is then parsed by a parser that is trained only with the sentences contained in that set.

The intuition behind this algorithm is that different sets of sentences are likely to manifest different syntactic patterns. Consequently, the best way to learn the syntactic patterns of any given set of sentences might be to train the parser on the sentences contained in the set.

While simple, in Section 5 it is shown to improve the performance of the Seginer parser.

The Basic Quality-Based Algorithm (BZL). The idea of the basic ZL algorithm is that sentences for which the parser provides low quality parses manifest different syntactic patterns than the sentences for which the parser provides high quality parses. The main challenge is therefore to estimate the quality of the produced parses without supervision.

The algorithm has three stages. In the first, we create the fully-trained model by training the parser using all of the N sentences of T. We then parse these N sentences using the fully-trained model.

In the second, we compute a parse confidence score for each of the N sentences, based on the N parses produced in the first stage. We divide the training sentences to two subsets: a high quality subset H consisting of the top scored N_H sentences, and a lower quality subset L consisting of the other $N_L = N - N_H$ sentences.

As is common practice for this problem (Klein and Manning, 2004; Seginer, 2007), the test set is contained in the training set. This methodology is a valid one because the training set is unannotated. Our test set is thus naturally divided into two subsets, a high quality subset HT consisting of the test set sentences contained in H and a lower quality subset LT consisting of the test set sentences contained in L.

In the third stage, each of the test subsets is parsed by a model trained only on its corresponding training subset. This stage is motivated by our assumption that the high and low quality subsets manifest dissimilar syntactic patterns, and consequently the statistics of the parser's parameters suitable for one subset differ from those suitable for another.

We compute the confidence score in the second stage using the unsupervised PUPA algorithm (Reichart and Rappoport, 2009b). POS tags for it are induced using the fully unsupervised algorithm of Clark (2003). The parser we experiment with is the incremental parser of Seginer (2007), whose input consists of raw sentences and does not include any kind of supervised POS tags (created either manually or by a supervised algorithm). Consequently, our algorithm is fully unsupervised. The only parameter it has is N_H but ZL improves parser performance for most N_H values.

BZL is related to boosting. In boosting after training one member of the ensemble, examples are reweighted such that examples that are classified correctly are down-weighted. BZL does something similar: it uses PUPA to estimate which sentences are given high quality parse trees, and down-weights examples with high (low) PUPA score to 0 when training the L-trained (H-trained) model. However, in boosting the entire test set is annotated by the same learning model, while ZL parses each test subset with a model trained on its corresponding training subset.

The Extended Quality-Based Algorithm (EZL). The basic algorithm produces an ensemble of two parsing experts: the one trained on H and the one trained on L. It uses the ensemble to parse the test set by applying the H-trained expert to HT and the L-trained expert to LT. Naturally, there are other ways to utilize the ensemble to parse the test set. In addition, even if parse trees generated by the experts are better with high probability than those of the fully trained parser, they are not guaranteed to be so. The fully trained parser is therefore also a valuable member in the ensemble. Consequently, we introduce an extended zoomed learning algorithm (EZL).

The extended version is implemented as a final fourth stage of the previously described basic algorithm. In this stage, the two test subsets are parsed by the fully trained parsing model, in addition to being parsed by the zooming parsing models. We now have two parses for each test sentence s: $P_Z(s)$, the parse created by a parser trained with the sentences contained in its corresponding training subset, and $P_F(s)$, created by the fully trained parser.

For each of the two parses of each test sentence, a confidence score is computed by PUPA. As will be reviewed below, PUPA uses a *set* of parsed sentences to compute the statistics on which its scores are based. Therefore, there are two sources for a difference between the scores of the two parse trees of a given test sentence: the difference between the trees themselves, and the difference between the parses of the other sentences in the set.

The PUPA score for $P_Z(s)$ is computed using the parses created for the sentences contained in the test subset of s by a parser trained with the corresponding training subset. The PUPA score for $P_F(s)$ is computed using the parses created for the entire test set by the fully trained parser.

The algorithm now outputs a final parse by selecting for each sentence the parse tree having the higher PUPA score.

The PUPA Confidence Score. In the second and fourth stages of the confidence-based algorithms, an unsupervised confidence score is computed for each of the induced parse trees. The confidence score algorithm we use is the POS-based Unsupervised Parse Assessment (PUPA) algorithm (Reichart and Rappoport, 2009b). We provide here a brief description of this algorithm.

The input to PUPA is a set I of parsed sentences, and its output consists of a confidence score in $[0, 1]$ assigned to each sentence in I.

The PUPA algorithm collects statistics of the syntactic structures (parse tree constituents) contained in the set I of parsed sentences. The constituent representation is based on the POS tags of the words in the yield of the constituent and of the words in the yields of neighboring constituents. We follow Reichart and Rappoport (2009b) and induce the POS tags using the fully unsupervised POS induction algorithm of Clark (2003).

The algorithm then goes over each individual tree in the set I and scores it according to the collected statistics The PUPA algorithm is guided by the idea that syntactic structures that are frequently created by the parser are more likely to be correct than structures the parser produces less frequently. Therefore, constituents that are more frequent in the set I receive higher scores after proper regularization is applied to prevent potential biases. The tree score is a combination of the scores of its constituents.

Full details of the PUPA algorithm are given in (Reichart and Rappoport, 2009b). The resulting score was shown to be strongly correlated with the extrinsic quality of the parse tree, defined to be its F-score similarity to the manually created (gold standard) parse tree of the sentence.

4 Experimental Setup

We experimented with three English corpora: the WSJ Penn Treebank (Marcus et al., 1993) consisting of economic newspaper texts, the BROWN corpus (Francis and Kucera, 1979) consisting of texts of various English genres (e.g. fiction, humor, romance, mystery and adventure) and the GENIA corpus (Kim et al., 2003) consisting of abstracts of scientific articles from the biological domain. All corpora were stripped of all annotation (bracketing and POS tags).

For all corpora we report the parser performance on the entire corpus (WSJ: 49206 sentences, BROWN: 24243 sentences, GENIA: 4661 sentences). For WSJ we also provide an analysis of the performance of the parser when applied to sentences of bounded length. These sub-corpora are WSJ10 (7422 sentences), WSJ20 (25522 sentences) and WSJ40 (47513 sentences) where WSJY denotes the subset of WSJ containing sentences of length at most Y (excluding punctuation).

Seginer's parser achieves its best reported results when trained on the full WSJ corpus. Consequently, for all corpora, we compare the performance of the parser when trained with the ZL algorithms to its performance when trained with the full corpus.

The POS tags required as input by the PUPA algorithm are induced by the fully unsupervised POS induction algorithm of Clark (2003)[2]. Reichart and Rappoport (2009b) demonstrated an unsupervised technique for the estimation of the number of induced POS tags with which the correlation between PUPA's score and the parse F-score is maximized. When exploring an experimental setup identical to our WSJ setup, they set the number of induced tags to be 5. We therefore induced 5 POS tags for each corpus, using all its sentences as input for Clark's algorithm. Our implementation of the PUPA algorithm will be made available on line.

For each corpus we performed K experiments with each of the three ZL algorithms, where K equals to the number of sentences in the corpus divided by 1000 (rounded upwards). In each experiment the size of the high quality H and lower quality L training subsets is different. H consists of the N_H top ranked sentences according to PUPA (or N_H randomly selected sentences for RZL), with N_H changing from 1000 upwards in steps of 1000. L consists of the rest of the sentences in the training corpus (WSJ). The results reported for RZL are averaged over 10 runs.

We report the parser performance on the test corpus for each training protocol. Following the unsupervised parsing literature multiple brackets and brackets covering a single word are not counted, but the sentence level bracket is. We exclude punctua-

Table 1: Performance of the EZL, BZL and RZL algorithms in the WSJ experiments (results for BROWN and GENIA are shown in Table 2). Results are presented for four test corpora WSJ10, WSJ20, WSJ40 and the entire WSJ. **Top table:** Results for various values of N_H (the number of sentences in the high quality training subset). Evaluation is performed for all sentences in the test corpora. For each algorithm, the top line is its F-score performance and the bottom line is the difference from the F-score of the fully-trained Seginer parser (denoted by F(Full)). The EZL algorithm is superior. **Bottom table:** Results for various lower quality test subsets. Presented are the differences from the F-score of the fully-trained Seginer parser. The test subsets selected by different algorithms for a specific N_H value are not necessarily identical and for the sub-corpora they are not necessarily of identical size. Reported are the improvements for the LT's of smallest size which is over 10%, 20%, and 30% of the test corpus (the top table reports results for the entire test set, which is why we can report F-scores there). The LT set size is denoted with $|LT|$.

tion and null elements as in (Klein, 2005). To evaluate the quality of a parse tree with respect to its gold standard, the unlabeled parsing F-score is used.

5 Results

Entire Corpus Results. We start by discussing the effect of ZL on the performance of the Seginer parser when no length restriction is imposed on the test corpus sentences (WSJ, BROWN and GENIA).

Table 1 (top, right section, for WSJ), Figure 1 (top line, right graph, for WSJ), and Table 2 (the left section of each table, top table for BROWN and bottom table for GENIA) present the difference between the F-score performance of the Seginer parser when trained with the ZL algorithms and the parser's performance when trained with the entire corpus.

For all test corpora and sizes of the high quality training subset (N_H), zoomed learning improves the parser performance. ZL improves the parser performance by 1.13% (WSJ), 1.46% (BROWN, the number does not appear in the table) and 4.47% (GENIA).

For WSJ, the most substantial improvement is provided by EZL, while for BROWN and GENIA the best results for some N_H values are achieved by BZL and for others by EZL (and for GENIA with small N_H values even by RZL).

Note, that for all three corpora zoomed learning with random selection (RZL) improves the parser performance on the entire test corpus, although to a lesser extent than confidence-based ZL. This is true for almost all N_H values, including those that do not appear in the tables. See Figure 1 (top line, rightmost graph) for WSJ.

We follow the unsupervised parsing literature and provide performance analysis for WSJ sentences of bounded length (WSJ10, WSJ20 and WSJ40). To prevent clutter, for BROWN and GENIA we report only entire corpus results.

Table 1 (top, left three sections) and Figure 1 (top line, three leftmost graphs) present results for WSJ10, WSJ20 and WSJ40.

The result patterns for the sub-corpora are similar to those reported for the entire WSJ corpus. EZL and BZL both improve over the fully-trained parser, and

Table 2: Results for the BROWN (top table) and GENIA (bottom table) corpora. Results are presented for the entire corpus (left column section), the low quality test subset (middle column section, LT) and the high quality test subset (right column section, HT) of each corpus, as a function of the high quality training set size (N_H). Since the tables present entire corpus results, the training and test subsets are identical.

the improvement of the former is more substantial.

Baselines. A key principle of ZL is the selection of subsets that are better parsed by a parser trained only with the sentences they contain than with a parser trained with the entire training corpus. To verify the importance of this principle we considered two alternative training protocols.

In the first, the entire test corpus is parsed with a parser that was trained with a subset of randomly selected sentences from the training set. We run this protocol for all three corpora (and for the WSJ sub-corpora) with various training set sizes and obtained substantial degradation in the parser performance. The performance monotonically increases with the training set size and reached its maximum when the entire corpus is used. We conclude that using less training material harms the parser performance if a test subset is not carefully selected.

The second protocol is the ‘less is more protocol of Spitkovsky et al., (2010) in which we parsed each test corpus using a parser that was trained with all training sentences of a bounded length. Unlike in their paper, in which this protocol improves the perofrmance of the DMV unsupervised dependency parser (Klein and Manning, 2004), for the Seginer parser the protocol harms the results. When parsing the entire WSJ with a WSJ10-trained parser or with a WSJ20-trained parser, the F-score results are 59.99% and 72.22% compared to 76.00% of the fully-trained parser. For GENIA the numbers are 15.61 and 35.87 compared to 42.71 and for BROWN they are 36.05 and 50.02 compared to 57.19 [3].

It is also interesting that sentence length is generally not a good subset selection criterion for ZL. When parsing WSJ10 with a WSJ10-trained parser, F-score results are 59.29 while the F-score of the fully-trained parser on this corpus is 76.00. The same phenomenon is observed with WSJ20 (F-score of 61.90 with WSJ20 training and of 64.82 with the entire WSJ training), and for the BROWN corpus (65.01 vs. 69.43 for BROWN10 and 61.90 vs 62.92 for BROWN20). For GENIA, however, while parsing GENIA10 with a GENIA10-trained parser harms the performance (45.28 vs. 60.23), parsing GENIA20 with a GENIA20-trained parser enhances the performance (53.23 vs. 50.00).

These results emphasize the power of random selection for ZL as random selection does provide a good selection criterion.

LT vs. HT. In what follows we analyze the ZL algorithms aiming to characterize their strengths and weaknesses.

Table 1 (bottom), the middle and right sections of Table 2 (both tables) and Figure 1 (second and third lines) present the performance of the ZL algorithms on the lower quality and higher quality test subsets (LT and HT). The results patterns for WSJ and BROWN are different than those of GENIA.

For WSJ (and its sub-corpora) and BROWN,

[3] We repeated this protocol multiple times for each corpus, training the parser with sentences of length 5 to 45 in steps of 5. In all cases we observed performance degradation compared to the fully-trained parser.

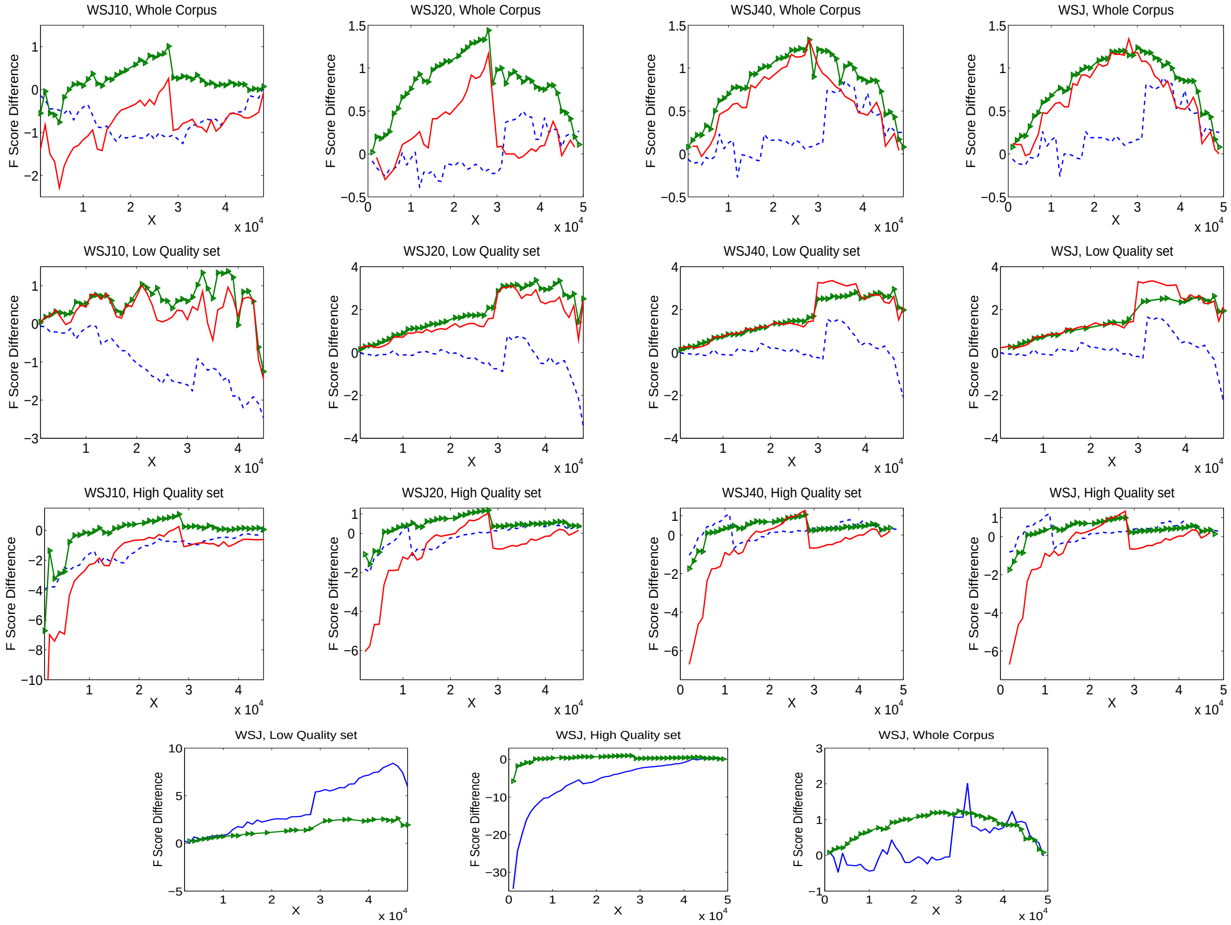

Figure 1: WSJ results. **Top Three Lines:** Difference in F-score performance of the Seginer parser between training with ZL and training with the entire WSJ corpus. Results are presented for the entire corpus (top line), the lower quality test subset (LT, middle line) and the higher quality test subset (HT, bottom line) as a function of the size of the high quality training subset $X = N_H$, measured in sentences. The curve with triangles is for the extended zoomed learning algorithm (EZL), the solid curve is for the basic zoomed learning algorithm (BZL) and the dashed curve is for zoomed learning with random selection (RZL). **Bottom line:** Comparison between the performance of the Seginer parser with the EZL algorithm (curves with triangles) and when subset selection is performed using the oracle F-score of the trees (solid curves). F-score differences from the performance of the fully trained parser are presented for the WSJ test corpus as a function of N_H, the high quality training subset size. Oracle selection is superior for the lower quality subset but inferior for the high quality subset.

confidence-based ZL (BZL and EZL) provides a substantial improvement for LT. For WSJ, F-score improvement is up to 1.32% (WSJ10), 3.13% (WSJ20), 3.35% (WSJ40) and 3.23% (the entire WSJ). For BROWN the improvement is up to 1.42%.

For HT, confidence-based ZL is less effective when these corpora are considered. As indicated in the third line of Figure 1, for WSJ and its subcorpora, EZL leads to a small improvement on HT, while BZL generally leads to a performance degradation on this test subset. For BROWN (the right section of Table 2 (top)), confidence-based ZL generally leads to a performance degradation on HT.

For GENIA, EZL and BZL improve the parser performance on both LT and HT for most N_H values. Understanding this difference is a subject for future research. Our initial hypothesis is that due to the relative small size of the GENIA corpus (4661 sentences compared 24243 and 49206 sentences of WSJ and BROWN respectively), there is more room for improvement in the parser performance on this corpus, and consequently ZL improves on both sets.

Oracle Analysis. Confidence-based ZL is based on the idea that sentences for which the fully-trained parser provides parses of similar quality manifest similar syntactic patterns. Consequently, the parser performance on a set of such sentences can be improved if it is trained only with the sentences contained in the set. An oracle experiment, where selection is based on the F-score computed using the gold standard tree instead of on the PUPA score, can shed light on the validity of this idea.

Figure 1 (bottom line) compares the performance of EZL with that of the oracle-based zoomed learning algorithm when the test corpus is the entire WSJ. For the low quality test subset, oracle selection is dramatically better than confidence-based selection. For the high quality test subset the opposite pattern holds, that is, EZL is superior. These differences lead to the entire corpus pattern where EZL is superior for most N_H values.

Oracle-based and confidence-based zoomed learning demonstrate the same trend: they improve over the baseline for LT much more than for HT. For HT, oracle-based ZL even harms results and so does BZL, which does not benefit from the averaging effect of EZL. The magnitude of the effect of oracle-based zoomed learning is much stronger. These results support our idea that training the parser on a set selected by a well-designed confidence test leads to improvement of the parser performance for the selected sentences when the fully-trained parser produces parses of mediocre quality for them.

Integration of the experimental results for zoomed learning with the three selection methods: random, confidence-based and oracle-based leads to an important conclusion that should guide future research. The more accurate the confidence score used by the zoomed learning algorithm, the more substantial is the performance improvement for the low quality test subset, at the cost of more substantial degradation in the performance on the high quality subset (but recall the different GENIA pattern which should be further explored).

EZL **Variants.** For confidence-based ZL we explored two methods for utilizing the ensemble members for generating a final parse tree for each of the test sentences. In BZL, the L-trained parser and the H-trained parser generate parse trees for LT and HT sentences respectively. In EZL, for each sentence the final parse is selected between the parse created by a parser trained with the sentences contained in its corresponding training subset, and the parse created by the fully trained parser.

There are other ways to use the ensemble members. While for all corpora it is beneficial to use the L-trained parser for the low quality test subset (LT), the results for WSJ and BROWN imply that it might be better to use the fully-trained parser or the EZL algorithm to parse the high quality test subset (HT). We have experimented with these methods and got only a minor improvement over the results reported here (improvement is more substantial for BROWN than for WSJ but does not exceed 0.5% for both). This can also be inferred from the relative minor performance degradation of BZL and EZL on HT.

We also explored a ZL scenario in which the entire test set is parsed either by the H-trained parser or by the L-trained parser. These protocols result in substantial degradation in parser performance (compared to the fully-trained parser) since the performance of the H-trained parser on LT and the performance of the L-trained parser on HT are poor.

6 Conclusions

We introduced zoomed learning – a training algorithm for unsupervised parsers. We applied three variants of ZL to the best fully unsupervised parsing algorithm (Seginer, 2007) and show an improvement of up to 4.47% in three English domains: WSJ, BROWN and GENIA.

Future research should focus on the development of more accurate estimators of parser output quality, and experimentation with different corpora, languages and parsers.

Developing a quality assessment algorithm for dependency trees will allow us to apply confidence-based ZL to unsupervised dependency parsing. Particularly, it will enable us to explore the combination of the methods proposed in (Spitkovsky et al., 2010) with ZL for the DMV model and to integrate the PUPA score into their bootstrapping algorithm.

Another direction is to apply ZL to other NLP tasks and ML areas, supervised and unsupervised.

Abstract

Parser disambiguation with precision grammars generally takes place via statistical ranking of the parse yield of the grammar using a supervised parse selection model. In the standard process, the parse selection model is trained over a hand-disambiguated treebank, meaning that without a significant investment of effort to produce the treebank, parse selection is not possible. Furthermore, as treebanking is generally streamlined with parse selection models, creating the initial treebank without a model requires more resources than subsequent treebanks. In this work, we show that, by taking advantage of the constrained nature of these HPSG grammars, we can learn a discriminative parse selection model from raw text in a purely unsupervised fashion. This allows us to bootstrap the treebanking process and provide better parsers faster, and with less resources.

1 Introduction

Parsing with precision grammars is generally a two-stage process: (1) the full parse yield of the precision grammar is calculated for a given item, often in the form of a packed forest for efficiency (Oepen and Carroll, 2000; Zhang et al., 2007); and (2) the individual analyses in the parse forest are ranked using a statistical model ("parse selection"). In the domain of treebank parsing, the Charniak and Johnson (2005) reranking parser adopts an analogous strategy, except that ranking and pruning are incorporated into the first stage, and the second stage is based on only the top-ranked parses from the first stage. For both styles of parsing, however, parse selection is based on a statistical model learned from a pre-existing treebank associated with the grammar. Our interest in this paper is in completely removing this requirement of parse selection on explicitly treebanked data, ie the development of fully unsupervised parse selection models.

The particular style of precision grammar we experiment with in this paper is HPSG (Pollard and Sag, 1994), in the form of the DELPH-IN suite of grammars (`http://www.delph-in.net/`). One of the main focuses of the DELPH-IN collaboration effort is multilinguality. To this end, the Grammar Matrix project (Bender et al., 2002) has been developed which, through a set of questionnaires, allows grammar engineers to quickly produce a core grammar for a language of their choice. Bender (2008) showed that by using and expanding on this core grammar, she was able to produce a broad-coverage precision grammar of Wambaya in a very short amount of time. However, the Grammar Matrix can only help with the first stage of parsing. The statistical model used in the second stage of parsing (ie parse selection) requires a treebank to learn the features, but as we explain in Section 2, the treebanks are created by parsing, preferably *with* a statistical model. In this work, we look at methods for bootstrapping the production of these statistical models without having an annotated treebank. Since many of the languages that people are building new grammars for are under-resourced, we can't depend on having any external information or NLP tools, and so the methods we examine are purely unsupervised, using nothing more than the grammars them-

MIT, Massachusetts, USA, 9-11 October 2010.

selves and raw text. We find that, not only can we produce models that are suitable for kick-starting the treebanking process, but the accuracy of these models is comparable to parsers trained on gold standard data (Clark and Curran, 2007b; Miyao and Tsujii, 2008), which have been successfully used in applications (Miyao et al., 2008).

2 The problem

The current method of training a parse selection model uses the [incr tsdb()] treebanking mechanism (Oepen, 2001) and works well for updating models for mature grammars, although even for these grammars, building a new model for a different domain requires a time-consuming initial treebanking effort. The treebanks used with DELPH-IN grammars are *dynamic* treebanks (Oepen et al., 2004) created by parsing text and having an annotator select the correct analysis (or discard all of them). The annotation process involves making binary decisions based on so-called parse discriminants (Carter, 1997). Whenever the grammar is changed, the treebank can be quickly updated by re-parsing and re-applying the old annotation decisions. This treebanking process not only produces gold standard trees, but also a set of non-gold trees which provides the negative training data necessary for a discriminative maximum entropy model.

The standard process for creating a parse selection model is:

1. parse the training set, recording up to 500 highest-ranking parses for each sentence;

2. treebank the training set;

3. extract features from the gold and non-gold parses;

4. learn feature weights using the TADM toolkit.[1] (Malouf, 2002)

The useful training data from this process is the parses from those sentences for which: more than one parse was found; and at least one parse has been annotated as correct. That is, there needs to be both gold and non-gold trees for any sentence to be used in training the discriminative model.

There are two issues with this process for new grammars. Firstly, treebanking takes many person-hours, and is hence both time-consuming and expensive. Complicating that is the second issue: N-best parsing requires a statistical model. While it is possible to parse exhaustively with no model, parsing is much slower, since the unpacking of results is time-consuming. Selective unpacking (Zhang et al., 2007) speeds this up a great deal, but requires a parse selection model. Treebanking is also much slower when the parser must be run exhaustively, since there are usually many more analyses to manually discard.

This work hopes to alleviate both problems. By producing a statistical model without requiring human treebanking, we can have a working and efficient parser with less human effort. Even if the top-1 parses this parser produces are not as accurate as those trained on gold standard data, this model can be used to produce the N-best analyses for the treebanker. Since our models are much better than random selection, we can afford to reduce N and still have a reasonable likelihood that the correct parse is in that top N, making the job of the treebanker much faster, and potentially leading to even better parse selection accuracy based on semi-supervised or fully-supervised parse selection.

3 Data and evaluation

Our ultimate goal is to use these methods for under-resourced languages but, since there are no pre-existing treebanks for these languages, we have no means to measure which method produces the best results. Hence, in this work, we experiment with languages and grammars where we have gold standard data, in order to be able to evaluate the quality of the parse selection models. Since we have gold-standard trained models to compare with, this enables us to fully explore how these unsupervised methods work, and show which methods are worth trying in the more time-consuming and resource-intensive future experiments on other languages. It is worth reinforcing that the gold-standard data is used for evaluation only, except in calculating the supervised parse selection accuracy as an upper-bound.

The English Resource Grammar (ERG:

[1] http://tadm.sourceforge.net/

Language	Sentences	Average words	Average parses
Japanese	6769	10.5	49.6
English	4855	9.0	59.5

Table 1: Initial model training data, showing the average word length per sentence, and also the ambiguity measured as the average number of parses found per sentence.

Flickinger (2002)) is an HPSG-based grammar of English that has been under development for many person years. In order to examine the cross-lingual applicability of our methods, we also use Jacy, an HPSG-based grammar of Japanese (Siegel and Bender, 2002). In both cases, we use grammar versions from the "Barcelona" release, from mid-2009.

3.1 Training Data

Both of our grammars come with statistical models, and the parsed data and gold standard annotations used to create these models are freely available. As we are trying to simulate a fully unsupervised setup, we didn't want any influence from these earlier models. Hence, in our experiments we used the parsed data from those sentences that received less than 500 parses and ignored any ranking, thus annulling the effects of the statistical model. This led to a reduced data set, both in the number of sentences, and in the fact that the more ambiguous sentences were discarded, but it allows clean comparison between different methods, without incorporating external information. The details of our training sets are shown in Table 1,[2] indicating that the sentence lengths are relatively short, and hence the ambiguity (measured as average parses per sentence) is low for both our grammars. The ambiguity figures also suggest that the Japanese grammar is more constrained (less ambiguous) than the English grammar, since there are, on average, more parses per sentence for English, even with a lower average sentence length.

3.2 Test Data

The test data sets used throughout our experiments are described in Table 2. The *tc-006* data set is from the same Tanaka Corpus (Tanaka, 2001) which was used for the Japanese training data. There is a wider variety of treebanked data available for the English grammar than for the Japanese. We use the *jhpstg$_t$* data set, which consists of text from Norwegian tourism brochures, from the same LOGON corpus as the English training data (Oepen et al., 2004). In order to have some idea of domain effects, we also use the *catb* data set, the text of an essay on open-source development.[3] We see here that the sentences are longer, particularly for the English data. Also, since we are not artificially limiting the parse ambiguity by ignoring those with 500 or more parses, the ambiguity is much higher. This ambiguity figure gives some indication of the difficulty of the parse selection task. Again we see that the English sentences are more ambiguous, much more in this case, making the parse selection task difficult. In fact, the English ambiguity figures are an under-estimate, since some of the longer sentences timed out before producing a parse count. This ambiguity can be a function of the sentence length or the language itself, but also of the grammar. A more detailed and informative grammar makes more distinctions, not all of which are relevant for every analysis.

Test Set	Language	Sentences	Average words	Average parses
tc-006	Japanese	904	10.7	383.9
jhpstg$_t$	English	748	12.8	4115.1
catb	English	534	17.6	9427.3

Table 2: Test data, showing the average word length per sentence, and also the ambiguity measured as the average number of parses found per sentence. Note that the ambiguity figures for the English test sets are under-estimates, since some of the longer sentences timed out before giving an analysis count.

3.3 Evaluation

The exact match metric is the most common accuracy metric used in work with the DELPH-IN tool set, and refers to the percentage of sentences for which the top parse matched the gold parse in every way. This is akin to the sentence accuracy that is occasionally reported in the parsing literature, except

[2] Any sentences that do not have both gold and non-gold analyses (ie, had no correct parse, only one parse, or none) are not included in these figures.

[3] The Cathedral and the Bazaar, by Eric Raymond. Available from: `http://catb.org/esr/writings/cathedral-bazaar/`

that it also includes fine-grained syntactico-semantic features that are not often present in other parsing frameworks. Exact match is a useful metric for parse selection evaluation, but it is very blunt-edged, and gives no way of evaluating *how close* the top parse was to the gold standard. Since these are very detailed analyses, it is possible to get one detail wrong and still have a useful analysis. Hence, in addition to exact match, we also use the EDM$_{NA}$ evaluation defined by Dridan (2009). This is a predicate–argument style evaluation, based on the semantic output of the parser (MRS: Minimal Recursion Semantics (Copestake et al., 2005)). This metric is broadly comparable to the predicate–argument dependencies of CCGBank (Hockenmaier and Steedman, 2007) or of the ENJU grammar (Miyao and Tsujii, 2008), and also somewhat similar to the grammatical relations (GR) of the Briscoe and Carroll (2006) version of DepBank. The EDM$_{NA}$ metric matches triples consisting of predicate names and the argument type that connects them.[4]

4 Initial Experiments

All of our experiments are based on the same basic process: (1) for each sentence in the training data described in Section 3.1, label a subset of analyses as correct and the remainder as incorrect; (2) train a model using the same features and learner as in the standard process of Section 2; (3) parse the test data using that model; and (4) evaluate the accuracy of the top analyses. The differences lay in how the 'correct' analyses are selected each time. Each of the following sections detail different methods for nominating which of the (up to 500) analyses from the training data should be considered pseudo-gold for training the parse selection model.

4.1 Upperbound and baseline models

As a first step we evaluated each data set using an upperbound and a baseline model. The upperbound model in this case is the model trained with gold standard annotations. These accuracy figures are slightly lower than others found in the literature for this data, since, to allow for comparison, we limited the training data to the sets described in Table 1. By throwing out those sentences with more than 500 parses, we exclude much of the data that is used in the standard model and so our exact match figures are slightly lower than might be expected.

Test Set	**Exact**	**EDM**		
	Match	**Precision**	**Recall**	**F-score**
tc-006	72.90	0.961	0.957	0.959
jhpstg$_t$	48.07	0.912	0.908	0.910
catb	22.29	0.838	0.839	0.839

Table 3: Accuracy of the gold standard-based parse selection model.

Test Set	**Exact**	**EDM**		
	Match	**Precision**	**Recall**	**F-score**
tc-006	17.26	0.779	0.839	0.807
jhpstg$_t$	12.48	0.720	0.748	0.734
catb	8.30	0.646	0.698	0.671

Table 4: Accuracy of the baseline model, trained on randomly selected pseudo-gold analyses.

For the baseline model, we used random selection to select our gold analyses. For this experiment, we randomly assigned one parse from each sentence in the training data to be correct (and the remainder of analyses as incorrect), and then used that 'gold standard' to train the model. Results for the upperbound and baseline models are shown in Tables 3 and 4.

As expected, the results for Japanese are much higher, since the lower ambiguity makes this an easier task. The *catb* test set results suffer, not only from being longer, more ambiguous sentences, but also because it is completely out of the domain of the training data.

The exact match results from the random baseline are approximately what one might expect, given the respective ambiguity levels in Table 2. The EDM figures are perhaps higher than might be expected given random selection from the entire parse forest. This results from using a precision grammar, with an inbuilt notion of grammaticality, hence constraining the parser to only produce somewhat reasonable parses, and creating a reasonably high baseline for our parse selection experiments.

We also tried a separate baseline, eliminating the parse selection model altogether, and using random selection directly to select the top analysis. The exact match and EDM precision results were slightly lower than using random selection to train a model,

[4] The full EDM metric also includes features such as tense and aspect, but this is less comparable to the other metrics mentioned.

which may be due to the learner giving weight to features that are common across the training data, but the differences weren't significant. Recall was significantly lower when using random selection directly, due to the time outs caused by running without a model. For this reason, we use the random selection-based model results as our baseline for the other unsupervised parse selection models, noting that correctly identifying approximately three quarters of the dependencies in the *jhpstg*$_t$ set, and over 80% when using the Japanese grammar, is a fairly high baseline.

4.2 First attempts

As a first approach to unsupervised parse selection, we looked at two heuristics to designate some number of the analyses as 'gold' for training. Both of these heuristics looked independently at the parses of each sentence, rather than calculating any numbers across the whole training set.

The first method builds on the observation from the random selection-based model baseline experiment that just giving weight to common features could improve parser accuracy. In this case, we looked at the edges of the parsing chart. For each sentence, we counted the number of times an edge was present in an analysis, and used that number (normalised by the total number of times any edge was used) as the *edge weight*. We then calculated an analysis score by summing the edge weights of all the edges in that analysis, and dividing by the number of edges, to give an average edge weight for an analysis. All analyses that had the best analysis score for a sentence were designated 'gold'. Since it was possible for multiple analyses to have the same score, there could be multiple gold analyses for any one sentence. If all the analyses had the same score, this sentence could not be used as part of the training data. This method has the effect of selecting the parse(s) most like all the others, by some definitions the *centroid* of the parse forest. This has some relationship to the partial training method described by Clark and Curran (2006), where the most frequent dependencies where used to train a model for the C&C CCG parser. In that case, however, the dependencies were extracted only from analyses that matched the gold standard supertag sequence, rather than the whole parse forest.

Test Set	**Exact Match**		**F-score**	
	Edges	**Branching**	**Edges**	**Branching**
tc-006	17.48	21.35	0.815	0.822
jhpstg$_t$	15.27	17.53	0.766	0.780
catb	9.36	10.86	0.713	0.712

Table 5: Accuracy for each test set, measured both as percentage of sentences that exactly matched the gold standard, and f-score over elementary dependencies.

The second heuristic we tried is one often used as a baseline method: degree of right (or left) branching. In this instance, we calculated the degree of branching as the number of right branches in a parse divided by the number of left branches (and vice versa for Japanese, a predominantly left-branching language). In the same way as above, we designated all parses with the best branching score as 'gold'. Again, this is not fully discriminatory, and it was common to get multiple gold trees for a given sentence.

Table 5 shows the results for these two methods. All the results show an improvement over the baseline, with all but the F-score for the Edges method of *tc-006* being at a level of statistical significance.[5] The only statistically significant difference between the Edges and Branching methods is over the *jhpstg*$_t$ data set. While improvement over random is encouraging, the results were still uninspiring and so we moved on to slightly more complex methods, described in the next section.

5 Supertagging Experiments

The term *supertags* was first used by Bangalore and Joshi (1999) to describe fine-grained part of speech tags which include some structural or dependency information. In that original work, the supertags were LTAG (Schabes and Joshi, 1991) elementary trees, and they were used for the purpose of speeding up parsing by restricting the allowable leaf types. Subsequent work involving supertags has mostly focussed on this efficiency goal, but they can also be used to inform parse selection. Dalrymple (2006) and Blunsom (2007) both look at how discriminatory a tag sequence is in filtering a parse forest. This

[5] All statistical significance tests in these experiments use the computationally-intensive randomisation test described in Yeh (2000), with $p < 0.05$.

work has shown that tag sequences can be successfully used to restrict the set of parses produced, but generally are not discriminatory enough to distinguish a single best parse. Toutanova et al. (2002) present a similar exploration but also go on to include probabilities from a HMM model into the parse selection model as features. There has also been some work on using lexical probabilities for domain adaptation of a model (Hara et al., 2007; Rimell and Clark, 2008). In Dridan (2009), tag sequences from a supertagger are used together with other factors to re-rank the top 500 parses from the same parser and English grammar we use in this research, and achieve some improvement in the ranking where tagger accuracy is sufficiently high. We use a similar method, one level removed, in that we use the tag sequences to select the 'gold' parse(s) that are then used to train a model, as in the previous sections.

5.1 Gold Supertags

In order to test the viability of this method, we first experimented using gold standard tags, extracted from the gold standard parses. Supertags come in many forms, depending on both the grammar formalism and the implementation. For this work, we use HPSG lexical types (lextypes), the native word classes in the grammars. These lextypes encode part of speech and subcategorisation information, as well as some more idiosyncratic features of words, such as restrictions on preposition forms, mass/count distinctions and comparative versus superlative forms of adjectives. As a few examples from the English grammar, `v_np_le` represents a basic transitive verb, while `n_pp_c-of_le` represents a count noun that optionally takes a prepositional phrase complement headed by *of*. The full definition of a lextype consists of a many-featured AVM (attribute value matrix), but the type names have been deliberately chosen to represent the main features of each type. In the Dridan (2009) work, parse ranking showed some improvement when morphological information was added to the tags. Hence, we also look at more fine-grained tags constructed by concatenating appropriate morphological rules onto the lextypes, as in `v_np_le:past_verb_orule` (ie a simple transitive verb with past tense).

We used these tags by extracting the tag sequence from the leaf types of all the parses in the forest, marking as 'gold' any parse that had the same sequence as the gold standard parse and then training the models as before. Table 6 shows the results from parsing with models based on both the basic lextype and the lextype with morphology. The results are promising. They still fall well below training purely on gold standard data (at least for the in-domain sets), since the tag sequences are not fully discriminatory and hence noise can creep in, but accuracy is significantly better than the heuristic methods tried earlier. This suggested that, at least with a reasonably accurate tagger, this was a viable strategy for training a model. With no significant difference between the basic and +morph versions of the tag set, we decided to use the basic lextypes as tags, since a smaller tag set should be easier to tag with. However, we first had to train a tagger, without using any gold standard data.

Test Set	Exact Match		F-score	
	lextype	+morph	lextype	+morph
tc-006	40.49	41.37	0.903	0.903
jhpstg$_t$	32.93	32.93	0.862	0.858
catb	20.41	19.85	0.798	0.794

Table 6: Accuracy using gold tag sequence compatibility to select the 'gold' parse(s).

5.2 Unsupervised Supertagging

Research into unsupervised part-of-speech tagging with a tag dictionary (sometimes called weakly supervised POS tagging) has been going on for many years (cf Merialdo (1994), Brill (1995)), but generally using a fairly small tag set. The only work we know of on unsupervised tagging for the more complex *supertags* is from Baldridge (2008), and more recently, Ravi et al. (2010a). In this work, the constraining nature of the (CCG) grammar is used to mitigate the problem of having a much more ambiguous tag set. Our method has a similar underlying idea, but the implementation differs both in the way we extract the word-to-tag mappings, and also how we extract and use the information from the grammar to initialise the tagger model.

We chose to use a simple first-order Hidden Markov Model (HMM) tagger, using the implementation of Dekang Lin,[6] which re-estimates probabilities, given an initial model, using the Baum-Welch variant of the Expectation-Maximisation (EM) algorithm. One possibility for an initial model was to extract the word-to-lextype mappings from the grammar lexicon as Baldridge does, and make all starting probabilities uniform. However, our lexicon maps between lextypes and *lemmas*, rather than inflected word forms, which is what we'd be tagging. That is to say, from the lexicon we could learn that the lemma *walk* can be tagged as `v_pp*_dir_le`, but we could not directly extract the fact that therefore *walked* should also receive that tag.[7] For this reason, we decided it would be simplest to initialise our probability estimates using the output of the parser, feeding in only those tag sequences which are compatible with analyses in the parse forest for that item. This method takes advantage of the fact that, because the grammars are heavily constrained, the parse forest only contains viable tag sequences. Since parsing without a model is slow, we restricted the training set to those sentences shorter than a specific word length (12 for English and 15 for Japanese, since that was the less ambiguous grammar and hence faster).

Table 7 shows how much parsed data this gave us. From this parsed data we extracted tag-to-word and tag-to-tag frequency counts from all parses for all sentences, and used these frequencies to produce the emission and transition probabilities, respectively. The emission probabilities were taken directly from the normalised frequency counts, but for the transition probabilities we allow for all possible transitions, and add one to all counts before normalising. This model we call our *initial counts* model. The *EM trained* model is then produced by starting with this initial model and running the Baum-Welch algorithm using raw text sentences from the training corpus.

5.3 Supertagging-based parse selection models

We use both the *initial counts* and *EM trained* models to tag the training data from Table 1 and then compared this with the extracted tag sequences used in the gold tag experiment. Since we could no longer assume that our tag sequence would be present within the extracted tag sequences, we used the percentage of tokens from a parse whose lextype matched our tagged sequence as the parse score. Again, we marked as 'gold' any parse that had the best parse score for each sentence, and trained a new parse selection model.

	Japanese	**English**
Parsed Sentences	9760	3770
Average Length	9.63	6.36
Average Parses	80.77	96.29
Raw Sentences	13500	9410
Raw Total Words	146053	151906

Table 7: Training data for the HMM tagger (both the parsed data from which the initial probabilities were derived, and the raw data which was used to estimated the *EM trained* models).

	Exact Match		**F-score**	
Test Set	**Initial counts**	**EM trained**	**Initial counts**	**EM trained**
tc-006	32.85	40.38	0.888	0.898
jhpstg$_t$	26.29	24.04	0.831	0.827
catb	14.61	14.42	0.782	0.783

Table 8: Accuracy using tag sequences from a HMM tagger to select the 'correct' parse(s). The *initial counts* model was based on using counts from a parse forest to approximate the emission and transition probabilities. The *EM trained* model used the Baum Welch algorithm to estimate the probabilities, starting from the initial counts state.

Table 8 shows the results of parsing with these models. The results are impressive, significantly higher than all our previous unsupervised methods.

Interestingly, we note that there is no significant difference between the *initial count* and *EM trained* models for the English data. To explore why this might be so, we looked at the tagger accuracy for both models over the respective training data sets, shown in Table 9. The results are not conclusive. For both languages, the *EM trained* model is *less* accurate, though not significantly so for Japanese. However, this insignificant tagger accuracy decrease for Japanese produced a significant *increase* in parser accuracy, while a more pronounced tagger accuracy decrease had no significant effect on parser accuracy in English.

[6] Available from `http://webdocs.cs.ualberta.ca/~lindek/hmm.htm`

[7] Morphological processing occurs before lexicon lookup in the PET parser.

Language	Initial counts	EM trained
Japanese	84.4	83.3
English	71.7	64.6

Table 9: Tagger accuracy over the training data, using both the *initial counts* and the *EM trained* models.

There is much potential for further work in this direction, experimenting with more training data or more estimation iterations, or even looking at different estimators as suggested in Johnson (2007) and Ravi et al. (2010b). There is also the issue of whether tag accuracy is the best measure for indicating potential parse accuracy. The Japanese parsing results are already equivalent to those achieved using gold standard tags. It is possible that parsing accuracy is reasonably insensitive to tagger accuracy, but it is also possible that there is a better metric to look at, such as tag accuracy over frequently confused tags.

6 Discussion

The results of Table 8 show that, using no human annotated data, we can get exact match results that are almost half way between our random baseline and our gold-standard-trained upperbound. EDM F-scores of 90% and 83% over in-domain data compare well with dependency-based scores from other parsers, although a direct comparison is very difficult to do (Clark and Curran, 2007a; Miyao et al., 2007). It still remains to see whether this level of accuracy is good enough to be useful. The main aim of this work is to bootstrap the treebanking process for new grammars, but to conclusively show the efficacy of our methods in that situation requires a long-term experiment that we are now starting, based on the results we have here. Another possible use for these methods was alluded to in Section 2: producing a new model for a new domain.

Results at every stage have been much worse for the *catb* data set, compared to the other jhpstg_t English data set. While sentence length plays some part, the major reason for this discrepancy was domain mismatch between the training and test data. One method that has been successfully used for domain adaption in parsing is self-training (McClosky et al., 2006). In this process, data from the new domain is parsed with the parser trained on the old domain, and then the top analyses of the parsed new domain data are added to the training data, and the parser is re-trained. This is generally considered a semi-supervised method, since the original parser is trained on gold standard data. In our case, we wanted to test whether parsing data from the new domain using our *unsupervised* parse selection model was accurate enough to still get an improvement using self-training for domain adaptation.

Source of ‘Gold’ Data	Exact Match	F-score
Random Selection	8.30	0.671
Supertags (*initial counts*)	14.61	0.782
Gold Standard	22.29	0.839
Self-training	15.92	0.791

Table 10: Accuracy results over the out-of-domain *catb* data set, using the *initial counts* unsupervised model to produce in-domain training data in a self-training set up. The previous results are shown for easy comparison.

It is not immediately clear what one might consider to be the ‘domain’ of the *catb* test set, since domain is generally very vaguely defined. In this case, there was a limited amount of text available from other essays by the same author.[8] While the topics of these essays vary, they all relate to the social side of technical communities, and so we used this to represent in-domain data for the *catb* test set. It is, however, a fairly small amount of data for self-training, being only around 1000 sentences. We added the results of parsing this data to the training set we used to create the *initial counts* model and again retrained and parsed. Table 10 shows the results. Previous results for the *catb* data set are given for comparison.

The results show that the completely unsupervised parse selection method produces a top parse that is at least accurate enough to be used in self-training, providing a cheap means of domain adaptation. In future work, we hope to explore this avenue of research further.

7 Conclusions and Further Work

Comparing Tables 8 and 4, we can see that for both English and Japanese, we are able to achieve parse selection accuracy well above our baseline of a ran-

[8] `http://www.catb.org/esr/writings/homesteading/`

dom selection-based model using only the information available in the grammar and raw text. This was in part because it is possible to extract a reasonable tagging model from uncorrected parse data, due to the constrained nature of these grammars. These models will hopefully allow grammar engineers to more easily build statistical models for new languages, using nothing more than their new grammar and raw text.

Since fully evaluating the potential for building models for new *languages* is a long-term ongoing experiment, we looked at a more short-term evaluation of our unsupervised parse selection methods: building models for new *domains*. A preliminary self-training experiment, using our *initial counts* tagger trained model as the starting point, showed promising results for domain adaptation.

There are plenty of directions for further work arising from these results. The issues surrounding what makes a good tagger for this purpose, and how can we best learn one without gold training data, would be one possibly fruitful avenue for further exploration. Another interesting slant would be to investigate domain effects of the tagger. Previous work has already found that training just a lexical model on a new domain can improve parsing results. Since the optimal tagger 'training' we saw here (for English) was merely to read off frequency counts for parsed data, it would be easy to retrain the tagger on different domains. Alternatively, it would be interesting so see how much difference it makes to train the tagger on one set of data, and use that to tag a model training set from a different domain. Other methods of incorporating the tagger output could also be investigated. Finally, a user study involving a grammar engineer working on a new language would be useful to validate the results we found here and confirm whether they are indeed helpful in bootstrapping a new grammar.

Uptraining for Accurate Deterministic Question Parsing

Abstract

It is well known that parsing accuracies drop significantly on out-of-domain data. What is less known is that some parsers suffer more from domain shifts than others. We show that dependency parsers have more difficulty parsing questions than constituency parsers. In particular, deterministic shift-reduce dependency parsers, which are of highest interest for practical applications because of their linear running time, drop to 60% labeled accuracy on a question test set. We propose an *uptraining* procedure in which a deterministic parser is trained on the output of a more accurate, but slower, latent variable constituency parser (converted to dependencies). Uptraining with 100K unlabeled questions achieves results comparable to having 2K labeled questions for training. With 100K unlabeled and 2K labeled questions, uptraining is able to improve parsing accuracy to 84%, closing the gap between in-domain and out-of-domain performance.

1 Introduction

Parsing accuracies on the popular Section 23 of the Wall Street Journal (WSJ) portion of the Penn Treebank have been steadily improving over the past decade. At this point, we have many different parsing models that reach and even surpass 90% dependency or constituency accuracy on this test set (McDonald et al., 2006; Nivre et al., 2007; Charniak and Johnson, 2005; Petrov et al., 2006; Carreras et al., 2008; Koo and Collins, 2010). Quite impressively, models based on deterministic shift-reduce parsing algorithms are able to rival the other computationally more expensive models (see Nivre (2008) and references therein for more details). Their linear running time makes them ideal candidates for large scale text processing, and our model of choice for this paper.

Unfortunately, the parsing accuracies of all models have been reported to drop significantly on out-of-domain test sets, due to shifts in vocabulary and grammar usage (Gildea, 2001; McClosky et al., 2006b; Foster, 2010). In this paper, we focus our attention on the task of parsing questions. Questions pose interesting challenges for WSJ-trained parsers because they are heavily underrepresented in the training data (there are only 334 questions among the 39,832 training sentences). At the same time, questions are of particular interest for user facing applications like question answering or web search, which necessitate parsers that can process questions in a fast and accurate manner.

We start our investigation in Section 3 by training several state-of-the-art (dependency and constituency) parsers on the standard WSJ training set. When evaluated on a question corpus, we observe dramatic accuracy drops exceeding 20% for the deterministic shift-reduce parsers. In general, dependency parsers (McDonald et al., 2006; Nivre et al., 2007), seem to suffer more from this domain change than constituency parsers (Charniak and Johnson, 2005; Petrov et al., 2006). Overall, the latent variable approach of Petrov et al. (2006) appears to generalize best to this new domain, losing only about 5%. Unfortunately, the parsers that generalize better to this new domain have time complexities that are cubic in the sentence length (or even higher), rendering them impractical for web-scale text processing.

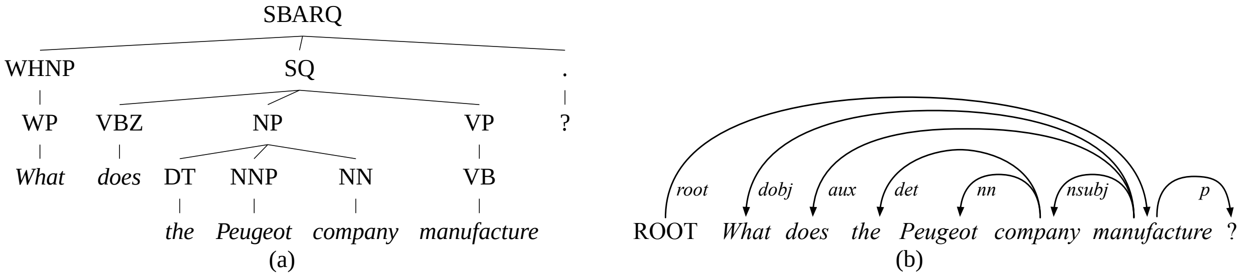

Figure 1: Example constituency tree from the QuestionBank (a) converted to labeled Stanford dependencies (b).

We therefore propose an *uptraining* method, in which a deterministic shift-reduce parser is trained on the output of a more accurate, but slower parser (Section 4). This type of domain adaptation is reminiscent of self-training (McClosky et al., 2006a; Huang and Harper, 2009) and co-training (Blum and Mitchell, 1998; Sagae and Lavie, 2006), except that the goal here is not to further improve the performance of the very best model. Instead, our aim is to train a computationally cheaper model (a linear time dependency parser) to match the performance of the best model (a cubic time constituency parser), resulting in a computationally efficient, yet highly accurate model.

In practice, we parse a large amount of unlabeled data from the target domain with the constituency parser of Petrov et al. (2006) and then train a deterministic dependency parser on this noisy, automatically parsed data. The accuracy of the linear time parser on a question test set goes up from 60.06% (LAS) to 76.94% after uptraining, which is comparable to adding 2,000 labeled questions to the training data. Combining uptraining with 2,000 labeled questions further improves the accuracy to 84.14%, fully recovering the drop between in-domain and out-of-domain accuracy.

We also present a detailed error analysis in Section 5, showing that the errors of the WSJ-trained model are primarily caused by sharp changes in syntactic configurations and only secondarily due to lexical shifts. Uptraining leads to large improvements across all error metrics and especially on important dependencies like subjects (nsubj).

2 Experimental Setup

We used the following experimental protocol throughout the paper.

2.1 Data

Our main training set consists of Sections 02-21 of the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1993), with Section 22 serving as development set for source domain comparisons. For our target domain experiments, we evaluate on the QuestionBank (Judge et al., 2006), which includes a set of manually annotated questions from a TREC question answering task. The questions in the QuestionBank are very different from our training data in terms of grammatical constructions and vocabulary usage, making this a rather extreme case of domain-adaptation. We split the 4,000 questions contained in this corpus in three parts: the first 2,000 questions are reserved as a small target-domain training set; the remaining 2,000 questions are split in two equal parts, the first serving as development set and the second as our final test set. We report accuracies on the developments sets throughout this paper, and test only at the very end on the final test set.

We convert the trees in both treebanks from constituencies to labeled dependencies (see Figure 1) using the Stanford converter, which produces 46 types of labeled dependencies[1] (de Marneffe et al., 2006). We evaluate on both unlabeled (UAS) and labeled dependency accuracy (LAS).[2]

Additionally, we use a set of 2 million questions collected from Internet search queries as unlabeled target domain data. All user information was anonymized and only the search query string was retained. The question sample is selected at random after passing two filters that select queries that are

[1] We use the Stanford Lexicalized Parser v1.6.2.

[2] Because the QuestionBank does not contain function tags, we decided to strip off the function tags from the WSJ before conversion. The Stanford conversion only uses the -ADV and -TMP tags, and removing all function tags from the WSJ changed less than 0.2% of the labels (primarily tmod labels).

similar in style to the questions in the QuestionBank: (i) the queries must start with an English function word that can be used to start a question (what, who when, how, why, can, does, etc.), and (ii) the queries have a maximum length of 160 characters.

2.2 Parsers

We use multiple publicly available parsers, as well as our own implementation of a deterministic shift-reduce parser in our experiments. The dependency parsers that we compare are the deterministic shift-reduce MaltParser (Nivre et al., 2007) and the second-order minimum spanning tree algorithm based MstParser (McDonald et al., 2006). Our shift-reduce parser is a re-implementation of the MaltParser, using a standard set of features and a linear kernel SVM for classification. We also train and evaluate the generative lexicalized parser of Charniak (2000) on its own, as well as in combination with the discriminative reranker of Charniak and Johnson (2005). Finally, we run the latent variable parser (a.k.a. BerkeleyParser) of Petrov et al. (2006), as well as the recent product of latent variable grammars version (Petrov, 2010). To facilitate comparisons between constituency and dependency parsers, we convert the output of the constituency parsers to labeled dependencies using the same procedure that is applied to the treebanks. We also report their F_1 scores for completeness.

While the constituency parsers used in our experiments view part-of-speech (POS) tagging as an integral part of parsing, the dependency parsers require the input to be tagged with a separate POS tagger. We use the TnT tagger (Brants, 2000) in our experiments, because of its efficiency and ease of use. Tagger and parser are always trained on the same data.

3 Parsing Questions

We consider two domain adaptation scenarios in this paper. In the first scenario (sometimes abbreviated as WSJ), we assume that we do not have any labeled training data from the target domain. In practice, this will always be the case when the target domain is unknown or very diverse. The second scenario (abbreviated as WSJ+QB) assumes a small amount of labeled training data from the target domain. While this might be expensive to obtain, it is certainly feasible for narrow domains (e.g. questions), or when a high parsing accuracy is really important.

3.1 No Labeled Target Domain Data

We first trained all parsers on the WSJ training set and evaluated their performance on the two domain specific evaluation sets (newswire and questions). As can be seen in the left columns of Table 1, all parsers perform very well on the WSJ development set. While there are differences in the accuracies, all scores fall within a close range. The table also confirms the commonly known fact (Yamada and Matsumoto, 2003; McDonald et al., 2005) that constituency parsers are more accurate at producing dependencies than dependency parsers (at least when the dependencies were produced by a deterministic transformation of a constituency treebank, as is the case here).

This picture changes drastically when the performance is measured on the QuestionBank development set (right columns in Table 1). As one

Our shift-reduce parser	—	83.70	78.27	91.32	—	80.44	74.29	88.80
Our shift-reduce parser (gold POS)	—	89.39	86.60	100.00	—	87.31	84.15	100.00

Table 2: Parsing accuracies for parsers trained on newswire and question data and evaluated on a question test set.

might have expected, the accuracies are significantly lower, however, the drop for some of the parsers is shocking. Most notably, the deterministic shift-reduce parsers lose almost 25% (absolute) on labeled accuracies, while the latent variable parsers lose around 12%.[3] Note also that even with gold POS tags, LAS is below 70% for our deterministic shift-reduce parser, suggesting that the drop in accuracy is primarily due to a syntactic shift rather than a lexical shift. These low accuracies are especially disturbing when one considers that the average question in the evaluation set is only nine words long and therefore potentially much less ambiguous than WSJ sentences. We will examine the main error types more carefully in Section 5.

Overall, the dependency parsers seem to suffer more from the domain change than the constituency parsers. One possible explanation is that they lack the global constraints that are enforced by the (context-free) grammars. Even though the MstParser finds the globally best spanning tree, all constraints are local. This means for example, that it is not possible to require the final parse to contain a verb (something that can be easily expressed by a top-level production of the form S → NP VP in a context free grammar). This is not a limitation of dependency parsers in general. For example, it would be easy to enforce such constraints in the Eisner (1996) algorithm or using Integer Linear Programming approaches (Riedel and Clarke, 2006; Martins et al., 2009). However, such richer modeling capacity comes with a much higher computational cost.

Looking at the constituency parsers, we observe that the lexicalized (reranking) parser of Charniak and Johnson (2005) loses more than the latent variable approach of Petrov et al. (2006). This difference doesn't seem to be a difference of generative vs. discriminative estimation. We suspect that the latent variable approach is better able to utilize the little evidence in the training data. Intuitively speaking, some of the latent variables seem to get allocated for modeling the few questions present in the training data, while the lexicalization contexts are not able to distinguish between declarative sentences and questions.

To verify this hypothesis, we conducted two additional experiments. In the first experiment, we collapsed the question specific phrasal categories SQ and SBARQ to their declarative sentence equivalents S and SBAR. When the training and test data are processed this way, the lexicalized parser loses 1.5% F_1, while the latent variable parser loses only 0.7%. It is difficult to examine the grammars, but one can speculate that some of the latent variables were used to model the question specific constructions and the model was able to re-learn the distinctions that we purposefully collapsed. In the second experiment, we removed all questions from the WSJ training set and retrained both parsers. This did not make a significant difference when evaluating on the WSJ development set, but of course resulted in a large performance drop when evaluating on the QuestionBank. The lexicalized parser came out ahead in this experiment,[4] confirming our hypothesis that the latent variable model is better able to pick up the small amount of relevant evidence that is present in the WSJ training data (rather than being systematically

[3] The difference between our shift-reduce parser and the MaltParser are due to small differences in the feature sets.

[4] The F_1 scores were 52.40% vs. 56.39% respectively.

better suited for modeling questions).

3.2 Some Labeled Target Domain Data

In the above experiments, we considered a situation where we have no labeled training data from the target domain, as will typically be the case. We now consider a situation where a small amount of labeled data (2,000 manually parsed sentences) from the domain of interest is available for training.

We experimented with two different ways of utilizing this additional training data. In a first experiment, we trained models on the concatenation of the WSJ and QuestionBank training sets (we did not attempt to weight the different corpora). As Table 2 shows (left columns), even a modest amount of labeled data from the target domain can significantly boost parsing performance, giving double-digit improvements in some cases. While not shown in the table, the parsing accuracies on the WSJ development set where largely unaffected by the additional training data.

Alternatively, one can also train models exclusively on the QuestionBank data, resulting in question specific models. The parsing accuracies of these domain-specific models are shown in the right columns of Table 2, and are significantly lower than those of models trained on the concatenated training sets. They are often times even lower than the results of parsers trained exclusively on the WSJ, indicating that 2,000 sentences are not sufficient to train accurate parsers, even for quite narrow domains.

4 Uptraining for Domain-Adaptation

The results in the previous section suggest that parsers without global constraints have difficulties dealing with the syntactic differences between declarative sentences and questions. A possible explanation is that similar word configurations can appear in both types of sentences, but with very different syntactic interpretation. Local models without global constraints are therefore mislead into dead-end interpretations from which they cannot recover (McDonald and Nivre, 2007). Our approach will therefore be to use a large amount of unlabeled data to bias the model towards the appropriate distribution for the target domain. Rather than looking for feature correspondences between the domains (Blitzer et al., 2006), we propose to use automatically labeled target domain data to learn the target domain distribution directly.

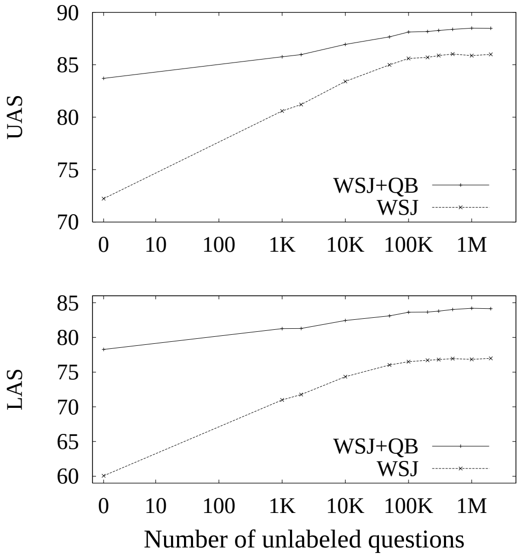

Figure 2: Uptraining with large amounts of unlabeled data gives significant improvements over two different supervised baselines.

4.1 Uptraining vs. Self-training

The idea of training parsers on their own output has been around for as long as there have been statistical parsers, but typically does not work well at all (Charniak, 1997). Steedman et al. (2003) and Clark et al. (2003) present co-training procedures for parsers and taggers respectively, which are effective when only very little labeled data is available. McClosky et al. (2006a) were the first to improve a state-of-the-art constituency parsing system by utilizing unlabeled data for self-training. In subsequent work, they show that the same idea can be used for domain adaptation if the unlabeled data is chosen accordingly (McClosky et al., 2006b). Sagae and Tsujii (2007) co-train two dependency parsers by adding automatically parsed sentences for which the parsers agree to the training data. Finally, Suzuki et al. (2009) present a very effective semi-supervised approach in which features from multiple generative models estimated on unlabeled data are combined in a discriminative system for structured prediction.

All of these approaches have in common that their ultimate goal is to improve the final performance. Our work differs in that instead of improving the

Uptraining on Petrov (2010)	85.21	76.19	90.74	88.63	84.14	93.53

Table 3: Uptraining substantially improves parsing accuracies, while self-training gives only minor improvements.

performance of the best parser, we want to build a more efficient parser that comes close to the accuracy of the best parser. To do this, we parse the unlabeled data with our most accurate parser and generate noisy, but fairly accurate labels (parse trees) for the unlabeled data. We refer to the parser used for producing the automatic labels as the base parser (unless otherwise noted, we used the latent variable parser of Petrov et al. (2006) as our base parser). Because the most accurate base parsers are constituency parsers, we need to convert the parse trees to dependencies using the Stanford converter (see Section 2). The automatically parsed sentences are appended to the labeled training data, and the shift-reduce parser (and the part-of-speech tagger) are trained on this new training set. We did not increase the weight of the WSJ training data, but weighted the QuestionBank training data by a factor of ten in the WSJ+QB experiments.

4.2 Varying amounts of unlabeled data

Figure 2 shows the efficacy of uptraining as a function of the size of the unlabeled data. Both labeled (LAS) and unlabeled accuracies (UAS) improve sharply when automatically parsed sentences from the target domain are added to the training data, and level off after 100,000 sentences. Comparing the end-points of the dashed lines (models having access only to labeled data from the WSJ) and the starting points of the solid lines (models that have access to both WSJ and QuestionBank), one can see that roughly the same improvements (from 72% to 86% UAS and from 60% to 77% LAS) can be obtained by having access to 2,000 labeled sentences from the target domain or uptraining with a large amount of unlabeled data from the target domain. The benefits seem to be complementary and can be combined to give the best results. The final accuracy of 88.63 / 84.14 (UAS / LAS) on the question evaluation set is comparable to the in-domain performance on newswire data (88.24 / 84.69).

4.3 Varying the base parser

Table 3 then compares uptraining on the output of different base parsers to pure self-training. In these experiments, the same set of 500,000 questions was parsed by different base parsers. The automatic parses were then added to the labeled training data and the parser was retrained. As the results show, self-training provides only modest improvements of less than 2%, while uptraining gives double-digit improvements in some cases. Interestingly, there seems to be no substantial difference between uptraining on the output of a single latent variable parser (Petrov et al., 2006) and a product of latent variable grammars (Petrov, 2010). It appears that the roughly 1% accuracy difference between the two base parsers is not important for uptraining.

4.4 POS-less parsing

Our uptraining procedure improves parse quality on out-of-domain data to the level of in-domain accuracy. However, looking closer at Table 3, one can see that the POS accuracy is still relatively low (93.53%), potentially limiting the final accuracy.

To remove this limitation (and also the dependence on a separate POS tagger), we experimented with word cluster features. As shown in Koo et al. (2008), word cluster features can be used in conjunction with POS tags to improve parsing accuracy. Here, we use them instead of POS tags in order to further reduce the domain-dependence of our model. Similar to Koo et al. (2008), we use the Brown clustering algorithm (Brown et al., 1992) to produce a deterministic hierarchical clustering of our input vocabulary. We then extract features based on vary-

	UAS	LAS	POS
Part-of-Speech Tags	88.35	84.05	93.53
Word Cluster Features	87.92	83.73	—

Table 4: Parsing accuracies of uptrained parsers with and without part-of-speech tags and word cluster features.

ing cluster granularities (6 and 10 bits in our experiments). Table 4 shows that roughly the same level of accuracy can be achieved with cluster based features instead of POS tag features. This change makes our parser completely deterministic and enables us to process sentences in a single left-to-right pass.

5 Error Analysis

To provide a better understanding of the challenges involved in parsing questions, we analyzed the errors made by our WSJ-trained shift-reduce parser and also compared them to the errors that are left after uptraining.

5.1 POS errors

Many parsing errors can be traced back to POS tagging errors, which are much more frequent on out-of-domain data than on in-domain data (88.8% on the question data compared to above 95.0% on WSJ data). Part of the reason for the lower POS tagging accuracy is the higher unknown word ratio (7.3% on the question evaluation set, compared to 3.4% on the WSJ evaluation set). Another reason is a change in the lexical distribution.

For example, wh-determiners (WDT) are quite rare in the WSJ training data (relative frequency 0.45%), but five times more common in the QuestionBank training data (2.49%). In addition to this frequency difference, 52.43% of the WDTs in the WSJ are the word “which” and 46.97% are“that”. In the QuestionBank on the other hand, “what” is by far the most common WDT word (81.40%), while “which” and “that” account only for 13.65% and 4.94% respectively. Not surprisingly the most common POS error involves wh-determiners (typically the word “what”) being incorrectly labeled as Wh-pronouns (WP), resulting in head and label errors like the one shown in Figure 3(a).

To separate out POS tagging errors from parsing errors, we also ran experiments with correct (gold) POS tags. The parsing accuracies of our shift-reduce parser using gold POS tags are listed in the last rows of Tables 1 and 2. Even with gold POS tags, the deterministic shift-reduce parser falls short of the accuracies of the constituency parsers (with automatic tags), presumably because the shift-reduce model is making only local decisions and is lacking the global constraints provided by the context-free grammar.

Dep. Label	Frequency	WSJ	Uptrained
nsubj	934	41.02	88.64
amod	556	78.21	86.00
dobj	555	70.10	83.12
attr	471	8.64	93.49
aux	467	77.31	82.56

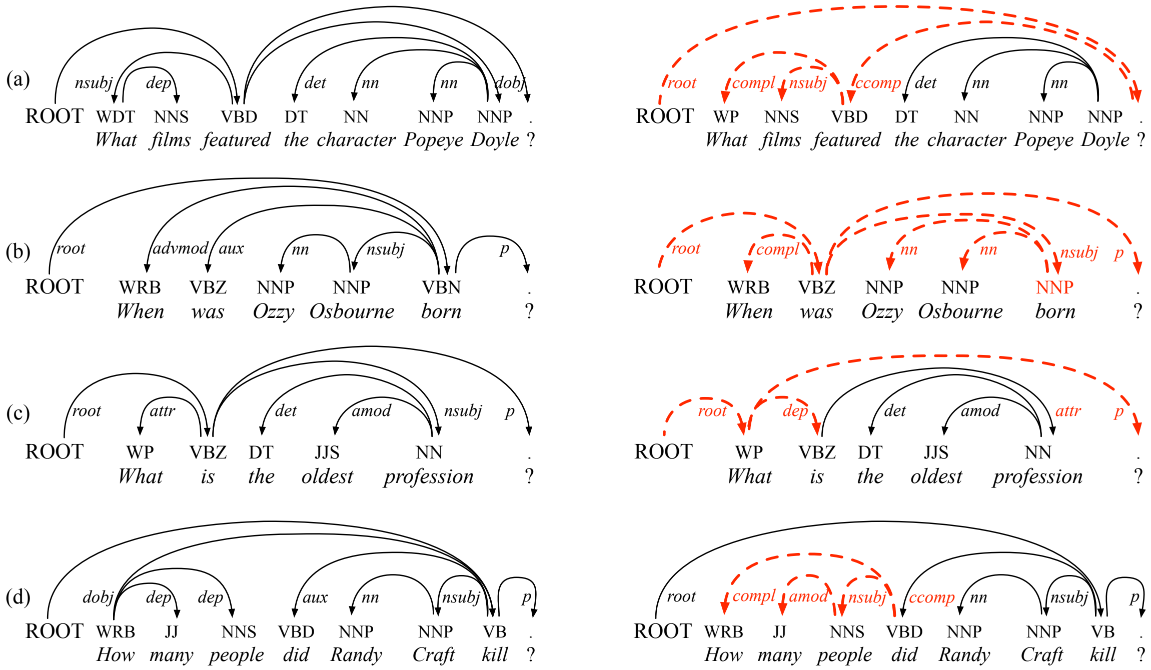
Table 5: F_1 scores for the most frequent labels in the QuestionBank development set. Uptraining leads to huge improvements compared to training only on the WSJ.

5.2 Dependency errors

To find the main error types, we looked at the most frequent labels in the QuestionBank development set, and analyzed the ones that benefited the most from uptraining. Table 5 has the frequency and F-scores of the dependency types that we are going to discuss in the following. We also provide examples which are illustrated in Figure 3.

nsubj: The WSJ-trained model is often producing parses that are missing a subject (nsubj). Questions like “What is the oldest profession?” and “When was Ozzy Osbourne born?” should have “profession” and “Osbourne” as nsubjs, but in both cases the WSJ-trained parser did not label any subj (see Figures 3(b) and 3(c)). Another common error is to mislabel nsubj. For example, the nsubj of “What are liver enzymes?” should be enzymes, but the WSJ-trained parser labels “What” as the nsubj, which makes sense in a statement but not in a question.

amod: The model is overpredicting “amod”, resulting in low precision figures for this label. An example is “How many points make up a perfect fivepin bowling score?”. The Stanford dependency uses “How” as the head of “many” in noun phrases like “How many points”, and the relation is a generic “dep”. But in the WSJ model prediction, “many’s” head is “points,” and the relation mislabeled as amod. Since it’s an adjective preceding the noun,



(a)
nsubj dep dobj det nn nn
ROOT WDT NNS VBD DT NN NNP NNP .
What films featured the character Popeye Doyle ?
root compl nsubj ccomp det nn nn

root compl amod nsubj ccomp nn nsubj p
ROOT WRB JJ NNS VBD NNP NNP VB .
How many people did Randy Craft kill ?

Figure 3: Example questions from the QuestionBank development set and their correct parses (left), as well as the predictions of a model trained on the WSJ (right).

the WSJ model often makes this mistake and therefore the precision is much lower when it doesn't see more questions in the training data.

dobj: The WSJ model doesn't predict object extraction well. For example, in "How many people did Randy Craft kill?" (Figure 3(d)), the direct object of kill should be "How many people." In the Stanford dependencies, the correct labels for this noun phrase are "dobj dep dep," but the WSJ model predicts "compl amod nsubj." This is a common error caused by the different word order in questions. The uptrained model is much better at handling these type of constructions.

attr: An attr (attributive) is a wh-noun phrase (WHNP) complement of a copular verb. In the WSJ training data, only 4,641 out of 950,028 dependencies are attr (0.5%); in the QuestionBank training data, 1,023 out of 17,069 (6.0%) are attr. As a consequence, the WSJ model cannot predict this label in questions very well.

aux: "What does the abbreviation AIDS stand for?" should have "stand" as the main head of the sentence, and "does" as its aux. However, the WSJ model labeled "does" as the main head. Similar patterns occur in many questions, and therefore the WSJ has a very low recall rate.

In contrast, mostly local labels (that are not related to question/statement structure differences) have a consistently high accuracy. For example: det has an accuracy of 98.86% with the WSJ-trained model, and 99.24% with the uptrained model.

6 Conclusions

We presented a method for domain adaptation of deterministic shift-reduce parsers. We evaluated multiple state-of-the-art parsers on a question corpus and showed that parsing accuracies degrade substantially on this out-of-domain task. Most notably, deterministic shift-reduce parsers have difficulty dealing with the modified word order and lose more than 20% in accuracy. We then proposed a simple, yet very effective *uptraining* method for domain-adaptation. In a nutshell, we trained a deterministic shift-reduce parser on the output of a more accurate, but slower parser. Uptraining with large amounts of unlabeled data gives similar improvements as having access to 2,000 labeled sentences from the target domain. With 2,000 labeled questions and a large amount of unlabeled questions, uptraining is able to close the gap between in-domain and out-of-domain accuracy.

Acknowledgements

We would like to thank Ryan McDonald for running the MstParser experiments and for many fruitful discussions on this topic. We would also like to thank Joakim Nivre for help with the MatlParser and Marie-Catherine de Marneffe for help with the Stanford Dependency Converter.

Abstract

This paper approaches the scope learning problem via simplified shallow semantic parsing. This is done by regarding the cue as the predicate and mapping its scope into several constituents as the arguments of the cue. Evaluation on the BioScope corpus shows that the structural information plays a critical role in capturing the relationship between a cue and its dominated arguments. It also shows that our parsing approach significantly outperforms the state-of-the-art chunking ones. Although our parsing approach is only evaluated on negation and speculation scope learning here, it is portable to other kinds of scope learning.

1 Introduction

Recent years have witnessed an increasing interest in the analysis of linguistic scope in natural language. The task of scope learning deals with the syntactic analysis of what part of a given sentence is under user's special interest. For example, of negation assertion concerned, a negation cue (e.g., *not*, *no*) usually dominates a fragment of the given sentence, rather than the whole sentence, especially when the sentence is long. Generally, scope learning involves two subtasks: cue recognition and its scope identification. The former decides whether a word or phrase in a sentence is a cue of a special interest, where the semantic information of the word or phrase, rather than the syntactic information, plays a critical role. The latter determines the sequences of words in the sentence which are dominated by the given cue.

Recognizing the scope of a special interest (e.g., negative assertion and speculative assertion) is essential in information extraction (IE), whose aim is to derive factual knowledge from free text. For example, Vincze et al. (2008) pointed out that the extracted information within the scope of a negation or speculation cue should either be discarded or presented separately from factual information. This is especially important in the biomedical and scientific domains, where various linguistic forms are used extensively to express impressions, hypothesized explanations of experimental results or negative findings. Besides, Vincez et al. (2008) reported that 13.45% and 17.70% of the sentences in the abstracts subcorpus of the BioScope corpus contain negative and speculative assertions, respectively, while 12.70% and 19.44% of the sentences in the full papers subcorpus contain negative and speculative assertions, respectively. In addition to the IE tasks in the biomedical domain, negation scope learning has attracted increasing attention in some natural language processing (NLP) tasks, such as sentiment classification (Turney, 2002). For example, in the sentence "*The chair is not comfortable but cheap*", although both the polarities of the words "*comfortable*" and "*cheap*" are positive, the polarity of "the chair" regarding the attribute "*cheap*" keeps positive while the polarity of "the chair" regarding the attribute "*comfortable*" is reversed due to the negation cue "*not*". Similarly, seeing the increasing interest in speculation scope learning, the CoNLL'2010 shared task (Farkas et al., 2010) aims to detect uncertain information in resolving the scopes of speculation cues.

Most of the initial research in this literature focused on either recognizing negated terms or identifying speculative sentences, using some heuristic

rules (Chapman et al., 2001; Light et al., 2004), and machine learning methods (Goldin and Chapman, 2003; Medlock and Briscoe, 2007). However, scope learning has been largely ignored until the recent release of the BioScope corpus (Szarvas et al., 2008), where negation/speculation cues and their scopes are annotated explicitly. Morante et al. (2008) and Morante and Daelemans (2009a & 2009b) pioneered the research on scope learning by formulating it as a chunking problem, which classifies the words of a sentence as being inside or outside the scope of a cue. Alternatively, Özgür and Radev (2009) and Øvrelid et al. (2010) defined heuristic rules for speculation scope learning from constituency and dependency parse tree perspectives, respectively.

Although the chunking approach has been evaluated on negation and speculation scope learning and can be easily ported to other scope learning tasks, it ignores syntactic information and suffers from low performance. Alternatively, even if the rule-based methods may be effective for a special scope learning task (e.g., speculation scope learning), it is not readily adoptable to other scope learning tasks (e.g., negation scope learning). Instead, this paper explores scope learning from parse tree perspective and formulates it as a simplified shallow semantic parsing problem, which has been extensively studied in the past few years (Carreras and Màrquez, 2005). In particular, the cue is recast as the predicate and the scope is recast as the arguments of the cue. The motivation behind is that the structured syntactic information plays a critical role in scope learning and should be paid much more attention, as indicated by previous studies in shallow semantic parsing (Gildea and Palmer, 2002; Punyakanok et al., 2005). Although our approach is evaluated only on negation and speculation scope learning here, it is portable to other kinds of scope learning.

The rest of this paper is organized as follows. Section 2 reviews related work. Section 3 introduces the Bioscope corpus on which our approach is evaluated. Section 4 describes our parsing approach by formulating scope learning as a simplified shallow semantic parsing problem. Section 5 presents the experimental results. Finally, Section 6 concludes the work.

2 Related Work

Most of the previous research on scope learning falls into negation scope learning and speculation scope learning.

Negation Scope Learning

Morante et al. (2008) pioneered the research on negation scope learning, largely due to the availability of a large-scale annotated corpus, the Bioscope corpus. They approached negation cue recognition as a classification problem and formulated negation scope identification as a chunking problem which predicts whether a word in the sentence is inside or outside of the negation scope, with proper post-processing to ensure consecutiveness of the negation scope. Morante and Daelemans (2009a) further improved the performance by combing several classifiers and achieved the accuracy of ~98% for negation cue recognition and the PCS (Percentage of Correct Scope) of ~74% for negation scope identification on the abstracts subcorpus. However, this chunking approach suffers from low performance, in particular on long sentences. For example, given golden negation cues on the Bioscope corpus, Morante and Daelemans (2009a) only got the performance of 50.26% in PCS on the full papers subcorpus (22.8 words per sentence on average), compared to 87.27% in PCS on the clinical reports subcorpus (6.6 words per sentence on average).

Speculation Scope Learning

Similar to Morante and Daelemans (2009a), Morante and Daelemans (2009b) formulated speculation scope identification as a chunking problem which predicts whether a word in the sentence is inside or outside of the speculation scope, with proper post-processing to ensure consecutiveness of the speculation scope. They concluded that their method for negation scope identification is portable to speculation scope identification. However, of speculation scope identification concerned, it also suffers from low performance, with only 60.59% in PCS for the clinical reports subcorpus of short sentences.

Alternatively, Özgür and Radev (2009) employed some heuristic rules from constituency parse tree perspective on speculation scope identification. Given golden speculation cues, their rule-based method achieves the accuracies of 79.89%

and 61.13% on the abstracts and the full papers subcorpora, respectively. The more recent CoNLL'2010 shared task was dedicated to the detection of speculation cues and their linguistic scope in natural language processing (Farkas et al., 2010). As a representative, Øvrelid et al. (2010) adopted some heuristic rules from dependency parse tree perspective to identify their speculation scopes.

3 Cues and Scopes in the BioScope Corpus

This paper employs the BioScope corpus (Szarvas et al., 2008; Vincze et al., 2008) [1], a freely downloadable resource from the biomedical domain, as the benchmark corpus. In this corpus, every sentence is annotated with negation cues and speculation cues (if it has), as well as their linguistic scopes. Figure 1 shows a self-explainable example. It is possible that a negation/speculation cue consists of multiple words, i.e., "can not"/"*indicate that*" in Figure 1.

```
<sentence id="S26.8">These findings <xcope
id="X26.8.2"><cue type="speculation"
ref="X26.8.2">indicate that</cue> <xcope
id="X26.8.1">corticosteroid resistance in bron-
chial asthma <cue type="negation"
ref="X26.8.1">can not</cue> be explained by
abnormalities in corticosteroid receptor charac-
teristics</xcope></xcope>.</sentence>
```

Figure 1: An annotated sentence in the BioScope corpus

The Bioscope corpus consists of three subcorpora: biological full papers from FlyBase and from BMC Bioinformatics, biological paper abstracts from the GENIA corpus (Collier et al., 1999), and clinical (radiology) reports. Among them, the full papers subcorpus and the abstracts subcorpus come from the same genre, and thus share some common characteristics in statistics, such as the number of words in the negation/speculation scope to the right (or left) of the negation/speculation cue and the average scope length. In comparison, the clinical reports subcorpus consists of clinical radiology reports with short sentences. For detailed statistics and annotation guidelines about the three subcorpora, please see Morante and Daelemans (2009a & 2009b).

For preprocessing, all the sentences in the Bioscope corpus are tokenized and then parsed using the Berkeley parser (Petrov and Klein, 2007) [2] trained on the GENIA TreeBank (GTB) 1.0 (Tateisi et al., 2005)[3], which is a bracketed corpus in (almost) PTB style. 10-fold cross-validation on GTB1.0 shows that the parser achieves the performance of 86.57 in F1-measure. It is worth noting that the GTB1.0 corpus includes all the sentences in the abstracts subcorpus of the Bioscope corpus.

4 Scope Learning via Simplified Shallow Semantic Parsing

In this section, we first formulate the scope learning task as a simplified shallow semantic parsing problem. Then, we deal with it using a simplified shallow semantic parsing framework.

4.1 Formulating Scope Learning as a Simplified Shallow Semantic Parsing Problem

Given a parse tree and a predicate in it, shallow semantic parsing recognizes and maps all the constituents in the sentence into their corresponding semantic arguments (roles) of the predicate or not. As far as scope learning considered, the cue can be regarded as the predicate[4], while its scope can be mapped into several constituents dominated by the cue and thus can be regarded as the arguments of the cue. In particular, given a cue and its scope which covers $word_m$, …, $word_n$, we adopt the following two heuristic rules to map the scope of the cue into several constituents which can be deemed as its arguments in the given parse tree.

1) The cue itself and all of its ancestral constituents are non-arguments.
2) If constituent *X* is an argument of the given cue, then *X* should be the highest constituent dominated by the scope of $word_m$, …, $word_n$. That is to say, *X*'s parent constituent must cross-bracket or include the scope of $word_m$, …, $word_n$.

[1] http://www.inf.u-szeged.hu/rgai/bioscope

[2] http://code.google.com/p/berkeleyparser/

[3] http://www-tsujii.is.s.u-tokyo.ac.jp/GENIA

[4] If a speculation cue consists of multiply words (e.g., *whether or not*), the first word (e.g., *whether*) is chosen to represent the speculation signal. However, the last word (e.g., *not*) is chosen to represent the negation cue if it consists of multiple words (e.g., *can not*).

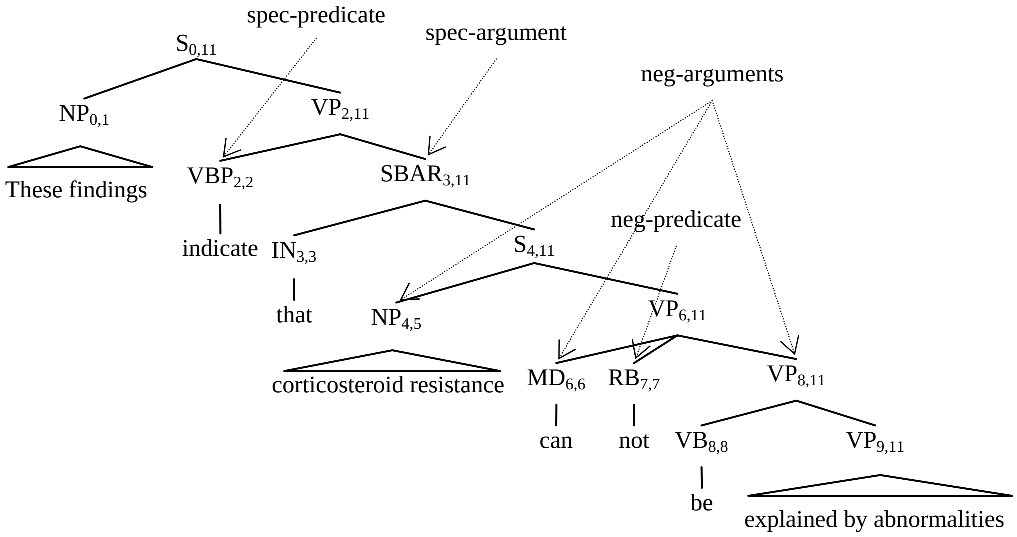

Figure 2: Examples of a negation/speculation cue and its arguments in a parse tree

The first rule ensures that no argument covers the cue while the second rule ensures no overlap between any two arguments. These two constraints between a cue and its arguments are consistent with shallow semantic parsing (Carreras and Màrquez, 2005). For example, in the sentence "*These findings indicate that corticosteroid resistance can not be explained by abnormalities*", the negation cue "*can not*" has the negation scope "*corticosteroid resistance can not be explained by abnormalities*" while the speculation cue "*indicate that*" has the speculation scope "*indicate that corticosteroid resistance can not be explained by abnormalities*". As shown in Figure 2, the node "$RB_{7,7}$" (i.e., *not*) represents the negation cue "*can not*" while its arguments include three constituents {$NP_{4,5}$, $MD_{6,6}$, and $VP_{8,11}$}. Similarly, the node "$VBP_{2,2}$" (i.e., *indicate*) represents the speculation cue "*indicate that*" while its arguments include one constituent $SBAR_{3,11}$. It is worth noting that according to the above rules, scope learning via shallow semantic parsing, i.e. determining the arguments of a given cue, is robust to some variations in the parse trees. This is also empirically justified by our later experiments. For example, if the $VP_{6,11}$ in Figure 2 is incorrectly expanded by the rule $VP_{6,11} \rightarrow MD_{6,6}+RB_{7,7}+VB_{8,8}+VP_{9,11}$, the negation scope of the negation cue "*can not*" can still be correctly detected as long as {$NP_{4,5}$, $MD_{6,6}$, $VB_{8,8}$, and $VP_{9,11}$} are predicated as the arguments of the negation cue "*can not*".

Compared with common shallow semantic parsing which needs to assign an argument with a semantic label, scope identification does not involve semantic label classification and thus could be divided into three consequent phases: argument pruning, argument identification and post-processing.

4.2 Argument Pruning

Similar to the predicate-argument structures in common shallow semantic parsing, the cue-scope structures in scope learning can be also classified into several certain types and argument pruning can be done by employing several heuristic rules accordingly to filter out constituents, which are most likely non-arguments of a given cue. Similar to the heuristic algorithm proposed in Xue and Palmer (2004) for argument pruning in common shallow semantic parsing, the argument pruning algorithm adopted here starts from designating the cue node as the current node and collects its siblings. It then iteratively moves one level up to the parent of the current node and collects its siblings. The algorithm ends when it reaches the root of the parse tree. To sum up, except the cue node itself and its ancestral constituents, any constituent in the parse tree whose parent covers the given cue will be collected as argument candidates. Taking the negation cue node "$RB_{7,7}$" in Figure 2 as an example, constituents {$MD_{6,6}$, $VP_{8,11}$, $NP_{4,5}$, $IN_{3,3}$, VBP$_{2,2}$, and NP$_{0,1}$} are collected as its argument candidates consequently.

Feature	Remarks
B1	Cue itself: the word of the cue, e.g., not, rather_than. (*can_not*)
B2	Phrase Type: the syntactic category of the argument candidate. (*NP*)
B3	Path: the syntactic path from the argument candidate to the cue. (*NP<S>VP>RB*)
B4	Position: the positional relationship of the argument candidate with the cue. “left” or “right”. (*left*)

Table 1: Basic features and their instantiations for argument identification in scope learning, with NP4,5 as the focus constituent (i.e., the argument candidate) and “can not” as the given cue, regarding Figure 2.

Feature	Remarks
Argument Candidate (AC) related	
AC1	The headword (AC1H) and its POS (AC1P). (*resistance*, *NN*)
AC2	The left word (AC2W) and its POS (AC2P). (*that*, *IN*)
AC3	The right word (AC3W) and its POS (AC3P). (*can*, *MD*)
AC4	The phrase type of its left sibling (AC4L) and its right sibling (AC4R). (*NULL*, *VP*)
AC5	The phrase type of its parent node. (*S*)
AC6	The subcategory. (*S:NP+VP*)
Cue/Predicate (CP) related	
CP1	Its POS. (*RB*)
CP2	Its left word (CP2L) and right word (CP2R). (*can*, *be*)
CP3	The subcategory. (*VP:MD+RB+VP*)
CP4	The phrase type of its parent node. (*VP*)

Table 2: Additional features and their instantiations for argument identification in scope identification, with NP4,5 as the focus constituent (i.e., the argument candidate) and “can not” as the given cue, regarding Figure 2.

4.3 Argument Identification

Here, a binary classifier is applied to determine the argument candidates as either valid arguments or non-arguments. Similar to argument identification in common shallow semantic parsing, the structured syntactic information plays a critical role in scope learning.

Basic Features

Table 1 lists the basic features for argument identification. These features are also widely used in common shallow semantic parsing for both verbal and nominal predicates (Xue, 2008; Li et al., 2009).

Additional Features

To capture more useful information in the cue-scope structures, we also explore various kinds of additional features. Table 2 shows the features in better capturing the details regarding the argument candidate and the cue. In particular, we categorize the additional features into three groups according to their relationship with the argument candidate (AC, in short) and the given cue/predicate (CP, in short).

Some features proposed above may not be effective in argument identification. Therefore, we adopt the greedy feature selection algorithm as described in Jiang and Ng (2006) to pick up positive features incrementally according to their contributions on the development data. The algorithm repeatedly selects one feature each time, which contributes most, and stops when adding any of the remaining features fails to improve the performance.

4.4 Post-Processing

Although a cue in the BioScope corpus always has only one continuous block as its scope (including the cue itself), the scope identifier may result in discontinuous scope due to independent predication in the argument identification phase. Given the golden negation/speculation cues, we observe that 6.2%/9.1% of the negation/speculation scopes predicted by our scope identifier are discontinuous.

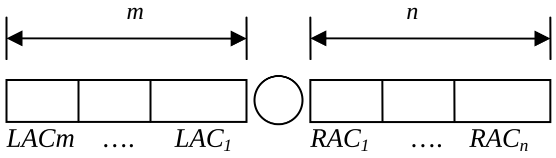

Figure 3: Projecting the left and the right argument candidates into the word level.

Figure 3 demonstrates the projection of all the argument candidates into the word level. According to our argument pruning algorithm in Section 4.2, except the words presented by the cue, the projection covers the whole sentence and each constituent (*LAC*$_i$ or *RAC*$_j$ in Figure 3) receives a probability distribution of being an argument of the given cue in the argument identification phase.

Since a cue is deemed inside its scope in the BioScope corpus, our post-processing algorithm first includes the cue in its scope and then starts to identify the left and the right scope boundaries, respectively.

As shown in Figure 3, the left boundary has *m+1* possibilities, namely the cue itself, the leftmost word of constituent *LAC*$_i$ (1<=*i*<=*m*). Supposing *LAC*$_i$ receives probability of P_i being an argument, we use the following formula to determine *LAC*$_{k*}$ whose leftmost word represents the boundary of the left scope. If k^*=0, then the cue itself represents its left boundary.

$$k^* = \arg\max_k \prod_{i=1}^{k} P_i * \prod_{i=k+1}^{m} (1 - P_i)$$

Similarly, the right boundary of the given cue can be decided.

4.5 Cue Recognition

Automatic recognition of cues of a special interest is the prerequisite for a scope learning system. The approaches to recognizing cues of a special interest usually fall into two categories: 1) substring matching approaches, which require a set of cue words or phrases in advance (e.g., Light et al., 2004); 2) machine learning approaches, which train a classifier with either supervised or semi-supervised learning methods (e.g., Özgür and Radev, 2009; Szarvas, 2008). Without loss of generality, we adopt a machine learning approach and train a classifier with supervised learning. In particular, we make an independent classification for each word with a BIO label to indicate whether it is the first word of a cue, inside a cue, or outside of it, respectively.

Inspired by previous studies on similar tasks such as WSD and nominal predicate recognition in shallow semantic parsing (Lee and Ng, 2002; Li et al., 2009), where various features on the word itself, surrounding words and syntactic information have been successfully used, we believe that such information is also valuable to automatic recognition of cues. Table 3 shows the features employed for cue recognition. In particular, we categorize these features into three groups: 1) features about the cue candidate itself (CC in short); 2) features about surrounding words (SW in short); and 3) structural features derived from the syntactic parse tree (SF in short).

Feature	**Remarks**
Cue Candidate (CC) related	
CC1	The cue candidate itself. (*indicate*)
CC2	The stem of the cue candidate. (*indicate*)
CC3	The POS tag of the cue candidate. (*VBP*)
Surrounding Words (SW) related	
SW1	The left surrounding words with the window size of 3. (*these*, *findings*)
SW2	The right surrounding words with the window size of 3. (*that*, *corticosteroid*, *resistance*)
Structural Features (SF)	
SF1	The subcategory of the candidate node. (*VP-->VBP+SBAR*)
SF2	The subcategory of the candidate node's parent. (*S-->NP+VP*)
SF3	POS tag of the candidate node + Phrase type of its parent node + Phrase type of its grandpa node. (*VBP* + *VP* + *S*)

Table 3: Features and their instantiations for cue recognition, with VBP$_{2,2}$ as the cue candidate, regarding Figure 2.

5 Experimentation

We have evaluated our simplified shallow semantic parsing approach to negation and speculation scope learning on the BioScope corpus.

5.1 Experimental Settings

Following the experimental setting in Morante et al. (2008) and Morante and Daelemans (2009a & 2009b), the abstracts subcorpus is randomly divided into 10 folds so as to perform 10-fold cross-validation, while the performance on both the papers and clinical reports subcorpora is evaluated using the system trained on the whole abstracts subcorpus. In addition, SVMLight[5] is selected as our classifier.

For cue recognition, we report its performance using precision/recall/F1-measure. For scope identification, we report the accuracy in PCS (Percentage of Correct Scopes) when the golden cues are given, and report precision/recall/F1-measure when the cues are automatically recognized.

5.2 Experimental Results on Golden Parse Trees and Golden Cues

In order to select beneficial features from the additional features proposed in Section 4.3, we randomly split the abstracts subcorpus into the training data and the development data with proportion of 4:1. After performing the greedy feature selection algorithm on the development data, 7 features {CFACCP5, CP2R, CFCP1, AC1P, CP3, CFACCP7, AC4R} are selected consecutively for negation scope identification while 11 features {CFACCP5, AC2W, CFACCP2, CFACCP4, AC5, CFCP1, CFACCP7, CFACCP1, CP4, AC3P, CFAC2} are selected for speculation scope identification. Table 4 gives the contribution of additional features on the development data. It shows that the additional features significantly improve the performance by 11.66% in accuracy from 74.93% to 86.59% ($\chi^2; p < 0.01$) for negation scope identification and improve the performance by 11.07% in accuracy from 77.29% to 88.36% ($\chi^2; p < 0.01$) for speculation scope identification. The feature selection experiments suggest that the features (e.g., CFACCP5, AC2W, CFCP1) related to neighboring words of the cue play a critical role for both negation and speculation scope identification. This may be due to the fact that neighboring words usually imply important sentential information. For example, "*can not be*" indicates a passive clause while "*did not*" indicates an active clause.

Since the additional selected features significantly improve the performance for both negation and speculation scope identification, we will include those additional selected features in all the remaining experiments.

Task	Features	Acc (%)
Negation scope identification	Baseline +selected features	74.93 86.59
Speculation scope identification	Baseline +selected features	77.29 88.36

Table 4: Contribution of additional selected features on the development dataset of the abstracts subcorpus

Since all the sentences in the abstracts subcorpus are included in the GTB1.0 corpus while we do not have golden parse trees for the sentences in the full papers and the clinical reports subcorpora, we only evaluate the performance of scope identification on the abstracts subcorpus with golden parse trees. Table 5 presents the performance on the abstracts subcorpus by performing 10-fold cross-validation. It shows that given golden parse trees and golden cues, speculation scope identification achieves higher performance (e.g., ~3.3% higher in accuracy) than negation scope identification. This is mainly due to the observation on the BioScope corpus that the scope of a speculation cue can be usually characterized by its POS and the syntactic structures of the sentence where it occurs. For example, the scope of a verb in active voice usually starts at the cue itself and ends at its object (e.g., the speculation cue "*indicate that*" in Figure 2 scopes the fragment of "*indicate that corticosteroid resistance can not be explained by abnormalities*"). Moreover, the statistics on the abstracts subcorpus shows that the number of arguments per speculation cue is smaller than that of arguments per negation cue (e.g., 1.5 vs. 1.8).

Task	Acc (%)
Negation scope identification	83.10
Speculation scope identification	86.41

Table 5: Accuracy (%) of scope identification with golden parse trees and golden cues on the abstracts subcorpus using 10-fold cross-validation

It is worth nothing that we adopted the post-processing algorithm proposed in Section 4.4 to ensure the continuousness of identified scope. As to examine the effectiveness of the algorithm, we abandon the proposed algorithm by simply taking the left and right-most boundaries of any nodes in the tree which are classified as in scope. Experiments on the abstracts subcorpus using 10-fold cross-validation shows that the simple post-processing rule gets the performance of 80.59 and 86.08 in accuracy for negation and speculation

[5] http://svmlight.joachims.org/

scope identification, respectively, which is lower than the performance in Table 5 achieved by our post-processing algorithm.

5.3 Experimental Results on Automatic Parse Trees and Golden Cues

The GTB1.0 corpus contains 18,541 sentences in which 11,850 of them (63.91%) overlap with the sentences in the abstracts subcorpus[6]. In order to get automatic parse trees, we train the Berkeley parser with the remaining 6,691 sentences in GTB1.0, which achieves the performance of 85.22 in F1-measure on the remaining 11,850 sentences in GTB1.0. Table 6 shows the performance of scope identification on automatic parse trees and golden cues. In addition, we also report an oracle performance to explore the best possible performance of our system by assuming that our scope finder can always correctly determine whether a candidate is an argument or not. That is, if an argument candidate falls within the golden scope, then it is a argument. This is to measure the impact of automatic syntactic parsing itself. Table 6 shows that:

1) For both negation and speculaiton scope identification, automatic syntactic parsing lowers the performance on the abstracts subcorpus (e.g., from 83.10% to 81.84% in accuracy for negation scope identification and from 86.41% to 83.74% in accuracy for speculaiton scope identification). However, the performance drop shows that both negation and speculation scope identification are not as senstive to automatic syntactic parsing as common shallow semantic parsing, whose performance might decrease by about ~10 in F1-measure (Toutanova et al., 2005). This indicates that scope identification via simplified shallow semantic parsing is robust to some variations in the parse trees.
2) Although speculation scope identification consistently achieves higher performance than negaiton scope identification when golden parse trees are availabe, speculation scope identification achieves comparable performance with negation scope identification on the abstracts subcorpus and the full papers subcorpus while speculation scope identification even performs ~20% lower in accuracy than negation scope identification on the clinical report subcorpus. This is largely due to that specuaiton scope identification is more sensitive to syntactic parsing errors than negation scope identification due to the wider scope of a speculation cue while the sentences of the clinical reports come from a different genre, which indicates low performance in syntactic parsing.
3) Given the performance gap between the performance of our scope finder and the oracle performance, there is still much room for further performance improvement.

Task	Method	Abstracts	Papers	Clinical
Negation scope identification	auto	81.84	62.70	85.21
	oracle	94.37	83.33	98.39
Speculation scope identification	auto	83.74	61.29	67.90
	oracle	95.69	83.72	83.29

Table 6: Accuracy (%) of scope identification on the three subcorpora using automatic parser trained on 6,691 sentences in GTB1.0

Task	Method	Abstracts	Papers	Clinical
Negation scope identification	M et al. (2008)	57.33	n/a	n/a
	M & D (2009a)	73.36	50.26	87.27
	Our baseline	73.42	53.70	88.42
	Our final	81.84	64.02	89.79
Speculation scope identification	M & D (2009b)	77.13	47.94	60.59
	Ö & R (2009)	79.89	61.13	n/a
	Our baseline	77.39	54.55	61.92
	Our final	83.74	63.49	68.78

Table 7: Performance comparison of our system with the state-of-the-art ones in accuracy (%). Note that all the performances achieved on the full papers subcorpus and the clinical subcorpus are achieved using the whole GTB1.0 corpus of 18,541 sentences while all the performances achieved on the abstract subcorpus are achieved using 6,691 sentences from GTB1.0 due to overlap of the abstract subcorpus with GTB1.0.

Table 7 compares our performance with related ones. It shows that even our baseline system with the four basic features presented in Table 1 achieves comparable performance with Morante et al. (2008) and Morante and Daelemans (2009a & 2009b). This further indicates the appropriateness of our simplified shallow semantic parsing approach and the effectiveness of structured syntactic information on scope identification. It also shows that our final system significantly outperforms the

[6] There are a few cases where two sentences in the abstracts subcorpus map into one sentence in GTB1.0.

state-of-the-art ones using a chunking approach, especially on the abstracts and full papers subcorpora. However, the improvement on the clinical reports subcorpora for negation scope identification is much less apparent, partly due to the fact that the sentences in this subcorpus are much simpler (with average length of 6.6 words per sentence) and thus a chunking approach can achieve high performance. Table 7 also shows that our parsing approach to speculation scope identification outperforms the rule-based method in Özgür and Radev (2009), where 10-fold cross-validation is performed on both the abstracts and the full papers subcorpora.

5.4 Experimental Results with Automatic Parse Trees and Automatic Cues

So far negation/speculation cues are assumed to be manually annotated and available. Here we turn to a more realistic scenario in which cues are automatically recognized. In the following, we first report the results of cue recognition and then the results of scope identification with automatic cues.

Cue Recognition

Task	Features	R (%)	P (%)	F1
Negation cue recognition	CC + SW	93.80	94.39	94.09
	CC+SW+SF	95.50	95.72	95.61
Speculation cue recognition	CC + SW	83.77	92.04	87.71
	CC+SW+SF	84.33	93.07	88.49

Table 8: Performance of automatic cue recognition with gold parse trees on the abstracts subcorpus using 10-fold cross-validation

Table 8 lists the performance of cue recognition on the abstracts subcorpus, assuming all words in the sentences as candidates. It shows that as a complement to features derived from word/pos information (CC+SW features), structural features (SF features) derived from the syntactic parse tree significantly improve the performance of cue recognition by about 1.52 and 0.78 in F1-measure for negation and speculation cue recognition, respectively, and thus included thereafter. In addition, we have also experimented on only these words, which happen to be a cue or inside a cue in the training data as cue candidates. However, this experimental setting achieves a lower performance than that when all words are considered.

Task	Corpus	R (%)	P (%)	F1
Negation cue recognition	Abstracts	94.99	94.35	94.67
	Papers	90.48	87.47	88.95
	Clinical	86.81	88.54	87.67
Speculation cue recognition	Abstracts	83.74	93.14	88.19
	Papers	73.02	82.31	77.39
	Clinical	33.33	91.77	48.90

Table 9: Performance of automatic cue recognition with automatic parse trees on the three subcorpora

Table 9 presents the performance of cue recognition achieved with automatic parse trees on the three subcorpora. It shows that:

1) The performance gap of cue recognition between golden parse trees and automatic parse trees on the abstracts subcorpus is not salient (e.g., 95.61 vs. 94.67 in F1-measure for negation cues and 88.49 vs. 88.19 for speculation cues), largely due to the features defined for cue recognition are local and insenstive to syntactic variations.
2) The performance of negation cue recognition is higher than that of speculation cue recognition on all the three subcorpora. This is prabably due to the fact that the collection of negation cue words or phrases is limitted while speculation cue words or phrases are more open. This is illustrated by our statistics that about only 1% and 1% of negation cues in the full papers and the clinical reports subcorpora are absent from the abstracts subcorpus, compared to about 6% and 20% for speculation cues.
3) Unexpected, the recall of speculation cue recognition on the clinical reports subcorpus is very low (i.e., 33.33% in recall measure). This is probably due to the absence of about 20% speculation cues from the training data of the abstracts subcorpus. Moreover, the speculation cue "*or*", which accounts for about 24% of specuaiton cues in the clinical reports subcorpus, only acheives about 2% in recall largely due to the errors caused by the classifier trained on the abstracts subcorpus, where only about 11% of words "*or*" are annotated as speculation cues.

Scope Identification with Automatic Cue Recognition

Table 10 lists the performance of both negation and speculation scope identification with automatic cues and automatic parse trees. It shows that automatic cue recognition lowers the performance by

3.34, 6.80, and 8.38 in F1-measure for negation scope identification on the abstracts, the full papers and the clinical reports subcorpora, respectively, while it lowers the performance by 6.50, 13.14 and 31.23 in F1-measures for speculation scope identification on the three subcorpora, respectively, suggesting the big challenge of cue recognition in the two scope learning tasks.

Task	Corpus	R (%)	P (%)	F1
Negation scope identification	Abstracts	78.77	78.24	78.50
	Papers	58.20	56.27	57.22
	Clinical	80.62	82.22	81.41
Speculation scope identification	Abstracts	73.34	81.58	77.24
	Papers	47.51	53.55	50.35
	Clinical	25.59	70.46	37.55

Table 10: Performance of both negation and speculation scope identification with automatic cues and automatic parse trees

6 Conclusion

In this paper we have presented a new approach to scope learning by formulating it as a simplified shallow semantic parsing problem, which has been extensively studied in the past few years. In particular, we regard the cue as the predicate and map its scope into several constituents which are deemed as arguments of the cue. Evaluation on the Bioscope corpus shows the appropriateness of our parsing approach and that structured syntactic information plays a critical role in capturing the domination relationship between a cue and its dominated arguments. It also shows that our parsing approach outperforms the state-of-the-art chunking ones. Although our approach is only evaluated on negation and speculation scope learning here, it is portable to other kinds of scope learning.

For the future work, we will explore tree kernel-based methods to further improve the performance of scope learning in better capturing the structural information, and apply our parsing approach to other kinds of scope learning.

Abstract

We describe a model for the lexical analysis of Arabic text, using the lists of alternatives supplied by a broad-coverage morphological analyzer, SAMA, which include stable lemma IDs that correspond to combinations of broad word sense categories and POS tags. We break down each of the hundreds of thousands of possible lexical labels into its constituent elements, including lemma ID and part-of-speech. Features are computed for each lexical token based on its local and document-level context and used in a novel, simple, and highly efficient two-stage supervised machine learning algorithm that overcomes the extreme sparsity of label distribution in the training data. The resulting system achieves accuracy of 90.6% for its first choice, and 96.2% for its top two choices, in selecting among the alternatives provided by the SAMA lexical analyzer. We have successfully used this system in applications such as an online reading helper for intermediate learners of the Arabic language, and a tool for improving the productivity of Arabic Treebank annotators.

1 Background and Motivation

This paper presents a methodology for generating high quality lexical analysis of highly inflected languages, and demonstrates excellent performance applying our approach to Arabic. Lexical analysis of the written form of a language involves resolving, explicitly or implicitly, several different kinds of ambiguities. Unfortunately, the usual ways of talking about this process are also ambiguous, and our general approach to the problem, though not unprecedented, has uncommon aspects. Therefore, in order to avoid confusion, we begin by describing how we define the problem.

In an inflected language with an alphabetic writing system, a central issue is how to interpret strings of characters as forms of words. For example, the English letter-string 'winds' will normally be interpreted in one of four different ways, all four of which involve the sequence of two formatives ***wind+s***. The stem 'wind' might be analyzed as (1) a noun meaning something like "air in motion", pronounced [w**I**nd] , which we can associate with an arbitrary but stable identifier like ***wind_n1***; (2) a verb ***wind_v1*** derived from that noun, and pronounced the same way; (3) a verb ***wind_v2*** meaning something like "(cause to) twist", pronounced [wa**I**nd]; or (4) a noun ***wind_n2*** derived from that verb, and pronounced the same way. Each of these "lemmas", or dictionary entries, will have several distinguishable senses, which we may also wish to associate with stable identifiers. The affix '-s' might be analyzed as the plural inflection, if the stem is a noun; or as the third-person singular inflection, if the stem is a verb.

We see this analysis as conceptually divided into four parts: 1) *Morphological analysis*, which recognizes that the letter-string 'winds' might be (perhaps among other things) ***wind/N*** + ***s/PLURAL*** or ***wind/V*** + ***s/3SING***; 2) *Morphological disambiguation*, which involves deciding, for example, that in the phrase "the four winds", 'winds' is probably a plural noun, i.e. ***wind/N*** + ***s/PLURAL***; 3) *Lemma analysis*, which involves recognizing that the stem wind in 'winds' might be any of the four lemmas listed above – perhaps with a further listing of senses or other sub-entries for each of them; and 4) *Lemma disambiguation*, deciding, for example, that

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 725–735,
MIT, Massachusetts, USA, 9-11 October 2010.

the phrase "the four winds" probably involves the lemma ***wind_n1***.

Confusingly, the standard word-analysis tasks in computational linguistics involve various combinations of pieces of these logically-distinguished operations. Thus, "part of speech (POS) tagging" is mainly what we've called "morphological disambiguation", except that it doesn't necessarily require identifying the specific stems and affixes involved. In some cases, it also may require a small amount of "lemma disambiguation", for example to distinguish a proper noun from a common noun. "Sense disambiguation" is basically a form of what we've called "lemma disambiguation", except that the sense disambiguation task may assume that the part of speech is known, and may break down lexical identity more finely than our system happens to do. "Lemmatization" generally refers to a radically simplified form of "lemma analysis" and "lemma disambiguation", where the goal is simply to collapse different inflected forms of any similarly-spelled stems, so that the strings 'wind', 'winds', 'winded', 'winding' will all be treated as instances of the same thing, without in fact making any attempt to determine the identity of "lemmas" in the traditional sense of dictionary entries.

Linguists use the term *morphology* to include all aspects of lexical analysis under discussion here. But in most computational applications, "morphological analysis" does not include the disambiguation of lemmas, because most morphological analyzers do not reference a set of stable lemma IDs. So for the purposes of this paper, we will continue to discuss lemma analysis and disambiguation as conceptually distinct from morphological analysis and disambiguation, although, in fact, our system disambiguates both of these aspects of lexical analysis at the same time.

The lexical analysis of textual character-strings is a more complex and consequential problem in Arabic than it is in English, for several reasons. First, Arabic inflectional morphology is more complex than English inflectional morphology is. Where an English verb has five basic forms, for example, an Arabic verb in principle may have dozens. Second, the Arabic orthographic system writes elements such as prepositions, articles, and possessive pronouns without setting them off by spaces, roughly as if the English phrase "in a way" were written "inaway". This leads to an enormous increase in the number of distinct "orthographic words", and a substantial increase in ambiguity. Third, short vowels are normally omitted in Arabic text, roughly as if English "in a way" were written "nway".

As a result, a whitespace/punctuation-delimited letter-string in Arabic text typically has many more alternative analyses than a comparable English letter-string does, and these analyses have many more parts, drawn from a much larger vocabulary of form-classes. While an English "tagger" can specify the morphosyntactic status of a word by choosing from a few dozen tags, an equivalent level of detail in Arabic would require thousands of alternatives. Similarly, the number of lemmas that might play a role in a given letter-sequence is generally much larger in Arabic than in English.

We start our labeling of Arabic text with the alternative analyses provided by SAMA v. 3.1, the Standard Arabic Morphological Analyzer (Maamouri et al., 2009). SAMA is an updated version of the earlier Buckwalter analyzers (Buckwalter, 2004), with a number of significant differences in analysis to make it compatible with the LDC Arabic Treebank 3-v3.2 (Maamouri et al., 2004). The input to SAMA is an Arabic orthographic word (a string of letters delimited by whitespace or punctuation), and the output of SAMA is a set of alternative analyses, as shown in Table 1. For a typical word, SAMA produces approximately a dozen alternative analyses, but for certain highly ambiguous words it can produce hundreds of alternatives.

The SAMA analyzer has good coverage; for typical texts, the correct analysis of an orthographic word can be found somewhere in SAMA's list of alternatives about **95%** of the time. However, this broad coverage comes at a cost; the list of analytic alternatives must include a long Zipfian tail of rare or contextually-implausible analyses, which collectively are correct often enough to make a large contribution to the coverage statistics. Furthermore, SAMA's long lists of alternative analyses are not evaluated or ordered in terms of overall or contextual plausibility. This makes the results less useful in most practical applications.

Our goal is to rank these alternative analyses so that the correct answer is as near to the top of the list

Token	Lemma	Vocalization	Segmentation	Morphology	Gloss
yHlm	Halam-u_1	yaHolumu	ya + Holum + u	IV3MS + IV + IV-SUFF_MOOD:I	he / it + dream + [ind.]
yHlm	Halam-u_1	yaHoluma	ya + Holum + a	IV3MS + IV + IV-SUFF_MOOD:S	he / it + dream + [sub.]
yHlm	Halum-u_1	yaHolumo	ya + Holum + o	IV3MS + IV + IV-SUFF_MOOD:J	he / it + be gentle + [jus.]
qbl	qabil-a_1	qabila	qabil + a	PV + PV-SUFF_SUBJ:3MS	accept/receive/approve + he/it [verb]
qbl	qabol_1	qabol	qabol	NOUN	Before

Table 1: Partial output of SAMA for ***yHlm*** and ***qbl***. On average, every token produces more than 10 such analyses

as possible. Despite some risk of confusion, we'll refer to SAMA's list of alternative analyses for an orthographic word as potential *labels* for that word. And despite a greater risk of confusion, we'll refer to the assignment of probabilities to the set of SAMA labels for a particular Arabic word in a particular textual context as *tagging*, by analogy to the operation of a stochastic part-of-speech tagger, which similarly assigns probabilities to the set of labels available for a word in textual context.

Although our algorithms have been developed for the particular case of Arabic and the particular set of lexical-analysis labels produced by SAMA, they should be applicable without modification to the sets of labels produced by any broad-coverage lexical analyzer for the orthographic words of any highly-inflected language.

In choosing our approach, we have been motivated by two specific applications. One application aims to help learners of Arabic in reading text, by offering a choice of English glosses with associated Arabic morphological analyses and vocalizations. SAMA's excellent coverage is an important basis for this help; but SAMA's long, unranked list of alternative analyses for a particular letter-string, where many analyses may involve rare words or alternatives that are completely implausible in the context, will be confusing at best for a learner. It is much more helpful for the list to be ranked so that the correct answer is almost always near the top, and is usually one of the top two or three alternatives.

In our second application, this same sort of ranking is also helpful for the linguistically expert native speakers who do Arabic Treebank analysis. These annotators understand the text without difficulty, but find it time-consuming and fatiguing to scan a long list of rare or contextually-implausible alternatives for the correct SAMA output. Their work is faster and more accurate if they start with a list that is ranked accurately in order of contextual plausibility.

Other applications are also possible, such as vocalization of Arabic text for text-to-speech synthesis, or lexical analysis for Arabic parsing. However, our initial goals have been to rank the list of SAMA outputs for human users.

We note in passing that the existence of set of stable "lemma IDs" is an unusual feature of SAMA, which in our opinion ought to be emulated by approaches to lexical analysis in other languages. The lack of such stable lemma IDs has helped to disguise the fact that without lemma analysis and disambiguation, morphological analyses and disambiguation is only a partial solution to the problem of lexical analysis.

In principle, it is obvious that lemma disambiguation and morphological disambiguation are mutually beneficial. If we know the answer to one of the questions, the other one is easier to answer. However, these two tasks require rather different sets of contextual features. Lemma disambiguation is similar to the problem of word-sense disambiguation – on some definitions, they are identical – and as a result, it benefits from paragraph-level and document-level bag-of-words attributes that help to characterize what the text is "about" and therefore which lemmas are more likely to play a role in it. In contrast, morphological disambiguation mainly depends on features of nearby words, which help to characterize how inflected forms of these lemmas might fit into local phrasal structures.

2 Problem and Methodology

Consider a collection of tokens (observations), t_i, referred to by index $i \in \{1, \ldots, n\}$, where each token is associated with a set of p features, x_{ij}, for the j^{th} feature, and a label, l_i, which is a combination of a lemma and a morphological analysis. We use indicator functions y_{ik} to indicate whether or not the k^{th} label for the i^{th} token is present. We represent the complete set of features and labels for the entire training data using matrix notation as X and Y, respectively. Our goal is to predict the label l (or equivalently, the vector y for a given feature vector x.

A standard linear regression model of this problem would be

$$\mathbf{y} = \mathbf{x}\beta + \epsilon \tag{1}$$

The standard linear regression estimate of β (ignoring, for simplicity the fact that the ys are 0/1) is:

$$\hat{\beta} = (X_{train}^T X_{train})^{-1} X_{train}^T Y_{train} \tag{2}$$

where Y_{train} is an $n \times h$ matrix containing 0s and 1s indicating whether or not each of the h possible labels is the correct label (l_i) for each of the n tokens t_i, X_{train} is an $n \times p$ matrix of context features for each of the n tokens, the coefficients $\hat{\beta}$ are $p \times h$.

However, this is a large, sparse, multiple label problem, and the above formulation is neither statistically nor computationally efficient. Each observation $(\mathbf{x}, \mathbf{y})$ consists of thousands of features associated with thousands of potential labels, almost all of which are zero. Worse, the matrix of coefficients β, to be estimated is large ($p \times h$) and one should thus use some sort of transfer learning to share strength across the different labels.

We present a novel principled and highly computationally efficient method of estimating this multilabel model. We use a two stage procedure, first using a subset (X_{train1}, Y_{train1}) of training data to give a fast approximate estimate of β; we then use a second smaller subset of the training data $(X_{train2}, Y_{train2},)$ to "correct" these estimates in a way that we will show can be viewed as a specialized shrinkage. Our first stage estimation approximates β, but avoids the expensive computation of $(X_{train}^T X_{train})^{-1}$. Our second stage corrects (shrinks) these initial estimates in a manner specialized to this problem. The second stage takes advantage of the fact that we only need to consider those candidate labels produced by SAMA. Thus, only dozens of the thousands of possible labels are considered for each token.

We now present our algorithm. We start with a corpus D of documents d of labeled Arabic text. As described above, each token, t_i is associated with a set of features characterizing its context, computed from the other words in the same document, and a label, $l_i = (\text{lemma}_i, \text{morphology}_i)$, which is a combination of a lemma and a morphological analysis. As described below, we introduce a novel factorization of the morphology into 15 different components.

Our estimation algorithm, shown in Algorithm 1, has two stages. We partition the training corpus into two subsets, one of which (X_{train1}) is used to estimate the coefficients βs and the other of which (X_{train2}) is used to optimally "shrink" these coefficient estimates to reduce variance and prevent overfitting due to data sparsity.

For the first stage of our estimation procedure, we simplify the estimate of the (β) matrix (Equation 2) to avoid the inversion of the very high dimensional ($p \times p$) matrix ($X^T X$) by approximating ($X^T X$) by its diagonal, Var(X), the inverse of which is trivial to compute; i.e. we estimate β using

$$\hat{\beta} = \text{Var}(X_{train1})^{-1} X_{train1}^T Y_{train1} \tag{3}$$

For the second stage, we assume that the coefficients for each feature can be shrunk differently, but that coefficients for each feature should be shrunk the same regardless of what label they are predicting. Thus, for a given observation we predict:

$$\hat{g}_{ik} = \sum_{j=1}^{p} w_j \hat{\beta}_{jk} x_{ij} \tag{4}$$

where the weights w_j indicate how much to shrink each of the p features.

In practice, we fold the variance of each of the j features into the weight, giving a slightly modified equation:

$$\hat{g}_{ik} = \sum_{j=1}^{p} \alpha_j \beta^*_{jk} x_{ij} \tag{5}$$

where $\beta^* = X_{train1}^T Y_{train1}$ is just a matrix of the counts of how often each context feature shows up with each label in the first training set. The vector α, which we will estimate by regression, is just the shrinkage weights w rescaled by the feature variance.

Note that the formation here is different from the first stage. Instead of having each observation be a token, we now let each observation be a (token, label) pair, but only include those labels that were output by SAMA. For a given token t_i and potential label l_k, our goal is to approximate the indicator function $g(i, k)$, which is 1 if the k^{th} label of token t_i is present, and 0 otherwise. We find candidate labels using a morphological analyzer (namely SAMA), which returns a set of possible candidate labels, say $C(t)$, for each Arabic token t. Our predicted label for t_i is then $\text{argmax}_{k \in C(t_i)} g(i, k)$.

The regression model for learning the weights α_j in the second stage thus has a row for each label $g(i, k)$ associated with a SAMA candidate for each token $i = n_{train1+1} \ldots n_{train2}$ in the second training set. The value of $g(i, k)$ is predicted as a function of the feature vector $z_{ijk} = \beta_{jk}^* x_{ij}$.

The shrinkage coefficients, α_j, could be estimated from theory, using a version of James-Stein shrinkage (James and Stein, 1961), but in practice, superior results are obtained by estimating them empirically. Since there are only p of them (unlike the $p * h$ βs), a relatively small training set is sufficient. We found that regression-SVMs work slightly better than linear regression and significantly better than standard classification SVMs for this problem.

Prediction is then done in the obvious way by taking the tokens in a test corpus D_{test}, generating context features and candidate SAMA labels for each token t_i, and selected the candidate label with the highest score $\hat{g}(i, k)$ that we set out to learn. More formally, The model parameters β^* and α produced by the algorithm allow one to estimate the most likely label for a new token t_i out of a set of candidate labels $C(t_i)$ using

$$k_{pred} = \text{argmax}_{k \in C(t_i)} \sum_{j=1}^{p} \alpha_j \beta_{jk}^* x_{ij} \qquad (6)$$

The most expensive part of the procedure is estimating β^*, which requires for each token in corpus D_1, (a subset of D), finding the co-occurrence frequencies of each label element (a lemma, or a part of the morphological segmentation) with the target token and jointly with the token and with other tokens or characters in the context of the token of interest. For example, given an Arabic token, ***"yHlm"***, we count what fraction of the time it is associated with each lemma (e.g. ***Halam-u_1***), *count(lemma=**Halam-u_1**, token=**yHlm**)* and each segment (e.g. "ya"), *count(segment=**ya**, token=**yHlm**)*. (Of course, most tokens never show up with most lemmas or segments; this is not a problem.) We also find the base rates of the components of the labels (e.g., *count(lemma=**Halam-u_1**)*, and what fraction of the time the label shows up in various contexts, e.g. *count(lemma=**Halam-u_1**, previous token = **yHlm**)*. We describe these features in more detail below.

Algorithm 1 Training algorithm.

```
Input: A training corpus $D_{train}$ of $n$ observations $(X_{train}, Y_{train})$
Partition $D_{train}$ into two sets, $D_1$ and $D_2$, of sizes $n_{train1}$ and $n_{train2} = n - n_{train1}$ observations
// Using $D_1$, estimate $\beta^*$
$\beta_{jk}^* = \sum_{i=1}^{n_{train1}} x_{ij} y_{ik}$ for the $j^{th}$ feature and $k^{th}$ label
// Using $D_2$, estimate $\alpha_j$
// Generate new "features" $Z$ and the true labels $g(i, k)$ for each of the SAMA candidate labels for each of the tokens in $D_2$
$z_{ijk} = \beta_{jk}^* x_{ij}$ for $i$ in $i = n_{train1} + 1 \ldots n_{train2}$
Estimate $\alpha_j$ for the above (feature,label) pairs $(z_{ijk}, g(i, k))$ using Regression SVMs
Output: $\alpha$ and $\beta^*$
```

3 Features and Labels used for Training

Our approach to tagging Arabic differs from conventional approaches in the two-part shrinkage-based method used, and in the choice of both features and labels used in our model. For features, we study both local context variables, as described above, and document-level word frequencies. For the labels, the key question is what labels are included and how they are factored. Standard "taggers" work by doing an n-way classification of all the alternatives, which is not feasible here due to the thousands of possible labels. Standard approaches such as Conditional Random Fields (CRFs) are intractable with so many labels. Moreover, few if any taggers do any lemma disambiguation; that is partly because one must start with some standard inventory of lemmas, which are not available for most languages, perhaps because the importance of lemma disambiguation has been underestimated.

We make a couple of innovations to deal with these issues. First, we perform lemma disambiguation in addition to “tagging”. As mentioned above, lemmas and morphological information are not independent; the choice of lemma often influences morphology and vice versa. For example, Table 1 contains two analyses for the word **qbl**. For the first analysis, where the lemma is ***qabil-a_1*** and the gloss is *accept/receive/approve + he/it [verb]*, the word is a verb. However, for the second analysis, where the lemma is ***qabol_1*** and the gloss is *before*, the word is a noun.

Simultaneous lemma disambiguation and tagging introduces additional complexity: An analysis of ATB and SAMA shows that there are approximately 2,200 possible morphological analyses (“tags”) and 40,000 possible lemmas; even accounting for the fact that most combinations of lemmas and morphological analyses don’t occur, the size of the label space is still in the order of tens of thousands. To deal with data sparsity, our second innovation is to factor the labels. We factor each label l into a set of 16 label elements (**LE**s). These include lemmas, as well as morphological elements such as basic part-of-speech, suffix, gender, number, mood, etc. These are explained in detail below. Thus, since each label l is a set of 15 categorical variables, each $\mathbf{y}$ in the first learning stage is actually a vector with 16 nonzero components and thousands of zeros. Since we do simultaneous estimation of the entire set of label elements, the value $g(i, k)$ being predicted in the second learning phase is 1 if the entire label set is correct, and zero otherwise. We do *not* learn separate models for each label.

3.1 Label Elements (LEs)

The fact that there are tens of thousands of possible labels presents the problem of extreme sparsity of label distribution in the training data. We find that a model that estimates coefficients β^* to predict a single label (a label being in the Cartesian product of the set of label elements) yields poor performance. Therefore, as just mentioned, we factor each label l into a set of label elements (**LE**s), and learn the correlations β^* between features and label elements, rather than features and entire label sets. This reduces, but does not come close to eliminating, the problem sparsity. A complete list of these **LE**s and their possible values is detailed in Table 2.

LE	**Description**
lemma	Lemma
pre1	Closer prefix
pre2	Farther prefix
det	Determiner
pos	Basic POS
dpos	Additional data on basic pos
suf	Suffix
perpos	Person (basic pos)
numpos	Number (basic pos)
genpos	Gender (basic pos)
persuf	Person (suffix)
numsuf	Number (suffix)
gensuf	Gender (suffix)
mood	Mood of verb
pron	Pronoun suffix

Table 2: Label Elements (**LE**s). Examples of additional data on basic POS include whether a noun is proper or common, whether a verb is transitive or not, etc. Both the basic POS and its suffix may have person, gender and number data.

3.2 Features

3.2.1 Local Context Features

We take (t, l) pairs from D_2, and for each such pair generate features Z based on co-occurrence statistics β^* in D_1, as mentioned in Algorithm 2. These statistics include unigram co-occurrence frequencies of each label with the target token and bigram co-occurrence of the label with the token and with other tokens or characters in the context of the target token. We define them formally in Table 3. Let $Z_{baseline}$ denote the set of all such basic features based on the local context statistics of the target token, namely the words and letters preceding and following it. We will use this set to create a baseline model.

Statistic	Description
Freq	$count_{D_1}(t, l)$
PrevWord	$count_{D_1}(t, l, t_{-1})$
NextWord	$count_{D_1}(t, l, t_{+1})$
PreviLetter	$count_{D_1}(t, l, \text{first letter}(t_{-1}))$
NextiLetter	$count_{D_1}(t, l, \text{first letter}(t_{+1})$
PrevfLetter	$count_{D_1}(t, l, \text{last letter}(t_{-1})$
NextfLetter	$count_{D_1}(t, l, \text{last letter}(t_{+1})$

Table 3: Co-occurrence statistics β^*. We use these to generate feature sets for our regression SVMs.

For each label element (**LE**) e, we define a set of features Z_e similar to $Z_{baseline}$; these features are based on co-occurrence frequencies of the particular **LE** e, not the entire label l.

Finally, we define an aggregate feature set Z_{aggr} as follows:

$$Z_{aggr} = Z_{baseline} \quad \bigcup \quad \{Z_e\} \qquad (7)$$

where $e \in \{$*lemma, pre1, pre2, det, pos, dpos, suf, perpos, numpos, genpos, persuf, numsuf, gensuf, mood, pron*$\}$.

3.2.2 Document Level Features

When trying to predict the lemma, it is useful to include not just the words and characters immediately adjacent to the target token, but also the all the words in the document. These words capture the "topic" of the document, and help to disambiguate different lemmas, which tend to be used or not used based on the topic being discussed, similarly to the way that word sense disambiguation systems in English sometimes use the "bag of words" the document to disambiguate, for example a "bank" for depositing money from a "bank" of a river. More precisely, we augment the features for each target token with the counts of each word in the document (the "term frequency" *tf*) in which the token occurs with a given label.

$$Z_{full} = Z_{aggr} \quad \bigcup \quad Z_{tf} \qquad (8)$$

This set Z_{full} is our final feature set. We use Z_{full} to train an SVM model M_{full}; this is our final predictive model.

3.3 Corpora used for Training and Testing

We use three modules of the Penn Arabic Treebank (ATB) (Maamouri et al., 2004), namely ATB1, ATB2 and ATB3 as our corpus of labeled Arabic text, D. Each ATB module is a collection of newswire data from a particular agency. ATB1 uses the Associated Press as a source, ATB2 uses Ummah, and ATB3 uses Annahar. D contains a total of 1,835 documents, accounting for approximately 350,000 words. We construct the training and testing sets D_{train} and D_{test} from D using 10-fold cross validation, and we construct D_1 and D_2 from D_{train} by randomly performing a 9:1 split.

As mentioned earlier, we use the SAMA morphological analyzer to obtain candidate labels $C(t)$ for each token t while training and testing an SVM model on D_2 and D_{test} respectively. A sample output of SAMA is shown in Table 1. To improve coverage, we also add to $C(t)$ all the labels l seen for t in D_1. We find that doing so improves coverage to **98%**. This is an upper bound on the accuracy of our model.

$$C(t) = \text{SAMA}(t) \quad \bigcup \quad \{l|(t, l) \in D_1\} \qquad (9)$$

4 Results

We use two metrics of accuracy: **A1**, which measures the percentage of tokens for which the model assigns the highest score to the correct label or **LE** value (or **E1**$= 100 - A1$, the corresponding percentage error), and **A2**, which measures the percentage of tokens for which the correct label or **LE** value is one of the two highest ranked choices returned by the model (or **E2** = $100 - A2$). We test our model M_{full} on D_{test} and achieve **A1** and **A2** scores of 90.6% and 96.2% respectively. The accuracy achieved by our M_{full} model is, to the best of our knowledge, higher than prior approaches have been able to achieve so far for the problem of combined morphological and lemma disambiguation. This is all the more impressive considering that the upper bound on accuracy for our model is **98%** because, as described above, our set of candidate labels is incomplete.

In order to analyze how well different **LE**s can be predicted, we train an SVM model M_e for each **LE** e using the feature set Z_e, and test all such models on D_{test}. The results for all the **LE**s are reported in the form of error percentages **E1** and **E2** in Table 4.

Model	**E1**	**E2**	**Model**	**E1**	**E2**
M_{lemma}	11.1	4.9	M_{pre1}	1.9	1.4
M_{pre2}	0.2	0	M_{det}	0.7	0.1
M_{pos}	23.4	4.0	M_{dpos}	10.3	1.9
M_{suf}	7.6	2.5	M_{perpos}	3.0	0.1
M_{numpos}	3.2	0.2	M_{genpos}	1.8	0.1
M_{persuf}	3.2	0.1	M_{numsuf}	8.2	0.5
M_{gensuf}	11.6	0.4	M_{mood}	1.6	1.4
M_{pron}	1.8	0.6	M_{case}	14.7	5.9
$\boldsymbol{M_{full}}$	**9.4**	**3.8**	-	-	-

Table 4: Results of M_e for each **LE** e. **Note:** The results reported are 10 fold cross validation test accuracies and no parameters have been tuned on them.

A comparison of the results for M_{full} with the results for M_{lemma} and M_{pos} is particularly informative. We see that M_{full} is able to achieve a substantially lower **E1** error score (9.4%) than M_{lemma} (11.1%) and M_{pos} (23.4%); in other words, we find that our full model is able to predict lemmas and basic parts-of-speech more accurately than the individual models for each of these elements.

We examine the effect of varying the size of D_2, i.e. the number of SVM training instances, on the performance of M_{full} on D_{test}, and find that with increasing sizes of D_2, **E1** reduces only slightly from 9.5% to 9.4%, and shows no improvement thereafter. We also find that the use of document-level features in M_{lemma} reduces **E1** and **E2** percentages for M_{lemma} by 5.7% and 3.2% respectively.

4.1 Comparison to Alternate Approaches

4.1.1 Structured Prediction Models

Preliminary experiments showed that knowing the predicted labels (lemma + morphology) of the surrounding words can slightly improve the predictive accuracy of our model. To further investigate this effect, we tried running experiments using different structured models, namely CRF (Conditional Random Fields) (Lafferty et al., 2001), (Structured) MIRA (Margin Infused Relaxation Algorithm) (Crammer et al., 2006) and Structured Perceptron (Collins, 2002). We used linear chain CRFs as implemented in MALLET Toolbox (McCallum, 2001) and for Structured MIRA and Perceptron we used their implementations from EDLIN Toolbox (Ganchev and Georgiev, 2009). However, given the vast label space of our problem, running these methods proved infeasible. The time complexity of these methods scales badly with the number of labels; It took a week to train a linear chain CRF for only $\sim$ 50 labels and though MIRA and Perceptron are online algorithms, they also become intractable beyond a few hundred labels. Since our label space contains combinations of lemmas and morphologies, so even after factoring, the dimension of the label space is in the order of thousands.

We also tried a naïve version (two-pass approximation) of these structured models. In addition to the features in Z_{full}, we include the predicted labels for the tokens preceding and following the target token as features. This new model is not only slow to train, but also achieves only slightly lower error rates (1.2% lower **E1** and 1.0% lower **E2**) than M_{full}. This provides an upper bound on the benefit of using the more complex structured models, and suggests that given their computational demands our (unstructured) model M_{full} is a better choice.

4.1.2 MADA

(Habash and Rambow, 2005) perform morphological disambiguation using a morphological analyzer. (Roth et al., 2008) augment this with lemma disambiguation; they call their system MADA. Our work differs from theirs in a number of respects. Firstly, they don't use the two step regression procedure that we use. Secondly, they use only "unigram" features. Also, they do not learn a single model from a feature set based on labels and **LE**s; instead, they combine models for individual elements by using weighted agreement. We trained and tested MADA v2.32 using its full feature set on the same D_{train} and D_{test}. We should point out that this is not an exact comparison, since MADA uses the older Buckwalter morphological analyzer.[1]

4.1.3 Other Alternatives

Unfactored Labels: To illustrate the benefit obtained by breaking down each label l into

[1] A new version of MADA was released very close to the submission deadline for this conference.

LEs, we contrast the performance of our M_{full} model to an SVM model $M_{baseline}$ trained using only the feature set $Z_{baseline}$, which only contains features based on entire labels, those based on individual **LE**s.

Independent lemma and morphology prediction: Another alternative approach is to predict lemmas and morphological analyses separately. We construct a feature set $Z_{lemma'} = Z_{full} - Z_{lemma}$ and train an SVM model $M_{lemma'}$ using this feature set. Labels are then predicted by simply combining the results predicted independently by M_{lemma} and $M_{lemma'}$. Let M_{ind} denote this approach.

Unigram Features: Finally, we also consider a context-less approach, i.e. using only "unigram" features for labels as well as **LE**s. We call this feature set Z_{uni}, and the corresponding SVM model M_{uni}.

The results of these various models, along with those of M_{full} are summarized in Table 5. We see that M_{full} has roughly half the error rate of the state-of-the-art MADA system.

Model	**E1**	**E2**
$M_{baseline}$	13.6	9.1
M_{ind}	18.7	6.0
M_{uni}	11.6	6.4
M_{cheat}	8.2	2.8
MADA	**16.9**	**12.6**
$\boldsymbol{M_{full}}$	**9.4**	**3.8**

Table 5: Percent error rates of alternative approaches. **Note:** The results reported are 10 fold cross validation test accuracies and no parameters have been tuned on them. We used same train-test splits for all the datasets.

5 Related Work

(Hajic, 2000) show that for highly inflectional languages, the use of a morphological analyzer improves accuracy of disambiguation. (Diab et al., 2004) perform tokenization, POS tagging and base phrase chunking using an SVM based learner. (Ahmed and Nürnberger, 2008) perform word-sense disambiguation using a Naive Bayesian model and rely on parallel corpora and matching schemes instead of a morphological analyzer. (Kulick, 2010) perform simultaneous tokenization and part-of-speech tagging for Arabic by separating closed and open-class items and focusing on the likelihood of possible stems of open-class words. (Mohamed and Kübler, 2010) present a hybrid method between word-based and segment-based POS tagging for Arabic and report good results. (Toutanova and Cherry, 2009) perform joint lemmatization and part-of-speech tagging for English, Bulgarian, Czech and Slovene, but they do not use the two step estimation-shrinkage model described in this paper; nor do they factor labels. The idea of joint lemmatization and part-of-speech tagging has also been discussed in the context of Hungarian in (Kornai, 1994).

A substantial amount of relevant work has been done previously for Hebrew. (Adler and Elhadad, 2006) perform Hebrew morphological disambiguation using an unsupervised morpheme-based HMM, but they report lower scores than those achieved by our model. Moreover, their analysis doesn't include lemma IDs, which is a novelty of our model. (Goldberg et al., 2008) extend the work of (Adler and Elhadad, 2006) by using an EM algorithm, and achieve an accuracy of 88% for full morphological analysis, but again, this does not include lemma IDs. To the best of our knowledge, there is no existing research for Hebrew that does what we did for Arabic, namely to use simultaneous lemma and morphological disambiguation to improve both. (Dinur et al., 2009) show that prepositions and function words can be accurately segmented using unsupervised methods. However, by using this method as a preprocessing step, we would lose the power of a *simultaneous solution* for these problems. Our method is closer in style to a CRF, giving much of the accuracy gains of simultaneous solution, while being about 4 orders of magnitude easier to train.

We believe that our use of factored labels is novel for the problem of simultaneous lemma and morphological disambiguation; however, (Smith et al., 2005) and (Hatori et al., 2008) have previously made use of features based on parts of labels in CRF models for morphological disambiguation and word-sense disambiguation respectively. Also, we note that there is a similarity between our two-stage machine learning approach and log-linear models in machine translation that break the data in two parts, estimating log-probabilities of generative models from one part, and discriminatively re-weighting the models using the second part.

6 Conclusions

We introduced a new approach to accurately predict labels consisting of both lemmas and morphological analyses for Arabic text. We obtained an accuracy of over 90% – substantially higher than current state-of-the-art systems. Key to our success is the factoring of labels into lemma and a large set of morphosyntactic elements, and the use of an algorithm that computes a simple initial estimate of the coefficient relating each contextual feature to each label element (simply by counting co-occurrence) and then regularizes these features by shrinking each of the coefficients for each feature by an amount determined by supervised learning using only the candidate label sets produced by SAMA.

We also showed that using features of word n-grams is preferable to using features of only individual tokens of data. Finally, we showed that a model using a full feature set based on labels as well as factored components of labels, which we call label elements (**LE**s) works better than a model created by combining individual models for each **LE**. We believe that the approach we have used to create our model can be successfully applied not just to Arabic but also to other languages such as Turkish, Hungarian and Finnish that have highly inflectional morphology. The current accuracy of of our model, getting the correct answer among the top two choices 96.2% of the time is high enough to be highly useful for tasks such as aiding the manual annotation of Arabic text; a more complete automation would require that accuracy for the single top choice.

Acknowledgments

We woud like to thank everyone at the Linguistic Data Consortium, especially Christopher Cieri, David Graff, Seth Kulick, Ann Bies, Wajdi Zaghouani and Basma Bouziri for their help. We also wish to thank the anonymous reviewers for their comments and suggestions.

What a Parser can Learn from a Semantic Role Labeler and *Vice Versa*

Abstract

In many NLP systems, there is a unidirectional flow of information in which a parser supplies input to a semantic role labeler. In this paper, we build a system that allows information to flow in both directions. We make use of semantic role predictions in choosing a single-best parse. This process relies on an averaged perceptron model to distinguish likely semantic roles from erroneous ones. Our system penalizes parses that give rise to low-scoring semantic roles. To explore the consequences of this we perform two experiments. First, we use a baseline generative model to produce n-best parses, which are then re-ordered by our semantic model. Second, we use a modified version of our semantic role labeler to predict semantic roles at parse time. The performance of this modified labeler is weaker than that of our best full SRL, because it is restricted to features that can be computed directly from the parser's packed chart. For both experiments, the resulting semantic predictions are then used to select parses. Finally, we feed the selected parses produced by each experiment to the full version of our semantic role labeler. We find that SRL performance can be improved over this baseline by selecting parses with likely semantic roles.

1 Introduction

In the semantic role labeling task, words or groups of words are described in terms of their relations to a predicate. For example, the sentence *Robin admires Leslie* has two semantic role-bearing words: *Robin* is the agent or experiencer of the *admire* predicate, and *Leslie* is the patient. These semantic relations are distinct from syntactic relations like subject and object – the proper nouns in the sentence *Leslie is admired by Robin* have the same semantic relationships as *Robin admires Leslie*, even though the syntax differs.

Although syntax and semantics do not always align with each other, they are correlated. Almost all automatic semantic role labeling systems take a syntactic representation of a sentence (taken from an automatic parser or a human annotator), and use the syntactic information to predict semantic roles. When a semantic role labeler predicts an incorrect role, it is often due to an error in the parse tree. Consider the erroneously annotated sentence from the Penn Treebank corpus shown in Figure 1. If a semantic role labeling system relies heavily upon syntactic attachment decisions, then it will likely predict that *in 1956* describes the time that asbestos was used, rather than when it ceased to be used.

Errors of this kind are common in treebanks and in automatic parses. It is telling, though, that while the hand-annotated Penn Treebank (Marcus et al., 1993), the Charniak parser (Charniak, 2001), and the C&C parser (Clark and Curran, 2004) all produce the erroneous parse from Figure 1, the hand-annotated Propbank corpus of verbal semantic roles (Palmer et al., 2005) correctly identifies *in 1956* as a temporal modifier of *stopped*, rather than *using*. This demonstrates that while syntactic attachment decisions like these are difficult for humans and for automatic parsers, a human reader has little difficulty identifying the correct semantic relationship between the temporal modifier and the verbs. This is likely due to the fact that the meaning suggested by the parse in Figure 1 is unlikely – the reader instinctively feels that a temporal modifier fits better with the verb *stop* than with the verb *use*.

In this paper, we will use the idea that semantic roles predicted by correct parses are more natural than semantic roles predicted by erroneous parses. By modifying a state-of-the-art CCG semantic role labeler to predict semantic roles at parse time, or by using it to select from an n-best list, we can prefer analyses that yield likely semantic roles. Syntactic analysis is treated not as an autonomous task, but rather as a contributor to the final goal of semantic role labeling.

2 Related Work

There has been a great deal of work in joint parsing and semantic role labeling in recent years. Two notable efforts have been the CoNLL 2008 and 2009 shared tasks

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 736–744,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

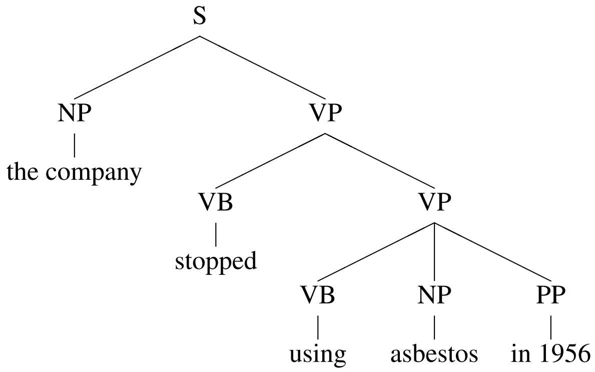

Figure 1: A parse tree based on the treebank parse of wsj_0003.3. Notice that the temporal adjunct is erroneously attached low. In a syntax-based SRL system, this will likely lead to a role prediction error.

(Surdeanu et al., 2008; Hajič et al., 2009). Many of these systems perform joint syntactic and semantic analysis by generating an n-best list of syntactic parses, labeling semantic roles on all of them, then re-ranking these parses by some means. Our approach differs from this strategy by abandoning the preliminary ranking and predicting semantic roles at parse time. By doing this, we effectively open semantic roles in the entire parse forest to examination by the ranking model, rather than restricting the model to an n-best list generated by a baseline parser. The spirit of this work more closely resembles that of Finkel and Manning (2009) , which improves both parsing and named entity recognition by combining the two tasks.

3 Why Predicting Semantic Roles in a Packed Chart is Difficult

Predicting semantic roles in the environment of a packed chart is difficult when using an atomic CFG. In order to achieve the polynomial efficiency appropriate for wide-coverage parsing, it is necessary to "pack" the chart – that is, to combine distinct analyses of a given span of words that produce the same category. The only other widely used option for wide-coverage parsing is to use beam search with a narrow beam, which runs the risk of search errors. On methodological grounds we prefer an exhaustive search, since systems that rely heavily on heuristics for their efficiency are difficult to understand, debug or improve. It is straightforward to read off the highest scoring parse from a packed chart, and similarly routine to generate an n-best list containing a highly-ranked subset of the parses. However, a packed chart built on an atomic CFG does not make available all of the features that are important to many CFG-based SRL systems. In particular, the very useful treepath feature, which lists the categories touched by walking the tree from the predicate to the target word, only makes sense when you have a complete tree, so cannot easily be computed from the chart (Figure 2). Chart edges can be lexicalized with their headwords, and this information would be useful in role labeling – but even this misses vital subcategorization information that would be available in the complete parse. An ideal formalism for our purpose would condense into the category label a wide range of information about combinatory potential, heads, and syntactic dependencies. At the same time it should allow the creation of a packed chart, come with labeled training data, and have a high-quality parser and semantic role labeler already available. Fortunately, Combinatory Categorial Grammar offers these desiderata, so this is our formalism of choice.

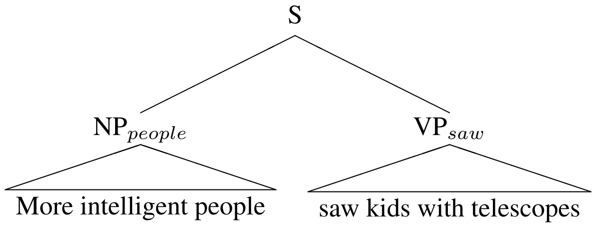

Figure 2: In the context of a packed chart, it is meaningless to speak of a treepath between *saw* and *people* because multiple analyses are "packed" under a single category.

4 Combinatory Categorial Grammar

Combinatory Categorial Grammar (Steedman, 2000) is a grammar formalism that describes words in terms of their combinatory potential. For example, determiners belong to the category np/n, or "the category of words that become noun phrases when combined with a noun to the right". The rightmost category indicates the argument that the category is seeking, the leftmost category indicates the result of combining this category with its argument, and the slash (/ or \) indicates the direction of combination. Categories can be nested within each other: a transitive verb like *devoured* belongs to the category

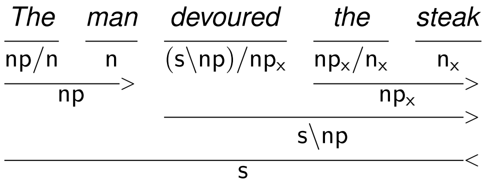

Figure 3: A simple CCG derivation.

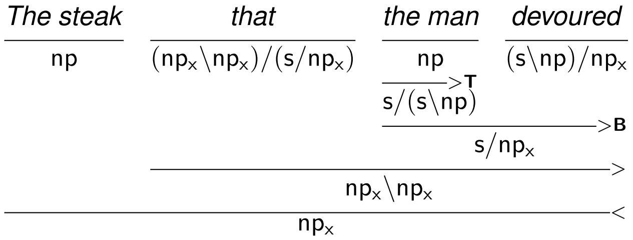

Figure 4: An example of CCG's treatment of relative clauses. The syntactic dependency between *devoured* and *steak* is the same as it was in figure 3. Co-indexations (the '*x*s') have been added here and above to aid the eye in following the relevant [*devoured-steak*] dependency.

(s\np)/np, or "the category that would become a sentence if it could combine with a noun phrase to the right and another noun phrase to the left". An example of how categories combine to make sentences is shown in Figure 3. CCG has many capabilities that go beyond that of a typical context-free grammar. First, it has a sophisticated internal system of managing syntactic heads and dependencies[1]. These dependencies are used to great effect in CCG-based semantic role labeling systems (Gildea and Hockenmaier, 2003; Boxwell et al., 2009), as they do not suffer the same data-sparsity effects encountered with treepath features in CFG-based SRL systems. Secondly, CCG permits these dependencies to be passed through intermediary categories in grammatical structures like relative clauses. In Figure 4, *the steak* is still in the object relation to *devoured*, even though the verb is inside a relative clause. Finally and most importantly, *these dependencies are represented directly on the CCG categories themselves*. This is what makes CCG resistant to the problem described in Section 3 – because the dependency is formed when the two heads combine, it is available to be used as a local feature by the semantic role labeler.

5 Semantic Role Labeling

We use a modified version of the Brutus semantic role labeling system (Boxwell et al., 2009)[2]. The original version of this system takes complete CCG derivations as input, and predicts semantic roles over them. For our purposes, however, it is necessary to modify the system to make semantic predictions at parse time, inside a packed chart, before the complete derivation is available. For this reason, it is necessary to remove the global features from the system (that is, features that rely on the complete parse), leaving only local features (features that are known at the moment that the predicate is attached to the argument). Crucially, dependency features count as "local" features, even though they have the potential to connect words that are very far apart in the sentence.

Brutus is arranged in a two-stage pipeline. First, a maximum entropy classifier[3] predicts, for each predicate in turn, which words in the sentence are likely headwords of semantic roles. Then, a second maximum entropy classifier assigns role labels to each of these words. The features used in the identification model of the local-only version of Brutus are as follows:

- **Words.** A three-word window surrounding the candidate word. For example, if we were considering the word *steak* in Figure 3, the three features would be represented as word_-1=the, word_0=steak, and word_1=#, with the last feature representing an out-of-bounds index.

- **Predicate.** The predicate whose semantic roles the system is looking for. For example, the sentence in figure 3 contains one predicate: *devour*.

- **Syntactic Dependency.** As with a previous approach in CCG semantic role labeling (Gildea and Hockenmaier, 2003), this feature shows the exact nature of the syntactic dependency between the predicate and the word we are considering, if any such dependency exists. This feature is represented by the category of the predicate, the argument slot that this word fits into, and whether or not the predicate is the head of the resultant category, represented with a left or right arrow. In the example from figure 3, the relationship between *devoured* and *steak* would be represented as (s\np)/np.2.→.

The second maximum entropy classifier uses all of the features from the identifier, plus several more:

[1] A complete explanation of CCG predicate-argument dependencies can be found in the CCGbank user manual (Hockenmaier and Steedman, 2005)

[3] Brutus uses Zhang Le's maxent toolkit, available at http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html.

Model	P	R	F
Local	89.8%	80.8%	85.1%
Global	89.8%	84.3%	87.0%

Table 1: SRL results for treebank parses, using the local model described in Section 5 and the full global model.

- **Before / After.** A binary indicator feature indicating whether the candidate word is before or after the predicate.

- **Result Category Detail.** This indicates the feature on the result category of the predicate. Possible values include dcl (for declarative sentences), pss (for passive sentences), ng (for present-progressive phrases like "running the race"), etc. These are read trivially off of the verbal category.

- **Argument Mapping.** An argument mapping is a prediction of a likely set of semantic roles for a given CCG predicate category. For example, a likely argument mapping for devoured:(s[dcl]\np)/np is [Arg0,Arg1]. These are predicted from string-level features, and are useful for bringing together otherwise independent classification decisions for individual roles. Boxwell et al. (2009) describe this feature in detail.

The Maximum-Entropy models were trained to 500 iterations. To prevent overfitting, we used Gaussian priors with global variances of 1 and 5 for the identifier and the labeler, respectively. Table 1 shows SRL performance for the local model described above, and the full global CCG-system described by Boxwell et al. (2009). We use the method for calculating the accuracy of Propbank verbal semantic roles described in the CoNLL-2008 shared task on semantic role labeling (Surdeanu et al., 2008). Because the Brutus SRL system is not designed to accommodate Nombank roles (Meyers et al., 2004), we restrict ourselves to predicting Propbank roles in the present work.

The local system has the same precision as the global one, but trails it on recall and F-measure. Note that this performance is achieved with gold standard parses.

6 Performing Semantic Role Predictions at Parse Time

Recall that the reasoning for using a substantially pared down version of the Brutus SRL system is to allow it to predict semantic roles in the context of a packed chart. Because we predict semantic roles for each constituent immediately after the constituent is formed and before it is added to the chart, we can use semantic roles to inform parsing. We use a CKY parsing algorithm, though this approach could be easily adapted to other parse strategies.

Whenever two constituents are combined, the SRL system checks to see if either of the constituents contains predicates. The system then attempts to identify semantic roles in the other constituent related to this predicate. This process repeats at every step, creating a combined syntax-semantics parse forest. Crucially, this allows us to use features derived from the semantic roles to rank parses inside the packed chart. This could result in an improvement over ranking completed parses, because reranking completed parses requires first generating an n-best list of parse candidates, potentially preventing the re-ranker from examining high value parses falling outside the n-best list.

In order to train our parse model, it is necessary to first employ a baseline parse model over the training set. The baseline model is a PCFG model, where the products of the probabilities of individual rule applications are used to rank candidate parses. We use a cross-fold validation technique to parse the training set (train on sections 02-20 to parse section 21, train on sections 02-19 and 21 to parse section 20, and so on). As we parse these sentences, we use the local SRL model described in Section 5 to predict semantic roles inside the packed chart. We then iterate over the packed chart and extract features based on the semantic roles in it, effectively learning from every possible semantic role in the parse forest. Notice that this does not require enumerating every parse in the forest (which would be prohibitively expensive) – the roles are labeled at parse time and can therefore be read directly from the packed chart. For each role in the packed chart, we label it as a "good" semantic role if it appears in the human-judged Propbank annotation for that sentence, and a "bad" semantic role if it does not.

The features extracted from the packed chart are as follows:

- **Role**. The semantic role itself, concatenated with the predicate. For example, play.Arg1. This will represent the intuition described in Section 1 that certain roles are more semantically appealing than others.

- **Role and Headword**. The semantic role concatenated with the predicate and the headword of the semantic role. This reflects the idea that certain words fit with particular roles better than others.

These features are used to train an averaged perceptron model to distinguish between likely and unlikely semantic roles. We incorporate the perceptron directly with the parser using a packed feature forest implementation, following an approach used by the current state-of-the-art CCG parser (Clark and Curran, 2004). By preferring sentences with good semantic roles, we hope to produce parses that give better overall semantic role predictions. The parser prefers spans with better semantic roles, and breaks ties that would have arisen using the baseline model alone. Similarly the baseline model can break ties between equivalent semantic roles; this has the added benefit of encouraging normal-form derivations in cases of spurious ambiguity. The result is a single-best complete parse with semantic roles already predicted. Once the single-best parse is selected, we allow the global SRL model to predict any additional roles over the parse, to catch those roles that are difficult to predict from local features alone.

7 Experiment 1: Choosing a Single-Best Derivation from an N-best List

Our first experiment demonstrates our model's performance in a ranking task. In this task, a list of candidate parses are generated by our baseline model. This baseline model treats rule applications as a PCFG – each rule application (say, np + s\np = s) is given a probability in the standard way. The rule probabilities are unsmoothed maximum likelihood estimates derived from rule counts in the training portion of CCGbank. After n-best derivations are produced by the baseline model, we use the Brutus semantic role labeler to assign roles to each candidate derivation. We vary the size of the n-best list from 1 to 10 (note that an n-best list of size 1 is equivalent to the single-best baseline parse). We then use the semantic model to re-rank the candidate parses and produce a single-best parse. The outcomes are shown in Table 2.

n	P	R	F
1	85.1	71.7	77.8
2	85.9	74.8	79.9
5	**84.5**	**76.8**	**80.5**
10	83.7	76.8	80.1
C&C	83.6	76.8	80.0

Table 2: SRL performance on the development set (section 00) for various values of n. The final row indicates SRL performance on section 00 parses from the Clark and Curran CCG parser.

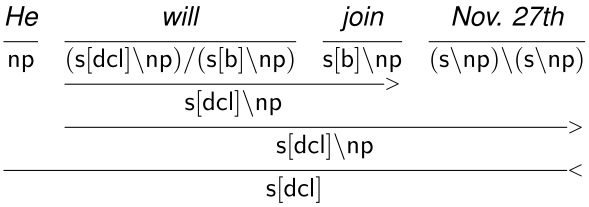

Figure 5: The single-best analysis for *He will join Nov 27th* according to the baseline model. Notice that the temporal adjunct is attached high, leading the semantic role labeler to fail to identify ArgM-TMP.

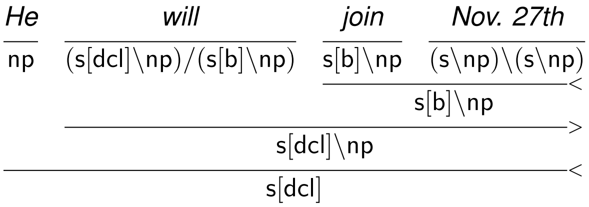

Figure 6: The second-best analysis of *He will join Nov 27th*. This analysis correctly predicts *Nov 27th* as the ArgM-TMP of *join*, and the semantic model correctly re-ranks this analysis to the single-best position.

The availability of even two candidate parses yields a 2.1% boost to the balanced F-measure. This is because the semantic role labeler is very sensitive to syntactic attachment decisions, and in many cases the set of rule applications used in the derivation are very similar or even the same. Consider the simplified version of a phenomenon found in wsj_0001.1 shown in Figures 5 and 6. The only difference in rule applications in these derivations is whether the temporal adjunct attaches to s[b]\np or s[dcl]\np. Because the s[dcl]\np case is slightly more common in the treebank, the baseline model identifies it as the single-best parse, and identifies the derivation in figure 6 as the second-best parse. The semantic model, however, correctly recognizes that the semantic roles predicted by the derivation in Figure 6 are superior to those predicted by the derivation in figure 5. This demonstrates how a second or third-best parse according to the baseline model can be greatly superior to the single-best in terms of semantics.

8 Experiment 2: Choosing a Single-Best Derivation Directly from the Packed Chart

One potential weakness with the n-best list approach described in Section 7 is choosing the size of the n-best list. As the length of the sentence grows, the number of candidate analyses grows. Because sentences in the treebank and in real-world applications are of varying length and complexity, restricting ourselves to an n-best list of a particular size opens us to considering some badly mangled derivations on short, simple sentences, and not enough derivations on long, complicated ones. One possible solution to this is to simply choose a single best derivation directly from the packed chart using the semantic model, eschewing the baseline model entirely except for breaking ties. In this approach, we use the local SRL model described in section 6 to predict semantic roles at parse time, inside the packed chart. This frees us from the need to have a complete derivation (as in the n-best list approach in Section 7). We use the semantic model to choose a single-best parse from the packed chart, then we pass this complete parse through the global SRL model to give it all the benefits afforded to the parses in the n-best approach. The results for the semantic model compared to the baseline model are shown in table 3. Interestingly, the semantic model performs considerably worse than the baseline model. To understand why, it is necessary to remember that the semantic model uses only semantic features – probabilities of rule applications are not considered. Therefore, the semantic model is perfectly happy to predict derivations with sequences of highly unlikely rule applications so long as they predict a role that the model has been trained to prefer.

Model	P	R	F
Baseline	85.1	71.7	77.8
Semantic	82.7	70.5	76.1

Table 3: A comparison of the performance of the baseline model and the semantic model on semantic role labeling. The semantic model, when unrestrained by the baseline model, performs substantially worse.

Apparently, the reckless pursuit of appealing semantic roles can ultimately harm semantic role labeling accuracy as well as parse accuracy. Consider the analysis shown in Figure 7. Because the averaged perceptron semantic model is not sensitive to the relationships between different semantic roles, and because Arg1 of *name* is a "good" semantic role, the semantic model predicts as many of them as it can. The very common np-appositive construction is particularly vulnerable to this kind of error, as it can be easily mistaken for a three-way coordination (like *carrots, peas and watermelon*). Many of the precision errors generated by the local model are of this nature, and the global model is unlikely to remove them, given the presence of strong dependencies between each of the "subjects" and the predicate.

Coordination errors are also common when dealing with relative clause attachment. Consider the analysis in Figure 8. To a PCFG model, there is little difference between attaching the relative clause to *the researchers* or *Lorillard nor the researchers*. The semantic model, however, would rather predict two semantic roles than just one (because study:Arg0 is a highly appealing semantic role). Once again, the pursuit of appealing semantic roles has led the system astray.

We have shown in Section 7 that the semantic model can improve SRL performance when it is constrained to the most likely PCFG derivations, but enumerating n-best lists is costly and cumbersome. We can, however, combine the semantic model with the baseline PCFG. Our method for doing this is designed to avoid the kinds of error described above. We first identify the highest-scoring parse according to the PCFG model. This parse will be used in later processing unless we are able to identify another parse that satisfies the following criteria:

1. It must be closely related to the parse that has the best score according to the semantic model. To identify such parses, we ask the chart unpacking algorithm to generate all the parses that can be reached by making up to five attachment changes to this semantically preferred parse – no more.

2. It must have a PCFG score that is not much less than that of the single-best PCFG parse. We do this by requiring that it has a score that is within a factor of α of the best available. That is, the single-best parse from the semantic model must satisfy

$$\log P(\text{sem}) > \log P(\text{baseline}) + \log(\alpha)$$

where the α value is tuned on the development set.

If no semantically preferred parse meets the above criteria, the single-best PCFG parse is used. We find that the PCFG-preferred parse is used about 35% of the time and an alternative used instead about 65% of the time. The SRL performance for this regime, using a range of cut-off factors, is shown in table 4. On this basis we select a cut-off of 0.5 as suitable for use for final testing. On the development set this method gives the best precision in extracting dependencies, but is slightly inferior to the method using a 2-best list on recall and balanced F-measure.

Factor (α)	P	R	F
0.5	86.3	71.9	78.5
0.1	85.4	72.0	78.1

Table 4: SRL accuracy when the semantic model is constrained by the baseline model

9 Results and Discussion

We use the method for calculating SRL performance described in the CoNNL 2008 and 2009 shared tasks. However, because the semantic role labeler we use was not designed to work with Nombank (and it is difficult to separate Nombank and Propbank predicates from the publicly released shared task output), it is not feasible to compare results with the candidate systems described there. We can, however, compare our two experimental models with our baseline parser and the current state-of-the-art CCG

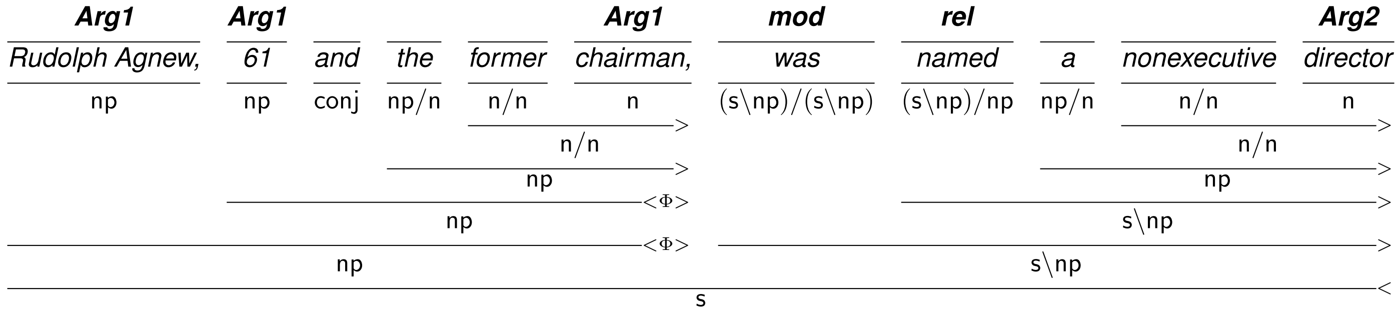

Figure 7: A parse produced by the unrestricted semantic model. Notice that *Rudolph Agnew, 61 and the former chairman* is erroneously treated as a three-way conjunction, assigning semantic roles to all three heads.

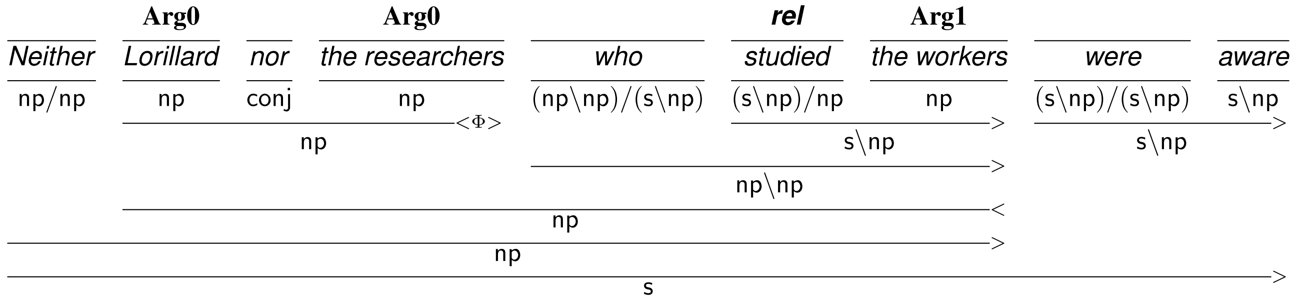

Figure 8: Relative clause attachment poses problems when preceded by a conjunction – the system generally prefers attaching relative clauses high. In this case, the relative clause should be attached low.

parser (Clark and Curran, 2004). The results on the test set (WSJ Section 23, <40 words) are shown in Table 5.

There are many areas for potential improvement for the system. The test set scores of both of our experimental models are lower than their development set scores,where the n-best model outperforms even the Clark and Curran parser in the SRL task. This may be due to vocabulary issues (we are of course unable to evaluate if the vocabulary of the training set more closely resembles the development set or the test set). If there are vocabulary issues, they could be alleviated by experimenting with POS based lexical features, or perhaps even generalizing a latent semantics over heads of semantic roles (essentially identifying broad categories of words that appear with particular semantic roles, rather than counting on having encountered that particular word in training). Alternately, this drop in performance could be caused by a mismatch in the average length of sentences, which would cause our α factor and the size of our n-best lists (which were tuned on the development set) to be suboptimal. We anticipate the opportunity to further explore better ways of determining n-best list size. We also anticipate the possibility of integrating the semantic model with a state-of-the-art CCG parser, potentially freeing the ranker from the limitations of a simple PCFG baseline.

It is also worth noting that the chart-based model seems heavily skewed towards precision. Because the parser can dig deeply into the chart, it is capable of choosing a parse that predicts only semantic roles that it is highly confident about. By choosing these parses (and not parses with less attractive semantic roles), the model can maximize the average score of the semantic roles it predicts. This tendency towards identifying only the most certain roles is consistent with high-precision low-recall results. The n-best parser has a much more restricted set of semantic roles from parses more closely resembling the single-best parse, and therefore is less likely to be presented with the opportunity to choose parses that do away with less likely (but still reasonable) roles.

10 Conclusions and Future Work

In this paper, we discuss the procedure for identifying semantic roles at parse time, and using these roles to guide the parse. We demonstrate that using semantic roles to guide parsing can improve overall SRL performance, but that these same benefits can be realized by re-ranking an n-best list with the same model. Regardless, there are several reasons why it is useful to have the ability to predict semantic roles inside the chart.

Predicting semantic roles inside the chart could be used to perform SRL on very long or unstructured passages.

	SRL			Labeled Deps		
Model	P	R	F	P	R	F
Baseline	84.7	70.7	77.0	80.0	79.8	79.9
Rank n=5	82.0	73.7	77.7	80.1	80.0	80.0
Chart	90.0	68.4	77.7	82.3	80.2	81.2
C&C	83.3	77.6	80.4	84.9	84.6	84.7
Char	77.1	75.5	76.5	-	-	-

Table 5: The full system results on the test set of the WSJ corpus (Section 23). Included are the baseline parser, the n-best reranking model from Section 7, the single-best chart-unpacking model from Section 8, and the state-of-the-art C&C parser. The final row shows the SRL performance obtained by Punyakanok et al. (2008) using the Charniak parser. Unfortunately, their results are evaluated based on spans of words (rather than headword labels), which interferes with direct comparison. The Charniak parser is a CFG-style parser, making labeled dependency non-applicable.

Most parsing research on the Penn Treebank (the present work included) focuses on sentences of 40 words or less, because parsing longer sentences requires an unacceptably large amount of computing resources. In practice, however, semantic roles are rarely very distant from their predicates – generally they are only a few words away; often they are adjacent. In long sentences, the prediction of an entire parse may be unnecessary for the purposes of SRL.

The CKY parsing algorithm works by first predicting all constituents spanning two words, then all constituents spanning three words, then four, and so on until it predicts constituents covering the whole sentence. By setting a maximum constituent size (say, ten or fifteen), we could abandon the goal of completing a spanning analysis in favor of identifying semantic roles in the neighborhood of their predicates, eliminating the need to unpack the chart at all. This could be used to efficiently perform SRL on poorly structured text or even spoken language transcriptions that are not organized into discrete sentences. Doing so would also eliminate the potentially noisy step of automatically separating out individual sentences in a larger text. Alternately, roles predicted in the chart could even be incorporated into a low-precision-high-recall information retrieval system seeking a particular semantic relationship by scanning the chart for a particular semantic role.

Another use for the packed forest of semantic roles could be to predict complete sets of roles for a given sentence using a constraint based method like integer linear programming. Integer linear programming takes a large number of candidate results (like semantic roles), and applies a set of constraints over them (like "roles may not overlap" or "no more than one of each role is allowed in each sentence") to find the optimal set. Doing so could eliminate the need to unpack the chart at all, effectively producing semantic roles without committing to a single syntactic analysis.

Abstract

Graph-based methods have gained attention in many areas of Natural Language Processing (NLP) including Word Sense Disambiguation (WSD), text summarization, keyword extraction and others. Most of the work in these areas formulate their problem in a graph-based setting and apply unsupervised graph clustering to obtain a set of clusters. Recent studies suggest that graphs often exhibit a hierarchical structure that goes beyond simple flat clustering. This paper presents an unsupervised method for inferring the hierarchical grouping of the senses of a polysemous word. The inferred hierarchical structures are applied to the problem of word sense disambiguation, where we show that our method performs significantly better than traditional graph-based methods and agglomerative clustering yielding improvements over state-of-the-art WSD systems based on sense induction.

1 Introduction

A number of NLP problems can be cast into a graph-based framework, in which entities are represented as vertices in a graph and relations between them are depicted by weighted or unweighted edges. For instance, in unsupervised WSD a number of methods (Widdows and Dorow, 2002; Véronis, 2004; Agirre et al., 2006) have constructed word co-occurrence graphs for a target polysemous word and applied graph-clustering to obtain the clusters (senses) of that word.

Similarly in text summarization, Mihalcea (2004) developed a method, in which sentences are represented as vertices in a graph and edges between them are drawn according to their common tokens or words of a given POS category, e.g. nouns. Graph-based ranking algorithms, such as PageRank (Brin and Page, 1998), were then applied in order to determine the significance of sentences. In the same vein, graph-based methods have been applied to other problems such as determining semantic similarity of text (Ramage et al., 2009).

Recent studies (Clauset et al., 2006; Clauset et al., 2008) suggest that graphs exhibit a hierarchical structure (e.g. a binary tree), in which vertices are divided into groups that are further subdivided into groups of groups, and so on, until we reach the leaves. This hierarchical structure provides additional information as opposed to flat clustering by explicitly including organisation at all scales of a graph (Clauset et al., 2008). In this paper, we present an unsupervised method for inferring the hierarchical structure (binary tree) of a graph, in which vertices are the contexts of a polysemous word and edges represent the similarity between contexts. The method that we use to infer that hierarchical structure is the Hierarchical Random Graphs (HRGs) algorithm due to Clauset et al. (2008).

The binary tree produced by our method groups the contexts of a polysemous word at different heights of the tree. Thus, it induces the senses of that word at different levels of sense granularity. To evaluate our method, we apply it to the problem of noun sense disambiguation showing that inferring the hierarchical structure using HRGs provides additional information from the observed graph leading to improved WSD performance compared to: (1)

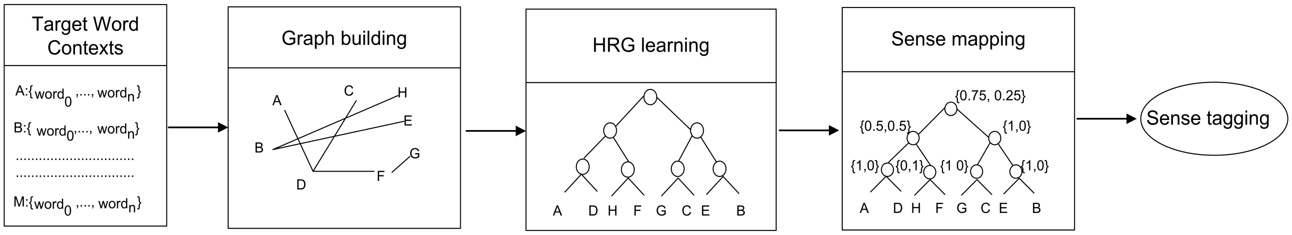

Figure 1: Stages of the proposed method.

simple flat clustering, and (2) traditional agglomerative clustering. Finally, we compare our results with state-of-the-art sense induction systems and show that our method yields improvements. Figure 1 shows the different stages of the proposed method that we describe in the following sections.

2 Related work

Typically, graph-based methods, when applied to unsupervised sense disambiguation represent each word w_i co-occurring with the target word tw as a vertex. Two vertices are connected via an edge if they co-occur in one or more contexts of tw. Once the co-occurrence graph of tw has been constructed, different graph clustering algorithms are applied to induce the senses. Each cluster (induced sense) consists of a set of words that are semantically related to the particular sense. Figure 2 shows an example of a graph for the target word *paper* that appears with two different senses *scholarly article* and *newspaper*.

Véronis (2004) has shown that co-occurrence graphs are small-world networks that contain highly dense subgraphs representing the different clusters (senses) of the target word (Véronis, 2004). To identify these dense regions Véronis's algorithm iteratively finds their hubs, where a hub is a vertex with a very high *degree*. The degree of a vertex is defined to be the number of edges incident to that vertex. The identified hub is then deleted along with its direct neighbours from the graph producing a new cluster.

For example, in Figure 2 the highest degree vertex, *news*, is the first hub, which would be deleted along with its direct neighbours. The deleted region corresponds to the *newspaper* sense of the target word *paper*. Véronis (2004) further processed the identified clusters (senses), in order to assign the rest of graph vertices to the identified clusters by utilising the *minimum spanning tree* of the original graph.

In Agirre et al. (2006), the algorithm of Véronis (2004) is analysed and assessed on the SensEval-3 dataset (Snyder and Palmer, 2004), after optimising its parameters on the SensEval-2 dataset (Edmonds and Dorow, 2001). The results show that the WSD F-Score outperforms the Most Frequent Sense (MFS) baseline by approximately 10%, while inducing a large number of clusters (with averages of 60 to 70).

Another graph-based method is presented in (Dorow and Widdows, 2003). They extract only noun neighbours that appear in conjunctions or disjunctions with the target word. Additionally, they extract second-order co-occurrences. Nouns are represented as vertices, while edges between vertices are drawn, if their associated nouns co-occur in conjunctions or disjunctions more than a given number of times. This co-occurrence frequency is also used to weight the edges. The resulting graph is then pruned by removing the target word and vertices with a low degree. Finally, the MCL algorithm (Dongen, 2000) is used to cluster the graph and produce a set of clusters (senses) each one consisting of a set of contextually related words.

Chinese Whispers (CW) (Biemann, 2006) is a parameter-free[1] graph clustering method that has been applied in sense induction to cluster the co-occurrence graph of a target word (Biemann, 2006), as well as a graph of collocations related to the target word (Klapaftis and Manandhar, 2008). The evaluation of the collocational-graph method in the SemEval-2007 sense induction task (Agirre and Soroa, 2007) showed promising results.

All the described methods for sense induction ap-

[1] One needs to specify only the number of iterations. The number of clusters is generated automatically.

Observed graph

Figure 3: Running example of graph creation

ply flat graph clustering methods to derive the clusters (senses) of a target word. As a result, they neglect the fact that their constructed graphs often exhibit a hierarchical structure that is useful in several tasks including word sense disambiguation.

3 Building a graph of contexts

This section describes the process of creating a graph of contexts for a polysemous target word. Figure 3 provides a running example of the different stages of our method. In the example, the target word *paper* appears with the *scholarly article* sense in the contexts *A*, *B*, and with the *newspaper* sense in the contexts *C* and *D*.

3.1 Corpus preprocessing

Let bc denote the base corpus consisting of the contexts containing the target word tw. In our work, a context is defined as a paragraph[2] containing the target word.

The aim of this stage is to capture nouns contextually related to tw. Initially, the target word is removed from bc and part-of-speech tagging is applied to each context. Following the work in (Véronis, 2004; Agirre et al., 2006) only nouns are kept and lemmatised. In the next step, the distribution of each noun in the base corpus is compared to the distribution of the same noun in a reference corpus[3] using the log-likelihood ratio (G^2) (Dunning, 1993). Nouns with a G^2 below a pre-specified threshold (parameter p_1) are removed from each paragraph of the base corpus. The upper left part of Figure 3 shows the words kept as a result of this stage.

3.2 Graph creation

Graph vertices: To create the graph of vertices, we represent each context c_i as a vertex in a graph G.

Graph edges: Edges between the vertices of the graph are drawn based on their similarity, defined in Equation 1, where $sim_{cl}(c_i, c_j)$ is the *collocational weight* of contexts c_i, c_j and $sim_{wd}(c_i, c_j)$ is their bag-of-words weight. If the edge weight $W(c_i, c_j)$ is above a prespecified threshold (parameter p_3), then an edge is drawn between the corresponding vertices in the graph.

$$W(c_i, c_j) = \frac{1}{2}(sim_{cl}(c_i, c_j) + sim_{wd}(c_i, c_j)) \quad (1)$$

Collocational weight: The limited polysemy of collocations can be exploited to compute the similarity between contexts c_i and c_j. In our setting, a collocation is a juxtaposition of two nouns within the same context. Thus, given a context c_i, each of its nouns is combined with any other noun yielding a total of $\binom{N}{2}$ collocations for a context with N nouns. Each collocation, cl_{ij} is weighted using the log-likelihood ratio (G^2) (Dunning, 1993) and is filtered out if the G^2 is below a prespecified threshold (parameter p_2). At the end of this process, each context c_i of tw is associated with a vector of collocations (v_i). The upper right part of Figure 3 shows the collocations associated with each context of our example.

[2] Our definition of *context* is equivalent to an instance of the target word in the SemEval-2007 sense induction task dataset (Agirre and Soroa, 2007).

[3] The British National Corpus, 2001, Distributed by Oxford University Computing Services.

Given two contexts c_i and c_j, we calculate their collocational weight using the Jaccard coefficient on the collocational vectors, i.e. $sim_{cl}(c_i, c_j) = \frac{|v_i \cap v_j|}{|v_i \cup v_j|}$. The selection of Jaccard is based on the work of Weeds et al. (2004), who analyzed the variation in a word's distributionally nearest neighbours with respect to a variety of similarity measures. Their analysis showed that there are three classes of measures, i.e. those selecting distributionally more general neighbours (e.g. cosine), those selecting distributionally less general neighbours (e.g. AMCRM-Precision (Weeds et al., 2004)) and those without a bias towards the distributional generality of a neighbour (e.g. Jaccard). In our setting, we are interested in calculating the similarity between two contexts without any bias. We selected Jaccard, since the rest of that class's measures are based on pointwise mutual information that assigns high weights to infrequent events.

Bag-of-words weight: Estimating context similarity using collocations may provide reliable estimates regarding the existence of an edge in the graph, however, it also suffers from data sparsity. For this reason, we also employ a bag-of-words model. Specifically, each context c_i is associated with a vector g_i that contains the nouns kept as result of the corpus preprocessing stage. The upper left part of Figure 3 shows the words associated with each context of our example. Given two contexts c_i and c_j, we calculate their bag-of-words weight using the Jaccard coefficient on the word vectors, i.e. $sim_{wd}(c_i, c_j) = \frac{|g_i \cap g_j|}{|g_i \cup g_j|}$.

The collocational weight and bag-of-words weight are averaged to derive the edge weight between two contexts as defined in Equation 1. The resulting graph of our running example is shown on the bottom of Figure 3. This graph is the input to the *hierarchical random graphs* method (Clauset et al., 2008) described in the next section.

4 Hierarchical Random Graphs for sense induction

In this section, we describe the process of inferring the hierarchical structure of the graph of contexts using *hierarchical random graphs* (Clauset et al., 2008).

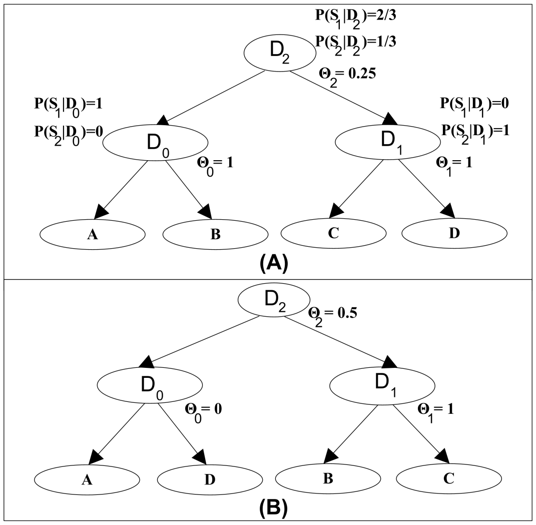

Figure 4: Two dendrograms for the graph in Figure 3.

4.1 The Hierarchical Random Graph model

A dendrogram is a binary tree with n leaves and $n-1$ parents. Figure 4 shows an example of two dendrograms with 4 leaves and 3 parents. Given a set of n contexts that we need to arrange hierarchically, let us denote by $G = (V, E)$ the graph of contexts, where $V = \{v_0, v_1 \dots v_n\}$ is the set of vertices, $E = \{e_0, e_1 \dots e_m\}$ is the set of edges and $e_k = \{v_i, v_j\}$.

Given an undirected graph G, each of its n vertices is a leaf in a dendrogram, while the internal nodes of that dendrogram indicate the hierarchical relationships among the leaves. We denote this organisation by $D = \{D_1, D_2, \dots D_{n-1}\}$, where each D_k is an internal node. Every pair of nodes (v_i, v_j) is associated with a unique D_k, which is their lowest common ancestor in the tree. In this manner D partitions the edges that exist in G.

The primary assumption in the hierarchical random graph model is that edges in G exist independently, but with a probability that is not identically distributed. In particular, the probability that an edge $\{v_i, v_j\}$ exists in G is given by a parameter θ_k associated with D_k, the lowest common ancestor of v_i and v_j in D. In this manner, the topological structure D and the vector of probabilities $\vec{\theta}$ define the HRG given by $H(D, \vec{\theta})$ (Clauset et al., 2008).

4.2 HRG parameterisation

Assuming a uniform prior over all HRGs, the target is to identify the parameters of D and $\vec{\theta}$, so that the chosen HRG is statistically similar to G. Let D_k be an internal node of dendrogram D and $f(D_k)$ be the number of edges between the vertices of the subtrees of the subtree rooted at D_k that actually exist in G. For example, in Figure 4(A), $f(D_2) = 1$, because there is one edge in G connecting vertices B and C. Let $l(D_k)$ be the number of leaves in the left subtree of D_k, and $r(D_k)$ be the number of leaves in the right subtree. For example in Figure 4(A), $l(D_2) = 2$ and $r(D_2) = 2$. The likelihood of the hierarchical random graph $(D, \vec{\theta})$ is defined in Equation 2, where $A(D_k) = l(D_k)r(D_k) - f(D_k)$.

$$L(D, \vec{\theta}) = \prod_{D_k \in D} \theta_k^{f(D_k)} (1 - \theta_k)^{A(D_k)} \qquad (2)$$

The probabilities θ_k that maximise the likelihood of a dendrogram D can be easily estimated using the method of MLE i.e $\overline{\theta}_k = \frac{f(D_k)}{l(D_k)r(D_k)}$. Substituting this into Equation 2 yields Equation 3. For numerical reasons, it is more convenient to work with the logarithm of the likelihood which is defined in Equation 4, where $h(\overline{\theta}_k) = -\overline{\theta}_k \log \overline{\theta}_k - (1 - \overline{\theta}_k) \log (1 - \overline{\theta}_k)$.

$$L(D) = \prod_{D_k \in D} [\overline{\theta}_k^{\overline{\theta}_k} (1 - \overline{\theta}_k)^{1 - \overline{\theta}_k}]^{l(D_k)r(D_k)} \qquad (3)$$

$$\log L(D) = - \sum_{D_k \in D} h(\overline{\theta}_k) l(D_k) r(D_k) \qquad (4)$$

As can be observed, each term $-l(D_k)r(D_k)h(\overline{\theta}_k)$ is maximised when θ_k approaches 0 or 1. This means that high-likelihood dendrograms partition vertices into subtrees, such that the connections among their vertices in the observed graph are either very rare or very common (Clauset et al., 2008). For example, consider the two dendrograms in Figures 4(A) and 4(B). We observe that 4(A) is more likely than 4(B), since it provides a better division of the network leaves. Particularly, the likelihood of 4(A) is $L(D_1) = (1^1 \cdot (1-1)^1) \cdot (1^1 \cdot (1-1)^1) \cdot (0.25^1 \cdot (1-0.25)^3) = 0.105$, while the likelihood of 4(B) is $L(D_2) = (0^0 \cdot (1-0)^1) \cdot (1^1 \cdot (1-1)^1) \cdot (0.5^2 \cdot (1-0.5)^2) = 0.062$.

4.2.1 MCMC sampling

Finding the values of θ_k using the MLE method is straightforward. However, this is not the case for maximising the likelihood function over the space of all possible dendrograms. Given a graph with n vertices, i.e. n leaves in each dendrogram, the total number of different dendrograms is super-exponential ($(2n-3)!! \approx \sqrt{2}(2n)^{n-1}e^{-n}$) (Clauset et al., 2006).

To deal with this problem, we use a Markov Chain Monte Carlo (MCMC) method that samples dendrograms from the space of dendrogram models with probability proportional to their likelihood. Each time MCMC samples a dendrogram with a new highest likelihood, that dendrogram is stored. Hence, our goal is to choose the highest likelihood dendrogram once MCMC has converged.

Following the work in (Clauset et al., 2008), we pick a set of transitions between dendrograms, where a transition is a re-arrangement of the subtrees of a dendrogram. In particular, given a current dendrogram D_{curr}, each internal node D_k of D_{curr} is associated with three subtrees of D_{curr}. For instance, in Figure 5A, the subtrees st_1 and st_2 are derived from the two children of D_k and the third st_3 from its sibling. Given a current dendrogram, D_{curr}, the algorithm proceeds as follows:

1. Choose an internal node, $D_k \in D_{curr}$ uniformly.

2. Generate two possible new configurations of the subtrees of D_k (See Figure 5).

3. Choose one of the configurations uniformly to generate a new dendrogram, D_{next}.

4. Accept or reject D_{next} according to Metropolis-Hastings (MH) rule.

5. If transition is accepted, then $D_{curr} = D_{next}$.

6. GOTO 1.

According to MH rule (Newman and Barkema, 1999), a transition is accepted if $\log L(D_{next}) \geq \log L(D_{curr})$; otherwise the transition is accepted with probability $\frac{L(D_{next})}{L(D_{curr})}$. These transitions define an ergodic Markov chain, hence its stationary distribution can be reached (Clauset et al., 2008).

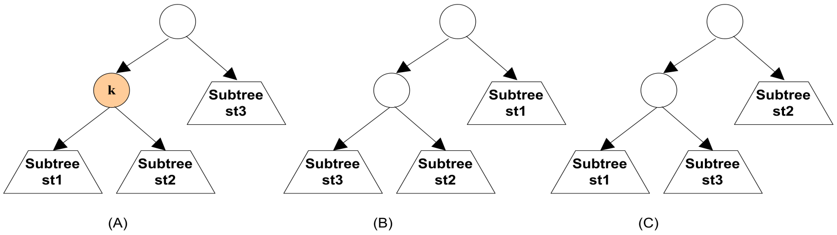

Figure 5: (A) current configuration for internal node D_k and its associated subtrees (B) first alternative configuration, (C) second alternative configuration. Note that swapping $st1$, $st2$ in (A) results in an equivalent tree. Hence, this configuration is excluded.

In our experiments, we noticed that the algorithm converged relatively quickly. The same behaviour (roughly $O(n^2)$ steps) was also noticed in Clauset et al. (2008), when considering graphs with thousands of vertices.

5 HRGs for sense disambiguation

5.1 Sense mapping

The output of HRG learning is a dendrogram D with n leaves (contexts) and $n-1$ internal nodes. To perform sense disambiguation, we mapped the internal nodes to gold standard senses using a sense-tagged corpus. Such a sense-tagged corpus is needed when induced word senses need to be mapped to a gold standard sense inventory.

Instead of using a hard mapping from the dendrogram internal nodes to the Gold Standard (GS) senses, we use a soft probabilistic mapping and calculate $P(s_k|D_i)$, i.e the probability of sense s_k given node D_i. Let $F(D_i)$ be the set of training contexts grouped by internal node D_i. Let $F'(s_k)$ be the set of training contexts that are tagged with sense s_k. Then the conditional probability, $P(s_k|D_i)$, is defined in Equation 5.

$$P(s_k|D_i) = \frac{|F(D_i) \cap F'(s_k)|}{|F(D_i)|} \quad (5)$$

Table 1 provides a sense-tagged corpus for the running example of Figure 3. Using this corpus and the tree in Figure 4(A), $P(s_1|D_2) = \frac{2}{3}$ and $P(s_2|D_2) = \frac{1}{3}$. In Figure 4(A) the rest of the calculated conditional probabilities are given.

5.2 Sense tagging

For evaluation we compared the proposed method against the current state-of-the-art sense induction systems in the WSD task. We followed the setting of SemEval-2007 sense induction task (Agirre and Soroa, 2007). In this setting, the base corpus (bc) (Section 3.1) for a target word consists both of the training and testing corpus. As a result, a testing context c_j of tw is a leaf in the generated dendrogram. The process of disambiguating c_j is straightforward exploiting the structural information provided by HRGs.

GS sense	Context ID	Context words
s_1	A	journal, scholar, observation science, **paper**
s_1	B	scholar, scholar, author, publication, **paper**
s_2	D	times, guardian, journalist, **paper**

Table 1: Sense-tagged corpus for the example in Figure 3

$$w(s_k, c_j) = \sum_{D_i \in H(c_j)} P(s_k|D_i) \cdot \theta_i \quad (6)$$

$$w(s^*, c_j) = \text{argmax}\, s_k(w(s_k, c_j)) \quad (7)$$

Let $H(c_j)$ denote the set of parents for context c_j. Then, the weight assigned to sense s_k is the sum of weighted scores provided by each identified parent. This is shown in Equation 6, where θ_i is the probability associated with each internal node D_i from the hierarchical random graph (see Figure 4(A)). This probability reflects the discriminating ability of internal nodes.

Finally, the highest weight determines the winning sense for context c_j (Equation 7). In our example (Figure 4(A)), $w(s_1, C) = (0 \cdot 1 + \frac{2}{3} \cdot 0.25) = 0.16$ and $w(s_2, C) = (1 \cdot 1 + \frac{1}{3} \cdot 0.25) = 1.08$. Hence, s_2 is the winning sense.

Parameter	Range
G^2 word threshold (p_1)	15,25,35,45
G^2 collocation threshold (p_2)	10,15,20
Edge similarity threshold (p_3)	0.05,0.09,0.13

Table 2: Parameter values used in the evaluation.

6 Evaluation

6.1 Evaluation setting & baselines

We evaluate our method on the nouns of the SemEval-2007 word sense induction task (Agirre and Soroa, 2007) under the second evaluation setting of that task, i.e. supervised evaluation. Specifically, we use the standard WSD measures of precision and recall in order to produce their harmonic mean (F-Score). The official scoring software of that task has been used in our evaluation. Note that the unsupervised measures of that task are not directly applicable to our induced hierarchies, since they focus on assessing flat clustering methods.

The first aim of our evaluation is to test whether inferring the hierarchical structure of the constructed graphs improves WSD performance. For that reason our first baseline, Chinese Whispers Unweighted version (*CWU*), takes as input the same unweighted graph of contexts as HRGs in order to produce a flat clustering. The set of produced clusters is then mapped to GS senses using the training dataset and performance is then measured on the testing dataset. We followed the same sense mapping method as in the SemEval-2007 sense induction task (Agirre and Soroa, 2007).

Our second baseline, Chinese Whispers Weighted version (*CWW*), is similar to the previous one, with the difference that the edges of the input graph are weighted using Equation 1. For clustering the graphs of *CWU* and *CWW* we employ, *Chinese Whispers*[4] (Biemann, 2006).

The second aim of our evaluation is to assess whether the hierarchical structure inferred by HRGs is more informative than the hierarchical structure inferred by traditional Hierarchical Clustering (*HAC*). Hence, our third baseline, takes as input a similarity matrix of the graph vertices and performs bottom-up clustering with average-linkage, which has already been used in WSI in (Pantel and Lin, 2003) and was shown to have superior or similar performance to single-linkage and complete-linkage in the related problem of learning a taxonomy of senses (Klapaftis and Manandhar, 2010).

To calculate the similarity matrix of vertices we follow a process similar to the one used in Section 4.2 for calculating the probability of an internal node. The similarity between two vertices is calculated according to the degree of connectedness among their direct neighbours. Specifically, we would like to assign high similarity to pairs of vertices, whose neighbours are close to forming a clique.

Given two vertices (contexts) c_i and c_j, let $N(c_i, c_j)$ be the set of their neighbours and $K(c_i, c_j)$ be the set of edges between the vertices in $N(c_i, c_j)$. The maximum number of edges that could exist between vertices in $N(c_i, c_j)$ is $\binom{|N(c_i,c_j)|}{2}$. Thus, the similarity of c_i, c_j is set equal to the number of edges that actually exist in that neighbourhood divided by the total number of edges that could exist ($\frac{|K(c_i,c_j)|}{\binom{|N(c_i,c_j)|}{2}}$).

The disambiguation process using the HAC tree is identical to the one presented in Section 5.2 with the only difference that the internal probability, θ_i, in Equation 6 does not exist for HAC. Hence, we replaced it with the factor $\frac{1}{|H(D_i)|}$, where $H(D_i)$ is the set of children of internal node D_i. This factor provides lower weights for nodes high in the tree, since their discriminating ability will possibly be lower.

6.2 Results & discussion

Table 2 shows the parameter values used in the evaluation. Figure 6(A) shows the performance of the proposed method against the baselines for $p_3 = 0.05$ and different p_1 and p_2 values. Figure 6(B) illustrates the results of the same experiment using $p_3 = 0.09$. In both figures, we observe that *HRGs* outperform the *CWU* baseline under all parameter combinations. In particular, all of the 12 performance differences for $p_3 = 0.09$ are statistically significant using McNemar's test at 95% confidence level, while for $p_3 = 0.05$ only 2 out of the 12 performance differences were not judged as significant from the test.

The picture is the same for $p_3 = 0.13$, where *CWU* performs significantly worse than for $p_3 =$

[4] The number of iterations for CW was set to 200.

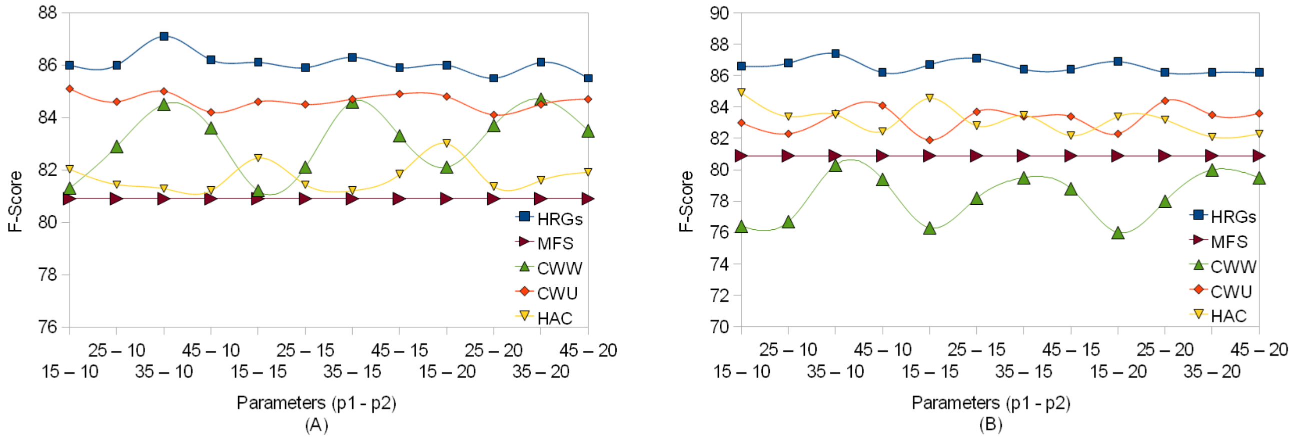

Figure 6: Performance analysis of HRGs, CWU, CWW & HAC for different parameter combinations (Table 2). **(A)** All combinations of p_1, p_2 and $p_3 = 0.05$. **(B)** All combinations of p_1, p_2 and $p_3 = 0.09$.

0.05 and $p_3 = 0.09$. Specifically, the largest performance difference between *HRGs* and *CWU* is 9.4% at $p_1 = 25$, $p_2 = 10$ and $p_3 = 0.13$. Setting the vertex similarity threshold (p_3) equal to 0.13 leads to more sparse and disconnected graphs, which causes *Chinese Whispers* to produce a large number of clusters. This leads to sparsity problems and unreliable mapping of clusters to GS senses due to the lack of adequate training data. In contrast, *HRGs* suffer less at this high threshold, although their performance when $p_3{<}0.13$ is better.

This picture does not change for the weighted version of *Chinese Whispers* (*CWW*) which performs worse than *CWU*. This is because *CWW* produces a smaller number of clusters than *CWU* that conflate the target word senses. It seems that using weighted edges creates a bias towards the MFS, in effect missing rare senses of a target word. This means that a number of words in the bag-of-words context vectors and collocations in the collocational context vectors (Section 3.2) are associated to more than one sense of the target word and most strongly associated to the MFS. As a result, increasing the p_1 threshold to 25 and 35 leads to a higher performance for *CWW*, since many of these words and collocations are filtered out.

Overall, the comparison of *HRGs* against the *CWU* and *CWW* baselines has shown that inferring the hierarchical structure of observed graphs leads to improved WSD performance as opposed to using flat clustering. This is because *HRGs* are able to infer both the hierarchical structure of the graph and include the probabilities, θ_k, associated with each internal node. These probabilities reflect the discriminating ability of each node, offering information missed by flat clustering.

In Figures 6(A) and 6(B) we observe that *HRGs* perform significantly better than HAC. In particular, all of their performance differences are statistically significant for these parameter values. The largest performance difference is 6.0% at $p_1 = 45$, $p_2 = 10$ and $p_3 = 0.05$. However, this picture is not the same when considering a higher context similarity threshold ($p_3 = 0.13$) as Figure 7 shows. In particular, *HRGs* and *HAC* perform similarly for $p_3 = 0.13$, while the majority of performance differences are not statistically significant.

The similar behaviour of *HRGs* and *HAC* at this threshold is caused both by the worse performance of *HRGs* and the improved performance of *HAC* as opposed to lower p_3 values. As it has been mentioned, setting $p_3 = 0.13$ leads to sparse and disconnected graphs. Additionally, the likelihood function (Equation 3) is maximised when the probability, θ_k, of an internal node, D_k, approaches 0 or 1. This creates a bias towards dendrograms, in which a large number of internal nodes have zero probability. These dendrograms might be a good-fit to the observed graph, but not to the GS.

In contrast, *HAC* is less affected, because it never considers creating an internal node, when the maximum similarity among any pair of two candidate

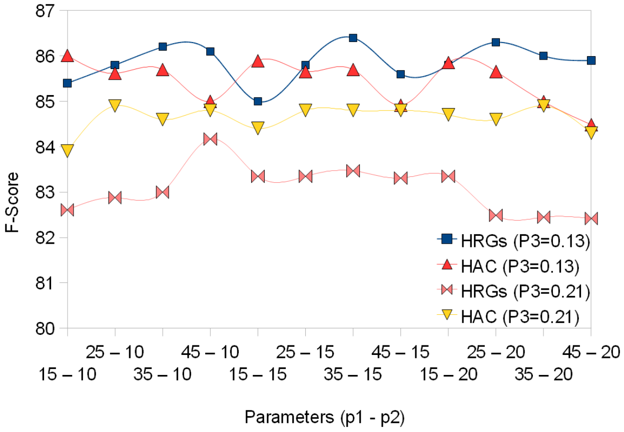

Figure 7: Performance of *HRGs* and *HAC* for different parameter combinations (Table 2). All combinations of p_1, p_2 and $p_3 \geq 0.13$.

subtrees is zero. Additionally, our experiments show that *HAC* is unable to deal with noise when considering sparse graphs (p_3<0.13). For that reason, the F-Score of *HAC* increases as the edge similarity threshold decreases.

To further investigate this issue and test whether *HAC* is able to achieve a higher F-Score than HRGs in higher p_3 values, we executed two more experiments for *HAC* and *HRGs* increasing p_3 to 0.17 and 0.21 respectively. In the first case we observed that the performance of *HAC* remained relatively stable compared to $p_3 = 0.13$, while in the second case the performance of *HAC* decreased as Figure 7 shows. In both cases, *HAC* performed significantly better than *HRGs*.

Overall, the comparison of *HRGs* against *HAC* has shown that *HRGs* perform significantly better than *HAC* when considering connected or less sparse graphs (p_3<0.13). This is due to the fact that *HAC* creates dendrograms, in which connections within the clusters are dense, while connections between the clusters are sparse, i.e. it only considers assortative structures. In contrast, HRGs also consider disassortative dendrograms, i.e. dendrograms in which vertices are less likely to be connected on small scales than on large ones, as well as mixtures of assortative and disassortative (Clauset et al., 2008). This is achieved by allowing the probability θ_k of a node k to vary arbitrarily throughout the dendrogram.

HAC performs similarly or better than *HRGs* for largely disconnected and sparse graphs, because HRGs become biased towards disassortative trees which are not a good fit to the GS (Figure 7). Despite that, our evaluation has also shown that the best performance of *HAC* (F-Score = 86.0% at $p_1 = 15$, $p_2 = 10$, $p_3 = 0.13$) is significantly lower than the best performance of *HRGs* (F-Score = 87.6% at $p_1 = 35$, $p_2 = 10$, $p_3 = 0.09$).

6.3 Comparison to state-of-the-art methods

Table 3 compares the best performing parameter combination of our method against state-of-the-art methods. Table 3 also includes the best performance of our baselines, i.e *HAC*, *CWU* and *CWW*.

Brody & Lapata (2009) presented a sense induction method that is related to Latent Dirichlet Allocation (Blei et al., 2003). In their work, they model the target word instances as samples from a multinomial distribution over senses which are successively characterized as distributions over words (Brody and Lapata, 2009). A significant advantage of their method is the inclusion of more than one layer in the LDA setting, where each layer corresponds to a different feature type e.g. dependency relations, bigrams, etc. The inclusion of different feature types as separate models in the sense induction process can easily be modeled in our setting, by inferring a different hierarchy of target word instances according to each feature type, and then combining all of them to a consensus tree. In this work, we have focused on extracting a single hierarchy combining word co-occurrence and bigram features.

Niu et al. (2007) developed a vector-based method that performs sense induction by grouping the contexts of a target word using three types of features, i.e. POS tags of neighbouring words, word co-occurrences and local collocations. The *sequential information bottleneck* algorithm (Slonim et al., 2002) is applied for clustering. *HRGs* perform slightly better than the methods of Brody & Lapata (2009) and Niu et al. (2007), although the differences are not significant (McNemar's test at 95% confidence level).

Klapaftis & Manandhar (2008) developed a graph-based sense induction method, in which vertices correspond to collocations related to the target word and edges between vertices are drawn ac-

System	Performance (%)
HRGs	87.6
(Brody and Lapata, 2009)	87.3
(Niu et al., 2007)	86.8
(Klapaftis and Manandhar, 2008)	86.4
HAC	86.0
CWU	85.1
CWW	84.7
(Pedersen, 2007)	84.5
MFS	80.9

Table 3: HRGs against recent methods & baselines.

cording to the co-occurrence frequency of the corresponding collocations. The constructed graph is smoothed to identify more edges between vertices and then clustered using Chinese Whispers (Biemann, 2006). This method is related to the basic inputs of our presented method. Despite that, it is a flat clustering method that ignores the hierarchical structure exhibited by observed graphs. The previous section has shown that inferring the hierarchical structure of graphs leads to superior WSD performance.

Pedersen (2007) presented *SenseClusters*, a vector-based method that clusters second order co-occurrence vectors using k-means, where k is automatically determined using the Adapted Gap Statistic (Pedersen and Kulkarni, 2006). As can be observed, *HRGs* perform significantly better than the methods of Pedersen (2007) and Klapaftis & Manandhar (2008) (McNemar's test at 95% confidence level).

Finally, Table 3 shows that the best performing parameter combination of HRGs achieves a significantly higher F-Score than the best performing parameter combination of *HAC*, *CWU* and *CWW*. Furthermore, HRGs outperform the most frequent sense baseline by 6.7%.

7 Conclusion & future work

We presented an unsupervised method for inferring the hierarchical grouping of the senses of a polysemous word. Our method creates a graph, in which vertices correspond to contexts of a polysemous target word and edges between them are drawn according to their similarity. The *hierarchical random graphs* algorithm (Clauset et al., 2008) was applied to the constructed graph in order to infer its hierarchical structure, i.e. binary tree.

The learned tree provides an induction of the senses of a given word at different levels of sense granularity and was applied to the problem of WSD. The WSD process mapped the tree's internal nodes to GS senses using a sense tagged corpus, and then tagged new instances by exploiting the structural information provided by the tree.

Our experimental results have shown that our graphs exhibit hierarchical organisation that can be captured by *HRGs*, in effect providing improved WSD performance compared to flat clustering. Additionally, our comparison against hierarchical agglomerative clustering with average-linkage has shown that *HRGs* perform significantly better than *HAC* when the graphs do not suffer from sparsity (disconnected graphs). The comparison with state-of-the-art sense induction systems has shown that our method yields improvements.

Our future work focuses on using different feature types, e.g. dependency relations, second-order co-occurrences, named entities and others to construct our undirected graphs and then applying HRGs, in order to measure the impact of each feature type on the induced hierarchical structures within a WSD setting. Moreover, following the work in (Clauset et al., 2008), we are also working on using MCMC in order to sample more than one dendrogram at equilibrium, and then combine them to a consensus tree. This consensus tree might be able to express a larger amount of topological features of the initial undirected graph.

Finally in terms of evaluation, our future work also focuses on evaluating *HRGs* using a fine-grained sense inventory, extending the evaluation on the SemEval-2010 WSI task dataset (Manandhar et al., 2010) as well as applying HRGs to other related tasks such as taxonomy learning.

Towards Conversation Entailment: An Empirical Investigation

Chen Zhang **Joyce Y. Chai**
Department of Computer Science and Engineering

East Lansing, MI 48824, USA
{zhangch6, jchai}@cse.msu.edu

Abstract

While a significant amount of research has been devoted to textual entailment, automated entailment from conversational scripts has received less attention. To address this limitation, this paper investigates the problem of conversation entailment: automated inference of hypotheses from conversation scripts. We examine two levels of semantic representations: a basic representation based on syntactic parsing from conversation utterances and an augmented representation taking into consideration of conversation structures. For each of these levels, we further explore two ways of capturing long distance relations between language constituents: implicit modeling based on the length of distance and explicit modeling based on actual patterns of relations. Our empirical findings have shown that the augmented representation with conversation structures is important, which achieves the best performance when combined with explicit modeling of long distance relations.

1 Introduction

Textual entailment has received increasing attention in recent years (Dagan et al., 2005; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Giampiccolo et al., 2008; Bentivogli et al., 2009). Given a segment from a textual document, the task of textual entailment is to automatically determine whether a given hypothesis can be entailed from the segment. The capability of such kind of inference can benefit many text-based applications such as information extraction and question answering.

Textual entailment has mainly focused on inference from written text in monologue. Recent years also observed an increasing amount of conversational data such as conversation scripts of meetings, call center records, court proceedings, as well as online chatting. Although conversation is a form of language, it is different from monologue text with several unique characteristics. The key distinctive features include turn-taking between participants, grounding between participants, different linguistic phenomena of utterances, and conversation implicatures. Traditional approaches dealing with textual entailment were not designed to handle these unique conversation behaviors and thus to support automated entailment from conversation scripts.

Example 1:
Conversation Segment:
B: My mother also was very very independent. She had her own, still had her own little house and still driving her own car,
A: Yeah.
B: at age eighty-three.
Hypothesis:
(1) B's mother is eighty-three.
(2) B is eighty-three.

To address this limitation, our previous work (Zhang and Chai, 2009) has initiated an investigation on the problem of *conversation entailment*. The problem was formulated as follows: given a conversation discourse *D* and a hypothesis *H* concerning its participant, the goal was to identify whether *D* entails *H*. For instance, as in Example 1, the first hypothesis can be entailed from the

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 756–766,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

conversation segment while the second hypothesis cannot. While our previous work has provided some interesting preliminary observations, it mostly focused on data collection and initial experiments and analysis using a small set of development data. It is not clear whether the previous results are generally applicable, how different components in the entailment framework interact with each other, and how different representations may influence the entailment outcome.

To reach a better understanding of conversation entailment, we conducted a further investigation based on the larger set of test data collected in our previous work (Zhang and Chai, 2009). We specifically examined two levels of representations: a basic representation based on syntactic parsing from conversation utterances and an augmented representation taking into consideration of conversation structures. For each of these levels, we further explored two ways of capturing long distance relations: (1) implicit modeling based on the length of distance and (2) explicit modeling based on actual patterns of relations. Our empirical findings have shown that augmented representation with conversation structures is important in conversation entailment. Combining conversation structures with explicit modeling of long distance relations results in the best performance.

2 Related Work

Our work here is related to recent advances in textual entailment, automated processing of conversation scripts, and our initial investigation on conversation entailment.

There is a large body of work on textual entailment initiated by the Pascal Recognizing Textual Entailment (RTE) Challenges (Dagan et al., 2005; Bar-Haim et al., 2006; Giampiccolo et al., 2007; Giampiccolo et al., 2008; Bentivogli et al., 2009). Different approaches have been developed, for example, based on logic proving (Tatu and Moldovan, 2005; Bos and Markert, 2005; Raina et al., 2005) and graph match (Haghighi et al., 2005; de Salvo Braz et al., 2005; MacCartney et al., 2006). Supervised learning approaches have also been applied to measure the similarities between training and testing pairs (Zanzotto and Moschitti, 2006). In the most recent RTE Challenge (Bentivogli et al., 2009), the best system achieves 73.5% of accuracy, while the median performance among all participants is 60.4%. These results indicate that, while progress has been made, textual entailment remains a challenging problem.

As more and more conversation data becomes available, researchers have investigated automated processing of conversation data to acquire useful information, for example, related to opinions (Somasundaran et al., 2007; Somasundaran et al., 2008; Somasundaran et al., 2009), biographic attributes (Garera and Yarowsky, 2009), social networks (Jing et al., 2007), and agreements and disagreements between participants (Galley et al., 2004). Recent studies have also developed approaches to summarize conversations (Murray and Carenini, 2008) and to model conversation structures (dialogue acts) from online Twitter conversations (Ritter et al., 2010). Here we address a different angle regarding conversation scripts, namely conversation entailment.

In our previous work (Zhang and Chai, 2009), we started an initial investigation on conversation entailment. We have collected a dataset of 875 instances. Each instance consists of a conversation segment and a hypothesis (as described in Section 1). The hypotheses are statements about conversation participants and are further categorized into four types: about their profile information, their beliefs and opinions, their desires, and their communicative intentions. We developed an approach that is motivated by previous work on textual entailment. We use clauses in the logic-based approaches as the underlying representation of our system. Based on this representation, we apply a two stage entailment process similar to MacCartney et al. (2006) developed for textual entailment: an alignment stage followed by an entailment stage.

Building upon our previous work, in this paper, we systematically examine different representations of the conversation segment and different modeling of long distance relations between language constituents. We compare the roles of these different representations on the performance of entailment prediction using a larger testing dataset that was not previously evaluated. This analysis allows better understanding of the problem and provides insight on potential solutions.

3 Overall Framework

In our previous work (Zhang and Chai, 2009), conversation entailment is formulated as the following: given a conversation segment D which is represented by a set of clauses $D = d_1 \wedge \ldots \wedge d_m$, and a hypothesis H represented by another set of clauses $H = h_1 \wedge \ldots \wedge h_n$, the prediction on whether D entails H is determined by the product of probabilities that each hypothesis clause h_j is entailed from all the conversation segment clauses $d_1 \ldots d_m$ as follows. This is based on a simple assumption that whether a clause is entailed from a conversation segment is conditionally independent from other clauses.

$$\begin{aligned} & P(D \vDash H | D, H) \\ & \quad = P(D \vDash h_1, \ldots, D \vDash h_n | D, h_1, \ldots, h_n) \\ & \quad = \prod_{j=1}^{n} P(D \vDash h_j | D = d_1 \ldots d_m, h_j) \\ & \quad = \prod_{j=1}^{n} P(d_1 \ldots d_m \vDash h_j | d_1, \ldots, d_m, h_j) \qquad (1) \end{aligned}$$

A clause here is similar to a sentence in first-order predicate calculus. It is made up by *terms* and *predicates*. A term is either: 1) an entity described by a noun phrase, e.g., *John Lennon*, *mother*, or *she*; or 2) an action or event described by a verb phrase, e.g., *marry* in "John married Eva in 1940". A predicate represents either: 1) a property (i.e., unary) for a term, e.g., $Russian(company)$, or $recently(visit)$; or 2) a relation (i.e., binary) between two terms, e.g., $subj(visit, Prime\ Minister)$ and $obj(visit, Brazil)$ in "Prime Minister recently visited Brazil".

Given the clause representation, we follow the idea similar to MacCartney et al. (2006), and predict the entailment decision in two stages of processing: (1) an alignment model aligns terms in the hypothesis to terms in the conversation segment; and (2) an inference model predicts the entailment based on the alignment between the hypothesis and the conversation segment.

3.1 Alignment Model

An **alignment** is defined as a mapping function g between a term x in the conversation segment and a term y in the hypothesis. $g(x, y) = 1$ if x and y are aligned; otherwise $g(x, y) = 0$. It is possible that multiple terms from the segment are mapped to one term in the hypothesis ($g(x_1, y) = g(x_2, y) = 1$), or vice versa ($g(x, y_1) = g(x, y_2) = 1$). To predict these alignments, the problem is formulated as binary classification: given any two terms x from the conversation and y from the hypothesis, decide the value of their alignment function $g(x, y)$.

3.2 Inference Model

Once an alignment between a hypothesis and a conversation segment is established, an inference model is applied to predict whether the conversation segment entails the hypothesis given such alignment. More specifically, as shown in Equation 1, given a clause from the hypothesis h_j, a set of clauses from the conversation segment $d_1, \ldots, d_m$, and an alignment g between them, the goal is to predict whether $d_1, \ldots, d_m$ entails h_j under the alignment g.

The prediction is treated differently according to different types of clauses. If h_j is a property clause (i.e., takes one argument $h_j(\cdot)$), a property inference model is applied; otherwise (i.e., relational clauses with two arguments $h_j(\cdot, \cdot)$), a relational inference model is applied.

In this paper we follow the same framework. However our focus here is on the new question that how different levels of semantic representation and different approaches of modeling long distance relationship affect the alignment and inference models as well as the overall entailment performance.

4 Semantic Representation

Given the clause representation described earlier, an important question is what information from the conversation segment should be captured and represented. To address this question, we examined two levels of shallow semantic representation. The first level is basic representation which only captures the information from all the utterances in the conversation segment. The second representation includes conversation structures (e.g., speakers and dialogue acts). Next we use Example 2 to illustrate these representations.

Example 2:
Conversation Segment:
B: Have you seen *Sleeping with the Enemy*?
A: No. I've heard that's really great, though.
B: You have to go see that one.
Hypothesis:
B suggests A to watch *Sleeping with the Enemy*.

4.1 Basic Representation

The first representation is based on the syntactic parsing from conversation utterances and we call it a *basic* representation. Figure 1(a) shows an example of dependency structures for several utterances that are derived from the Stanford parser (Klein and Manning, 2003), and Figure 1(b) shows the corresponding clause representation. In the dependency structure, the vertices represent entities (e.g., x_1) and actions (e.g., x_3) within an utterance. They correspond to terms in the clause representation. An edge between vertices captures a dependency relation and is represented as predicates in the clause representation. For example, the edge between x_1 and x_3 indicates x_1 is the subject of x_3, which is represented by the clause representation $subj(x_3, x_1)$. Similar representation also applies to the hypothesis as shown in Figure 1(c), 1(d).

4.2 Augmented Representation

The second representation is built upon the basic representation and incorporates conversation structure across turns and utterances. We call it an *augmented* representation. Figure 2(a) shows the augmented structures of the conversation segment and Figure 2(b) shows the corresponding clause representation. Compared to the basic representation, there are two additional types of vertices (i.e., terms) highlighted in the figures:

- Vertices representing utterances (e.g., $u_1 \ldots u_4$). Their corresponding terms capture the dialogue acts for the utterances (e.g. $u_1 = yes\_no\_question$). To focus our effort, currently we only apply annotated dialogue acts provided in the Switchboard corpus (Godfrey and Holliman, 1997). Two edges are added to connect different utterances. The first edge connects each utterance vertex to the head of the corresponding utterance to indicate the specific content of the utterance (e.g., $content(u_1, x_3)$). The second edge connects an utterance to its succeeding utterance to indicate the temporal progression of the conversation (e.g., $follow(u_2, u_1)$).
- Vertices representing speakers or participants (e.g., s_A, s_B). One edge is added to connect each utterance to its speaker (e.g., $speaker(u_1, s_B)$).

Note that since our clause representations are mainly based on the dependency relations, they are mostly syntactic-driven. However, it does capture some shallow semantics such as who is the agent (i.e., subject) or the patient (i.e., object) of an event. The incorporation of speakers and dialogue acts in our augmented representations provides additional semantics of conversation discourse.

5 Modeling LDR

A critical part in predicting entailment is to recognize the semantic relationship between two language constituents, especially when these two constituents are not directly related. In Figure 2(a), for example, we want to recognize that x_9 (*You*) is the (logical) subject of x_{11} (see). Here we experimented two ways of modeling such long distance relations (LDR).

5.1 Implicit Modeling of LDR

The first method characterizes the relationship simply by the distance between two constituents in the dependency structure (or augmented structure). For example, in Figure 2(a) the distance between x_{11} and x_9 is 3. We call this method an *implicit* modeling of long distance relationship.

The advantage of implicit modeling is that it is easy to implement based on the dependency structure. However, its limitation is that the distance measure does not capture sufficient information of semantic relations between language constituents.

5.2 Explicit Modeling of LDR

The second way of modeling long distance relationship is called *explicit* modeling. It uses a string to

(b) augmented representation of the conversation segment

Figure 2: The dependency and conversation structures and corresponding augmented representation of Example 2

describe the path from one constituent to the other: $v_1 e_1 \ldots v_{l-1} e_{l-1} v_l$, where $v_1, \ldots, v_l$ are the vertices on the path and $e_1, \ldots, e_{l-1}$ are the edges. Each v_i describes the type of the vertex in the dependency structure, which is either a noun (N), a verb (V), or an utterance (U). Each e_i describes whether the edge is forward (→) or backward (←). For example, in Figure 2(a), the path from x_{11} to x_9 is $V \rightarrow V \rightarrow V \leftarrow N$.

This kind of string representation of paths in syntactic parse is known as a way of modeling "shallow semantics" between any two constituents in a language structure. It is largely used in other NLP tasks such as semantic role labeling (Pradhan et al., 2008). The difference here is our paths are extracted from dependency parses as opposed to traditional constituent parses, and our paths also incorporate the representation of conversation structures (e.g., utterances and speakers).

6 Applications in Entailment Models

In this section we describe how different representations and modeling of LDR are used in the alignment and inference models.

6.1 Applications in Alignment Model

Although a noun and a verb can potentially be aligned, to simplify the problem, we restrict the problem to the alignment between two nouns or two verbs. We trained an alignment model for nouns and one for verbs separately.

Table 1 summarizes a set of features used in the alignment models. Most of these features are shared by the model for noun alignment and the model for verb alignment. These features include whether the two strings are the same, two terms have the same stem, the similarity between the two terms either based on WordNet or distributional statistics (Lin, 1998).

To learn the alignment model for nouns, we annotated the noun alignments for the development data used in PASCAL RTE-3 Challenge (Giampiccolo et al., 2007) and trained a logistic regression model based on the features in Table 1. Cross-validation on the same dataset shows relatively satisfying performance (96.4% precision and 94.9% recall). In this paper, we focus on the alignment between verbs since it appears more difficult.

	Noun Align.	Verb Align.
Verb *be* identification		✓
String equality	✓	✓
Stemmed equality	✓	✓
Acronym equality	✓	
Named entity equality	✓	
WordNet similarity	✓	✓
Distributional similarity	✓	✓
Subject consistency		✓
Object consistency		✓

Table 1: Features for alignment models

A major difference between noun alignment and verb alignment is that, for verb alignment the consistency of their arguments is also important. For two events (described by two verbs) to be aligned, at least their subjects (usually denoting the executers of actions) and objects (usually denoting the receivers of actions) should match to each other respectively. Note that, although actions/events also depend on other arguments or adjuncts, here we only consider the subjects and objects and leave the consistency check of other arguments/adjuncts to downstream processes. Based on two different ways of modeling long distance relationship (as described in Section 5), we explored two methods for modeling argument consistency (AC) in verb alignment models.

6.1.1 Implicit Modeling of AC

The first approach models argument consistency based on implicit modeling of the relationship between a verb and its aligned subject/object. Specifically, given a pair of verb terms (x, y) where x is from the conversation segment and y is from the hypothesis, let s_y be the subject of y and s_x be the aligned entity of s_y in the conversation (in case of multiple alignments, s_x is the one closest to x). The subject consistency of the verbs (x, y) is then measured by the distance between s_x and x in the dependency structure. Similarly, the distance between a verb and its aligned object is used as a measure of the object consistency.

In Example 2, to decide whether the conversation term *see* (x_{11} in Figure 1(a), 1(b), and 2) and the hypothesis term *watch* (x_4 in Figure 1(c), 1(d)) should be aligned, we first identify the subject of x_4 in the hypothesis, which is x_2 (A). We then look for

x_2's alignments in the conversation segment, among which x_9 (*You*) is the closest to x_{11} (*see*). In Figure 2(a), we find the distance between x_{11} and x_9 is 3.

Using the implicit modeling of argument consistency, we follow the same approach as in our previous work (Zhang and Chai, 2009) and trained a logistic regression model to predict verb alignment based on the features in Table 1.

6.1.2 Explicit Modeling of AC

The second approach captures argument consistency based on explicit modeling of the relationship between a verb and its aligned subject (or object). Given a pair of verb terms (x, y), let s_y be the subject of y and s_x be the aligned entity of s_y in the conversation closest to x, we use the string describing the path from x to s_x as the feature to capture subject consistency. For example, in Figure 2(a), the path from x_{11} to x_9 is $V \rightarrow V \rightarrow V \leftarrow N$.

This string representation of paths is used to capture both the subject consistency and the object consistency. Since they are non-numerical features, and the variability of their values can be extremely large, so we applied an instance-based classification model (e.g., k-nearest neighbor) to determine alignments between verb terms. We measure the distance between two path features by their minimal string edit distance, and then simply use the Euclidean distance to measure the closeness between any two verbs. Again this model is trained from our development data described in Zhang and Chai (2009).

Figure 3 shows an example of alignment between the conversation terms and hypothesis terms in Example 2. Note that in this figure the alignment between $x_5 = suggests$ from the hypothesis and $u_4 = opinion$ from the conversation segment is a *pseudo alignment*, which directly maps a verb term in the hypothesis to an utterance term represented by its dialogue act. This alignment is obtained by following the same set of rules learned from the development dataset as in (Zhang and Chai, 2009).

6.2 Applications in Inference Model

As mentioned earlier, once an alignment is established, the inference model is to predict whether each clause in the hypothesis is entailed from the conversation segment. Two separate models were used to handle the inference of property clauses ($h_j(x)$) and and the inference of relational clauses ($h_j(x, y)$). Property clauses involve less variables and are relatively simple, so we used the same property inference model as in (Zhang and Chai, 2009). Here we focus on relational inference model and examine how different modeling of long distance relationship may affect relation inference.

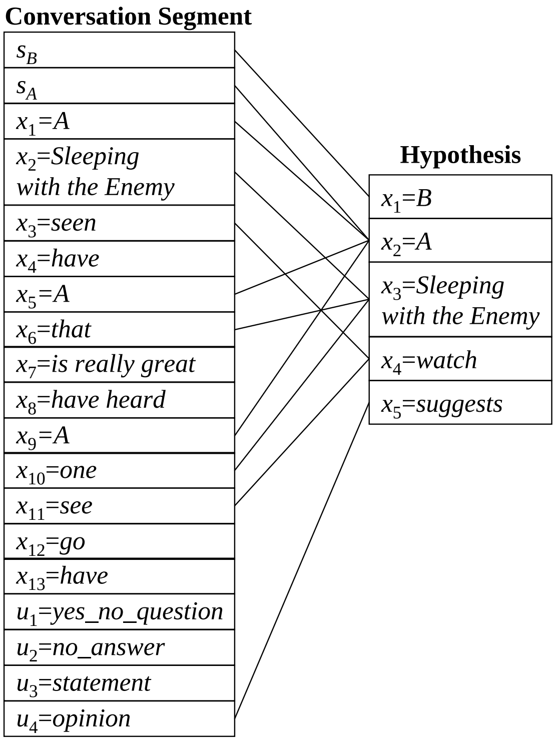

Figure 3: The alignment result for Example 2

For a relation h between x and y to be entailed from a conversation segment, we need to find a same or similar relation in the conversation segment between x's and y's counterparts (i.e., aligned entities of x and y in the conversation segment).

More specifically, given a relational clause from the hypothesis, $h_j(x, y)$, we find the sets of terms $X' = \{x' | x' \in D, g(x', x) = 1\}$ and $Y' = \{y' | y' \in D, g(y', y) = 1\}$, which are aligned with x and y, respectively. We then find the closest relation between these two sets of terms, (x^*, y^*), such that the distance between x^* and y^* is the smallest for any $x^* \in X'$ and $y^* \in Y'$. For instance, in the hypothesis of Example 2 there are terms x_5=*suggests* and x_4=*watch*, and a relational clause $obj(x_5, x_4)$ describing an action-object relation between them. Their counterparts in the conversation segment are $X' = \{u_4 = viewpoint\}$ and $Y' = \{x_3 = seen, x_{11} = see\}$. So the closest pair of terms between these two sets is u_4 and x_{11}. Consequently, whether the target relational clause $h_j(x, y)$ is entailed is determined by the relationship between x^* and y^*. Such relationship can be modeled either implicitly or explicitly.

6.3 Implicit modeling of relation inference

In this model we follow the simple idea that the shorter a path is between two terms, the more likely these two terms have a direct relationship. So we predefine a threshold, λ_L. We predict that $h_j(x, y)$ is entailed if the distance between x^* and y^* is smaller than λ_L. However, as can be seen, this distance does not reflect whether the type of relationship between x^* and y^* is similar to the relationship that holds between x and y.

6.4 Explicit modeling of relation inference

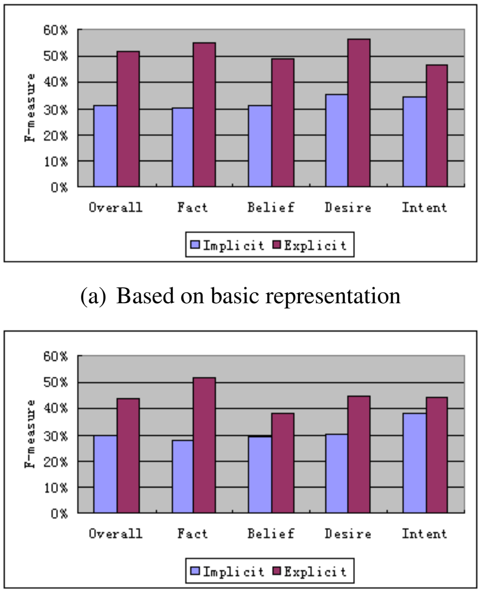
In order to capture more semantics from the relation between two terms, we use explicit modeling of the relationship between terms x^* and y^*. In the previous example, the relationship between u_4 and x_{11} is modeled by the path from u_4 to x_{11}, $U \leftarrow V \leftarrow V \leftarrow V$.

Given this characterization, the prediction of whether $h_j(x, y)$ is entailed from the conversation segment is formulated as a binary classification problem, using a k-nearest neighbor classification model with following features:

1. Explicit modeling of long distance relationship, i.e., the path from x^* to y^* in the dependency structure of the conversation segment;
2. The types (*N*, *V*, or *U*) of x, y, x^*, and y^*;
3. The type of relation between x and y, for example, *obj* in $obj(x, y)$;
4. The order (i.e., before or after) between x and y, and between x^* and y^*;
5. The specific type of the hypothesis.

7 Evaluation and Analysis

We evaluated different model configurations using our data[1]. This dataset consists of 291 development instances and 584 testing instances. The hypotheses were categorized into four types: (1) fact: profile and social relations of conversation participants (accounted for 47% of the development data and 49% of the testing data); (2) belief: participants' beliefs and opinions (34% and 35%); (3) desire: participants' desire of certain actions or outcomes (11% and 4%); (4) intent: communicative intent that captures some perlocutionary force from one participant to the other (e.g. A stops B from doing something; A disagreees with B on something, 8% and 12%)



(a) Based on basic representation

(b) Based on augmented representation

Figure 4: Evaluation of verb alignment

Note that in our original work (Zhang and Chai, 2009), only development data were used to show some initial observations. Here we trained our models on the development data and results shown are from the testing data.

7.1 Evaluation of Alignment Models

The evaluation of alignment models is based on pairwise decision. For each pair of terms (x, y), where x is from a conversation segment and y is from a hypothesis, we measure whether the model correctly predicts that the two terms should or should not be aligned. Because the alignment classification has extremely unbalanced classes, we use precision-recall of true alignments as evaluation metrics.

Figure 4(a) and 4(b) shows the comparison (F-measure) of two alignment models for verb align-

[1] The data is available for download at `http://links.cse.msu.edu:8000/lair/projects/conversationentailment_data.html`.

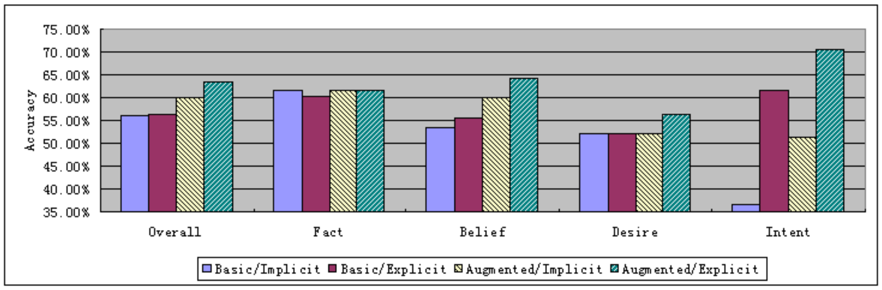


Figure 5: Evaluation of inference models based on different representations

ment, based on the basic representation and the augmented representation, respectively. Note that we cannot directly compare the results between these two figures since they involve different number of alignment instances[2]. Nevertheless, we can see the overall trend within each figure: the explicit model outperforms the implicit model. This suggests that the explicit modeling of semantic relationship between verbs and arguments works better than the implicit modeling used in previous work. Furthermore, the improvement is most noticeable when hypotheses are *facts* (24.8% with the basic representation and 24.1% with the augmented representation), and least when hypotheses are *intents* (12.2% with the basic representation and 6.2% with the augmented representation).

7.2 Evaluation of Inference Models

In order to compare different inference models, in this section (and this section only) we use gold-standard alignment results. They are obtained from manual annotation in our evaluation. We evaluated two inference models, one with implicit modeling of long distance relationship and one with explicit modeling. Evaluations were conducted based on both the basic representation and the augmented representation. Figure 5 shows the four groups of evaluation results.

Overall speaking, the augmented representation outperforms the basic representation for both implicit modeling and explicit modeling of long distance relationship (McNemar's tests, $p < 0.05$). The explicit model performs better than implicit model only based on augmented representation (McNemar's test, $p < 0.05$).

Clause Representation	Relation modeling		Improvement
	Implicit	Explicit	
Basic	53.9%	53.9%	0
Augmented	54.8%	58.7%	**3.9%**

Table 2: Entailment performance with different representations and LDR modeling

The results were further broken down by different hypothesis types. For the *fact* type of hypotheses, there is no difference between different representations and modeling of long distance relationship. This is not surprising since most hypotheses about partipants' profiling information can be inferred directly from the utterances. The augmented representation affects the *intent* type of hypothesis most significantly, so does the explicit modeling of long distance relationship.

7.3 Interaction between Clause Representations and LDR Modeling

It was shown in previous sections that the augmented representation helps entailment prediction compared to the basic representation. Here we want to study how they interact with other entailment components and what is their effect in the enhanced modeling of long distance relations. Specifically, we test the performance of implicit and explicit modeling of long distance relations under two different representation settings: the basic representation and the augmented representation.

Table 2 compares the performance (accuracy) of entailment models with different relationship modeling. We can see that the explicit model makes improvement over the implicit model for augmented representation (McNemar's test, $p < 0.05$), while no improvement is made for basic representation. These evaluation results appear to suggest that there

[2] The alignment based on the augmented representation in Figure 4(b) also includes pseudo alignments.

is an interaction between clause representations and semantic modeling of long distance relations: the modeling of long distance relations between language constituents appears only effective when conversation structure is incorporated in the representation.

It is interesting to see the difference in the prediction performances on *fact* hypotheses and *intent* hypotheses. For *fact*, the most benefit of incorporating explicit modeling of long distance relationship appears at the alignment stage, but not much at the inference stage. However, this situation is different for *intent*, where the benefit of explicitly modeling long distance relationship mostly happened at the inference stage. This observation suggests that the effects of different types of modeling may vary for different types of hypotheses, which indicates that hypothesis type dependent models may be beneficial.

8 Discussion and Conclusion

This paper presents an empirical investigation on conversation entailment. We specifically examine two levels of representation of conversation segments and two different ways of modeling long distance relations between language constituents. Our findings indicate that, although traditional architecture and approaches for textual entailment remain important, additional representation and processing that address conversation structures is critical. The augmented representation with conversation structures, together with explicit modeling of semantic relations between language constituents, results in the best performance (58.7% accuracy).

The work here only represents an initial step towards conversation entailment. Conversation phenomena are rich and complex. Conversation entailment is extremely difficult. Besides the same challenges faced by textual entailment, it is further complicated by conversation implicature. Although our current data enables us to start an initial investigation, its small size poses significant limitations on technology development and evaluation. For example, our studies have indicated hypothesis type-dependent approaches may be beneficial, however we do not have sufficient data to yield reasonable models. A more systematical approach to collect and create a larger set of data is crucial. Innovative community-based approaches (e.g., through web) for data collection and annotation can be pursued in the future. As more techniques in semantic processing (e.g., semantic role) become available, future work should also capture deeper semantics, address pragmatics, and incorporate richer world knowledge.

Finally, as the technology in conversation entailment is developed, its applications in NLP problems should be explored. Example applications include information extraction, question answering, summarization from conversation scripts, and modeling of conversation participants. These applications may provide new insights on the nature of the conversation entailment problem and its potential solutions.

The Necessity of Combining Adaptation Methods

Abstract

Problems stemming from domain adaptation continue to plague the statistical natural language processing community. There has been continuing work trying to find general purpose algorithms to alleviate this problem. In this paper we argue that existing general purpose approaches usually only focus on one of two issues related to the difficulties faced by adaptation: 1) difference in base feature statistics or 2) task differences that can be detected with labeled data.

We argue that it is *necessary* to combine these two classes of adaptation algorithms, using evidence collected through theoretical analysis and simulated and real-world data experiments. We find that the combined approach often outperforms the individual adaptation approaches. By combining simple approaches from each class of adaptation algorithm, we achieve state-of-the-art results for both Named Entity Recognition adaptation task and the Preposition Sense Disambiguation adaptation task. Second, we also show that applying an adaptation algorithm that finds shared representation between domains often impacts the choice in adaptation algorithm that makes use of target labeled data.

1 Introduction

While recent advances in statistical modeling for natural language processing are exciting, the problem of domain adaptation remains a big challenge. It is widely known that a classifier trained on one domain (e.g. news domain) usually performs poorly on a different domain (e.g. medical domain) (Jiang and Zhai, 2007; Daumé III, 2007). The inability of current statistical models to handle multiple domains is one of the key obstacles hindering the progress of NLP.

Several general purpose algorithms have been proposed to address the domain adaptation problem: (Blitzer et al., 2006; Jiang and Zhai, 2007; Daumé III, 2007; Finkel and Manning, 2009). It is widely believed that the drop in performance of statistical models on new domains is due to the shift of the joint distribution of labels and examples, $P(Y, X)$, from domain to domain, where X represents the input space and Y represents the output space. In general, we can separate existing adaptation algorithms into two categories:

Focuses on $P(X)$ This type of adaptation algorithm attempts to resolve the difference between the feature space statistics of two domains. While many different techniques have been proposed, the common goal of these algorithms is to find a better shared representation that brings the source domain and the target domain closer. Often these algorithms do not use labeled examples in the target domain. The works (Blitzer et al., 2006; Huang and Yates, 2009) all belong to this category.

Focuses on $P(Y|X)$ These adaptation algorithms assume that there exists a small amount of labeled data for the target domain. Instead of training two weight vectors independently (one for source and the other for the target domain), these algorithms try to relate the source and target weight vectors. This is often achieved by using a special designed regularization term. The works (Chelba and Acero, 2004; Daumé III, 2007; Finkel and Manning, 2009) belong to this category.

It is important to give the definition of an adaptation *framework*. An adaptation framework is specified by the data/resources used and a specific learning algorithm. For example, a framework that used only source labeled examples and one that used both source and target labeled examples should be considered as two different frameworks, even though they might use exactly the same training algorithm. Note that the goal of a good adaptation framework is to perform well on the target domain and quite often we only need to change the data/resource used to increase the performance without changing the training algorithm. We refer to frameworks that do not use target labeled data and focus on $P(X)$ as **Unlabeled Adaptation Frameworks** and refer to frameworks that use algorithms that focus on $P(Y|X)$ as **Labeled Adaptation Frameworks**.

The major difference between unlabeled adaptation frameworks and labeled adaptation frameworks is the use of *target labeled examples*. Unlabeled adaptation frameworks do not use target labeled examples[1], while the labeled adaptation frameworks make use of *target labeled examples*. Under this definition, we consider that a model trained on both source and target labeled examples (later referred as **S**+**T**) is a labeled adaptation framework.

It is important to combine the labeled and unlabeled adaptation frameworks for two reasons:

- **Mutual Benefit**: We analyze these two types of frameworks and find that they address different adaptation issues. Therefore, it is often beneficial to apply them together.

- **Complex Interaction**: Another, probably more important issue, is that these two types of frameworks are *not* independent. Different representations will impact how much a labeled adaptation algorithm can transfer information between domains. Therefore, in order to have a clear picture of what is the best labeled adaptation framework, it is necessary to analyze these two domain adaptation frameworks together.

In this paper, we assume we have both a small amount of target labeled data and a large amount of unlabeled data so that we can perform both unlabeled and labeled adaptation. *The goal of our paper is to point out the* **necessity** *of applying these two adaptation frameworks together*. To the best of our knowledge, this is the first paper that both theoretically and empirically analyzes the interdependence between the impact of labeled and unlabeled adaptation frameworks.

The contribution of this paper is as follows:

- Propose a theoretical analysis of the "Frustratingly Easy" (FE) framework (Daumé III, 2007) (Section 3).

  The theoretical analysis shows that for FE to be effective the domains must already be "close". At some threshold of "closeness" it is better to switch from FE to just pool all training together as one domain.

- Demonstrate the complex interaction between unlabeled and labeled approaches (Section 4)

  We construct artificial experiments that demonstrate how applying unlabeled adaptation may impact the behavior of two labeled adaptation approaches.

- Empirically analyze the interaction on real datasets (Section 5).

  We show that in general combining both approaches on the tasks of preposition sense disambiguation and named entity recognition works better than either individual method. Our approach not only achieves state-of-the-art results on these two tasks but it also reveals something surprising – finding a better shared representation often makes a simple source+target approach the best adaptation framework in practice.

2 Two Adaptation Aspects: A Review

Why do we need two types of adaptation frameworks? First, unlabeled adaptation frameworks are necessary since many features only exist in one domain. Therefore, it is important to develop algorithms that find features which work across domains. On the other hand, labeled adaptation frameworks

[1] Note that we still use labeled data from source domain in an unlabeled adaptation framework.

are also required because we would like to take advantages of target labeled data. Even though different domains may have different definitions for labels (say in named entity recognition, specific definition of PER/LOC/ORG may change), labeled data should still be useful. We summarize these distinctions in Table 1.

While these two aspects of adaptation both saw significant progress in the past few years, little analysis has been done on the interaction between these two types of algorithms[2].

In order to have a deep analysis, it is necessary to choose specific adaptation algorithms for each aspect of adaptation framework. While we mainly conduct analysis on the algorithms we picked, we would like to point out that the necessity of combining these two types of adaptation algorithms has been largely ignored in the community.

As our example adaptation algorithms we selected:

Labeled adaptation: FE framework One of the most popular adaptation frameworks that requires the use of labeled target data is the "Frustratingly Easy" (FE) adaptation framework (Daumé III, 2007). However, why and when this framework works remains unclear in the NLP community. The FE framework can be viewed as an framework that extends the feature space, and it requires source and target labeled data to work. We denote n as the total number of features[3] and m is the number of the "domains", where one of the domains is the target domain. The FE framework creates a global weight vector in $\mathbb{R}^{n(m+1)}$, an extended space for all domains. The representation $\mathbf{x}$ of the t-th domain is mapped by $\Phi_t(\mathbf{x}) \in \mathbb{R}^{n(m+1)}$. In the extended space, the first n features consist of the "shared" block, which is always active across all tasks. The $(t+1)$-th block (the $(nt+1)$-th to the $(nt+n)$-th features) is a "specific" block, and is only active when extracting examples from the task t. More formally,

$$\Phi_t(\mathbf{x}) = \begin{bmatrix} \underbrace{\mathbf{x}}_{\text{shared}} & \overbrace{\mathbf{0}\ldots\mathbf{0}}^{(t-1)\text{ blocks}} & \underbrace{\mathbf{x}}_{\text{specific}} & \overbrace{\mathbf{0}\ldots\mathbf{0}}^{(m-t)\text{ blocks}} \end{bmatrix}. \tag{1}$$

A *single* weight vector $\bar{\mathbf{w}}$ is obtained by training on the modified labeled data $\{y_i^t, \Phi_t(\mathbf{x}_i^t)\}_{t=1}^m$. Given that this framework only extends the feature space, in this paper, we also call it the *feature extension* framework (still called FE). We will see in Section 3 that this framework is equivalent to applying a regularization trick that bridges the source and the target domains. As it will become clear in Section 3, in fact, this framework is only effective when there is target labeled data and hence belongs to labeled adaptation frameworks.

Although FE framework is quite popular in the community, there are other even simpler labeled adaptation frameworks that allow the use of target labeled data. For example, one of the simplest frameworks is the **S+T** framework, which simply trains a single model on the pooled and unextended source and target training data.

Unlabeled adaptation: Adding cluster-like features Recall that unlabeled adaptation frameworks find the features that "work" across domain. In this paper, we find such features in two steps. First, we use word clusters generated from unlabeled text and/or third party resources that spans domains. Then, for every feature template that contains a word, we *append* another feature template that uses the word's cluster instead of the word itself. This technique is used in many recent works including dependency parsing and NER (Koo et al., 2008; Ratinov and Roth, 2009). Note that the unlabeled text need not come from the source or target domain. In fact, in this paper, we use clusters generated with the Reuters 1996 dataset, a superset of the CoNLL03 NER dataset (Koo et al., 2008; Liang, 2005). We adopt the Brown cluster algorithm to find the word cluster (Brown et al., 1992; Liang, 2005). We can use other resources to create clusters as well. For example, in the NER domain, we also include gazetteers[4] as an unlabeled cluster resource, which can bring the domains together quite effectively.

[2] Among the previously mentioned work, (Jiang and Zhai, 2007) is a special case given that it discusses both aspects of adaptation algorithms. However, little analysis on the interaction of the two aspects is discussed in that paper

[3] We assume that the number of features in each domain is equal.

[4] Our gazetteers comes from (Ratinov and Roth, 2009).

Framework	Labeled Data	Unlabeled Data	Common Approach
Unlabeled Adaptation (Focus on $P(X)$)	Source	Encompasses Source and Target. May use other third party resources (dictionaries, gazetteers, etc.).	Generate features that span domains using unlabeled data and/or third party resources.
Labeled Adaptation (Focus on $P(Y\|X)$)	Source and Target	None	Train classifier(s) using both source and target training data, relating the two.

Table 1: Comparison between two general adaptation frameworks discussed in this paper. Each framework is specified by its setting (data required) and its learning algorithm. Multiple previous adaptation approaches fit in one of either framework.

While other more complex algorithms (Ando and Zhang, 2005; Blitzer et al., 2006) for finding better shared representation (without using labeled target data) have been proposed, we find that using straightforward clustering features is quite effective in general.

3 Analysis of the FE Framework

In this section, we propose a simple yet informative analysis of the FE algorithm from the perspective of multi-task learning. *Note that we ignore the effect of unlabeled adaptation in this section, and focus on the analysis of the FE framework as a representative labeled adaptation framework.*

3.1 Mistake Bound Analysis

While (Daumé III, 2007) proposed this framework for adaptation, a very similar idea had been proposed in (Evgeniou and Pontil, 2004) as a novel regularization term for *multitask* learning with support vector machines. Assume that $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_m$ are the weight vector for the first domain to the m-th domain, respectively. The baseline approach is to assume that each weight vector is independent. Assume that we adopt a SVM-like optimization problem that consider all m tasks, the baseline approach is equivalent to using the following regularization term in the objective function: $\sum_{t=1}^{m} \|\mathbf{w}_t\|^2$.

In (Evgeniou and Pontil, 2004; Daumé III, 2007), they assume that $\mathbf{w}_t = \mathbf{u} + \mathbf{v}_t$, for $t = 1, \ldots m$, where $\mathbf{v}_t$ is the specific weight vector for t-th domain and $\mathbf{u}$ is a *shared* weight vector across all domains. The new regularization term then becomes

$$\|\mathbf{u}\|^2 + \sum_{t=1}^{m} \|\mathbf{v}_t\|^2. \quad (2)$$

Note that these two regularization terms are different, given that the new regularization term makes $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_m$ not independent anymore. It follows that

$$\mathbf{w}_t^T \mathbf{x} = (\mathbf{u} + \mathbf{v}_t)^T \mathbf{x} = \bar{\mathbf{w}}^T \Phi_t(\mathbf{x}),$$

where

$$\bar{\mathbf{w}}^T = \begin{bmatrix} \mathbf{u}^T & \mathbf{v}_1^T & \ldots & \mathbf{v}_m^T \end{bmatrix}.$$

and $\|\bar{\mathbf{w}}\|^2$ equals to Eq. (2). Therefore, we can think feature extension framework as a learning framework that adopts Eq. (2) as its regularization term.

The **FE** framework was in fact originally designed for the problem of multitask learning so in the following, we propose a simple mistake bound analysis based on the *multitask* setting, where we calculate the mistakes on *all* domains[5]. We focus on multitask setting for two reasons: 1) the analysis is very easy and intuitive, and 2) in Section 4.1, we empirically confirm that the analysis holds for the adaptation setting.

In the following, we assume that the training algorithm used in the FE framework is the online perceptron learning algorithm (Novikoff, 1963). This allows us to analyze the mistake bound of the **FE** framework with the perceptron algorithm. The bound can give us an insight on when and why one should adopt the **FE** framework. By using the standard mistake bound theorem (Novikoff, 1963), we show:

Theorem 1. *Let $\mathcal{D}_t$ be the labeled data of domain t. Assume that there exist $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_m$ such that*

$$y\mathbf{w}_t^T \mathbf{x} \geq \mu, \forall (\mathbf{x}, y) \in \mathcal{D}_t,$$

and assume that $\max_{(\mathbf{x},y)\in\mathcal{D}_t} \|\mathbf{x}\| \leq R^2, \forall t = 1 \ldots m$. *Then, the number of mistakes made with online perceptron training (Novikoff, 1963) and the*

[5] In the adaptation setting, one generally only cares about the performance on the target domain.

FE framework is bounded by

$$\frac{2R^2}{\mu^2}(\sum_{t=1}^{m} \|\mathbf{w}_t\|^2 - \frac{\| \sum_{t=1}^{m} \mathbf{w}_t \|^2}{m+1}). \qquad (3)$$

Proof. Define $\bar{\mathbf{w}}$ as a vector in $\mathbb{R}^{n(m+1)}$. We claim that there exists a set $S_{\bar{\mathbf{w}}}$ such that for all $\bar{\mathbf{w}} \in S_{\bar{\mathbf{w}}}$, $\bar{\mathbf{w}}^T \Phi_t(\mathbf{x}) = \mathbf{w}_t^T \mathbf{x}$ for any domain $t = 1 \ldots m$. Note that $\Phi_t(x)$ is defined in Eq. (1). We can construct $S_{\bar{\mathbf{w}}}$ in the following way:

$$S_{\bar{\mathbf{w}}} = \{\begin{bmatrix} s & (\mathbf{w}_1 - s) & \ldots & (\mathbf{w}_m - s)\end{bmatrix} \mid s \in \mathbb{R}^n\},$$

where s is an arbitrary vector with n elements.

In order to obtain the best possible bound, we would like to find the most compressed weight vector in $S_{\bar{\mathbf{w}}}$, $\mathbf{w}^* = \min_{\bar{\mathbf{w}} \in S_{\bar{\mathbf{w}}}} \|\bar{\mathbf{w}}\|^2$.

The optimization problem has an analytical solution:

$$\|\mathbf{w}^*\|^2 = \sum_{t=1}^{m} \|\mathbf{w}_t\|^2 - \| \sum_{t=1}^{m} \mathbf{w}_t \|^2/(m+1).$$

The proof is completed by the standard mistake bound theorem and the following fact: $\max_{\mathbf{x}} \|\phi_t(\mathbf{x})\|^2 = 2 \max_{\mathbf{x}} \|\mathbf{x}\|^2 \leq 2R^2$. □

3.2 Mistake Bound Comparison

In the following, we would like to explore under what circumstances the **FE** framework can work better than individual models and the **S+T** framework using Theorem 1. The analysis is done based on the assumption that all frameworks use the perceptron algorithm.

Before showing the bound analysis, note that the framework proposed by (Evgeniou and Pontil, 2004; Finkel and Manning, 2009) is a generalization over these three frameworks (**FE**, **S+T**, and the baseline)[6]. However, our goal in this paper is different: we try to provide a deep discussion on *when and why* one should use a particular framework.

Here, we compare the mistake bounds of the feature sharing framework to that of the baseline approach, which learns each task independently[7]. In order to make the comparison easier, we make some simplifying assumptions. First, we assume that the problem contains only two tasks, 1 and 2. We also assume that $\|\mathbf{w}_1\| = \|\mathbf{w}_2\| = a$. These assumptions greatly reduce the complexity of the analysis and can give us greater insight into the comparisons.

Following the assumptions and Theorem 1, the mistake bound for the FE frameworks is

$$4(2 - \cos(\mathbf{w}_1, \mathbf{w}_2))R^2 a^2/(3\mu^2) \qquad (4)$$

This line of analysis leads to interesting bound comparisons for two cases. In the first case, we assume that task 1 and task 2 are essentially the same. In the second, more common case, we assume that they are different.

First, when we know a priori that task 1 and task 2 are essentially the same, we can combine the training data from the two tasks and train them as a single task. Therefore, given that we do not need to expand the feature space, the number of mistakes is now bounded by $R^2 a^2/\mu^2$. Note that this bound is in fact better than (4) with $\cos(\mathbf{w}_1, \mathbf{w}_2) = 1$. Therefore, if we know a priori that these two tasks are the same, training a single model is better than using the feature shared approach.

In practice, it is often the case that the two tasks are not the same. In this case, the number of mistakes of an independent approach on *both* task 1 and 2 will be bounded by the summation of the mistake bounds of task 1 and task 2. Therefore, using the independent approach, the number of mistakes for the perceptron algorithm on *both* tasks is bounded by $2R^2 a^2/\mu^2$. The following results can be obtained by directly comparing the two bounds,

Corollary 1. *Assume there exists* $\mathbf{w}_1$ *and* $\mathbf{w}_2$ *which separate* $\mathcal{D}_1$ *and* $\mathcal{D}_2$ *respectively with functional margin* μ*, and* $\|\mathbf{w}_1\| = \|\mathbf{w}_2\| = a$*. In this case: (4) will be smaller than the bound of individual approach,* $2R^2 a^2/\mu^2$*, if and only if* $\cos(\mathbf{w}_1, \mathbf{w}_2) = (\mathbf{w}_1^T \mathbf{w}_2)/(\|\mathbf{w}_1\|\|\mathbf{w}_2\|) > \frac{1}{2}$.

If we assume that there is no difference in $P(X)$ between domains and hence we can treat $\cos(\mathbf{w}_1, \mathbf{w}_2)$ as the similarity between two tasks, the above argument suggests:

- If the two tasks are very different, the baseline approach (building two models) is better than **FE** and **S+T**.

[6] The framework proposed by (Evgeniou and Pontil, 2004; Finkel and Manning, 2009) is a generalization of Eq. (1). It allows the user to weight each block of features. If we put zero weight on the shared block, it becomes the baseline approach. On the other hand, if we put zero weight on all task-specific blocks, the framework becomes the **S+T** approach.

[7] Note that mistake bound results can be generalized to generalization bound results. See (Zhang, 2002).

- If the tasks are similar enough, **FE** is better than baseline and **S+T**.
- If the tasks are almost the same, **S+T** becomes better than **FE** and baseline.

In Section 4.1, we will evaluate whether these claims can be justified empirically.

4 Artificial Data Experiment Study

In this section we will present artificial experiments. We have two primary goals: 1) verifying the analysis proposed in Section 3, and 2) showing that the representation shift will impact the behavior of the **FE** algorithm. The second point will be verified again in the real world experiments in Section 5.

Data Generation In the following artificial experiments we experiment with domain adaptation by generating training and test data for two tasks, source and target, where we can control the difference between task definitions. The general procedure can be divided into two steps: 1) generating weight vectors $\mathbf{z}_1$ and $\mathbf{z}_2$ (for source and target respectively), and 2) randomly generating labeled instances for training and testing using $\mathbf{z}_1$ and $\mathbf{z}_2$.

The different experiments start with the same basic $\mathbf{z}_1$ and $\mathbf{z}_2$, but then may alter these weights to introduce task dissimilarities or similarities. The basic $\mathbf{z}_1$ and $\mathbf{z}_2$ are both generated by a multivariate Gaussian distribution with mean $\mathbf{z}$ and a diagonal covariance matrix βI:

$$\mathbf{z}_1 \sim \mathcal{N}(\mathbf{z}, \beta I), \mathbf{z}_2 \sim \mathcal{N}(\mathbf{z}, \beta I),$$

where $\mathcal{N}$ is the normal distribution and $\mathbf{z}$ is random vector with zero mean. Note that $\mathbf{z}$ is only used to generate $\mathbf{z}_1$ and $\mathbf{z}_2$. There is one parameter, β, that controls the variance of the Gaussian distribution. Hence we use β to roughly control the "angle" of $\mathbf{z}_1$ and $\mathbf{z}_2$. When β is close to zero, $\mathbf{z}_1$ and $\mathbf{z}_2$ will be very similar. On the other hand, when β is large, $\mathbf{z}_1$ and $\mathbf{z}_2$ can be very different. In these experiments, we vary β between 0.01 and 5 so that we are experimenting only with tasks where the weight the task difference is the "angle" or cosine between $\mathbf{z}_1$ and $\mathbf{z}_2$. Once we obtain the $\mathbf{z}_1$ and $\mathbf{z}_2$, we normalize them to the unit length.

After selecting $\mathbf{z}_1$ and $\mathbf{z}_2$, we then generate labeled instances $(\mathbf{x}, y)$ for the source task in the following way. For each example $\mathbf{x}$, we randomly generate n binary features, where each feature has 20% chance to be active. We then label the example by

$$y = sign(\mathbf{z}_1^T \mathbf{x}),$$

The data for the target task is generated similarly with $\mathbf{z}_2$. In these experiments, we fix the number of features n to be 500 and generate 100 source training examples and 40 target training examples, along with 1000 target testing examples. This matches the reasonable case in NLP where there are more features than training examples and each feature vector is sparse. In all of the experiments, we report the averaged testing error rate on the target testing data.

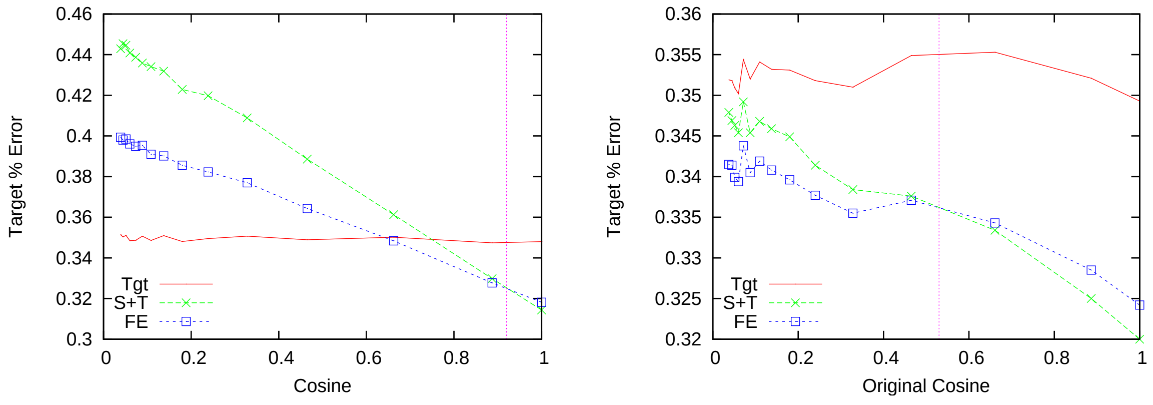
4.1 Experiment 1, FE algorithm

Goal The goal here is to verify our theoretical analysis in Section 3. Note that we do not introduce representation shift in this experiment and assume that both source and target domains use exactly the same features.

Result Figure 1(a) shows the performance of the three training algorithms as variance decreases and thus cosine between weight vectors (or measure of task similarity) goes to 1. Note that **FE** labeled adaptation framework beats **TGT** once the task cosine passes approximately 0.6. Initially FE slightly outperforms **S+T** until the tasks are close enough together that it is better to treat all the data as coming from one task. Note that while the experiments are based on the adaptation setting, the results match our analysis based on the multitask setting in Section 3.

4.2 Experiment 2, Unseen Features

Goal So far we have not considered the difference in $P(X)$ between domains. In the previous experiment, we used only cosine as our task similarity measurement to decide what is the best framework. However, task similarity should consider the difference in both $P(X)$ and $P(Y|X)$, and the cosine measurement is not sufficient for this. Here we construct a simple example to show that even a simple representation shift can change the behavior of the labeled adaptation framework. This case shows that **S+T** can be better than **FE** even when the tasks are not similar according to the cosine measurement.



(a) Basic Similarity

(b) Shared Features

Figure 1: Artificial Experiment comparing labeled adaptation performance vs. cosine between base weight vectors that defines two tasks, before and after cross-domain shared features are added. Figure (a) shows results from experiment 1. For **FE** adaptation algorithm to work the tasks need to be close (cosine $>$ 0.6), and if the tasks are close enough (cosine $\approx$ 1, dividing line) then it is better to just pool source and target training data together (the **S+T** algorithm). Figure (b) shows results for experiment 3 when shared features are added to the base weight vectors as used in experiment 1. Here the cosine similarity measure is between the base task weight vectors before the shared features have been added. Both labeled adaptation algorithms effectively use the shared features to improve over just training on target. With shared features added the dividing line where **S+T** improves over **FE** decreases so even for tasks that are initially further apart, once clusters are added the **S+T** algorithm does better than **FE**. Each point represents the average of 2000 training runs with random initial $\mathbf{z}_1$ and $\mathbf{z}_2$ generating data.

Result The second experiment deals with the case where features may appear in only one domain but should be treated like known features in the other domain. An example of this are out of vocabulary words that may not exist in a small target training task, but have synonyms in the source training data. In this case if we had features grouping words (say by word meanings) then we would recover this cross-domain information. In this experiment we want to explore which adaptation algorithm performs best *before* these features are applied.

To simulate this case we start with similar weight vectors $\mathbf{z}_1$ and $\mathbf{z}_2$ (sampled with variance = 0.00001, cos($\mathbf{z}_1$,$\mathbf{z}_2$) $\approx$ 1), but then shift some set of dimensions so that they represent features that appear only in one domain.

$$\mathbf{z}_1 = (\mathbf{a}_1, \mathbf{b}_1) \rightarrow \mathbf{z}'_1 = (\mathbf{0}, \mathbf{b}_1, \mathbf{a}_1)$$
$$\mathbf{z}_2 = (\mathbf{a}_2, \mathbf{b}_2) \rightarrow \mathbf{z}'_2 = (\mathbf{a}_2, \mathbf{b}_2, \mathbf{0})$$

By changing the ratio of the size of the dissimilar subset $\mathbf{a}$ to the similar subset $\mathbf{b}$ we can make the two weight vectors $\mathbf{z}'_1$ and $\mathbf{z}'_2$ more or less similar. Using these two new weight vectors we can proceed as above, generating training and testing data.

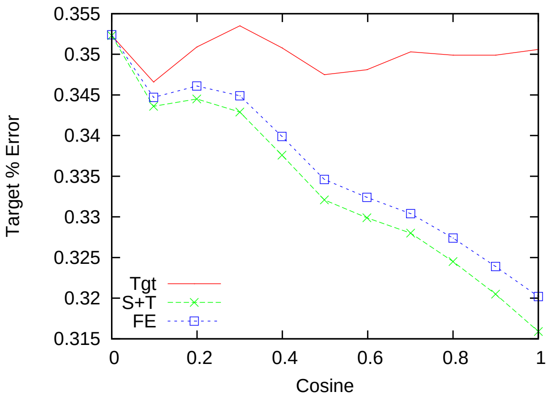


Figure 2: Artificial Experiment where unknown features are included in source or target domains, but not the other. The simple **S+T** adaptation framework is best able to exploit the set of shared features so performs best over the whole space of similarity in this setting.

Figure 2 shows the performance of the three algorithms on this data as the number of unrelated features are decreased. Over the entire range the combined algorithm **S+T** does better since it more efficiently exploits the shared similar $\mathbf{b}$ subset of the feature space. When the **FE** algorithm tries to create the shared features, it considers both the similar subset $\mathbf{b}$ and dissimilar subset $\mathbf{a}$. However, since $\mathbf{a}$ should not be shared, **FE** algorithm becomes less effective than the **S+T** algorithm. See the bound comparison in Section 3.2 for more intuitions. With this experiment we have demonstrated that there is a need to consider label and unlabeled adaptation frameworks together.

4.3 Experiment 3, Shared Features

Goal A good unlabeled adaptation framework should try to find features that "work" across domains. However, it is not clear how these newly added features will impact the behavior of the labeled adaptation frameworks. In this experiment, we show that the new shared features will bring the domains together, and hence make **S+T** a very strong adaptation framework.

Result For the third experiment we start with the same setup as in the first experiment, but then augment the initial weight vector with additional shared weights. These shared weights correspond to the introduction of features that appear in both domains and have the same meaning relative to the tasks, the ideal result of unlabeled adaptation methods.

To generate this case we again start with $\mathbf{z}_1$ and $\mathbf{z}_2$ of varying similarity as in section 4.1, then generate a random weight vector for shared features and append this to both weight vectors.

$$\mathbf{z}_s \sim \mathcal{N}(0, I), \mathbf{z}_1'' = (\mathbf{z}_1, \gamma\mathbf{z}_s), \mathbf{z}_2'' = (\mathbf{z}_2, \gamma\mathbf{z}_s),$$

where γ is used to put increased importance on the shared weight vectors by increasing the total weight of that section relative to the base $\mathbf{z}_1$ and $\mathbf{z}_2$ subsets. In our experiments we use 100 shared features to the 500 base features and set γ to 2.

Figure 1(b) shows the performance of the labeled adaptation algorithms once shared features had been added. Here the x-axis is the cosine between the original task weight vectors, demonstrating how the shared features improve performance on potentially dissimilar tasks. Whereas in the first experiment **FE** does not improve over just training on target data until the cosine is greater than 0.6, once shared features have been added then both **FE** and **S+T** use these features to learn with originally dissimilar tasks. Furthermore the shared features tend to push the tasks 'closer' so that **S+T** improves over **FE** earlier. Comparing to Figure 1(a), there are regions where before shared features are added it is better to use **FE**, and after shared features are added it is better to use **S+T**. This shows that labeled adaptation and unlabeled are *not* independent. Therefore, it is important to combine these two aspects to see the real contribution of each adaptation framework.

In these three artificial experiments we have demonstrated cases where both **FE** or **S+T** are the best algorithm before and after representation changes like those created with unlabeled adaptation are imposed. This fact points to the perhaps obvious conclusion that there is not a single best adaptation algorithm, and the determination of specific best practices depends on task similarity (in both $P(X)$ and $P(Y|X)$), especially after being brought closer together with other adaptation approaches. If there is one common trend it is that often once two tasks have been brought close together using a shared representation, then the tasks are now close enough such that the simple **S+T** algorithm does well.

5 Real World Experiments

In Section 4, we have shown through artificial data experiments that labeled and unlabeled adaptation algorithms are not independent. In this section, we focus on experiments with real datasets.

For the labeled adaptation algorithms, we have the following options:

- **TGT**: Only uses target labeled training dataset.
- **FE**: Uses both labeled datasets.
- **FE$^+$**: Uses both labeled datasets. A modification of the FE algorithm, equivalent to multiplying the "shared" part of the FE feature vector (Eq. (1)) by 10 (Finkel and Manning, 2009).
- **S+T**: Uses both source and target labeled datasets to train a single model with all labeled data directly.

Throughout all of our experiments, we use SVMs trained with a modified java implementation[8] of LIBLINEAR as our underlying learning classifier (Hsieh et al., 2008). For the tasks that require structures, we model each individual decision using

[8] Our code is modified from the version available on `http://www.bwaldvogel.de/liblinear-java/`

Algorithm	**TGT**	**FE**	**FE$^+$**	**S+T**
SRC labeled data?	no	yes		
Target labeled data	Token F1			
(a) MUC7 Dev	58.6	70.5	**74.3**	73.1
(a) + cluster	77.5	82.5	**83.3**	**83.3**
(b) MUC7 Train	73.0	78.2	**80.1**	78.7
(b) + cluster	85.4	86.4	86.2	**86.5**

Table 2: **NER Experiments.** We bold face the best accuracy in a row and underline the runner up. Both unlabeled adaptation algorithms (adding cluster features) and labeled adaptation algorithm (using source labeled data) help the performance significantly. Moreover, adding cluster-like features also changes the behavior of the labeled adaptation algorithms. Note that after adding cluster features, **S+T** becomes quite competitive with (or slightly better than) the **FE$^+$** approach. The size of MUC7 develop set is roughly 20% of the size of the MUC7 training set.

a local SVM classifier then make our prediction using a greedy approach from left to right. While we could use a more complex model such as Conditional Random Field (Lafferty et al., 2001), as we will see later, our simple model generates state-of-the-art results for many tasks. Regarding parameter selection, we selected the SVM regularization parameter for the baseline model (**TGT**) and then fix it for all algorithms[9].

Named Entity Recognition Our first task is Named Entity Recognition (NER). The source domain is from the CoNLL03 shared task (Tjong Kim Sang and De Meulder, 2003) and the target domain is from the MUC7 dataset. The goal of this adaptation system is to maximize the performance on the test data of MUC7 dataset with CoNLL training data and (some) MUC7 labeled data. As an unlabeled adaptation method to address feature sparsity, we add cluster-like features based on the gazetteers and word clustering resources used in (Ratinov and Roth, 2009) to bridge the source and target domain. We experiment with both MUC development and training set as our target labeled sets.

The experimental results are in Table 2. First, notice that addressing the feature sparsity issue helps the performance significantly. Adding cluster-like features improves the Token-F1 by around 10%. On the other hand, adding target labeled data also helps the results significantly. Moreover, using both target labeled data and cluster-like shared representation are mutually beneficial in all cases.

Importantly, adding cluster-like features changes the behavior of the labeled adaptation algorithms. When the cluster-like features are not added, the **FE$^+$** algorithm is in general the best labeled adaptation framework. This result agrees with the results showed in (Finkel and Manning, 2009), where the authors show that **FE$^+$** is the best labeled adaptation framework in their settings. However, after adding the cluster-like features, the simple **S+T** approach becomes very competitive to both **FE** and **FE$^+$**. This matches our analysis in Section 4: *resolving features sparsity will change the behavior of labeled adaptation frameworks.*

We compare the simple **S+T** algorithm with cluster-like features to other published results on adapting from CoNLL dataset to MUC7 dataset in table 3. Past works on this setting often only focus on one class of adaption approach. For example, (Ratinov and Roth, 2009) only use the cluster-like features to address the feature sparsity problem, and (Finkel and Manning, 2009) only use target labeled data without using gazetteers and word-cluster information. Notice that because of combining two classes of adaption algorithms, our approach is significantly better than these two systems[10].

Preposition Sense Disambiguation We also test the combination of unlabeled and labeled adaption on the task of Preposition Sense Disambiguation. Here the data contains multiple prepositions where each preposition has many different senses. The goal is to predict the right sense for a given preposition in the testing data. The source domain is the SemEval 2007 preposition WSD Task and the target domain is from the dataset annotated in (Dahlmeier et al., 2009). Our feature design mainly comes from (Tratz and Hovy, 2009) (who do not evaluate their system on our target data). As our un-

[9] We use L2-hinge loss for all of the experiments, with $C = 2^{-4}$ for NER experiments and $C = 2^{-5}$ for the PSD experiments.

[10] The work (Ratinov and Roth, 2009) also combines their system with several document-level features. While it is possible to add these features in our system, we do not include any global features for the sake of simplicity. Note that our system is competitive to (Ratinov and Roth, 2009) even though our system does not use global features.

Systems	Cluster?	TGT?	P.F1	T.F1
Our NER	y	y	**84.1**	**86.5**
FM09	n	y	79.98	N/A
RR09	y	n	N/A	83.2
RR09 + global	y	n	N/A	86.2

Table 3: Comparisons between different NER systems. P.F1 and T.F1 represent the phrase-level and token-level F1 score, respectively. We use "Cluster?" to indicate if cluster features are used and use "TGT?" to indicate if target labeled data is used. Previous systems often only use one class of adaptation algorithms. Using both adaptation aspects makes our system perform significantly better than FM09 and RR09.

Algorithm	**TGT**	**FE**	**FE**$^+$	**S+T**
SRC labeled data?	no	yes		
Target labeled data	Accuracy			
10% Tgt	43.8	48.2	**51.3**	49.7
10% Tgt + Cluster	44.9	50.5	51.8	**52.0**
100% Tgt	59.5	60.5	60.3	**61.2**
100% Tgt + Cluster	61.3	62.0	61.2	**62.1**

Table 4: **Preposition Sense Disambiguation**. We mark the best accuracy in a row using the bold font and underline the runner up. Note that both adding cluster features and adding source labeled data help the performance significantly. Moreover, adding clusters also changes the behavior of the labeled adaptation algorithms.

labeled adaptation approach we augment all word based features with cluster information from separately generated hierarchical Brown clusters (Brown et al., 1992).

The experimental results are in Table 4. Note that we see phenomena similar to what happened in the NER experiments. First, both labeled and unlabeled adaptation improves the system. When only 10% of the target labeled data is used, the inclusion of the source labeled data helps significantly. When there is more labeled data, labeled and unlabeled adaption have similar impact. Again, using unlabeled adaption changes the behavior of the labeled adaption algorithms.

In Table 5, we compare our system to (Dahlmeier et al., 2009), who do not use the SemEval data but jointly train their preposition sense disambiguation system with a semantic role labeling system. With both labeled and unlabeled adaption, our system is significantly better.

Systems	ACC
Our PSD (**S**+**T** and cluster)	62.1
DNS09	56.5
DNS09 + SRL	58.8

Table 5: Comparison between different PSD systems. Note that after adding cluster features and source labeled data with **S+T** approach, our system outperforms the state-of-the-art system proposed in (Dahlmeier et al., 2009), even though they jointly learn a PSD and SRL system together.

6 Conclusion

In this paper, we point out the necessities of combining labeled and unlabeled adaptation algorithms. We analyzed the FE algorithm both theoretically and empirically, demonstrating that it requires both a minimal amount of task similarity to work, and past a certain level of similarity other, simpler approaches are better. More importantly, through artificial data experiments we found that applying unlabeled adaptation algorithms may change the behavior of labeled adaptation algorithms as representations change, and hence affect the choice of labeled adaptation algorithm. Experiments with real-world datasets confirmed that combinations of both adaptation methods provide the best results, often allowing the use of simple labeled adaptation approaches. In the future, we hope to develop a joint algorithm which addresses both labeled and unlabeled adaptation at the same time.

Acknowledgment We thank Vivek Srikumar for providing the baseline implementation of preposition sense disambiguation. We also thank anonymous reviewers for their useful comments. Abstract

Using multi-layer neural networks to estimate the probabilities of word sequences is a promising research area in statistical language modeling, with applications in speech recognition and statistical machine translation. However, training such models for large vocabulary tasks is computationally challenging which does not scale easily to the huge corpora that are nowadays available. In this work, we study the performance and behavior of two neural statistical language models so as to highlight some important caveats of the classical training algorithms. The induced word embeddings for extreme cases are also analysed, thus providing insight into the convergence issues. A new initialization scheme and new training techniques are then introduced. These methods are shown to greatly reduce the training time and to significantly improve performance, both in terms of perplexity and on a large-scale translation task.

1 Introduction

Statistical language models play an important role in many practical applications, such as machine translation and automatic speech recognition. Let $\mathcal{V}$ be a finite vocabulary, statistical language models define distributions over sequences of words w_1^L in $\mathcal{V}^\star$ usually factorized as:

$$P(w_1^L) = P(w_1) \prod_{l=1}^{L} P(w_l | w_1^{l-1})$$

Modeling the joint distribution of several discrete random variables (such as words in a sentence) is difficult, especially in real-world Natural Language Processing applications where $\mathcal{V}$ typically contains dozens of thousands words.

Many approaches to this problem have been proposed over the last decades, the most widely used being back-off n-gram language models. n-gram models rely on a Markovian assumption, and despite this simplification, the maximum likelihood estimate (MLE) remains unreliable and tends to underestimate the probability of very rare n-grams, which are hardly observed even in huge corpora. Conventional smoothing techniques, such as Kneser-Ney and Witten-Bell back-off schemes (see (Chen and Goodman, 1996) for an empirical overview, and (Teh, 2006) for a Bayesian interpretation), perform back-off on lower order distributions to provide an estimate for the probability of these unseen events. n-gram language models rely on a discrete space representation of the vocabulary, where each word is associated with a discrete index. In this model, the morphological, syntactic and semantic relationships which structure the lexicon are completely ignored, which negatively impact the generalization performance of the model. Various approaches have proposed to overcome this limitation, notably the use of word-classes (Brown et al., 1992; Niesler, 1997), of generalized back-off strategies (Bilmes et al., 1997) or the explicit integration of morphological information in the random-forest model (Xu and Jelinek, 2004; Oparin et al., 2008).

One of the most successful alternative to date is to use *distributed word representations* (Bengio et al., 2003), where distributionally similar words are represented as neighbors in a continuous space. This

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 778–788,
MIT, Massachusetts, USA, 9-11 October 2010.

turns n-grams distributions into smooth functions of the word representations. These representations and the associated probability estimates are jointly computed in a multi-layer neural network architecture. This approach has showed significant and consistent improvements when applied to automatic speech recognition (Schwenk, 2007; Emami and Mangu, 2007; Kuo et al., 2010) and machine translation tasks (Schwenk et al., 2006). Hence, continuous space language models are becoming increasingly used. These successes have revitalized the research on neuronal architectures for language models, and given rise to several new proposals (see, for instance, (Mnih and Hinton, 2007; Mnih and Hinton, 2008; Collobert and Weston, 2008)). A major difficulty with these approaches remains the complexity of training, which does not scale well to the massive corpora that are nowadays available. Practical solutions to this problem are discussed in (Schwenk, 2007), which introduces a number of optimization and tricks to make training doable. Even then, training a neuronal language model typically takes days.

In this paper, we empirically study the convergence behavior of two multi-layer neural networks for statistical language modeling, comparing the standard model of (Bengio et al., 2003) with the log-bilinear (LBL) model of (Mnih and Hinton, 2007). Our contributions are the following: we first propose a reformulation of Mnih and Hinton's model, which reveals its similarity with extant models, and allows a direct and fair comparison with the standard model. For the standard model, these results highlight the impact of parameter initialization. We first investigate a re-initialization method which allows to escape from the local extremum the standard model converges to. While this method yields a significative improvement, the underlying assumption about the structure of the model does not meet the requirement of very large-scale tasks. We therefore introduce a different initialization strategy, called *one vector initialization*. Experimental results show that these novel training strategies drastically reduce the total training time, while delivering significant improvements both in terms of perplexity and in a large-scale translation task.

The rest of this paper is organized as follows. We first describe, in Section 2, the standard and the LBL language models. By reformulating the latter, we show that both models are very similar and emphasize the remaining differences. Section 2.4 discusses complexity issues and possible solutions to reduce the training time. We then report, in Section 3, preliminary experimental results that enlighten some caveats of the standard approach. Based on these observations, we introduce in Section 4 novel and more efficient training schemes, yielding improved performance and a reduced training time both on small and large scale experiments.

2 Continuous space language models

Learning a language model amounts to estimate the parameters of the discrete conditional distribution over words given each possible history, where the history corresponds to some function of the preceding words. For an n-gram model, the history contains the $n-1$ preceding words, and the model parameters correspond to $P(w_l|w_{l-n+1}^{l-1})$. Continuous space language models aim at computing these estimates based on a distributed representation of words (Bengio et al., 2003), thereby reducing the sparsity issues that plague conventional maximum likelihood estimation. In this approach, each word in the vocabulary is mapped into a real-valued vector and the conditional probability distributions are then expressed as a (parameterized) smooth function of these feature vectors. The formalism of neural networks allows to express these two steps in a well-known framework, where, crucially, the mapping and the model parameters can be learned in conjunction. In the next paragraphs, we describe the two continuous space language models considered in our study and present the various issues associated with the training of such models, as well as their most common remedies.

2.1 The standard model

In the following, we will consider words as indices in a finite dictionary of size V; depending on the context, w will either refer to the word or to its index in the dictionary. A word w can also be represented by a 1-of-V coding vector $\mathbf{v}$ of $\mathbb{R}^V$ in which all elements are null except the w^{th}. In the standard approach of (Bengio et al., 2003), the feed-forward network takes as input the $n-1$ word history and delivers an estimate of the probability $P(w_l|w_{l-n+1}^{l-1})$

as its output. It consists of three layers.

The first layer builds a continuous representation of the history by mapping each word into its real-valued representation. This mapping is defined by $\mathbf{R}^T\mathbf{v}$, where $\mathbf{R} \in \mathbb{R}^{V \times m}$ is a *projection matrix* and m is the dimension of the continuous projection word space. The output of this layer is a vector $\mathbf{i}$ of $(n-1)m$ real numbers obtained by concatenating the representations of the context words. The projection matrix $\mathbf{R}$ is shared along all positions in the history vector and is learned automatically.

The second layer introduces a non-linear transform, where the output layer activation values are defined by $\mathbf{h} = \tanh\left(\mathbf{W_{ih}}\mathbf{i} + \mathbf{b_{ih}}\right)$, where $\mathbf{i}$ is the input vector, $\mathbf{W_{ih}} \in \mathbb{R}^{H \times (n-1)m}$ and $\mathbf{b_{ih}} \in \mathbb{R}^H$ are the parameters of this layer. The vector $\mathbf{h} \in \mathbb{R}^H$ can be considered as an higher (more abstract) representation of the context than $\mathbf{i}$.

The third layer is an output layer that estimates the desired probability, thanks to the *softmax* function:

$$\begin{aligned} P(w_l = k | w_{l-n+1}^{l-1}) &= \frac{\exp(\mathbf{o_k})}{\sum_{k'} \exp(\mathbf{o_{k'}})} \quad (1) \\ \mathbf{o} &= \mathbf{W_{ho}}\mathbf{h} + \mathbf{b_{ho}}, \quad (2) \end{aligned}$$

where $\mathbf{W_{ho}} \in \mathbb{R}^{V \times H}$ and $\mathbf{b_{ho}} \in \mathbb{R}^V$ are respectively the projection matrix and the bias term associated with this layer. The w^{th} component in $\mathbf{P}$ corresponds to the estimated probability of the w^{th} word of the vocabulary given the input history vector.

The standard model has two hyper-parameters (the dimension of projection space m and the size of hidden layer, H) that define the architecture of the neural network and a set of free parameters $\mathbf{\Theta}$ that need to be learned from data: the projection matrix $\mathbf{R}$, the weight matrix $\mathbf{W_{ih}}$, the bias vector $\mathbf{b_{ih}}$, the weight matrix $\mathbf{W_{ho}}$ and the bias vector $\mathbf{b_{ho}}$.

In this model, the projection matrices $\mathbf{R}$ and $\mathbf{W_{ho}}$ play similar roles as they define maps between the vocabulary and the hidden representation. The fact that $\mathbf{R}$ assigns similar representations to history words w_1 and w_2 implies that these words can be exchanged with little impact on the resulting probability distribution. Likewise, the similarity of two lines in $\mathbf{W_{ho}}$ is an indication that the corresponding words tend to have a similar behavior, i.e. tend to have a similar probabilities of occurrence in all contexts. In the remainder, we will therefore refer to $\mathbf{R}$ as the matrix representing the **context space**, and to $\mathbf{W_{ho}}$ as the matrix for the **prediction space**.

2.2 The log-bilinear model

The work reported (Mnih and Hinton, 2007) describes another parameterization of the architecture introduced in the previous section. This parameterization is based on Factored Restricted Boltzmann Machine. According to (Mnih and Hinton, 2007), this model, termed the *log-bilinear* language model (LBL), achieves, for large vocabulary tasks, better results in terms of perplexity than the standard model, even if the reasons beyond this improvement remain unclear.

In this section, we will describe this model and show how it relates to the standard model. The LBL model estimates the n-gram parameters by:

$$P(w_l | w_{l-n+1}^{l-1}) = \frac{\exp(-E(w_l; w_{l-n+1}^{l-1}))}{\sum_w \exp(-E(w; w_{l-n+1}^{l-1}))} \quad (3)$$

In this equation, E is an *energy function* defined as:

$$\begin{aligned} E(w_l; w_1^{l-1}) = &- \left(\sum_{k=l-n+1}^{l-1} \mathbf{v_k}^T \mathbf{R} \mathbf{C}_k^T \right) \mathbf{R}^T \mathbf{v}_l \\ & \qquad\qquad\qquad\qquad\qquad\qquad (4) \\ &- \mathbf{b_r}^T \mathbf{R}^T \mathbf{v}_l - \mathbf{b_v}^T \mathbf{v}_l \\ = &- \mathbf{v}_l^T \mathbf{R} \left(\sum_{k=l-n+1}^{l-1} \mathbf{C}_k \mathbf{R}^T \mathbf{v_k} + \mathbf{b_r} \right) \\ &- \mathbf{v}_l^T \mathbf{b_v} \qquad\qquad\qquad\qquad (5) \end{aligned}$$

where $\mathbf{R}$ is the projection matrix introduced above, $(\mathbf{v}_k)_{l-n+1 \leq k \leq l-1}$ are the 1-of-V coding vectors for the history words and $\mathbf{v}_l$ is the coding vector for w_l; $\mathbf{C}_k \in \mathbb{R}^{m \times m}$ is a combination matrix and $\mathbf{b_r}$ and $\mathbf{b_v}$ denote bias vectors. All these parameters need to be learned during training.

Equation (4) can be rewritten using the notations introduced for the standard model. We then rename $\mathbf{b_r}$ and $\mathbf{b_v}$ respectively $\mathbf{b_{ih}}$ and $\mathbf{b_{ho}}$. We also denote $\mathbf{i}$ the concatenation of the $(n-1)$ vectors $\mathbf{R}^T\mathbf{v_k}$; likewise $\mathbf{W_{ih}}$ denotes the $H \times (n-1)m$ matrix obtained by concatenating row-wise the $(n-1)$ matrices $\mathbf{C}_k$. With these new notations, equations (4) and (3) can be rewritten as:

$$\mathbf{h} = \mathbf{W_{ih}}\mathbf{i} + \mathbf{b_{ih}}$$
$$\mathbf{o} = \mathbf{R}\mathbf{h} + \mathbf{b_{ho}}$$
$$P(w_l = k|w_{l-n+1}^{l-1}) = \frac{\exp(\mathbf{o_k})}{\sum_{k'} \exp(\mathbf{o_{k'}})}$$

This formulation allows to highlight the similarity of the LBL model and the standard model. These two models differ only by the activation function of their hidden layer (linear for the LBL model and tangent hyperbolic for the standard model) and by their definition of the prediction space: for the LBL model, the context space and the prediction space are the same ($\mathbf{R} = \mathbf{W_{ho}}$, and thus $H = m$), while in the standard model, the prediction space is defined independently from the context space. This restriction drastically reduces the number of free parameters of the LBL model.

It is finally noteworthy to outline the similarity of this model with standard maximum entropy language models (Lau et al., 1993; Rosenfeld, 1996). Let $\mathbf{x}$ denote the binary vector formed by stacking the (n-1) 1-of-V encodings of the history words; then the conditional probability distributions estimated in the model are proportional to $\exp F(x)$, where F is an affine transform of $\mathbf{x}$. The main difference with MaxEnt language models are thus the restricted form of the feature functions, which only test one history word, and the particular representation of F, which is defined as:

$$F(\mathbf{x}) = \mathbf{R}\mathbf{W_{ih}}\mathbf{R'}^T\mathbf{v} + \mathbf{R}\mathbf{b_{ih}} + \mathbf{b_{ho}}$$

where, as before, $\mathbf{R}'$ is formed by concatenating $(n-1)$ copies of the projection matrix $\mathbf{R}$.

2.3 Training and inference

Training the two models introduced above can be achieved by maximizing the log-likelihood $\mathcal{L}$ of the parameters Θ. This optimization is usually performed by stochastic back-propagation as in (Bengio et al., 2003). For all our experiments, the learning rate is fixed at 5×10^{-3}. The learning weight decay and the the weight decay (respectively 1×10^{-9} and 0) seem to have a minor impact on the results. Learning starts with a random initialization of the parameters under the uniform distribution and converges to a local maximum of the log-likelihood function. Moreover, to prevent overfitting, an early stopping strategy is adopted: after each epoch, training is stopped when the likelihood of a validation set stops increasing.

2.4 Complexity issues

The main problem with neural language models is their computational complexity. For the two models presented in this section, the number of floating point operations needed to predict the label of a single example is[1]:

$$((n-1) \cdot m + 1) \times H + (H + 1) \times V \qquad (6)$$

where the first term of the sum corresponds to the computation of the hidden layer and the second one to the computation of the output layer. The projection of the context words amounts to select one row of the projection matrix $\mathbf{R}$, as the words are represented with a 1-of-V coding vector. We can therefore assume that the computation complexity of the first layer is negligible. Most of the computation time is thus spent in the output layer, which implies that the computing time grows linearly with the vocabulary size. Training these models for large scale tasks is therefore challenging, and a number of tricks have been introduced to make training and inference tractable (Schwenk and Gauvain, 2002; Schwenk, 2007).

Short list A simple method to reduce the complexity in inference and in learning is to reduce the size of the output vocabulary (Schwenk, 2007): rather than estimating the probability $P(w_l = w|w_{l-n+1}^{l-1})$ for all words in the vocabulary, we only estimate it for the N most frequent words of the training set (the so-called *short-list*). In this case, two vocabularies need to be considered, corresponding respectively to the *context vocabulary* $\mathcal{V}_c$ used to define the history; and the *prediction vocabulary* $\mathcal{V}_p$. However, this method fails to deliver any probability estimate for words outside of the prediction vocabulary, meaning that a fall-back strategy needs to be defined for those words. In practice, neural network

[1] Recall that learning requires to repeatedly predict the label for all the examples in the training set.

language models are combined with a conventional n-gram model as described in (Schwenk, 2007).

Batch mode and resampling Additional speed-ups can be obtained by propagating several examples at once through the network (Bilmes et al., 1997). This "batch mode" allows to factorize the matrix operations and cut down both inference and training time. In all our experiments, we used a batch size of 64. Moreover, the training time is linear in the number of examples in the training data[2]. Training on very large corpora, which, nowadays, comprise billions of word tokens, cannot be performed exhaustively and requires to adopt *resampling* strategies, whereby, at each epoch, the system is trained with only a small random subset of the training data. This approach enables to effectively estimate neural language models on very large corpora; it has also been observed empirically that sampling the training data can increase the generalization performance (Schwenk, 2007).

3 A head-to-head comparison

In this section, we analyze a first experimental study of the two neural network language models introduced in Section 2 in order to better understand the differences between these models especially in terms of the word representations they induce. Based on this study, we will propose, in the next section, improvements of both the speed and the prediction capacity of the models. In all our experiments, 4-gram language models are used.

3.1 Corpus

The data we use for training is a large monolingual corpus, containing all the English texts in the parallel data of the Arabic to English NIST 2009 constrained task[3]. It consists of 176 millions word tokens with $532,557$ different word types as the size of vocabulary. The perplexity is computed with respect to the 2006 NIST test data, which is used here as our development data.

3.2 Convergence study

In a first experiment, we trained the two models in the same setting: we choose to consider a small vocabulary comprising the $10,000$ most frequent words. The same vocabulary is used to constrain the words occurring in the history and the words to be predicted. The size of hidden layer is set to $m = H = 200$, the history contains the 3 preceding words, we use a batch size of 64, a resampling rate of 5% and no weight decay.

Figure 1 displays the perplexity convergence curve measured on the development data for the standard and the LBL models[4]. The convergence perplexities after the combination with the standard back-off model are also provided for all the models in table 2 (see section 4.3). We can observe that the LBL model converges faster than the standard model: the latter needs 13 epochs to reach the stopping criteria, while the former only needs 6 epochs. However, upon convergence, the standard model reaches a lower perplexity than the LBL model.

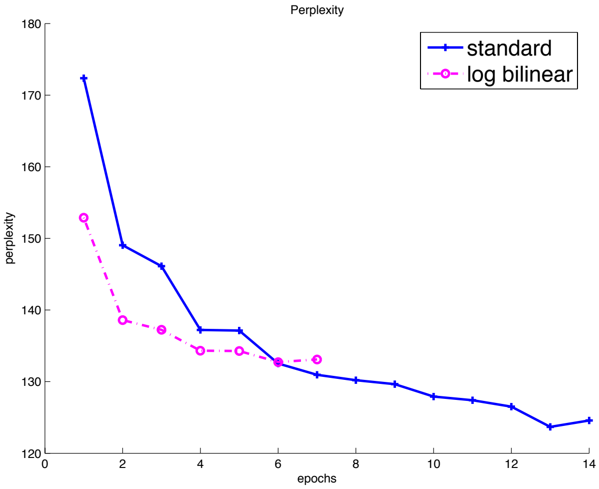

Figure 1: Convergence rate of the standard and the LBL models evaluated by the evolution of the perplexity on a development set

As described in Section 2.2, the main difference between the standard and the LBL model is the way the context and the prediction spaces are defined: in the standard model, the two spaces are distinct; in

[2] Equation (6) gives the complexity of inference for a single example.

[3] `http://www.itl.nist.gov/iad/mig/tests/mt/2009/MT09_ConstrainedResources.pdf`

[4] The use of a back-off 4-model estimated with the modified Knesser-Ney smoothing on the same training data achieves a perplexity of 141 on the development data.

the LBL model, they are bound to be the same. With a smaller number of parameters, the LBL model can not capture as many characteristics of the data as the standard model, but it converges faster[5]. This difference in convergence can be explained by the scarcity of the updates in the projection matrix $\mathbf{R}$ in the standard model: during backpropagation, only those weights that are associated with words in the history are updated. By contrast, each training sample updates all the weights in the prediction matrix $\mathbf{W_{ho}}$.

3.3 An analysis of the continuous word space

To deepen our understanding, we propose to further analyze the induced word embeddings by finding, for some randomly selected words, the five nearest neighbors (according to the Euclidian distance) in the context space and in the prediction space of the two models. Results are presented in Table 1.

If we look first at the standard model, the global picture is that for frequent words (*is*, *are*, and, to a lesser extend, *have*), both spaces seem to define meaningful neighborhood, corresponding to semantic and syntactic similarities; this is less true for rarer words, where we see a greater discrepancy between the context and prediction spaces. For instance, the date *1947* seems to be randomly associated in the context space, while the 5 nearest words in the prediction space form a consistent set of dates. The same trend is also observed for the word *Castro*. Our interpretation is that for less frequent words, the projection vectors are hardly ever updated and remain close to their original random initialization.

By contrast, the similarities in the (unique) projection space of the LBL remain consistent for all frequency ranges, and are very similar to the prediction space of the standard model. This seems to validate our hypothesis that in the standard model, the prediction space is learned much faster than the context space and corroborates our interpretation of the impact of the scarce updates of rare words. Another possible explanation is that there is no clear relation between the context space and the target function: the context space is learned only indirectly by backpropagation. As a result, due to the random initialization of the parameters and to data sparsity, many vectors of $\mathbf{R}$ might be blocked in some local maxima, meaning that similar vectors cannot be grouped in a consistent way and that the induced similarity is more “loose”.

4 Improving the standard model

In Section 3.2, we observed that slightly better results can be obtained with the standard rather than with the LBL model. The latter is however much faster to train, and seems to induce better projection matrices. Both effects can be attributed to the particular parameterization of this model, which uses the same projection matrix both for the context and for the prediction spaces. In this section, we propose several new learning regimes that allowed us to improve the standard model in terms of both speed and prediction capacity. All these improvements rely on the idea of sharing word representations. While this idea is not new (see for instance (Collobert and Weston, 2008)), our analysis enables to better understand its impact on the convergence rate. Finally, the improvements we propose are evaluated on a real-word machine translation task.

4.1 Improving performances with re-initialization

The experiments reported in the previous section suggest that it is possible to improve the performances of the standard model by building a better context space. Thus, we introduce a new learning regime, called *re-initialization* which aims to improve the context space by re-injecting the information on word neighborhoods that emerges in the prediction space. One possible implementation of this idea is as follows:

1. train a standard model until convergence;

2. use the prediction space of this model to initialize the context space of a new model; the prediction space is chosen randomly;

3. train this new model.

[5] We could increase the number of parameters of the LBL model for a fairer comparison with the standard model. However, this would also increase the size of the vocabulary and cause two new issues: on one hand, the time complexity would drastically increase for the LBL model, and on the other hand, both models would not be comparable in terms of perplexity as their vocabulary would be different.

Table 1: The 5 closest words in the representation spaces of the standard and LBL language models.

word (frequency)	*model*	*space*	*5 most closest words*

	LBL	both	Clark Singh Sabri Rafsanjani Sen

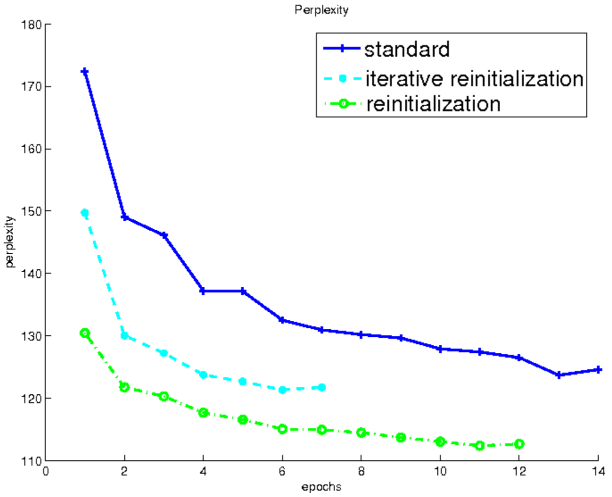

Figure 2: Evolution of the perplexity on a development set for various initialization regimes.

The evolution of the perplexity with respect to training epochs for this new method is plotted on Figure 2, where we only represent the evolution of the perplexity during the third training step. As can be seen, at convergence, the perplexity the model estimated with this technique is about 10% smaller than the perplexity of the standard model.

This result can be explained by considering the re-initialization as a form of annealing technique: re-initializing the context space allows to escape from the local extrema the standard model converges to. The fact that the prediction space provides a good initialization of the context space also confirms our analysis that one difficulty with the standard model is the estimation of the context space parameters.

4.2 Iterative re-initialization

The *re-initialization* policy introduced in the previous section significantly reduces the perplexity, at the expense of a longer training time, as it requires to successively train two models. As we now know that the parameters of the prediction space are faster to converge, we introduce a second training regime called *iterative re-initialization* which aims to take advantage of this property. We summarize this new training regime as follows:

1. Train the model for one epoch.
2. Use the prediction space parameters to reinitialize the context space.
3. Iterate steps (1) and (2) until convergence.

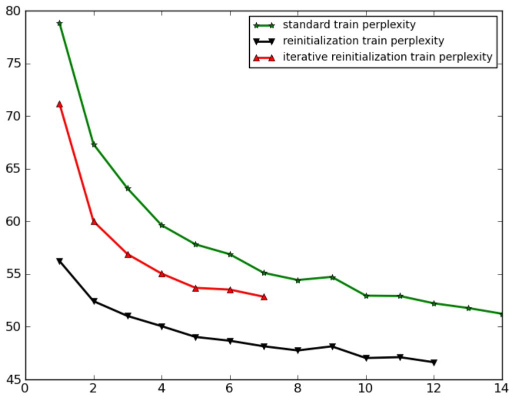

Figure 3: Evolution of the perplexity on the training data for various initialization regimes.

This regimes yields a model that is somewhat in-between the standard and LBL models as it adds a relationship between the two representation spaces, which lacks in the former model. This relationship is however not expressed through the tying of the corresponding parameters; instead we let the prediction space guide the convergence of the context space. As a consequence, we hope that it can achieve a convergence speed as fast as the one of the LBL model without degrading its prediction capacity.

The result plotted on Figure 2 shows that this indeed the case: using this training regime, we obtained a perplexity similar to the one of the standard model, while at the same time reducing the total training time by more than a half, which is of great practical interest (each epoch lasts approximately 8 hours on a 3GHz Xeon processor).

Figure 3 displays the perplexity convergence curve measured on the training data for the standard learning regime as well as for the *re-initialization* and *iterative re-initialization*. These results show the same trend as for the perplexity measured on the development data, and suggest a regularization effect of the re-initialization schemes rather than allowing the models to escape local optima.

4.3 One vector initialization

Principle The new training regimes introduced above outperform the standard training regime both in terms of perplexity and of training time. However, exchanging information between the context and prediction spaces is only possible when the same vocabulary is used in both spaces. As discussed in Section 2.4, this configuration is not realistic for very large-scale tasks. This is because increasing the number of predicted word types is much more computationally demanding than increasing the number of types in the context vocabulary. Thus, the former vocabulary is typically order of magnitudes larger than the latter, which means that the re-initialization strategies can no longer be directly used.

It is nonetheless possible to continue drawing inspirations from the observations made in Section 3, and, crucially, to question the random initialization strategy. As discussed above, this strategy may explain why the neighborhoods in the induced context space for the less frequent types were difficult to interpret. As a straightforward alternative, we consider a different initialization strategy where all the words in the context vocabulary are initially projected onto the same (random) point in the context space. The intuition is that it will be easier to build meaningful neighborhoods, especially for rare types, if all words are initially considered similar and only diverge if there is sufficient evidence in the training data to suggest that they should. This model is termed the *one vector initialization* model.

Experimental evaluation To validate this approach, we compare the convergence of a standard model trained (with the standard learning regime) with the one vector initialization regime. The context vocabulary is defined by the $532,557$ words occurring in the training data and the prediction vocabulary by the $10,000$ most frequent words[6]. All other parameters are the same as in the previous experiments. Based on the curves displayed on Figure 4, we can observe that the model obtained with the one vector initialization regime outperforms the model trained with a completely random initialization. Moreover, the latter reaches convergence in only 14 epochs, while the learning regime we propose only needs 9 epochs. Convergence is even faster than when we used the standard training regime and a small context vocabulary.

[6] In this case, the distinction between the *context* and the *prediction* vocabulary rules out the possibility of a relevant comparison based on perplexity between the continuous space language model and a standard back-off language model.

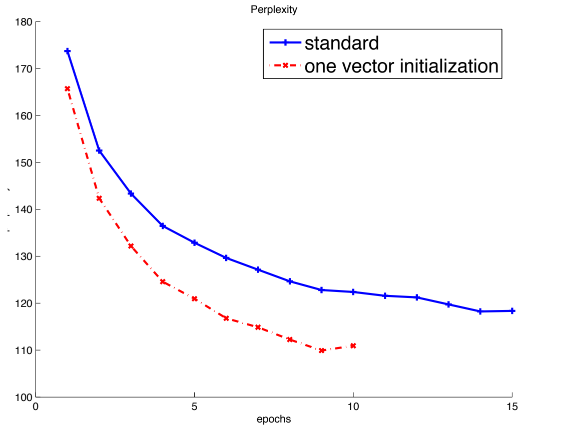

Figure 4: Perplexity with all-10, 000, 200 − 200 models

Table 2: Summary of the perplexity (*PPX*) results measured on the same development set with the different continuous space language models. For all of them, the probabilities are combined with the back-off n-gram model

(a) with the standard model

(b) with the one vector initialization model

Figure 5: Comparison of the word embedding in the context space for numbers (red points).

To illustrate the impact of our initialization scheme, we also used a principal component analysis to represent the induced word representations in a two dimensional space. Figure 5 represents the vectors associated with numbers[7] in red, while all other words are represented in blue. Two different models are used: the standard model on the left, and the one vector initialization model on the right. We can observe that, for the standard model, most of the red points are scattered all over a large portion of the representation space. On the opposite, for the one vector initialization model, points associated with numbers are much more concentrated: this is simply because all the points are originally identical, and the training aim to spread the point around this starting point. We also created the closest word list reported in Table 3, in a manner similar to Table 1. Clearly, the new method seems to yield more meaningful neighborhoods in the context space.

It is finally noteworthy to mention that when used with a small context vocabulary (as in the experimental setting of Section 4.1) this initialization strategy underperforms the standard initialization. This is simply due to the much greater data sparsity in the large context vocabulary experiments, where the rarer word types are really rare (they typically occur once or twice). By contrast, the rarer words in the small vocabulary tasks occurred more than several hundreds times in the training corpus, which was more than sufficient to guide the model towards satisfactory projection matrices. This finally suggests that there still exists room for improvement if we can find more efficient initialization strategies than starting from one or several random points.

4.4 Statistical machine translation experiments

As a last experiment, we compare the various models on a large scale machine translation task. Statistical language models are key component of current statistical machine translation systems (Koehn, 2010), where they both help disambiguate lexical choices in the target language and influence the choice of the right word ordering. The integration of a neural network language model in such a system is far from easy, given the computational cost of computing word probabilities, a task that is performed repeatedly during the search of the best translation. We then had to resort to a two pass decoding approach: the first pass uses a conventional back-off language model to produce a n-best list (the n most likely translations and their associated scores); in the second pass, the probability of the neural language model is computed for each hypothesis and the n-

[7] Number are all the words consisting only of digits, with an optional sign, point or comma such as: *1947*; *0,001*; *-8,2*.

Table 3: The 5 closest words in the context space of the standard and one vector initialization language models

word (freq.)	*model*	*5 closest words*
is	standard	was are were been remains
$900,350$	1 vector init.	was are be were been

1	1 vector init.	4160th 3651st 3487th 3378th 3558th

best list is accordingly reordered to produce the final translations.

The different language models discussed in this article are evaluated on the Arabic to English NIST 2009 constrained task. For the continuous space language model, the training data consists in the parallel corpus used to train the translation model (previously described in section 3.1). The development data is again the 2006 NIST test set and the test data is the official 2008 NIST test set. Our system is built using the open-source Moses toolkit (Koehn et al., 2007) with default settings. To set up our baseline results, we used an extensively optimized standard back-off 4-grams language model using Kneser-Ney smoothing described in (Allauzen et al., 2009). The weights used during the reranking are tuned using the Minimum Error Rate Training algorithm (Och, 2003). Performance is measured based on the BLEU (Papineni et al., 2002) scores, which are reported in Table 4.

Table 4: BLEU scores on the NIST MT08 test set with different language models.

$\mathcal{V}_c$ size	*Model*	*# epochs*	*BLEU*
all	baseline	-	37.8
10000	log bilinear	6	38.2
	standard	13	38.3
	iterative reinit.	6	38.4
	reinit.	11	38.4
all	standard	14	38.6
	one vector init.	9	**38.7**

All the experimented neural language models yield to a significant BLEU increase. The best result is obtained by the one vector initialization standard model which achieves a 0.9 BLEU improvement. While this results is similar to the one obtained with the standard model, the training time is reduced here by a third.

5 Conclusion

In this work, we proposed three new methods for training neural network language models and showed their efficiency both in terms of computational complexity and generalization performance in a real-word machine translation task. These methods rely on conclusions drawn from a careful study of the convergence rate of two state-of-the-art models and are based on the idea of sharing the distributed word representations during training.

Our work highlights the impact of the initialization and the training scheme for neural network language models. Both our experimental results and our new training methods can be closely related to the pre-training techniques introduced by (Hinton and Salakhutdinov, 2006). Our future work will thus aim at studying the connections between our empirical observations and the deep learning framework.

Enhancing domain portability of Chinese segmentation model using chi-square statistics and bootstrapping

Baobao Chang, Dongxu Han

Abstract

Almost all Chinese language processing tasks involve word segmentation of the language input as their first steps, thus robust and reliable segmentation techniques are always required to make sure those tasks well-performed. In recent years, machine learning and sequence labeling models such as Conditional Random Fields (CRFs) are often used in segmenting Chinese texts. Compared with traditional lexicon-driven models, machine learned models achieve higher F-measure scores. But machine learned models heavily depend on training materials. Although they can effectively process texts from the same domain as the training texts, they perform relatively poorly when texts from new domains are to be processed. In this paper, we propose to use χ^2 statistics when training an SVM-HMM based segmentation model to improve its ability to recall OOV words and then use bootstrapping strategies to maintain its ability to recall IV words. Experiments show the approach proposed in this paper enhances the domain portability of the Chinese word segmentation model and prevents drastic decline in performance when processing texts across domains.

1 Introduction

Chinese word segmentation plays a fundamental role in Chinese language processing tasks, because almost all Chinese language processing tasks are assumed to work with segmented input. After intensive research for more than twenty years, the performance of Chinese segmentation made considerable progress. The bakeoff series hosted by the Chinese Information Processing Society (CIPS) and ACL SIGHAN shows that an F measure of 0.95 can be achieved in the closed test tracks, in which only specified training materials can be used in learning segmentation models[1].

Traditional word segmentation approaches are lexicon-driven (Liang, 1987) and assume predefined lexicons of Chinese words are available. Segmentation results are obtained by finding a best match between the input texts and the lexicons. Such lexicon-driven approaches can be rule-based, statistic-based or in some hybrid form.

Xue (2003) proposed a novel way of segmenting Chinese texts, and it views the Chinese word segmentation task as a character tagging task. According to Xue's approach, no predefined Chinese lexicons are required; a tagging model is learned by using manually segmented training texts. The model is then used to assign each character a tag indicating the position of this character within a word. Xue's approach has become the most popular approach to Chinese word segmentation for its high performance and unified way of dealing with out-of-vocabulary (OOV) issues. Most segmentation work began to follow this approach later. Major improvements in this line of research include: 1) More sophisticated learning models were introduced other than the maximum entropy model that Xue used, such as the conditional random fields (CRFs) model which fits the sequence tagging tasks much better than the maximum entropy model (Tseng et al.,2005). 2) More tags were in-

[1] http://www.sighan.org/bakeoff2005/data/results.php.htm

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 789–798,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

troduced, as Zhao et al. (2006) shows 6 tags are superior to 4 tags. 3) New feature templates were added, such as the templates that were used in representing numbers, dates, letters etc. (Low et al., 2005)

Character tagging approaches require manually segmented training texts to learn models usually in a supervised way. The performance is always evaluated on a test set from the same domain as the training set. Such evaluation does not reveal its ability to deal with domain variation. Actually, when test set is from other domains than the domain where training set is from, the learned model normally underperforms substantially.

One of the main reasons of such performance degradation lies in the model's ability to cope with OOV words. Actually, even when the test set has the same domain properties as the training set, the ability of the model to recall OOV words is still the main obstacle to achieve better performance of segmentation. However, when the test set is different with the training set in nature, the OOV recall normally drops much more substantially, and becomes much lower.

Apart from the supervised approach, Sun et al. (2004) proposed an unsupervised way of Chinese word segmentation. The approach did not use any predefined lexicons or segmented texts. A statistic named as *md*, combining the mutual information and *t* score, was proposed to measure whether a string of characters forms word. The unsupervised nature of the approach means good ability to deal with domain variation. However, the approach did not show a segmentation performance as good as that of the supervised approach. The approach was not evaluated in F measurement, but in accuracy of word break prediction. As their experiment showed, the approach successfully predicted 85.88% of the word breaks, which is much lower than that of the character tagging approach if in terms of F measurement.

Aiming at preventing the OOV recall from dropping sharply and still maintaining an overall performance as good as that of the state-of-art segmenter when working with heterogeneous test sets, we propose in this paper to use a semi-supervised way for Chinese word segmentation task. Specifically, we propose to use χ^2 statistics together with bootstrapping strategies to build Chinese word segmentation model. The experiment shows the approach can effectively promote the OOV recall and lead to a higher overall performance. In addition, instead of using the popular CRF model, we use another sequence labeling model in this paper --- the hidden Markov Support Vector Machines (SVM-HMM) Model (Altun et al., 2003). We just wish to show that there are alternatives other than CRF model to use and comparable results can be obtained.

Our work differs from the previous supervised work in its ability to cope with domain variation and differs from the previous unsupervised work in its much better overall segmentation performance.

The rest of the paper is organized as follows: In section 2, we give a brief introduction to the hidden Markov Support Vector Machines, on which we rely to build the segmentation model. In section 3, we list the segmentation tags and the basic feature templates we used in the paper. In section 4 we show how χ^2 statistics can be encoded as features to promote OOV recall. In section 5 we give the bootstrapping strategy. In section 6, we report the experiments and in section 7 we present our conclusions.

2 The hidden Markov support vector machines

The hidden Markov support vector machine (SVM-HMM) is actually a special case of the structural support vector machines proposed by Tsochantaridis et al. (2005). It is a powerful model to solve the structure predication problem. It differs from support vector machine in its ability to model complex structured problems and shares the max-margin training principles with support vector machines. The hidden Markov support vector machine model is inspired by the hidden Markov model and is an instance of structural support vector machine dedicated to solve sequence labeling learning, a problem that CRF model is assumed to solve. In the SVM-HMM model, the sequence labeling problem is modeled by learning a discriminant function *F*: *X*×*Y*→*R* over the pairs of input sequence and label sequence, thus the prediction of the label sequence can be derived by maximizing *F* over all possible label sequences for a specific given input sequence x.

$$f(\mathbf{x};\mathbf{w}) = \arg\max_{\mathbf{y}\in Y} F(\mathbf{x},\mathbf{y};\mathbf{w})$$

In the structural SVMs, *F* is assumed to be linear in some combined feature representation of the input sequence and the label sequence $\boldsymbol{\psi}(\mathbf{x},\mathbf{y})$, i.e.

$$F(\mathbf{x},\mathbf{y};\mathbf{w}) = \langle \mathbf{w}, \boldsymbol{\psi}(\mathbf{x},\mathbf{y}) \rangle$$

Where **w** denotes a parameter vector, for the SVM-HMMs, the discriminant function is defined as follows.

$$F(x,y;\mathbf{w}) = \sum_{t=1..T}\sum_{y\in\Sigma}\langle \overline{\mathbf{w}}_y, \mathbf{\Phi}(\mathbf{x}^t)\rangle \delta(y^t,y) + \eta \sum_{t=1..T-1}\sum_{y\in\Sigma}\sum_{y'\in\Sigma} \hat{\mathbf{w}}_{y,y'}\delta(y^t,y)\delta(y^{t+1},y')$$

Here $\mathbf{w} = (\overline{\mathbf{w}}, \hat{\mathbf{w}})$, $\mathbf{\Phi}(\mathbf{x}^t)$ is the vector of features of the input sequence. $\delta(y^t, y)$ is the Kronecker function, i.e.,

$$\delta(y^t,y) = \begin{cases} 1 & \text{if } y^t = y \\ 0 & \text{if } y^t \neq y \end{cases}$$

The first term of the discriminant function is used to model the interactions between input features and labels, and the second term is used to model interactions between nearby labels. $\eta > 0$ is a scaling factor which balances the two types of contributions. (Tsochantaridis et al., 2005)

Like SVMs, parameter vector **w** is learned with the maximum margin principle by using training data. To control the complexity of the training problem, the cutting plane method is used to solve the resulted constrained optimization problem. Thus only a small subset of constraints from the full-sized optimization is checked to ensure a sufficiently accurate solution. Roughly speaking, SVM-HMM differs from CRF in its principle of training, and both of them could be used to deal with sequence labeling problem like Chinese word segmentation.

3 The tag set and the basic feature templates

As in most other work on segmentation, we use a 4-tag tagset, that is S for the character being a single-character-word by itself, B for the character beginning a multi-character-word, E for the character ending a multi-character-word and M for a character occurring in the middle of a multi-character-word.

We use the following feature templates, as are widely used in most segmentation work:

(a) C_n (n = -2, -1, 0, 1, 2)
(b) C_nC_{n+1} (n = -2, -1, 0, 1)
(c) $C_{-1}C_{+1}$

Here C refers to a character; n refers to the position index relative to the current character. By setting the above feature templates, we actually set a 5-character window to extract features, the current character, 2 characters to its left and 2 characters to its right.

In addition, we also use the following feature templates to extract features representing the character type:

(d) T_n (n = -2, -1, 0, 1, 2)
(e) T_nT_{n+1} (n = -2, -1, 0, 1)
(f) $T_{-1}T_{+1}$

Here T refers to a character type, and its value can be digit, letter, punctuation or Chinese character. The type feature is important, for there are two versions of Arabic numbers, Latin alphabets and punctuations in the Chinese texts. This is because all three kinds of characters have their internal codes defined in ASCII table, but the Chinese encoding standard like GB18030 assigns them with other double-byte codes. This causes problems for model learning as we encounter in the experiment. The training data we adopt in this paper only use numbers, letters and punctuation of double-byte codes. But the test data use both the double-byte and single-byte codes. If the type features are not introduced, most of the numbers, letters and punctuation of single-byte can not be segmented correctly. The type feature establishes links between the two versions of codes, for both versions of a digit, a letter or punctuation share the same type feature value. Actually, the encoding problem could be alternatively solved by a character normalization process. That is the mapping all single-byte versions of digits, letters and punctuations in the test sets into their double-byte counterparts as in the training set. We use the type features here to avoid any changes to the test sets.

4 The χ2 statistic features

χ^2 test is one of hypothesis test methods, which can be used to test if two events co-occur just by chance or not. A lower χ^2 score normally means the two co-occurred events are independent; otherwise they are dependent on each other. χ^2 score is widely used in computational linguistics to extract collocations or terminologies. Unsupervised segmentation approach also mainly relies on mutual information and t-score to identify words in Chinese texts (Sun et al., 2004). Inspired by their work, we believe that χ^2 statistics could also be incorporated into supervised segmentation models to deal with the OOV issue. The idea is very straightforward. If two continuous characters in the test set have a higher χ^2 score, it is highly likely they form a word or are part of a word even they are not seen in the training set.

The χ^2 score of a character bigram (i.e. two continuous characters in the text) C_1C_2 can be computed by the following formula.

$$\chi^2(C_1,C_2)=\frac{n\times(a\times d-b\times c)^2}{(a+b)\times(a+c)\times(b+d)\times(c+d)}$$

Here,

a refers to all counts of bigram C_1C_2 in the text;

b refers to all counts of bigrams that C_1 oc-curs but C_2 does not;

c refers to all counts of bigrams that C_1 does not occur but C_2 occurs;

d refers to all counts of bigrams that both C_1 and C_2 do not occur.

n refers to total counts of all bigrams in the text, apparently, $n= a + b + c + d$.

We do the χ^2 statistics computation to the training set and the test set respectively. To make the χ^2 statistics from the training set and test set comparable, we normalize the χ^2 scores by the following formula.

$$\chi^2_{norm}(C_1,C_2)=\left\lfloor\frac{\chi^2(C_1,C_2)-\chi^2_{\min}}{\chi^2_{\max}-\chi^2_{\min}}\times 10\right\rfloor$$

To make the learned model sensitive to the χ^2 statistics, we then add two more feature templates as follows:

(g) X_nX_{n+1} (n = -2, -1, 0, 1)

(h) $X_{-1}X_{+1}$

The value of the feature X_nX_{n+1} is the normalized χ^2 score of the bigram C_nC_{n+1}. Note we also compute the normalized χ^2 score to bigram $C_{-1}C_{+1}$, which is to measure the association strength of two intervened characters.

By using the χ^2 features, statistics from the test set are introduced into segmentation model, and it makes the resulted model more aware of the test set and therefore more robust to test domains other than training domains.

Because the normalized χ^2 score is one of 11 possible values 0, 1, 2, …, 10, templates (g)-(h) generate 55 features in total.

All features generated from the templates (a)-(f) together with the 55 χ^2 features form the whole feature set. The training set and test set are then converted into their feature representations. The feature representation of the training set is then used to learn the model and the feature representation of the test set is then used for segmentation and evaluated by comparison with gold standard segmentation. The whole process is shown in Figure-1.

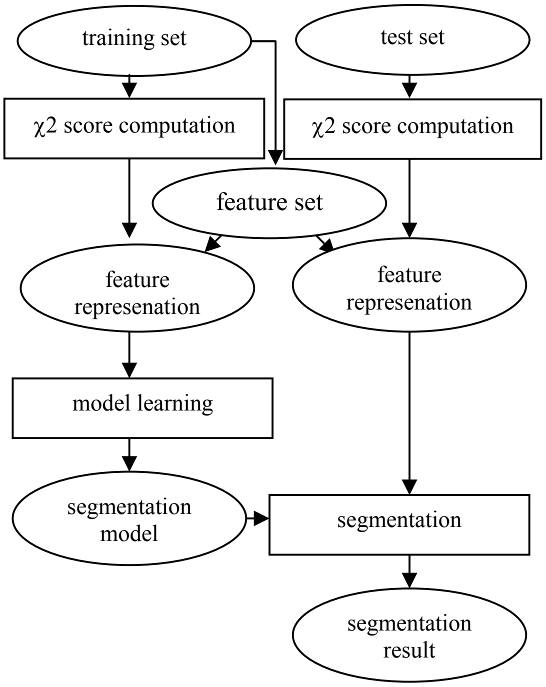

Figure-1. The workflow

By this way, an OOV word in the test set might be found by the segmentation model if the bigrams extracted from this word take higher χ^2 scores.

5 the bootstrapping strategy

The addition of the χ^2 features can be also problematic as we will see in the experiments. Even though it could promote the OOV recall significantly, it also leads to drops in in-vocabulary (IV) recall.

We are now in a dilemma. If we use χ^2 features, we get high OOV recall but a lower IV recall. If we do not use the χ^2 feature, we get a lower OOV recall but a high IV recall. To keep the IV recall from falling, we propose to use a bootstrapping method. Specifically, we choose to use both models with χ^2 features and without χ^2 features. We train two models firstly, one is χ^2-based and the other not. Then we do the segmentation for the test set with the two models simultaneously. Two segmentation results can be obtained. One result is produced by the χ^2-based model and has a high OOV recall. The other result is produced by the non-χ^2-based model and has a higher IV recall. Then we compare the two results and extract all sentences that have equal segmentations with the two models as the intersection of the two results. It is not difficult to understand that the intersection of the two results has both high OOV recall and high IV recall, if we also extract these sentences from the gold standard segmentation and perform evaluations. We then put the intersection results into the training set to form a new training set. By this new training set, we train again to get two new models, one χ^2-based and the other not. Then the two new models are used to segment the test set. Then we do again intersection to the two results and their common parts are again put into the training set. We repeat this process until a plausible result is obtained.

The whole process can be informally described as the following algorithm:

```
1. let training set T to be the original training set;
2. for I = 0 to K
    1) train the $\chi^2$-based model by using training set T;
    2) train the non-$\chi^2$-based model by using training set T;
    3) do segmentation by using the $\chi^2$-based model;
    4) do segmentation by using the non-$\chi^2$-based model;
    5) do intersection to the two segmentation results
    6) put the intersection results into the training set and get the enlarged training set T
3. train the non-$\chi^2$-based model using training set T, and take the output of this model as the final output;
4. end.
```

6 The experiments and discussions

6.1 On the training set and test set

For training the segmentation model, we use the training data provided by Peking University for bakeoff 2005[2]. The training set has about 1.1 million words in total. The PKU training data is actually consisted of all texts of the People's Daily newspaper in January of 1998. So the training data represents very formal written Chinese and mainly are news articles. A characteristic of the PKU data is that all Arabic numbers, Latin letters and punctuations in the data are all double-byte GB codes; there are no single-byte ASCII versions of these characters in the PKU training data.

We use three different test sets. The first one (denoted by A) is all texts of the People's Daily of February in 1998[3]. Its size and the genre of the texts are very similar to the training data. We use this test set to show how well the SVM-HMM can be used to model segmentation problem and the performance that a segmentation model achieves when applied to the texts from the same domain.

The second and the third test sets are set to test how well the segmentation model can apply to texts from other domains. The second test set (denoted by B) is from the literature domain and the third (denoted by C) from computer domain. We segmented them manually according to the guidelines of Peking University[4] to use as gold standard segmentations. The genres of the two test set are very different from the training set. There are even typos in the texts. In the computer test set, there are many numbers and English words. And most of the numbers and letters are single-byte ASCII codes.

The sizes and the OOV rates of the three test sets are shown in Table-1.

Table-1. Test sets statistics

test set	domain	word count	OOV rate
A	Newspaper	1,152,084	0.036
B	Literature	72,438	0.058
C	Computer	69,671	0.159

For all the experiments, we use the same evaluation measure as most of previous work on segmentation, that is the Recall(R), Precision(P), F measure (F=2PR/(P+R)), IV word recall and OOV word recall. In addition, we also evaluate all the test results with sentence accuracies (SA), which is the proportion of the correctly segmented sentences in the test set.

6.1 SVM-HMM vs. CRF

To show how well the SVM-HMM model can be used to model segmentation tasks and its performance compared to that of CRF model, we use the training set to train two models, one with SVM-HMM and the other with CRF.

The implementations of SVM-HMM and CRF model we use in the paper can be found and downloaded respectively via Internet. [5]

To make the results comparable, we use the same feature templates, that is feature template (a)-(c). However, SVM-HMM takes interactions between nearby labels into the model, which means there is a label bigram feature template implicitly used in the SVM-HMM. So when training the CRF model we also use explicitly the label bigram feature template to model interactions between nearby labels[6].

For the SVM-HMM model, we set ε to 0.25. This is a parameter to control the accuracy of the solution of the optimization problem. We set C to half of the number of the sentences in the training data according to our understanding to the models. The C parameter is set to trade off the margin size and training error. For CRF model, we use all parameters to their default value. We do not do parameter optimizations to both models with respect their performances.

We use test set A to test both models. For both models, we use the same cutoff frequency to feature extraction. Only those features that are seen more than three times in texts are actually used in the models. The performances of the two models are shown in Table-2, which shows SVM-HMM can be used to model Chinese segmentation tasks

[5] http://www.cs.cornell.edu/People/tj/svm_light/svm_hmm.html, and http://sourceforge.net/projects/crfpp/

[6] specified by the B template as the toolkit requires.

and comparable results can be achieved like CRF model.

6.2 The baseline model

To test how well the segmentation model applies to other domain texts, we only use the SVM-HMM model with the same parameters as in section 6.1 and the same cutoff frequency.

For a baseline model, we only use feature templates (a)-(c), the performances of the basic model on the three test sets are shown in Table-3.

For the test set A, which is from the same domain as the training data, an F-score 0.95 is achieved.

For test set B and C, both are from different domains with the training data, the F-scores drop significantly. Especially the OOV recalls fall drastically, which means the model is very sensitive to the domain variation. Even the IV recalls fall significantly. This also shows the domain portability of the segmentation model is still an obstacle for the segmentation model to be used in cross-domain applications.

6.3 The type features

As we noted before, there are different encoding types for the Arabic numbers, Latin letters and punctuations. Especially, test set C is full of single-byte version of such numbers, letters and punctuations. The introduction of type features may improve performance of the model to the test set. Therefore, we use the feature tem-plates (a)-(f) to train a type sensitive model with the training data. This gives segmentation results shown in table-4. (The symbol ↓ means performance drop compared with a previous model)

As we can see, for test set A, the type features almost contribute nothing; the F-score has a very slight change. The IV recall even has a slight fall while the OOV recall rises a little.

For test set C, the type features bring about very significant improvement. The F-score rises from 0.7956 to 0.9057, and the OOV recall rises from 0.3487 to 0.6839. Different with the test set A, even the IV recall for test set C rises slightly. The reason of such a big improvement lies in that there are many single-byte digits, letters and punctuations in the texts.

Unlike test set C, there are not so many single-byte characters in test set B. Even though the OOV recall does rise significantly, the change in OOV recall for test set B is not as much as that for test set B. Type features contribute much to cross domain texts.

6.4 The $\chi2$-based model

Compared with OOV recall for test set A, the OOV recall for test set B and C are still lower. To promote the OOV recall, we use the feature templates (a)-(h) to train a χ^2-based model with the training data. This gives segmentation results shown in table-5.

As we see from table-5, the introduction of the χ^2 features does not improve the overall performance. Only F-score for test set A improves slightly, the other two get bad. But the OOV recall for the three test sets does improve, especially for test set B and C. The IV recalls for the three test sets drop, especially for test set B and C. That's why the F scores for test B and C drop.

6.5 Bootstrapping

To increase the OOV recall and prevent the IV recall from falling, we use the bootstrapping strategy in section 5.

We set K = 3 and run the algorithm shown in section 5. We just do the bootstrapping to test set B and C, because what we are concerned with in this paper is to improve the performance of the model to different domains. This gives results shown in Table-6. As we see in Table-6, almost all evaluation measurements get improved. Not only the OOV recall improves significantly, but also the IV recall improves compared with the type-sensitive model.

To illustrate how the bootstrapping strategy works, we also present the performance of the intermediate models on test set C in each pass of the bootstrapping in table-7 and table-8. Table-7 is results of the intermediate χ^2-based models for test set C. Table-8 is results of the intermediate non-χ^2-based models for test set C. Figure-2 illustrates changes in OOV recalls of both non-χ^2-based models and χ^2-based models as the bootstrapping algorithm advances for test set C. Figure-3 illustrates changes in IV re-calls of both non-χ^2-based models and χ^2-based models for test set C. As we can see from Figure-2 and Figure-3, the ability of non-χ^2-based model gets improved to the OOV

Table-7. Performance of the intermediate χ^2-based models for test set C

1	0.9070	0.9249	0.9159	0.9478	0.8044	0.4869
2	0.9093	0.9254	0.9173	0.9476	0.8087	0.4947
3	0.9111	0.9266	0.9188	0.9481	0.8133	0.5030
4	0.9113	0.9268	0.9190	0.9482	0.8138	0.5039

Table-9. Performance of the intersection of the intermediate χ^2-based model and non-χ^2-based model for test C

I	P	R	F	Riv	Roov	SA
0	0.9431	0.9539	0.9485	0.9664	0.8832	0.6783
1	0.9259	0.9434	0.9345	0.9609	0.8491	0.5992
2	0.9178	0.9379	0.9277	0.9582	0.8316	0.5724
3	0.9143	0.9347	0.9244	0.9559	0.8250	0.5616

recall of the χ^2-based model as the bootstrapping algorithm advances. The abilities to recall IV words of both models improve, and even the final IV recall of the χ^2-based model surpasses the IV recall of the type sensitive model shown in Table-3. (0.9412 vs. 0.9381). To save the space of the paper, we do not list all the intermediate results for test set B. We just show the changes in OOV recalls and IV recalls as illustrated in Figure-4 and Figure-5. One can see from Figure-4 and Figure-5, the bootstrapping strategy also works for test set B in a similar way as it works for test set C.

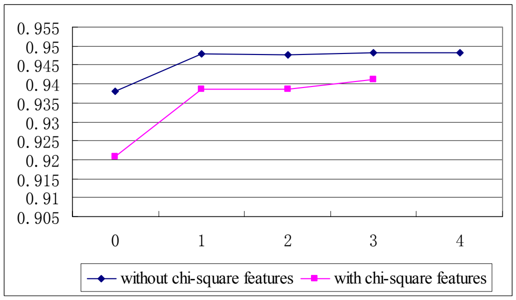

Figure-3 the Changes in IV recalls for test set C as boot-strapping algorithm advances

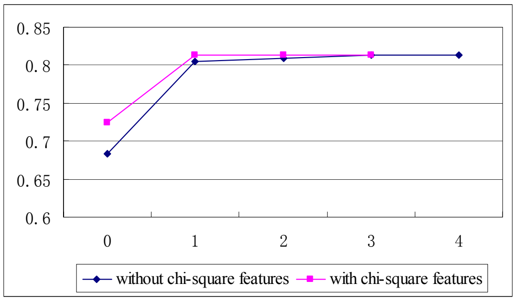

Figure-2 the Changes in OOV recalls for test set C as boot-strapping algorithm advances

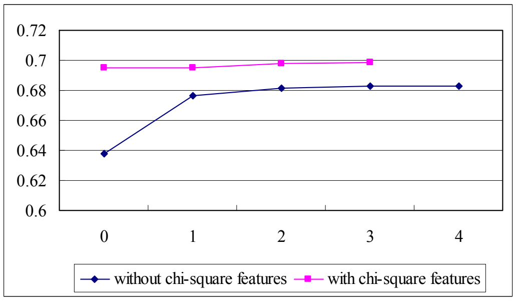

Figure-4 the Changes in OOV recalls for test set B as boot-strapping algorithm advances

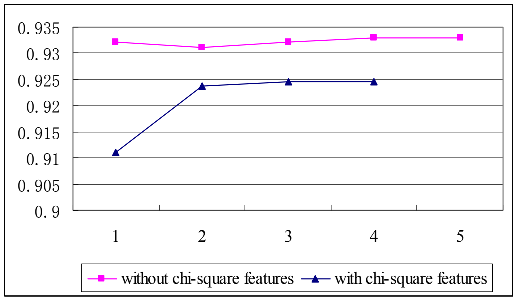

Figure-5 the Changes in IV recalls for test set B as boot-strapping algorithm advances

As we mentioned in section 5, the intersection of the results produced by χ^2-based model and non-χ^2-based model has both high OOV recall and high IV recall, that's the reason why bootstrapping strategy works. This can be seen from Table-9. However, as the algorithm progresses, both the OOV recall and IV recall of the intersection results fall, but are still higher than OOV recall and IV recall of the final results on the whole test set.

As we said before, we give also sentence accuracies of all segmentation models. With the χ^2 statistics and bootstrapping strategies, the sentence accuracy also rises. 2.8% more sentences on test set B and 7.5% more sentences on test set C are correctly segmented, compared with the type-sensitive model.

7 Conclusions

Sequence labeling models are widely used in Chinese word segmentation recently. High performance can be achieved when the test data is from the same domain as the training data. However, if the test data is assumed to be from other domains than the domain of the training data, the segmentation models always underperform substantially. To enhance the portability of the sequence labeling segmentation models to other domains, this paper proposes to use χ^2 statistics and bootstrapping strategy. The experiment shows the approach significantly increases both IV recall and OOV recall when processing texts from different domains.

We also show in this paper that hidden Markov support vector machine which is also a sequence labeling model like CRF can be used to model the Chinese word segmentation problem, by which high F-score results can be obtained like those of CRF model.

One concern to the bootstrapping approach in this paper is that it takes time to work with, which will make it difficult to be incorporated into language applications that need to responses in real time. However, we believe that such an approach can be used in offline contexts. For online use in a specified domain, one can first train models by using the approach in the paper with prepared raw texts from the specified domain and then use the final non-χ^2-based model to segment new texts of the same domain, since statistics of the target domain are more or less injected into the model by the iteration of bootstrapping.

Abstract

We present a novel approach to distributional-only, fully unsupervised, POS tagging, based on an adaptation of the EM algorithm for the estimation of a Gaussian mixture. In this approach, which we call Latent-Descriptor Clustering (LDC), word types are clustered using a series of progressively more informative descriptor vectors. These descriptors, which are computed from the immediate left and right context of each word in the corpus, are updated based on the previous state of the cluster assignments. The LDC algorithm is simple and intuitive. Using standard evaluation criteria for unsupervised POS tagging, LDC shows a substantial improvement in performance over state-of-the-art methods, along with a several-fold reduction in computational cost.

1 Introduction

Part-of-speech (POS) tagging is a fundamental natural-language-processing problem, and POS tags are used as input to many important applications. While state-of-the-art supervised POS taggers are more than 97% accurate (Toutanova et al., 2003; Tsuruoka and Tsujii, 2005), unsupervised POS taggers continue to lag far behind. Several authors addressed this gap using limited supervision, such as a dictionary of tags for each word (Goldwater and Griffiths, 2007; Ravi and Knight, 2009), or a list of word prototypes for each tag (Haghighi and Klein, 2006). Even in light of all these advancements, there is still interest in a completely unsupervised method for POS induction for several reasons. First, most languages do not have a tag dictionary. Second, the preparation of such resources is error-prone. Third, while several widely used tag sets do exist, researchers do not agree upon any specific set of tags across languages or even within one language. Since tags are used as basic features for many important NLP applications (e.g. Headden et al. 2008), exploring new, statistically motivated, tag sets may also be useful. For these reasons, a fully unsupervised induction algorithm has both a practical and a theoretical value.

In the past decade, there has been a steady improvement on the completely unsupervised version of POS induction (Schütze, 1995; Clark, 2001; Clark, 2003; Johnson, 2007; Gao and Johnson, 2008; Graça et al., 2009; Abend et al., 2010; Lamar et al., 2010; Reichart et al., 2010; Berg-Kirkpatrick et al., 2010). Some of these methods use morphological cues (Clark, 2001; Clark, 2003; Abend et al., 2010; Reichart et al., 2010; Berg-Kirkpatrick et al., 2010), but all rely heavily on distributional information, *i.e.*, bi-

gram statistics. Two recent papers advocate *non-disambiguating* models (Abend et al., 2010; Lamar et al., 2010): these assign the same tag to all tokens of a word type, rather than attempting to disambiguate words in context. Lamar et al. (2010) motivate this choice by showing how removing the disambiguation ability from a state-of-the-art disambiguating model results in increasing its accuracy.

In this paper, we present a novel approach to non-disambiguating, distributional-only, fully unsupervised, POS tagging. As in all non-disambiguating distributional approaches, the goal, loosely stated, is to assign the same tag to words whose contexts in the corpus are similar. Our approach, which we call Latent-Descriptor Clustering, or LDC, is an iterative algorithm, in the spirit of the K-means clustering algorithm and of the EM algorithm for the estimation of a mixture of Gaussians.

In conventional K-means clustering, one is given a collection of N objects described as N data points in an r-dimensional Euclidean space, and one seeks a clustering that minimizes the sum of intra-cluster squared distances, *i.e.*, the sum, over all data points, of the squared distance between that point and the centroid of its assigned cluster. In LDC, we similarly state our goal as one of finding a tagging, *i.e.*, cluster assignment, A, that minimizes the sum of intra-cluster squared distances. However, unlike in conventional K-means, the N objects to be clustered are themselves described by vectors—in a suitable manifold—that depend on the clustering A. We call these vectors *latent descriptors*.

Specifically, each object to be clustered, *i.e.*, each word type w, is described in terms of its *left-tag context* and *right-tag context*. These context vectors are the counts of the K different tags occurring, under tagging A, to the left and right of tokens of word type w in the corpus. We normalize each of these context vectors to unit length, producing, for each word type w, two points $L_A(w)$ and $R_A(w)$ on the $(K–1)$-dimensional unit sphere. The latent descriptor for w consists of the pair $(L_A(w), R_A(w))$—more details in Section 2.

A straightforward approach to this latent-descriptor K-means problem is to adapt the classical iterative K-means algorithm so as to handle the latent descriptors. Specifically, in each iteration, given the assignment A obtained from the previous iteration, one first computes the latent descriptors for all word types as defined above, and then proceeds in the usual way to update cluster centroids and to find a new assignment A to be used in the next iteration.

For reasons to be discussed in Section 5, we instead prefer a *soft-assignment* strategy, inspired from the EM algorithm for the estimation of a mixture of Gaussians. Thus, rather than the hard assignment A, we use a soft-assignment matrix P. P_{wk}, interpreted as the probability of assigning word w to cluster k, is, essentially, proportional to $\exp\{- d_{wk}^2/2\sigma^2\}$, where d_{wk} is the distance between the latent descriptor for w and the centroid, *i.e.*, Gaussian mean, for k. Unlike the Gaussian-mixture model however, we use the same mixture coefficient and the same Gaussian width for all k. Further, we let the Gaussian width σ decrease gradually during the iterative process. As is well-known, the EM algorithm for Gaussian mixtures reduces in the limit of small σ to the simpler K-means clustering algorithm. As a result, the last few iterations of LDC effectively implement the hard-assignment K-means-style algorithm outlined in the previous paragraph. The soft assignment used earlier in the process lends robustness to the algorithm.

The LDC approach is shown to yield substantial improvement over state-of-the-art methods for the problem of fully unsupervised, distributional only, POS tagging. The algorithm is conceptually simple and easy to implement, requiring less than 30 lines of Matlab code. It runs in a few seconds of computation time, as opposed to hours or days for the training of HMMs.

2 Notations and Statement of Problem

The LDC algorithm is best understood in the context of the latent-descriptor K-means optimization problem. In this section, we set up our notations and define this problem in detail. For simplicity, induced tags are henceforth referred to as *labels*, while *tags* will be reserved for the gold-standard tags, to be used later for evaluation.

Let W denote the set of word types $w_1,…,w_N$, and let T denote the set of labels, *i.e.*, induced tags. The sizes of these sets are $|W| = N$ and $|T| = K$. In the experiments presented in Section 4, N is 43,766 and K is either 50 or 17. For any word token t in the corpus, we denote the word type of t by $w(t)$. The frequency of word type w in the corpus is denoted $f(w)$; thus, $\Sigma_w f(w) = 1$.

For a word type w_1, the *left-word context* of w_1, $L(w_1)$, is defined as the N-dimensional vector whose n-th component is the number of bigrams, *i.e.*, pairs of consecutive tokens (t_{i-1}, t_i) in the corpus, such that $w(t_i) = w_1$ and $w(t_{i-1}) = n$. Similarly, we define the *right-word context* of w_1, $R(w_1)$, as the N-dimensional vector whose n-th component is the number of bigrams (t_i, t_{i+1}) such that $w(t_i) = w_1$ and $w(t_{i+1}) = n$. We let L (resp. R) be the $N \times N$ matrix whose w-th row is $L(w)$ (resp. $R(w)$).

S^{K-1} is the unit sphere in the K-dimensional Euclidean space $\mathbb{R}^K$. For any $x \in \mathbb{R}^K$, we denote by $\lambda(x)$ the projection of x on S^{K-1}, *i.e.*, $\lambda(x) = x/\|x\|$.

A labeling is a map A: $W \rightarrow T$. Given a labeling A, we define $\widetilde{L}_A(w_1)$, the *left-label context* of word type w_1, as the K-dimensional vector whose k-th component is the number of bigrams (t_{i-1}, t_i) in the corpus such that $w(t_i) = w_1$ and $A(w(t_{i-1})) = k$. We define the *left descriptor* of word type w as:

$$L_A(w) = \lambda(\widetilde{L}_A(w)).$$

We similarly define the right-label context of w_1, $\widetilde{R}_A(w_1)$, as the K-dimensional vector whose k-th component is the number of bigrams (t_i, t_{i+1}) such that $w(t_i) = w_1$ and $A(w(t_{i+1})) = k$, and we define the *right descriptor* of word type w as:

$$R_A(w) = \lambda(\widetilde{R}_A(w)).$$

In short, any labeling A defines two maps, L_A and R_A, each from W to S^{K-1}.

For any function $g(w)$ defined on W, $<g(w)>$ will be used to denote the average of $g(w)$ weighted by the frequency of word type w in the corpus:

$$<g(w)> = \Sigma_w f(w) g(w).$$

For any label k, we define:

$$C_L(k) = \lambda(< L_A(w): A(w) = k >).$$

Thus, $C_L(k)$ is the projection on S^{K-1} of the weighted average of the left descriptors of the word types labeled k. We sometimes refer to $C_L(k)$ as the left centroid of cluster k. Note that $C_L(k)$ depends on A in two ways, first in that the average is taken on words w such that $A(w) = k$, and second through the global dependency of L_A on A. We similarly define the right centroids:

$$C_R(k) = \lambda(< R_A(w): A(w) = k >).$$

Informally, we seek a labeling A such that, for any two word types w_1 and w_2 in W, w_1 and w_2 are labeled the same if and only if $L_A(w_1)$ and $L_A(w_2)$ are close to each other on S^{K-1} and so are $R_A(w_1)$ and $R_A(w_2)$. Formally, our goal is to find a labeling A that minimizes the objective function:

$$F(A) = <\|L_A(w) - C_L(A(w))\|^2 + \|R_A(w) - C_R(A(w))\|^2>.$$

Note that, just as in conventional K-means clustering, $F(A)$ is the sum of the intra-cluster squared distances. However, unlike conventional K-means clustering, the descriptors of the objects to be clustered depend themselves on the clustering. We accordingly refer to L_A and R_A as *latent descriptors*, and to the method described in the next section as **Latent-Descriptor Clustering**, or LDC.

Note, finally, that we do not seek the *global* minimum of $F(A)$. This global minimum, 0, is obtained by the trivial assignment that maps all word types to a unique label. Instead, we seek a minimum under the constraint that the labeling be non-trivial. As we shall see, this constraint need not be imposed explicitly: the iterative LDC algorithm, when suitably initialized and parameterized, converges to non-trivial local minima of $F(A)$—and these are shown to provide excellent taggers.

3 Methods

Recall that a mixture of Gaussians is a generative model for a random variable taking values in a Euclidean space $\mathbb{R}^r$. With K Gaussians, the model is parameterized by:

- K mixture parameters, *i.e.*, K non-negative numbers adding up to 1;
- K means, *i.e.*, K points $\mu_1,\ldots,\mu_K$ in $\mathbb{R}^r$;
- K variance-covariance $d\times d$ matrices.

The collection of all parameters defining the model is denoted by θ. EM is an iterative algorithm used to find a (local) maximizer of the likelihood of N observed data points $x_1,\ldots,x_N \in \mathbb{R}^r$. Each iteration of the algorithm includes an E phase and an M phase. The E phase consists of computing, based on the current θ, a probabilistic assignment of each of the N observations to the K Gaussian distributions. These probabilistic assignments form an $N\times K$ stochastic matrix P, *i.e.*, a matrix of non-negative numbers in which each row sums to 1. The M phase consists of updating the model parameters θ, based on the current assignments P. For more details, see, e.g., Bishop (2006).

The structure of the LDC algorithm is very similar to that of the EM algorithm. Thus, each iteration of LDC consists of an E phase and an M phase. As observations are replaced by latent descriptors, an iteration of LDC is best viewed as starting with the M phase. The M phase first starts by building a pair of latent-descriptor matrices L_P and R_P, from the soft assignments obtained in the previous iteration. Note that these descriptors are now indexed by P, the matrix of probabilistic assignments, rather than by hard assignments A as in the previous section.

L_P and R_P are obtained by a straightforward adaptation of the definition given in the previous section to the case of probabilistic assignments. Thus, the latent descriptors consist of the left-word and right-word contexts (recall that these are given by matrices L and R), mapped into left-label and right-label contexts through multiplication by the assignment matrix P, and scaled to unit length:

$$L_P = \lambda(LP)$$
$$R_P = \lambda(RP).$$

With these latent descriptors in hand, we proceed with the M phase of the algorithm as usual. Thus, the left mean $\mu^L{}_k$ for Gaussian k is the weighted average of the left latent descriptors $L_P(w)$, scaled to unit length. The weight used in this weighted average is $P_{wk}\times f(w)$ (remember that $f(w)$ is the frequency of word type w in the corpus). Note that the definition of the Gaussian mean $\mu^L{}_k$ parallels the definition of the cluster centroid $C_L(k)$ given in the previous section; if the assignment P happens to be a hard assignment, $\mu^L{}_k$ is actually identical to $C_L(k)$. The right Gaussian mean $\mu^R{}_k$ is computed in a similar fashion. As mentioned, we do not estimate any mixture coefficients or variance-covariance matrices.

The E phase of the iteration takes the latent descriptors and the Gaussian means, and computes a new $N\times K$ matrix of probabilistic assignments P. These new assignments are given by:

$$P_{wk} = \frac{1}{Z}\exp\{-[\| L_P(w) - \mu_k^L \|^2 + \| R_P(w) - \mu_k^R \|^2]/2\sigma^2\}$$

with Z a normalization constant such that $\sum_k P_{wk} = 1$. σ is a parameter of the model, which, as mentioned, is gradually decreased to enforce convergence of P to a hard assignment.

The description of the M phase given above does not apply to the first iteration, since the M phase uses P from the previous iteration. To initialize the algorithm, *i.e.*, create a set of left and right descriptor vectors in the M phase of the first iteration, we use the left-word and right-word contexts L and R. These matrices however are of very high dimension ($N\times N$), and thus sparse and noisy. We therefore reduce their dimensionality, using reduced-rank singular-value decomposition. This yields two $N\times r_1$ matrices, L_1 and R_1. A natural choice for r_1 is $r_1 = K$, and this was indeed used for $K = 17$. For $K = 50$, we also use $r_1 = 17$. The left and right descriptors for the first iteration are obtained by scaling each row of matrices L_1 and R_1 to unit length. The Gaussian centers $\mu^L{}_k$ and $\mu^R{}_k$, $k = 1,\ldots,K$, are set equal to the left and right descriptors of the K

most frequent words in the corpus. This completes the description of the LDC algorithm.[1]

While this algorithm is intuitive and simple, it does not easily lend itself to mathematical analysis; indeed there is no *a priori* guarantee that it will behave as desired. Even for the simpler, hard-assignment, K-means-style version of LDC outlined in the previous section, there is no equivalent to the statement—valid for the conventional K-means algorithm—that each iteration lowers the intra-cluster sum of squared distances $F(A)$; this is a mere consequence of the fact that the descriptors themselves are updated on each iteration. The soft-assignment version of LDC does not directly attempt to minimize $F(A)$, nor can it be viewed as likelihood maximization—as is EM for a Gaussian mixture—since the use of latent descriptors precludes the definition of a generative model for the data. This theoretical difficulty is compounded by the use of a variable σ.

Empirically however, as shown in the next section, we find that the LDC algorithm is very well behaved. Two simple tools will be used to aid in the description of the behavior of LDC.

The first tool is an objective function $G(P)$ that parallels the definition of $F(A)$ for hard assignments. For a probabilistic assignment P, we define $G(P)$ to be the weighted average, over all w and all k, of $\|L_P(w) - \mu^L_k\|^2 + \|R_P(w) - \mu^R_k\|^2$; the weight used in this average is $P_{wk}\times f(w)$, just as in the computation of the Gaussian means. Clearly, G is identical to F on any P that happens to be a hard assignment. Thus, G is actually an extension of the objective function F to soft assignments.

The second tool will allow us to compute a tagging accuracy for soft assignments. For this purpose, we simply create, for any probabilistic assignment P, the obvious labeling $A = A^*(P)$ that maps w to k with highest P_{wk}.

4 Results

In order to evaluate the performance of LDC, we apply it to the *Wall Street Journal* portion of the Penn Treebank corpus (1,173,766 tokens, all lower-case, resulting in $N = 43{,}766$ word types). We compare the induced labels with two gold-standard tagsets:

- **PTB45**, the standard 45-tag PTB tagset. When using PTB45 as the gold standard, models induce 50 labels, to allow comparison with Gao and Johnson (2008) and Lamar et al. (2010).

- **PTB17**, the PTB tagset coarse-grained to 17 tags (Smith and Eisner 2005). When using PTB17 as the gold standard, models induce 17 labels.

In order to compare the labels generated by the unsupervised model with the tags of each tagset, we use two map-based criteria:

- **MTO**: many-to-one tagging accuracy, *i.e.*, fraction of correctly-tagged tokens in the corpus under the so-called many-to-one mapping, which takes each induced tag to the gold-standard POS tag with which it co-occurs most frequently. This is the most prevalent metric in use for unsupervised POS tagging, and we find it the most reliable of all criteria currently in use. Accordingly, the study presented here emphasizes the use of MTO.

- **OTO**: best tagging accuracy achievable under a so-called one-to-one mapping, *i.e.*, a mapping such that at most one induced tag is sent to any POS tag. The optimal one-to-one mapping is found through the Hungarian algorithm[2].

[1] The LDC code, including tagging accuracy evaluation, is available at http://www.dam.brown.edu/people/elie/code/.

[2] Code by Markus Beuhren is available at http://www.mathworks.com/matlabcentral/fileexchange/6543-functions-for-the-rectangular-assignment-problem

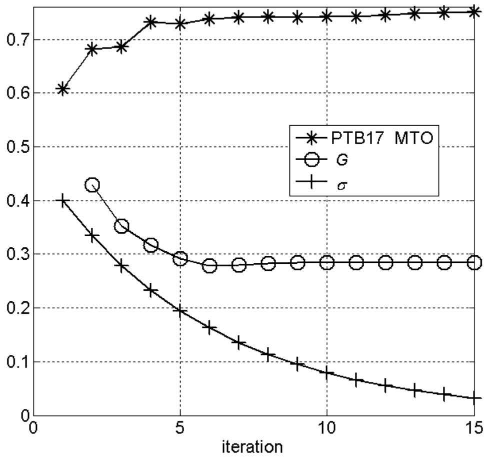

Figure 1: Convergence of LDC with $K = 17$. Bottom curve: σ -schedule, *i.e.*, sequence of Gaussian widths employed. Middle curve: Objective function $G(P)$ (see Section 3). Top curve: Many-to-one tagging accuracy of labeling $A^*(P)$, evaluated against PTB17.

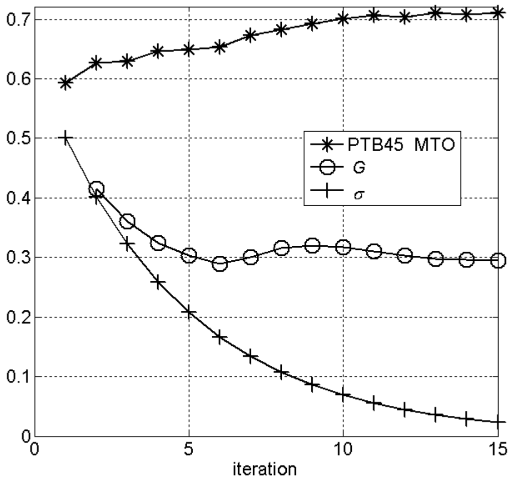

Figure 2: Same as Figure 1 but with $K = 50$. Top curve shows the MTO accuracy of the labeling evaluated against PTB45.

Figures 1 and 2 show the behavior of the LDC algorithm for K = 17 and K = 50 respectively. From the G curves as well as from the MTO scoring curves (using the labeling $A^*(P)$ defined at the end of Section 3), it is clear that the algorithm converges. The figures show only the first 15 iterations, as little change is observed after that. The schedule of the σ parameter was given the simple form $\sigma(t) = \sigma_1 \exp\{-c(t-1)\}$, t = 1,2,…, and the parameters σ_1 and c were adjusted so as to get the best MTO accuracy. With the σ-schedules used in these experiments, P typically converges to a hard assignment in about 45 iterations, σ being then 10^{-5}.

While the objective function $G(P)$ mostly decreases, it does show a hump for K = 50 around iteration 9. This may be due to the use of latent descriptors, or of a variable σ, or both. The MTO score sometimes decreases by a small fraction of a percent, after having reached its peak around the 15th iteration.

Note that we start σ at 0.4 for K = 17, and at 0.5 for K = 50. Although we chose two slightly different σ schedules for the two tagsets in order to achieve optimal performance on each tagset, an identical sequence of σ can be used for both with only a 1% drop in PTB17 score.

As the width of the Gaussians narrows, each vector is steadily pushed toward a single choice of cluster. This forced choice, in turn, produces more coherent descriptor vectors for all word types, and yields a steady increase in tagging accuracy.

Criterion	Model	PTB17	PTB45
MTO	LDC	**0.751**	**0.708**
	SVD2	0.740	0.658
	HMM-EM	0.647	0.621
	HMM-VB	0.637	0.605
	HMM-GS	0.674	0.660
OTO	LDC	**0.593**	0.483
	SVD2	0.541	0.473
	HMM-EM	0.431	0.405
	HMM-VB	0.514	0.461
	HMM-GS	0.466	**0.499**

Table 1. Tagging accuracy comparison between several models for two tagsets and two mapping criteria. Note that LDC significantly outperforms all HMMs (Gao and Johnson, 2008) in every case except PTB45 under the OTO mapping. LDC also outperforms SVD2 (Lamar et al., 2010) in all cases.

Table 1 compares the tagging accuracy of LDC with several recent models of Gao and Johnson (2008) and Lamar et al. (2010).

The LDC results shown in the top half of the table, which uses the MTO criterion, were obtained with the same σ-schedules as used in Figures 1 and 2. Note that the LDC algorithm is deterministic. However, the randomness in the sparse-matrix implementation of reduced-rank SVD used in the initialization step causes a small variability in performance (the standard deviation of the MTO score is 0.0004 for PTB17 and 0.003 for PTB45). The LDC results reported are averages over 20 runs. Each run was halted at iteration 15, and the score reported uses the labeling $A^*(P)$ defined at the end of Section 3.

The LDC results shown in the bottom half of the table, which uses the OTO criterion, were obtained with a variant of the LDC algorithm, in which the M phase estimates not only the Gaussian means but also the mixture coefficients. Also, different σ-schedules were used,[3]

For both PTB17 and PTB45, and under both criteria, LDC's performance nearly matches or exceeds (often by a large margin) the results achieved by the other models. We find the large increase achieved by LDC in the MTO performance under the PTB45 tagset particularly compelling. It should be noted that Abend et al. (2010) report 71.6% MTO accuracy for PTB45, but they treat all punctuation tags differently in their evaluation and therefore these results cannot be directly compared. Berg-Kirkpatrick et al. (2010) report 75.5% MTO accuracy for PTB45 by incorporating other features such as morphology; Table 1 is limited to distributional-only methods.

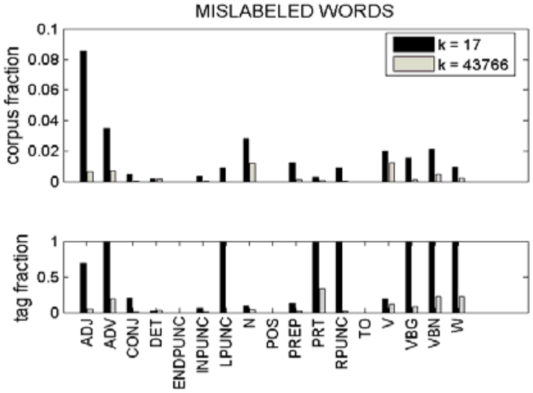

Figure 3: Mislabeled words per tag, using the PTB17 tagset. Black bars indicate mislabeled words when 17 clusters are used. Gray bars indicate words that continue to be mislabeled even when every word type is free to choose its own label, as if each type were in its own cluster—which defines the theoretically best possible non-disambiguating model. Top: fraction of the corpus mislabeled, broken down by gold tags. Bottom: fraction of tokens of each tag that are mislabeled. Many of the infrequent tags are 100% mislabeled because no induced label is mapped to these tags under MTO.

Figure 3 demonstrates the mistakes made by LDC under the MTO mapping. From the top graph, it is clear that the majority of the missed tokens are open-class words – most notably adjectives and adverbs. Over 8% of the tokens in the corpus are mislabeled adjectives – roughly one-third of all total mislabeled tokens (25.8%). Furthermore, the corresponding bar in the bottom graph indicates that over half of the adjectives are labeled incorrectly. Similarly, nearly 4% of the mislabeled tokens are adverbs, but *every* adverb in the corpus is mislabeled because no label is mapped to this tag – a common oc-

[3] All details are included in the code available at http://www.dam.brown.edu/people/elie/code/.

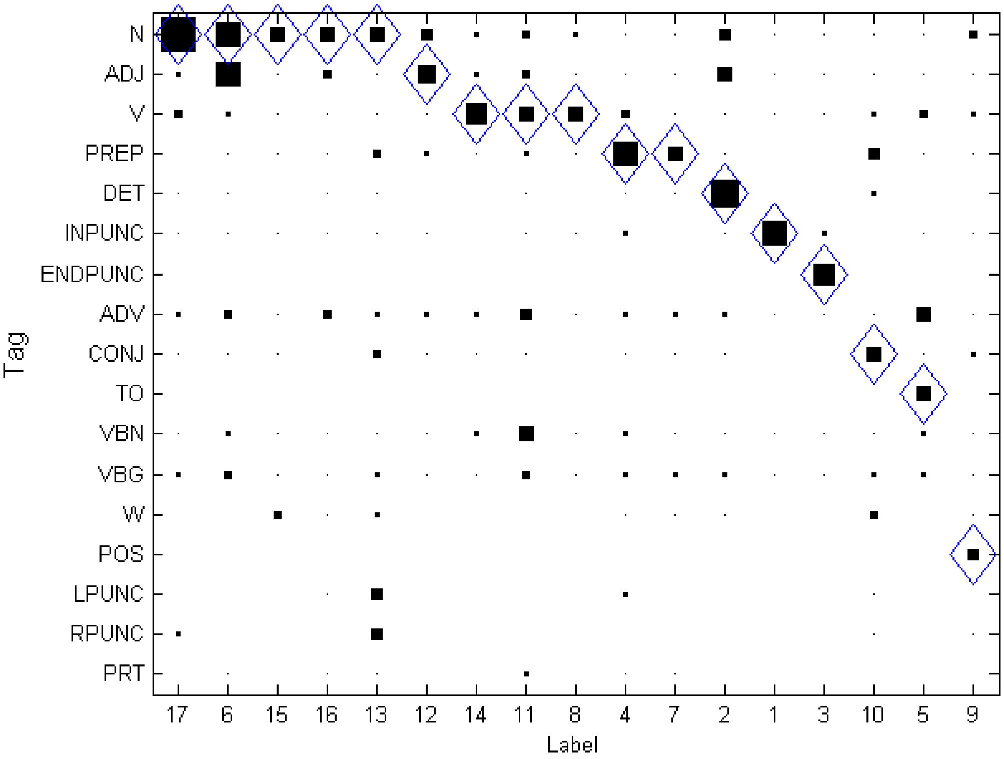

Figure 4: The confusion matrix for LDC's labeling under PTB17. The area of a black square indicates the number of tokens in each element of the confusion matrix. The diamonds indicate the induced tag under the MTO mapping. Several labels are mapped to N (Noun), and one of these labels causes appreciable confusion between nouns and adjectives. Because multiple labels are dedicated to a single tag (N, V and PREP), several tags (in this case 7) are left with no label.

currence under MTO, shared by seven of the seventeen tags.

To further illuminate the errors made by LDC, we construct the confusion matrix (figure 4). Element (*i,j*) of this matrix stores the fraction of all tokens of POS tag *i* that are given label *j* by the model. In a perfect labeling, exactly one element of each row and each column would be non-zero. As illustrated in figure 4, the confusion matrices produced by LDC are far from perfect. LDC consistently splits the Nouns into several labels and often confuses Nouns and Adjectives under a single label. These types of mistakes have been observed as well in models that use supervision (Haghighi and Klein, 2006).

5 Discussion

When devising a model for unsupervised POS induction, one challenge is to choose a model of adequate complexity, this choice being related to the bias-variance dilemma ubiquitous in statistical estimation problems. While large datasets are available, they are typically not large enough to allow efficient unsupervised learnability in models that are powerful enough to capture complex features of natural languages. Ambiguity is one of these features. Here we propose a new approach to this set of issues: start with a model that explicitly entertains ambiguity, and gradually constrain it so that it eventually converges to an unambiguous tagger.

Thus, although the algorithm uses probabilistic assignments, of Gaussian-mixture type, the goal is the construction of hard assignments. By requiring the Gaussians to be isotropic with uniform width and by allowing that width to shrink to zero, the algorithm forces the soft assignments to converge to a set of hard assignments. Based on its performance, this simulated-annealing-like approach appears to provide a good compromise in the choice of model complexity.

LDC bears some similarities with the algorithm of Ney, Essen and Kneser (1994), further implemented, with extensions, by Clark (2003). Both models use an iterative approach to minimize an objective function, and both initialize with frequent words. However, the model of Ney et al. is, in essence, an HMM where each word type is constrained to belong to a single class (i.e., in HMM terminology, be emitted by a single hidden state). Accordingly, the objective function is the data likelihood under this constrained HMM. This takes into account only the rightward transition probabilities. Our approach is conceptually rather different from an HMM. It is more similar to the approach of Schütze (1995) and Lamar et al. (2010), where each word type is mapped into a descriptor vector derived from its left and right tag contexts. Accordingly, the objective function is that of the *K*-means clustering problem, namely a sum of intra-cluster squared distances. This objective function, unlike the likelihood under an HMM, takes into account both left and right contexts. It also makes use in a crucial way of cluster centroids (or Gaussian means), a notion that has no counterpart in the HMM approach. We note that LDC achieves much better results (by about 10%) than a recent implementation of the Ney et al. approach (Reichart et al. 2010).

The only parameters in LDC are the two parameters used to define the σ schedule, and r_1 used in the first iteration. Performance was generally found to degrade gracefully with changes in these parameters away from their optimal values. When σ was made too large in the first few iterations, it was found that the algorithm converges to the trivial minimum of the objective function $F(A)$, which maps all word types to a unique label (see section 2). An alternative would be to estimate the variance for each Gaussian separately, as is usually done in EM for Gaussian mixtures. This would not necessarily preclude the use of an iteration-dependent scaling factor, which would achieve the goal of gradually forcing the tagging to become deterministic. Investigating this and related options is left for future work.

Reduced-rank SVD is used in the initialization of the descriptor vectors, for the optimization to get off the ground. The details of this initialization step do not seem to be too critical, as witnessed by robustness against many parameter changes. For instance, using only the 400 most frequent words in the corpus—instead of all words—in the construction of the left-word and right-word context vectors in iteration 1 causes no appreciable change in performance.

The probabilistic-assignment algorithm was found to be much more robust against parameter changes than the hard-assignment version of LDC, which parallels the classical *K*-means clustering algorithm (see Section 1). We experimented with this hard-assignment latent-descriptor clustering algorithm (data not shown), and found that a number of additional devices were necessary in order to make it work properly. In particular, we found it necessary to use reduced-rank SVD on each iteration of the algorithm—as opposed to just the first iteration in the version presented here—and to gradually increase the rank *r*. Further, we found it necessary to include only the most frequent words at the beginning, and only gradually incorporate rare words in the algorithm. Both of these devices require fine tuning. Provided they are indeed appropriately tuned, the same level of performance as in the probabilistic-assignment version could be achieved. However, as mentioned, the behavior is much less robust with hard clustering.

Central to the success of LDC is the dynamic interplay between the progressively harder cluster assignments and the updated latent descriptor vectors. We operate under the assumption that if all word types were labeled optimally, words that share a label should have similar descriptor vectors arising from this optimal labeling. These similar vectors would continue to be clustered together, producing a stable equilibrium in the dynamic process. The LDC algorithm demonstrates that, despite starting far from this optimal labeling, the alternation between vector updates and assignment updates is able to produce steadily improving clusters, as seen by the steady increase of tagging accuracy.

We envision the possibility of extending this approach in several ways. It is a relatively simple matter to extend the descriptor vectors to include context outside the nearest neighbors, which may well improve performance. In view of the computational efficiency of LDC, which runs in under one minute on a desktop PC, the added computational burden of working with the extended context is not likely to be prohibitive. LDC could also be extended to include morphological or other features, rather than relying exclusively on context. Again, we would anticipate a corresponding increase in accuracy from this additional linguistic information.

Abstract

We define a probabilistic morphological analyzer using a data-driven approach for Syriac in order to facilitate the creation of an annotated corpus. Syriac is an under-resourced Semitic language for which there are no available language tools such as morphological analyzers. We introduce novel probabilistic models for segmentation, dictionary linkage, and morphological tagging and connect them in a pipeline to create a probabilistic morphological analyzer requiring only labeled data. We explore the performance of models with varying amounts of training data and find that with about 34,500 labeled tokens, we can outperform a reasonable baseline trained on over 99,000 tokens and achieve an accuracy of just over 80%. When trained on all available training data, our joint model achieves 86.47% accuracy, a 29.7% reduction in error rate over the baseline.

1 Introduction

Our objective is to facilitate the annotation of a large corpus of classical Syriac (referred to simply as “Syriac” throughout the remainder of this work). Syriac is an under-resourced Western Semitic language of the Christian Near East and a dialect of Aramaic. It is currently employed almost entirely as a liturgical language but was a true spoken language up until the eighth century, during which time many prolific authors wrote in Syriac. Even today there are texts still being composed in or translated into Syriac. By automatically annotating these texts with linguistically useful information, we will facilitate systematic study by scholars of Syriac, the Near East, and Eastern Christianity. Furthermore, languages that are linguistically similar to Syriac (e.g., Arabic and Hebrew) may benefit from the methodology presented here.

Our desired annotations include morphological segmentation, links to dictionary entries, and morphological attributes. Typically, annotations of this kind are made with the assistance of language tools, such as morphological analyzers, segmenters, or part-of-speech (POS) taggers. Such tools do not exist for Syriac, but some labeled data does exist: Kiraz (1994) compiled an annotated version of the Peshitta New Testament (1920) and a concordance thereof. We aim to replicate this kind of annotation on a much larger scale with more modern tools, building up from the labeled New Testament data, our only resource. Motivated by this state of affairs, our learning and annotation framework requires only labeled data.

We approach the problem of Syriac morphological annotation by creating five probabilistic sub-models that can be trained in a supervised fashion and combined in a joint model of morphological annotation. We introduce novel algorithms for segmentation, dictionary linkage, and morphological tagging. We then combine these sub-models into a joint n-best pipeline. This joint model outperforms a strong, though naïve, baseline for all amounts of training data over about 9,900 word tokens.

1.1 Syriac Background

Since Syriac is an abjad, its writing system does not require vowels. As a dialect of Aramaic, it is an inflected language with a templatic (non-concatenative) morphology, based on a system of triliteral consonantal roots, with prefixes, suffixes, infixes, and enclitic particles. Syriac is written from

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 810–820,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

right to left. For the purposes of this work, all Syriac is transliterated according to the Kiraz (1994) transliteration[1] and is written left-to-right whenever transliterated; the Syriac appearing in the Serto script in this paper is shown right-to-left.

Since there is no standardized nomenclature for the parts of a Syriac word, we define the following terms to facilitate the definitions of segmentation, dictionary linkage, and morphological tagging:

- word token - contiguous characters delimited by whitespace and/or punctuation
- stem - an inflected form of the baseform and the main part of the word to which prefixes and suffixes can be attached; the affixes do not inflect the stem but include prepositions, object suffixes, and enclitic pronouns
- baseform - the dictionary citation form; also known as a lexeme or lemma
- root - the form from which the baseform is derived

To clarify, we will use an example word token ܠܡܠܟܟܘܢ, *LMLCCON*, which means "to your (masculine plural) king". For this word, the stem is ܡܠܟ, *MLC*; the baseform is ܡܠܟܐ, *MLCA* "king"; and the root is ܡܠܟ, *MLC*. To clarify, note that the word token (including the stem) can be spoken and written with vowels as diacritics; however, since the vowels are not written in common practice and since most text does not include them, this work omits any indication of vowels. Furthermore, the stem is an inflected baseform and does not necessarily form a word on its own. Also, the (unvocalized) stem and root are not necessarily identical. In Syriac, the same root ܡܠܟ, *MLC* is the foundation for other words such as promise, counsel, deliberate, reign, queen, kingdom, and realm.

1.2 Sub-tasks

Segmentation, or tokenization as it is sometimes called (e.g., Habash and Rambow, 2007), is the process of dividing a word token into its prefix(es) (if any), a stem, and a suffix (if any). For Syriac, each word token consists of exactly one stem, from zero to three prefixes, and zero or one suffix. Each prefix is exactly one character in length. Segmentation does not include the process of parsing the stem for its inflectional morphology; that step is handled separately in subsequent processes described below. While segmenting a Syriac word, we can handle all prefixes as a single unit. It is trivial to segment a prefix cluster into its individual prefixes (one character per prefix). Suffixes may be multiple characters in length and encode the morphological attributes of the suffix itself (not of the stem); the suffix usually encodes the object of the stem and has its own grammatical attributes, which we list later. As an example of token segmentation, for the word token ܠܡܠܟܟܘܢ, *LMLCCON*, the prefix is ܠ, *L* "to", the stem is ܡܠܟ, *MLC* "king", and the suffix is ܟܘܢ, *CON* "(masculine plural) your".

Dictionary linkage is the process of linking a stem to its associated baseform and root. In most Syriac dictionaries, all headwords are either baseforms or roots, and for a given word these are the only relevant entries in the dictionary. Each Syriac stem is derived from a baseform, and each baseform is derived from a root. There is ambiguity in this correspondence which can be caused by, among other things, homographic stems generated from different roots or even from homographic roots. As such, linkage may be thought of as two separate processes: (1) baseform linkage, where the stem is mapped to its most likely baseform; and (2) root linkage, where the baseform is mapped to its most likely root. For our example ܠܡܠܟܟܘܢ, *LMLCCON*, baseform linkage would map stem ܡܠܟ, *MLC* to baseform ܡܠܟܐ, *MLCA*, and root linkage would map baseform ܡܠܟܐ, *MLCA* to root ܡܠܟ, *MLC*.

Morphological tagging is the process of labeling each word token with its morphological attributes. Morphological tagging may be thought of as two separate tagging tasks: (1) tagging the stem and (2) tagging the suffix. For Syriac, scholars have defined for this task a set of morphological attributes consisting of twelve attributes for the stem and four attributes for the suffix. The attributes for the stem are as follows: grammatical category, verb conjugation, aspect, state, number, person, gender, pronoun type, demonstrative category, noun type, numeral type, and participle type. The morphological

[1] According to this transliteration all capital letters including *A* (ܐ, olaph) and *O* (ܘ, waw) are consonants. Additionally, the semi-colon (*;*), representing (ܝ, yod), is also a consonant.

Attribute	Value
Grammatical Category	noun
Verb Conjugation	N/A
Aspect	N/A
State	emphatic
Number	singular
Person	N/A
Gender	masculine
Pronoun Type	N/A
Demonstrative Category	N/A
Noun Type	common
Numeral Type	N/A
Participle Type	N/A

Table 1: The values for the morphological attributes of the stem ܡܠܟ, *MLC*, “king”.

Attribute	Value
Gender	masculine
Person	second
Number	plural
Contraction	normal suffix

Table 2: The values for the morphological attributes of the suffix ܟܘܢ, *CON*, “(masculine plural) your”.

attributes for the suffix are gender, person, number, and contraction. The suffix contraction attribute encodes whether the suffix is normal or contracted, a phonological process involving the attachment of an enclitic pronoun to a participle. These morphological attributes were heavily influenced by those used by Kiraz (1994), but were streamlined in order to focus directly on grammatical function. During morphological tagging, each stem is labeled for each of the stem attributes, and each suffix is labeled for each of the suffix attributes. For a given grammatical category (or POS), only a subset of the morphological attributes is applicable. For those morphological attributes (both of the stem and of the suffix) that do not apply, the correct label is “N/A” (not applicable). Tables 1 and 2 show the correct stem and suffix tags for the word ܠܡܠܟܟܘܢ, *LMLCCON*.

The remainder of the paper will proceed as follows: Section 3 outlines our approach. In Section 4, we describe our experimental setup; we present results in Section 5. Section 6 contrasts previous work with our approach. Finally, in Section 7 we briefly conclude and offer directions for future work.

2 The Syromorph Approach

Since lack language tools, we focus on automatically annotating Syriac text in a data-driven fashion based on the labeled data we have available. Since segmentation, linkage, and morphological tagging are not mutually independent tasks, we desire models for the sub-tasks to influence each other. To accommodate these requirements, we use a joint pipeline model (Finkel et al., 2006). In this section, we will first discuss this joint pipeline model, which we call **syromorph**. We then examine each of the individual sub-models.

2.1 Joint Pipeline Model

Our approach is to create a joint pipeline model consisting of a segmenter, a baseform linker, a root linker, a suffix tagger, and a stem tagger. Figure 1 shows the dependencies among the sub-models in the pipeline for a single word. Each sub-model (oval) has access to the data and predictions (rectangles) indicated by the arrows. For example, for a given word, the stem tagger has access to the previously predicted stem, baseform, root, and suffix tag. The baseform linker has access to the segmentation, most importantly the stem.

The training of **syromorph** is straightforward. Each of the individual sub-models is trained separately on the true labeled data. Features are extracted from the local context in the sentence. The local context consists first of predictions for the entire sentence from earlier sub-tasks (those sub-tasks upon which the sub-task in question depends). We created the dependencies shown in Figure 1 taking into account the difficulty of the tasks and natural dependencies in the language. In addition to the predictions for the entire sentence from previous sub-tasks, the local context also includes the previous *o* tags of the current sub-task, as the standard order *o* Markov model does. For example, when the stem tagger is being trained on a particular sentence, the local context consists of the words in the sentence, the predicted segmentation, baseform, root, and suffix tags for each word in the sentence, and additionally the labels for the previous *o* stems. To further elaborate

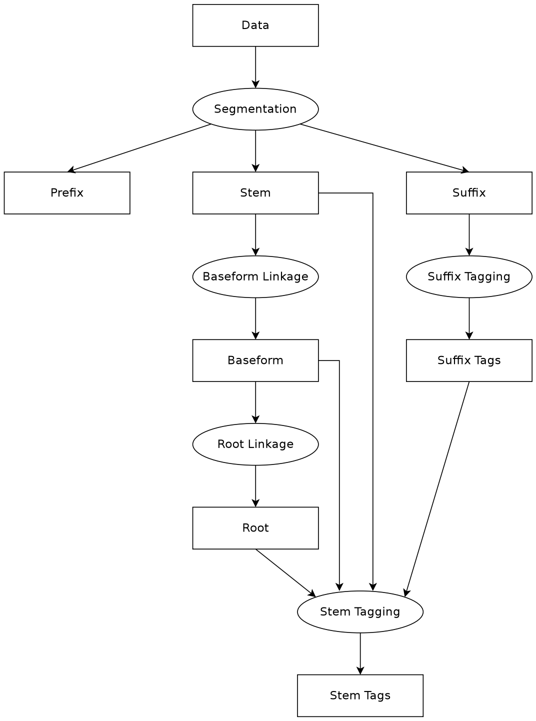

Figure 1: The **syromorph** model. Each rectangle is an input or output and each oval is a process employing a sub-model.

on the example, since features are extracted from the local context, for stem tagging we extract features such as current stem, previous stem, current baseform, previous baseform, current root, previous root, current suffix tags, and previous suffix tags. (Here, "previous" refers to labels on the immediately preceding word token.)

2.2 Segmentation

The **syromorph** segmentation model is a hybrid word- and consonant-level model, based on the model of Haertel et al. (2010) for data-driven diacritization. Each of our probabilistic sequence models is a maximum entropy Markov model (MEMM). Haertel et al. (2010) showed that the distribution over labels is different for known and words and rare words. In this work, we only consider words not seen in training (i.e., "unknown") to be rare. Following Haertel et al.'s (2010) model, a separate model is trained for each word type seen in training with the intent of choosing the best segmentation given that word. This approach is closely related to the idea of ambiguity classes mentioned in Hajič and Hladká (1998).

To handle unknown words, we back off to a consonant-level model. Our consonant-level segmentation model uses the notion of BI (Beginning and Inside) tags, which have proven successful in named-entity recognition. Since there are three labels in which we are interested (prefix, stem, and suffix), we apply the beginning and inside notion to each of them to create six tags: BEGINNING-PREFIX, INSIDE-PREFIX, BEGINNING-STEM, INSIDE-STEM, BEGINNING-SUFFIX, and INSIDE-SUFFIX. We train an MEMM to predict one of these six tags for each consonant. Furthermore, we constrain the decoder to allow only legal possible transitions given the current prediction, so that prefixes must come before stems and stems before suffixes. In order to capture the unknown word distributions, we train the consonant-level model on words occurring only once during training.

We call this word- and consonant-level segmentation model **hybrid**. As far as we are aware, this is a novel approach to segmentation.

2.3 Dictionary Linkage

For dictionary linkage, we divide the problem into two separate tasks: baseform linkage and root linkage. For both of these tasks, we use a hybrid model similar to that used for segmentation, consisting of a collection of separate MEMMs for each word type (either a stem or baseform, depending on the linker) and a model for unknown (or rare) words. For the unknown words, we compare two distinct approaches.

The first approach for unknown words is based on the work of Chrupała (2006), including the Morfette system. Instead of predicting a baseform given a stem, we predict what Chrupała calls a lemma-class. A lemma-class is the transformation specified by the minimum edit distance between the baseform (which he calls a lemma) and the stem. The transformation is a series of tuples, where each tuple includes (1) whether it was an insertion or deletion, (2) the letter inserted or deleted, and (3) the position of the insertion or deletion in the string (positions begin at zero). All operations are assumed to occur sequentially, as in Morfette. For example, the transformation of *XE;N* to *XEA* would proceed as follows: delete *;* from position 2, insert *A* into position 2, delete *N* from position 3.

In **hybrid-morfette** baseform linkage (respectively, root linkage), we predict a lemma-class (i.e., transformation) for each baseform (respectively, root). The predicted transformation is then applied to the stem (respectively, baseform) in order to construct the actual target baseform (respectively, root). The advantage to this method is that common transformations are grouped into a single class, thereby allowing the model to generalize and adequately predict baseforms (and roots) that have not been seen during training, but whose transformations have been seen. This model is trained on all words in order to capture as many transformations as possible.

The second approach for unknown words, called **hybrid-maxent**, uses an MEMM trained on all words seen in training. Given a stem (respectively, baseform), this approach predicts only baseforms (respectively, roots) that were observed in training data. Thus, this method has a distinct disadvantage when it comes to predicting new forms. This approach corresponds directly to the approach to handling unknown -words by Toutanova and Manning (2000) for POS tagging.

With regard to baseform and root linkage, we do not use the dictionary to constrain possible baseforms or roots, since we make no initial assumptions about the completeness of a dictionary.

2.4 Morphological Tagging

For morphological tagging, we break the task into two separate tasks: tagging the suffix and tagging the stem. Since there are a number of values that need to be predicted, we define two ways to approach the problem. We call the first approach the monolithic approach, in which the label is the concatenation of all the morphological attribute values. Table 3 illustrates the tagging of an example sentence: the stem tag and suffix tag columns contain the monolithic tags for stem tagging and suffix tagging. We use an MEMM to predict a monolithic tag for each stem or suffix and call this model **maxent-mono**. No co-occurrence restrictions among related or complementary morphological tags are directly enforced. Co-occurrence patterns are observed in the data, learned, and encoded in the models of the tagging process. It is worth noting further that constraints provided by the baseforms – predicted by dictionary linkage – on the morphological attributes are likewise not directly enforced. Enforcement of such constraints would require an infusion of expert knowledge into the system.

The second approach is to assume that morphological attributes are independent of each other. We call this the independent approach. Here, each tag is predicted by a tagger for a single morphological attribute. For example, the gender model is ignorant of the other 11 sub-tags during stem tagging. Using its local context (which does not include other stem sub-tags), the model predicts the best gender for a given word. The top prediction of each of these taggers (12, for stem tagging) is then combined naïvely with no notion of what combinations may be valid or invalid. We use MEMMs for each of the single-attribute taggers. This model is called **maxent-ind**.

2.5 Decoding

Our per-task decoders are beam decoders, with beam-size b. In particular, we limit the number of per-stage back-pointers to b due to the large size of the tagset for some of our sub-models. Although Viterbi decoding produces the most probable label sequence given a sequence of unlabeled words, it is potentially intractible on our hybrid models due to the unbounded dependence on previous consonant-level decisions. Our beam decoders produce a good approximation when tuned properly.

Decoding in **syromorph** consists of extending the per-task decoders to allow transitions from each sub-model to the next sub-model in the pipe. For example, in our pipeline, the first sub-model is segmentation. We predict the top n segmentations for the sentence (i.e., sequences of segmentations), where n is the number of transitions to maintain between each sub-task. Then, we run the remaining sub-tasks with each of the n sequences as a possible context. After each sub-task is completed, we narrow the number of possible contexts back to n.

We swept b and n for various values, and found $b = 5$ and $n = 5$ to be good values that balanced between accuracy and time; larger values saw only minute gains in accuracy.

3 Experimental Setup

We are using the Syriac Peshitta New Testament in the form compiled by Kiraz (1994).[2] This data is segmented, annotated with baseform and root, and labeled with morphological attributes. Kiraz and others in the Syriac community refined and corrected the original annotation while preparing a digital and print concordance of the New Testament. We augmented Kiraz's version of the data by segmenting suffixes and by streamlining the tagset. The dataset consists of 109,640 word tokens.

Table 3 shows part of a tagged Syriac sentence using this tagset. The suffix and stem tags consist of indices representing morphological attributes. In the example sentence, the suffix tag 1011 represents the values "masculine", "N/A", "plural", "normal suffix" for the suffix attributes of gender, person, number, and contraction. Each value of 0 for each stem and suffix attribute represents a value of "N/A", except for that of grammatical category, which always must have a value other than "N/A". Therefore, the suffix tag 0000 means there is no suffix.

For the stem tags, the attribute order is the same as that shown in Table 1 from top to bottom. The following describes the interpretation of the stem values represented in Table 3. Grammatical category values 0, 2, and 3 represent "verb", "noun", and "pronoun", respectively. (Grammatical category has no "N/A" value.) The verb conjugation value 1 represents "peal conjugation". Aspect value 1 represents "perfect". State value 3 represents "emphatic". Number values 1 and 2 represent "singular" and "plural". Person values 2 and 3 represent "second" and "third" person. Gender values 2 and 3 represent "masculine" and "feminine". Pronoun type value 2 represents "demonstrative". Demonstrative category value 2 represents "far". Finally, noun type 2 represents "common". The last two columns of 0 represent "N/A" for numeral type and particle type.

We implement five sub-tasks: segmentation, baseform linkage, root linkage, suffix tagging, and stem tagging. We compare each sub-task to a naïve approach as a baseline. In addition to desiring good sub-models, we also want a joint pipeline model that significantly outperforms the naïve joint approach, which is formed by using each of the following baselines in the pipeline framework.

The baseline implementation of segmentation is to choose the most-frequent label: for a given word, the baseline predicts the segmentation with which that word appeared most frequently during training. For unknown words, it chooses the largest prefix and largest suffix that is possible for that word from the list of prefixes and suffixes seen during training. (This naïve baseline for unknown words does not take into account the fact that the stem is often at least three characters in length.)

For dictionary linkage, the baseline is similar: both baseform linkage and root linkage use the most-frequent label approach. Given a stem, the baseline baseform linker predicts the baseform with which the stem was seen most frequently during training; likewise, the baseline root linker predicts the root from the baseform in a similar manner. For the unknown stem case, the baseline baseform linker predicts the baseform to be identical to the stem. For the unknown baseform case, the baseline root linker predicts a root identical to the first three consonants of the baseform, since for Syriac the root is exactly

[2] The Way International, a Biblical research ministry, annotated this version of the New Testament by hand and required 15 years to do so.

three consonants in a large majority of the cases.

The baselines for stem and suffix tagging are the most-frequent label approaches. These baselines are similar to **maxent-mono** and **maxent-ind**, using the monolithic and independent approaches used by **maxent-mono** and **maxent-ind**. The difference is that instead of using maximum entropy, the naïve most-frequent approach is used in its place.

The joint baseline tagger uses each of the component baselines in the n-best joint pipeline framework. Because this framework is modular, we can trivially swap in and out different models for each of the subtasks.

4 Experimental Results

Since we are focusing on under-resourced circumstances, we sweep the amount of training data and produce learning curves to better understand how our models perform in such circumstances. For each point in our learning curves and for all other evaluations, we employ ten-fold cross-validation. The learning curves use the chosen percentage of the data for training and a fixed-size test set from each fold and report the average accuracy.

The reported task accuracy requires the entire output for that task to be correct in order to be counted as correct. For example, during stem tagging, if one of the sub-tags is incorrect, then the entire tag is said to be incorrect. Furthermore, for **syromorph**, the outputs of every sub-task must be correct in order for the word token to be counted as correct.

Moving beyond token-level metrics, in order to understand performance of the system at the level of individual decisions (including N/A decisions), we compute decision-level accuracy: we call this metric **total-decisions**. For the **syromorph** method reported here, there are a total of 20 decisions: 2 for segmentation (prefix and suffix boundaries), 1 for baseform linkage, 1 for root linkage, 4 for suffix tagging, and 12 for stem tagging. This accuracy helps us to assess the number of decisions a human annotator would need to correct, if data were preannotated by a given model. Excluding N/A decisions, we compute per-decision coverage and accuracy. These metrics are called **applicable-coverage** and **applicable-accuracy**.

We show results on both the individual sub-tasks and the entire joint task. Since previous subtasks can adversely affect tasks further down in the pipeline, we evaluate the sub-models by placing them in the pipeline with other (simulated) submodels that correctly predict every instance. For example, when testing a root linker, we place the root linker to be evaluated in the pipeline with a segmenter, baseform linker, and taggers that return the correct label for every prediction. This gives an upper-bound for the individual model, removes the possibility of error propagation, and shows how well that model performs without the effects of the other models in the pipeline.

For our results, unknown accuracy is the accuracy of unknown instances, specific to the task, at training time. In the case of baseform linkage, for example, a stem is considered unknown if that stem was not seen during training. It is therefore possible to have a known word with an unknown stem and vice versa. As in other NLP problems, unknown instances are a manifestation of training data sparsity.

4.1 Baseline Results

Table 4 is grouped by sub-task and reports the results of each of the baseline sub-tasks in the first row of each group. Each of the baselines performs surprisingly well. The accuracies of the baselines for most of the tasks are high because the ambiguity of the labels given the instance is quite low: the average ambiguity across word types for segmentation, baseform linkage, root linkage, suffix tagging, and stem tagging are 1.01, 1.05, 1.02, 1.35, and 1.47, respectively.

Preliminary experiments indicated that if we had trained a baseline model using a single prediction (a monolithic concatenation of the predictions for all tasks) per token rather than separating the tasks, the baseline tagging accuracy would have been lower. Note that the unknown tagging accuracy for the monolithic suffix tagger is not applicable, because there were no test suffixes that were not seen during training.

4.2 Individual Model Results

Table 4 also shows the results for the individual models. In the table, SEG, BFL, RTL, SUFFIX, and STEM represent segmentation, baseform linkage, root linkage, suffix tagging, and stem tagging,

	Model	Total	Known	Unk

	ind. baseline	53.24	86.90	0.00
	maxent-mono	**89.48**	**92.87**	**57.04**
	maxent-ind	88.43	90.26	40.59

Table 4: Word-level accuracies for the individual submodels used in the **syromorph** approach.

respectively. Even though the baselines were high, each individual model outperformed its respective baseline, with the exception of the root linker. Two of the most interesting results are the known accuracy of the baseform linkers **hybrid-maxent** and **hybrid-morfette**. As hybrid models, the difference between them lies only in the treatment of unknown words; however, the known accuracy of the morfette model drops fairly significantly. This is due to the unknown words altering the weights for features in which those words occur. For instance, if the previous word is unknown and a baseform that was never seen was predicted, then the weights on the next word for all features that contain that unknown word will be quite different than if that previous word were a known word.

It is also worth noting that the stem tagger is by far the worst model in this group of models, but it is also the most difficult task. The largest gains in improving the entire system would come from focusing attention on that task.

4.3 Joint Model Results

Table 5 shows the accuracies for the joint models. The joint model incorporating "maxent" variants performs best overall and on known cases. The joint model incorporating the "morfette" variants performs best on unknown cases.

Model	Total	Known	Unk
Baseline	80.76	85.74	28.07
Morfette Monolithic	85.96	89.85	**44.86**
Maxent Monolithic	**86.47**	**90.77**	40.93

Table 5: Word-level accuracies for various joint **syromorph** models.

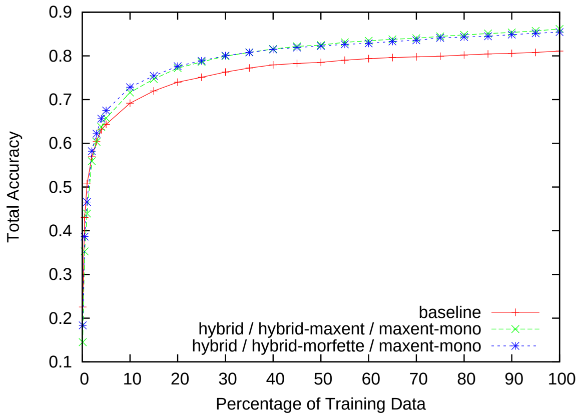

Figure 2: The total accuracy of the joint model.

Decision-level metrics for the SEG:**hybrid** / BFL and RTL:**hybrid-maxent** / SUFFIX and STEM:**maxent-mono** model are as follows: for **total-decisions**, the model achieves an accuracy of 97.08%, compared to 95.50% accuracy for the baseline, amounting to a 35.11% reduction in error rate over the baseline; for **applicable-coverage** and **applicable-accuracy** this model achieved 93.45% and 93.81%, respectively, compared to the baseline's 90.03% and 91.44%.

Figures 2, 3, and 4 show learning curves for total, known, and unknown accuracies for the joint pipeline model. As can be seen in Figure 2, by the time we reach 10% of the training data, **syromorph** is significantly better than the baseline. In fact, at 35% of the training data, our joint pipeline model outperforms the baseline trained with all available training data.

Figure 3 shows the baseline performing quite well on known words with very low amounts of data. Since the x-axis varies the amount of training data, the meaning of "known" and "unknown" evolves as we move to the right of the graph; consequently, the

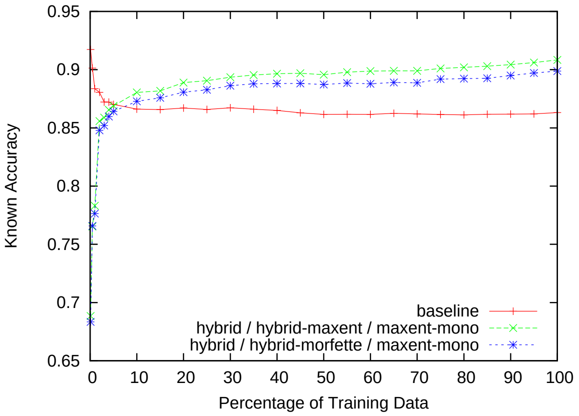

Figure 3: The accuracy of the joint model on known words.

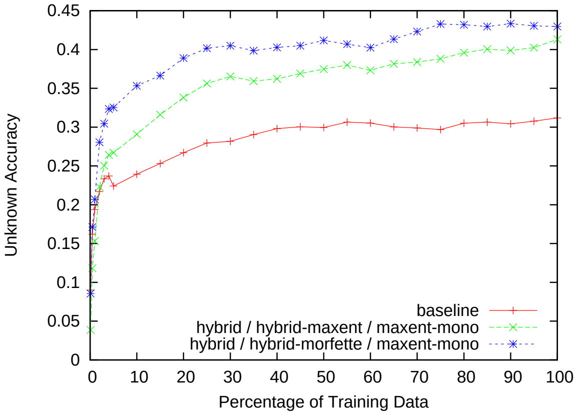

Figure 4: The accuracy of the joint model on unknown words.

left and right sides of the graph are incomparable. When the percentage of training data is very low, the percentage of unknown words is high, and the number of known words is relatively low. On this dataset, the more frequent words tend to be less ambiguous, giving the most-frequent taggers an advantage in a small random sample. For this reason, the baseline performs very well on known accuracy with lower amounts of training data.

Figure 4 clearly shows that **hybrid-morfette** linkers outperform **hybrid-maxent** linkers on unknown words. However, Figures 2- 4 show that **hybrid-morfette**'s advantage on unknown words is counteracted by its lower performance on known words; therefore, it has slightly lower overall accuracy than **hybrid-maxent**.

5 Related Work

The most closely related work to our approach is the Morfette tool for labeling inflectional morphology (Chrupała et al., 2008). Chrupała et al. created a tool that labels Polish, Romanian, and Spanish with morphological information as well as baseforms. It is a supervised learning approach that requires data labeled with both morphological tags and baseforms. This approach creates two separate models (a morphological tagger and a lemmatizer) and combines the decoding process in order to create a joint model that predicts both morphological tags and the baseform. Morfette uses MEMMs for both models and has access to predicted labels in the feature set. Reported accuracy rates are 96.08%, 93.83%, and 81.19% for joint accuracy on datasets trained with fewer than 100,000 tokens for Romanian, Spanish, and Polish, respectively. The major difference between this work and ours is the degree of morphological analysis required by the languages. Chrupała et al. neglect segmentation, a task not as intuitive for their languages as it is for Syriac. These languages also require only linkage to a baseform, as no root exists.

Also closely related is the work of Daya, Roth, and Wintner (2008) on Hebrew. The authors use the notion of patterns into which root consonants are injected to compose Semitic words. They employ linguistic knowledge (specifically, lists of prefixes, suffixes, and "knowledge of word-formation processes" combined with SNoW, a multi-class classifier that has been shown to work well in other NLP tasks. The major difference between this approach and the method presented in this paper is that this method does not require the extra knowledge required to encode word-formation processes. A further point of difference is our use of hybrid word- and consonant-level models, after Haertel et al. (2010). Their work builds on the work of Shacham and Wintner (2007), which is also related to that of Habash and Rambow, described below.

Work by Lee et al. (2003) is the most relevant work for segmentation, since they segment Arabic, closely related to Syriac, with a data-driven approach. Lee et al. use an unsupervised algorithm bootstrapped with manually segmented data to learn the segmentation for Arabic without any additional language resources. At the heart of the algorithm is a word-level trigram language model, which captures the correct weights for prefixes and suffixes. They report an accuracy of 97%. We opted to use our own segmenter because we felt we could achieve higher accuracy with the **hybrid** segmenter.

Mohamed and Kübler (2010a, 2010b) report on closely related work for morphological tagging. They use a data-driven approach to find the POS tags for Arabic, using both word tokens and segmented words as inputs for their system. Although their segmentation performance is high, they report that accuracy is lower when first segmenting word tokens. They employ TiMBL, a memory-based learner, as their model and report an accuracy of 94.74%.

Habash and Rambow (2005) currently have the most accurate approach for Arabic morphological analysis using additional language tools. They focus on morphological disambiguation (tagging), given morphological segmentation in the output of the morphological analyzer. For each word, they first run it through the morphological analyzer to reduce the number of possible outputs. They then train a separate Support Vector Machine (SVM) for each morphological attribute (ten in all). They look at different ways of combining these outputs to match an output from the morphological analyzer. For their best model, they report an overall tag accuracy of 97.6%.

Others have used morphological analyzers and other language tools for morphological disambiguation coupled with segmentation. The following works exemplify this approach: Diab et al. (2004) use a POS tagger to jointly segment, POS tag, and chunk base-phrases for Arabic with SVMs. Kudo et al. (2004) use SVMs to morphologically tag Japanese. Smith et al. (2005) use SVMs for segmentation, lemmatization, and POS tagging for Arabic, Korean, and Czech. Petkevič (2001) use a morphological analyzer and additional simple rules for morphological disambiguation of Czech. Mansour et al. (2007) and Bar-haim et al. (2008) both use hidden Markov models to POS tag Hebrew, with the latter including segmentation as part of the task.

For Syriac, a morphological analyzer is not available. Kiraz (2000) created a Syriac morphological analyzer using finite-state methods; however, it was developed on outdated and now inaccessible equipment and is no longer working or available to us.

6 Conclusions and Future Work

We have shown that we can effectively model segmentation, linkage to headwords in a dictionary, and morphological tagging using a joint model called **syromorph**. We have introduced novel approaches for segmentation, dictionary linkage, and morphological tagging, and each of these approaches has outperformed its corresponding naïve baseline. Furthermore, we have shown that for Syriac, a data-driven approach seems to be an appropriate way to solve these problems in an under-resourced setting.

We hope to use this combined model for pre-annotation in an active learning setting to aid annotators in labeling a large Syriac corpus. This corpus will contain data spanning multiple centuries and a variety of authors and genres. Future work will require addressing issues encountered in this corpus. In addition, there is much to do in getting the overall tag accuracy closer to the accuracy of individual decisions. We leave further feature engineering for the stem tagger and the exploration of possible new morphological tagging techniques for future work.

Finally, future work includes the application of the **syromorph** methodology to other under-resourced Semitic languages.

Acknowledgments

We would like to thank David Taylor of the Oriental Institute at Oxford University for collaboration on the design of the simplified tagset. We also recognize the assistance of Ben Hansen of BYU on a subset of the experimental results. Finally, we would like to thank the anonymous reviewers for helpful guidance.

Abstract

This paper examines tagging models for spontaneous English speech transcripts. We analyze the performance of state-of-the-art tagging models, either generative or discriminative, left-to-right or bidirectional, with or without latent annotations, together with the use of ToBI break indexes and several methods for segmenting the speech transcripts (i.e., conversation side, speaker turn, or human-annotated sentence). Based on these studies, we observe that: (1) bidirectional models tend to achieve better accuracy levels than left-to-right models, (2) generative models seem to perform somewhat better than discriminative models on this task, and (3) prosody improves tagging performance of models on conversation sides, but has much less impact on smaller segments. We conclude that, although the use of break indexes can indeed significantly improve performance over baseline models without them on conversation sides, tagging accuracy improves more by using smaller segments, for which the impact of the break indexes is marginal.

1 Introduction

Natural language processing technologies, such as parsing and tagging, often require reconfiguration when they are applied to challenging domains that differ significantly from newswire, e.g., blogs, twitter text (Foster, 2010), or speech. In contrast to text, conversational speech represents a significant challenge because the transcripts are not segmented into sentences. Furthermore, the transcripts are often disfluent and lack punctuation and case information. On the other hand, speech provides additional information, beyond simply the sequence of words, which could be exploited to more accurately assign each word in the transcript a part-of-speech (POS) tag. One potentially beneficial type of information is prosody (Cutler et al., 1997).

Prosody provides cues for lexical disambiguation, sentence segmentation and classification, phrase structure and attachment, discourse structure, speaker affect, etc. Prosody has been found to play an important role in speech synthesis systems (Batliner et al., 2001; Taylor and Black, 1998), as well as in speech recognition (Gallwitz et al., 2002; Hasegawa-Johnson et al., 2005; Ostendorf et al., 2003). Additionally, prosodic features such as pause length, duration of words and phones, pitch contours, energy contours, and their normalized values have been used for speech processing tasks like sentence boundary detection (Liu et al., 2005).

Linguistic encoding schemes like ToBI (Silverman et al., 1992) have also been used for sentence boundary detection (Roark et al., 2006; Harper et al., 2005), as well as for parsing (Dreyer and Shafran, 2007; Gregory et al., 2004; Kahn et al., 2005). In the ToBI scheme, aspects of prosody such as tone, prominence, and degree of juncture between words are represented symbolically. For instance, Dreyer and Shafran (2007) use three classes of automatically detected ToBI break indexes, indicating major intonational breaks with a `4`, hesitation with a `p`, and all other breaks with a `1`.

Recently, Huang and Harper (2010) found that they could effectively integrate prosodic informa-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 821–831,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

tion in the form of this simplified three class ToBI encoding when parsing spontaneous speech by using a prosodically enriched PCFG model with latent annotations (PCFG-LA) (Matsuzaki et al., 2005; Petrov and Klein, 2007) to rescore n-best parses produced by a baseline PCFG-LA model without prosodic enrichment. However, the prosodically enriched models by themselves did not perform significantly better than the baseline PCFG-LA model without enrichment, due to the negative effect that misalignments between automatic prosodic breaks and true phrase boundaries have on the model.

This paper investigates methods for using state-of-the-art taggers on conversational speech transcriptions and the effect that prosody has on tagging accuracy. Improving POS tagging performance of speech transcriptions has implications for improving downstream applications that rely on accurate POS tags, including sentence boundary detection (Liu et al., 2005), automatic punctuation (Hillard et al., 2006), information extraction from speech, parsing, and syntactic language modeling (Heeman, 1999; Filimonov and Harper, 2009). While there have been several attempts to integrate prosodic information to improve parse accuracy of speech transcripts, to the best of our knowledge there has been little work on using this type of information for POS tagging. Furthermore, most of the parsing work has involved generative models and rescoring/reranking of hypotheses from the generative models. In this work, we will analyze several factors related to effective POS tagging of conversational speech:

- discriminative versus generative POS tagging models (Section 2)
- prosodic features in the form of simplified ToBI break indexes (Section 4)
- type of speech segmentation (Section 5)

2 Models

In order to fully evaluate the difficulties inherent in tagging conversational speech, as well as the possible benefits of prosodic information, we conducted experiments with six different POS tagging models. The models can be broadly separated into two classes: generative and discriminative. As the first of our generative models, we used a Hidden Markov Model (HMM) trigram tagger (Thede and Harper, 1999), which serves to establish a baseline and to gauge the difficulty of the task at hand. Our second model, HMM-LA, was the latent variable bigram HMM tagger of Huang et al. (2009), which achieved state-of-the-art tagging performance by introducing latent tags to weaken the stringent Markov independence assumptions that generally hinder tagging performance in generative models.

For the third model, we implemented a bidirectional variant of the HMM-LA (HMM-LA-Bidir) that combines evidence from two HMM-LA taggers, one trained left-to-right and the other right-to-left. For decoding, we use a product model (Petrov, 2010). The intuition is that the context information from the left and the right of the current position is complementary for predicting the current tag and thus, the combination should serve to improve performance over the HMM-LA tagger.

Since prior work on parsing speech with prosody has relied on generative models, it was necessary to modify equations of the model in order to incorporate the prosodic information, and then perform rescoring in order to achieve gains. However, it is far simpler to directly integrate prosody as features into the model by using a discriminative approach. Hence, we also investigate several log-linear models, which allow us to easily include an arbitrary number and varying kinds of possibly overlapping and non-independent features.

First, we implemented a Conditional Random Field (CRF) tagger, which is an attractive choice due to its ability to learn the globally optimal labeling for a sequence and proven excellent performance on sequence labeling tasks (Lafferty et al., 2001). In contrast to an HMM which optimizes the joint likelihood of the word sequence and tags, a CRF optimizes the conditional likelihood, given by:

$$p_\lambda(t|w) = \frac{\exp \sum_j \lambda_j F_j(t,w)}{\sum_t \exp \sum_j \lambda_j F_j(t,w)} \qquad (1)$$

where the λ's are the parameters of the model to estimate and F indicates the feature functions used. The denominator in (1) is $Z_\lambda(x)$, the normalization factor, with:

$$F_j(t,w) = \sum_i f_j(t,w,i)$$

Class	Model Name	Latent Variable	Bidirectional	N-best-Extraction	Markov Order
Generative	Trigram HMM			√	2nd
	HMM-LA	√		√	1st
	HMM-LA-Bidir	√	√		1st
Discriminative	Stanford Bidir		√		2nd
	Stanford Left5				2nd
	CRF				2nd

Table 1: Description of tagging models

The objective we need to maximize then becomes :

$$\mathcal{L} = \sum_n \left[\sum_j \lambda_j F_j(t_n, w_n) - \log Z_\lambda(x_n) \right] - \frac{\|\lambda\|^2}{2\sigma^2}$$

where we use a spherical Gaussian prior to prevent overfitting of the model (Chen and Rosenfeld, 1999) and the wide-spread quasi-Newtonian L-BFGS method to optimize the model parameters (Liu and Nocedal, 1989). Decoding is performed with the Viterbi algorithm.

We also evaluate state-of-the-art Maximum Entropy taggers: the Stanford Left5 tagger (Toutanova and Manning, 2000) and the Stanford bidirectional tagger (Toutanova et al., 2003), with the former using only left context and the latter bidirectional dependencies.

Table 1 summarizes the major differences between the models along several dimensions: (1) generative versus discriminative, (2) directionality of decoding, (3) the presence or absence of latent annotations, (4) the availability of n-best extraction, and (5) the model order.

In order to assess the quality of our models, we evaluate them on the section 23 test set of the standard newswire WSJ tagging task after training all models on sections 0-22. Results appear in Table 2. Clearly, all the models have high accuracy on newswire data, but the Stanford bidirectional tagger significantly outperforms the other models with the exception of the HMM-LA-Bidir model on this task.[1]

Model	Accuracy
Trigram HMM	96.58
HMM-LA	97.05
HMM-LA-Bidir	97.16
Stanford Bidir	97.28
Stanford Left5	97.07
CRF	96.81

Table 2: Tagging accuracy on WSJ

3 Experimental Setup

In the rest of this paper, we evaluate the tagging models described in Section 2 on conversational speech. We chose to utilize the Penn Switchboard (Godfrey et al., 1992) and Fisher treebanks (Harper et al., 2005; Bies et al., 2006) because they provide gold standard tags for conversational speech and we have access to corresponding automatically generated ToBI break indexes provided by (Dreyer and Shafran, 2007; Harper et al., 2005)[2].

We utilized the Fisher dev1 and dev2 sets containing 16,519 sentences (112,717 words) as the primary training data and the entire Penn Switchboard treebank containing 110,504 sentences (837,863 words) as an additional training source[3]. The treebanks were preprocessed as follows: the tags of auxiliary verbs were replaced with the AUX tag, empty nodes

[1] Statistically significant improvements are calculated using the sign test ($p < 0.05$).

[2] A small fraction of words in the Switchboard treebank do not align with the break indexes because they were produced based on a later refinement of the transcripts used to produce the treebank. For these cases, we heuristically added break *1* to words in the middle of a sentence and *4* to words that end a sentence.

[3] Preliminary experiments evaluating the effect of training data size on performance indicated using the additional Switchboard data leads to more accurate models, and so we use the combined training set.

and function tags were removed, words were downcased, punctuation was deleted, and the words and their tags were extracted. Because the Fisher treebank was developed using the lessons learned when developing Switchboard, we chose to use its eval portion for development (the first 1,020 tagged sentences containing 7,184 words) and evaluation (the remaining 3,917 sentences with 29,173 words).

We utilize the development set differently for the generative and discriminative models. Since the EM algorithm used for estimating the parameters in the latent variable models introduces a lot of variability, we train five models with a different seed and then choose the best one based on dev set performance. For the discriminative models, we tuned their respective regularization parameters on the dev set. All results reported in the rest of this paper are on the test set.

4 Integration of Prosodic Information

In this work, we use three classes of automatically generated ToBI break indexes to represent prosodic information (Kahn et al., 2005; Dreyer and Shafran, 2007; Huang and Harper, 2010): `4`, `1`, and `p`. Consider the following speech transcription example, which is enriched with ToBI break indexes in parentheses and tags: `i(1)/PRP did(1)/VBD n't(1)/RB you(1)/PRP know(4)/VBP i(1)/PRP did(1)/AUX n't(1)/RB...` The speaker begins an utterance, and then restarts the utterance. The automatically predicted break `4` associated with `know` in the utterance compellingly indicates an intonational phrase boundary and could provide useful information for tagging if we can model it appropriately.

To integrate prosody into our generative models, we utilize the method from (Dreyer and Shafran, 2007) to add prosodic breaks. As Figure 1 shows, ToBI breaks provide a secondary sequence of observations that is parallel to the sequence of words that comprise the sentence. Each break b_i in the secondary sequence is generated by the same tag t_i as that which generates the corresponding word w_i, and so it is conditionally independent of its corresponding word given the tag:

$$P(w, b|t) = P(w|t)P(b|t)$$

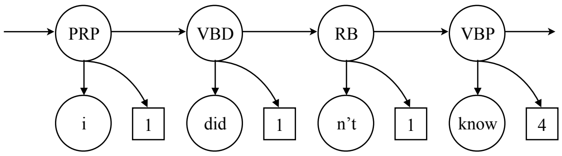

Figure 1: Parallel generation of words and breaks for the HMM models

The HMM-LA taggers are then able to split tags to capture implicit higher order interactions among the sequence of tags, words, and breaks.

The discriminative models are able to utilize prosodic features directly, enabling the use of contextual interactions with other features to further improve tagging accuracy. Specifically, in addition to the standard set of features used in the tagging literature, we use the feature templates presented in Table 3, where each feature associates the break b_i, word w_i, or some combination of the two with the current tag t_i[4].

Break and/or word values	Tag value
b_i=B	t_i = T
b_i=B & b_{i-1}=C	t_i = T
w_i=W & b_i=B	t_i = T
w_{i+1}=W & b_i=B	t_i = T
w_{i+2}=W & b_i=B	t_i = T
w_{i-1}=W & b_i=B	t_i = T
w_{i-2}=W & b_i=B	t_i = T
w_i=W & b_i=B & b_{i-1}=C	t_i = T

Table 3: Prosodic feature templates

5 Experiments

5.1 Conversation side segmentation

When working with raw speech transcripts, we initially have a long stream of unpunctuated words, which is called a conversation side. As the average length of conversation side segments in our data is approximately 630 words, it poses quite a challenging tagging task. Thus, we hypothesize that it is on these large segments that we should achieve the most

[4] We modified the Stanford taggers to handle these prosodic features.

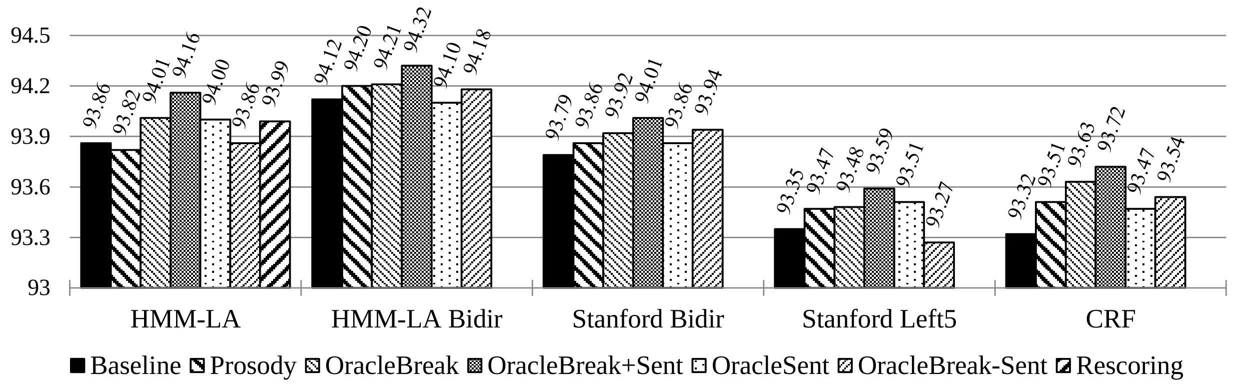

Figure 2: Tagging accuracy on conversation sides

improvement from the addition of prosodic information.

In fact, as the baseline results in Figure 2 show, the accuracies achieved on this task are much lower than those on the newswire task. The trigram HMM tagger accuracy drops to 92.43%, while all the other models fall to within the range of 93.3%-94.12%, a significant departure from the 96-97.3% range on newswire sentences. Note that the Stanford bidirectional and HMM-LA tagger perform very similarly, although the HMM-LA-Bidir tagger performs significantly better than both. In contrast to the newswire task on which the Stanford bidirectional tagger performed the best, on this genre, it is slightly worse than the HMM-LA tagger, albeit the difference is not statistically significant.

With the direct integration of prosody into the generative models (see Figure 2), there is a slight but statistically insignificant shift in performance. However, integrating prosody directly into the discriminative models leads to significant improvements in the CRF and Stanford Left5 taggers. The gain in the Stanford bidirectional tagger is not statistically significant, however, which suggests that the left-to-right models benefit more from the addition of prosody than bidirectional models.

5.2 Human-annotated sentences

Given the lack-luster performance of the tagging models on conversation side segments, even with the direct addition of prosody, we chose to determine the performance levels that could be achieved on this task using human-annotated sentences, which we will refer to as sentence segmentation. Figure 3 reports the baseline tagging accuracy on sentence segments, and we see significant improvements across all models. The HMM Trigram tagger performance increases to 93.00%, while the increase in accuracy for the other models ranges from around 0.2-0.3%. The HMM-LA taggers once again achieve the best performance, with the Stanford bidirectional close behind. Although the addition of prosody has very little impact on either the generative or discriminative models when applied to sentences, the baseline tagging models (i.e., not prosodically enriched) significantly outperform all of the prosodically enriched models operating on conversation sides.

At this point, it would be apt to suggest using automatic sentence boundary detection to create shorter segments. Table 4 presents the results of using baseline models without prosodic enrichment trained on the human-annotated sentences to tag automatically segmented speech[5]. As can be seen, the results are quite similar to the conversation side segmentation performances, and thus significantly lower than when tagging human-annotated sentences. A caveat to consider here is that we break the standard assumption that the training and test set be drawn from the same distribution, since the training data is human-annotated and the test is automatically segmented. However, it can be quite challenging to create a corpus to train on that represents the biases of the systems that perform automatic sentence segmentation. Instead, we will examine an-

[5] We used the Baseline Structural Metadata System described in Harper et al. (2005) to predict sentence boundaries.

other segmentation method to shorten the segments automatically, i.e., by training and testing on speaker turns, which preserves the train-test match, in Section 5.5.

Model	Accuracy
HMM-LA	93.95
HMM-LA-Bidir	94.07
Stanford Bidir	93.77
Stanford Left5	93.35
CRF	93.29

Table 4: Baseline tagging accuracy on automatically detected sentence boundaries

5.3 Oracle Break Insertion

As we believe one of the major roles that prosodic cues serve for tagging conversation sides is as a proxy for sentence boundaries, perhaps the efficacy of the prosodic breaks can, at least partially, be attributed to errors in the automatically induced break indexes themselves, as they can misalign with syntactic phrase boundaries, as discussed in Huang and Harper (2010). This may degrade the performance of our models more than the improvement achieved from correctly placed breaks. Hence, we conduct a series of experiments in which we systematically eliminate noisy phrase and disfluency breaks and show that under these improved conditions, prosodically enriched models can indeed be more effective.

To investigate to what extent noisy breaks are impeding the possible improvements from prosodically enriched models, we replaced all `4` and `p` breaks in the training and evaluation sets that did not align to the correct phrase boundaries as indicated by the treebank with break `1` for both the conversation sides and human-annotated sentences. The results from using Oracle Breaks on conversation sides can be seen in Figure 2. All models except Stanford Left5 and HMM-LA-Bidir significantly improve in accuracy when trained and tested on the Oracle Break modified data. On human-annotated sentences, Figure 3 shows improvements in accuracies across all models, however, they are statistically insignificant.

To further analyze why prosodically enriched models achieve more improvement on conversation sides than on sentences, we conducted three more Oracle experiments on conversation sides. For the first, OracleBreak-Sent, we further modified the data such that all breaks corresponding to a sentence ending in the human-annotated segments were converted to break `1`, thus effectively only leaving inside sentence phrasal boundaries. This modification results in a significant drop in performance, as can be seen in Figure 2.

For the second, OracleSent, we converted all the breaks corresponding to a sentence end in the human-annotated segmentations to break `4`, and all the others to break `1`, thus effectively only leaving sentence boundary breaks. This performed largely on par with OracleBreak, suggesting that the phrase-aligned prosodic breaks seem to be a stand-in for sentence boundaries.

Finally, in the last condition, OracleBreak+Sent, we modified the OracleBreak data such that all breaks corresponding to a sentence ending in the human-annotated sentences were converted to break

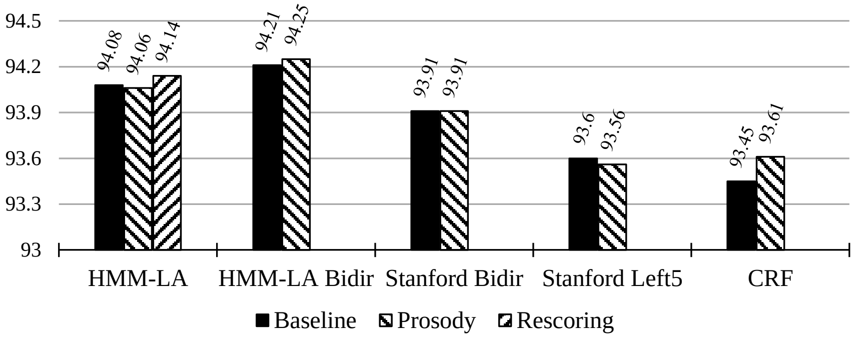

Figure 4: Tagging accuracy on speaker turns

4 (essentially combining OracleBreak and OracleSent). As Figure 2 indicates, this modification results in the best tagging accuracies for all the models. All models were able to match or even improve upon the baseline accuracies achieved on the human segmented data. This suggests that when we have breaks that align with phrasal and sentence boundaries, prosodically enriched models are highly effective.

5.4 N-best Rescoring

Based on the findings in the previous section and the findings of (Huang and Harper, 2010), we next apply a rescoring strategy in which the search space of the prosodically enriched generative models is restricted to the n-best list generated from the baseline model (without prosodic enrichment). In this manner, the prosodically enriched model can avoid poor tag sequences produced due to the misaligned break indexes. As Figure 2 shows, using the baseline conversation side model to produce an n-best list for the prosodically enriched model to rescore results in significant improvements in performance for the HMM-LA model, similar to the parsing results of (Huang and Harper, 2010). The size of the n-best list directly impacts performance, as reducing to $n = 1$ is akin to tagging with the baseline model, and increasing $n \to \infty$ amounts to tagging with the prosodically enriched model. We experimented with a number of different sizes for n and chose the best one using the dev set. Figure 3 presents the results for this method applied to human-annotated sentences, where it produces only marginal improvements[6].

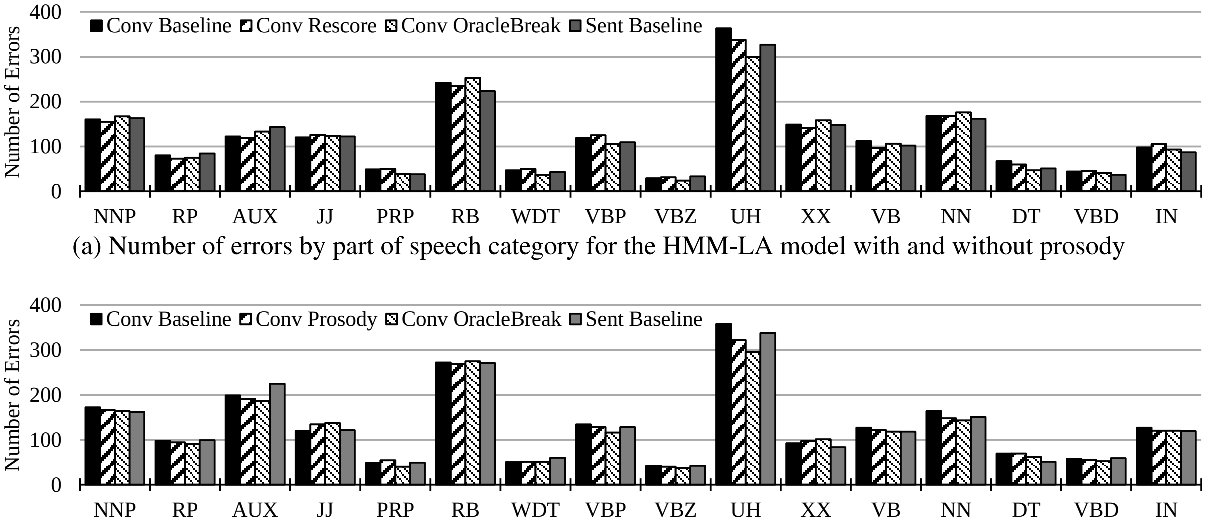
5.5 Speaker turn segmentation

The results presented thus far indicate that if we have access to close to perfect break indexes, we can use them effectively, but this is not likely to be true in practice. We have also observed that tagging accuracy on shorter conversation sides is greater than longer conversation sides, suggesting that post-processing the conversation sides to produce shorter segments would be desirable.

We thus devised a scheme by which we could automatically extract shorter speaker turn segments from conversation sides. For this study, speaker turns, which effectively indicate speaker alternations, were obtained by using the metadata in the treebank to split the sentences into chunks based on speaker change. Every time a speaker begins talking after the other speaker was talking, we start a new segment for that speaker. In practice, this would need to be done based on audio cues and automatic transcriptions, so these results represent an upper bound.

Figure 4 presents tagging results on speaker turn segments. For most models, the difference in accuracy achieved on these segments and that of human-annotated sentences is statistically insignificant. The only exception is the Stanford bidirectional tagger,

[6] Rescoring using the CRF model was also performed, but led to a performance degradation. We believe this is due to the fact that the prosodically enriched CRF model was able to directly use the break index information, and so restricting it to the baseline CRF model search space limits the performance to that of the baseline model.



(a) Number of errors by part of speech category for the HMM-LA model with and without prosody

(b) Number of errors by part of speech category for the CRF model with and without prosody

Figure 5: Error reduction for prosodically enriched HMM-LA (a) and CRF (b) models

which performs worse on these slightly longer segments. With the addition of break indexes, we see marginal changes in most of the models; only the CRF tagger receives a significant boost. Thus, models achieve performance gains from tagging shorter segments, but at the cost of limited usefulness of the prosodic breaks. Overall, speaker turn segmentation is an attractive compromise between the original conversation sides and human-annotated sentences.

6 Discussion

Across the different models, we have found that taggers applied to shorter segments, either sentences or speaker turns, do not tend to benefit significantly from prosodic enrichment, in contrast to conversation sides. To analyze this further we broke down the results by part of speech for the two models for which break indexes improved performance the most: the CRF and HMM-LA rescoring models, which achieved an overall error reduction of 2.8% and 2.1%, respectively. We present those categories that obtained the greatest benefit from prosody in Figure 5 (a) and (b). For both models, the UH category had a dramatic improvement from the addition of prosody, achieving up to a 10% reduction in error.

For the CRF model, other categories that saw impressive error reductions were NN and VB, with 10% and 5%, respectively. Table 5 lists the prosodic features that received the highest weight in the CRF model. These are quite intuitive, as they seem to represent places where the prosody indicates sentence or clausal boundaries. For the HMM-LA model, the VB and DT tags had major reductions in error of 13% and 10%, respectively. For almost all categories, the number of errors is reduced by the addition of breaks, and further reduced by using the OracleBreak processing described above.

Weight	**Feature**
2.2212	w_i=um & b_i=4 & t=UH
1.9464	w_i=uh & b_i=4 & t=UH
1.7965	w_i=yes & b_i=4 & t=UH
1.7751	w_i=and & b_i=4 & t=CC
1.7554	w_i=so & b_i=4 & t=RB
1.7373	w_i=but & b_i=4 & t=CC

Table 5: Top break 4 prosody features in CRF prosody model

To determine more precisely the effect that the segment size has on tagging accuracy, we extracted the oracle tag sequences from the HMM-LA and CRF baseline and prosodically enriched models across conversation sides, sentences, and speaker turn segments. As the plot in Figure 6 shows, as we increase the n-best list size to 500, the oracle accuracy of the models trained on sentences in-

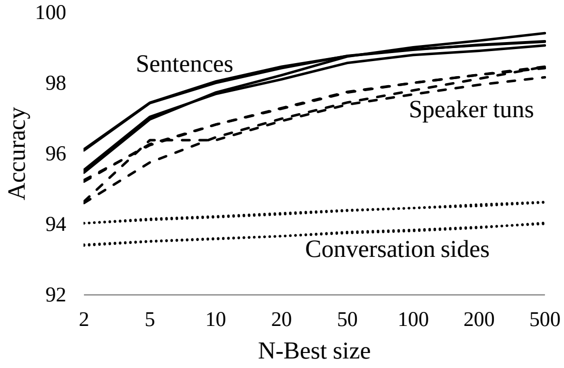


Figure 6: Oracle comparison: solid lines for sentences, dashed lines for speaker turns, and dotted lines for conversation sides

creases rapidly to 99%; whereas, the oracle accuracy of models on conversation sides grow slowly to between 94% and 95%. The speaker turn trained models, however, behave closely to those using sentences, climbing rapidly to accuracies of around 98%. This difference is directly attributable to the length of the segments. As can be seen in Table 6, the speaker turn segments are more comparable in length to sentences.

	Train	**Eval**
Conv	627.87 ± 281.57	502.98 ± 151.22
Sent	7.52± 7.86	7.45 ± 8.29
Speaker	15.60± 29.66	15.27± 21.01

Table 6: Length statistics of different data segmentations

Next, we return to the large performance degradation when tagging speech rather than newswire text to examine the major differences among the models. Using two of our best performing models, the Stanford bidirectional and HMM-LA, in Figure 7 we present the categories for which performance degradation was the greatest when comparing performance of a tagger trained on WSJ to a tagger trained on spoken sentences and conversation sides. The performance decrease is quite similar across both models, with the greatest degradation on the NNP, RP, VBN, and RBS categories.

Unsurprisingly, both the discriminative and generative bidirectional models achieve the most impressive results. However, the generative HMM-LA and HMM-LA-Bidir models achieved the best results across all three segmentations, and the best overall result, of 94.35%, on prosodically enriched sentence-segmented data. Since the Stanford bidirectional model incorporates all of the features that produced its state-of-the-art performance on WSJ, we believe the fact that the HMM-LA outperforms it, despite the discriminative model's more expressive feature set, is indicative of the HMM-LA's ability to more effectively adapt to novel domains during training. Another challenge for the discriminative models is the need for regularization tuning, requiring additional time and effort to train several models and select the most appropriate parameter each time the domain changes. Whereas for the HMM-LA models, although we also train several models, they can be combined into a product model, such as that described by Petrov (2010), in order to further improve performance.

Since the prosodic breaks are noisier features than the others incorporated in the discriminative models, it may be useful to set their regularization parameter separately from the rest of the features, however, we have not explored this alternative. Our experiments used human transcriptions of the conversational speech; however, realistically our models would be applied to speech recognition transcripts. In such a case, word error will introduce noise in addition to the prosodic breaks. In future work, we will evaluate the use of break indexes for tagging when there is lexical error. We would also apply the n-best rescoring method to exploit break indexes in the HMM-LA bidirectional model, as this would likely produce further improvements.

7 Conclusion

In this work, we have evaluated factors that are important for developing accurate tagging models for speech. Given that prosodic breaks were effective knowledge sources for parsing, an important goal of this work was to evaluate their impact on various tagging model configurations. Specifically, we have examined the use of prosodic information for tagging conversational speech with several different discriminative and generative models across three different speech transcript segmentations. Our find-

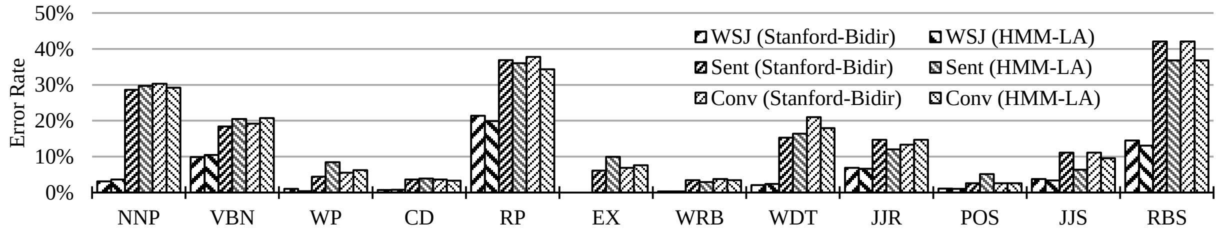

Figure 7: Comparison of error rates between the Standford Bidir and HMM-LA models trained on WSJ, sentences, and conversation sides

ings suggest that generative models with latent annotations achieve the best performance in this challenging domain. In terms of transcript segmentation, if sentences are available, it is preferable to use them. In the case that no such annotation is available, then using automatic sentence boundary detection does not serve as an appropriate replacement, but if automatic speaker turn segments can be obtained, then this is a good alternative, despite the fact that prosodic enrichment is less effective.

Our investigation also shows that in the event that conversation sides must be used, prosodic enrichment of the discriminative and generative models produces significant improvements in tagging accuracy (by direct integration of prosody features for the former and by restricting the search space and rescoring with the latter). For tagging, the most important role of the break indexes appears to be as a stand in for sentence boundaries. The oracle break experiments suggest that if the accuracy of the automatically induced break indexes can be improved, then the prosodically enriched models will perform as well, or even better, than their human-annotated sentence counterparts.

Abstract

This paper proposes a fast and simple unsupervised word segmentation algorithm that utilizes the local predictability of adjacent character sequences, while searching for a least-effort representation of the data. The model uses branching entropy as a means of constraining the hypothesis space, in order to efficiently obtain a solution that minimizes the length of a two-part MDL code. An evaluation with corpora in Japanese, Thai, English, and the ”CHILDES” corpus for research in language development reveals that the algorithm achieves an accuracy, comparable to that of the state-of-the-art methods in unsupervised word segmentation, in a significantly reduced computational time.

1 Introduction

As an inherent preprocessing step to nearly all NLP tasks for writing systems without orthographical marking of word boundaries, such as Japanese and Chinese, the importance of word segmentation has lead to the emergence of a micro-genre in NLP focused exclusively on this problem.

Supervised probabilistic models such as Conditional Random Fields (CRF) (Lafferty et al., 2001) have a wide application to the morphological analysis of these languages. However, the development of the annotated training corpora necessary for their functioning is a labor-intensive task, which involves multiple stages of manual tagging. Because of the scarcity of labeled data, the domain adaptation of morphological analyzers is also problematic, and semi-supervised algorithms that address this issue have also been proposed (e.g. Liang, 2005; Tsuboi et al., 2008).

Recent advances in unsupervised word segmentation have been promoted by human cognition research, where it is involved in the modeling of the mechanisms that underlie language acquisition. Another motivation to study unsupervised approaches is their potential to support the domain adaptation of morphological analyzers through the incorporation of unannotated training data, thus reducing the dependency on costly manual work. Apart from the considerable difficulties in discovering reliable criteria for word induction, the practical application of such approaches is impeded by their prohibitive computational cost.

In this paper, we address the issue of achieving high accuracy in a practical computational time through an efficient method that relies on a combination of evidences: the local predictability of character patterns, and the reduction of effort achieved by a given representation of the language data. Both of these criteria are assumed to play a key role in native language acquisition. The proposed model allows experimentation in a more realistic setting, where the learner is able to apply them simultaneously. The

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 832–842,
MIT, Massachusetts, USA, 9-11 October 2010.

method shows a high performance in terms of accuracy and speed, can be applied to language samples of substantial length, and generalizes well to corpora in different languages.

2 Related Work

The principle of least effort (Zipf, 1949) postulates that the path of minimum resistance underlies all human behavior. Recent research has recognized its importance in the process of language acquisition (Kit, 2003). Compression-based word induction models comply to this principle, as they reorganize the data into a more compact representation while identifying the vocabulary of a text. The minimum description length framework (MDL) (Rissanen, 1978) is an appealing means of formalizing such models, as it provides a robust foundation for learning and inference, based solely on compression.

The major problem in MDL-based word segmentation is the lack of standardized search algorithms for the exponential hypothesis space (Goldwater, 2006). The representative MDL models compare favorably to the current state-of-the-art models in terms of accuracy. Brent and Cartwright (1996) carried out an exhaustive search through the possible segmentations of a limited subset of the data. Yu (2000) proposed an EM optimization routine, which achieved a high accuracy, in spite of a lower compression than the gold standard segmentation.

As a solution to the aforementioned issue, the proposed method incorporates the local predictability of character sequences into the inference process. Numerous studies have shown that local distributional cues can serve well the purpose of inducing word boundaries. Behavioral science has confirmed that infants are sensitive to the transitional probabilities found in speech (Saffran et al., 1996). The increase in uncertainty following a given word prefix is a well studied criterion for morpheme boundary prediction (Harris, 1955). A good deal of research has been conducted on methods through which such local statistics can be applied to the word induction problem (e.g. Kempe, 1999; Huang and Powers, 2003; Jin and Tanaka-Ishii, 2006). Hutchens and Adler (1998) noticed that entropic chunking has the effect of reducing the perplexity of a text.

Most methods for unsupervised word segmentation based solely on local statistics presume a certain – albeit minimum – level of acquaintance with the target language. For instance, the model of Huang and Powers (2003) involves some parameters (Markov chain order, numerous threshold values) that allow its adaptation to the individuality of written Chinese. In comparison, the method proposed in this paper generalizes easily to a variety of languages and domains, and is less dependent on annotated development data.

The state-of-the-art in unsupervised word segmentation is represented by Bayesian models. Goldwater et al. (2006) justified the importance of context as a means of avoiding undersegmentation, through a method based on hierarchical Dirichlet processes. Mochihashi et al. (2009) proposed extensions to this method, which included a nested character model and an optimized inference procedure. Johnson and Goldwater (2009) have proposed a novel method based on adaptor grammars, whose accuracy surpasses the aforementioned methods by a large margin, when appropriate assumptions are made regarding the structural units of a language.

3 Proposed Method

3.1 Word segmentation with MDL

The proposed two-part code incorporates some extensions of models presented in related work, aimed at achieving a more precise estimation of the representation length. We first introduce the general two-part code, which consists of:

- the model, embodied by a codebook, i.e., a lexicon of unique word types $M = \{w_1, ..., w_{|M|}\}$,
- the source text D, obtained through encoding the corpus using the lexicon.

The total description length amounts to the number of bits necessary for simultaneous transmission of the codebook and the source text. Therefore, our objective is to minimize the combined description length of both terms:

$$L(D, M) = L(M) + L(D|M).$$

The description length of the data given M is calculated using the Shannon-Fano code:

$$L(D|M) = -\sum_{j=1}^{|M|} \#w_j \log_2 P(w_j),$$

where $\#w_j$ stands for the frequency of the word w_j in the text.

Different strategies have been proposed in the literature for the calculation of the codebook cost. A common technique in segmentation and morphology induction models is to calculate the product of the total length in characters of the lexicon and an estimate of the per-character entropy. In this way, both the probabilities and lengths of words are taken into consideration. The use of a constant value is an effective and easily computable approach, but it is far from precise. For instance, in Yu (2000) the average entropy per character is measured against the original corpus, but this model does not capture the effects of the word distributions on the observed character probabilities. For this reason, we propose a different method: the codebook is modeled as a separate Markov chain of characters.

A lexicon of characters M' is defined. The description length of the lexicon data D' given M' is then calculated as:

$$L(D'|M') = -\sum_{i=1}^{|C|} \#c_i \log_2 P(c_i),$$

where $\#c_i$ denotes the frequency of a character c_i in the lexicon of hypothesis M. The term $L(M')$ is constant for any choice of hypothesis, as is represents the character set of a corpus.

The total description length under the proposed model is thus calculated as:

$$L(M) + L(D|M) = L(M') + L(D'|M') + L(D|M) = \\ -\sum_{i=1}^{|C|} \#c_i \log_2 P(c_i) - \sum_{j=1}^{|M|} \#w_j \log_2 P(w_j) + O(1).$$

A rigorous definition should include two additional terms, $L(\theta|M)$ and $L(\theta'|M')$, which give the representation cost of the parameters of both models. The $L(\theta|M)$ can be calculated as:

$$L(\theta|M) = \frac{|M|-1}{2} * \log_2 S,$$

where $|M|-1$ gives the number of parameters (degrees of freedom), and S is the size of the dataset (the total length of the text in characters). The parametric complexity term is calculated in the same way for the lexicon. For a derivation of the above formula, refer to e.g. Li (1998).

MDL is closely related to Bayesian inference. Depending on the choice of a universal code, the two approaches can overlap, as is the case with the two-part code discussed in this paper. It can be shown that the model selection in our method is equivalent to a MAP inference, conducted under the assumption that the prior probability of a model decreases exponentially with its length (Goldwater, 2006). Thus, the task that we are trying to accomplish is to conduct a focused search through the hypothesis space that will allow us to obtain an approximation of the MAP solution in a reasonable time.

The MDL framework does not provide standard search algorithms for obtaining the hypotheses that minimize the description length. In the rest of this section, we will describe an efficient technique suitable for the word segmentation task.

3.2 Obtaining an initial hypothesis

First, a rough initial hypothesis is built by an algorithm that combines the branching entropy and MDL criteria.

Given a set $\mathcal{X}$, comprising all the characters found in a text, the entropy of branching at position k of the text is defined as:

$$H(X_k|x_{k-1}, ..., x_{k-n}) = \\ -\sum_{x \in \mathcal{X}} P(x|x_{k-1}, ..., x_{k-n}) \log_2 P(x|x_{k-1}, ..., x_{k-n}),$$

where x_k represents the character found at position k, and n is the order of the Markov model over characters. For brevity, hereafter we shall denote the observed sequence $\{x_{k-1}, ..., x_{k-n}\}$ as $\{x_{k-1:k-n}\}$.

The above definition is extended to combine the entropy estimates in the left-to-right and right-to-left directions, as this factor has reportedly improved performance figures for models based on branching entropy (Jin and Tanaka-Ishii, 2006). The estimates in both directions are summed up, yielding a single value per position:

$$\begin{aligned}&H'(X_{k;k-1}|x_{k-1:k-n};x_{k:k+n-1}) = \\ &-\sum_{x\in\mathcal{X}} P(x|x_{k-1:k-n})\log_2 P(x|x_{k-1:k-n}) \\ &-\sum_{x\in\mathcal{X}} P(x|x_{k:k+n-1})\log_2 P(x|x_{k:k+n-1}).\end{aligned}$$

Suffix arrays are employed during the collection of frequency statistics. For a character model of order n over a testing corpus of size t and a training corpus of size m, suffix arrays allow these to be acquired in $O(tn \log m)$ time. Faster implementations reduce the complexity to $O(t(n+\log m))$. For further discussion, see Manber and Myers (1991). During the experiments, we did not use the caching functionality provided by the suffix array library, but instead kept the statistics for the current iterative pass (n-gram order and direction) in a local table.

The chunking technique we adopt is to insert a boundary when the branching entropy measured in sequences of length n exceeds a certain threshold value ($H(X|x_{k-1:k-n}) > \beta$). Both n and β are fixed.

Within the described framework, the increase in context length n promotes precision and recall at first, but causes a performance degradation when the entropy estimates become unreliable due to the reduced frequencies of long strings. High threshold values produce a combination of high precision and low recall, while low values result in low precision and high recall.

Since the F-score curve obtained as decreasing values are assigned to the threshold is typically unimodal as in many applications of MDL, we employ a bisection search routine for the estimation of the threshold (Algorithm 1).

All positions of the dataset are sorted by their entropy values. At each iteration, at most two new hypotheses are built, and their description lengths are calculated in time linear to the data size. The computational complexity of the described routine is $O(t \log t)$, where t is the corpus length in characters.

The order of the Markov chain n used during the entropy calculation is the only input variable of the proposed model. Since different values perform the best across the various languages, the most appropriate settings can be obtained with the help of a small annotated corpus. However, the MDL objective also enables unsupervised optimization against a sufficiently large unlabeled dataset. The order that minimizes the description length of the data can be discovered in a few iterations of Algorithm 1 with increasing values of n, and it typically matches the optimal value of the parameter (Table 1).

Algorithm 1 Generates an initial hypothesis.

```
thresholds[] := sorted $H(X_k)$ values;
threshold := median of thresholds[];
step := length of thresholds[]/4;
direction := ascending;
minimum := $+\infty$;
while $step > 0$ do
    nextThreshold := thresholds[] value one step in last direction;
    DL = calculateDL(nextThreshold);
    if $DL < minimum$ then
        minimum:= DL; threshold := nextThreshold;
        step := step/2; continue;
    end if
    reverse direction;
    nextThreshold := thresholds[] value one step in last direction;
    if $DL < minimum$ then
        minimum:= DL; threshold := nextThreshold;
        step := step/2; continue;
    end if
    reverse direction;
    step := step/2;
end while

Table 1: Length in bits of the solutions proposed by Algorithm 1 with respect to the character n-gram order.

Although an acceptable initial segmentation can be built using the described approach, it is possible to obtain higher accuracy with an extended model that takes into account the statistics of Markov chains from several orders during the entropy calculation. This can be done by summing up the entropy estimates, in the way introduced earlier for combining the values in both directions:

$$\begin{aligned}&H''(X_{k;k-1}|x_{k-1:k-n};x_{k:k+n-1}) = \\ &-\sum_{n=1}^{n_{max}}(\sum_{x\in\mathcal{X}} P(x|x_{k-1:k-n})\log_2 P(x|x_{k-1:k-n}) \\ &+\sum_{x\in\mathcal{X}} P(x|x_{k:k+n-1})\log_2 P(x|x_{k:k+n-1})),\end{aligned}$$

where n_{max} is the index of the highest order to be taken into consideration.

3.3 Refining the initial hypothesis

In the second phase of the proposed method, we will refine the initial hypothesis through the reorganization of local co-occurrences which produce redundant description length. We opt for greedy optimization, as our primary interest is to further explore the impact that description length minimization has on accuracy. Of course, such an approach is unlikely to obtain global minima, but it is a feasible means of conducting the optimization process, and guarantees a certain increase in compression.

Since a preliminary segmentation is available, it is convenient to proceed by inserting or removing boundaries in the text, thus splitting or merging the already discovered tokens. The ranked positions involved in the previous step can be reused here, as this is a way to bias the search towards areas of the text where boundaries are more likely to occur. Boundary insertion should start in regions where the branching entropy is high, and removal should first occur in regions where the entropy is close to zero. A drawback of this approach is that it omits locations where the gains are not immediately obvious, as it cannot assess the cumulative gains arising from the merging or splitting of all occurrences of a certain pair (Algorithm 2).

A clean-up routine, which compensates for this shortage, is also implemented (Algorithm 3). It operates directly on the types found in the lexicon produced by Algorithm 2, and is capable of modifying a large number of occurrences of a given pair in a single step. The lexicon types are sorted by their contribution to the total description length of the corpus. For each word type, splitting or merging is attempted at every letter, beginning from the center. The algorithm eliminates unlikely types with low contribution, which represent mostly noise, and redistributes their cost among more likely ones. The design of the merging routine makes it impossible to produce types longer than the ones already found in the lexicon, as an exhaustive search would be prohibitive.

The evaluation of each hypothetical change in the segmentation requires that the description length of the two-part code is recalculated. In order to

Algorithm 2 Compresses local token co-occurrences.

```
path[][]:= positions sorted by $H(X_k)$ values;
minimum := DL of model produced at initialization;
repeat
    for i = max $H(X_k)$ to min $H(X_k)$ do
        pos:= path[i][k];
        if no boundary exists at pos then
            leftToken := token to the left;
            rightToken := token to the right;
            longToken := leftToken + rightToken;
            calculate DL after splitting;
            if $DL < minimum$ then
                accept split, update model, update DP variables;
            end if
        end if
    end for
    for i = min $H(X_k)$ to max $H(X_k)$ do
        merge leftToken and rightToken into longToken
        if DL will decrease (analogous to splitting)
    end for
until no change is evident in model
```

Algorithm 3 A lexicon clean-up procedure.

```
types[] := lexicon types sorted by cost;
minimum := DL of model produced by Algorithm 2;
repeat
    for i = min cost to max cost do
        for pos = middle to both ends of types[i] do
            longType := types[i];
            leftType := sequence from first character to pos;
            rightType:= sequence from pos to last character;
            calculate DL after splitting longType into leftType and rightType;
            if $DL < minimum$ then
                accept split, update model, update DP variables;
                break out of inner loop;
            end if
        end for
    end for
    types[] := lexicon types sorted by cost;
    for i = max cost to min cost do
        for pos = middle to both ends of types[i] do
            merge leftType and rightType into longType if
            DL will decrease (analogous to splitting)
            break out of inner loop;
        end for
    end for
until no change is evident in model
```

make this optimization phase computationally feasible, dynamic programming is employed in Algorithms 2 and 3. The approach adopted for the recalculation of the source text term $L(D|M)$ is explained below. The estimation of the lexicon cost is analogous. The term $L(D|M)$ can be rewritten as:

$$L(D|M) = -\sum_{j=1}^{|M|} \#w_j \log_2 \frac{\#w_j}{N} =$$

$$-\sum_{j=1}^{|M|} \#w_j \log_2 \#w_j + N \log_2 N = T_1 + T_2,$$

where $\#w_j$ is the frequency of w_j in the segmented corpus, and $N = \sum_{j=1}^{|M|} \#w_j$ is the cumulative token count. In order to calculate the new length, we keep the values of the terms T_1 and T_2 obtained at the last change of the model. Their new values are computed for each hypothetical split or merge on the basis of the last values, and the expected description length is calculated as their sum. If the produced estimate is lower, the model is modified and the new values of T_1 and T_2 are stored for future use.

In order to maintain precise token counts, Algorithms 2 and 3 recognize the fact that recurring sequences (”byebye” etc.) appear in the corpora, and handle them accordingly. Known boundaries, such as the sentence boundaries in the CHILDES corpus, are also taken into consideration.

4 Experimental Settings

We evaluated the proposed model against four datasets. The first one is *the Bernstein-Ratner corpus* for language acquisition based on transcripts from the CHILDES database (Bernstein-Ratner, 1987). It comprises phonetically transcribed utterances of adult speech directed to 13 through 21-month-old children. We evaluated the performance of our learner in the cases when the few boundaries among the individual sentences are available to it (B), and when it starts from a blank state (N). The *Kyoto University Corpus* (Kurohashi and Nagao, 1998) is a standard dataset for Japanese morphological and dependency structure analysis, which comprises newspaper articles and editorials from the Mainichi Shimbun. The *BEST* corpus for word segmentation and named entity recognition in Thai language combines text from a variety of sources including encyclopedias (E), newspaper articles (N), scientific articles (A), and novels (F). The *WSJ* subset of the *Penn Treebank II Corpus* incorporates selected stories from the Wall Street Journal, year 1989 (Marcus et al., 1994). Both the original text (O), and a version in which all characters were converted to lower case (L) were used.

Corpus	Language	Size (MB)	Chars (K)	Tokens (K)	Types (K)
CHILDES-B/N	English	0.1	95.8	33.3	1.3

BEST-All	Thai	51.2	17424.0	4371.8	73.4

Table 2: Corpora used during the evaluation. Precise token and type counts have been omitted for Wikipedia and Asahi, as no gold standard segmentations are available.

The datasets listed above were built by removing the tags and blank spaces found in the corpora, and concatenating the remaining text. We added two more training datasets for Japanese, which were used in a separate experiment solely for the acquisition of frequency statistics. One of them was created from 200,000 randomly chosen Wikipedia articles, stripped from structural elements. The other one contains text from the year 2005 issues of Asahi Newspaper. Statistics regarding all described datasets are presented in Table 2.

One whole corpus is segmented in each experiment, in order to avoid the statement of an extended model that would allow the separation of training and test data. This setting is also necessary for the direct comparison between the proposed model and other recent methods evaluated against the entire CHILDES corpus.

We report the obtained precision, recall and F-score values calculated using boundary, token and type counts. Precision (P) and recall (R) are defined as:

$$P = \frac{\#correct\ units}{\#\ output\ units}, \quad R = \frac{\#correct\ units}{\#gold\ standard\ units}.$$

Boundary, token and lexicon F-scores, denoted as B-F and T-F and L-F, are calculated as the

Table 3: Comparison of the proposed method (2a, 2b) with the model of Jin and Tanaka-Ishii (2006) (1). Execution times include the obtaining of frequency statistics, and are represented by averages over 10 runs.

harmonic averages of the corresponding precision and recall values ($F = 2PR/(P + R)$). As a rule, boundary-based evaluation produces the highest scores among the three evaluation modes, as it only considers the correspondence between the proposed and the gold standard boundaries at the individual positions of the corpora. Token-based evaluation is more strict – it accepts a word as correct only if its beginning and end are identified accurately, and no additional boundaries lie in between. Lexicon-based evaluation reflects the extent to which the vocabulary of the original text has been recovered. It provides another useful perspective for the error analysis, which in combination with token scores can give a better idea of the relationship between the accuracy of induction and item frequency.

The system was implemented in Java, however it handled the suffix arrays through an external C library called Sary.[1] All experiments were conducted on a 2 GHz Core2Duo T7200 machine with 2 GB RAM.

5 Results and Discussion

The scores we obtained using the described instantiations of the branching entropy criterion at the initialization phase are presented in Table 3, along with those generated by our own implementation of the method presented in Jin and Tanaka-Ishii (2006), where the threshold parameter α was adjusted manually for optimal performance.

The heuristic of Jin and Tanaka-Ishii takes advantage of the trend that branching entropy decreases as the observed character sequences become longer; sudden rises can thus be regarded as an indication of locations where a boundary is likely to exist. Their method uses a common value for thresholding the entropy change throughout all n-gram orders, and combines the boundaries discovered in both directions in a separate step. These properties of the method would lead to complications if we tried to employ it in the first phase of our method (i.e. a step parameter for iterative adjustment of the threshold value, rules for combining the boundaries, etc.).

The proposed criterion with an automatically determined threshold value produced slightly worse results than that of Jin and Tanaka-Ishii at the CHILDES corpus. However, we found out that our approach achieves approximately 1% higher score when the best performing threshold value is selected from the candidate list. There are two observations that account for the suboptimal threshold choice by our algorithm. On one hand, the correspondence between description length and F-score is not absolutely perfect, and this may pose an obstacle to the optimization process for relatively small language samples. Another issue lies in the bisection search routine, which suggests approximations of the description length minima. The edge that our method has on the Kyoto corpus can be attributed to a better estimation of the optimal treshold value due to the larger amount of data.

The experimental results obtained at the completion of Algorithm 3 are summarized in Tables 4 and 5. Presented durations include the obtaining of frequency statistics. The n_{max} parameter is set to the value which maximizes the compression during the initial phase, in order to make the results representative of the case in which no annotated development corpora are accessible to the algorithm.

It is evident that after the optimization carried out in the second phase, the description length is reduced to levels significantly lower than the ground truth. In this aspect, the algorithm outperforms the EM-based method of Yu (2000).

Table 5: Description length - proposed versus reference segmentation.

We conducted experiments involving various initialization strategies: scattering boundaries at random throughout the text, starting from entirely unsegmented state, or considering each symbol of the text to be a separate token. The results obtained with random initialization confirm the strong relationship between compression and segmentation accuracy, evident in the increase of token F-score between the random initialization and the termination of the algorithm, where description length is lower (Table 6). They also reveal the importance of the branching entropy criterion to the generation of hypotheses that maximize the evaluation scores and compression, as well as the role it plays in the reduction of computational time.

T-F-Score		Description	Time
Random Init	Refinement	Length	(ms)
0.0441 (0.25)	0.3833	387603.02	6660.4
0.0713 (0.50)	0.3721	383279.86	4975.1
0.0596 (0.75)	0.2777	412743.67	3753.3

Table 6: Experimental results for CHILDES-N with randomized initialization and search path. The numbers in brackets represent the seed boundaries/character ratios.

The greedy algorithms fail to suggest any optimizations that improve the compression in the extreme cases when the boundaries/character ratio is either 0 or 1. When no boundaries are given, splitting operations produce unique types with a low frequency that increase the cost of both parts of the MDL code, and are rejected. The algorithm runs slowly, as each evaluation operates on candidate strings of enormous length. Similarly, when the corpus is broken down into single-character tokens, merging individual pairs does not produce any increase in compression. This could be achieved by an algorithm that estimates the total effect from merging all instances of a given pair, but such an algorithm would be computationally infeasible for large corpora.

Finally, we tried randomizing the search path for Algorithm 2 after an entropy-guided initialization, to observe a small deterioration in accuracy in the final segmentation (less than 1% on average).

Figure 1a illustrates the effect that training data size has on the accuracy of segmentation for the Kyoto corpus. The learning curves are similar throughout the different corpora. For the CHILDES corpus, which has a rather limited vocabulary, token F-score above 70% can be achieved for datasets as small as 5000 characters of training data, provided that reasonable values are set for the n_{max} parameter (we used the values presented in Table 4 throughout these experiments).

Figure 1b shows the evolution of token F-score by stage for all corpora. The initialization phase seems to have the highest contribution to the formation of the final segmentation, and the refinement phase is highly dependent on the output it produces. As a consequence, results improve when a more adequate language sample is provided during the learning of local dependencies at initialization. This is evident in the experiments with the larger unlabeled Thai and Japanese corpora.

For Japanese language with the setting for the n_{max} parameter that maximized compression, we observed an almost 4% increase in the token F-score produced at the end of the first phase with the Asahi corpus as training data. Only a small (less than 1%) rise was observed in the overall performance. The quite larger dataset of randomly chosen Wikipedia articles achieved no improvement. We attributed this

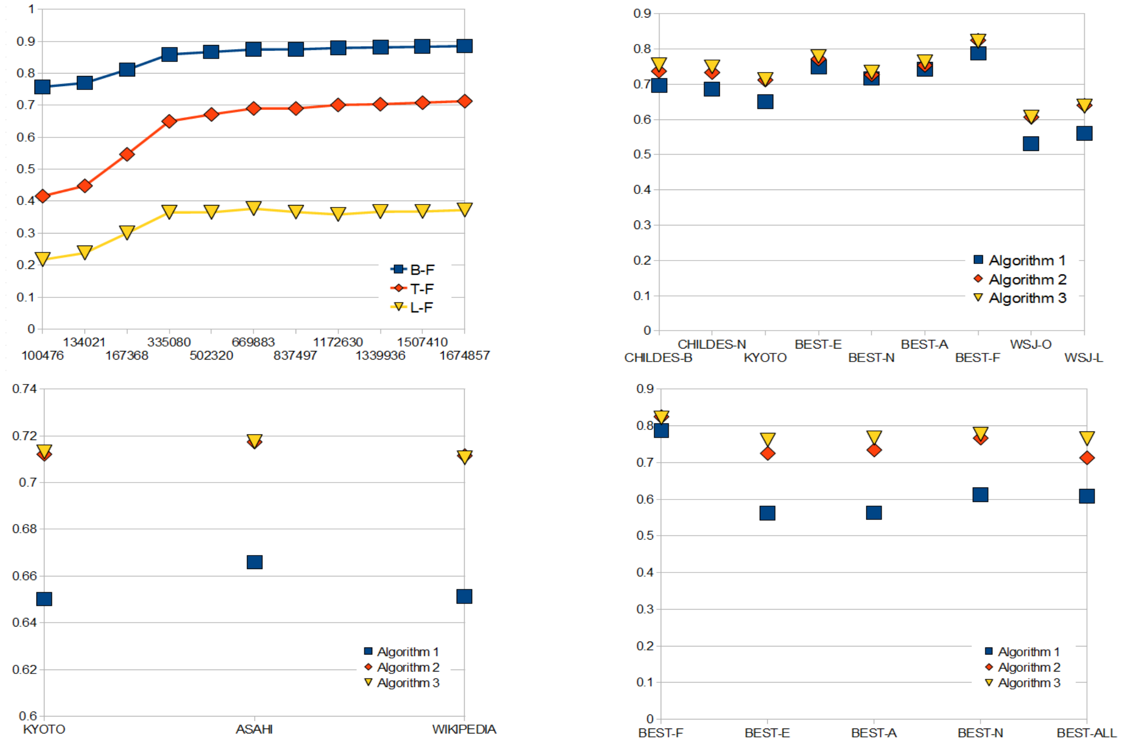

Figure 1: a) corpus size / accuracy relationship (Kyoto); b) accuracy levels by phase; c) accuracy levels by phase with various corpora for frequency statistics (Kyoto); d) accuracy levels by phase with different corpora for frequency statistics (BEST).

to the higher degree of correspondence between the domains of the Asahi and Kyoto corpora (Figure 1c).

Experiments with the BEST corpus reveal better the influence of domain-specific data on the accuracy of segmentation. Performance deteriorates significantly when out-of-domain training data is used. In spite of its size, the assorted composite corpus, in which in-domain and out-of-domain training data are mixed, produces worse results than the corpora which include only domain-specific data (Figure 1d).

Finally, a comparison of the proposed method with Bayesian n-gram models is presented in Table 7. Through the increase of compression in the refinement phase of the algorithm, accuracy is improved by around 3%, and the scores approach those of the explicit probabilistic models of Goldwater et al. (2009) and Mochihashi et al. (2009). The proposed learner surpasses the other unsupervised word induction models in terms of processing speed. It should be noticed that a direct comparison of accuracy is not possible with Mochihashi et al. (2009), as they evaluated their system with separate datasets for training and testing. Furthermore, different segmentation standards exist for Japanese, and therefore the ”ground truth” provided by the Kyoto corpus cannot be considered an ideal measure of accuracy.

6 Conclusions and Future Work

This paper has presented an efficient algorithm for unsupervised word induction, which relies on a combination of evidences. New instantiations of the branching entropy and MDL criteria have been proposed and evaluated against corpora in different languages. The MDL-based optimization eliminates the discretion in the choice of the context length and threshold parameters, common in segmentation models based on local statistics. At the same time, the branching entropy criterion enables a constrained search through the hypothesis space, allowing the proposed method to demonstrate a very high

performance in terms of both accuracy and speed.

Possible improvements of the proposed method include modeling the dependencies among neighboring tokens, which would allow the evaluation of the context to be reflected in the cost function. Mechanisms for stochastic optimization implemented in the place of the greedy algorithms could provide an additional flexibility of search for such more complex models. As the proposed approach provides significant performance improvements, it could be utilized in the development of more sophisticated novel word induction schemes, e.g. ensemble models trained independently with different data. Of course, we are also going to explore the model's potential in the setting of semi-supervised morphological analysis.

A Fast Decoder for Joint Word Segmentation and POS-Tagging Using a Single Discriminative Model

Yue Zhang and **Stephen Clark**
University of Cambridge Computer Laboratory
William Gates Building,
15 JJ Thomson Avenue,
Cambridge CB3 0FD, UK
{yue.zhang, stephen.clark}@cl.cam.ac.uk

Abstract

We show that the standard beam-search algorithm can be used as an efficient decoder for the global linear model of Zhang and Clark (2008) for joint word segmentation and POS-tagging, achieving a significant speed improvement. Such decoding is enabled by: (1) separating full word features from partial word features so that feature templates can be instantiated incrementally, according to whether the current character is separated or appended; (2) deciding the POS-tag of a potential word when its first character is processed. Early-update is used with perceptron training so that the linear model gives a high score to a correct partial candidate as well as a full output. Effective scoring of partial structures allows the decoder to give high accuracy with a small beam-size of 16. In our 10-fold cross-validation experiments with the Chinese Treebank, our system performed over 10 times as fast as Zhang and Clark (2008) with little accuracy loss. The accuracy of our system on the standard CTB 5 test was competitive with the best in the literature.

1 Introduction and Motivation

Several approaches have been proposed to solve word segmentation and POS-tagging jointly, including the reranking approach (Shi and Wang, 2007; Jiang et al., 2008b), the hybrid approach (Nakagawa and Uchimoto, 2007; Jiang et al., 2008a), and the single-model approach (Ng and Low, 2004; Zhang and Clark, 2008; Kruengkrai et al., 2009). These methods led to accuracy improvements over the traditional, pipelined segmentation and POS-tagging baseline by avoiding segmentation error propagation and making use of part-of-speech information to improve segmentation.

The single-model approach to joint segmentation and POS-tagging offers consistent training of all information, concerning words, characters and parts-of-speech. However, exact inference with dynamic programming can be infeasible if features are defined over a large enough range of the output, such as over a two-word history. In our previous work (Zhang and Clark, 2008), which we refer to as Z&C08 from now on, we used an approximate decoding algorithm that keeps track of a set of partially built structures for each character, which can be seen as a dynamic programming chart which is greatly reduced by pruning.

In this paper we follow the line of single-model research, in particular the global linear model of Z&C08. We show that effective decoding can be achieved with standard beam-search, which gives significant speed improvements compared to the decoding algorithm of Z&C08, and achieves accuracies that are competitive with the state-of-the-art. Our research is also in line with recent research on improving the speed of NLP systems with little or no accuracy loss (Charniak et al., 2006; Roark and Hollingshead, 2008).

Our speed improvement is achieved by the use of a single-beam decoder. Given an input sentence, candidate outputs are built incrementally, one character at a time. When each character is processed, it is combined with existing candidates in all possible ways to generate new candidates, and an agenda is used to keep the N-best candidate outputs from

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 843–852,

the begining of the sentence to the current character. Compared to the multiple-beam search algorithm of Z&C08, the use of a single beam can lead to an order of magnitude faster decoding speed.

1.1 The processing of partial words

An important problem that we solve in this paper is the handling of partial words with a single beam decoder for the global model. As we pointed out in Z&C08, it is very difficult to score partial words properly when they are compared with full words, although such comparison is necessary for incremental decoding with a single-beam. To allow comparisons with full words, partial words can either be treated as full words, or handled differently.

We showed in Z&C08 that a naive single-beam decoder which treats partial words in the same way as full words failed to give a competitive accuracy. An important reason for the low accuracy is over-segmentation during beam-search. Consider the three characters "自来水 (tap water)". The first two characters do not make sense when put together as a single word. Rather, when treated as two single-character words, they can make sense in a sentence such as "请 (please) 自 (self) 来 (come) 取 (take)". Therefore, when using single-beam search to process "自来水 (tap water)", the two-character word candidate "自来" is likely to have been thrown off the agenda before the third character "水" is considered, leading to an unrecoverable segmentation error.

This problem is even more severe for a joint segmentor and POS-tagger than for a pure word segmentor, since the POS-tags and POS-tag bigram of "自" and "来" further supports them being separated when "来" is considered. The multiple-beam search decoder we proposed in Z&C08 can be seen as a means to ensure that the three characters "自来水" always have a chance to be considered as a single word. It explores candidate segmentations from the beginning of the sentence until each character, and avoids the problem of processing partial words by considering only full words. However, since it explores a larger part of the search space than a single-beam decoder, its time complexity is correspondingly higher.

In this paper, we treat partial words differently from full words, so that in the previous example, the decoder can take the first two characters in "自来水 (tap water)" as a partial word, and keep it in the beam before the third character is processed. One challenge is the representation of POS-tags for partial words. The POS of a partial word is undefined without the corresponding full word information. Though a partial word can make sense with a particular POS-tag when it is treated as a complete word, this POS-tag is not necessarily the POS of the full word which contains the partial word. Take the three-character sequence "下雨天" as an example. The first character "下" represents a single-character word "below", for which the POS can be LC or VV. The first two characters "下雨" represent a two-character word "rain", for which the POS can be VV. Moreover, all three characters when put together make the word "rainy day", for which the POS is NN. As discussed above, assigning POS tags to partial words as if they were full words leads to low accuracy.

An obvious solution to the above problem is not to assign a POS to a partial word until it becomes a full word. However, lack of POS information for partial words makes them less competitive compared to full words in the beam, since the scores of full words are futher supported by POS and POS ngram information. Therefore, not assigning POS to partial words potentially leads to over segmentation. In our experiments, this method did not give comparable accuracies to our Z&C08 system.

In this paper, we take a different approach, and assign a POS-tag to a partial word when its first character is separated from the final character of the previous word. When more characters are appended to a partial word, the POS is not changed. The idea is to use the POS of a partial word as the predicted POS of the full word it will become. Possible predictions are made with the first character of the word, and the likely ones will be kept in the beam for the next processing steps. For example, with the three characters "下雨天", we try to keep two partial words (besides full words) in the beam when the first word "下" is processed, with the POS being VV and NN, respectively. The first POS predicts the two-character word "下雨"，and the second the three-character word "下雨天". Now when the second character is processed, we still need to maintain the possible POS NN in the agenda, which predicts the three-character word "下雨天".

As a main contribution of this paper, we show that the mechanism of predicting the POS at the first character gives competitive accuracy. This mechanism can be justified theoretically. Unlike alphabetical languages, each Chinese character represents some specific meanings. Given a character, it is natural for a human speaker to know immediately what types of words it can start. The allows the knowledge of possible POS-tags of words that a character can start, using information about the character from the training data. Moreover, the POS of the previous words to the current word are also useful in deciding possible POS for the word.[1]

The mechanism of first-character decision of POS also boosts the efficiency, since the enumeration of POS is unecessary when a character is appended to the end of an existing word. As a result, the complexity of each processing step is reduce by half compared to a method without POS prediction.

Finally, an intuitive way to represent the status of a partial word is using a flag explicitly, which means an early decision of the segmentation of the next incoming character. We take a simpler alternative approach, and treat every word as a partial word until the next incoming character is separated from the last character of this word. Before a word is confirmed as a full word, we only apply to it features that represent its current partial status, such as character bigrams, its starting character and its part-of-speech, etc. Full word features, including the first and last characters of a word, are applied immediately after a word is confirmed as complete.

An important component for our proposed system is the training process, which needs to ensure that the model scores a partial word with predicted POS properly. We use the averaged perceptron (Collins, 2002) for training, together with the "early update" mechanism of Collins and Roark (2004). Rather than updating the parameters after decoding is complete, the modified algorithm updates parameters at any processing step if the correct partial candidate falls out of the beam.

In our experiments using the Chinese Treebank data, our system ran an order of magnitude faster than our Z&C08 system with little loss of accuracy. The accuracy of our system was competitive with other recent models.

2 Model and Feature Templates

We use a linear model to score both partial and full candidate outputs. Given an input x, the score of a candidate output y is computed as:

$$\text{Score}(y) = \Phi(y) \cdot \vec{w},$$

where $\Phi(y)$ is the global feature vector extracted from y, and $\vec{w}$ is the parameter vector of the model.

Figure 1 shows the feature templates for the model, where templates 1 – 14 contain only segmentation information and templates 15 – 29 contain both segmentation and POS information. Each template is instantiated according to the current character in the decoding process. Row "For" shows the conditions for template instantiation, where "s" indicates that the corresponding template is instantiated when the current character starts a new word, and "a" indicates that the corresponding template is instantiated when the current character does not start a new word. In the row for feature templates, w, t and c are used to represent a word, a POS-tag and a character, respectively. The subscripts are based on the current character, where w_{-1} represents the first word to the left of the current character, and p_{-2} represents the POS-tag on the second word to the left of the current character, and so on. As an example, feature template 1 is instantiated when the current character starts a new word, and the resulting feature value is the word to the left of this character. $start(w)$, $end(w)$ and $len(w)$ represent the first character, the last character and the length of word w, respectively. The length of a word is normalized to 16 if it is larger than 16. $cat(c)$ represents the POS category of character c, which is the set of POS-tags seen on character c, as we used in Z&C08.

Given a partial or complete candidate y, its global feature vector $\Phi(y)$ is computed by instantiating all applicable feature templates from Table 1 for each character in y, according to whether or not the character is separated from the previous character.

The feature templates are mostly taken from, or inspired by, the feature templates of Z&C08. Templates 1, 2, 3, 4, 5, 8, 10, 12, 13, 14, 15, 19, 20,

[1] The next incoming characters are also a useful source of information for predicting the POS. However, our system achieved competitive accuracy with Z&C08 without such character lookahead features.

Table 1: Feature templates.

24, 27 and 29 concern complete word information, and they are used in the model to differentiate correct and incorrect output structures in the same way as our Z&C08 model. Templates 6, 7, 9, 16, 17, 18, 21, 22, 23, 25, 26 and 28 concern partial word information, whose role in the model is to indicate the likelihood that the partial word including the current character will become a correct full word. They act as guidance for the action to take for the current character according to the context, and are the crucial reason for the effectiveness of the algorithm with a small beam-size.

```
function Decode(sent, agenda):
    Clear(agenda)
    AddItem(agenda, “”)
    for index in [0..Len(sent)]:
        for cand in agenda:
            new ← Append(cand, sent[index])
            AddItem(agenda, new)
            for pos in TagSet():
                new ← Sep(cand, sent[index], pos)
                AddItem(agenda, new)
        agenda ← N-Best(agenda)
    return Best(agenda)
```

Figure 1: The incremental beam-search decoder.

2.1 Decoding

The decoding algorithm builds an output candidate incrementally, one character at a time. Each character can either be attached to the current word or separated as the start a new word. When the current character starts a new word, a POS-tag is assigned to the new word. An agenda is used by the decoder to keep the N-best candidates during the incremental process. Before decoding starts, the agenda is initialized with an empty sentence. When a character is processed, existing candidates are removed from the agenda and extended with the current character in all possible ways, and the N-best newly generated candidates are put back onto the agenda. After all input characters have been processed, the highest-scored candidate from the agenda is taken as the output.

Pseudo code for the decoder is shown in Figure 1. CLEAR removes all items from the agenda, ADDITEM adds a new item onto the agenda, N-BEST returns the N highest-scored items from the agenda, and BEST returns the highest-scored item from the agenda. LEN returns the number of characters in a sentence, and *sent*[i] returns the ith character from the sentence. APPEND appends a character to the last word in a candidate, and SEP joins a character as the start of a new word in a candidate, assigning a POS-tag to the new word.

Both our decoding algorithm and the decoding algorithm of Z&C08 run in linear time. However, in order to generate possible candidates for each character, Z&C08 uses an extra loop to search for possible words that end with the current character. A restriction to the maximum word length is applied to limit the number of iterations in this loop, without which the algorithm would have quadratic time complexity. In contrast, our decoder does not search backword for the possible starting character of any word. Segmentation ambiguities are resolved by binary choices between the actions append or separate for each character, and no POS enumeration is required when the character is appended. This improves the speed by a significant factor.

2.2 Training

The learning algorithm is based on the generalized perceptron (Collins, 2002), but parameter adjustments can be performed at any character during the decoding process, using the "early update" mechanism of Collins and Roark (2004).

The parameter vector of the model is initialized as all zeros before training, and used to decode training examples. Each training example is turned into the raw input format, and processed in the same way as decoding. After each character is processed, partial candidates in the agenda are compared to the corresponding gold-standard output for the same characters. If none of the candidates in the agenda are correct, the decoding is stopped and the parameter vector is updated by adding the global feature vector of the gold-standard partial output and subtracting the global feature vector of the highest-scored partial candidate in the agenda. The training process then moves on to the next example. However, if any item in the agenda is the same as the corresponding gold-standard, the decoding process moves to the next character, without any change to the parameter values. After all characters are processed, the decoder prediction is compared with the training example. If the prediction is correct, the parameter vector is not changed; otherwise it is updated by adding the global feature vector of the training example and subtracting the global feature vector of the decoder prediction, just as the perceptron algorithm does. The same training examples can be used to train the model for multiple iterations. We use the averaged parameter vector (Collins, 2002) as the final model.

Pseudocode for the training algorithm is shown in Figure 2. It is based on the decoding algorithm in Figure 1, and the main differences are: (1) the training algorithm takes the gold-standard output and the parameter vector as two additional arguments; (2) the training algorithm does not return a prediction, but modifies the parameter vector when necessary; (3) lines 11 to 20 are additional lines of code for parameter updates.

Without lines 11 to 16, the training algorithm is exactly the same as the generalized perceptron algorithm. These lines are added to ensure that the agenda contains highly probable candidates during the whole beam-search process, and they are crucial to the high accuracy of the system. As stated earlier, the decoder relies on proper scoring of partial words to maintain a set of high quality candidates in the agenda. Updating the value of the parameter vector for partial outputs can be seen as a means to ensure correct scoring of partial candidates at any character.

2.3 Pruning

We follow Z&C08 and use several pruning methods, most of which serve to to improve the accuracy by removing irrelevant candidates from the beam. First, the system records the maximum number of characters that a word with a particular POS-tag can have. For example, from the Chinese Treebank that we used for our experiments, most POS are associated with only with one- or two-character words. The only POS-tags that are seen with words over ten characters long are NN (noun), NR (proper noun) and CD (numbers). The maximum word length information is initialized as all ones, and updated according to each training example before it is processed.

Second, a tag dictionary is used to record POS-tags associated with each word. During decoding, frequent words and words with "closed set" tags[2] are only allowed POS-tags according to the tag dictionary, while other words are allowed every POS-tag to make candidate outputs. Whether a word is a frequent word is decided by the number of times it has been seen in the training process. Denoting the num-

[2] "Closed set" tags are the set of POS-tags which are only associated with a fixed set of words, according to the Penn Chinese Treebank specifications (Xia, 2000).

```
function TRAIN(sent, agenda, gold-standard, $\vec{w}$):
    CLEAR(agenda)
    ADDITEM(agenda, “”)
    for index in [0..LEN(sent)]:
        for cand in agenda:
            new ← APPEND(cand, sent[index])
            ADDITEM(agenda, new)
            for pos in TAGSET():
                new ← SEP(cand, sent[index], pos)
                ADDITEM(agenda, new)
        agenda ← N-BEST(agenda)
        for cand in agenda:
            if cand = gold-standard[0:index]:
                CONTINUE
        $\vec{w}$ ← $\vec{w}$ + $\Phi$(gold-standard[0:index])
        $\vec{w}$ ← $\vec{w}$ - $\Phi$(BEST(agenda))
        return
    if BEST(agenda) $\neq$ gold-standard:
        $\vec{w}$ ← $\vec{w}$ + $\Phi$(gold-standard)
        $\vec{w}$ ← $\vec{w}$ - $\Phi$(BEST(agenda))
        return
    return
```

Figure 2: The incremental learning function.

ber of times the most frequent word has been seen with M, a word is a frequent word if it has been seen more than $M/5000 + 5$ times. The threshold value is taken from Z&C08, and we did not adjust it during development. Word frequencies are initialized as zeros and updated according to each training example before it is processed; the tag dictionary is initialized as empty and updated according to each training example before it is processed.

Third, we make an additional record of the initial characters for words with “closed set” tags. During decoding, when the current character is added as the start of a new word, “closed set” tags are only assigned to the word if it is consistent with the record. This type of pruning is used in addition to the tag dictionary to prune invalid partial words, while the tag dictionary is used to prune complete words. The record for initial character and POS is initially empty, and udpated according to each training example before it is processed.

Finally, at any decoding step, we group partial candidates that are generated by separating the current character as the start of a new word by the signature $p_0p_{-1}w_{-1}$, and keep only the best among those having the same $p_0p_{-1}w_{-1}$. The signature $p_0p_{-1}w_{-1}$ is decided by the feature templates we use: it can be shown that if two candidates *cand1* and *cand2* generated at the same step have the same signature, and the score of *cand1* is higher than the score of *cand2*, then at any future step, the highest scored candidate generated from *cand1* will always have a higher score than the highest scored candidate generated from *cand2*.

From the above pruning methods, only the third was not used by Z&C08. It can be seen as an extra mechanism to help keep likely partial words in the agenda and improve the accuracy, but which does not give our system a speed advantage over Z&C08.

3 Experiments

We used the Chinese Treebank (CTB) data to perform one set of development tests and two sets of fi-

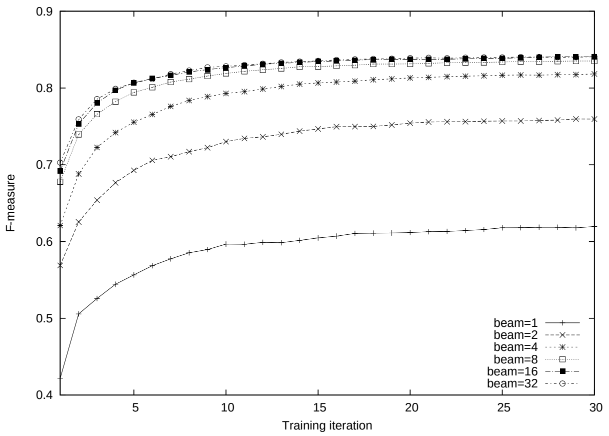

Figure 3: The influence of beam-sizes, and the convergence of the perceptron.

nal tests. The CTB 4 was split into two parts, with the CTB 3 being used for a 10-fold cross validation test to compare speed and accuracies with Z&C08, and the rest being used for development. The CTB 5 was used to perform the additional set of experiments to compare accuracies with other recent work.

We use the standard F-measure to evaluate output accuracies. For word segmentation, precision is defined as the number of correctly segmented words divided by the total number of words in the output, and recall is defined as the number of correctly segmented words divided by the total number of words in the gold-standard output. For joint segmentation and POS-tagging, precision is defined as the number of correctly segmented and POS-tagged words divided by the total number of words from the output, and recall is defined as the correctly segmented and POS-tagged words divided by the total number of words in the gold-standard output.

All our experiments were performed on a Linux platform, and a single 2.66GHz Intel Core 2 CPU.

3.1 Development tests

Our development data consists of 150K words in 4798 sentences. 80% of the data were randomly chosen as the development training data, while the rest were used as the development test data. Our development tests were mainly used to decide the size of the beam, the number of training iterations, the effect of partial features in beam-search decoding, and the effect of incremental learning (i.e. early update).

Figure 3 shows the accuracy curves for joint segmentation and POS-tagging by the number of training iterations, using different beam sizes. With the size of the beam increasing from 1 to 32, the accuracies generally increase, while the amount of increase becomes small when the size of the beam becomes 16. After the 10th iteration, a beam size of 32 does not always give better accuracies than a beam size of 16. We therefore chose 16 as the size of the beam for our system.

The testing times for each beam size between 1 and 32 are 7.16s, 11.90s, 18.42s, 27.82s, 46.77s and 89.21s, respectively. The corresponding speeds in the number of sentences per second are 111.45, 67.06, 43.32, 28.68, 17.06 and 8.95, respectively.

Figure 3 also shows that the accuracy increases with an increased number of training iterations, but the amount of increase becomes small after the 25th iteration. We chose 29 as the number of iterations to train our system.

The effect of incremental training: We compare the accuracies by incremental training using early update and normal perceptron training. In the normal perceptron training case, lines 11 to 16 are taken out of the training algorithm in Figure 2. The algorithm reached the best performance at the 22nd iteration, with the segmentation F-score being 90.58% and joint F-score being 83.38%. In the incremental training case, the algorithm reached the best accuracy at the 30th training iteration, obtaining a segmentation F-score of 91.14% and a joint F-score of 84.06%.

3.2 Final tests using CTB 3

CTB 3 consists of 150K words in 10364 sentences. We follow Z&C08 and split it into 10 equal-sized parts. In each test, one part is taken as the test data and the other nine are combined together as the training data. We compare the speed and accuracy with the joint segmentor and tagger of Z&C08, which is publicly available as the ZPar system, version 0.2[3].

The results are shown in Table 2, where each row shows one cross validation test. The column headings “sf”, “jf”, “time” and “speed” refer to segmentation F-measure, joint F-measure, testing time (in

Table 2: Speed and acccuracy comparisons with Z&C08 by 10-fold cross validation.

seconds) and testing speed (in the number of sentences per second), respectively.

Our system gave a joint segmentation and POS-tagging F-score of 91.37%, which is only 0.04% lower than that of ZPar 0.2. The speed of our system was over 10 times as fast as ZPar 0.2.

3.3 Final tests using CTB 5

We follow Kruengkrai et al. (2009) and split the CTB 5 into training, development testing and testing sets, as shown in Table 3. We ignored the development test data since our system had been developed in previous experiments.

	Sections	Sentences	Words
Training	1–270 400–931 1001–1151	18,085	493,892
Dev	301–325	350	6,821
Test	271–300	348	8,008

Table 3: Training, development and test data on CTB 5.

Kruengkrai et al. (2009) made use of character type knowledge for spaces, numerals, symbols, alphabets, Chinese and other characters. In the previous experiments, our system did not use any knowledge beyond the training data. To make the comparison fairer, we included knowledge of English letters and Arabic numbers in this experiment. During both training and decoding, English letters and Arabic numbers are segmented using simple rules, treating consecutive English letters or Arabic numbers as a single word.

The results are shown in Table 4, where row "N07" refers to the model of Nakagawa and Uchimoto (2007), rows "J08a" and "b" refer to the models of Jiang et al. (2008a) and Jiang et al. (2008b), and row "K09" refers to the models of Kruengkrai et al. (2009). Columns "sf" and "jf" refer to segmentation and joint accuracies, respectively. Our system gave comparable accuracies to these recent works, obtaining the best (same as the error-driven version of K09) joint F-score.

	sf	jf
K09 (error-driven)	97.87	93.67
our system	97.78	93.67

4 Related Work

The effectiveness of our beam-search decoder showed that the joint segmentation and tagging problem may be less complex than previously perceived (Zhang and Clark, 2008; Jiang et al., 2008a). At the very least, the single model approach with a simple decoder achieved competitive accuracies to what has been achieved so far by the reranking (Shi and Wang, 2007; Jiang et al., 2008b) models and an ensemble model using machine-translation techniques (Jiang et al., 2008a). This may shed new light on joint segmentation and POS-tagging methods.

Kruengkrai et al. (2009) and Zhang and Clark (2008) are the most similar to our system among related work. Both systems use a discriminatively trained linear model to score candidate outputs. The work of Kruengkrai et al. (2009) is based on Nakagawa and Uchimoto (2007), which separates the processing of known words and unknown words, and uses a set of segmentation tags to represent the segmentation of characters. In contrast, our model is conceptually simpler, and does not differentiate known words and unknown words. Moreover, our model is based on our previous work, in line with Zhang and Clark (2007), which does not treat word segmentation as character sequence labeling.

Our learning and decoding algorithms are also different from Kruengkrai et al. (2009). While Kruengkrai et al. (2009) perform dynamic programming and MIRA learning, we use beam-search to perform incremental decoding, and the early-update version of the perceptron algorithm to train the model. Dynamic programming is exact inference, for which the time complexity is decided by the locality of feature templates. In contrast, beam-search is approximate and can run in linear time. The parameter updating for our algorithm is conceptually and computationally simpler than MIRA, though its performance can be slightly lower. However, the early-update mechanism we use is consistent with our incremental approach, and improves the learning of the beam-search process.

5 Conclusion

We showed that a simple beam-search decoding algorithm can be effectively applied to the decoding problem for a global linear model for joint word segmentation and POS-tagging. By guiding search with partial word information and performing learning for partial candidates, our system achieved significantly faster speed with little accuracy loss compared to the system of Z&C08.

Abstract

Part-of-speech (POS) tag distributions are known to exhibit *sparsity* — a word is likely to take a single predominant tag in a corpus. Recent research has demonstrated that incorporating this sparsity constraint improves tagging accuracy. However, in existing systems, this expansion come with a steep increase in model complexity. This paper proposes a simple and effective tagging method that directly models tag sparsity and other distributional properties of valid POS tag assignments. In addition, this formulation results in a dramatic reduction in the number of model parameters thereby, enabling unusually rapid training. Our experiments consistently demonstrate that this model architecture yields substantial performance gains over more complex tagging counterparts. On several languages, we report performance exceeding that of more complex state-of-the art systems.[1]

1 Introduction

Since the early days of statistical NLP, researchers have observed that a part-of-speech tag distribution exhibits "one tag per discourse" *sparsity* — words are likely to select a single predominant tag in a corpus, even when several tags are possible. Simply assigning to each word its most frequent associated tag in a corpus achieves 94.6% accuracy on the WSJ portion of the Penn Treebank. This distributional sparsity of syntactic tags is not unique to English — similar results have been observed across multiple languages. Clearly, explicitly modeling such a powerful constraint on tagging assignment has a potential to significantly improve the accuracy of an unsupervised part-of-speech tagger learned without a tagging dictionary.

In practice, this sparsity constraint is difficult to incorporate in a traditional POS induction system (Mérialdo, 1994; Johnson, 2007; Gao and Johnson, 2008; Graça et al., 2009; Berg-Kirkpatrick et al., 2010). These sequence models-based approaches commonly treat token-level tag assignment as the primary latent variable. By design, they readily capture regularities at the *token-level*. However, these approaches are ill-equipped to directly represent *type-based constraints* such as sparsity. Previous work has attempted to incorporate such constraints into token-level models via heavy-handed modifications to inference procedure and objective function (e.g., posterior regularization and ILP decoding) (Graça et al., 2009; Ravi and Knight, 2009). In most cases, however, these expansions come with a steep increase in model complexity, with respect to training procedure and inference time.

In this work, we take a more direct approach and treat a word type and its allowed POS tags as a primary element of the model. The model starts by generating a tag assignment for each word type in a vocabulary, assuming one tag per word. Then, token-level HMM emission parameters are drawn conditioned on these assignments such that each word is only allowed probability mass on a single assigned tag. In this way we restrict the parameterization of a

Table 1: Upper bound on tagging accuracy assuming each word type is assigned to majority POS tag. Across all languages, high performance can be attained by selecting a single tag per word type.

token-level HMM to reflect lexicon sparsity. This model admits a simple Gibbs sampling algorithm where the number of latent variables is proportional to the number of word types, rather than the size of a corpus as for a standard HMM sampler (Johnson, 2007).

There are two key benefits of this model architecture. First, it directly encodes linguistic intuitions about POS tag assignments: the model structure reflects the one-tag-per-word property, and a type-level tag prior captures the skew on tag assignments (e.g., there are fewer unique determiners than unique nouns). Second, the reduced number of hidden variables and parameters dramatically speeds up learning and inference.

We evaluate our model on seven languages exhibiting substantial syntactic variation. On several languages, we report performance exceeding that of state-of-the art systems. Our analysis identifies three key factors driving our performance gain: 1) selecting a model structure which directly encodes tag sparsity, 2) a type-level prior on tag assignments, and 3) a straightforward naïve-Bayes approach to incorporate features. The observed performance gains, coupled with the simplicity of model implementation, makes it a compelling alternative to existing more complex counterparts.

2 Related Work

Recent work has made significant progress on unsupervised POS tagging (Mérialdo, 1994; Smith and Eisner, 2005; Haghighi and Klein, 2006; Johnson, 2007; Goldwater and Griffiths, 2007; Gao and Johnson, 2008; Ravi and Knight, 2009). Our work is closely related to recent approaches that incorporate the sparsity constraint into the POS induction process. This line of work has been motivated by empirical findings that the standard EM-learned unsupervised HMM does not exhibit sufficient word tag sparsity.

The extent to which this constraint is enforced varies greatly across existing methods. On one end of the spectrum are clustering approaches that assign a single POS tag to each word type (Schutze, 1995; Lamar et al., 2010). These clusters are computed using an SVD variant without relying on transitional structure. While our method also enforces a singe tag per word constraint, it leverages the transition distribution encoded in an HMM, thereby benefiting from a richer representation of context.

Other approaches encode sparsity as a soft constraint. For instance, by altering the emission distribution parameters, Johnson (2007) encourages the model to put most of the probability mass on few tags. This design does not guarantee "structural zeros," but biases towards sparsity. A more forceful approach for encoding sparsity is posterior regularization, which constrains the posterior to have a small number of expected tag assignments (Graça et al., 2009). This approach makes the training objective more complex by adding linear constraints proportional to the number of word types, which is rather prohibitive. A more rigid mechanism for modeling sparsity is proposed by Ravi and Knight (2009), who minimize the size of tagging grammar as measured by the number of transition types. The use of ILP in learning the desired grammar significantly increases the computational complexity of this method.

In contrast to these approaches, our method directly incorporates these constraints into the structure of the model. This design leads to a significant reduction in the computational complexity of training and inference.

Another thread of relevant research has explored the use of features in unsupervised POS induction (Smith and Eisner, 2005; Berg-Kirkpatrick et al., 2010; Hasan and Ng, 2009). These methods demonstrated the benefits of incorporating linguistic features using a log-linear parameterization, but requires elaborate machinery for training. In our work, we demonstrate that using a simple naïve-Bayes approach also yields substantial performance gains, without the associated training complexity.

3 Generative Story

We consider the unsupervised POS induction problem without the use of a tagging dictionary. A graphical depiction of our model as well as a summary of random variables and parameters can be found in Figure 1. As is standard, we use a fixed constant K for the number of tagging states.

Model Overview The model starts by generating a tag assignment $\boldsymbol{T}$ for each word type in a vocabulary, assuming one tag per word. Conditioned on $\boldsymbol{T}$, features of word types $\boldsymbol{W}$ are drawn. We refer to $(\boldsymbol{T}, \boldsymbol{W})$ as the lexicon of a language and ψ for the parameters for their generation; ψ depends on a single hyperparameter β.

Once the lexicon has been drawn, the model proceeds similarly to the standard token-level HMM: Emission parameters θ are generated conditioned on tag assignments $\boldsymbol{T}$. We also draw transition parameters ϕ. Both parameters depend on a single hyperparameter α. Once HMM parameters (θ, ϕ) are drawn, a token-level tag and word sequence, (t, w), is generated in the standard HMM fashion: a tag sequence t is generated from ϕ. The corresponding token words w are drawn conditioned on t and θ.[2] Our full generative model is given by:

$$
\begin{aligned}
&P(\boldsymbol{T}, \boldsymbol{W}, \theta, \psi, \phi, \boldsymbol{t}, \boldsymbol{w} | \alpha, \beta) = \\
&\quad P(\boldsymbol{T}, \boldsymbol{W}, \psi | \beta) && \text{[Lexicon]} \\
&\quad P(\phi, \theta | \boldsymbol{T}, \alpha, \beta) && \text{[Parameter]} \\
&\quad P(\boldsymbol{w}, \boldsymbol{t} | \phi, \theta) && \text{[Token]}
\end{aligned}
$$

We refer to the components on the right hand side as the lexicon, parameter, and token component respectively. Since the parameter and token components will remain fixed throughout experiments, we briefly describe each.

Parameter Component As in the standard Bayesian HMM (Goldwater and Griffiths, 2007), all distributions are independently drawn from symmetric Dirichlet distributions:

$$P(\phi, \theta | \boldsymbol{T}, \alpha, \beta) = \prod_{t=1}^{K} \left(P(\phi_t | \alpha) P(\theta_t | \boldsymbol{T}, \alpha) \right)$$

The transition distribution ϕ_t for each tag t is drawn according to $\text{DIRICHLET}(\alpha, K)$, where α is the shared transition and emission distribution hyperparameter. In total there are $O(K^2)$ parameters associated with the transition parameters.

In contrast to the Bayesian HMM, θ_t is not drawn from a distribution which has support for each of the n word types. Instead, we condition on the type-level tag assignments $\boldsymbol{T}$. Specifically, let $S_t = \{i | T_i = t\}$ denote the indices of the word types which have been assigned tag t according to the tag assignments $\boldsymbol{T}$. Then θ_t is drawn from $\text{DIRICHLET}(\alpha, S_t)$, a symmetric Dirichlet which only places mass on word types indicated by S_t. This ensures that each word will only be assigned a single tag at inference time (see Section 4).

Note that while the standard HMM, has $O(Kn)$ emission parameters, our model has $O(n)$ effective parameters.[3]

Token Component Once HMM parameters (ϕ, θ) have been drawn, the HMM generates a token-level corpus $\boldsymbol{w}$ in the standard way:

$$P(\boldsymbol{w}, \boldsymbol{t} | \phi, \theta) = \prod_{(w,t) \in (\boldsymbol{w}, \boldsymbol{t})} \left(\prod_j P(t_j | \phi_{t_{j-1}}) P(w_j | t_j, \theta_{t_j}) \right)$$

Note that in our model, conditioned on $\boldsymbol{T}$, there is precisely one $\boldsymbol{t}$ which has non-zero probability for the token component, since for each word, exactly one θ_t has support.

3.1 Lexicon Component

We present several variations for the lexical component $P(\boldsymbol{T}, \boldsymbol{W} | \psi)$, each adding more complex parameterizations.

Uniform Tag Prior (1TW) Our initial lexicon component will be uniform over possible tag assignments as well as word types. Its only purpose is

[2] Note that t and w denote tag and word sequences respectively, rather than individual tokens or tags.

[3] This follows since each θ_t has $S_t - 1$ parameters and $\sum_t S_t = n$.

VARIABLES

$\boldsymbol{W}$: Word types $(W_1, \ldots, W_n)$ (obs)

$\boldsymbol{T}$: Tag assigns $(T_1, \ldots, T_n)$

$\boldsymbol{w}$: Token word seqs (obs)

$\boldsymbol{t}$: Token tag assigns (det by $\boldsymbol{T}$)

PARAMETERS

ψ: Lexicon parameters

θ : Token word emission parameters

ϕ : Token tag transition parameters

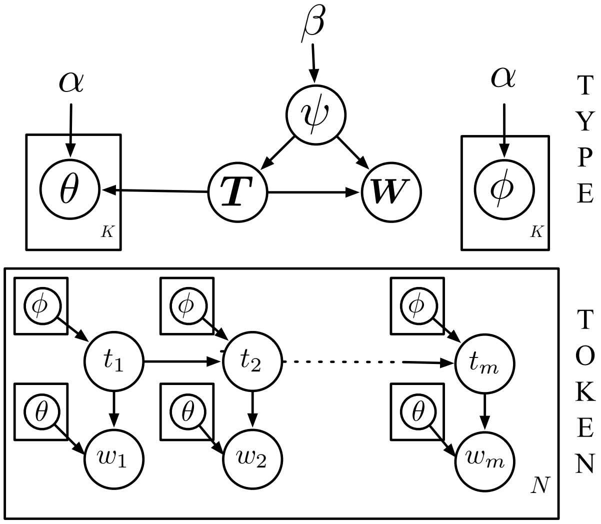

Figure 1: Graphical depiction of our model and summary of latent variables and parameters. The type-level tag assignments $\boldsymbol{T}$ generate features associated with word types $\boldsymbol{W}$. The tag assignments constrain the HMM emission parameters θ. The tokens $\boldsymbol{w}$ are generated by token-level tags $\boldsymbol{t}$ from an HMM parameterized by the lexicon structure. The hyperparameters α and β represent the concentration parameters of the token- and type-level components of the model respectively. They are set to fixed constants.

to explore how well we can induce POS tags using only the one-tag-per-word constraint. Specifically, the lexicon is generated as:

$$\begin{aligned} P(\boldsymbol{T}, \boldsymbol{W}|\psi) =& P(\boldsymbol{T})P(\boldsymbol{W}|\boldsymbol{T}) \\ =& \prod_{i=1}^{n} P(T_i)P(W_i|T_i) = \left(\frac{1}{Kn}\right)^n \end{aligned}$$

This model is equivalent to the standard HMM except that it enforces the one-word-per-tag constraint.

Learned Tag Prior (PRIOR) We next assume there exists a single prior distribution ψ over tag assignments drawn from $\textsc{Dirichlet}(\beta, K)$. This alters generation of $\boldsymbol{T}$ as follows:

$$P(\boldsymbol{T}|\psi) = \prod_{i=1}^{n} P(T_i|\psi)$$

Note that this distribution captures the frequency of a tag across word types, as opposed to tokens. The $P(T|\psi)$ distribution, in English for instance, should have very low mass for the DT (determiner) tag, since determiners are a very small portion of the vocabulary. In contrast, NNP (proper nouns) form a large portion of vocabulary. Note that these observations are not modeled by the standard HMM, which instead can model token-level frequency.

Word Type Features (FEATS): Past unsupervised POS work have derived benefits from features on word types, such as suffix and capitalization features (Hasan and Ng, 2009; Berg-Kirkpatrick et al., 2010). Past work however, has typically associated these features with token occurrences, typically in an HMM. In our model, we associate these features at the type-level in the lexicon. Here, we consider suffix features, capitalization features, punctuation, and digit features. While possible to utilize the feature-based log-linear approach described in Berg-Kirkpatrick et al. (2010), we adopt a simpler naïve Bayes strategy, where all features are emitted independently. Specifically, we assume each word type W consists of feature-value pairs (f, v). For each feature type f and tag t, a multinomial ψ_{tf} is drawn from a symmetric Dirichlet distribution with concentration parameter β. The $P(\boldsymbol{W}|\boldsymbol{T}, \psi)$ term in the lexicon component now decomposes as:

$$\begin{aligned} P(\boldsymbol{W}|\boldsymbol{T}, \psi) &= \prod_{i=1}^{n} P(W_i|T_i, \psi) \\ &= \prod_{i=1}^{n} \left(\prod_{(f,v) \in W_i} P(v|\psi_{T_i f}) \right) \end{aligned}$$

4 Learning and Inference

For inference, we are interested in the posterior probability over the latent variables in our model. During training, we treat as observed the language word types $\boldsymbol{W}$ as well as the token-level corpus $\boldsymbol{w}$. We utilize Gibbs sampling to approximate our collapsed model posterior:

$$P(\boldsymbol{T},\boldsymbol{t}|\boldsymbol{W},\boldsymbol{w},\alpha,\beta) \propto P(\boldsymbol{T},\boldsymbol{t},\boldsymbol{W},\boldsymbol{w}|\alpha,\beta)$$
$$= \int P(\boldsymbol{T},\boldsymbol{t},\boldsymbol{W},\boldsymbol{w},\psi,\theta,\phi,\boldsymbol{w}|\alpha,\beta)d\psi d\theta d\phi$$

Note that given tag assignments $\boldsymbol{T}$, there is only one setting of token-level tags $\boldsymbol{t}$ which has mass in the above posterior. Specifically, for the ith word type, the set of token-level tags associated with token occurrences of this word, denoted $\boldsymbol{t}^{(i)}$, must all take the value T_i to have non-zero mass. Thus in the context of Gibbs sampling, if we want to block sample T_i with $\boldsymbol{t}^{(i)}$, we only need sample values for T_i and consider this setting of $\boldsymbol{t}^{(i)}$.

The equation for sampling a single type-level assignment T_i is given by,

$$P(T_i,\boldsymbol{t}^{(i)}|\boldsymbol{T}_{-i},\boldsymbol{W},\boldsymbol{t}^{(-i)},\boldsymbol{w},\alpha,\beta) =$$
$$P(T_i|\boldsymbol{W},\boldsymbol{T}_{-i},\beta)P(\boldsymbol{t}^{(i)}|T_i,\boldsymbol{t}^{(-i)},\boldsymbol{w},\alpha)$$

where $\boldsymbol{T}_{-i}$ denotes all type-level tag assignment except T_i and $\boldsymbol{t}^{(-i)}$ denotes all token-level tags except $\boldsymbol{t}^{(i)}$. The terms on the right-hand-side denote the type-level and token-level probability terms respectively. The type-level posterior term can be computed according to,

$$P(T_i|\boldsymbol{W},\boldsymbol{T}_{-i},\beta) \propto$$
$$P(T_i|\boldsymbol{T}_{-i},\beta) \prod_{(f,v)\in W_i} P(v|T_i,f,\boldsymbol{W}_{-i},\boldsymbol{T}_{-i},\beta)$$

All of the probabilities on the right-hand-side are Dirichlet, distributions which can be computed analytically given counts.

The token-level term is similar to the standard HMM sampling equations found in Johnson (2007). The relevant variables are the set of token-level tags that appear before and after each instance of the ith word type; we denote these context pairs with the set $\{(t^b,t^a)\}$ and they are contained in $\boldsymbol{t}^{(-i)}$. We use w to represent the ith word type emitted by the HMM:

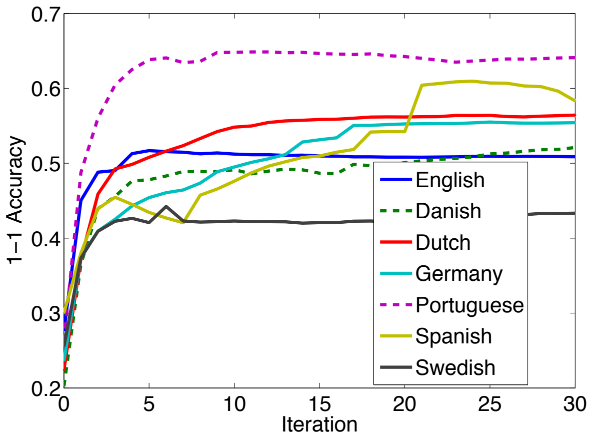

Figure 2: Graph of the one-to-one accuracy of our full model (+FEATS) under the best hyperparameter setting by iteration (see Section 5). Performance typically stabilizes across languages after only a few number of iterations.

$$P(\boldsymbol{t}^{(i)}|T_i,\boldsymbol{t}^{(-i)},\boldsymbol{w},\alpha) \propto$$
$$\prod_{(t^b,t^a)} P(w|T_i,\boldsymbol{t}^{(-i)},\boldsymbol{w}^{(-i)},\alpha)$$
$$P(T_i|t^b,\boldsymbol{t}^{(-i)},\alpha)P(t^a|T_i,\boldsymbol{t}^{(-i)},\alpha)$$

All terms are Dirichlet distributions and parameters can be analytically computed from counts in $\boldsymbol{t}^{(-i)}$ and $\boldsymbol{w}^{(-i)}$ (Johnson, 2007).

Note that each round of sampling T_i variables takes time proportional to the size of the corpus, as with the standard token-level HMM. A crucial difference is that the number of parameters is greatly reduced as is the number of variables that are sampled during each iteration. In contrast to results reported in Johnson (2007), we found that the performance of our Gibbs sampler on the basic 1TW model stabilized very quickly after about 10 full iterations of sampling (see Figure 2 for a depiction).

5 Experiments

We evaluate our approach on seven languages: English, Danish, Dutch, German, Portuguese, Spanish, and Swedish. On each language we investigate the contribution of each component of our model. For all languages we do not make use of a tagging dictionary.

Model	Hyper-	English		Danish		Dutch		German		Portuguese		Spanish		Swedish	
	param.	1-1	m-1	1-1	m-1	1-1	m-1	1-1	m-1	1-1	m-1	1-1	m-1	1-1	m-1

Table 3: Multi-lingual Results: We report token-level one-to-one and many-to-one accuracy on a variety of languages under several experimental settings (Section 5). For each language and setting, we report one-to-one (1-1) and many-to-one (m-1) accuracies. For each cell, the first row corresponds to the result using the best hyperparameter choice, where best is defined by the 1-1 metric. The second row represents the performance of the median hyperparameter setting. Model components cascade, so the row corresponding to +FEATS also includes the PRIOR component (see Section 3).

Language	# Tokens	# Word Types	# Tags
English	1173766	49206	45

Spanish	89334	16458	47
Swedish	191467	20057	41

Table 2: Statistics for various corpora utilized in experiments. See Section 5. The English data comes from the WSJ portion of the Penn Treebank and the other languages from the training set of the CoNLL-X multilingual dependency parsing shared task.

5.1 Data Sets

Following the set-up of Johnson (2007), we use the whole of the Penn Treebank corpus for training and evaluation on English. For other languages, we use the CoNLL-X multilingual dependency parsing shared task corpora (Buchholz and Marsi, 2006) which include gold POS tags (used for evaluation). We train and test on the CoNLL-X training set. Statistics for all data sets are shown in Table 2.

5.2 Setup

Models To assess the marginal utility of each component of the model (see Section 3), we incrementally increase its sophistication. Specifically, we evaluate three variants: The first model (1TW) only encodes the one tag per word constraint and is uniform over type-level tag assignments. The second model (+PRIOR) utilizes the independent prior over type-level tag assignments $P(\boldsymbol{T}|\psi)$. The final model (+FEATS) utilizes the tag prior as well as features (e.g., suffixes and orthographic features), discussed in Section 3, for the $P(\boldsymbol{W}|\boldsymbol{T}, \psi)$ component.

Hyperparameters Our model has two Dirichlet concentration hyperparameters: α is the shared hyperparameter for the token-level HMM emission and transition distributions. β is the shared hyperparameter for the tag assignment prior and word feature multinomials. We experiment with four values for each hyperparameter resulting in 16 (α, β) combinations:

α	β
$0.001, 0.01, 0.1, 1.0$	$0.01, 0.1, 1.0, 10$

Iterations In each run, we performed 30 iterations of Gibbs sampling for the type assignment variables $\boldsymbol{W}$.[4] We use the final sample for evaluation.

Evaluation Metrics We report three metrics to evaluate tagging performance. As is standard, we report the *greedy one-to-one* (Haghighi and Klein, 2006) and the *many-to-one* token-level accuracy obtained from mapping model states to gold POS tags. We also report word type level accuracy, the fraction of word types assigned their majority tag (where the mapping between model state and tag is determined by greedy one-to-one mapping discussed above).[5]

For each language, we aggregate results in the following way: First, for each hyperparameter setting,

[4] Typically, the performance stabilizes after only 10 iterations.

[5] We choose these two metrics over the Variation Information measure due to the deficiencies discussed in Gao and Johnson (2008).

we perform five runs with different random initialization of sampling state. Hyperparameter settings are sorted according to the median one-to-one metric over runs. We report results for the best and median hyperparameter settings obtained in this way. Specifically, for both settings we report results on the median run for each setting.

Tag set As is standard, for all experiments, we set the number of latent model tag states to the size of the annotated tag set. The original tag set for the CoNLL-X Dutch data set consists of compounded tags that are used to tag multi-word units (MWUs) resulting in a tag set of over 300 tags. We tokenize MWUs and their POS tags; this reduces the tag set size to 12. See Table 2 for the tag set size of other languages. With the exception of the Dutch data set, no other processing is performed on the annotated tags.

6 Results and Analysis

We report token- and type-level accuracy in Table 3 and 6 for all languages and system settings. Our analysis and comparison focuses primarily on the one-to-one accuracy since it is a stricter metric than many-to-one accuracy, but also report many-to-one for completeness.

Comparison with state-of-the-art taggers For comparison we consider two unsupervised taggers: the HMM with log-linear features of Berg-Kirkpatrick et al. (2010) and the posterior regularization HMM of Graça et al. (2009). The system of Berg-Kirkpatrick et al. (2010) reports the best unsupervised results for English. We consider two variants of Berg-Kirkpatrick et al. (2010)'s richest model: optimized via either EM or LBFGS, as their relative performance depends on the language. Our model outperforms theirs on four out of five languages on the best hyperparameter setting and three out of five on the median setting, yielding an average absolute difference across languages of 12.9% and 3.9% for best and median settings respectively compared to their best EM or LBFGS performance. While Berg-Kirkpatrick et al. (2010) consistently outperforms ours on English, we obtain substantial gains across other languages. For instance, on Spanish, the absolute gap on median performance is 10%.

	Top 5	Bottom 5
Gold	NNP NN JJ CD NNS	RBS PDT # ” ,
1TW	**CD** WRB **NNS** VBN **NN**	PRP$ WDT : MD .
+PRIOR	**CD JJ NNS** WP$ **NN**	-RRB- **,** $ ” .
+FEATS	**JJ NNS CD NNP** UH	**,** PRP$ **#** . “

Table 5: Type-level English POS Tag Ranking: We list the top 5 and bottom 5 POS tags in the lexicon and the predictions of our models under the best hyperparameter setting.

Our second point of comparison is with Graça et al. (2009), who also incorporate a sparsity constraint, but does via altering the model objective using posterior regularization. We can only compare with Graça et al. (2009) on Portuguese (Graça et al. (2009) also report results on English, but on the reduced 17 tag set, which is not comparable to ours). Their best model yields 44.5% one-to-one accuracy, compared to our best median 56.5% result. However, our full model takes advantage of word features not present in Graça et al. (2009). Even without features, but still using the tag prior, our median result is 52.0%, still significantly outperforming Graça et al. (2009).

Ablation Analysis We evaluate the impact of incorporating various linguistic features into our model in Table 3. A novel element of our model is the ability to capture type-level tag frequencies. For this experiment, we compare our model with the uniform tag assignment prior (1TW) with the learned prior (+PRIOR). Across all languages, +PRIOR consistently outperforms 1TW, reducing error on average by 9.1% and 5.9% on best and median settings respectively. Similar behavior is observed when adding features. The difference between the featureless model (+PRIOR) and our full model (+FEATS) is 13.6% and 7.7% average error reduction on best and median settings respectively. Overall, the difference between our most basic model (1TW) and our full model (+FEATS) is 21.2% and 13.1% for the best and median settings respectively. One striking example is the error reduction for Spanish, which reduces error by 36.5% and 24.7% for the best and median settings respectively. We observe similar trends when using another measure – type-level accuracy (defined as the fraction of words correctly assigned their majority tag), according to which

Language	Metric	BK10 EM	BK10 LBFGS	G10	FEATS Best	FEATS Median
English	1-1	48.3	56.0	–	50.9	47.8
	m-1	68.1	75.5	–	66.4	66.4
Danish	1-1	42.3	42.6	–	52.1	43.2
	m-1	66.7	58.0	–	61.2	60.7
Dutch	1-1	53.7	55.1	–	56.4	51.5
	m-1	67.0	64.7	–	69.0	67.3
Portuguese	1-1	50.8	43.2	44.5	64.1	56.5
	m-1	75.3	74.8	69.2	74.5	70.1
Spanish	1-1	–	40.6	–	58.3	50.0
	m-1	–	73.2	–	68.9	57.2

Table 4: Comparison of our method (FEATS) to state-of-the-art methods. Feature-based HMM Model (Berg-Kirkpatrick et al., 2010): The KM model uses a variety of orthographic features and employs the EM or LBFGS optimization algorithm; Posterior regulariation model (Graça et al., 2009): The G10 model uses the posterior regularization approach to ensure tag sparsity constraint.

Language	1TW	+PRIOR	+FEATS
English	21.1	28.8	42.8
Danish	10.1	20.7	45.9
Dutch	23.8	32.3	44.3
German	12.8	35.2	60.6
Portuguese	18.4	29.6	61.5
Spanish	7.3	27.6	49.9
Swedish	8.9	14.2	33.9

Table 6: Type-level Results: Each cell report the type-level accuracy computed against the most frequent tag of each word type. The state-to-tag mapping is obtained from the best hyperparameter setting for 1-1 mapping shown in Table 3.

our full model yields 39.3% average error reduction across languages when compared to the basic configuration (1TW).

Table 5 provides insight into the behavior of different models in terms of the tagging lexicon they generate. The table shows that the lexicon tag frequency predicated by our full model are the closest to the gold standard.

7 Conclusion and Future Work

We have presented a method for unsupervised part-of-speech tagging that considers a word type and its allowed POS tags as a primary element of the model. This departure from the traditional token-based tagging approach allows us to explicitly capture type-level distributional properties of valid POS tag assignments as part of the model. The resulting model is compact, efficiently learnable and linguistically expressive. Our empirical results demonstrate that the type-based tagger rivals state-of-the-art tag-level taggers which employ more sophisticated learning mechanisms to exploit similar constraints.

In this paper, we make a simplifying assumption of one-tag-per-word. This assumption, however, is not inherent to type-based tagging models. A promising direction for future work is to explicitly model a distribution over tags for each word type. We hypothesize that modeling morphological information will greatly constrain the set of possible tags, thereby further refining the representation of the tag lexicon.

Abstract

We explore the task of automatically classifying dialogue acts in 1-on-1 online chat forums, an increasingly popular means of providing customer service. In particular, we investigate the effectiveness of various features and machine learners for this task. While a simple bag-of-words approach provides a solid baseline, we find that adding information from dialogue structure and inter-utterance dependency provides some increase in performance; learners that account for sequential dependencies (CRFs) show the best performance. We report our results from testing using a corpus of chat dialogues derived from online shopping customer-feedback data.

1 Introduction

Recently, *live chats* have received attention due to the growing popularity of chat services and the increasing body of applications. For example, large organizations are increasingly providing support or information services through live chat. One advantage of chat-based customer service over conventional telephone-based customer service is that it becomes possible to semi-automate aspects of the interaction (e.g. conventional openings or canned responses to standard questions) without the customer being aware of it taking place, something that is not possible with speech-based dialogue systems (as synthesised speech is still easily distinguishable from natural speech). Potentially huge savings can be made by organisations providing customer help services if we can increase the degree of automation of live chat.

Given the increasing impact of live chat services, there is surprisingly little published computational linguistic research on the topic. There has been substantially more work done on dialogue and dialogue corpora, mostly in spoken dialogue (e.g. Stolcke et al. (2000)) but also multimodal dialogue systems in application areas such as telephone support service (Bangalore et al., 2006) and tutoring systems (Litman and Silliman, 2004). Spoken dialogue analysis introduces many complications related to the error inherent in current speech recognition technologies. As an instance of written dialogue, an advantage of live chats is that recognition errors are not such an issue, although the nature of language used in chat is typically ill-formed and turn-taking is complicated by the semi-asynchronous nature of the interaction (e.g. Werry (1996)).

In this paper, we investigate the task of automatic classification of *dialogue acts* in 1-on-1 live chats, focusing on "information delivery" chats since these are proving increasingly popular as part of enterprise customer-service solutions. Our main challenge is to develop effective features and classifiers for classifying aspects of 1-on-1 live chat. Much of the work on analysing dialogue acts in spoken dialogues has relied on non-lexical features, such as prosody and acoustic features (Stolcke et al., 2000; Julia and Iftekharuddin, 2008; Sridhar et al., 2009), which are not available for written dialogues. Previous dialogue-act detection for chat systems has used bags-of-words (hereafter, BoW) as features for dialogue-act detection; this simple approach has shown some promise (e.g. Bangalore et al. (2006), Louwerse and Crossley (2006) and Ivanovic (2008)). Other features such as keywords/ontologies (Purver et al., 2005; Forsyth, 2007) and lexical cues (Ang et al., 2005) have also been used for dialogue act classification.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 862–871,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

In this paper, we first re-examine BoW features for dialogue act classification. As a baseline, we use the work of Ivanovic (2008), which explored 1-grams and 2-grams with Boolean values in 1-on-1 live chats in the MSN Online Shopping domain (this dataset is described in Section 5). Although this work achieved reasonably high performance (up to a micro-averaged F-score of around 80%), we believe that there is still room for improvement using BoW only. We extend this work by using ideas from related research such as text categorization (Debole and Sebastiani, 2003), and explore variants of BoW based on analysis of live chats, along with feature weighting. Finally, our main aim is to explore new features based on dialogue structure and dependencies between utterances[1] that can enhance the use of BoW for dialogue act classification. Our hypothesis is that, for task-oriented 1-on-1 live chats, the structure and interactions among utterances are useful in predicting future dialogue acts: for example, conversations typically start with a greeting, and questions and answers typically appear as adjacency pairs in a conversation. Therefore, we propose new features based on structural and dependency information derived from utterances (Sections 4.2 and 4.3).

2 Related Work

While there has been significant work on classifying dialogue acts, the bulk of this has been for spoken dialogue. Most such work has considered: (1) defining taxonomies of dialogue acts; (2) discovering useful features for the classification task; and (3) experimenting with different machine learning techniques. We focus here on (2) and (3); we return to (1) in Section 3.

For classifying dialogue acts in spoken dialogue, various features such as dialogue cues, speech characteristics, and n-grams have been proposed. For example, Samuel et al. (1998) utilized the characteristics of spoken dialogues and examined speaker direction, punctuation marks, cue phrases and n-grams for classifying spoken dialogues. Jurafsky et al. (1998) used prosodic, lexical and syntactic features for spoken dialogue classification. More recently, Julia and Iftekharuddin (2008) and Sridhar et al. (2009) achieved high performance using acoustic and prosodic features. Louwerse and Crossley (2006), on the other hand, used various n-gram features—which could be adapted to both spoken and written dialogue—and tested them using the Map Task Corpus (Anderson et al., 1991). Extending the discourse model used in previous work, Bangalore et al. (2006) used n-grams from the previous 1–3 utterances in order to classify dialogue acts for the target utterance.

There has been substantially less effort on classifying dialogue acts in written dialogue: Wu et al. (2002) and Forsyth (2007) have used keyword-based approaches for classifying online chats; Ivanovic (2008) tested the use of n-gram features for 1-on-1 live chats with MSN Online Shopping assistants.

Various machine learning techniques have been investigated for the dialogue classification task. Samuel et al. (1998) used transformation-based learning to classify spoken dialogues, incorporating Monte Carlo sampling for training efficiency. Stolcke et al. (2000) used Hidden Markov Models (HMMs) to account for the structure of spoken dialogues, while Wu et al. (2002) also used transformation- and rule-based approaches plus HMMs for written dialogues. Other researchers have used Bayesian based approaches, such as naive Bayes (e.g. (Grau et al., 2004; Forsyth, 2007; Ivanovic, 2008)) and Bayesian networks (e.g. (Keizer, 2001; Forsyth, 2007)). Maximum entropy (e.g. (Ivanovic, 2008)), support vector machines (e.g. (Ivanovic, 2008)), and hidden Markov models (e.g. (Bui, 2003)) have also all been applied to automatic dialogue act classification.

3 Dialogue Acts

A number of dialogue act taxonomies have been proposed, designed mainly for spoken dialogue. Many of these use the Dialogue Act Markup in Several Layers (DAMSL) scheme (Allen and Core, 1997). DAMSL was originally applied to the TRAINS corpus of (transcribed) spoken task-oriented dialogues, but various adaptations of it have since been proposed for specific types of dialogue. The Switchboard corpus (Godfrey et al., 1992) defines 42 types of dialogue acts from human-to-human telephone conversations. The HCRC Map Task corpus (Ander-

[1] An *utterance* is the smallest unit to deliver a participant's message(s) in a turn.

son et al., 1991) defines a set of 128 dialogue acts to model task-based spoken conversations.

For casual online chat dialogues, Wu et al. (2002) define 15 dialogue act tags based on previously-defined dialogue act sets (Samuel et al., 1998; Shriberg et al., 1998; Jurafsky et al., 1998; Stolcke et al., 2000). Forsyth (2007) defines 15 dialogue acts for casual online conversations, based on 16 conversations with 10,567 utterances. Ivanovic (2008) proposes 12 dialogue acts based on DAMSL for 1-on-1 online customer service chats.

Ivanovic's set of dialogue acts for chat dialogues has significant overlap with the dialogue act sets of Wu et al. (2002) and Forsyth (2007) (e.g. GREETING, EMOTION/EXPRESSION, STATEMENT, QUESTION). In our work, we re-use the set of dialogue acts proposed in Ivanovic (2008), due to our targeting the same task of 1-on-1 IM chats, and indeed experimenting over the same dataset. The definitions of the dialogue acts are provided in Table 1, along with examples.

4 Feature Selection

In this section, we describe our initial dialogue-act classification experiments using simple BoW features, and then introduce two groups of new features based on structural information and dependencies between utterances.

4.1 Bag-of-Words

n-gram-based BoW features are simple yet effective for identifying similarities between two utterances, and have been used widely in previous work on dialogue act classification for online chat dialogues (Louwerse and Crossley, 2006; Ivanovic, 2008). However, chats containing large amounts of noise such as typos and emoticons pose a greater challenge for simple BoW approaches. On the other hand, keyword-based features (Forsyth, 2007) have achieved high performance; however, keyword-based approaches are more domain-dependent. In this work, we chose to start with a BoW approach based on our observation that commercial live chat services contain relatively less noise; in particular, the commercial agent tends to use well-formed, formulaic prose.

Previously, Ivanovic (2008) explored Boolean 1-gram and 2-gram features to classify MSN Online Shopping live chats, where a user requests assistance in purchasing an item, in response to which the commercial agent asks the customer questions and makes suggestions. Ivanovic (2008) achieved solid performance over this data (around 80% F-score). While 1-grams performed well (as live chat utterances are generally shorter than, e.g., sentences in news articles), we expect 2- and 3-grams are needed to detect formulaic expressions, such as *No problem* and *You are welcome*. We would also expect a positive effect from combining n-grams due to increasing the coverage of feature words. We thus test 1-, 2- and 3-grams individually, as well as the combination of 1- and 2-grams together (i.e. 1+2-grams) and 1-, 2- and 3-grams (i.e. 1+2+3-grams); this results in five BoW sets. Also, unlike Ivanovic (2008), we test both raw words and lemmas; we expect the use of lemmas to perform better than raw words as our data is less noisy. As the feature weight, in addition to simple Boolean, we also experiment with *TF*, *TF·IDF* and *Information Gain (IG)*.

4.2 Structural Information

Our motivation for using structural information as a feature is that the location of an utterance can be a strong predictor of the dialogue act. That is, dialogues are sequenced, comprising turns (i.e. a given user is sending text), each of which is made up of one or more messages (i.e. strings sent by the user). Structured classification methods which make use of this sequential information have been applied to related tasks such as tagging semantic labels of key sentences in biomedical domains (Chung, 2009) and post labels in web forums (Kim et al., 2010).

Based on the nature of live chats, we observed that the utterance position in the chat, as well as in a turn, plays an important role when identifying its dialogue act. For example, an utterance such as *Hello* will occur at the beginning of a chat while an utterance such as *Have a nice day* will typically appear at the end. The position of utterances in a turn can also help identify the dialogue act; i.e. when there are several utterances in a turn, utterances are related to each other, and thus examining the previous utterances in the same turn can help correctly predict the target utterance. For example, the greeting (*Welcome to ..*) and question (*How may I help you?*) could occur in

Dialogue Act, Definition and Examples
Conventional_Closing: Various ways of ending a conversation e.g. *Bye Bye*
Conventional_Opening: Greeting and other ways of starting a conversation e.g. *Hello Customer*
Downplayer: A backwards-linking label often used after Thanks to down play the contribution e.g. *You are welcome, my pleasure*
Expressive: An acknowledgement of a previous utterance or an indication of the speaker's mood. e.g. *haha,* $:-)$ *wow*
No_Answer: A backward-linking label in the form of a negative response to a YesNo-question e.g. *no, nope*
Open_Question: A question that cannot be answered with only a *yes* or *no*. The answer is usually some form of explanation or statement. e.g. *how do I use the international version?*
Request: Used to express a speaker's desire that the learner do something – either performing some action or simply waiting. e.g. *Please let me know how I can assist you on MSN Shopping today.*
Response_Ack: A backward-linking acknowledgement of the previous utterance. Used to confirm that the previous utterance was received/accepted. e.g. *Sure*
Statement: Used for assertions that may state a belief or commit the speaker to doing something e.g. *I am sending you the page which will pop up in a new window on your screen.*
Thanks: Conventional thanks e.g. *Thank you for contacting us.*
Yes_Answer: A backward-linking label in the form of an affirmative response to a YesNo-Question e.g. *yes, yeah*
YesNo_Question: A closed question which can be answered in the affirmative or negative. e.g. *Did you receive the page, Customer?*

Table 1: The set of dialogue acts used in this research, taken from Ivanovic (2008)

the same turn. We also noticed that identifying the utterance author can help classify the dialogue act (previously used in Ivanovic (2008)).

Based on these observations, we tested the following four structural features:

- Author information,
- Relative position in the chat,
- Author + Relative position,
- Author + Turn-relative position among utterances in a given turn.

We illustrate our structural features in Table 2, which shows an example of a 1-on-1 live chat. The participants are the agent (A) and customer (C); *Uxx* indicates an utterance (U) with ID number xx. This conversation has 42 utterances in total. The relative position is calculated by dividing the utterance number by the total number of utterances in the dialogue; the turn-relative position is calculated by dividing the utterance position by the number of utterances in that turn. For example, for utterance 4 (U4), the relative position is $\frac{4}{42}$, while its turn-relative position is $\frac{2}{3}$ since *U4* is the second utterance among *U3,4,5* that the customer makes in a single turn.

4.3 Utterance Dependency

In recent work, Kim et al. (2010) demonstrated the importance of dependencies between post labels in web forums. The authors introduced series of features based on structural dependencies among posts. They used relative position, author information and automatically predicted labels from previous post(s) as dependency features for assigning a semantic label to the current target post.

Similarly, by examining our chat corpus, we observed significant dependencies between utterances. First, 1-on-1 (i.e. agent-to-user) dialogues often contain dependencies between adjacent utterances by different authors. For example, in Table 2, when the agent asks *Is that correct?*, the expected response from the user is a *Yes* or *No*. Another example is that when the agent makes a greeting, such as *Have a nice day*, then the customer will typically respond with a greeting or closing remark, and not a *Yes* or *No*. Second, the flow of dialogues is in general cohesive, unless the topic of utterances changes dramatically (e.g. *U5: Are you still there?*, *U22: brb in 1 min* in Table 2). Third, we observed that between utterances made by the same author (either agent or user), the target utterance relies on previous utterances made by the same author, especially when

ID	Utterance
A:U1	Hello Customer, welcome to MSN Shopping.
A:U2	My name is Krishna and I am your online Shopping assistant today.
C:U3	Hello!
C:U4	I'm trying to find a sports watch.
C:U5	are you still there?
A:U6	I understand that you are looking for sports watch.
A:U7	Is that correct?
C:U8	yes, that is correct.
..	
C:U22	brb in 1 min
C:U23	Thank you for waiting
..	
A:U37	Thank you for allowing us to assist you regarding wrist watch.
A:U38	I hope you found our session today helpful.
A:U39	If you have any additional questions or you need additional information, please log in again to chat with us. We are available 24 hours a day, 7 days a week for your help.
A:U40	Thank you for contacting MSN Shopping.
A:U41	Have a nice day! Good Bye and Take Care.
C:U42	You too.

Table 2: An example of a 1-on-1 live chat, with turn and utterance structure

the agent and user repeatedly question and answer. With these observations, we checked the likelihood of dialogue act pairings between two adjacent utterances, as well as between two adjacent utterances made by the same author. Overall, we found strong co-occurrence (as measured by number of occurrences of labels across adjacency pairs) between certain pairs of dialogue acts (e.g. (YESNO_QUESTION →YES_ANSWER/NO_ANSWER) and (REQUEST →YES_ANSWER)). STATEMENT, on the other hand, can associate with most other dialogue acts.

Based on this, we designed the following five utterance dependency features; by combining these, we obtain 31 feature sets.

1. Dependency of utterances regardless of author
   (a) Dialogue act of previous utterance
   (b) Accumulated dialogue act(s) of previous utterances
   (c) Accumulated dialogue acts of previous utterances in a given turn
2. Dependency of utterances made by a single author
   (a) Dialogue act of previous utterance by same author; a dialogue act can be in the same turn or in the previous turn
   (b) Accumulated dialogue acts of previous utterances by same author; dialogue acts can be in the same turn or in the previous turn

To capture utterance dependency, Bangalore et al. (2006) previously used n-gram BoW features from the previous 1–3 utterances. In contrast, instead of using utterances which indirectly encode dialogue acts, we directly use the dialogue act classifications, as done in Stolcke et al. (2000). The motivation is that, due to the high performance of simple BoW features, using dialogue acts directly would capture the dependency better than indirect information from utterances, despite introducing some noise. We do not build a probabilistic model of dialogue transitions the way Stolcke et al. (2000) does, but follow an approach similar to that used in Kim et al. (2010) in using predicted dialogue act(s) labels learned in previous step(s) as a feature.

5 Experiment Setup

As stated earlier, we use the data set from Ivanovic (2008) for our experiments; it contains 1-on-1 live chats from an information delivery task. This dataset contains 8 live chats, including 542 manually-segmented utterances. The maximum and minimum number of utterances in a dialogue are 84 and 42, respectively; the maximum number of utterances in a turn is 14. The live chats were manually tagged with the 12 dialogue acts described in Section 3. The utterance distribution over the dialogue acts is described in Table 3.

For our experiments, we calculated TF, TF·IDF and IG (Information Gain) over the utterances, which were optionally lemmatized with the `morph` tool (Minnen et al., 2000). We then built a dialogue act classifier using three different machine learners: SVM-HMM (Joachims, 1998),[2] naive Bayes

Table 4: Best accuracy achieved by the different learners over different feature sets and weighting methods (1 = 1-gram; 1+2+3 = 1/2/3-grams; B = Boolean; IG = information gain)

from the WEKA machine learning toolkit (Witten and Frank, 2005), and Conditional Random Fields (CRF) using CRF++.[3] Note that we chose to test CRF and SVM-HMM as previous work (e.g. (Samuel et al., 1998; Stolcke et al., 2000; Chung, 2009)) has shown the effectiveness of structured classification models on sequential dependencies. Thus, we expect similar effects with CRF and SVM-HMM. Finally, we ran 8-fold cross-validation using the feature sets described above (partitioning across the 8 sessions). All results are presented in terms of classification accuracy. The accuracy of a zero-R (i.e. majority vote) baseline is 0.36.

6 Evaluation

6.1 Testing Bag-of-Words Features

Table 4 shows the best accuracy achieved by the different learners, in combination with BoW representations and feature weighting methods. Note that the CRF learner ran using 1-grams only, as CRF++ does not accept large numbers of features. As a benchmark, we also tested the method in Ivanovic (2008) and present the best performance over words (rather than lemmas). Overall, we found using just 1-grams produced the best performance for all learners, although SVM achieved the best performance when using all three n-gram orders (i.e. 1+2+3). Since the utterances are very short, 2-grams or 3-grams alone are too sparse to be effective. Among the feature weighting methods, Boolean and IG achieved higher accuracy than TF and TF·IDF. Likewise, due to the short utterances, simple Boolean values were often the most effective. However, as IG was computed using the training data, it also achieved high performance. When comparing the learners, we found that CRF produced the best performance, due to its ability to capture inter-utterance dependencies. Finally, we confirmed that using lemmas results in higher accuracy.

n-gram	Boolean	TF	TF·IDF	IG
1	.731	.511	.517	.766
2	.603	.530	.601	.614
3	.474	.463	.472	.482
1+2	.756	.511	.522	**.777**
1+2+3	.773	.511	.528	**.777**

Table 5: Accuracy of different feature representations and weighting methods for SVM-HMM

Table 5 shows the accuracy over all feature sets; for brevity, we show this for SVM only since the pattern is similar across all learners.

6.2 Using Structural Information

In this section, we describe experiments using structural information—i.e. author and/or position—with BoWs. As with the base BoW technique, we used 1-gram lemmas with Boolean values, based on the results from Section 6.1. Table 6 shows the results: *Pos* indicates the relative position of an utterance in the whole dialogue, *Author* means author information, and Pos_{turn} indicates the relative position of the utterance in a turn. All methods outperformed the baseline; methods that surpassed the results for the simple BoW method (for the given learner) at a

[3] http://crfpp.sourceforge.net/

Feature	Learners		
	CRF	SVM	NB
BoW	.862	.731	.672
BoW+Author	.860	.655	.649
BoW+Pos	.862	.721	.655
BoW+Pos$_{absolute}$	**.863**	.631	.524
BoW+Author+Pos	**.875**	.700	.642
BoW+Author+Pos$_{turn}$	**.871**	.651	.631

Table 6: Accuracy with structural information

level of statistical significance (based on randomised estimation, $p < 0.05$) are boldfaced.

Overall, using CRFs with Author and Position information produced better performance than using BoW alone. Clearly, the ability of CRFs to natively optimise over structural dependencies provides an advantage over other learners.

Relative position cannot of course be measured directly in an actual online application; hence Table 6 also includes the use of "absolute position" as a feature. We see that, for CRF, the absolute position feature shows an insignificant drop in accuracy as compared to the use of relative position. (However, we do see a significant drop in performance when using this feature with SVM and NB.)

6.3 Using Utterance Dependency

We next combined the inter-utterance dependency features with the BoW features. Since we use the dialogue acts directly in utterance dependency, we first experimented using gold-standard dialogue act labels. We also tested using the dialogue acts which were automatically learned in previous steps.

Table 7 shows performance using both the gold-standard and learned dialogue acts. The different features listed are as follows: *LabelList/L* indicates those corresponding to all utterances in a dialogue preceding the target utterance; *LabelPrev/P* indicates a dialogue act from a previous utterance; *LabelAuthor/A* indicates a dialogue act from a previous utterance by the same author; and *LabelPrev*$_t$*/LabelAuthor*$_t$ indicates the previous utterance(s) and previously same-authored utterance(s) in a turn, respectively. Since the accuracy for SVM and NB using learned labels is similar to that using gold standard labels, for brevity we report the performance for CRF using learned labels only. Results that exceed the BoW accuracy at a level of statistical significance ($p < 0.05$) are boldfaced.

Features	Dialogue Acts			
	Goldstandard			**Learned**
	CRF	HMM	NB	CRF
BoW	.862	.731	.672	.862
BoW+LabelList(L)	.795	.435	.225	.803
BoW+LabelPrev(P)	**.875**	.661	.364	**.876**
BoW+LabelAuthor(A)	**.865**	.633	.559	**.865**
BoW+LabelPrev$_t$(P$_t$)	**.873**	.603	.557	**.873**
BoW+LabelAuthor$_t$(A$_t$)	.862	.587	.535	.851
BoW+L+P	.804	.428	.227	.808
BoW+L+A	.799	.404	.225	.804
BoW+L+P$_t$	.803	.413	.229	.804
BoW+L+A$_t$	.808	.408	.216	.801
BoW+P+A	**.873**	.631	.517	**.869**
BoW+P+P$_t$	**.878**	.579	.539	**.875**
BoW+P+A$_t$	**.871**	.603	.519	**.867**
BoW+A+P$_t$	.847	.594	.519	.849
BoW+A+A$_t$	**.869**	.594	.530	**.871**
BoW+P$_t$+A$_t$	**.871**	.592	.519	**.867**
BoW+L+P+A	.812	.419	.231	.804
BoW+L+P+P$_t$	.816	.423	.229	.812
BoW+L+P+A$_t$	.808	.397	.225	.806
BoW+L+A+P$_t$	.810	.388	.225	.810
BoW+L+A+A$_t$	.812	.415	.216	.801
BoW+L+P$_t$+A$_t$	.810	.375	.205	.816
BoW+P+A+P$_t$	**.875**	.602	.522	**.876**
BoW+P+A+A$_t$	.862	.609	.511	**.864**
BoW+P+P$_t$+A$_t$	**.873**	.594	.515	**.867**
BoW+A+P$_t$+A$_t$	**.865**	.594	.517	**.864**
BoW+L+P+A+P$_t$	.817	.410	.231	.810
BoW+L+P+A+A$_t$	.814	.411	.223	.810
BoW+L+P+P$_t$+A$_t$	.816	.382	.205	.806
BoW+L+A+P$_t$+A$_t$	.812	.406	.203	.808
BoW+P+A+P$_t$+A$_t$	**.865**	.583	.513	**.865**
BoW+L+P+A+P$_t$+A$_t$	.816	.399	.205	.803

Table 7: Accuracy for the different learners with dependency features

Utterance dependency features worked well in combination with CRF only. Individually, *Prev* and *Prev*$_t$ (i.e. BoW+P+P$_t$) helped to achieve higher accuracies, and the *Author* feature was also beneficial. However, *List* decreased the performance, as the flow of dialogues can change, and when a larger history of dialogue acts is included, it tends to introduce noise. Comparing use of gold-standard and learned dialogue acts, the reduction in accuracy was not statistically significant, indicating that we can

Feature	CRF	SVM	NB
C+LabelList	.9557	.4613	.2565
C+LabelPrev	.9649	.6365	.5720
C+LabelAuthor	**.9686**	.6310	.5424
C+LabelPrev$_t$	**.9686**	.5738	.5738
C+LabelAuthor$_t$	.9561	.6125	.5332

Table 8: Accuracy with Structural and Dependency Information: *C* means lemmatized Unigram+Position+Author

achieve high performance on dialogue act classification even with interactively-learned dialogue acts. We believe this demonstrates the robustness of the proposed techniques.

Finally, we tested the combination of features from structural and dependency information. That is, we used a base feature (unigrams with Boolean value), relative position, author information, combined with each of the different dependency features – LabelList, LabelPrev, LabelAuthor, LabelPrev$_t$ and LabelAuthor$_t$.

Table 8 shows the performance when using these combinations, for each dependency feature. As we would expect, CRFs performed well with the combined features since CRFs can incorporate the structural and dependency information; the achieved the highest accuracy of 96.86%.

6.4 Error Analysis and Future Work

Finally, we analyzed the errors of the best-performing feature set (i.e. *BoW+Position+Author+LabelAuthor*). In Table 9, we present a confusion matrix of errors, for CONVENTIONAL_CLOSING (Cl), CONVENTIONAL_OPENING (Op), DOWNPLAYER (Dp), EXPRESSIVE (Ex), NO_ANSWER (No), OPEN_QUESTION (Qu), REQUEST (Rq), RESPONSE_ACK (Ack), STATEMENT (St), THANKS (Ta), YES_ANSWER (Yes), and YESNO_QUESTION (YN). Rows indicate the correct dialogue acts and columns indicate misclassified dialogue acts.

Looking over the data, STATEMENT is a common source of misclassification, as it is the majority class in the data. In particularly, a large number of REQUEST and RESPONSE_ACK utterances were tagged as STATEMENT. We did not include punctuation such as question marks in our feature sets; including this would likely improve results further.

In future work, we plan to investigate methods for automatically cleansing the data to remove typos, and taking account of temporal gaps that can sometimes arise in online chats (e.g. in Table 2, there is a time gap between *C:U22 brb in 1 min* and *C:U23 Thank you for waiting*).

7 Conclusion

We have explored an automated approach for classifying dialogue acts in 1-on-1 live chats in the shopping domain, using bag-of-words (BoW), structural information and utterance dependency features. We found that the BoW features perform remarkably well, with slight improvements when using lemmas rather than words. Including structural and inter-utterance dependency information further improved performance. Of the learners we experimented with, CRFs performed best, due to their ability to natively capture sequential dialogue act dependencies.

sujian@i2r.a-star.edu.sg

Abstract

Event Anaphora Resolution is an important task for cascaded event template extraction and other NLP study. Previous study only touched on event pronoun resolution. In this paper, we provide the first systematic study to resolve event noun phrases to their verbal mentions crossing long distances. Our study shows various lexical, syntactic and positional features are needed for event noun phrase resolution and most of them, such as morphology relation, synonym and etc, are different from those features used for conventional noun phrase resolution. Syntactic structural information in the parse tree modeled with tree kernel is combined with the above diverse flat features using a composite kernel, which shows more than 10% F-score improvement over the flat features baseline. In addition, we employed a twin-candidate based model to capture the pair-wise candidate preference knowledge, which further demonstrates a statistically significant improvement. All the above contributes to an encouraging performance of 61.36% F-score on OntoNotes corpus.

1 Introduction

Anaphora resolution, the task of resolving a given text expression to its referred expression in prior texts, is important for intelligent text processing systems. Most previous works on anaphora resolution aim at object anaphora which both the anaphor and its antecedent are mentions of the same real world object.

In contrast, an event anaphora[1] as defined in (Asher, 1993) is an anaphoric reference to an event, fact, and proposition which is representative of eventuality and abstract objects. Consider the following example:

There has been ***[the first break in the case]****.*
...
The investigation into the attack which crippled the ship took a positive turn when Yemeni investigators ***[discovered]*** *bomb making equipment in a house said to be close to the port where the ship is anchored.*
...
Now that investigators have had ***[their first major break]****, the confidence level here has risen, but U.S. officials still warn a long investigation lies ahead.*

The two anaphors ***[the first break in the case]*** and ***[their first major break]*** in the above example refer to the same event, "*Yemeni investigators* ***[discovered]*** b*omb making equipment.*" Here, we take the main verb of the event, ***[discovered]*** as the representation of this event and the antecedent of the two anaphors.

Event anaphora (both pronouns and noun phrases) contributes a significant proportion in an anaphora corpus. For example, OntoNotes has 19.97% of its entity chains contains at least one verb mention. Event anaphora resolution also provides critical links for cascaded event template extraction. It provides useful information for the further inference in other natural language processing (NLP) tasks such as discourse relation and entailment as well. Consider the following sentences from OntoNotes,

"In northern Iraq, U.S. warplanes ***[hit]*** *targets including a ridge east of Mosul, where Iraqi troops have been entrenched.*
Two F Tomcats ***[struck]*** *the targets.*
After ***[today's air strikes]****, 13 Iraqi soldiers abandoned their posts and surrendered to Kurdish fighters."*

Resolving the event chain ***[hit] - [struck] - [today's air strikes]*** will provide us details about the "*air strike*" event mentioned in different sentences and

[1] The definition according to (Asher, 1993) includes both gerunds (e.g. destruction) and inflectional verbs (e.g. destroying). In our study, we only focus on the inflectional verbs, as the gerunds are well studied in the conventional anaphora resolution systems.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 872–881,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

also provide us a clue for a temporal/causal relation between these two events, *"Two F Tomcats struck the targets"* and *"13 Iraqi soldiers abandoned their posts and surrendered to Kurdish fighters"*.

In (Asher, 1993) chapter 6, a method to resolve the references to abstract entities using discourse representation theory is discussed. However, no computational system was proposed for event anaphora resolution. (Byron, 2002; Müller, 2007; Chen *et al,* 2010) attempted event pronoun resolution. (Byron, 2002) proposed a knowledge deep approach for a much focused domain like trains spoken dialogue addressed in the paper. Their system resolved limited number of verbs with handcraft knowledge of relevant events. Clearly this approach is not suitable for general event anaphora resolution such as in news articles. Besides, there's also no performance report dedicated on event pronoun resolution, thus it's not clear how effective their approach is. (Müller, 2007) proposed a pronoun resolution system using a set of hand-crafted constraints such as "argumenthood" and "right-frontier condition" together with logistic regression model based on corpus counts. Their system targeted only three pronouns namely, *"it", "this"* and *"that"*. The event pronouns are resolved together with object pronouns. This preliminary explorative work only produced 11.94% F-score for event pronoun resolution which demonstrated the difficulties for event anaphora resolution. In our previous work (Chen *et al,* 2010), we proposed an event pronoun resolution system using various flat and structural knowledge. We managed to achieve a F-score of 57.9% on event pronouns. This paper is a significant improvement and extension from our previous one. Besides, (Pradhan, *et.al,* 2007) applied a conventional co-reference[2] resolution system to OntoNotes corpus using the same set of features for object noun phrase (NP) resolution. There is no specific performance reported on event anaphora resolution. According to our investigation elaborated in section 2.2, the event anaphors may not be correctly resolved in general, as majority of these features are inappropriate for event anaphora resolution.

In this paper, we provide the first systematic study to resolve NPs to event verbs. First, we explore various lexical, positional and syntactic features useful for the event NP resolution, which turns out quite different from conventional anaphora resolution except the sentence distance information. Syntactic structural information is further incorporated using a composite kernel. Furthermore, the candidate preference information is employed using a twin-candidate model. Our approach shows encouraging performance, 61.39% F-score on OntoNotes.

The rest of this paper is organized as follows. Section 2 introduces the framework and various features useful for event NP resolution. Section 3 presents the structural syntactic features and kernel functions to incorporate such features. Twin-candidate model is further introduced to capture the preference knowledge. Section 4 presents the experiment results with discussions. Section 5 concludes the paper.

2 The Resolution Framework

Our event NP resolution system adopts the common learning-based framework for object anaphora/co-reference resolution, as employed by (Soon *et al.*, 2001) and (Ng and Cardie, 2002a).

2.1 Training and Testing instance

In this learning framework, a training/testing instance has a form of $fv(candi_i, ana)$ where $candi_i$ is the i^{th} antecedent candidate of an anaphor ana. An instance is labeled as positive if $candi_i$ is the antecedent of ana, or negative if $candi_i$ is not. An instance is associated with a feature vector which records different properties and relations between ana and $candi_i$. These features will be discussed later in the paper.

During training, for each event NP, we will consider the preceding and succeeding verbs as antecedent candidates. The succeeding verbs are included to accommodate the cataphora phenomenon in which an antecedent occurs after its anaphor. A positive instance is formed by pairing the anaphor with its antecedent. And a set of negative instances is formed by pairing the anaphor with each of its candidates other than the antecedent, which follows the same negative instance selection strategy discussed in (Ng and Cardie, 2002a). Based on these generated training instances, we can train a

[2] Co-reference means two expressions denoting the same entity (e.g. "*admit guilty*" – "*confess*") while anaphora means the latter expression requires the earlier one's information for a correct interpretation (e.g. "*confess*" – "*the confession*"). Despite the difference in definitions, they share a similar set of features in resolution models.

binary classifier using any discriminative learning algorithm.

Testing instances are generated in the same manner except that all the preceding and succeeding verbs will be considered as candidates.

2.2 Flat Features

Table 1 gives a partial list of features used in conventional NP anaphora/co-reference resolution which focuses on objects in (Soon *et al*, 2001; Ng and Cardie, 2002b; Yang *et al*, 2003; Luo *et al*, 2004).

However, most of these features are not useful for our task except the shallow positional features. In event NP resolution, we focus on events instead of objects. Thus the features describing object characteristics such as number agreement, gender agreement and name alias will no longer function here. Secondly, our anaphor and antecedent pair consists of a verb and an NP. The difference in word syntactic categories will introduce extra difficulties using the conventional lexical features such as string matching and head matching. Furthermore, the difference in word syntactic categories will cripple the NP characteristic features for half of the pair. Grammatical features such as appositive structure are no long useful as well.

Conventional Features	*Applicable to Event Anaphora Resolution*
Positional Features	
Sentence Distance	Yes
Object Characteristics	
Number Agreement	No
Gender Agreement	No
Name alias	No
Lexical Features	
String Matching	No
Head Phrase Matching	No
Grammar Features	
Appositive Structure	No
NP Characteristics	
Definite / Indefinite NP	Partial
Demonstrative / Non-Demo NP	Partial
NP is a Proper Name	Partial

Table 1: Features for Conventional NP Resolution

Thus we have conducted a study on the effectiveness of potential important features for event NP resolution. They are elaborated in detail in the rest of this section.

- **Morphological Feature**

Morphological feature captures the inflectional and derivational relation between an anaphor and its antecedent candidate. The morphological feature helps to bridge the gap between different word syntactic categories. This feature represents how close the anaphor and a candidate are in their meanings. A candidate with an inflectional or derivational relation with the anaphor is more preferred to be the antecedent. For example, *"confess"* will be a better antecedent choice for *"confession"* comparing to other verbs. WordNet is used as our morphology knowledge source.

- **Synonym Feature**

Synonym feature is also to capture the similarity in meanings between the anaphor and its antecedent candidates. For example, *"assault"* is a preferable candidate for anaphor *"attack"* (in noun category). In the actual resolution, synonyms are generated from the derivational forms of the anaphor and candidates. This is to overcome the gap in word syntactic categories between an anaphor and its candidates. Two lists of synonyms (including synonyms of derivational forms) are generated for the anaphor and its candidate respectively. The synonym feature will be evaluated by comparing the two lists. Feature values include cases as "**B**oth are **I**n the others' synonym **L**ist (**BIL**)", "**O**ne **I**n the other's **L**ist (**OIL**)", "**L**ists are **O**verlapping (**LO**)" and "**L**ists are **M**utually **E**xclusive (**LME**)". These four values are considered as ordinal with a descending order of **BIL**>**OIL**>**LO**>**LME**. Higher order indicates a more similar word meaning between a candidate and the anaphor. WordNet is used during the synonym lists generation.

- **Fixed Pairings**

Fixed pairings are a list of commonly used referential pairs. For example, *"say - information"* and *"announce - statement"* are commonly used in an anaphoric relation. From a linguistics point of view, *"information"* is the patient role in a *"say"* action. The relation between *"say"* and *"information"* is different from the synonymy and morphology relation described previously. Fixed pairing list is automatically generated from training data by memorizing all encountered pairs of the head of NP anaphor and its verb antecedent. It is 1 if a candidate anaphor pair makes a hit in the fixed pairing list and 0 if the pair does not exist in the pairing list.

- **Named Entity Feature**

This feature indicates if a given NP is a named entity. A named entity is recognized using named entity recognizer for object entities representing person, location, organization and etc. An NP marked as person, location and organization is very unlikely to represent an event. This feature provides a strong heuristic to rule out inappropriate candidates.

- **Contextual Information Features**

This group of features measures the similarities and referential relations exist in the contexts of an anaphor and one of its candidates. These features are derived based on the following two intuitions. First, an event is not only represented by its main verb, the related information (e.g. roles of the action) can be extracted from surrounding contexts. Second, when an event is referred in a later occurrence, the related information is likely to reoccur in the contexts as well. Therefore, this group of feature is designed to capture such knowledge. There are two features in this group.

Context Words Similarity

This feature measures similarity between anaphor's contexts and its candidate's context. Stop words (such as *"in", "the"* and etc.) are removed from the contexts before calculating the similarity. The similarity is calculated based on a list of nearby 10 contextual words. The number of common words is used to represent the contextual similarity. Inflectional and derivational forms in the contextual words are considered as match cases.

Co-referential Relation(s) in Contexts

This feature is 1 if at least one object co-referential relation exists between the anaphor's contexts and its candidate's contexts. The idea is still to capture matching roles of action in the two contexts. For example,

> *"**[George W. Bush]**$_1$ **{approved}**$_2$ the new military plan .... **{[The president]**$_1$ **'s decision}**$_2$ agitated various anti-war groups ...".*

By knowing that the ***[George W. Bush]***$_1$ and ***[The president]***$_1$ co-refer with each other, ***{approved}***$_2$ is a preferable candidate for ***{The president's decision}***$_2$ as they share a common attribute value "*president Bush*".

- **NP Antecedent(s) Features**

When an NP co-refers a preceding NP, the original phrase will normally be replaced with a more concise expression which is the anaphor. By using the full expression from the antecedent, we can obtain extra knowledge for the later concise expression. For the antecedent knowledge of NPs, we used the OntoNote gold standard annotations for object co-references. There are 3 features in this group.

Morphological Feature with NP's Antecedent(s)

This feature is evaluated by comparing each of an NP's antecedents with its verb candidates for an inflectional or derivational relation. It is considered as a morphological relation if one of the NP's antecedents is inflectional or derivational to the verb.

Synonym Feature with NP's Antecedent(s)

Similar to the above, the synonym list generated from an NP's co-referential expressions is used to compare with its verb candidate's synonym list. The final feature value is taken to be the highest order as described in the previous section on synonym feature.

Named Entity Feature with NP's Antecedent(s)

Similar to the NP's named entity feature described previously, this feature is used to rule out inappropriate NPs for an event anaphoric relation. Consider the object co-referential expressions *"George W. Bush"* and *"the president"*, the first one will be marked as named entity but not the latter. By using the object NP's co-reference knowledge, we can rule out the inappropriate NP *"the president"* as it refers to an object.

- **Grammatical Role**

This set of feature aims to capture the grammatical roles of the anaphor and its antecedent candidates. The details of this set of features are tabulated in Table 2 below.

NP: *M*	
Sbj_Main	1 if *M* is subject in main clause; else 0.
Sbj_Sub	1 if *M* is subject in sub-clause; else 0.
Obj_Main	1 if *M* is object in main clause; else 0.
Obj_Sub	1 if *M* is object in sub-clause; else 0.
Verb: *V*	
Main	1 if *V* in main clause; else 0.
Sub	1 if *V* in sub-clause; else 0.

Table 2: Features representing Grammatical Roles

- **Positional and NP Characteristics Features**

Positional Features:	***NP:** M**; Verb:** V*
SentDist	# of Sentences between *M* and *V*;
PhraseDist	# of NPs between *M* and *V;*
WordDist	# of words between *M* and *V;*
NP Characteristic Features:	
NP_Def	1 if *M* is definite; else 0;
NP_Demo	1 if *M* is demonstrative; else 0;
NP_First	1 if *M* is the first NP in its sentence;

Table 3: Positional & NP Characteristic Features

A set of positional and NP characteristic features is employed in our resolution system. Positional features extend their counterparts in conventional NP anaphora resolution by incorporating phrase distance and word distance. NP characteristic features are applied to (possible) NP Anaphora. These features are tabulated in Table 3.

3 Incorporating Structural Syntactic Information

A parse tree that covers an event NP and its antecedent could provide us much syntactic information related to the pair. The commonly used syntactic knowledge for anaphora resolution, such as the governing relations, can be directly described by the tree structure. Other syntactic knowledge that may be helpful for anaphora resolution could also be implicitly represented in the parse tree. Such syntactic knowledge can be captured using a convolution tree kernel by comparing the number of common sub-structures in two trees. The implicit syntactic structural knowledge can be further combined with other knowledge through a composite kernel.

Normally, parsing is done on the sentence level. However, in many cases an event NP and its antecedent do not occur in the same sentence. To present their syntactic properties and relations in a single tree structure, we construct a syntax tree for the entire text, by attaching the parse trees of all its sentences to a pseudo upper node. Having obtained the parse tree of a text, we shall consider how to select the appropriate portion of the tree as the structural feature for a given instance. As each instance is related to an event NP and one of its candidates, the structured feature at least should be able to cover both of these two expressions.

3.1 Structural Syntactic Feature

Generally, the more portion of the parse tree is included, the more syntactic information would be provided. But at the same time, the more noisy information that comes from parsing errors and other sources would likely be introduced as well. In our study, we examine three possible structural features that contain different portions of the parse tree:

- **Minimum Expansion Tree**

This feature records the minimal structure covering both the NP and its verb candidate in the parse tree. It only includes the nodes occurring in the shortest path connecting the NP and its candidate, via the nearest commonly commanding node. When the anaphor and its antecedent are from different sentences, we will find a path through a pseudo “TOP” node which links all the parse trees of sentences of a text.

- **Simple Expansion Tree**

Minimum-Expansion could, to some degree, describe the syntactic relationships between an anaphor and its candidate. However, the tree structure surrounding the expression is not taken into consideration. To incorporate such information, feature Simple-Expansion not only contains all the nodes in Minimum-Expansion, but also includes the first-level children of those nodes between the antecedent and anaphor pair except the punctuations. Thus, Simple-Expansion contains a concise representation of surrounding syntax structures.

- **Full Expansion Tree**

This feature focuses on the whole tree structure between the candidate and anaphor. It not only includes all the nodes in Simple-Expansion, but also the nodes (beneath the nearest commanding parent) that cover the words between one candidate and the anaphor. In multi-sentence cases, only sentences containing the anaphors/antecedents are expanded. Such a feature keeps the most information related to the anaphor and candidate pair.

Figure 1 illustrates the differences of three syntactic tree structures. In each expansion tree, the involved sub-tree is shaded in grey with bold fonts and thicker lines.

3.2 Convolution Parse Tree Kernel and Composite Kernel

To capture the structural features in parse tree, we use the convolution tree kernel which is defined in (Collins and Duffy, 2002) and (Moschitti, 2004). Given two trees, the kernel will enumerate all their sub-trees and compute the number of common subtrees. As been proved, the convolution kernel can be efficiently computed in polynomial time on average. The above tree kernel only aims for the structured features. We also need a composite kernel to combine together the structured features and the flat features described in section 2.2. In our study we define the composite kernel as follows:

$$K_{comp}(x_1, x_2) = \frac{K_{tree}(x_1, x_2)}{|K_{tree}(x_1, x_2)|} + \frac{K_{flat}(x_1, x_2)}{|K_{flat}(x_1, x_2)|}$$

where K_{tree} is the convolution tree kernel defined for the structured features, and K_{flat} is the kernel applied to the flat features. Both kernels are divided by their respective length ($|K(x_1, x_2)| =$

$\sqrt{K(x_1,x_1)\cdot K(x_2,x_2)}$) for normalization. The new composite kernel K_{comp}, defined as the summation of normalized K_{tree} and K_{flat}.

3.3 Twin-Candidate Framework using Ranking SVM Model

In a ranking SVM kernel as in (Moschitti *et al,* 2006) for Semantic Role Labeling, two argument annotations (as argument trees) are presented to a ranking SVM model to decide which one is better. In our case, we have a slightly different setting. Instead of two argument trees, we present two syntactic trees from two candidates to the ranking SVM model. The idea is inspired by (Yang, *et.al,* 2005;2008). The intuition behind the twin-candidate model is to capture the information of how much one candidate is more preferred than another. The candidate wins most of the pair-wise comparisons will be selected as the antecedent.

The feature vector for each training instance has a form of $fv = (candi_i, candi_j)$. An instance is positive if $candi_i$ is a better choice than $candi_j$. Otherwise, it is a negative instance. For each feature vector, both tree structural features and flat features are used. Thus each feature vector has a detailed form of $fv = (t_i, t_j, v_i, v_j)$ where t_i and t_j are the parse trees of candidate i and j respectively; v_i and v_j are the flat feature vectors of candidate i and j respectively. Therefore the final SVM kernel is a joint kernel of tree kernel and flat kernel. In the training instances generation, we only generate those instances with one candidate being the antecedent. This follows the same strategy used in (Yang *et al*, 2008) for object anaphora resolution.

In the resolution process, a list of m candidates is extracted as described in section 2.1. A total of $\binom{m}{2}$ instances are generated by pairing-up the m candidates pair-wisely. We used a Round-Robin scoring scheme for antecedent selection. Suppose a SVM output for a testing instance $fv = (candi_i, candi_j)$ is positive, we will give a score 1 for $candi_i$ and -1 for $candi_j$. Similarly, if a SVM output for a testing instance $fv = (candi_i, candi_j)$ is negative, we will give a score -1 for $candi_i$ and 1 for $candi_j$. At last, the candidate with the highest final score is selected as the antecedent[3]. In order to handle a non-event NP encountered during the resolution, we empirically set a threshold to distinguish event anaphoric from non-event anaphoric.

4 Experiments and Discussions

4.1 Experimental Setup

OntoNotes Release 2.0 English corpus is used in our study. It contains 300k words of English newswire data (from the Wall Street Journal) and 200k words of English broadcast news data (from ABC, CNN, NBC, Public Radio International and Voice of America). Table 4 shows nearly 20% of the entity chains annotated in OntoNotes are event chains with at least one verb mention. This significant proportion demonstrates importance of event anaphora resolution in a text processing system.

Chain Type	*Count*	*Percentage*
Event Chain	1235	19.97%
Object Chain	4952	80.03%
Total	6187	100%

Table 4: Percentage of Event Chains in OntoNotes

Our resolution system focuses on the verb-NP links existing in the event chains. In total, we have extracted 977 verb-NP pairs from the OntoNotes corpus. To illustrate the task difficulties, the sentence distance between the anaphor and its antecedent is tabulated below in Table 5. The average sentence distance is 2.97.

SenDist	**0**	**1**	**2**	**3**	**4**	**5**
Count	102	436	143	66	38	69
SenDist	**6**	**7**	**8**	**9**	**10**	**>10**
Count	14	15	11	13	7	63

Table 5: Distribution of Sentence Distance

Due to the long separation distance, the number of candidates during resolution is very large. There are on average 30.49 candidates in training and 583.74 candidates in testing. There is no simple baseline for the task. The most recent verb for each NP will result an F-score almost zero as majority (78.7%) of the NPs are not anaphoric in OntoNotes**.** On the other hand, only 2.31% of verbs in OntoNotes are referred by an NP.

To conduct event NP resolution, an input raw text was preprocessed automatically by a pipeline of NLP components. The NP identification and the predicate-argument extraction were done based on Stanford Parser (Klein and Manning, 2003a;b) with F-score of 86.32% on Penn Treebank corpus. The named entity recognition process uses a SVM based NER trained and tested on ACE 2005 with 92.5(P) 84.3(R) 88.2(F).

[3] In a tie-breaking scenario, the candidate closer to anaphor is selected as antecedent.

4.2 Experiment Results and Discussion

In this section, we will present our experimental results with discussions. The performance measures we used are precision, recall and F-score. All the experiments are done with a 10-folds cross validation to evaluate the performances. In each experiment, the whole corpus is divided into 10 equal sized portions. In each fold, one of the portions is selected to be testing corpus while the remaining 9 are used for training. In case of statistical significance test for differences is needed, a one-tailed, paired-sample Student's t-Test is performed at 0.05 level of significance.

In the first set of experiment results, we are investigating effectiveness of each flat feature. The effectiveness of an individual feature is measured in a leave-one-out manner. That is the performance loss by removing a particular feature from the feature list. The greater performance drop after removing a feature indicates the more effective that feature is for event NP resolution. Table 6 presents the results of this set of experiments.

Feature	Precision	Recall	F-score
ALL	43.87%	42.86%	43.35%
-Morph	8.74%	5.84%	6.99%
-Synonym	7.24%	4.63%	5.64%
-Fixed_Pair	9.94%	5.43%	7.01%
-NE	12.40%	7.04%	8.95%
-Cont_Sim	10.35%	4.63%	6.37%
-Cont_Coref	8.17%	4.43%	5.72%
-Ante_Morph	11.00%	6.64%	8.26%
-Ante_Syn	11.95%	7.04%	8.84%
-Ante_NE	10.36%	7.24%	8.51%
-Gram_Role	11.76%	6.64%	8.45%
-Position	47.47%	32.11%	38.31%
-NP_Def	11.85%	6.04%	7.99%
-NP_Demo	7.85%	4.23%	5.48%
-NP_First	12.98%	7.04%	9.12%

Table 6: Effectiveness of Individual Flat Feature

In Table 6, the first line is performance using all the flat features. Each line below is the performance after removing the feature in that line from the resolution system. The observations in Table 6 suggest that all the features we have discussed in section 2.2 contribute a significant part in the resolution system. For most of the features (except position), the overall system is almost not functioning for the identification of the antecedent. The performance drops for most of features are over 30% in F-score. The conclusion we can draw from these observations is that the flat features are co-dependent to perform the event NP resolution task. Each feature's individual contribution is hard to be separated from the overall performance. All of them are essential parts in the resolution system. Positional feature will incur a 5.04% drop in F-score. Although it is comparatively smaller than the performance drop of the other features, it is still a significant part in the overall performance. Especially, after removing positional features, the recall decreases by 10.75%. Therefore, in the later on experiments, all the flat features are used for event NP resolution.

In the next set of experiments, we are aiming to investigate the individual effectiveness of each knowledge source. Table 7 reports the performance of these experiments.

	Precision	Recall	F-score
Flat	43.87%	42.86%	43.35%
Min-Exp	33.35%	19.95%	24.82%
Simple-Exp	22.22%	8.45%	12.24%
Full-Exp	33.33%	5.63%	9.63%

Table 7: Contribution from Single Knowledge Source

From Table 7, the flat feature set yields a baseline system with 43.35% F-score. By using each tree structure alone, we can only achieve a performance of 24.82% F-score using the minimum-expansion tree. These results indicate that the syntactic structural information alone cannot resolve event anaphoric noun phrases.

As we explained in section 3.2, a composite kernel can be used to combine flat features with syntactic structure feature. The third set of experiments is conducted to verify the performances of various tree structures combined with the flat features. The performances are reported in Table 8.

	Precision	Recall	F-score
Flat	43.87%	42.86%	43.35%
Flat+Min-Exp	65.78%	53.60%	59.01%
Flat+Sim-Exp	62.85%	49.64%	55.43%
Flat+Full-Exp	64.56%	50.77%	56.77%

Table 8: Comparison of Different Combinations

As Table 8 presents, all the three types of structural information improve the overall performance by over 10% in F-score. Obviously, syntactic structural information is very useful for event NP resolution when combined with flat features. Minimum expansion tree performs better than the other two structures. The performance difference in simple expansion and full expansion are statistically insignificant. This result shows that contextual structural information is considered as harmful rather than helpful in an event NP resolution. The minimum structural information covering the anaphor and antecedent is the most helpful as it introduces least noises. This finding is different from the conclusion in conventional pronoun resolution as reported in (Yang *et al,* 2006;) where simple expansion tree performs best. We consider this difference is caused by the distance of separation from the anaphor to its antecedent.

In the last set of experiment, we will present the performance from the twin-candidates based approach in Table 9. The first line is the best performance from single candidate model. The second line is performance using the twin-candidate approach.

Flat+Min-Exp	**Precision**	**Recall**	**F-score**
Single Candidate	65.78%	53.60%	59.01%
Twin-Candidates	66.41%	57.93%	61.36%

Table 9: Single Candidate V.S. Twin Candidates

Comparing to the single candidate model, the recall is significantly improved with similar level of precision. The difference in results is statistically significant. It reinforced our intuition that preference knowledge between two candidates is a contributive information source in event NP resolution.

Last but not least, we have conducted a study on the performance impact of various training data size. 10% from the whole corpus is kept as testing data. The remaining training data is further split into 10 equal sized portions. The experiments are conducted by gradually increase the number of training portion by one at each run. Due to time constraints, the learning curve experiments are conducted using single candidate model as the twin-candidate model is very time consuming. But it should be representative for twin-candidate scenario as well. The resulted learning curve is plotted in Figure 2.

As presented in Figure 2, the training data size increases, the performance curve quickly converged around 0.55 for F-score when the percentage of training data reaches near 50% of training data. After that, F-score still increases as more training data are used. But the rate of increment slows down. It reaches a relatively flat shape near 80% of training data are used. The last 3 experiment results (corresponding to last 3 points plotted in learning curve) are tested for statistical differences. The results show that they are statistically indifferent which suggests a saturated performance is achieved when the training data proportion reaches 80%.

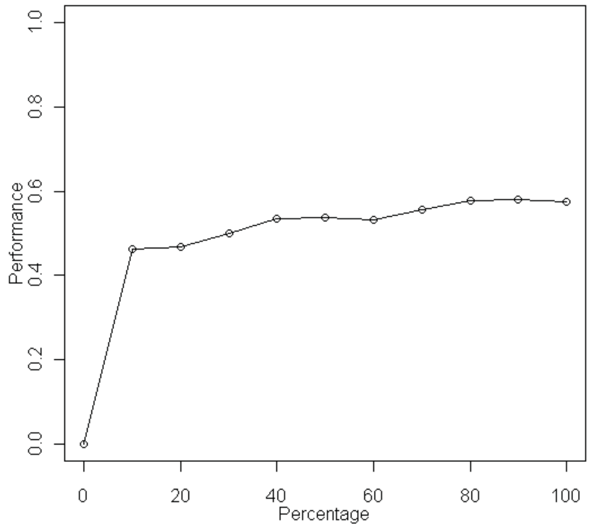

Figure 2: Learning Curve on Various Training Size

This learning curve shows that a satisfactory performance can be achieved with reasonable sized training corpus such as OntoNotes.

5 Conclusion and Future Work

The purpose of this paper is to conduct a systematic study of the event NP resolution, which is not available in the literature. We propose a resolution system utilizing a set of flat positional, lexical, syntactic features and structural syntactic features. The state-of-arts convolution tree kernel is used to extract indicative structural syntactic knowledge. A twin-candidates preference based approach is incorporated to reinforce the resolution system with candidate preference knowledge. Last but not least, we also proposed a study to examine how various training corpus sizes will affect the resolution performance.

In the future, we would like to further explore more semantic information can be employed into the system such as semantic role labels and verb frames.

A Tree Kernel-based Unified Framework for Chinese Zero Anaphora Resolution

Abstract

This paper proposes a unified framework for zero anaphora resolution, which can be divided into three sub-tasks: zero anaphor detection, anaphoricity determination and antecedent identification. In particular, all the three sub-tasks are addressed using tree kernel-based methods with appropriate syntactic parse tree structures. Experimental results on a Chinese zero anaphora corpus show that the proposed tree kernel-based methods significantly outperform the feature-based ones. This indicates the critical role of the structural information in zero anaphora resolution and the necessity of tree kernel-based methods in modeling such structural information. To our best knowledge, this is the first systematic work dealing with all the three sub-tasks in Chinese zero anaphora resolution via a unified framework. Moreover, we release a Chinese zero anaphora corpus of 100 documents, which adds a layer of annotation to the manually-parsed sentences in the Chinese Treebank (CTB) 6.0.

1 Introduction

As one of the most important techniques in discourse analysis, anaphora resolution has been a focus of research in Natural Language Processing (NLP) for decades and achieved much success in English recently (e.g. Soon et al. 2001; Ng and Cardie 2002; Yang et al. 2003, 2008; Kong et al. 2009).

However, there is little work on anaphora resolution in Chinese. A major reason for this phenomenon is that Chinese, unlike English, is a pro-drop language, whereas in English, definite noun phrases (e.g. *the company*) and overt pronouns (e.g. *he*) are frequently employed as referring expressions, which refer to preceding entities. Kim (2000) compared the use of overt subjects in English and Chinese. He found that overt subjects occupy over 96% in English, while this percentage drops to only 64% in Chinese. This indicates the prevalence of zero anaphors in Chinese and the necessity of zero anaphora resolution in Chinese anaphora resolution. Since zero anaphors give little hints (e.g. number or gender) about their possible antecedents, zero anaphora resolution is much more challenging than traditional anaphora resolution.

Although Chinese zero anaphora has been widely studied in the linguistics research (Li and Thompson 1979; Li 2004), only a small body of prior work in computational linguistics deals with Chinese zero anaphora resolution (Converse 2006; Zhao and Ng 2007). Moreover, zero anaphor detection, as a critical component for real applications of zero anaphora resolution, has been largely ignored.

This paper proposes a unified framework for Chinese zero anaphora resolution, which can be divided into three sub-tasks: zero anaphor detection, which detects zero anaphors from a text, anaphoricity determination, which determines whether a zero anaphor is anaphoric or not, and antecedent identification, which finds the antecedent for an anaphoric zero anaphor. To our best knowledge, this is the first systematic work dealing with all the three sub-tasks via a unified framework. Moreover, we release a Chinese zero anaphora corpus of 100 documents, which adds a layer of annotation to the

manually-parsed sentences in the Chinese Treebank (CTB) 6.0. This is done by assigning anaphoric/non-anaphoric zero anaphora labels to the null constituents in a parse tree. Finally, this paper illustrates the critical role of the structural information in zero anaphora resolution and the necessity of tree kernel-based methods in modeling such structural information.

The rest of this paper is organized as follows. Section 2 briefly describes the related work on both zero anaphora resolution and tree kernel-based anaphora resolution. Section 3 introduces the overwhelming problem of zero anaphora in Chinese and our developed Chinese zero anaphora corpus, which is available for research purpose. Section 4 presents our tree kernel-based unified framework in zero anaphora resolution. Section 5 reports the experimental results. Finally, we conclude our work in Section 6.

2 Related Work

This section briefly overviews the related work on both zero anaphora resolution and tree kernel-based anaphora resolution.

2.1 Zero anaphora resolution

Although zero anaphors are prevalent in many languages, such as Chinese, Japanese and Spanish, there only have a few works on zero anaphora resolution.

Zero anaphora resolution in Chinese

Converse (2006) developed a Chinese zero anaphora corpus which only deals with zero anaphora category "-NONE- *pro*" for dropped subjects/objects and ignores other categories, such as "-NONE- *PRO*" for non-overt subjects in non-finite clauses. Besides, Converse (2006) proposed a rule-based method to resolve the anaphoric zero anaphors only. The method did not consider zero anaphor detection and anaphoric identification, and performed zero anaphora resolution using the Hobbs algorithm (Hobbs, 1978), assuming the availability of golden anaphoric zero anaphors and golden parse trees.

Instead, Zhao and Ng (2007) proposed feature-based methods to zero anaphora resolution on the same corpus from Convese (2006). However, they only considered zero anaphors with explicit noun phrase referents and discarded those with split antecedents or referring to events. Moreover, they focused on the sub-tasks of anaphoricity determination and antecedent identification. For zero anaphor detection, a simple heuristic rule was employed. Although this rule can recover almost all the zero anaphors, it suffers from very low precision by introducing too many false zero anaphors and thus leads to low performance in anaphoricity determination, much due to the imbalance between positive and negative training examples.

Zero anaphora resolution in Japanese

Seki et al. (2002) proposed a probabilistic model for the sub-tasks of anaphoric identification and antecedent identification with the help of a verb dictionary. They did not perform zero anaphor detection, assuming the availability of golden zero anaphors. Besides, their model needed a large-scale corpus to estimate the probabilities to prevent them from the data sparseness problem.

Isozaki and Hirao (2003) explored some ranking rules and a machine learning method on zero anaphora resolution. However, they assumed that zero anaphors were already detected and each zero anaphor's grammatical case was already determined by a zero anaphor detector.

Iida et al. (2006) explored a machine learning method for the sub-task of antecedent identification using rich syntactic pattern features, assuming the availability of golden anaphoric zero anaphors.

Sasano et al. (2008) proposed a fully-lexicalized probabilistic model for zero anaphora resolution, which estimated case assignments for the overt case components and the antecedents of zero anaphors simultaneously. However, this model needed case frames to detect zero anaphors and a large-scale corpus to construct these case frames automatically.

For Japanese zero anaphora, we do not see any reports about zero anaphora categories. Moreover, all the above related works we can find on Japanese zero anaphora resolution ignore zero anaphor detection, focusing on either anaphoricity determination or antecedent identification. Maybe, it is easy to detect zero anaphors in Japanese. However, it is out of the scope of our knowledge and this paper.

Zero anaphora resolution in Spanish

As the only work we can find, Ferrandez and Peral (2000) proposed a hand-engineered rule-based method for both anaphoricity determination and antecedent identification. That is, they ignored zero anaphor detection. Besides, they only dealt with zero anaphors that were in the subject position.

2.2 Tree kernel-based anaphora resolution

Although there is no research on tree kernel-based zero anaphora resolution in the literature, tree kernel-based methods have been explored in traditional anaphora resolution to certain extent and achieved comparable performance with the dominated feature-based ones. One main advantage of kernel-based methods is that they are very effective at reducing the burden of feature engineering for structured objects. Indeed, the kernel-based methods have been successfully applied to mine structural information in various NLP techniques and applications, such as syntactic parsing (Collins and Duffy 2001; Moschitti 2004), semantic relation extraction (Zelenko et al. 2003; Zhao and Grishman 2005; Zhou et al. 2007; Qian et al. 2008), and semantic role labeling (Moschitti 2004).

Representative works in tree kernel-based anaphora resolution include Yang et al. (2006) and Zhou et al (2008). Yang et al. (2006) employed a convolution tree kernel on anaphora resolution of pronouns. In particular, a document-level syntactic parse tree for an entire text was constructed by attaching the parse trees of all its sentences to a new-added upper node. Examination of three parse tree structures using different construction schemes (Min-Expansion, Simple-Expansion and Full-Expansion) on the ACE 2003 corpus showed promising results. However, among the three constructed parse tree structures, there exists no obvious overwhelming one, which can well cover structured syntactic information. One problem with this tree kernel-based method is that all the constructed parse tree structures are context-free and do not consider the information outside the sub-trees. To overcome this problem, Zhou et al. (2008) proposed a dynamic-expansion scheme to automatically construct a proper parse tree structure for anaphora resolution of pronouns by taking predicate- and antecedent competitor-related information into consideration. Besides, they proposed a context-sensitive convolution tree kernel to compute the similarity between the parse tree structures. Evaluation on the ACE 2003 corpus showed that the dynamic-expansion scheme can well cover necessary structural information in the parse tree for anaphora resolution of pronouns and the context-sensitive convolution tree kernel much outperformed other tree kernels.

3 Task Definition

This section introduces the phenomenon of zero anaphora in Chinese and our developed Chinese zero anaphora corpus.

3.1 Zero anaphora in Chinese

A zero anaphor is a gap in a sentence, which refers to an entity that supplies the necessary information for interpreting the gap. Figure 1 illustrates an example sentence from Chinese TreeBank (CTB) 6.0 (File ID=001, Sentence ID=8). In this example, there are four zero anaphors denoted as Φi (i=1, 2, …4). Generally, zero anaphors can be understood from the context and do not need to be specified.

A zero anaphor can be classified into either anaphoric or non-anaphoric, depending on whether it has an antecedent in the discourse. Typically, a zero anaphor is non-anaphoric when it refers to an extra linguistic entity (e.g. the first or second person in a conversion) or its referent is unspecified in the context. Among the four anaphors in Figure 1, zero anaphors Φ1 and Φ4 are non-anaphoric while zero anaphors Φ2 and Φ3 are anaphoric, referring to noun phrase "建筑行为/building action" and noun phrase "新区管委会/new district managing committee" respectively.

Chinese zero anaphora resolution is very difficult due to following reasons: 1) Zero anaphors give little hints (e.g. number or gender) about their possible antecedents. This makes antecedent identification much more difficult than traditional anaphora resolution. 2) A zero anaphor can be either anaphoric or non-anaphoric. In our corpus described in Section 3.2, about 60% of zero anaphors are non-anaphoric. This indicates the importance of anaphoricity determination. 3) Zero anaphors are not explicitly marked in a text. This indicates the necessity of zero anaphor detection, which has been largely ignored in previous research and has proved to be difficult in our later experiments.

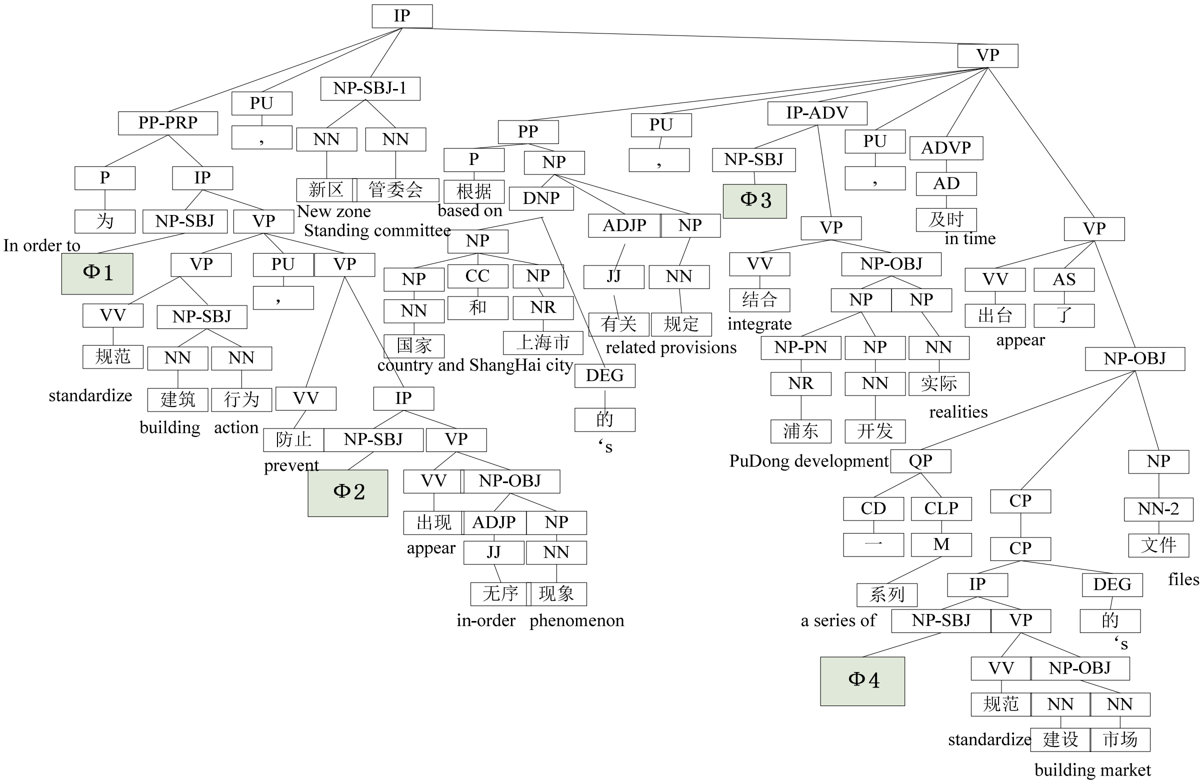

Figure 1: An example sentence from CTB 6.0, which contains four zero anaphors

(the example is : 为规范建筑行为，防止出现无序现象，新区管委会根据国家和上海市的有关规定，结合浦东开发实际，及时出台了一系列规范建设市场的文件/ In order to standardize the building action and prevent the inorder phenomenon, the standing committee of new zone annouced a series of files to standardize building market based on the related provisions of China and Shanghai in time, and the realities of the development of Pudong are considered.)

3.2 Zero anaphora corpus in Chinese

Due to lack of an available zero anaphora corpus for research purpose, we develop a Chinese zero anaphora corpus of 100 documents from CTB 6.0, which adds a layer of annotation to the manually-parsed sentences. Hoping the public availability of this corpus can push the research of zero anaphora resolution in Chinese and other languages.

5	-NONE- *RNR*	Used for right node raising (Cataphora)	0	36
6	Others	Other unknown empty categories	92	92
Total (100 documents, 35089 words)			712	1720

Table 1: Statistics on different categories of zero anaphora (AZA and ZA indicates anaphoric zero anaphor and zero anaphor respectively)

Figure 2 illustrates an example sentence annotated in CTB 6.0, where the special tag “-NONE-” represents a null constituent and thus the occurrence of a zero anaphor. In our developed corpus, we need to annotate anaphoric zero anaphors using those null constituents with the special tag of “-NONE-”.

Table 1 gives the statistics on all the six categories of zero anaphora. Since we do not consider zero cataphora in the current version, we simply redeem them non-anaphoric. It shows that among 1720 zero anaphors, only 712 (about 40%) are anaphoric. This suggests the importance of anaphoricity determination in zero anaphora resolution. Table 3 further shows that, among 712 anaphoric zero anaphors, 598 (84%) are intra-sentential and no anaphoric zero anaphors have their antecedents occurring two sentences before.

Sentence distance	AZAs
0	598
1	114
>=2	0

Table 3 Distribution of anaphoric zero anaphors over sentence distances

Figure 3 shows an example in our corpus corresponding to Figure 2. For a non-anaphoric zero anaphor, we replace the null constituent with “E-***i*** ***NZA***”, where ***i*** indicates the category of zero anaphora, with “1” referring to “-NONE *T*” etc. For an anaphoric zero anaphor, we replace it with “E-***x-y-z-i*** ***AZA***”, where ***x*** indicates the sentence id of its antecedent, ***y*** indicates the position of the first word of its antecedent in the sentence, ***z*** indicates the position of the last word of its antecedent in the sentence, and ***i*** indicates the category id of the null constituent.

4 Tree Kernel-based Framework

This section presents the tree kernel-based unified framework for all the three sub-tasks in zero anaphora resolution. For each sub-task, different parse tree structures are constructed. In particular, the context-sensitive convolution tree kernel, as proposed in Zhou et al. (2008), is employed to compute the similarity between two parse trees via the SVM toolkit SVMLight.

In the tree kernel-based framework, we perform the three sub-tasks, zero anaphor detection, anaphoricity determination and antecedent identification in a pipeline manner. That is, given a zero anaphor candidate Z, the zero anaphor detector is first called to determine whether Z is a zero anaphor or not. If yes, the anaphoricity determiner is then invoked to determine whether Z is an anaphoric zero anaphor. If yes, the antecedent identifier is finally awaked to determine its antecedent. In the future work, we will explore better ways of integrating the three sub-tasks (e.g. joint learning).

4.1 Zero anaphor detection

At the first glance, it seems that a zero anaphor can occur between any two constituents in a parse tree. Fortunately, an exploration of our corpus shows that a zero anaphor always occurs just before a predicate[1] phrase node (e.g. VP). This phenomenon has also been employed in Zhao and Ng (2007) in generating zero anaphor candidates. In particular, if the predicate phrase node occurs in a coordinate structure or is modified by an adverbial node, we only need to consider its parent. As shown in Figure 1, zero anaphors may occur immediately to the left of规范/guide, 防止/avoid, 出现/appear, 根据/according to, 结合/combine, 出台/promulgate, which cover the four true zero anaphors. Therefore, it is simple but reliable in applying above heuristic rules to generate zero anaphor candidates.

Given a zero anaphor candidate, it is critical to construct a proper parse tree structure for tree kernel-based zero anaphor detection. The intuition behind our parser tree structure for zero anaphor detection is to keep the competitive information

[1] The predicate in Chinese can be categorized into verb predicate, noun predicate and preposition predicate. In our corpus, about 93% of the zero anaphors are driven by verb predicates. In this paper, we only explore zero anaphors driven by verb predicates.

about the predicate phrase node and the zero anaphor candidate as much as possible. In particular, the parse tree structure is constructed by first keeping the path from the root node to the predicate phrase node and then attaching all the immediate verbal phrase nodes and nominal phrase nodes. Besides, for the sub-tree rooted by the predicate phrase node, we only keep those paths ended with verbal leaf nodes and the immediate verbal and nominal nodes attached to these paths. Figure 4 shows an example of the parse tree structure corresponding to Figure 1 with the zero anaphor candidate Φ2 in consideration.

During training, if a zero anaphor candidate has a counterpart in the same position in the golden standard corpus (either anaphoric or non-anaphoric), a positive instance is generated. Otherwise, a negative instance is generated. During testing, each zero anaphor candidate is presented to the learned zero anaphor detector to determine whether it is a zero anaphor or not. Besides, since a zero anaphor candidate is generated when a predicate phrase node appears, there may be two or more zero anaphor candidates in the same position. However, there is normally one zero anaphor in the same position. Therefore, we just select the one with maximal confidence as the zero anaphor in the position and ignore others, if multiple zero anaphor candidates occur in the same position.

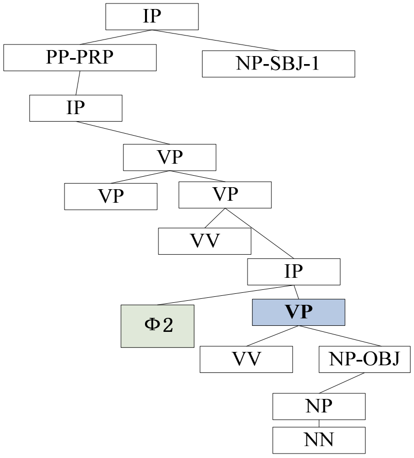

Figure 4: An example parse tree structure for zero anaphor detection with the predicate phrase node and the zero anaphor candidate Φ2 in black

4.2 Anaphoricity determination

To determine whether a zero anaphor is anaphoric or not, we limit the parse tree structure between the previous predicate phrase node and the following predicate phrase node. Besides, we only keep those verbal phrase nodes and nominal phrase nodes. Figure 5 illustrates an example of the parse tree structure for anaphoricity determination, corresponding to Figure 1 with the zero anaphor Φ2 in consideration.

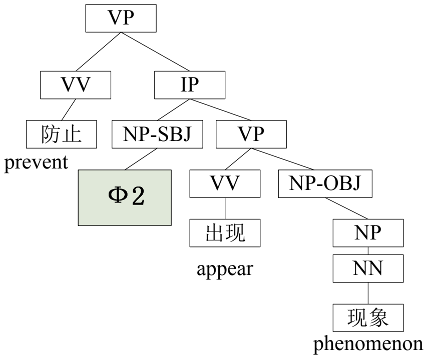

Figure 5: An example parse tree structure for anaphoricity determination with the zero anaphor Φ2 in consideration

4.3 Antecedent identification

To identify an antecedent for an anaphoric zero anaphor, we adopt the Dynamic Expansion Tree, as proposed in Zhou et al. (2008), which takes predicate- and antecedent competitor-related information into consideration. Figure 6 illustrates an example parse tree structure for antecedent identification, corresponding to Figure 1 with the anaphoric zero anaphor Φ 2 and the antecedent candidate “建筑行为/building action” in consideration.

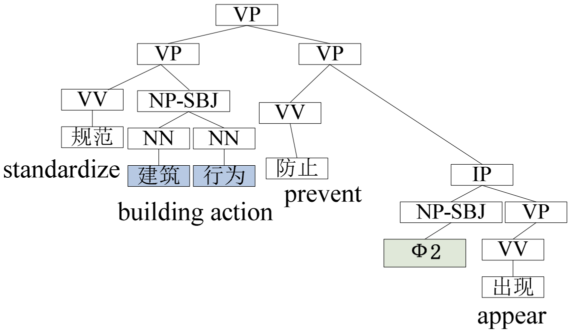

Figure 6: An example parse tree structure for antecedent identification with the anaphoric zero anaphor Φ2 and the antecedent candidate “建筑行为/building action” in consideration

In this paper, we adopt a similar procedure as Soon et al. (2001) in antecedent identification. Besides, since all the anaphoric zero anaphors have their antecedents at most one sentence away, we only consider antecedent candidates which are at most one sentence away. In particular, a document-level parse tree for an entire document is constructed by attaching the parse trees of all its sentences to a new-added upper node, as done in Yang et al. (2006), to deal with inter-sentential ones.

5 Experimentation and Discussion

We have systematically evaluated our tree kernel-based unified framework on our developed Chinese zero anaphora corpus, as described in Section 3.2. Besides, in order to focus on zero anaphor resolution itself and compare with related work, all the experiments are done on golden parse trees provided by CTB 6.0. Finally, all the performances are achieved using 5-fold cross validation.

5.1 Experimental results

Zero anaphor detection

Table 4 gives the performance of zero anaphor detection, which achieves 70.05%, 83.24% and 76.08 in precision, recall and F-measure, respectively. Here, the lower precision is much due to the simple heuristic rules used to generate zero anaphors candidates. In fact, the ratio of positive and negative instances reaches about 1:12. However, this ratio is much better than that (1:30) using the heuristic rule as described in Zhao and Ng (2007). It is also worth to point out that lower precision higher recall is much beneficial than higher precision lower recall as higher recall means less filtering of true zero anaphors and we can still rely on anaphoricity determination to filter out those false zero anaphors introduced by lower precision in zero anaphor detection.

P%	R%	F
70.05	83.24	76.08

Table 4: Performance of zero anaphor detection

Anaphoricity determination

Table 5 gives the performance of anaphoricity determination. It shows that anaphoricity determination on golden zero anaphors achieves very good performance of 89.83%, 84.21% and 86.93 in precision, recall and F-measure, respectively, although useful information, such as gender and number, is not available in anaphoricity determination. This indicates the critical role of the structural information in anaphoricity determination of zero anaphors. It also shows that anaphoricity determination on automatic zero anaphor detection achieves 77.96%, 53.97% and 63.78 in precision, recall and F-measure, respectively. In comparison with anaphoricity determination on golden zero anaphors, anaphoricity determination on automatic zero anaphor detection lowers the performance by about 23 in F-measure. This indicates the importance and the necessity for further research in zero anaphor detection.

	P%	R%	F
golden zero anaphors	89.83	84.21	86.93
zero anaphor detection	77.96	53.97	63.78

Table 5: Performance of anaphoricity determination

Antecedent identification

Table 6 gives the performance of antecedent identification given golden zero anaphors. It shows that antecedent identification on golden anaphoric zero anaphors achieves 88.93%, 68.36% and 77.29 in precision, recall and F-measure, respectively. It also shows that antecedent identification on automatic anaphoricity determination achieves 80.38%, 47.28% and 59.24 in precision, recall and F-measure, respectively, with a decrease of about 8% in precision, about 21% in recall and about 18% in F-measure, in comparison with antecedent identification on golden anaphoric zero anaphors. This indicates the critical role of anaphoricity determination in antecedent identification.

	P%	R%	F
golden anaphoric zero anaphors	88.90	68.36	77.29
anaphoricity determination	80.38	47.28	59.54

Table 6: Performance of antecedent identification given golden zero anaphors

Overall: zero anaphora resolution

Table 7 gives the performance of overall zero anaphora resolution with automatic zero anaphor detection, anaphoricity determination and antecedent identification. It shows that our tree kernel-based framework achieves 77.66%, 31.74% and 45.06 in precision, recall and F-measure. In comparison with Table 6, it shows that the errors caused by automatic zero anaphor detection decrease the performance of overall zero anaphora resolution by about 14 in F-measure, in comparison with golden zero anaphors.

P%	R%	F
77.66	31.74	45.06

Table 7: Performance of zero anaphora resolution

Figure 7 shows the learning curve of zero anaphora resolution with the increase of the number of the documents in experimentation, with the horizontal axis the number of the documents used and the vertical axis the F-measure. It shows that the F-measure is about 42.5 when 20 documents are used in experimentation. This figure increases very fast to about 45 when 50 documents are used while further increase of documents only slightly improves the performance.

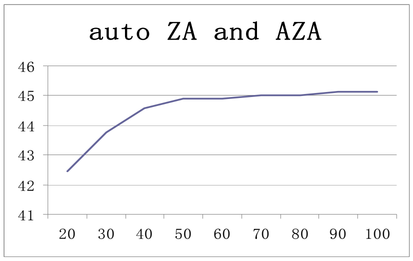

Figure 7: Learning curve of zero anaphora resolution over the number of the documents in experimentation

Table 8 shows the detailed performance of zero anaphora resolution over different sentence distance between a zero anaphor and its antecedent. It is expected that both the precision and the recall of intra-sentential resolution are much higher than those of inter-sentential resolution, largely due to the much more dependency of intra-sentential antecedent identification on the parse tree structures.

Sentence distance	P%	R%	F
0	85.12	33.28	47.85
1	46.55	23.64	31.36
2	-	-	-

Table 8: Performance of zero anaphora resolution over sentence distances

Table 9 shows the detailed performance of zero anaphora resolution over the two major zero anaphora categories, "-NONE- *PRO*" and "-NONE- *pro*". It shows that our tree kernel-based framework achieves comparable performance on them, both with high precision and low recall. This is in agreement with the overall performance.

ID	Category	P%	R%	F
3	-NONE- *PRO*	79.37	34.23	47.83
4	-NONE- *pro*	77.03	30.82	44.03

Table 9: Performance of zero anaphora resolution over major zero anaphora categories

5.2 Comparison with previous work

As a representative in Chinese zero anaphora resolution, Zhao and Ng (2007) focused on anaphoricity determination and antecedent identification using feature-based methods. In this subsection, we will compare our tree kernel-based framework with theirs in details.

Corpus

Zhao and Ng (2007) used a private corpus from Converse (2006). Although their corpus contains 205 documents from CBT 3.0, it only deals with the zero anaphors under the zero anaphora category of "-NONE- *pro*" for dropped subjects/objects. Furthermore, Zhao and Ng (2007) only considered zero anaphors with explicit noun phrase referents and discarded zero anaphors with split antecedents (i.e. split into two separate noun phrases) or referring to entities. As a result, their corpus is only about half of our corpus in the number of zero anaphors and anaphoric zero anaphors. Besides, our corpus deals with all the types of zero anaphors and all the categories of zero anaphora except zero cataphora.

Method

Zhao and Ng (2007) applied feature-based methods on anaphoricity determination and antecedent identification with most of features structural in nature. For zero anaphor detection, they used a very simple heuristic rule to generate zero anaphor candidates. Although this rule can recover almost all the zero anaphors, it suffers from very low precision by introducing too many false zero anaphors and thus may lead to low performance in anaphoricity determination, much due to the imbalance between positive and negative training examples with the ratio up to about 1:30.

In comparison, we propose a tree kernel-based unified framework for all the three sub-tasks in zero anaphora resolution. In particular, different parse tree structures are constructed for different sub-tasks. Besides, a context sensitive convolution tree kernel is employed to directly compute the similarity between the parse trees.

For fair comparison with Zhao and Ng (2007), we duplicate their system and evaluate it on our developed Chinese zero anaphora corpus, using the same J48 decision tree learning algorithm in Weka and the same feature sets for anaphoricity determination and antecedent identification.

Table 10 gives the performance of the feature-based method, as described in Zhao and Ng (2007), in anaphoricity determination on our developed corpus. In comparison with the tree kernel-based method in this paper, the feature-based method performs about 16 lower in F-measure, largely due to the difference in precision (63.61% vs 89.83%), when golden zero anaphors are given. It also shows that, when our tree kernel-based zero anaphor detector is employed [2], the feature-based method gets much lower precision with a gap of about 31%, although it achieves slightly higher recall.

	P%	R%	F
golden zero anaphors	63.61	79.71	70.76
zero anaphor detection	46.17	57.69	51.29

Table 10: Performance of the feature-based method (Zhao and Ng 2007) in anaphoricity determination on our developed corpus

	P%	R%	F
golden anaphoric zero anaphors	77.45	51.97	62.20
golden zero anaphpors and feature-based anaphoricity determination	75.17	29.69	42.57
overall: tree kernel-based zero anaphor detection and feature-based anaphoricity determination	70.67	23.64	35.43

Table 11: Performance of the feature-based method (Zhao and Ng 2007) in antecedent identification on our developed corpus

Table 11 gives the performance of the feature-based method, as described in Zhao and Ng (2007), in antecedent identification on our developed corpus. In comparison with our tree kernel-based method, it shows that 1) when using golden anaphoric zero anaphors, the feature-based method performs about 11%, 17% and 15 lower in precision, recall and F-measure, respectively; 2) when golden zero anaphors are given and feature-based anaphoricity determination is applied, the feature-based method performs about 5%, 18% and 17 lower in precision, recall and F-measure, respectively; and 3) when tree kernel-based zero anaphor detection and feature-based anaphoricity determination are applied, the feature-based method performs about 7%, 8% and 10 lower in precision, recall and F-measure, respectively.

In summary, above comparison indicates the critical role of the structural information in zero anaphora resolution, given the fact that most of features in the feature-based methods in Zhao and Ng (2007) are also structural, and the necessity of tree kernel methods in modeling such structural information, even if more feature engineering in the feature-based methods may improve the performance to a certain extent.

6 Conclusion and Further Work

This paper proposes a tree kernel-based unified framework for zero anaphora resolution, which can be divided into three sub-tasks: zero anaphor detection, anaphoricity determination and antecedent identification.

The major contributions of this paper include: 1) We release a wide-coverage Chinese zero anaphora corpus of 100 documents, which adds a layer of annotation to the manually-parsed sentences in the Chinese Treebank (CTB) 6.0. 2) To our best knowledge, this is the first systematic work dealing with all the three sub-tasks in Chinese zero anaphora resolution via a unified framework. 3) Employment of tree kernel-based methods indicates the critical role of the structural information in zero anaphora resolution and the necessity of tree kernel methods in modeling such structural information.

In the future work, we will systematically evaluate our framework on automatically-generated parse trees, construct more effective parse tree structures for different sub-tasks of zero anaphora resolution, and explore joint learning among the three sub-tasks.

Besides, we only consider zero anaphors driven by a verb predicate phrase node in this paper. In the future work, we will consider other situations. Actually, among the remaining 7% zero anaphors, about 5% are driven by a preposition phrase (PP) node, and 2% are driven by a noun phrase (NP) node. However, our preliminary experiments show that simple inclusion of those PP-driven and NP-driven zero anaphors will largely increase the imbalance between positive and negative instances, which significantly decrease the performance.

Finally, we will devote more on further developing our corpus, with the ultimate mission of annotating all the documents in CBT 6.0.

[2] We do not apply the simple heuristic rule, as adopted in Zhao and Ng (2007), in zero anaphor detection, due to its much lower performance, for fair comparison on the other two subtsaks..

Abstract

This paper proposes a method for automatically inserting commas into Japanese texts. In Japanese sentences, commas play an important role in explicitly separating the constituents, such as words and phrases, of a sentence. The method can be used as an elemental technology for natural language generation such as speech recognition and machine translation, or in writing-support tools for non-native speakers. We categorized the usages of commas and investigated the appearance tendency of each category. In this method, the positions where commas should be inserted are decided based on a machine learning approach. We conducted a comma insertion experiment using a text corpus and confirmed the effectiveness of our method.

1 Introduction

In Japanese sentences, commas are inserted to mark word boundaries that might be otherwise unclear because Japanese is a non-segmented language. They are also inserted at sharp semantic boundaries to improve the readability of a sentence. While there is a tendency about the positions where commas should be inserted in a Japanese sentence, there is no clear standard for these positions. Therefore, it is hard for non-natives of Japanese such as foreign students to insert commas properly, and the method for automatic comma insertion is required to support sentence generation by such people. In addition, this method is expected to be useful for improving readability of texts generated by automatic speech recognition or machine translation.

This paper proposes a method for automatically inserting commas into Japanese texts. There are several usages of commas, and the positions to insert commas depend on these usages. Therefore, we grouped the usages of commas into nine categories, and investigated the appearance tendency for each category to find the effective features of machine learning by using Japanese newspaper articles. Based on the analysis of comma positions, our method decides whether or not to insert a comma at each *bunsetsu*[1] boundary in an input sentence by machine learning.

We conducted an experiment on comma insertion using the Kyoto Text Corpus (Kurohashi and Nagao, 1998), and obtained higher recall and precision than those of the baseline, leading us to confirm the effectiveness of our method.

This paper is organized as follows: The next section presents related works. Section 3 gives preliminary analyses. Section 4 explains how our comma insertion method works. An experiment and discussions are presented in Sections 5 and 6, respectively.

2 Related Works

There have been many investigations on comma insertion into output texts of speech recognition systems to improve the readability (Christensen et al., 2001; Kim and Woodland, 2001; Liu et al., 2006; Shimizu et al., 2008). Their methods insert commas using pause information of speakers, based on the idea that a point at which a speaker takes a breath partly corresponds to a point where a comma is inserted. However, since pause information cannot be obtained from texts, we cannot use this approach because our targets are written texts.

In addition, there have been some investigations

[1] *Bunsetsu* is a linguistic unit in Japanese that roughly corresponds to a basic phrase in English. A bunsetsu consists of one independent word and zero or more ancillary words.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 892–901,
MIT, Massachusetts, USA, 9-11 October 2010.

on comma insertion into non-Japanese written texts (White and Rajkumar, 2008; Guo et al., 2010). In Japanese, there are several usages of commas, and some usages are specific to Japanese due to its linguistic nature. Therefore, just adopting the above mentioned methods, which have been developed to process non-Japanese texts, is not sufficient to enable high-quality comma insertion into Japanese sentences. Development of a method based on the detailed analysis of Japanese commas is required.

Furthermore, there have been some investigations on comma insertion into Japanese written texts (Hayashi, 1992; Suzuki et al., 1995). These investigations have adopted rule-based methods. However, the number of their rules is not necessarily sufficient, and no quantitative evaluation has been performed.

3 Analyses on Comma Usages

There have been several discussions on commas, including the draft of "Kutou-hou (punctuation)" made by Archives Division, Minister's Secretariat, Japanese Ministry of Education, Science and Culture in 1906. There are several usages of commas, and depending on the usage, the types of positions where commas are inserted are different. First, we examined some previous publications on commas (Honda, 1982; Inukai, 2002; Shogakukan's editiorial department, 2007). Based on the results of the examination, we classified the usages of commas into nine categories shown in Table 1. Here, commas in Japanese sentences and commas in English sentences have some common roles. In Japanese sentences, some commas have the same roles as commas in English sentences, but some commas have roles specific to Japanese due to its linguistic nature such as "Japanese is a non-segmented language" or "Japanese has *kanji* characters and *katakana* characters."

Table 1: Categorization of usages of commas

#	usage of comma
1	commas between clauses
2	commas indicating clear dependency relations
3	commas for avoiding reading mistakes and reading difficulty
4	commas indicating the subject
5	commas inserted after a conjunction or adverb at the beginning of a sentence
6	commas inserted between parallel words or phrases
7	commas inserted after an adverbial phrase to indicate time
8	commas emphasizing the adjacent word
9	other

Table 2: Size of the analysis data

sentences	11,821
bunsetsus	117,501
characters	503,970
commas	16,595
characters per sentence	42.63

In our study, positions where a comma should be inserted are detected by using machine learning. We investigated the Kyoto Text Corpus version 4.0 (Kurohashi and Nagao, 1998) to find the effective features. The Kyoto Text Corpus is a collection of Japanese articles of Mainichi newspaper. We used the articles on January 1st and from January 3rd to 11th in 1995 as the analysis data. Table 2 shows the size of the data. The data had been manually annotated with information on morphological analysis, bunsetsu segmentation and dependency[2] analysis. Clause boundaries were detected by the clause boundary detection program CBAP (Kashioka and Maruyama, 2004).

Out of all the inserted commas, only 1.43% were inserted at positions which were not bunsetsu boundaries. Therefore, we analyzed only commas inserted at bunsetsu boundaries. Of 105,680 bunsetsu boundaries, commas were inserted at 16,357 bunsetsu boundaries, that is, the rate of comma insertion was 15.48%. In the following sections, we focus on morphemes, clause boundaries, dependency relation and the number of characters between commas, and investigate their relations with commas.

3.1 Commas between Clauses

If a sentence consists of several clauses, inserting a comma between clauses makes clear the sentence

[2] A dependency in a Japanese sentence is a modification relation in which a modifier bunsetsu depends on a modified bunsetsu. That is, the modifier bunsetsu and the modified bunsetsu work as a modifier and a modifyee, respectively.

Table 3: Rates of comma insertion according to the clause boundary type

type of clause boundary	ratio of comma insertion (%)	
topicalized element-*wa*	16.94	(1,446/8,536)
adnominal clause	0.72	(43/5,960)
continuous clause	84.57	(2,685/3,175)
compound clause-*te*	23.31	(394/1,690)
quotational clause	4.40	(74/1,680)
supplement clause	17.53	(245/1,398)
discourse marker	60.13	(650/1,081)
compound clause-*ga*	93.85	(946/1,008)
compound clause-*de*	84.52	(606/717)
condition clause-*to*	81.66	(423/518)

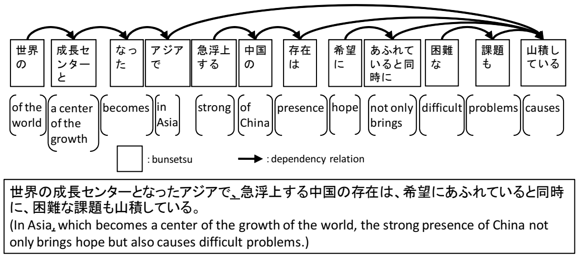
structure. Therefore, a clause boundary is considered to be a strong candidate of a position where a comma is inserted. For example, in the following sentence[3]:

- 国連による対イラク制裁解除に向け、関係の深い仏に一層の協力を求めるのが狙いとみられる。(Toward lifting the sanctions imposed on Iraq by United Nations, the aim seems to be to request further cooperation from France, which has close ties to Iraq.)

a comma is inserted at the clause boundary right after the continuous clause "国連による対イラク制裁解除に向け (Toward lifting the sanctions imposed on Iraq by United Nations)." Like this example, the same usage of commas is seen in English as well.

In the analysis data, there existed 29,278 clause boundaries excluding sentence breaks. Among them, commas were inserted at 8,805 positions (30.01%). The rate is higher than that of bunsetsu boundaries. This indicates that commas tend to be inserted at clause boundaries.

We investigated the rate of comma insertion about 114 types[4] of clause boundaries. Table 3 shows the top 10 clause boundary types according to the occurrence frequency, and the rates of comma insertion. In cases of "continuous clause" and "compound clause-*de*," the rates were higher than 84%. On the other hand, in cases of "adnominal clause" and "quotational clause," the rates were lower than 5%. This means that the likelihoods of comma insertion are different according to the clause boundary type.



世界の成長センターとなったアジアで、急浮上する中国の存在は、希望にあふれていると同時に、困難な課題も山積している。
(In Asia, which becomes a center of the growth of the world, the strong presence of China not only brings hope but also causes difficult problems.)

Figure 1: Commas making clear dependency relations

3.2 Commas and Dependency Structure

Commas have a role to make dependency relations clearer. Commas tend to be inserted right after a bunsetsu that depends on a distant bunsetsu. In Figure 1, although the bunsetsu "アジアで (in Asia)" depends on the bunsetsu "山積している (causes)," if the comma right after the bunsetsu "アジアで (in Asia)" is not inserted, the readers might mistakenly understand that the bunsetsu "アジアで (in Asia)" depends on the next bunsetsu "急浮上する (strong)." To avoid the mistake, the comma is inserted.

In the analysis data, there existed 66,984 bunsetsus which depend on the next bunsetsu. Among the bunsetsu boundaries right after them, 2,302 (3.44%) were the positions where a comma was inserted. On the other hand, in the case of a bunsetsu boundary right after a bunsetsu which does not depend on the next bunsetsu, the rate of comma insertion was 36.32% (14,055/38,696).

In addition, when the modifyee of a bunsetsu is located outside the clause containing the bunsetsu, i.e. to the right of the clause end, commas are considered to be more frequently inserted right after the bunsetsu because such bunsetsu causes more complex dependency structure. The rate of comma insertion right after such bunsetsu is 54.24%.

[3] We underlined commas which we mentioned in the example and the corresponding positions in the translation of the example.

[4] In our research, we used the types of clause boundaries defined by the Clause Boundary Annotation Program (Kashioka and Maruyama, 2004).

3.3 Commas for Avoiding Reading Mistakes and Reading Difficulty

Although, unlike English, Japanese is a non-segmented language, word boundaries are easy to detect because Japanese has three types of characters; *hiragana* characters, *katakana* characters, and *kanji* characters. However, if the same types of characters appear sequentially, readers may make a reading mistake or feel difficulty in reading them. To avoid such mistakes and difficulty, there is a usage of commas specific to Japanese.

In the following example, a comma is inserted between two sequentially appearing words "焼却 (burned)" and "灰 (ashes)" both of which consist of only *kanji* characters.

- 川崎さんの遺体を群馬県利根郡片品村花咲の知人宅に運んで焼却、灰を同村の山林に捨てたことを認める内容という。(He seemed to acknowledge that he had carried the corpse of Mr. Kawasaki to an acquaintance in Hanasaki, Katashina-mura, Tone-gun, Gunma Prefecture, burned it_and abandoned its ashes in the mountain forest in Katashina-mura.)

The comma was inserted because if there was no comma, the word boundary would become unclear and reading difficulty would be caused. Among 2,409 bunsetsu boundaries over which *kanji* characters appeared sequentially, commas were inserted at 2,188 (90.83%) bunsetsu boundaries. In the case of *katakana* characters, the rate was 97.69% (211/216). Commas tend to be inserted at most bunsetsu boundaries if *kanji* characters or *katakana* characters sequentially appear over a boundary.

3.4 Commas Indicating the Subject

Commas are considered to be inserted right after a bunsetsu that represents the subject of a sentence. For example, in Figure 2, a comma is inserted right after the bunsetsu "戦火は (war)" to indicate that the bunsetsu is the subject of the sentence. Here, we pay attention to the clause boundary of the type "topicalized element-*wa*." The rate that commas were inserted at the clause boundaries "topicalized element-*wa*" was 16.94% (1,446/8,536). This rate is almost the same as that of bunsetsu boundaries. On the other hand, the commas inserted at the clause boundaries "topicalized element-*wa*" accounted for 8.84% (1,446/16,357) of all the inserted commas.

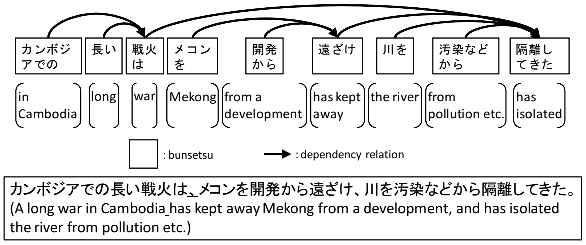


Figure 2: Comma insertion at the clause boundary "topicalized element-*wa*"

In the case of the clause boundary "topicalized element-*wa*" right after a bunsetsu which does not depend on the next bunsetsu (e.g., the bunsetsu "戦火は (war)" in Figure 2), the rate of comma insertion was 20.71% (1,426/6,886). The rate is higher than that of all the clause boundaries "topicalized element-*wa*." This shows that commas tend to be especially inserted at the "topicalized element-*wa*" right after bunsetsus which do not depend on the next bunsetsu.

3.5 Commas after Conjunction or Adverb

Commas tend to be inserted right after a conjunction or an adverb located at the beginning of a sentence. These commas correspond to English commas which are inserted right after a word such as "however" and "furthermore" located at the beginning of a sentence.

- しかし、私はそれに同感する気持ちになれない。(However, I do not feel like agreeing on it.)

In the analysis data, there existed 695 bunsetsus whose rightmost morpheme is a conjunction and which are located at the beginning of a sentence. Among them, commas were inserted right after 498 (71.65%) bunsetsus. In the case of bunsetsus whose rightmost morpheme is an adverb, the rate was 30.97% (140/452).

3.6 Commas Inserted between Parallel Words or Phrases

Commas have a function which makes clear separation between parallel words or phrases. The following example shows commas separating parallel nouns.

- むしろ地球規模の環境、人口、食糧など広範に国連の果たさなければならない役割は大きい。(The United Nations should play a lot of roles in a broad range of fields, such as the global environment, population, and food.)

In this example, commas are inserted to separate parallel nouns "環境 (environment)," "人口 (population)" and "食糧 (food)". In English, there are commas which perform the same role. In fact, commas were inserted between "environment" and "population" and between "population" and "food" in the translation of the above example. When bunsetsus whose rightmost morpheme is a noun appear sequentially, the rate of comma insertion between such bunsetsus is 59.39% (3,330/5,607).

Also, commas are inserted to separate parallel phrases. In the following example,

- メニューは前夜、首相が何を食べたかを調べて同じ献立を避けたり、和食と洋食のバランスを考えたりして決める。(The menu is decided by avoiding the menu the Prime Minister ate on the previous night, and by considering the balance between the Japanese food and the European food.)

a comma is inserted right after the bunsetsu "避けたり (avoiding)" to make clear separation between the parallel phrases "同じ献立を避けたり (by avoiding the menu)" and "和食と洋食のバランスを考えたりして (by considering the balance between the Japanese food and the European food)." The rate of comma insertion between two parallel phrases is 79.89% (751/940). This is much higher than that of bunsetsu boundaries, indicating that commas tend to be inserted when phrases are paralleled.

3.7 Number of Characters between Commas

If there are too many commas at a short distance, the sentence becomes hard to read. Therefore, the number of characters between commas is expected to be not too small. Also, because a long sequence of characters without a comma is generated if the distance between commas is very long, the occurrence frequency of such sequences of characters is considered to be low.

We investigated the number of characters between commas and its occurrence frequency. Figure 3 shows the results of investigation. When the number of characters between commas is either large or small, the occurrence frequency is low.

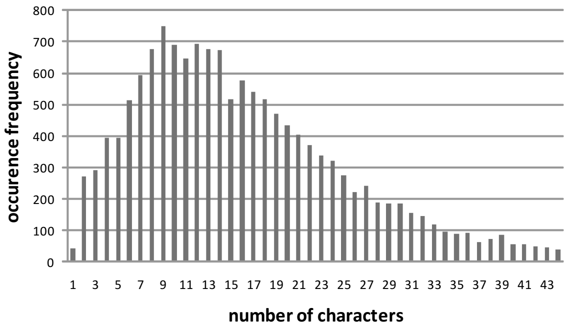

Figure 3: Number of characters between commas and its occurrence frequency

4 Comma Insertion Method

In our method, a sentence, on which morphological analysis, bunsetsu segmentation, clause boundary analysis and dependency analysis have been performed, is considered the input. Our method decides whether or not to insert a comma at each bunsetsu boundary in an input sentence. Based on the analysis results in Section 3, our method adopts the bunsetsu boundaries as candidate positions where a comma is inserted. Our method identifies the most appropriate combination among all combinations of positions where a comma can be inserted, by using the probabilistic model. In this paper, input sentences which consist of n bunsetsus are represented by $B = b_1 \cdots b_n$, and the results of comma insertion by $R = r_1 \cdots r_n$. Here, r_i is 1 if a comma is inserted right after bunsetsu b_i, and 0 otherwise. We indicate the j-th sequence of bunsetsus created by dividing an input sentence into m sequences as $L_j = b^j_1 \cdots b^j_{n_j} (1 \leq j \leq m)$, and then, $r^j_k = 0$ if $1 \leq k < n_j$, and $r^j_k = 1$ if $k = n_j$.

4.1 Probabilistic Model for Comma Insertion

When an input sentence B is provided, our method identifies the comma insertion R that maximizes the conditional probability $P(R|B)$. Assuming that whether or not to insert a comma right after a bunsetsu is independent of other commas except the

Table 4: Features used for the maximum entropy method

morphological information	the rightmost independent morpheme, i.e. head word, (part-of-speech and inflected form) and rightmost morpheme (part-of-speech) of a bunsetsu b_k^j
	the rightmost morpheme (a surface form) of b_k^j if the rightmost morpheme is a particle
	the first morpheme (part-of-speech) of b_{k+1}^j
commas inserted between clauses	whether or not a clause boundary exists right after b_k^j
	type of a clause boundary right after b_k^j if there exists a clause boundary
commas indicating clear dependency relations	whether or not b_k^j depends on the next bunsetsu
	whether or not b_k^j depends on a bunsetsu located after the final bunsetsu of the clause including the next bunsetsu of b_k^j
	whether or not b_k^j is depended on by the bunsetsu located right before it
	whether or not the dependency structure of a sequence of bunsetsus between b_k^j and b_1^j is closed
commas avoiding reading mistakes and reading difficulty	whether or not both the rightmost morpheme of b_k^j and first morpheme of b_{k+1}^j are *kanji* characters
	whether or not both the rightmost morpheme of b_k^j and first morpheme of b_{k+1}^j are *katakana* characters
commas indicating the subject	whether or not there exists a clause boundary "topicalized element-*wa*" right after b_k^j and b_k^j depends on the next bunsetsu
	whether or not there exists a clause boundary "topicalized element-*wa*" right after b_k^j and the string of characters right before b_k^j is "では (*dewa*)"
	the number of characters in a phrase indicating the subject[5] if there exists a clause boundary "topicalized element-*wa*" right after b_k^j
	whether or not a clause boundary "topicalized element-*wa*" exists right after b_k^j and a bunsetsu whose rightmost morpheme is a verb depends on the modified bunsetsu of b_k^j
commas inserted after a conjunction or adverb at the beginning of a sentence	whether or not b_k^j appears at the beginning of a sentence and its rightmost morpheme is a conjunction
	whether or not b_k^j appears at the beginning of a sentence and its rightmost morpheme is an adverb
commas inserted between parallel words or phrases	whether or not both the rightmost morphemes of b_k^j and b_{k+1}^j are nouns
	whether or not a predicate at the sentence end is depended on by b_k^j whose rightmost independent morpheme is a verb and by any of the bunsetsus which are located after b_k^j and of which the rightmost independent morpheme is a verb
number of characters from b_1^j to b_k^j	one of the following 4 categories if the number of characters from b_1^j to b_k^j is found there ([num = 1], [2 ≤ num ≤ 3], [4 ≤ num ≤ 21], [22 ≤ num])

one appearing immediately before that bunsetsu, $P(R|B)$ can be calculated as follows:

$$\begin{aligned}
& P(R|B) \\
=& P(r_1^1=0,\cdots,r_{n_1-1}^1=0,r_{n_1}^1=1,\cdots, \\
& \qquad r_1^m=0,\cdots,r_{n_m-1}^m=0,r_{n_m}^m=1|B) \\
\cong & P(r_1^1=0|B)\times\cdots \\
& \times P(r_{n_1-1}^1=0|r_{n_1-2}^1=0,\cdots,r_1^1=0,B) \\
& \times P(r_{n_1}^1=1|r_{n_1-1}^1=0,\cdots,r_1^1=0,B)\times\cdots \\
& \times P(r_1^m=0|r_{n_{m-1}}^{m-1}=1,B)\times\cdots \\
& \times P(r_{n_m-1}^m=0|r_{n_m-2}^m=0,\cdots,r_1^m=0,r_{n_{m-1}}^{m-1}=1,B) \\
& \times P(r_{n_m}^m=1|r_{n_m-1}^m=0,\cdots,r_1^m=0,r_{n_{m-1}}^{m-1}=1,B)
\end{aligned} \tag{1}$$

where $P(r_k^j = 1|r_{k-1}^j = 0, \cdots, r_1^j = 0, r_{n_{j-1}}^{j-1} = 1, B)$ is the probability that a comma is inserted right after a bunsetsu b_k^j when the sequence of bunsetsus B is provided and the position of j-th comma is identified. Similarly, $P(r_k^j = 0|r_{k-1}^j = 0, \cdots, r_1^j = 0, r_{n_{j-1}}^{j-1} = 1, B)$ is the probability that a comma is not inserted right after a bunsetsu b_k^j. These probabilities are estimated by the maximum entropy method. The result R which maximizes the conditional probability $P(R|B)$ is regarded as the most appropriate result of comma insertion, and calculated by dynamic programming.

4.2 Features on Maximum Entropy Method

To estimate $P(r^j_k = 1 | r^j_{k-1} = 0, \cdots, r^j_1 = 0, r^{j-1}_{n_{j-1}} = 1, B)$ and $P(r^j_k = 0 | r^j_{k-1} = 0, \cdots, r^j_1 = 0, r^{j-1}_{n_{j-1}} = 1, B)$ by the maximum entropy method, we used the features in Table 4 based on the analysis described in Section 3.

5 Experiment

To evaluate the effectiveness of our method, we conducted an experiment using a Japanese text corpus.

5.1 Outline of Experiment

As the experimental data, we used the newspaper articles in the Kyoto Text Corpus version 4.0 (Kurohashi and Nagao, 1998). We used the articles from January 14th to 17th as the test data. The training data is same as the analysis data. Table 5 shows the size of the test data. Here, we used the maximum entropy method tool (Le, 2008) with the default options except “-i 2000.”

In the evaluation, we obtained the recall, the precision and their harmonic mean, i.e., F-measure. The recall and precision are respectively defined as follows.

$$recall = \frac{\#\ of\ correctly\ inserted\ commas}{\#\ of\ commas\ in\ the\ correct\ data}$$

$$precision = \frac{\#\ of\ correctly\ inserted\ commas}{\#\ of\ inserted\ commas}$$

In our research, to realize automatic comma insertion with high quality, we analyzed each usage of commas and decided the features for the ME method based on the analysis. To confirm the effectiveness of our features, we established the baseline method as a comparative method whereby commas are inserted by the ME method in which only simple morphological information is used. The baseline method uses the morphological information in Table 4 and the information of the rightmost morpheme (a surface form) of a bunsetsu as features.

5.2 Experimental Results

Table 6 shows the experimental results of the baseline and our method. The recall and precision were 69.13% and 84.13% respectively, and we confirmed that our method had higher performance than the baseline method. The percentage of sentences wherein all commas were correctly inserted was 55.81%.

Table 5: Size of test data

sentences	4,659
bunsetsus	46,511
characters	198,899
commas	6,549
characters per sentence	42.69

Table 6: Experimental results

	recall	precision	F-measure
our method	69.13% (4,527/6,549)	84.13% (4,527/5,381)	75.90
baseline	51.38% (3,365/6,549)	70.90% (3,365/4,746)	59.58

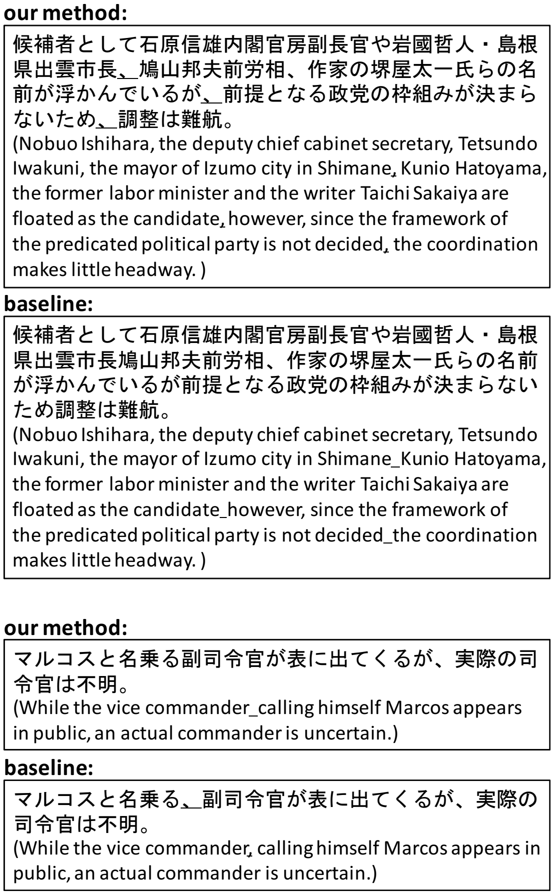
Figure 4 shows the comparison between the results of our method and the baseline method. The baseline method was not able to insert commas right after the bunsetsu “浮かんでいるが (are floated)” or “決まらないため (not decided)” but inserted commas at unnatural positions such as between “名乗る (calling himself)” and “副司令官が (the vice commander).” On the other hand, our method was able to insert commas properly at such bunsetsu boundaries.

6 Discussion

6.1 Error Analysis

Among positions where commas existed in the test data, there existed 2,022 positions where our method did not insert commas. Among them, 862 were clause boundaries, and the clause boundary “topicalized element-*wa*” accounted for 53.36% (460/862) of them. There were a lot of clause boundaries of the type “topicalized element-*wa*,” and the number of commas inserted at such boundaries was large. But, the rate of comma insertion itself was not very high. We can say that the four features about “topicalized element-*wa*” did not always work well. Ta-

[5] Phrases indicating the subject is a sequence of bunsetsus consisting of b^j_k and all bunsetsus that are connected to b^j_k when we trace their dependency relationship in modifier-to-modifyee direction.



our method:

(While the vice commander, calling himself Marcos appears in public, an actual commander is uncertain.)

Figure 4: Comparison of the results of our method and baseline method

ble 7 shows the results of comma insertion at the clause boundaries "topicalized element-*wa*." While there existed 601 commas at such boundaries in the test data, only 141 commas were inserted correctly. We need to consider more effective features about "topicalized element-*wa*."

As for other cases, there existed 130 bunsetsu boundaries between parallel words where commas were not inserted. One example of such case is shown below.

- **correct data:**
  ボウルに豚の背脂、_ニンニク、ショウガ、ネギのみじん切りを入れ、彩りの赤ピーマンも加えます。(Put pork backfat, garlic, ginger and shredded green onion in a bowl, and add red bell peppers for color.)

Table 7: Result of comma insertion at the clause boundaries "topicalized element-*wa*."

recall	precision	F-measure
23.46% (141/601)	59.49% (141/237)	33.65

- **our method:**
  ボウルに豚の背脂ニンニク、ショウガ、ネギのみじん切りを入れ、彩りの赤ピーマンも加えます。(Put pork backfat_ garlic, ginger and shredded green onion in a bowl, and add red bell peppers for color.)

In the correct data, a comma was inserted between the bunsetsu "背脂 (backfat)" and "ニンニク (garlic)."

If a comma should be inserted right after the bunsetsu ''背脂 (backfat)," the number of characters between commas would become too small to be judged as appropriate by the proposed method. So, the feature about the number of characters between commas may have had harmful effects there. On the other hand, a comma was inserted properly between the bunsetsu "ニンニク (garlic)" and "ショウガ (ginger)." This is because *katakana* characters appeared sequentially in addition to appearing as parallel nouns.

6.2 Unnatural Comma Insertion

When commas are inserted at obviously unnatural positions, they have a major impact on the understanding of a sentence by readers. Here, we investigated how many commas had been inserted at obviously unnatural positions by our method. For the article on January 14th (217 sentences, 2,349 bunsetsus) in the test data, we examined 47 commas inserted incorrectly. Three persons decided whether or not the inserted commas were obviously unnatural through consultations. Concretely, when all of the three persons felt that an inserted comma would make readers understand wrongly the meaning of the sentence, the comma was judged to be obviously unnatural.

Among 47 commas, 4 commas were judged obviously unnatural. This result shows that our method is capable of inserting commas at natural positions on some level.

Table 8: Comparison with human judgement

	recall	precision	F-measure
by human	78.30% (249/318)	80.58% (249/309)	79.42
our method	71.07% (226/318)	82.78% (226/273)	76.48

6.3 Comparison with Human Judgement

In our experiment, we evaluated the results of comma insertion of our method by comparing them with the correct data. However, the sufficient level to be reached by automatic comma insertion is uncertain. Here, we evaluated our method by comparing them with the results of comma insertion by another person. By using the same data as used in the subsection 6.2, we conducted an experiment on comma insertion by an annotator who was familiar with writing Japanese documents. Table 8 shows the recall, the precision and the F-measure. The second row shows the results of our method for the same data. As the F-measure of the annotator was 79.42, it turned out that comma insertion task was difficult even for humans. For F-measure, our method achieved 96.30% (76.48/79.42) of the annotator's result. Also, the precision of our method was 82.78%. Although the comma insertion task is difficult, our method was able to properly insert commas.

7 Conclusion

This paper proposed a method for inserting commas into Japanese texts. Our method appropriately inserts commas based on the machine learning method using such features as morphemes, dependencies and clause boundaries. An experiment by using the Kyoto Text Corpus (Kurohashi and Nagao, 1998) showed an F-measure of 75.90, and we confirmed the effectiveness of our method.

The analysis of the experimental results showed that our method cannot insert commas of the particular usage. As a future work, it is necessary to find more useful features for commas of this usage and improve the recall of our method. Also, we will examine "commas emphasizing the adjacent word" which were not included in our targets.

Using Unknown Word Techniques To Learn Known Words

Abstract

Unknown words are a hindrance to the performance of hand-crafted computational grammars of natural language. However, words with incomplete and incorrect lexical entries pose an even bigger problem because they can be the cause of a parsing failure despite being listed in the lexicon of the grammar. Such lexical entries are hard to detect and even harder to correct.

We employ an error miner to pinpoint words with problematic lexical entries. An automated lexical acquisition technique is then used to learn new entries for those words which allows the grammar to parse previously uncovered sentences successfully.

We test our method on a large-scale grammar of Dutch and a set of sentences for which this grammar fails to produce a parse. The application of the method enables the grammar to cover 83.76% of those sentences with an accuracy of 86.15%.

1 Introduction

In this paper, we present an automated two-phase method for treating *incomplete* or *incorrect* lexical entries in the lexicons of large-scale computational grammars. The performance of our approach is tested in a case study with the wide-coverage Alpino grammar (van Noord, 2006) of Dutch. When applied to real test sentences previously not covered by Alpino, the method causes a parsing coverage of 83.76% and the accuracy of the delivered analyses is 86.15%.

The main advantage of our approach is the successful combination of efficient *error mining* and *lexical acquisition* techniques. In the first phase, error mining pinpoints words which are listed in the lexicon of a given grammar but which nevertheless often lead to a parsing failure. This indicates that the current lexical entry for such a word is either wrong or incomplete and that one or more correct entries for this word are missing from the lexicon. Our idea is to treat the word as if it was unknown and, in the second phase, to employ lexical acquisition (LA) to learn the missing correct entries.

In the case study presented here, we employ the iterative error miner of de Kok et al. (2009). Since it has to be run on a large parsed corpus, we have parsed the Flemish Mediargus corpus (∼1.5 billion words) with Alpino. The reason for this choice is the relatively large lexical difference between standard Dutch and Flemish. This increases the chance to encounter words which are used in Flemish in a way not handled by Alpino yet.

For example, the word *afwater* (to drain) is listed as a first person singular present verb in the Alpino lexicon. However, the error miner identifies this word as the reason for the parsing failure of 9 sentences. A manual examination reveals that the word is used as a neuter noun in these cases– *het afwater* (the drainage). Since there is no noun entry in the lexicon, Alpino was not able to produce full-span analyses.

After the error miner identifies *afwater* as a problematic word, we employ our machine learning based LA method presented in Cholakov and van Noord (2010) to learn new entries for this word. This method has already been successfully applied to the task of learning lexical entries for unknown words and, as the error miner, it can be used 'out of the box'. LA correctly predicts a neuter noun en-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 902–912,
MIT, Massachusetts, USA, 9-11 October 2010.

try for *afwater* and the addition of this entry to the lexicon enables Alpino to cover the 9 problematic sentences from the Mediargus corpus.

It should be noted that since our approach cannot differentiate between incomplete and incorrect entries, no entry in the lexicon is modified. We simply add the lexical entries which, according to the LA method, are most suitable for a given problematic word and assume that, if these entries are correct, the grammar should be able to cover previously unparsable sentences in which the word occurs.

The remainder of the paper is organised as follows. Section 2 describes the error miner. Section 3 presents the Alpino grammar and parser and the LA technique we employ. Section 4 describes an experiment where error mining is performed on the Mediargus corpus and then, LA is applied to learn new lexical entries for problematic words. Section 5 discusses the effect which the addition of the new entries to the lexicon has on the parsing coverage and accuracy. Section 6 provides a comparison between our approach and previous work similar in nature. This section also discusses the application of our method to other systems and languages as well as some ideas for future research.

2 Error Mining

The error miner of de Kok et al. (2009) combines the strengths of the error mining methods of van Noord (2004) and Sagot and de la Clergerie (2006). The idea behind these methods is that grammar errors lead to the parsing failure of some grammatical sentences. By running the grammar over a large corpus, the corpus can be split into two subsets– the set of sentences which received a full-span parse and the set of sentences failed to parse. Words or n-grams which occur in the latter set have a suspicion of being the cause of parsing failures.

van Noord (2004) defines the suspicion of a word sequence as:

(1) $$S(w_i...w_j) = \frac{C(w_i...w_j|error)}{C(w_i...w_j)}$$

where $C(w_i...w_j)$ is the number of sentences which the sequence $w_i...w_j$ occurs in and $C(w_i...w_j|error)$ is the number of occurrences of the sequence in unparsable sentences.

While this method performs well in identifying words and n-grams that are unambiguously suspicious, it also assigns incorrectly a high suspicion to forms which happen to occur often in unparsable sentences by ‘bad luck’. The iterative error mining algorithm of Sagot and de la Clergerie (2006) tackles this problem by taking the following into account:

- If a form occurs within parsable sentences, it becomes less likely for it to be the cause of a parsing failure.
- The suspicion of a form depends on the suspicions of the other forms in the unparsable sentences it occurs in.
- A form observed in a shorter sentence is initially more suspicious than a form observed in a longer one.

However, because of data sparseness problems, this method is only able to handle unigrams and bigrams. Another potential problem is the absence of criteria to determine when to use unigrams and when bigrams to represent forms within a given sentence. Consider the trigram w_1, w_2, w_3 where w_2 is the cause of a parsing failure. In this case, the whole trigram as well as the bigrams w_1, w_2 and w_2, w_3 will become suspicious which would prevent the unigram w_2 from ‘manifesting’ itself.

To avoid this problem, de Kok et al. (2009) uses a preprocessor to the iterative miner of Sagot and de la Clergerie (2006) which iterates through a sentence of unigrams and expands unigrams to longer n-grams when there is evidence that this is useful. A unigram w_1 is expanded to a bigram w_1, w_2 if this bigram is more suspicious than both of its unigrams. The general algorithm is that the expansion to an n-gram $i...j$ is allowed when the following two conditions are fulfilled:

(2) $$\begin{aligned} &S(i...j) > S(i...j-1) \cdot expFactor \\ &S(i...j) > S(i+1...j) \cdot expFactor \end{aligned}$$

Within the preprocessor, suspicion is defined as shown in (1) and the *expFactor* is a parameter specially designed to deal with data sparseness.

As the error mining technique of de Kok et al. (2009) successfully overcomes the problems which the other error mining methods we discussed encounter, we have chosen to employ this technique in our experiment.

3 Automated Lexical Acquisition

3.1 The Alpino Grammar and Parser

Since we employ Alpino for the purposes of our case study, it is convenient to explain the LA method we have chosen to use in the context of this system.

The Alpino wide-coverage parser is based on a large stochastic attribute value grammar. The grammar takes a 'constructional' approach, with rich lexical representations stored in the lexicon and a large number of detailed, construction specific rules (about 800).

Currently, the lexicon contains over 100K lexical entries and a list of about 200K named entities. Each word is assigned one or more lexical types. For example, the verb *amuseert* (to amuse) is assigned two lexical types– *verb(hebben,sg3,intransitive)* and *verb(hebben,sg3,transitive)*– because it can be used either transitively or intransitively. The other type features indicate that it is a present third person singular verb and it forms perfect tense with the auxiliary verb *hebben*.

3.2 Learning Algorithm

The goal of the LA method we describe Cholakov and van Noord (2010) is to assign correct lexical type(s) to a given unknown word.

It takes into account only open-class lexical types: nouns, adjectives and verbs. The types considered in the learning process are called *universal types*[1].

For a given word, a maximum entropy (ME) based classifier takes various morphological and syntactic features as input and outputs a ranked list of lexical types. The probability of a lexical type *t*, given an unknown word and its context *c* is:

$$(3) \qquad p(t|c) = \frac{exp(\sum_i \Theta_i f_i(t,c))}{\sum_{t' \in T} exp(\sum_i \Theta_i f_i(t',c))}$$

where $f_i(t, c)$ may encode arbitrary characteristics of the context and $< \Theta_1, \Theta_2, ... >$ is a weighting parameter which maximises the entropy and can be evaluated by maximising the pseudo-likelihood on a training corpus (Malouf, 2002).

Features
i) a, af, afw, afwa
ii) r, er, ter, ater
iii) particle_yes #in this case *af*
iv) hyphen_no
v) noun⟨het,sg⟩, verb⟨sg1⟩
vi) noun(het,count,sg), noun(de,count,pl)
vii) noun(het), noun(count), noun(sg), noun(de) noun(pl)

Table 1: Features for *afwater*

Table 1 shows the features for *afwater*, the word we discussed in Section 1. Row **(i)** contains 4 separate features derived from the prefix of the word and 4 other suffix features are given in row **(ii)**. The two features in rows **(iii)** and **(iv)** indicate whether the word starts with a particle and if it contains a hyphen, respectively.

Further, the method we describe in Cholakov and van Noord (2009) is applied to generate the paradigm(s) of each word in question. This method uses a finite state morphology to generate possible paradigm(s) for a given word. The morphology does not have access to any additional linguistic information and thus, it generates all possible paradigms allowed by the word orthography. Then, the number of search hits Yahoo returns for each form in a given paradigm is combined with some simple heuristics to determine the correct paradigm(s). The web search heuristics are also able to determine the correct definite article (*de* or *het*) for words with noun paradigms.

One verb and one noun paradigm are generated for *afwater*. In these paradigms, *afwater* is listed as a first person singular present verb form and a singular *het* noun form, respectively. This information is explicitly used as features in the classifier which is shown in row **(v)** of Table 1.

Next, syntactic features for *afwater* are obtained by extracting a number of sentences which it occurs in from large corpora or Internet. These sentences are parsed with a different 'mode' of Alpino where this word is assigned all universal types, i.e. it is treated as being maximally ambiguous. For each sentence only the parse which is considered to be the best by the Alpino statistical disambiguation model

[1] The adjectives can be used as adverbs in Dutch and thus, the latter are not considered to be an open class.

is preserved. Then, the lexical type that has been assigned to *afwater* in this parse is stored. During parsing, Alpino's POS tagger (Prins and van Noord, 2001) keeps filtering implausible type combinations. For example, if a determiner occurs before the unknown word, all verb types are typically not taken into consideration. This heavily reduces the computational overload and makes parsing with universal types computationally feasible.

When all sentences have been parsed, a list can be drawn up with the types that have been used and their frequency:

(4) noun(het,count,sg) 54
noun(de,count,pl) 7
tmp_noun(het,count,sg) 4
adjective(no_e(adv)) 4
proper_name(sg,'ORG') 1

The lexical types assigned to *afwater* in at least 80% of the parses are used as features in the classifier. These are the two features in row **(vi)** of Table 1. Further, as illustrated in row **(vii)**, each attribute of the considered types is also taken as a separate feature.

After the classifier predicts lexical types for each word, these predictions are subject to two additional steps of processing. In the first one, the generated word paradigms are explicitly used as a filtering mechanism. When a word is assigned a verb or an adjective type by the classifier but there is no verb or adjective paradigm generated for it, all verb or adjective predictions for this word are discarded.

The output of this 'filtering' is further processed in the second step which deals with the correct prediction of subcategorization frames for verbs. Following the observations made in Korhonen et al. (2000), Lapata (1999) and Messiant (2008), Cholakov and van Noord (2010) employ a maximum likelihood estimate (MLE) from observed relative frequencies with an empirical threshold to filter out low probability frames.

Since some frames could be very infrequent and the MLE method may not capture them, the generated word paradigms are used to increase the number of contexts observed for a given verb. Additional sentences are extracted for each form in the paradigm of a given word predicted to be a verb. These sentences are again parsed with the universal types. Then we look up the assigned universal verb types, calculate the MLE for each subcategorization frame and filter out frames with MLE below some empirical threshold.

4 Learning New Lexical Entries

Before we start with the description of the experiment, it is important to note that Alpino is very robust– essentially, it always produces a parse. If there is no analysis spanning the whole sentence, the parser finds all parses for each substring and returns what it considers to be the best sequence of non-overlapping parses. However, in the context of this experiment, a sentence will be considered successfully parsed only if it receives a full-span analysis. For the sake of clarity, from now on we shall use the terms *coverage* and *cover* only with regard to such sentences. The term *parsing failure* shall refer to a sentence for which Alpino fails to produce a full-span analysis.

4.1 Error Mining on Mediargus

The first step in our experiment is to perform error mining on the Mediargus corpus. The corpus consists of texts from Flemish newspapers from the period between 1998 and 2007. It contains about 1.5 billion words (∼78M sentences). The corpus has been parsed with Alpino and the parsing results are fed into the error miner of de Kok et al. (2009). The parser has not produced a full-span analysis for 7.28% of the sentences (∼5.7M sentences).

When finished, the error miner stores the results in a data base containing potentially problematic n-grams. Each n-gram is linked to its suspicion score and the sentences which it occurs in and which were not covered by Alpino.

Before proceeding with LA, however, we should identify the n-grams which are indicative for a problem in the lexicon. The first step in this direction is to extract all *unigrams* from the data base which have a suspicion equal to or greater than 0.7 together with the uncovered sentences they occur in. This resulted in a list containing 4179 unique unigrams. Further, we select from this list only those unigrams which have lexical entries in the Alpino lexicon and occur in more than 5 sentences with no full-span parse. Sometimes, the error miner might be wrong about the exact word which causes the parsing failure for a given sentence. The 5 sentences empirical threshold is meant to guarantee that the selected words are systematically causing problems for the parser.

The result of this selection is 36 unigrams (words) which occur in a total of 388 uncovered sentences– an average of 10.78 sentences per word. The small number of selected words is due to the fact that most of the problematic 4179 unigrams represent tokenization errors (two or more words written as one) and spelling mistakes which, naturally, are not listed in the Alpino lexicon. Very few of the 4179 unigrams are actual unknown words. Table 2 shows some of the problematic unigrams and their suspicions.

opVorig	0.898989
GentHoewel	0.89759
Nieuwpoortl	0.897414
SportTijdens	0.897016
DirvenDe	0.896428
mistrap	0.896038
Dwoeurp	0.896013
passerde	0.89568
doorHugo	0.893901
goedkmaken	0.892407
ManneN	0.891539
toegnag	0.891523

Table 2: Problematic unigrams and their suspicions

It can be seen immediately that most of the unigrams presented in the table are tokenization errors. There are also some typos. The unigram *passerde* should be written as *passe**e**rde*, the past singular verb form of the verb ‘to pass’ and *toegnag* is the misspelled noun *toegang* (access). The only problematic unigram with a lexical entry in the Alpino lexicon is *mistrap* (misstep, to misstep).

Although the experiment setup yields a small test set, we employ it because the words in this set represent ‘clear-cut’ cases. This allows us to demonstrate better the effect of our technique.

4.2 Applying Lexical Acquisition

Our assumption is that incomplete or incorrect lexical entries prevented the production of full-span parses for the 388 sentences in which the 36 problematic words pinpointed by the error miner occur. That is why, in the second step of the experiment, these words are temporarily removed from the Alpino lexicon, i.e. they are treated as unknown words, and we employ the LA method presented in the previous section to learn offline new lexical entries for them.

The setup for the learning process is exactly the same as in Cholakov and van Noord (2010). The set of universal types consists of 611 types and the ME-based classifier has been trained on the same set of 2000 words as in Cholakov and van Noord (2010). Those types predicted by the classifier which account together for less than 5% of probability mass are discarded.

In order to increase the number of observed contexts for a given word when parsing with the universal types, up to 100 additional sentences in which the word occurs are extracted from Internet. However, when predicting new lexical entries for this word, we want to take into account only sentences where it causes a parsing failure. It is in such sentences where a new lexical entry can be learnt through LA. For example, the LA method would be able to predict a noun entry for *afwater* if it focuses only on contexts where it has a noun reading, i.e. on sentences not covered by Alpino.

That is why, the sentences we extracted from Internet are first parsed with the standard Alpino configuration. When averaging over the 36 sentence sets, it turns out that Alpino has been able to cover 10.05% of the sentences. Although we cannot be sure that the 36 words are the cause of a parsing failure in each of the uncovered sentences, this low coverage indicates once more that Alpino has systematic problems with sentences containing these words.

Then, the uncovered sentences from Internet together with the 388 problematic sentences from the Mediargus corpus are parsed with Alpino and the universal types. For example, the list of universal types assigned to *afwater* in (4) contains mostly noun types, i.e. the kind of types which are currently not in the lexicon for this word and which we want to learn.

The result of the LA process is the prediction of a total of 102 lexical types, or 2.83 types per word. This high number is due to the fact that 25 words receive verb predictions. Since a verb can have various subcategorization frames, there is one type assigned for each frame. For example, *inscheppen* (to spoon in(to)) receives 3 types which differ only in the subcategorization frame– *verb(hebben,inf,tr.)*, *verb(hebben,inf,intr.)* and *verb(hebben,inf,np_np)*. However, the infinitive in Dutch is also the form for plural present and *inscheppen* correctly receives 3 more predictions– *verb(hebben,pl,tr.)*, *verb(hebben,pl,intr.)* and *verb(hebben,pl,np_np)*.

Let us examine the most frequent types of lexicon errors for the 36 problematic words by looking at the current Alpino lexical entries for some of these words and the predictions they receive from the LA method. The original Alpino entries for 19 of the 25 words predicted to be verbs are a product of a specific lexical rule in the grammar. Consider the following sentences:

(5) a. Ik schep de soep in de kom.
I spoon the soup in the bowl
'I spoon the soup into the bowl.'
b. dat ik de soep de kom in schep
that I the soup the bowl in spoon
'that I spoon the soup into the bowl'
c. dat ik de soep de kom *in*schep
that I the soup the bowl in spoon
'that I spoon the soup into the bowl'

We see in (5-b) that the preposition *in* is used as a postposition in the relative clause. However, in such cases, there is linguistic evidence that *in* behaves as a separate verb particle. That is why, as shown in (5-c), people sometimes write *in* and the verb together when they occur next to each other in the sentence. To account for this, Alpino employs a special lexical rule. This rule assigns a certain type of subcategorization frame to verbs like *inscheppen* where a postposition can be interpreted as a separable particle. That subcategorization frame requires a noun phrase ('the soup' in (5-c)) and a locative NP ('the bowl' in (5-c)).

However, in some cases, the entries generated by this lexical rule cannot account for other possible usages of the verbs in question. For example,

(6) U moet deze zelf inscheppen.
you must this yourself spoon in.INF
'You have to spoon this in yourself.'

Alpino fails to parse this sentence because *inscheppen* is used without a locative NP. Now, when the LA method has predicted a transitive verb type for *inscheppen*, the parser should be able to cover the sentence. Other such examples from our data include ***weg****wist* (to erase.3PER.SG), ***onder****ligt* (to lie under.3PER.SG), etc.

Further, there are 10 words, including *afwater*, which represent cases of nominalisation currently not accounted for in the Alpino lexicon. The LA process correctly predicts noun types for these words. This should enable the parser to cover sentences like:

(7) Die moet een deel van het afwater vervoeren.
this must a part from the drainage transport/move
'This has to move a part of the drainage.'

where *afwater* is used as a noun.

There are also 3 words which correctly receive adjective predictions. Currently, their lexical entries are incomplete because they are assigned only past participle types in the lexicon. However, past participles in Dutch can also act as adjectives. For historical reasons, this systematic ambiguity is not treated as such in Alpino. Each participle should also have a separate adjective lexical entry but, as we see, this is not always the case.

5 Results

After LA is finished, we restore the original lexical entries for the 36 words but, additionally, each word is also assigned the types which have been predicted for it by the LA method. The 388 problematic sentences from the Mediargus corpus are then re-parsed with Alpino. We are interested in observing:

1. how many sentences receive a full-span analysis

2. how the parsing accuracy of Alpino changes

Table 3 shows that when the Alpino lexicon is extended with the lexical entries we learnt through LA, the parser is able to cover nearly 84% of the sentences, including the ones given in (6) and (7). Since there is no suitable baseline which this result can be compared to, we developed an additional model which indicates what is likely to be the maximum coverage that Alpino can achieve for those sentences by adding new lexical entries only.

In this second model, for each of the 36 words, we add to the lexicon all types which were successfully used for the respective word during the parsing with universal types. In this way, Alpino is free to choose from all types it has considered suitable for a given word, i.e. the parser is not limited by the outcome of the LA process but rather by the overall quality of the grammar.

The 'universal types' model performs better than ours– it achieves 87.9% coverage. Still, the performance of our model is close to this result, i.e. close to what we consider to be the maximal possible coverage of Alpino for these 388 sentences when only LA is used.

Model	Coverage (%)
Our model (Alpino + LA)	83.76
Universal types	87.89

Table 3: Coverage results for the re-parsed 388 problematic sentences

Some of the sentences which cannot be covered by both models are actually not proper sentences but fragments which were wrongly identified as sentences during tokenization. Many other cases include sentences like:

(8) Een gele frommel papier, Arabische lettertekens.
a yellow crease paper Arabic characters
'A yellow paper crease, Arabic characters.'

which is probably the caption of a photo or an illustration. However, because of the absence of a verb, Alpino splits the analysis into two parts– the part before the comma and the part after the comma.

Here is a more interesting case:

(9) Als we ons naar de buffettafel begeven, mistrap ik me.
when we us to the buffet proceed misstep I myself
'When we proceed to the buffet I misstep.'

The LA method does not predict a reflexive verb type for *mistrap* which prevents the production of a full-span analysis because Alpino cannot connect the reflexive pronoun *me* to *mistrap*. In this case, however, the universal type model outperforms ours. A reflexive verb type is among the universal types and thus, Alpino is able to use that type to deliver a full-span parse. We should note though, that LA correctly predicts a noun type for *mistrap* which enables Alpino to parse successfully the other 14 sentences which this word occurs in.

Let us now look at the correctness of the delivered parses. To estimate the accuracy of the parser, we have randomly selected 100 sentences out of the 388 sentences in the test set and we have manually annotated them in order to create a gold standard for evaluation.

Accuracy in Alpino is measured in terms of dependency relations. The accuracy for sentences which are not assigned a full-span analysis but a sequence of non-overlapping parses can still be larger than zero because, within these parses, some correct dependency relations could have been produced. That is why, though the coverage of Alpino for the selected 100 sentences is zero, we can still obtain a number for accuracy and use it as a baseline for comparison. Clearly, this baseline is expected to perform worse than both our model and the universal types one since those are able to cover most of the sentences and thus, they are likely to produce more correct dependency relations. However, it gives us an idea how much extra quality is gained when coverage improves.

The accuracy results for the 100 annotated sentences are given in Table 4. The average sentence length is 18.9 tokens.

Model	Accuracy (%)	msec/sentence
Alpino	63.35	803
Our model	86.15	718
Universal types	85.12	721

Table 4: Accuracy results for the 100 annotated sentences

Our model achieves the highest accuracy without increasing the parse times. Further, the baseline has a much lower result which shows that coverage is not gained on the expense of accuracy.

Our model and the universal types one achieve the same accuracy for most of the sentences. However, the universal types model has an important disadvantage which, in some cases, leads to the production of wrong dependency relations. The model predicts a large number of lexical types which, in turn, leads to large *lexical ambiguity*. This lexical ambiguity increases the number of possible analyses Alpino chooses from, thus making it harder for the parser to produce the correct analysis. Let us consider the following example where a sentence is covered by both models but the universal types model has lower accuracy:

(10) Dat wij het rechttrokken, pleit voor onze
that we it straighten.PAST.PL. plead for our
huidige conditie.
current condition
'It pleads for our condition that we straightened it.'

Here, *het* is the object of the verb *rechttrokken*. However, although there are transitive verb types among the universal types assigned to *rechttrokken*, Alpino chooses to use a verb type which subcategorizes for a measure NP. This causes for *het* to be analysed not as an object but as a measure complement, i.e. the produced dependency relation is incorrect.

The LA method, on the other hand, is much more restrictive but its predictions are also much more accurate. Since it considers sentences containing other forms of the paradigm of *rechttrokken* when predicting subcategorization frames, the LA method correctly assigns only one transitive and one intransitive verb type to this word. This allows Alpino to recognize *het* as the object of the verb and to produce the correct dependency relation.

The few cases where the universal types model outperforms ours include sentences like the one given in (9) where the application of our model could not enable Alpino to assign a full-span analysis. Sometimes, the LA method is too restrictive and does not output some of the correct types. These types, on the other hand, could be provided by the universal types model and could enable Alpino to cover a given sentence and thus, to produce more correct dependency relations. Allowing for the LA method to predict more types, however, has proven to be a bad solution because, due to the increased lexical ambiguity, this leads to lower parsing accuracy.

6 Discussion

6.1 Comparison to Previous Work

The performance of the technique we presented in this paper can be compared to the performance of a number of other approaches applied to similar tasks.

Zhang et al. (2006) and Villavicencio et al. (2007) use error mining to semi-automatically detect English multiword expressions (MWEs). Then, they employ LA to learn proper lexical entries for these MWEs and add them to the lexicon of a large-scale HPSG grammar of English (ERG; (Copestake and Flickinger, 2000)). This increases parsing coverage by 15% to 22.7% for a test set of 674 sentences containing MWEs and parsed with the PET parser (Callmeier, 2000). In both studies, however, the combination of error mining and LA is applied to a very specific task whereas our method is a general one.

Nicolas et al. (2008) employ a semi-automatic method to improve a large-scale morphosyntactic lexicon of French (Le*fff*; (Sagot et al., 2006)). The lexicon is used in two grammars– the FRMG (Thomasset and de la Clergerie, 2005), a hybrid Tree Adjoining/Tree Insertion Grammar, and the SxLFG-FR LFG grammar (Boullier and Sagot, 2006). The first step in this approach is also the application of an error miner (Sagot and de la Clergerie, 2006) which uses a parsed newspaper corpus (about 4.3M words) to pinpoint problematic unigrams.

The crucial difference with our method is in the second step. Nicolas et al. (2008) assign *underspecified* lexical entries to a given problematic unigram to allow the grammar to parse the uncovered sentences associated with this unigram. Then, these entries are ranked based on the number of successful parses they have been used in.

The use of underspecification, however, causes large ambiguity and severe parse overgeneration (observed also in Fouvry (2003)). As a consequence of that, the ranked list of lexical entries for each unigram is manually validated to filter out the wrong entries. The employment of LA in our approach, on the other hand, makes it fully automatic. The ranking of the predictions is done by the classifier and the predicted entries are good enough to improve the parsing coverage and accuracy without any manual work involved. Generally, recent studies (Baldwin, 2005; Zhang and Kordoni, 2006; Cholakov et al., 2008; Cholakov and van Noord, 2010) have clearly shown that when it comes to learning new lexical entries, elaborate LA techniques perform better and are more suitable for large-scale grammars than underspecification[2].

Further, the naive ranking system used in Nicolas et al. (2008) puts a correctly generated entry for an infrequent usage of a given word (e.g., a verb with a rare subcat frame) in the bottom of the ranked list because of the low number of sentences in which this entry is used. The LA method we employ is more sensitive to rare usages of words because it considers occurrences of the word in question outside the parsed corpus (very important if the corpus is domain-specific) and it also takes into account all forms in the paradigm(s) of the word. This increases the chances of a rare usage of this word to 'manifest' itself.

Nicolas et al. (2008) uses the lexical entries which remain after the manual validation to re-parse the newspaper corpus. 254 words (mostly verbs) are corrected and the parse coverage increases by 3.4% and 1.7% for the FRMG and the SxLFG, respectively. However, the authors do not mention how many of the original uncovered sentences they are able to cover and therefore, we cannot compare our coverage result. Nothing is said about the parsing accuracy. Even with manually validated lexical entries, it is still possible for the grammar to produce full-span but wrong analyses.

6.2 Application to Other Systems and Languages

It is important to note that this paper should be viewed as a case study where we illustrate the results of the application of what we believe to be a good algorithm for dealing with incomplete or incorrect lexical entries– namely, the combination of error mining and LA. However, our method is general enough to be applied to other large-scale grammars and languages.

The error mining is directly usable as soon as there is a large parsed corpus available. The LA technique we employed is also quite general provided that certain requirements are fulfilled. First, words have to be mapped onto some finite set of labels of which a subset of open-class (universal) labels has to be selected. This subset represents the labels which can be predicted for unknown words. Second, we need a parser to analyse sentences in which a given unknown word occurs. Finally, the ME-based classifier allows for arbitrary combinations of features and therefore, any (language-specific) features considered useful can be included. As for the paradigm generation method, the idea of combining a finite state morphology and web heuristics is general enough to be implemented for different languages.

We have already started investigating the applicability of our method to the FRMG and a large-scale grammar of German and the initial experiment and results we have obtained are promising.

6.3 Future Research

Currently, our algorithm handles only unigrams (words). However, it would be useful to extend it, so it can work with longer n-grams. For example, a given word could have some reading which is not yet handled in the lexicon only within a particular bi- or trigram.

Consider the bigram '*schampte af*' which has been identified as problematic by the error miner. It represents the particle verb '*afschampte*' (to glance.PAST.SG). Although the lexicon contains a verb entry for '*schampte*', there is no entry handling the case when this verb combines with the particle '*af*'. Another example is the bigram '*de slachtoffer*' (the victim). In standard Dutch, the noun '*slachtoffer*' goes with the '*het*' definite article which is marked in its lexical entry. However, in Flemish it is used with the '*de*' article.

Our method is currently not able to capture these two cases since they can be identified as problematic on bigram level and not when only unigrams are considered.

Further, the definition of what the error miner considers to be a successful parse is a rather crude one. As we saw, even if the grammar is able to produce a full-span analysis for a given sentence, this analysis could still not be the correct one. Therefore, it is possible that a word could have a problematic lexical entry even if it only occurs in sentences which are assigned a full-span parse. Currently, such a word will not be identified as problematic by the error miner. That is why, some (statistical) model which is capable of judging the plausibility of a parse should be developed and incorpo-

[2] In Nicolas et al. (2008) the authors also admit that an elaborate LA technique will produce better results.

rated in the calculation of the suspicions during error mining.

Abstract

The reliable extraction of knowledge from text requires an appropriate treatment of the time at which reported events take place. Unfortunately, there are very few annotated data sets that support the development of techniques for event time-stamping and tracking the progression of time through a narrative. In this paper, we present a new corpus of temporally-rich documents sourced from English Wikipedia, which we have annotated with TIMEX2 tags. The corpus contains around 120000 tokens, and 2600 TIMEX2 expressions, thus comparing favourably in size to other existing corpora used in these areas. We describe the preparation of the corpus, and compare the profile of the data with other existing temporally annotated corpora. We also report the results obtained when we use DANTE, our temporal expression tagger, to process this corpus, and point to where further work is required. The corpus is publicly available for research purposes.

1 Introduction

The reliable processing of temporal information is an important step in many NLP applications, such as information extraction, question answering, and document summarisation. Consequently, the tasks of identifying and assigning values to temporal expressions have recently received significant attention, resulting in the creation of mature corpus annotation guidelines (e.g. TIMEX2[1] and TimeML[2]), publicly available annotated corpora (ACE,[3] TimeBank[4]) and a number of automatic taggers (see, for example, (Mani and Wilson, 2000; Schilder, 2004; Hacioglu et al., 2005; Negri and Marseglia, 2005; Saquete, 2005; Han et al., 2006; Ahn et al., 2007)).

However, existing corpora have their limitations. In particular, the documents in these corpora tend to be limited in length and, in consequence, discourse structure. This impacts on the number, range and variety of temporal expressions they contain. Existing research carried out on the interpretation of temporal expressions, e.g. by (Baldwin, 2002; Ahn et al., 2005; Mazur and Dale, 2008), suggests that many temporal expressions in documents, especially news stories, can be interpreted fairly simply as being relative to a reference date that is typically the document creation date. This phenomenon does not carry over to longer, more narrative-style documents that describe extended sequences of events, as found, for example, in biographies or descriptions of protracted geo-political events. Consequently, existing corpora are not ideal as development data for systems intended to work on such historical narrations.

In this paper we introduce a new annotated corpus of temporal expressions that is intended to address this shortfall. The corpus, which we call WikiWars, consists of 22 documents from English Wikipedia that describe the historical course of wars. Despite the small number of documents, their length means that the corpus yields a large number of temporal expressions, and poses new challenges for tracking

temporal focus through extended texts. The corpus has been made available for others to use;[5] to give an indication of the difficulty of processing the temporal phenomena in the texts, we also report on the performance of DANTE, our temporal expression tagger, on detecting and interpreting the temporal expressions in the corpus.

The rest of this paper is organised as follows. In Section 2 we describe related work, focusing on the TIMEX2 annotation scheme, and existing corpora that contain annotations of temporal expressions using this scheme. Section 3 describes the process of creation of the WikiWars corpus. In Section 4 we comment on some artefacts of Wikipedia articles that impact on the annotation process and the use of this corpus. Then, in Section 5 we analyse the differences between the WikiWars corpus and the widely-used ACE corpora. In Section 6 we report on the performance of our temporal expression tagger on this data set. Finally, in Section 7, we conclude.

2 Related Work

At the time of writing, there are two mature, wide-coverage schemes for the annotation of temporal information in texts: TIMEX2 (Ferro et al., 2005) and TimeML (Pustejovsky et al., 2003; Boguraev et al., 2005), which is soon to become an ISO standard (Pustejovsky et al., 2010).

These schemes were used to annotate corpora that are often used in research on temporal expression recognition and normalisation: the series of corpora used for training and evaluation in the Automatic Content Extraction (ACE) program[6] run in 2004, 2005 and 2007, and the TimeBank Corpus.

The ACE corpora were prepared for the development and evaluation of systems participating in the ACE program. However, the evaluation corpora have never been publicly released, and thus are currently, for all practical purposes, unavailable. The ACE 2004 corpus contains news data only (broadcast news, newspaper and newswire), while the ACE 2005 and 2007 corpora contain news (broadcast and newswire), conversations (broadcast and telephone), UseNet discussions and web blogs. The 2005 and 2007 ACE corpora are annotated with the latest version of TIMEX2 (2005), while the 2004 corpus is annotated with the older 2003 version of TIMEX2; however, the differences are not very significant.

Apart from the unavailability of the evaluation data, there are two issues with the ACE corpora. One is that most of the documents are relatively short, so that the average number of temporal expressions per document is low (typically between seven and nine per document, including the document time stamp as a metadata element). This results in very limited temporal discourse structure, and relatively few underspecified and relative temporal expressions. Unfortunately, these are the more difficult temporal expressions to handle, and so the ACE corpora may not serve as a good baseline for performance more generally.

A second problem is that the ACE corpora appear to contain a significant number of errors in the gold standard annotations, with respect to both the annotated extents and the semantic values assigned, which do not always follow the TIMEX2 guidelines.

TimeBank v1.2 is a revised and improved version of TimeBank 1.1 resulting in a number of errors fixed and inconsistencies removed (see (Boguraev et al., 2007)). Unfortunely, this corpus has the same limitations as the ACE corpora in regard to document length and complexity of discourse structure. Further, TimeBank is annotated with TimeML, a scheme more complex than TIMEX2 since it also encompasses the tagging of events and temporal relations. However, TIMEX2 is sufficiently sophisticated for the annotation of most types of temporal expressions, and our review of the literature reveals that the majority of existing temporal taggers output TIMEX2 annotations. Since automatic conversion between TIMEX2 and TimeML annotations is not straightforward, TimeBank is of limited use for those who work specifically with TIMEX2.

3 Creating WikiWars

Given the above concerns, we were particularly interested in developing a corpus that would allow more rigorous testing of techniques for tracking time across extended narratives, since these give rise to more complex temporal phenomena than are found in simpler documents. To avoid copyright issues that might arise in the development and distribution of such a

[5] See www.TimexPortal.info/WikiWars.

[6] See www.itl.nist.gov/iad/mig/tests/ace.

corpus, we decided to use Wikipedia as a source. After considering various types of historical narrative, we settled on descriptions of the course of wars and conflicts as being particularly rich in the kinds of phenomena we wanted to explore.

3.1 Selecting Data

We queried Google with two phrases, 'most famous wars in history' and 'the biggest wars', and in each case chose the top-ranked result. One of the pages found proposed a list of the 10 most famous wars in history, and the other listed the names of the 20 biggest wars that happened in the 20th century, measured in terms of the number of military deaths. We combined the two lists, eliminated duplicates, and searched Wikipedia for articles describing these wars. Wikipedia did not contain an article for one war, and we considered two articles as inappropriate for our purposes since they did not describe the course of the wars, but rather some general information about the conflicts. This resulted in a final set of 22 articles. More details of the selection process and the URLs of the chosen Wikipedia articles are provided in the documentation distributed with the corpus.

3.2 Text Extraction and Preprocessing

To prepare the corpus, we first manually copied text from those sections of the webpages that described the course of the wars. This involved manual removal of picture captions and cross-page links. We then ran a script over the results of this extraction process to convert some Unicode characters into ASCII (ligatures, spaces, apostrophes, hyphens and other punctuation marks), and to remove citation links and a variety of other Wikipedia annotations.

Finally, we converted each of the text files into an SGML file: each document was wrapped in one `DOC` tag, inside which there are `DOCID`, `DOCTYPE` and `DATETIME` tags. The document time stamp is the date and time at which we downloaded the page from Wikipedia to our local repository. The proper content of the article is wrapped in a `TEXT` tag. This document structure intentionally follows that of the ACE 2005 and 2007 documents, so as to make the processing and evaluation of the WikiWars data highly compatible with the tools used to process the ACE corpora.

3.3 Creating Gold Standard Annotations

Having prepared the input SGML documents, we then processed them with the DANTE temporal expression tagger (see Mazur and Dale (2007)). DANTE outputs the original SGML documents augmented with an inline TIMEX2 annotation for each temporal expression found. These output files can be imported to Callisto,[7] an annotation tool that supports TIMEX2 annotations. Using a temporal expression tagger as a first-pass annotation tool not only significantly reduces the amount of human annotation effort required (creating a tag from scratch requires a number of clicks in the annotation tool), but also helps to minimize the number of errors that arise from overlooking markable expressions through 'annotator blindness'. The annotations produced by DANTE were then manually corrected in Callisto via the following process. First, Annotator 1 (the first author) corrected all the annotations produced by DANTE, both in terms of extent and the values provided for TIMEX2 attributes. This process also included the annotation of any temporal expression missed by the automatic tagger, and the removal of spurious matches. Then, Annotator 2 (the second author) checked all the revised annotations and prepared a list of errors found and doubts or queries in regard to potentially problematic annotations. Annotator 1 then verified and fixed the errors, after discussion in the case of disagreements.

The final SGML files containing inline annotations were then transformed into ACE APF XML annotation files, this being the stand-off markup format developed for ACE evaluations. This transformation was carried out using the `tern2apf` tool developed by NIST for the ACE 2004 evaluations, with some modifications introduced by us to adjust the tool to support ACE 2005 documents and to add a document ID as part of the ID of a TIMEX2 annotation (so that all annotations would have corpus-wide unique IDs).

The resulting corpus is thus available in two formats: one contains the original documents enriched with inline annotations, and the other consists of stand-off annotations in the ACE APF format.

[7] See `http://callisto.mitre.org`.

3.4 Some Deficiencies of TIMEX2

The annotation process described above revealed some issues with the use of TIMEX2 in practice. First, the flexibility of the TIMEX2 scheme, which can be at first seen as an advantage, actually makes it ambiguous. One instance of this phenomenon relates to the fact that the TIMEX2 guidelines state that the provision of some attribute values for what are called **event-based expressions** (such as *three weeks after the siege of Boston began* or *the first year of the American invasion*) is optional. Since our corpus has a significant number of such expressions, the decision as to whether or not to provide semantic values in such cases has a potentially large impact on the perceived performance of a tagger. In such cases, we decided only to provide the value when it is very clear from the article itself what the value should be.

Another area where TIMEX2 is not ideal is in regard to the annotation of time zones. First, only whole-hour time differences are supported, which eliminates some time zones (e.g. Afghanistan lies in UTC+04:30). Second, time zone information is supposed to be marked only for expressions which have it explicitly stated. However, it can often be inferred from the context that subsequent unadorned time references should inherit the same time zone as an earlier time reference.

We also found that, in a not insignificant number of cases, it is impossible to provide a precise and correct value for a temporal expression. For example, the TIMEX2 guidelines stipulate that the anchors of durations cannot have a MOD attribute, so if the anchor is *mid-August*, the value of the anchor must refer to August, which is not entirely correct as the semantics of *mid-* is lost.

TIMEX2 only supports nonspecific expressions which have explicit information about granularity. Expressions such as *a very short time* or *a short period of time* therefore cannot be provided with any value, since the context does not indicate whether the period involved should be measured in days, weeks, or months. One might consider using the typical durations of events of the corresponding types in such cases, but this solution also has problems (see (Pan et al., 2006)).

As is acknowledged in the TIMEX2 guidelines, the treatment of set expressions (i.e. recurring times and durations and frequencies, e.g. *twice a month*) is underdeveloped. One rule states that set expressions should not be anchored (Ferro et al., 2005, p. 42); this has the consequence that the full semantics of the expression *annually since 1955* cannot be provided, and the expression is therefore treated as two separate expressions, *annually* and *1955*.

Finally, alternative calendars are not supported, so an expression like *February in the pre-revolutionary Russian calendar* cannot receive a value unless it appears in an appositive construction which provides an alternative description. Similarly, consider Example (1):

(1) On *9 November 1799* (18 Brumaire of *the Year VIII*) Napoleon Bonaparte staged the coup of 18 Brumaire which installed the Consulate.

Here, *18 Brumaire of the Year VIII* is a date in an alternative calendar used in France, but we annotated only *the Year VIII* based on the trigger *year*. Note that *18 Brumaire* also occurs later in the sentence, but is not annotated.

3.5 Corpus Statistics

The corpus contains 22 documents with a total of almost 120,000 tokens[8] and 2,671 temporal expressions annotated in TIMEX2 format. In Table 1 we compare the WikiWars corpus with the other existing corpora. While the ACE 2005 Training corpus remains the largest corpus, WikiWars is larger than the ACE 2005 and 2007 evaluation corpora and the TimeBank v1.2 corpus, both in terms of number of tokens and TIMEX2 annotations. WikiWars has an order of magnitude more temporal expressions in each document, and a slightly higher density of temporal expressions than the other corpora.

Table 2 presents statistics on the individual documents that make up the corpus. The documents vary considerably in size, the smallest consisting of only 1,455 tokens, and the largest being eight times larger at 11,640 tokens. The density of TIMEX2 annotations varies from 1 in 23.1 tokens to 1 in 72.1 tokens, but for the majority of documents the ratio lies between 30 and 60.

[8] All token counts presented in Tables 1 and 2 were obtained using GATE's default English tokeniser; hyphenated words, e.g. *British-held* and *co-operation*, were treated as single tokens. For more information on GATE see (Cunningham et al., 2002).

4 The Nature of Wikipedia Articles

Wikipedia articles may be edited by a large number of people over a significant number of revisions. We checked how often the articles constituting WikiWars were modified in the period from January 2008 to February 2010. On average, each article was changed almost 52 times per month, with the monthly number of changes for a single article ranging from 1 to 372.[9] The minimum average for an individual document was 13.08 (17_AlgerianWar), and the maximum was 171.77 (07_IraqWar).

The nature of the revision process in Wikipedia leads to some artefacts that may be not typical of other document sources, such as news, where the text is usually carefully prepared by its author and checked by an editor. This is not to say that Wikipedia content is necessarily of low quality; this is an encyclopedia with many people and bots controlling its quality, and there exist manuals of style for authors to help them avoid errors and ambiguity and to ensure maximum consistency.[10] However, given the large number of editors with various degrees of fluency and experience in writing and editing, it would not be surprising if some parts of the texts are not perfect. In the process of preparing the gold standard annotations for the WikiWars corpus, we have made the following observations.

Document ID	Tokens	TIMEX2	$\frac{\text{Tokens}}{\text{TIMEX2}}$
01_WW2	5,593	169	33.1
02_WW1	10,370	264	39.3

Table 2: Statistics of the Wikipedia War corpus.

4.1 Broken Narratives

In some articles we have found situations where a sentence does not appear to cohere with those on either side of it. This may be the result of a number of modifications made by different authors, or it may be due to a lack of writing skill on the part of the person who wrote the paragraph in question. Example (2) below provides an example of this phenomenon: the sentence about de Gaulle being elected president contains a temporal expression which progresses the temporal focus in the narrative to 1959, but the later context of the article strongly suggests that the subsequent reference to *October* is in fact October 1958.

(2) ALN commandos committed numerous acts of sabotage in France in *August*$_{[1958]}$, and the FLN mounted a desperate campaign of terror in Algeria to intimidate Muslims into boycotting the referendum. Despite threats of reprisal, however, 80 percent of the Muslim electorate turned out to vote in *September*$_{[1958]}$, and of these 96 percent approved the constitution. In *February 1959*, de Gaulle was elected president of the new Fifth Republic. He visited Constantine in

[9] Note that these numbers are for the articles as a whole, and not just the sections which we extracted (although these are usually the major part of the article). Additionally, these edits include both major changes (e.g. adding a new section), minor changes (e.g. correcting a grammar error or adding a comma), vandalism (deletion of the page content or the on-purpose provision of false information) and restoring the page after an act of vandalism has been detected.

[10] See, for example, the manual of style concerning formatting dates and numbers, located at `http://en.wikipedia.org/wiki/Wikipedia:DATE`.

October$_{[1958]}$ to announce a program to end the war and create an Algeria closely linked to France.

It would appear that the reference to *February 1959* is a later addition to the text which has been made without the surrounding text being appropriately revised to accommodate this change. Clearly such instances of incoherence will cause problems for any process that attempts to track the temporal focus.

4.2 Ambiguous Writing

We have also found cases of a lack of precision in writing, which leads to ambiguous statements. Consider the following example:

(3) The Afghan government, having secured a treaty in *December 1978* that allowed them to call on Soviet forces, repeatedly requested the introduction of troops in Afghanistan in *the spring* and *summer of 1979*. They requested Soviet troops to provide security and to assist in the fight against the mujahideen rebels. On *April 14, 1979*, the Afghan government requested that the USSR send 15 to 20 helicopters with their crews to Afghanistan, and on *June 16*, the Soviet government responded and sent a detachment of tanks, BMPs, and crews to guard the government in Kabul and to secure the Bagram and Shindand airfields. In response to this request, an airborne battalion, commanded by Lieutenant Colonel A. Lomakin, arrived at the Bagram Air Base on *July 7*. [...]

After *a month*, the Afghan requests were no longer for individual crews and subunits, but for regiments and larger units. In *July*, the Afghan government requested that two motorized rifle divisions be sent to Afghanistan. *The following day*, they requested an airborne division in addition to the earlier requests.

Here, in the first paragraph there are four temporal expressions related to the Afghan government asking for troops and equipment. There is also one date related to the Soviets' reply to these requests and sending of tanks, and one date related to the arrival of an airborne battalion. The second paragraph starts with *after a month*; the first possible interpretation is that this is a month after the 7th July mentioned in the previous paragraph; i.e. the month would end on the 6th of August. But the following sentence reveals that this is not the case, as it mentions some requests for larger units that were made in July. Usually a narrative progresses forwards in time, not backwards, so the month must start either on 14th April or 16th June: if the second sentence elaborates the first one, then it is a month from 16th June; if it just mentions one of the requests for larger units, then it is probably a month from 14th April.

It is also unclear whether the second paragraph talks about the same request for airborne forces which was mentioned in the first paragraph: both these events are dated July. The phrase *In response to this request* is in fact placed very oddly, as its preceding sentence does not mention any request, but rather talks about the Soviets' response to requests. This may suggest that what at first looks just like a careless and ambiguous use of the expression *after a month* is in fact a larger problem of lack of coherency in these two paragraphs.

4.3 Use of Deictic Expressions

One of the articles, `07_IraqWar`, contained a number of deictic temporal expressions, indicative of the fact that the events described were happening contemporaneously to the time of writing (as is often the case in news stories); for example:

(4) a. Democrats plan to push legislation *this spring* that would force the Iraqi government to spend its own surplus to rebuild.

b. A protester said that despite the approval of the Interim Security pact, the Iraqi people would break it in a referendum *next year*.

Obviously, after some time these expressions will no longer make sense, since there is no 'at-the-time-of-writing' time stamp associated with these sentences: for the reader of a Wikipedia article, the reference date is the time of reading. In the case of the above example, these sentences were written in April and December 2008, respectively.[11] Arguably, these sentences should be corrected, making the temporal expressions fully-specified (e.g. *in spring of 2009* and *in 2009*), or context-dependent (e.g. *in spring of that year* and *the following year*) if there is a context in the article which supports their correct interpretation. Of course, not only the temporal expressions need to be revised, but also the tense and aspect of the verbs used in the sentences. In the gold standard annotations, however, we provided the values by interpreting these expressions with respect to the document time stamp (i.e. `2010-SP` and `2010`), as the text itself does not provide any evidence that other dates were intended.

[11] Somewhat laborious document archaeology allows this information to be extracted from Wikipedia's archive.

Table 4: The most frequent tokens in TEs in the WikiWars corpus.

4.4 Use of Time Zone Information

Consider the following example, which comes from the article `01_WW2`:

(5) On *December 7 (December 8 in Asian time zones), 1941*, Japan attacked British and American holdings with near simultaneous offensives against Southeast Asia and the Central Pacific.

The italicized temporal expression is difficult to detect, and it is not clear how it should be annotated. But it is also imprecise with respect to which time zone is intended: Asia encompasses 10 time zones. Therefore it is impossible to fully interpret the expression. Note also that the expression combines a time zone with a date, rather than with a time. While uncommon, this is not incorrect; but the TIMEX2 guidelines do not explicitly allow for this circumstance.

4.5 Quotes Missing a Time Stamp

Occasionally it happens that an article contains a quoted utterance, but there is no indication of when the utterance was made. For example, in the document `05_VietnamWar` we find the following:

(6) Nixon said in an announcement, “I am *tonight* announcing plans for the withdrawal of an additional 150,000 American troops to be completed during *the*

> *spring of next year*. This will bring a total reduction of 265,500 men in our armed forces in Vietnam below the level that existed when we took office *15 months ago*."

It is impossible to determine what dates are meant by the three temporal expressions present in the announcement. In some cases this information may be provided in citation footnotes, but this is not always the case; when this is absent, such expressions can only be annotated at the level of textual extent and a localised, context-dependent semantics.

5 Comparing WikiWars to the ACE Data

A comparison of WikiWars with the ACE corpora reveals some interesting differences.

5.1 Vocabulary Differences

First, we found differences on the level of the lexical triggers that signal the presence of temporal expressions. Because of space limitations, we provide here only the main findings.

Tables 3 and 4 present the 51 most frequent tokens, including punctuation, in the ACE 2005 Training and WikiWars corpus, respectively. Some tokens are combined into what we call **trigger classes**; for example, all weekday names belong to the class `WEEKDAYNAME`.[12]

We can see that there are many classes that fall into the top 51 positions for both corpora, e.g. the names of temporal units (such as *month* and *year*). But there are also clear differences. Month names are the most frequent class in WikiWars, while they are not so frequent in ACE. Similarly, year seasons ranked very highly in WikiWars, but do not figure in the rankings shown for ACE. On the other hand, weekday names are quite frequent in the ACE corpus, but do not occur in the table for WikiWars. This suggests that these corpora make different use of temporal expressions: in WikiWars we find many references to the more distant past, thus the high use of month names, but ACE documents tend to discuss temporally local issues, so they are more likely to refer to days in the weeks preceding and following the reference date.

Looking at individual tokens, we can see that deictic expressions such as *today*, *tonight*, *yesterday* and *tomorrow* are in the top 51 positions for ACE, but almost never occur in WikiWars: there are only three instances of *today*, two of *tomorrow* and one of *tonight* in the corpus, and all of these appear only in quoted speech. Similarly, *ago* occurred 113 times in ACE, but only twice in WikiWars: once in quoted speech, and once used incorrectly instead of *earlier* in a context-dependent expression. Other tokens which are frequent in ACE but rare in WikiWars are *recent*, *recently*, *current* and *currently*.

5.2 Temporal Discourse Structure

A more interesting property that WikiWars exhibits, and which is noticeably absent from the simpler ACE data, is what we might think of as a discourse mechanism for resetting the temporal focus. This is a feature of complex texts in general, rather than something that is specific to Wikipedia as a source. In these cases, the discourse does not follow a single global timeline from the beginning to the end of the document, but is rather divided into subdiscourses which describe separate chains of events that often have common temporal starting points. This is typical in the description of big, often international, conflicts, where one can distinguish several theaters of the war, i.e. the eastern and western theaters.

In most cases the switch to a different 'part of the story' can be determined not only by analysing the events and their geographic locations, but by recognizing that the first date appearing in the new subdiscourse is generally fully specified. This is, however, not always the case, as shown in the following example extracted from the article `01_WW2`:

(7) In northern Serbia, the Red Army, with limited support from Bulgarian forces, assisted the partisans in a joint liberation of the capital city of Belgrade on *October 20*$_{[1944]}$. *A few days later*, the Soviets launched a massive assault against German-occupied Hungary that lasted until the fall of Budapest in *February 1945*. [...]

By *the start of July*$_{[1944]}$, Commonwealth forces in Southeast Asia had repelled the Japanese sieges in Assam, pushing the Japanese back to the Chindwin River while the Chinese captured Myitkyina. In China, the Japanese were having greater successes, having fi-

[12] The entries in the table correspond to the lexical and punctuation clues that drive detection of temporal expressions: the high rank of colons and dashes comes from their use in document time stamps, which are considered markable by the TIMEX2 guidelines. The *T* token is a separator that often occurs in timestamps, e.g. *2005-01-25T11:08:00*; the question mark appears very often because some of the ACE timestamps are of the form *????-??-??T19:33:00*.

> nally captured Changsha in *mid-June*$_{[1944]}$ and the city of Hengyang by *early August*$_{[1944]}$. Soon after, they [. . .] by *the end of November*$_{[1944]}$ and successfully linking up their forces in China and Indochina by *the middle of December*$_{[1944]}$.

Clearly, quite sophisticated processing is required to handle this phenomenon adequately.

6 Automated Processing of WikiWars

After we developed the WikiWars corpus, we used it to evaluate our temporal expression tagger, DANTE, which had been developed for participation in ACE. Performance at finding temporal expressions in text is traditionally reported, for example by (Mani and Wilson, 2000; Negri and Marseglia, 2005; Teissèdre et al., 2010), in terms of precision, recall and F-measure. These can, however, be calculated in two ways, **lenient** and **strict**, corresponding to two tasks: **detection** (where a single character overlap between the gold standard and system annotation counts as a correct answer) and **recognition** (where an exact overlap is required).

Table 5 shows our tagger's initial performance on the data. While the lenient F-measure for extent recognition was comparable to that obtained for the ACE 2005 Training corpus (0.82 vs 0.78), the recall was much lower: 0.75 vs 0.87. The difference in strict results was even larger, where both precision and recall were lower for WikiWars than for ACE, resulting in an F-measure of 0.38. When evaluating also the `VAL` attribute, the strict F-measure was quite low for both corpora, but significantly lower for WikiWars: 0.17 vs 0.33. This illustrates how illusive it may be to trust the performance of a tagger measured on a single, possibly biased, data set.

In the light of the results of our comparison in Section 5, it is clear that at some of the performance loss here is simply due to domain differences with respect to lexical triggers. So, we extended DANTE's coverage with approximately 20 temporal triggers and modifiers to include the more common vocabulary that appeared in the WikiWars data; we also modified the recognition grammar to reduce the number of spurious matches and extent errors. These changes resulted in the improvements shown in Table 6. The performance on extent recognition improves significantly for both sets of data, but the gap between extent recognition and evaluation of the `VAL` attribute is much larger on WikiWars. This is most likely because the strategy of using the document time stamp for the interpretation of context-dependent expressions does not work at all for WikiWars documents, whereas it works well for ACE documents, in line with our earlier comments in regard to the genres of the documents. This emphasises the need to develop sophisticated methods for temporal focus tracking if we are to extend current time-stamping technologies beyond the relatively simplistic temporal structures found in currently available corpora.

	Lenient			Strict		
Corpus and Task	Prec	Rec	F	Prec	Rec	F
WW - Extent only	0.90	0.75	0.82	0.42	0.35	0.38
WW - Extent + VAL	0.22	0.18	0.20	0.19	0.16	0.17
ACE - Extent only	0.71	0.87	0.78	0.53	0.65	0.58
ACE - Extent +VAL	0.34	0.42	0.37	0.30	0.36	0.33

Table 5: Initial performance of DANTE on WikiWars and the ACE 2005 Training corpus.

	Lenient			Strict		
Corpus and Task	Prec	Rec	F	Prec	Rec	F
WW - Extent only	0.98	0.99	0.99	0.95	0.95	0.95
WW - Extent + VAL	0.59	0.60	0.59	0.58	0.59	0.58
ACE - Extent only	0.88	0.93	0.90	0.75	0.79	0.77
ACE - Extent +VAL	0.63	0.67	0.65	0.57	0.60	0.58

Table 6: Current performance of DANTE on WikiWars and the ACE 2005 Training corpus.

7 Conclusions and Future Work

We have presented a new corpus based on the historical descriptions of 22 wars sourced from English Wikipedia, and we have described in detail the methodology adopted to construct the corpus; the corpus can be easily extended in the same way. We annotated temporal expressions in these documents with TIMEX2 tags, which provide both the textual extents and the semantics of the expressions in the context of whole article.

Following an analysis of the differences between our new corpus and existing data sets, we then presented the results of automatic processing of the corpus. This demonstrates that differences in the vocabulary used for temporal expressions can be fairly straightforwardly incorporated in a tagging tool, but that appropriate processing of temporal structure in complex documents requires more sophisticated techniques than those required to handle existing corpora. The WikiWars Corpus provides data that tests these capabilities.

PEM: A Paraphrase Evaluation Metric Exploiting Parallel Texts

Chang Liu[1] and **Daniel Dahlmeier**[2] and **Hwee Tou Ng**[1,2]
[1]Department of Computer Science, National University of Singapore
[2]NUS Graduate School for Integrative Sciences and Engineering
{liuchan1,danielhe,nght}@comp.nus.edu.sg

Abstract

We present PEM, the first fully automatic metric to evaluate the quality of paraphrases, and consequently, that of paraphrase generation systems. Our metric is based on three criteria: *adequacy*, *fluency*, and *lexical dissimilarity*. The key component in our metric is a robust and shallow semantic similarity measure based on pivot language N-grams that allows us to approximate adequacy independently of lexical similarity. Human evaluation shows that PEM achieves high correlation with human judgments.

1 Introduction

In recent years, there has been an increasing interest in the task of paraphrase generation (PG) (Barzilay and Lee, 2003; Pang et al., 2003; Quirk et al., 2004; Bannard and Callison-Burch, 2005; Kauchak and Barzilay, 2006; Zhao et al., 2008; Zhao et al., 2009). At the same time, the task has seen applications such as machine translation (MT) (Callison-Burch et al., 2006; Madnani et al., 2007; Madnani et al., 2008), MT evaluation (Kauchak and Barzilay, 2006; Zhou et al., 2006a; Owczarzak et al., 2006), summary evaluation (Zhou et al., 2006b), and question answering (Duboue and Chu-Carroll, 2006).

Despite the research activities, we see two major problems in the field. First, there is currently no consensus on what attributes characterize a good paraphrase. As a result, works on the application of paraphrases tend to build their own PG system in view of the immediate needs instead of using an existing system.

Second, and as a consequence, no automatic evaluation metric exists for paraphrases. Most works in this area resort to ad hoc manual evaluations, such as the percentage of “yes” judgments to the question of “is the meaning preserved”. This type of evaluation is incomprehensive, expensive, and non-comparable between different studies, making progress hard to judge.

In this work we address both problems. We propose a set of three criteria for good paraphrases: *adequacy*, *fluency*, and *lexical dissimilarity*. Considering that paraphrase evaluation is a very subjective task with no rigid definition, we conduct experiments with human judges to show that humans generally have a consistent intuition for good paraphrases, and that the three criteria are good indicators.

Based on these criteria, we construct PEM (Paraphrase Evaluation Metric), a fully automatic evaluation metric for PG systems. PEM takes as input the original sentence R and its paraphrase candidate P, and outputs a single numeric score b estimating the quality of P as a paraphrase of R. PG systems can be compared based on the average scores of their output paraphrases. To the best of our knowledge, this is the first automatic metric that gives an objective and unambiguous ranking of different PG systems, which serves as a benchmark of progress in the field of PG.

The main difficulty of deriving PEM is to measure semantic closeness without relying on lexical level similarity. To this end, we propose *bag of pivot language N-grams* (*BPNG*) as a robust, broad-coverage, and knowledge-lean semantic representation for natural language sentences. Most importantly, BPNG does not depend on lexical or syntactic similarity, allowing us to address the conflicting requirements of paraphrase evaluation. The only linguistic re-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 923–932,
MIT, Massachusetts, USA, 9-11 October 2010.

source required to evaluate BPNG is a parallel text of the target language and an arbitrary other language, known as the pivot language.

We highlight that paraphrase evaluation and paraphrase recognition (Heilman and Smith, 2010; Das and Smith, 2009; Wan et al., 2006; Qiu et al., 2006) are related yet distinct tasks. Consider two sentences S_1 and S_2 that are the same except for the substitution of a single synonym. A paraphrase recognition system should assign them a very high score, but a paraphrase evaluation system would assign a relatively low one. Indeed, the latter is often a better indicator of how useful a PG system potentially is for the applications of PG described earlier.

The rest of the paper is organized as follows. We survey other automatic evaluation metrics in natural language processing (NLP) in Section 2. We define the task of paraphrase evaluation in Section 3 and develop our metric in Section 4. We conduct a human evaluation and analyze the results in Section 5. The correlation of PEM with human judgments is studied in Section 6. Finally, we discuss our findings and future work in Section 7 and conclude in Section 8.

2 Related work

The most well-known automatic evaluation metric in NLP is BLEU (Papineni et al., 2002) for MT, based on N-gram matching precisions. The simplicity of BLEU lends well to MT techniques that directly optimize the evaluation metric.

The weakness of BLEU is that it operates purely at the lexical surface level. Later works attempt to take more syntactic and semantic features into consideration (see (Callison-Burch et al., 2009) for an overview). The whole spectrum of NLP resources has found application in machine translation evaluation, including POS tags, constituent and dependency parses, WordNet (Fellbaum, 1998), semantic roles, textual entailment features, and more. Many of these metrics have been shown to correlate better with human judges than BLEU (Chan and Ng, 2008; Liu et al., 2010). Interestingly, few MT evaluation metrics exploit parallel texts as a source of information, when statistical MT is centered almost entirely around mining parallel texts.

Compared to these MT evaluation metrics, our method focuses on addressing the unique requirement of paraphrase evaluation: that lexical closeness does not necessarily entail goodness, contrary to the basis of MT evaluation.

Inspired by the success of automatic MT evaluation, Lin (2004) and Hovy et al. (2006) propose automatic metrics for summary evaluation. The former is entirely lexical based, whereas the latter also exploits constituent and dependency parses, and semantic features derived from WordNet.

The only prior attempt to devise an automatic evaluation metric for paraphrases that we are aware of is ParaMetric (Callison-Burch et al., 2008), which compares the collection of paraphrases discovered by automatic paraphrasing algorithms against a manual gold standard collected over the same sentences. The recall and precision of several current paraphrase generation systems are evaluated. ParaMetric does not attempt to propose a single metric to correlate well with human judgments. Rather, it consists of a few indirect and partial measures of the quality of PG systems.

3 Task definition

The first step in defining a paraphrase evaluation metric is to define a good paraphrase. Merriam-Webster dictionary gives the following definition: *a restatement of a text, passage, or work giving the meaning in another form*. We identify two key points in this definition: (1) that the meaning is preserved, and (2) that the lexical form is different. To which we add a third, that the paraphrase must be fluent.

The first and last point are similar to MT evaluation, where *adequacy* and *fluency* have been established as the standard criteria. In paraphrase evaluation, we have one more: *lexical dissimilarity*. Although lexical dissimilarity is seemingly the easiest to judge automatically among the three, it poses an interesting challenge to automatic evaluation metrics, as overlap with the reference has been the basis of almost all evaluation metrics. That is, while MT evaluation and paraphrase evaluation are conceptually closely related, the latter actually highlights the deficiencies of the former, namely that in most automatic evaluations, semantic equivalence is under-represented and substituted by lexical and syntactic equivalence.

The task of paraphrase evaluation is then defined as follows: Given an original sentence R and a paraphrase candidate P, output a numeric score b estimating the quality of P as a paraphrase of R by considering adequacy, fluency, and lexical dissimilarity. In this study, we use a scale of 1 to 5 (inclusive) for b, although that can be transformed linearly into any range desired.

We observe here that the overall assessment b is not a linear combination of the three measures. In particular, a high dissimilarity score is meaningless by itself. It could simply be that the paraphrase is unrelated to the source sentence, or is incoherent. However, when accompanied by high adequacy and fluency scores, it differentiates the mediocre paraphrases from the good ones.

4 Paraphrase Evaluation Metric (PEM)

In this section we devise our metric according to the three proposed evaluation criteria, namely adequacy, fluency, and dissimilarity. The main challenge is to measure the adequacy, or semantic similarity, completely independent of any lexical similarity. We address this problem in Sections 4.1 to 4.3. The remaining two criteria are addressed in Section 4.4, and we describe the final combined metric PEM in Section 4.5.

4.1 Phrase-level semantic representation

Without loss of generality, suppose we are to evaluate English paraphrases, and have been supplied many sentence-aligned parallel texts of French and English as an additional resource. We can then align the parallel texts at word level automatically using well-known algorithms such as GIZA++ (Och and Ney, 2003) or the Berkeley aligner (Liang et al., 2006; Haghighi et al., 2009).

To measure adequacy without relying on lexical similarity, we make the key observation that the aligned French texts can act as a proxy of the semantics to a fragment of an English text. If two English phrases are often mapped to the same French phrase, they can be considered similar in meaning. Similar observations have been made by previous researchers (Wu and Zhou, 2003; Bannard and Callison-Burch, 2005; Callison-Burch et al., 2006; Snover et al., 2009). We can treat the distribution of aligned French phrases as a semantic representation of the English phrase. The semantic distance between two English phrases can then be measured by their degree of overlap in this representation.

In this work, we use the widely-used phrase extraction heuristic in (Koehn et al., 2003) to extract phrase pairs from parallel texts into a phrase table[1]. The phrases extracted do not necessarily correspond to the speakers' intuition. Rather, they are units whose boundaries are preserved during translation. However, the distinction does not affect our work.

4.2 Segmenting a sentence into phrases

Having established a way to measure the similarity of two English phrases, we now extend the concept to sentences. Here we discuss how to segment an English sentence (the original or the paraphrase) into phrases.

From the phrase table, we know the frequencies of all the phrases and we approximate the probability of a phrase p by:

$$Pr(p) = \frac{N(p)}{\sum_{p'} N(p')} \tag{1}$$

$N(\cdot)$ is the count of a phrase in the phrase table, and the denominator is a constant for all p. We define the likelihood of segmenting a sentence S into a sequence of phrases $(p_1, p_2, \ldots, p_n)$ by:

$$Pr(p_1, p_2, \ldots, p_n | S) = \frac{1}{Z(S)} \prod_{i=1}^{n} Pr(p_i) \tag{2}$$

where $Z(S)$ is a normalizing constant. The best segmentation of S according to Equation 2 can be calculated efficiently using a dynamic programming algorithm. Note that $Z(S)$ does not need to be calculated, as it is the same for all different segmentations of S. The formula has a strong preference for longer phrases, since every $Pr(p_i)$ has a large denominator.

Many sentences are impossible to segment into known phrases, including all those containing out-of-vocabulary words. We therefore allow any single word w to be considered as a phrase, and if $N(w) = 0$, we use $N(w) = 0.5$ instead.

[1] The same heuristic is used in the popular MT package Moses.

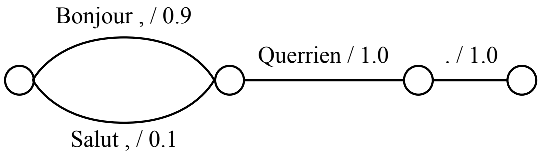

Figure 1: A confusion network in the pivot language

Figure 2: A degenerated confusion network in the pivot language

4.3 Sentence-level semantic representation

Simply merging the phrase-level semantic representations is insufficient to produce a sensible sentence-level semantic representation. For example, assume the English sentence *Morning , sir .* is segmented as a single phrase, because the following phrase pair is found in the phrase table:

En: Morning , sir .

Fr: Bonjour , monsieur .

However, another English sentence *Hello , Querrien .* has an out-of-vocabulary word *Querrien* and consequently the most probable segmentation is found to be "*Hello ,* ||| *Querrien* ||| .":

En: Hello ,

Fr: Bonjour , $(Pr(\text{Bonjour ,}|\text{Hello ,}) = 0.9)$

Fr: Salut , $(Pr(\text{Salut ,}|\text{Hello ,}) = 0.1)$

En: Querrien

Fr: Querrien

En: .

Fr: .

A naive comparison of the bags of French phrases aligned to *Morning , sir .* and *Hello , Querrien .* depicted above would conclude that the two sentences are completely unrelated, as their bags of aligned French phrases are completely disjoint. We tackle this problem by constructing a confusion network representation of the French phrases, as shown in Figures 1 and 2. The confusion network is formed by first joining the different French translations of every English phrase in parallel, and then joining these segments in series.

The confusion network is a compact representation of an exponentially large number of (likely malformed) weighted French sentences. We can easily enumerate the N-grams from the confusion network representation and collect the statistics for this ensemble of French sentences efficiently. In this work, we consider N up to 4. The N-grams for *Hello , Querrien .* are:

1-grams: Bonjour (0.9), Salut (0.1), *comma* (1.0), Querrien (1.0), *period* (1.0).

2-grams: Bonjour *comma* (0.9), Salut *comma* (0.1), *comma* Querrien (1.0), Querrien *period* (1.0).

3-grams: Bonjour *comma* Querrien (0.9), Salut *comma* Querrien (0.1), *comma* Querrien *period* (1.0).

4-grams: Bonjour *comma* Querrien *period* (0.9), Salut *comma* Querrien *period* (0.1).

We call this representation of an English sentence a *bag of pivot language N-grams* (BPNG), where French is the pivot language in our illustrating example. We can extract the BPNG of *Morning , sir .* analogously:

1-grams: Bonjour (1.0), *comma* (1.0), monsieur (1.0), *period* (1.0).

2-grams: Bonjour *comma* (1.0), *comma* monsieur (1.0), monsieur *period* (1.0).

3-grams: Bonjour *comma* monsieur (1.0), *comma* monsieur *period* (1.0).

4-grams: Bonjour *comma* monsieur *period* (1.0).

The BPNG of *Hello , Querrien.* can now be compared sensibly with that of the sentence *Morning , sir .* We use the F$_1$ agreement between the two BPNGs as a measure of the semantic similarity. The F$_1$ agreement is defined as

$$F_1 = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

The precision and the recall for an original sentence R and a paraphrase P is defined as follows. Let French N-gram $g \in$ BPNG$(R) \cup$BPNG(P), and $W_R(g)$ and $W_P(g)$ be the weights of g in the BPNG of R and P respectively, then

$$\text{Precision} = \frac{\sum_g \min(W_R(g), W_P(g))}{\sum_g W_P(g)}$$

$$\text{Recall} = \frac{\sum_g \min(W_R(g), W_P(g))}{\sum_g W_R(g)}$$

In our example, the numerators for both the precision and the recall are $0.9 + 1 + 1 + 0.9$, for the N-grams Bonjour, *comma*, *period*, and Bonjour *comma* respectively. The denominators for both terms are 10.0. Consequently, F_1 = Precision = Recall = 0.38, and we conclude that the two sentences are 38% similar. We call the resulting metric the *pivot language* F_1. Note that since F_1 is symmetric with respect to the precision and the recall, our metric is unaffected whether we consider *Morning, sir.* as the paraphrase of *Hello, Querrien .* or the other way round.

An actual example from our corpus is:

Reference sihanouk ||| put forth ||| this proposal ||| in ||| a statement ||| made ||| yesterday ||| .

Paraphrase shihanuk ||| put forward ||| this proposal ||| in his ||| yesterday ||| 's statement ||| .

The ||| sign denotes phrase segmentation as described earlier. Our semantic representation successfully recognizes that *put forth* and *put forward* are paraphrases of each other, based on their similar Chinese translation statistics (*ti2 chu1* in Chinese).

4.4 Fluency and dissimilarity

We measure the fluency of a paraphrase by a normalized language model score P_n, defined by

$$P_n = \frac{\log Pr(S)}{\text{length}(S)}$$

where $Pr(S)$ is the sentence probability predicted by a standard 4-gram language model.

We measure dissimilarity between two English sentences using the *target language* F_1, where we collect the bag of all N-grams up to 4-grams from each English (referred to as the target language) sentence. The target language F_1 is then defined as the F_1 agreement of the two bags of N-grams, analogous to the definition of the pivot language F_1. The target language F_1 correlates positively with the similarity of the two sentences, or equivalently, negatively with the dissimilarity of the two sentences.

4.5 The metric

To produce the final PEM metric, we combine the three component automatic metrics, pivot language F_1, normalized language model, and target language F_1, which measure adequacy, fluency, and dissimilarity respectively.

As discussed previously, a linear combination of the three component metrics is insufficient. We turn to support vector machine (SVM) regression with the radial basis function (RBF) kernel. The RBF is a simple and expressive function, commonly used to introduce non-linearity into large margin classifications and regressions.

$$\text{RBF}(x_i, x_j) = e^{-\gamma \|x_i - x_j\|^2}$$

We use the implementation in SVM^{light} (Joachims, 1999). The SVM is to be trained on a set of human-judged paraphrase pairs, where the three component automatic metrics are fit to the human overall assessment. After training, the model can then be used to evaluate new paraphrase pairs in a fully automatic fashion.

5 Human evaluation

To validate our definition of paraphrase evaluation and the PEM method, we conduct an experiment to evaluate paraphrase qualities manually, which allows us to judge whether paraphrase evaluation according to our definition is an inherently coherent and well-defined problem. The evaluation also allows us to establish an upper bound for the paraphrase evaluation task, and to validate the contribution of the three proposed criteria to the overall paraphrase score.

5.1 Evaluation setup

We use the Multiple-Translation Chinese Corpus (MTC)[2] as a source of paraphrases. The MTC corpus consists of Chinese news articles (993 sentences in total) and multiple sentence-aligned English translations. We select one human translation as the original text. Two other human translations and two automatic machine translations serve as paraphrases of the original sentences. We refer to the two human translations and the two MT systems as paraphrase systems *human1, human2, machine1,* and *machine2*.

We employ three human judges to manually assess the quality of 300 original sentences paired with each of the four paraphrases. Therefore, each judge assesses 1,200 paraphrase pairs in total. The

[2] LDC Catalog No.: LDC2002T01

judgment for each paraphrase pair consists of four scores, each given on a five-point scale:

- Adequacy (*Is the meaning preserved adequately?*)
- Fluency (*Is the paraphrase fluent English?*)
- Lexical Dissimilarity (*How much has the paraphrase changed the original sentence?*)
- Overall score

The instructions given to the judges for the overall score were as follows.

> *A good paraphrase should convey the same meaning as the original sentence, while being as different as possible on the surface form and being fluent and grammatical English. With respect to this definition, give an overall score from 5 (perfect) to 1 (unacceptable) for this paraphrase.*

The paraphrases are presented to the judges in a random order and without any information as to which paraphrase system produced the paraphrase.

In addition to the four paraphrase systems mentioned above, for each original English sentence, we add three more artificially constructed paraphrases with pre-determined "human" judgment scores: (1) the original sentence itself, with adequacy 5, fluency 5, dissimilarity 1, and overall score 2; (2) a random sentence drawn from the same domain, with adequacy 1, fluency 5, dissimilarity 5, and overall score 1; and (3) a random sentence generated by a unigram language model, with adequacy 1, fluency 1, dissimilarity 5, and overall score 1. These artificial paraphrases serve as controls in our evaluation. Our final data set therefore consists of 2,100 paraphrase pairs with judgments on 4 different criteria.

5.2 Inter-judge correlation

The first step in our evaluation is to investigate the correlation between the human judges. We use Pearson's correlation coefficient, a common measure of the linear dependence between two random variables.

We investigate inter-judge correlation at the sentence and at the system level. At the sentence level, we construct three vectors, each containing the 1,200 sentence level judgments from one judge for the overall score. The pair-wise correlations between these three vectors are then taken. Note that we exclude the three artificial control paraphrase systems from consideration, as that would inflate the correlation. At the system level, we construct three vectors each of size four, containing the average scores given by one judge to each of the four paraphrase systems human1, human2, machine1, and machine2. The correlations are then taken in the same fashion.

	Sentence Level		System Level	
	Judge A	Judge B	Judge A	Judge B
Judge B	0.6406	-	0.9962	-
Judge C	0.6717	0.5993	0.9995	0.9943

Table 1: Inter-judge correlation for overall paraphrase score

	Sentence Level	System Level
Adequacy	0.7635	0.7616
Fluency	0.3736	0.3351
Dissimilarity	-0.3737	-0.3937
Dissimilarity (A,F≥4)	0.8881	0.9956

Table 2: Correlation of paraphrase criteria with overall score

The results are listed in Table 1. The inter-judge correlation is between 0.60 and 0.67 at the sentence level and above 0.99 at the system level. These correlation scores can be considered very high when compared to similar results reported in MT evaluations, e.g., Blatz et al. (2003). The high correlation confirms that our evaluation task is well defined.

Having confirmed that human judgments correlate strongly, we combine the scores of the three judges by taking their arithmetic mean. Together with the three artificial control paraphrase systems, they form the human reference evaluation which we use for the remainder of the experiments.

5.3 Adequacy, fluency, and dissimilarity

In this section, we empirically validate the importance of our three proposed criteria: adequacy, fluency, and lexical dissimilarity. This can be done by measuring the correlation of each criterion with the overall score. The system and sentence level correlations are shown in Table 2.

We can see a positive correlation of adequacy and

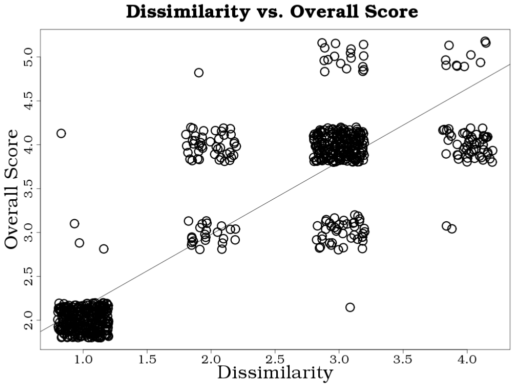

Figure 3: Scatter plot of dissimilarity vs. overall score for paraphrases with high adequacy and fluency.

fluency with the overall score, and the correlation with adequacy is particularly strong. Thus, higher adequacy and to a lesser degree higher fluency indicate higher paraphrase quality to the human judges.

On the other hand, dissimilarity is found to have a negative correlation with the overall score. This can be explained by the fact that the two human translations usually have much higher similarity with the reference translation, and at the same time are scored as better paraphrases. This effect dominates a simple linear fitting of the paraphrase score vs. the dissimilarity, resulting in the counter intuitive negative correlation. We note that a high dissimilarity alone tells us little about the quality of the paraphrase. Rather, we expect dissimilarity to be a differentiator between the mediocre and good paraphrases.

To test this hypothesis, we select the subset of paraphrase pairs that receive adequacy and fluency scores of at least four and again measure the correlation of the dissimilarity and the overall score. The result is tabulated in the last row of Table 2 and shows a strong correlation. Figure 3 shows a scatter plot of the same result[3].

The empirical results presented so far confirm that paraphrase evaluation is a well-defined task permitting consistent subjective judgments, and that adequacy, fluency, and dissimilarity are suitable criteria for paraphrase quality.

6 PEM vs. human evaluation

In the last section, we have shown that the three proposed criteria are good indicators of paraphrase quality. In this section, we investigate how well PEM can predict the overall paraphrase quality from the three automatic metrics (pivot language F_1, normalized language model, and target language F_1), designed to match the three evaluation criteria. We describe the experimental setup in Section 6.1, before we show the results in Section 6.2.

6.1 Experimental setup

We build the phrase table used to evaluate the pivot language F_1 from the FBIS Chinese-English corpus, consisting of about 250,000 Chinese sentences, each with a single English translation. The paraphrases are taken from the MTC corpus in the same way as the human experiment described in Section 5.1. Both FBIS and MTC are in the Chinese newswire domain.

We stem all English words in both data sets with the Porter stemmer (Porter, 1980). We use the maximum entropy segmenter of (Low et al., 2005) to segment the Chinese part of the FBIS corpus. Subsequently, word level Chinese-English alignments are generated using the Berkeley aligner (Liang et al., 2006; Haghighi et al., 2009) with five iterations of training. Phrases are then extracted with the widely-used heuristic in Koehn et al. (2003). We extract phrases of up to four words in length.

Bags of Chinese pivot language N-grams are extracted for all paraphrase pairs as described in Section 4.3. For computational efficiency, we consider only edges of the confusion network with probabilities higher than 0.1, and only N-grams with probabilities higher than 0.01 in the bag of N-grams. We collect N-grams up to length four.

The language model used to judge fluency is trained on the English side of the FBIS parallel text. We use SRILM (Stolcke, 2002) to build a 4-gram model with the default parameters.

The PEM SVM regression is trained on the paraphrase pairs for the first 200 original English sentences and tested on the paraphrase pairs of the remaining 100 original English sentences. Thus, there are 1,400 instances for training and 700 instances for testing. For each instance, we calculate the values

[3] We automatically add jitter (small amounts of noise) for ease of presentation.

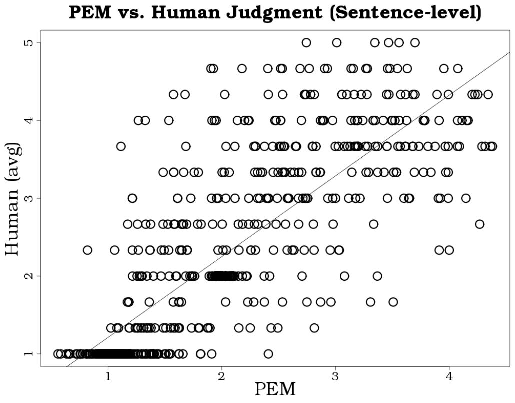

Figure 4: Scatter plot of PEM vs. human judgment (overall score) at the sentence level

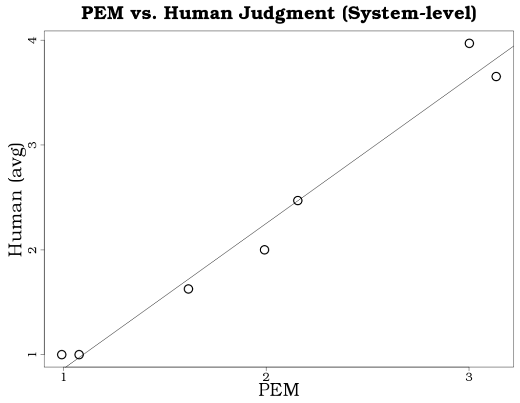

Figure 5: Scatter plot of PEM vs. human judgment (overall score) at the system level

of pivot language F$_1$, normalized language model score, and target language F$_1$. These values serve as the input features to the SVM regression and the target value is the human assessment of the overall score, on a scale of 1 to 5.

6.2 Results

As in the human evaluation, we investigate the correlation of the PEM scores with the human judgments at the sentence and at the system level. Figure 4 shows the sentence level PEM scores plotted against the human overall scores, where each human overall score is the arithmetic mean of the scores given by the three judges. The Pearson correlation between the automatic PEM scores and the human judgments is 0.8073. This is substantially higher than the sentence level correlation of MT metrics like BLEU. For example, the highest sentence level Pearson correlation by any metric in the Metrics-MATR 2008 competition (Przybocki et al., 2009) was 0.6855 by METEOR-v0.6; BLEU achieved a correlation of 0.4513.

	Sentence Level	System Level
PEM vs. Human Avg.	0.8073	0.9867
PEM vs. Judge A	0.5777	0.9757
PEM vs. Judge B	0.5281	0.9892
PEM vs. Judge C	0.5231	0.9718

Table 3: Correlation of PEM with human judgment (overall score)

Figure 5 shows the system level PEM scores plotted against the human scores. The Pearson correlation between PEM scores and the human scores at the system level is 0.9867.

We also calculate the Pearson correlation between PEM and each individual human judge. Here, we exclude the three artificial control paraphrase systems from the data, to make the results comparable to the inter-judge correlation presented in Section 5.2. The correlation is between 0.52 and 0.57 at the sentence level and between 0.97 and 0.98 at the system level. As we would expect, the correlation between PEM and a human judge is not as high as the correlation between two human judges, but PEM still shows a strong and consistent correlation with all three judges. The results are summarized in Table 3.

7 Discussion and future work

The paraphrases that we use in this study are not actual machine generated paraphrases. Instead, the English paraphrases are multiple translations of the same Chinese source sentence. Our seven "paraphrase systems" are two human translators, two machine translation systems, and three artificially created extreme scenarios. The reason for using multiple translations is that we could not find any PG system that can paraphrase a whole input sentence and is publicly available. We intend to obtain and evaluate paraphrases generated from real PG systems and compare their performances in a follow-up study.

Our method models paraphrasing up to the phrase level. Unfortunately, it makes no provisions for syntactic paraphrasing at the sentence level, which is probably a much greater challenge, and the literature offers few successes to draw inspirations from. We hope to be able to partially address this deficiency in future work.

The only external linguistic resource required by PEM is a parallel text of the target language and another arbitrary language. While we only use Chinese-English parallel text in this study, other language pairs need to be explored too. Another alternative is to collect parallel texts against multiple foreign languages, e.g., using Europarl (Koehn, 2005). We leave this for future work.

Our evaluation method does not require human-generated references like in MT evaluation. Therefore, we can easily formulate a paraphrase generator by directly optimizing the PEM metric, although solving it is not trivial:

$$\text{paraphrase}(R) = \arg\max_{P} \text{PEM}(P, R)$$

where R is the original sentence and P is the paraphrase.

Finally, the PEM metric, in particular the semantic representation BPNG, can be useful in many other contexts, such as MT evaluation, summary evaluation, and paraphrase recognition. To facilitate future research, we will package and release PEM under an open source license at `http://nlp.comp.nus.edu.sg/software`.

8 Conclusion

We proposed PEM, a novel automatic metric for paraphrase evaluation based on adequacy, fluency, and lexical dissimilarity. The key component in our metric is a novel technique to measure the semantic similarity of two sentences through their N-gram overlap in an aligned foreign language text. We conducted an extensive human evaluation of paraphrase quality which shows that our proposed metric achieves high correlation with human judgments. To the best of our knowledge, PEM is the first automatic metric for paraphrase evaluation.

Abstract

Extant Statistical Machine Translation (SMT) systems are very complex softwares, which embed multiple layers of heuristics and embark very large numbers of numerical parameters. As a result, it is difficult to analyze output translations and there is a real need for tools that could help developers to better understand the various causes of errors.

In this study, we make a step in that direction and present an attempt to evaluate the quality of the phrase-based translation model. In order to identify those translation errors that stem from deficiencies in the phrase table (PT), we propose to compute the *oracle BLEU-4 score*, that is the best score that a system based on this PT can achieve on a reference corpus. By casting the computation of the oracle BLEU-1 as an Integer Linear Programming (ILP) problem, we show that it is possible to efficiently compute accurate lower-bounds of this score, and report measures performed on several standard benchmarks. Various other applications of these oracle decoding techniques are also reported and discussed.

1 Phrase-Based Machine Translation

1.1 Principle

A Phrase-Based Translation System (PBTS) consists of a ruleset and a scoring function (Lopez, 2009). The ruleset, represented in the phrase table, is a set of phrase[1]pairs $\{(f, e)\}$, each pair expressing that the source phrase f can be rewritten (translated) into a target phrase e. *Translation hypotheses* are generated by iteratively rewriting portions of the source sentence as prescribed by the ruleset, until each source word has been consumed by exactly one rule. The order of target words in an hypothesis is uniquely determined by the order in which the rewrite operation are performed. The *search space* of the translation model corresponds to the set of all possible sequences of rules applications. The scoring function aims to rank all possible translation hypotheses in such a way that the best one has the highest score.

A PBTS is learned from a parallel corpus in two independent steps. In a first step, the corpus is aligned at the word level, by using alignment tools such as Giza++ (Och and Ney, 2003) and some symmetrisation heuristics; phrases are then extracted by other heuristics (Koehn et al., 2003) and assigned numerical weights. In the second step, the parameters of the scoring function are estimated, typically through Minimum Error Rate training (Och, 2003).

Translating a sentence amounts to finding the best scoring translation hypothesis in the search space. Because of the combinatorial nature of this problem, translation has to rely on heuristic search techniques such as greedy hill-climbing (Germann, 2003) or variants of best-first search like multi-stack decoding (Koehn, 2004). Moreover, to reduce the overall complexity of decoding, the search space is typically pruned using simple heuristics. For instance, the state-of-the-art phrase-based decoder Moses (Koehn et al., 2007) considers only a restricted number of translations for each source sequence[2] and enforces a distortion limit[3] over which phrases can be reordered. As a consequence, the best translation hypothesis returned by the decoder is not always the one with the highest score.

1.2 Typology of PBTS Errors

Analyzing the errors of a SMT system is not an easy task, because of the number of models that are combined, the size of these models, and the high complexity of the various decision making processes. For a SMT system, three different kinds of errors can be distinguished (Germann et al., 2004; Auli et al., 2009): *search errors*, *induction errors* and *model errors*. The former corresponds to cases where the hypothesis with the best score is missed by the search procedure, either because of the use of an ap-

[1] Following the usage in statistical machine translation literature, we use “phrase” to denote a subsequence of consecutive words.

[2] the ttl option of Moses, defaulting to 20.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 933–943,
MIT, Massachusetts, USA, 9-11 October 2010.

proximate search method or because of the restrictions of the search space. *Induction errors* correspond to cases where, given the model, the search space does not contain the reference. Finally, *model errors* correspond to cases where the hypothesis with the highest score is not the best translation according to the evaluation metric.

Model errors encompass several types of errors that occur during learning (Bottou and Bousquet, 2008)[4]. *Approximation errors* are errors caused by the use of a restricted and oversimplistic class of functions (here, finite-state transducers to model the generation of hypotheses and a linear scoring function to discriminate them) to model the translation process. *Estimation errors* correspond to the use of sub-optimal values for both the phrase pairs weights and the parameters of the scoring function. The reasons behind these errors are twofold: first, training only considers a finite sample of data; second, it relies on error prone alignments. As a result, some "good" phrases are extracted with a small weight, or, in the limit, are not extracted at all; and conversely that some "poor" phrases are inserted into the phrase table, sometimes with a really optimistic score.

Sorting out and assessing the impact of these various causes of errors is of primary interest for SMT system developers: for lack of such diagnoses, it is difficult to figure out which components of the system require the most urgent attention. Diagnoses are however, given the tight intertwining among the various component of a system, very difficult to obtain: most evaluations are limited to the computation of global scores and usually do not imply any kind of failure analysis.

1.3 Contribution and organization

To systematically assess the impact of the multiple heuristic decisions made during training and decoding, we propose, following (Dreyer et al., 2007; Auli et al., 2009), to work out *oracle scores*, that is to evaluate the best achievable performances of a PBTS. We aim at both studying the expressive power of PBTS and at providing tools for identifying and quantifying causes of failure.

Under standard metrics such as BLEU (Papineni et al., 2002), oracle scores are difficult (if not impossible) to compute, but, by casting the computation of the oracle unigram recall and precision as an Integer Linear Programming (ILP) problem, we show that it is possible to efficiently compute accurate lower-bounds of the oracle BLEU-4 scores and report measurements performed on several standard benchmarks.

The main contributions of this paper are twofold. We first introduce an ILP program able to efficiently find the best hypothesis a PBTS can achieve. This program can be easily extended to test various improvements to phrase-base systems or to evaluate the impact of different parameter settings. Second, we present a number of complementary results illustrating the usage of our oracle decoder for identifying and analyzing PBTS errors. Our experimental results confirm the main conclusions of (Turchi et al., 2008), showing that extant PBTs have the potential to generate hypotheses having very high BLEU-4 score and that their main bottleneck is their scoring function.

The rest of this paper is organized as follows: in Section 2, we introduce and formalize the oracle decoding problem, and present a series of ILP problems of increasing complexity designed so as to deliver accurate lower-bounds of oracle score. This section closes with various extensions allowing to model supplementary constraints, most notably reordering constraints (Section 2.5). Our experiments are reported in Section 3, where we first introduce the training and test corpora, along with a description of our system building pipeline (Section 3.1). We then discuss the baseline oracle BLEU scores (Section 3.2), analyze the non-reachable parts of the reference translations, and comment several complementary results which allow to identify causes of failures. Section 4 discuss our approach and findings with respect to the existing literature on error analysis and oracle decoding. We conclude and discuss further prospects in Section 5.

2 Oracle Decoder

2.1 The Oracle Decoding Problem

Definition To get some insights on the errors of phrase-based systems and better understand their limits, we propose to consider the *oracle decoding problem* defined as follows: given a source sentence, its reference translation[5] and a phrase table, what is the "best" translation hypothesis a system can generate? As usual, the quality of an hypothesis is evaluated by the similarity between the reference and the hypothesis. Note that in the oracle decoding problem, we are only assessing the ability of PBT systems to generate good candidate translations, irrespective of their ability to score them properly.

We believe that studying this problem is interesting for various reasons. First, as described in Section 3.4, comparing the best hypothesis a system could have generated and the hypothesis it actually generates allows us to carry on both quantitative and qualitative failure analysis. The oracle decoding problem can also be used to assess the *expressive power* of phrase-based systems (Auli et al., 2009). Other applications include computing acceptable pseudo-references for discriminative training (Tillmann and Zhang, 2006; Liang et al., 2006; Arun and

[4] We omit here *optimization errors*.

[5] The oracle decoding problem can be extended to the case of multiple references. For the sake of simplicity, we only describe the case of a single reference.

Koehn, 2007) or combining machine translation systems in a multi-source setting (Li and Khudanpur, 2009). We have also used oracle decoding to identify erroneous or difficult to translate references (Section 3.3).

Evaluation Measure To fully define the oracle decoding problem, a measure of the similarity between a translation hypothesis and its reference translation has to be chosen. The most obvious choice is the BLEU-4 score (Papineni et al., 2002) used in most machine translation evaluations.

However, using this metric in the oracle decoding problem raises several issues. First, BLEU-4 is a metric defined at the corpus level and is hard to interpret at the sentence level. More importantly, BLEU-4 is not decomposable[6]: as it relies on 4-grams statistics, the contribution of each phrase pair to the global score depends on the translation of the previous and following phrases and can not be evaluated in isolation. Because of its non-decomposability, maximizing BLEU-4 is hard; in particular, the phrase-level decomposability of the evaluation metric is necessary in our approach.

To circumvent this difficulty, we propose to evaluate the similarity between a translation hypothesis and a reference by the number of their common words. This amounts to evaluating translation quality in terms of unigram precision and recall, which are highly correlated with human judgements (Lavie et al.,). This measure is closely related to the BLEU-1 evaluation metric and the Meteor (Banerjee and Lavie, 2005) metric (when it is evaluated without considering near-matches and the distortion penalty). We also believe that hypotheses that maximize the unigram precision and recall at the sentence level yield corpus level BLEU-4 scores close the maximal achievable. Indeed, in the setting we will introduce in the next section, BLEU-1 and BLEU-4 are highly correlated: as all correct words of the hypothesis will be compelled to be at their correct position, any hypothesis with a high 1-gram precision is also bound to have a high 2-gram precision, etc.

2.2 Formalizing the Oracle Decoding Problem

The oracle decoding problem has already been considered in the case of word-based models, in which all translation units are bound to contain only one word. The problem can then be solved by a *bipartite graph matching* algorithm (Leusch et al., 2008): given a $n \times m$ binary matrix describing possible translation links between source words and target words[7], this algorithm finds the subset of links maximizing the number of words of the reference that have been translated, while ensuring that each word is translated only once.

Generalizing this approach to phrase-based systems amounts to solving the following problem: given a set of possible translation links between potential phrases of the source and of the target, find the subset of links so that the unigram precision and recall are the highest possible. The corresponding oracle hypothesis can then be easily generated by selecting the target phrases that are aligned with one source phrase, disregarding the others. In addition, to mimic the way OOVs are usually handled, we match identical OOV tokens appearing both in the source and target sentences. In this approach, the unigram precision is always one (every word generated in the oracle hypothesis matches exactly one word in the reference). As a consequence, to find the oracle hypothesis, we just have to maximize the recall, that is the number of words appearing both in the hypothesis and in the reference.

Considering phrases instead of isolated words has a major impact on the computational complexity: in this new setting, the optimal segmentations in phrases of both the source and of the target have to be worked out in addition to links selection. Moreover, constraints have to be taken into account so as to enforce a proper segmentation of the source and target sentences. These constraints make it impossible to use the approach of (Leusch et al., 2008) and concur in making the oracle decoding problem for phrase-based models more complex than it is for word-based models: it can be proven, using arguments borrowed from (De Nero and Klein, 2008), that this problem is NP-hard even for the simple unigram precision measure.

2.3 An Integer Program for Oracle Decoding

To solve the combinatorial problem introduced in the previous section, we propose to cast it into an Integer Linear Programming (ILP) problem, for which many generic solvers exist. ILP has already been used in SMT to find the optimal translation for word-based (Germann et al., 2001) and to study the complexity of learning phrase alignments (De Nero and Klein, 2008) models. Following the latter reference, we introduce the following variables: $f_{i,j}$ (resp. $e_{k,l}$) is a binary indicator variable that is true when the phrase contains all spans from between-word position i to j (resp. k to l) of the source (resp. target) sentence. We also introduce a binary variable, denoted $a_{i,j,k,l}$, to describe a possible link between source phrase $f_{i,j}$ and target phrase $e_{k,l}$. These variables are built from the entries of the phrase table according to *selection strategies* introduced in Section 2.4. In the following, index variables are so that:

$$0 \leq i < j \leq n, \text{in the source sentence and}$$
$$0 \leq k < l \leq m, \text{in the target sentence,}$$

[6] Neither at the sentence (Chiang et al., 2008), nor at the phrase level.

[7] The (i, j) entry of the matrix is 1 if the i^{th} word of the source can be translated by the j^{th} word of the reference, 0 otherwise.

where n (resp. m) is the length of the source (resp. target) sentence.

Solving the oracle decoding problem then amounts to optimizing the following objective function:

$$\max_{i,j,k,l} \sum_{i,j,k,l} a_{i,j,k,l} \cdot (l-k)\,, \tag{1}$$

under the constraints:

$$\forall x \in \llbracket 1, m \rrbracket : \sum_{k,l \text{ s.t. } k \leq x \leq l} e_{k,l} \leq 1 \tag{2}$$

$$\forall y \in \llbracket 1, n \rrbracket : \sum_{i,j \text{ s.t. } i \leq y \leq j} f_{i,j} = 1 \tag{3}$$

$$\forall k, l : \sum_{i,j} a_{i,j,k,l} = f_{k,l} \tag{4}$$

$$\forall i, j : \sum_{k,l} a_{i,j,k,l} = e_{i,j} \tag{5}$$

The objective function (1) corresponds to the number of target words that are generated. The first set of constraints (2) ensures that each word in the reference $\mathbf{e}$ appears in no more than one phrase. Maximizing the objective under these constraints amounts to maximizing the unigram recall. The second set of constraints (3) ensures that each word in the source $\mathbf{f}$ is translated exactly once, which guarantees that the search space of the ILP problem is the same as the search space of a phrase-based system. Constraints (4) bind the $f_{k,l}$ and $a_{i,j,k,l}$ variables, ensuring that whenever a link $a_{i,j,k,l}$ is active, the corresponding phrase $f_{k,l}$ is also active. Constraints (5) play a similar role for the reference.

The `Relaxed` Problem Even though it accurately models the search space of a phrase-based decoder, this programs is not really useful as is: due to out-of-vocabulary words or missing entries in the phrase table, the constraint that all source words should be translated yields infeasible problems[8]. We propose to relax this problem and allow some source words to remain untranslated. This is done by replacing constraints (3) by:

$$\forall y \in \llbracket 1, n \rrbracket : \sum_{i,j \text{ s.t. } i \leq y \leq j} f_{i,j} \leq 1$$

To better reflect the behavior of phrase-based decoders, which attempt to translate all source words, we also need to modify the objective function as follows:

$$\sum_{i,j,k,l} a_{i,j,k,l} \cdot (l-k) + \sum_{i,j} f_{i,j} \cdot (j-i) \tag{6}$$

The second term in this new objective ensures that optimal solutions translate as many source words as possible.

The `Relaxed-Distortion` Problem A last caveat with the `Relaxed` optimization program is caused by frequently occurring source tokens, such as function words or punctuation signs, which can often align with more than one target word. For lack of taking distortion information into account in our objective function, all these alignments are deemed equivalent, even if some of them are clearly more satisfactory than others. This situation is illustrated on Figure 1.

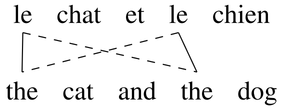

Figure 1: Equivalent alignments between "le" and "the". The dashed lines corresponds to a less interpretable solution.

To overcome this difficulty, we propose a last change to the objective function:

$$\sum_{i,j,k,l} a_{i,j,k,l} \cdot (l-k) + \sum_{i,j} f_{i,j} \cdot (j-i) \\ - \alpha \sum_{i,j,k,l} a_{i,j,k,l} |k-i| \tag{7}$$

Compared to the objective function of the relaxed problem (6), we introduce here a supplementary penalty factor which favors monotonous alignments. For each phrase pair, the higher the difference between source and target positions, the higher this penalty. If α is small enough, this extra term allows us to select, among all the optimal alignments of the `relaxed` problem, the one with the lowest distortion. In our experiments, we set α to $\min\{n, m\}$ to ensure that the penalty factor is always smaller than the reward for aligning two single words.

2.4 Selecting Indicator Variables

In the approach introduced in the previous sections, the oracle decoding problem is solved by selecting, among a set of possible translation links, the ones that yield the solution with the highest unigram recall.

We propose two strategies to build this set of possible translation links. In the first one, denoted *exact match*, an indicator $a_{i,j,k,l}$ is created if there is an entry (f, e) so that f spans from word position i to j in the source and e from word position k to l in the target. In this strategy, the ILP program considers exactly the same ruleset as conventional phrase-based decoders.

We also consider an alternative strategy, which could help us to identify errors made during the phrase extraction process. In this strategy, denoted *inside match*, an indicator $a_{i,j,k,l}$ is created when the following three criteria are met: *i)* f spans from position i to j of the source; *ii)* a *substring* of e, denoted $\bar{e}$, spans from position k to l

[8] An ILP problem is said to be *infeasible* when every possible solution violates at least one constraint.

of the reference; *iii)* $(f, \bar{e})$ is not an entry of the phrase table. The resulting set of indicator variables thus contains, at least, all the variables used in the exact match strategy. In addition, we license here the use of phrases containing words that do not occur in the reference. In fact, using such solutions can yield higher BLEU scores when the reward for additional correct matches exceeds the cost incurred by wrong predictions. These cases are symptoms of situations where the extraction heuristic failed to extract potentially useful subphrases.

2.5 Oracle Decoding with Reordering Constraints

The ILP problem introduced in the previous section can be extended in several ways to describe and test various improvements to phrase-based systems or to evaluate the impact of different parameter settings. This flexibility mainly stems from the possibility offered by our framework to express arbitrary constraints over variables. In this section, we illustrate these possibilities by describing how reordering constraints can easily be considered.

As a first example, the Moses decoder uses a distortion limit to constrain the set of possible reorderings. This constraint "enforces (...) that the last word of a phrase chosen for translation cannot be more than d[9] words from the leftmost untranslated word in the source" (Lopez, 2009) and is expressed as:

$$\forall a_{ijkl}, a_{i'j'k'l'} \text{ s.t. } k > k', \qquad a_{ijkl} \cdot a_{i'j'k'l'} \cdot |j - i' + 1| \leq d,$$

The maximum distortion limit strategy (Lopez, 2009) is also easily expressed and take the following form (assuming this constraint is parameterized by d):

$$\forall l < m - 1, \qquad a_{i,j,k,l} {\cdot} a_{i',j',l+1,l'} \cdot |i' - j - 1| < d$$

Implementing the "local" or MJ-d (Kumar and Byrne, 2005) reordering strategy is also straightforward, and implies using the following constraints:

$$\forall i, k, \left| \sum_{i' \leq i} a_{i',j',k',l'} - \sum_{k' \leq k} a_{i',j',k',l'} \right| \leq d$$

Similarly, It is possible to simulate decoding under the so-called IBM(d) reordering constraints[10] by considering the following constraints:

$$\forall \mu \leq m, \max_{\substack{i,k,l \\ j \leq \mu}} a_{i,j,k,l} \cdot j - \sum_{i,j,k,l} a_{i,j,k,l} \cdot (j - i) \leq d$$

In these constraints, the first factor corresponds to the rightmost translated word of the source and the second one to the number of translated source words. The constraints simply enforce that, at each step of the decoding, there are no more than d source words that were skipped.

Note that the constraints introduced above are not all linear in the problem variables; however they can easily be linearized using standard ILP techniques (Roth and Yih, 2005).

3 Oracle Decoding for Failure Analysis

3.1 Experimental Setting

We propose to use our oracle decoder to study the ability of a PBTS to translate from English to French and from German to English. These two languages pairs present different challenges: English to French translation is considered a relatively easy pair, notwithstanding the difficulties of generating the right inflection marks in French. Translating from German into English is more difficult, notably due to the productivity of inflectional and compounding processes in German, and also to significant differences in word ordering between these languages.

Our experiments are based on the corpora distributed for the WMT'09 constrained tasks (Callison-Burch et al., 2009). All data are tokenized, cleaned and converted to lowercase letters using the tools provided by the organizers. We then used a standard training pipeline to construct the translation model: the bitexts were aligned using Giza++[11], symmetrized using the `grow-diag-final-and` heuristic; the phrase table was extracted and scored using the tools distributed with Moses.[12] Finally, baseline systems were optimized using WMT'08 test set as development using MERT. Note that, for all these steps, we used the default value of the various parameters. The extracted phrase table is then used to find the oracle alignment on the task test set. Recall that oracle decoding do not use the scores estimated by Moses in any way.

In the experiments reported below, two settings are considered. In the first one, denoted NEWSCO, Moses was trained only on a small data set taken from the News Commentary corpus. Using a small sized corpus reduces both training time and decoding time, which allows us to quickly test different configurations of the decoder. In a second setting, denoted EUROPARL, Moses was trained on a larger corpora containing the entirety of the Europarl Corpus, but no in-domain data, to provide results on more realistic conditions. Statistics regarding the different corpora used are reported in Table 1. These statistics are computed on the lowercase cleaned corpora.

[9] This corresponds to the *dl* parameter of Moses

[10] Under IBM(d) constraints, the translation is done, phrase by phrase, from the beginning of the sentence until the end and only one of the first d untranslated phrase can be selected for translation.

% OOV	5.3%	3.1%	8.0%	5.2%

Table 1: Statistics regarding the training corpora: number of words, number of sentences, vocabulary and phrase table size and percentage of test words not appearing in the train set (OOV).

Finding the oracle alignment amounts to solving the ILP problems introduced above. Even though ILP problems are NP-hard in general, there exist several off-the-shelf ILP solvers able to efficiently find an optimal solution or decide that the problem is infeasible. In our experiments, we used the free solver `SCIP` (Achterberg, 2007). An optimal solution was found for all problems we considered. Decoding the $3,027$ sentences of WMT'09 test set takes about 10 minutes (wall time) for the NEWSCO setting, and several hours for the EUROPARL setting[13].

3.2 Oracle BLEU Score

Table 2 reports, for all considered settings, the BLEU-4 scores[14] achieved by our oracle decoder, as well as the number of source words used to generate the oracle hypothesis and the number of target words that are reachable. In these experiments, two objective functions were considered: first, we only consider the objective function corresponding to the relaxed problem defined by Eq. (6); second, we introduced an extra term in the objective to penalize distortion, as described by Eq. (7). Unless explicitly stated otherwise, we always used the exact match strategy.

The main result in 2 is that, for the two language pairs considered, the expressive power of PBTS is not the limiting factor to achieve high translation performance. In fact, for most sentences in the test set, excellent oracle hypotheses, which contain a very high proportion of reference words, are found. This remains true even when the phrase table is extracted from a small corpus. Given that the best BLEU-4 scores achieved during the WMT'09 evaluation are about 28 for the English to French task and 24 for the German to English task ((Callison-Burch et al., 2009), Tables 26 and 25), these results strongly suggest that the main bottleneck of current phrase-based translation systems is their scoring function rather than their expressive power. As we will discuss in Section 4, similar conclusions were drawn by (Auli et al., 2009) and (Turchi et al., 2008).

Several additional comments on these numbers are in order. Despite these very high BLEU scores, in most cases, the reference is only partly translated. In the most favorable case, for the English to French EUROPARL setting, only 26% of the references could be fully generated[15]. These numbers are consistent with the results reported in (Auli et al., 2009). Similarly, only about 31% of the source sentences are completely translated by the oracle decoder, which supports our choice to consider a relaxed version of the ILP problem. Finally, Table 2 also shows that introducing the distortion penalty does not affect the oracle performance of the decoder.

Considering the inside match strategy improves the performance of the oracle decoder: for instance, for the English to French NEWSCO setting, oracle decoder with the inside match strategy achieves a BLEU-4 score of 70.15 (a 2.5 points improvement over the baseline). To achieve this score, 21.45% of the phrases used during decoding were phrases that are not considered by the exact match strategy. Similar results can be observed for other settings, which highlights the significance of one kind of failure of the extraction heuristic: useful "subphrases" of actual phrase pairs are not always extracted.

The numbers in Table 2, no matter how good they may look, should be considered with caution: they only imply that, for most test sentences, all the information necessary to produce a good translation is available in the phrase table. However, the alignment decisions underlying these oracle hypotheses are sometimes hard to justify, and one has to accept that part of these good hypotheses translations are due to a series of lucky alignment errors. This is illustrated on Figure 2, which displays one such lucky oracle alignment based on the misalignment, during training, of the French preposition "des" (*of the*) with the English noun "stock". Such lucky errors are naturally also observed in the outputs of conventional decoders, even though phrase table filtering heuristics probably makes them somewhat more rare.

3.3 Analyzing Non-Reachable Parts of a Reference

Table 3 contains typical examples of sentence pairs that could not be fully generated by our oracle decoder. They

[13] All our experiments are run on a 8 cores computer, each core being a 2.2GHz Intel Processor; the decoder is multi-threaded.

[14] These are computed on lowercase with the default tokenization.

[15] Similar numbers were obtained, albeit much more slowly, with the `--constraint` option of Moses.

	training set	objective function	% source translated	% target generated	4-BLEU
en → fr	NewsCo	Relaxed	86.04%	84.74%	67.65
		Relaxed-Distortion	85.99%	84.77%	67.77
	EuroParl	Relaxed	93.66%	93.06%	85.05
		Relaxed-Distortion	93.65%	93.06%	85.08
de → en	NewsCo	Relaxed	82.57%	82.33%	64.60
		Relaxed-Distortion	82.59%	82.30%	64.65
	EuroParl	Relaxed	90.34%	91.16%	81.77
		Relaxed-Distortion	90.36%	91.12%	81.77

Table 2: Translation score of the ILP oracle decoder for the various settings described in Section 3.1

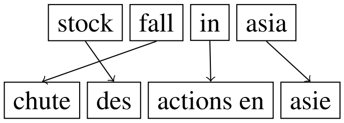

Figure 2: Example of alignment obtained by our oracle decoder

illustrate the three main reasons which cause some parts of the reference to remain *unreachable*:

- phrases are missing from the phrase table, either because they do not occur in the training corpus (OOVs) or because they failed to be extracted. In Table 3, OOV errors are mainly due to past tense forms translated into verbs conjugated in *passé simple* (“rejeta”, “rencontrèrent”, “renoua”) a French literary tense, mostly used in formal writings.
- obvious errors (misspelled words, misinterpretation or mistranslation, ...) in the reference. The reference of the fifth example contains one such error: the state name “Nevada” is translated to “n’évadiez” (literally “have not escaped”), yielding a very poor reference sentence.
- parts of the reference have no translation equivalence in the source. This can be either because references are produced in “context” and some pieces of information are moved across sentence boundaries or because these references are non-literal. The fourth example, which seems to be the translation of a title, falls into this category: the French part contains a reference to the context (“les SA” is referring to the bacteria the text is talking about) which is not in the source text. Non-literal translation are illustrated by the third example, where English “Monday” is translated into French “la veille” *(the day before)*.

While the first kind of errors is inherent to the use of a statistical approach, the last two kinds result from the quality of the data used in the evaluation and directly impact both training and evaluation of automatic translation systems: if they should not distort too much comparisons of MT systems, these errors prevent us from assessing the “global” quality of automatic translation and, if similar errors are found in the train set, they make learning harder as some probability mass is wasted to model them.

To provide a more quantitative analysis, we manually looked at all the non-aligned parts of some WMT’09 references and found that out of 800 references, more than 133 contain either an obvious translation error or can not be achieved by a PBTS[16]. Note that, while identifying these errors could be done in many ways, our oracle decoder makes it far easier.

3.4 Identifying Causes of Failure

By comparing the hypotheses found by the oracle decoder and the ones found by the phrase-based decoder, causes of failure can be easily identified. In this section, we will present several measures that allow us to identify and quantify several causes of failure.

Errors Caused by Search Space Pruning Recall from Section 1.1 that Moses uses several heuristics to prune the search space. In particular, there is a distortion limit and a limit on the number of target phrases considered for one source phrase. In this paragraph, we evaluate the impact of these two heuristics on translation quality.

Table 4 presents the average distortion computed on the oracle hypotheses, as well as the percentage of phrases used that have a distortion strictly greater than 6 (the default distortion limit of Moses). All these numbers are obtained by solving the Relaxed-Distortion problem. Surprisingly enough, the average distortion of oracle hypotheses is quite small, even for the German to English task, and the distortion constraint seems to be violated only in a few cases. It also appears that the distortion of the hypotheses generated in the NewsCo setting is significantly larger than in the EuroParl setting. This can be explained by the extra degrees of freedom in the

[16] Annotation at a finer level is an on-going effort; the annotated corpus is available from http://www.limsi.fr/Individu/wisniews/oracle_decoding.

①	– On Monday the American House of Representatives **rejected** the plan to support the financial system, into which up to 700 billion dollars (nearly 12 **billion Czech crowns**) was to be invested. – Lundi, la chambre des représentants américaine *rejeta* le projet de soutient du système financier, auquel elle aurait dû consacrer jusqu'à 700 milliards de dollars (près de 12 *bilions* de *kč*).
②	– Representatives of the legislators met with American Finance Minister Henry Paulson Saturday night in order to give the government fund a final form. – Dans la nuit de samedi à **dimanche**, des représentants des législateurs *rencontrèrent* le ministre des finances américain Henry Paulson, afin de donner au fond du gouvernement une forme finale.

	EUROPARL	3.21	13.32%
de → en	NEWSCO	5.16	25.37%
	EUROPARL	3.81	17.21%

Table 4: Average distortion and percentage of phrases with a distortion greater that Moses default distortion limit.

alignment decisions enabled by the use of larger training corpora and phrase table.

To evaluate the impact of the second heuristic, we computed the number of phrases discarded by Moses (because of the default *ttl* limit) but used in the oracle hypotheses. In the English to French NEWSCO setting, they account for 34.11% of the total number of phrases used in the oracle hypotheses. When the oracle decoder is constrained to use the same phrase table as Moses, its BLEU-4 score drops to 42.78. This shows that filtering the phrase table prior to decoding discards many useful phrase pairs and is seriously limiting the best achievable performance, a conclusion shared with (Auli et al., 2009).

Search Errors Search errors can be identified by comparing the score of the best hypothesis found by Moses and the score of the oracle hypothesis. If the score of the oracle hypothesis is higher, then there has been a search error; on the contrary, there has been an estimation error when the score of the oracle hypothesis is lower than the score of the best hypothesis found by Moses.

Based on the comparison of the score of Moses hypotheses and of oracle hypotheses for the English to French NEWSCO setting, our preliminary conclusion is that the number of search errors is quite limited: only about 5% of the hypotheses of our oracle decoder are actually getting a better score than Moses solutions. Again, this shows that the scoring function (model error) is one of the main bottleneck of current PBTS. Comparing these hypotheses is nonetheless quite revealing: while Moses mostly selects phrase pairs with high translation scores and generates monotonous alignments, our ILP decoder uses larger reorderings and less probable phrases to achieve better solutions: on average, the reordering score of oracle solutions is -5.74, compared to -76.78 for Moses outputs. Given the weight assigned through MERT training to the distortion score, no wonder that these hypotheses are severely penalized.

The Impact of Phrase Length The observed outputs do not only depend on decisions made during the search, but also on decisions made during training. One such decision is the specification of maximal length for the source and target phrases. In our framework, evaluating the impact of this decision is simple: it suffices to change the definition of indicator variables so as to consider only alignments between phrases of a given length.

In the English-French NEWSCO setting, the most restrictive choice, when only alignments between single words are authorized, yields an oracle BLEU-4 of 48.68; however, authorizing phrases up to length 2 allows to achieve an oracle value of 66.57, very close to the score achieved when considering all extracted phrases (67.77).

This is corroborated with a further analysis of our oracle alignments, which use phrases whose average source length is 1.21 words (respectively 1.31 for target words). If many studies have already acknowledged the predominance of “small” phrases in actual translations, our oracle scores suggest that, for this language pair, increasing the phrase length limit beyond 2 or 3 might be a waste of computational resources.

4 Related Work

To the best of our knowledge, there are only a few works that try to study the expressive power of phrase-based machine translation systems or to provide tools for analyzing potential causes of failure.

The approach described in (Auli et al., 2009) is very similar to ours: in this study, the authors propose to find and analyze the limits of machine translation systems by studying the *reference reachability*. A reference is reachable for a given system if it can be exactly generated by this system. Reference reachability is assessed using Moses in forced decoding mode: during search, all hypotheses that deviate from the reference are simply discarded. Even though the main goal of this study was to compare the search space of phrase-based and hierarchical systems, it also provides some insights on the impact of various search parameters in Moses, delivering conclusions that are consistent with our main results. As described in Section 1.2, these authors also propose a typology of the errors of a statistical translation systems, but do not attempt to provide methods for identifying them.

The authors of (Turchi et al., 2008) study the learning capabilities of Moses by extensively analyzing learning curves representing the translation performances as a function of the number of examples, and by corrupting the model parameters. Even though their focus is more on assessing the scoring function, they reach conclusions similar to ours: the current bottleneck of translation performances is not the representation power of the PBTS but rather in their scoring functions.

Oracle decoding is useful to compute reachable pseudo-references in the context of discriminative training. This is the main motivation of (Tillmann and Zhang, 2006), where the authors compute high BLEU hypotheses by running a conventional decoder so as to maximize a per-sentence approximation of BLEU-4, under a simple (local) reordering model.

Oracle decoding has also been used to assess the limitations induced by various reordering constraints in (Dreyer et al., 2007). To this end, the authors propose to use a beam-search based oracle decoder, which computes lower bounds of the best achievable BLEU-4 using dynamic programming techniques over finite-state (for so-called local and IBM constraints) or hierarchically structured (for ITG constraints) sets of hypotheses. Even though the numbers reported in this study are not directly comparable with ours[17], it seems that our decoder is not only conceptually much simpler, but also achieves much more optimistic lower-bounds of the oracle BLEU score. The approach described in (Li and Khudanpur, 2009) employs a similar technique, which is to guide a heuristic search in an hypergraph representing possible translation hypotheses with n-gram counts matches, which amounts to decoding with a n-gram model trained on the sole reference translation. Additional tricks are presented in this article to speed-up decoding.

Computing oracle BLEU scores is also the subject of (Zens and Ney, 2005; Leusch et al., 2008), yet with a different emphasis. These studies are concerned with finding the best hypotheses in a word graph or in a consensus network, a problem that has various implications for multi-pass decoding and/or system combination techniques. The former reference describes an exponential approximate algorithm, while the latter proves the NP-completeness of this problem and discuss various heuristic approaches. Our problem is somewhat more complex and using their techniques would require us to built word graphs containing all the translations induced by arbitrary segmentations and permutations of the source sentence.

5 Conclusions

In this paper, we have presented a methodology for analyzing the errors of PBTS, based on the computation of an approximation of the BLEU-4 oracle score. We have shown that this approximation could be computed fairly accurately and efficiently using Integer Linear Programming techniques. Our main result is a confirmation of the fact that extant PBTS systems are expressive enough to achieve very high translation performance with respect to conventional quality measurements. The main efforts should therefore strive to improve on the way phrases and hypotheses are scored during training. This gives further support to attempts aimed at designing context-dependent scoring functions as in (Stroppa et al., 2007; Gimpel and Smith, 2008), or at attempts to perform discriminative training of feature-rich models. (Bangalore et al., 2007).

We have shown that the examination of difficult-to-translate sentences was an effective way to detect errors or inconsistencies in the reference translations, making our approach a potential aid for controlling the quality or assessing the difficulty of test data. Our experiments have also highlighted the impact of various parameters.

Various extensions of the baseline ILP program have been suggested and/or evaluated. In particular, the ILP formalism lends itself well to expressing various constraints that are typically used in conventional PBTS. In

[17] The best BLEU-4 oracle they achieve on Europarl German to English is approximately 48; but they considered a smaller version of the training corpus and the WMT’06 test set.

our future work, we aim at using this ILP framework to systematically assess various search configurations. We plan to explore how replacing non-reachable references with high-score pseudo-references can improve discriminative training of PBTS. We are also concerned by determining how tight is our approximation of the BLEU-4 score is: to this end, we intend to compute the best BLEU-4 score within the n-best solutions of the oracle decoding problem.

Automatic Evaluation of Translation Quality for Distant Language Pairs

Abstract

Automatic evaluation of Machine Translation (MT) quality is essential to developing high-quality MT systems. Various evaluation metrics have been proposed, and BLEU is now used as the de facto standard metric. However, when we consider translation between distant language pairs such as Japanese and English, most popular metrics (e.g., BLEU, NIST, PER, and TER) do not work well. It is well known that Japanese and English have completely different word orders, and special care must be paid to word order in translation. Otherwise, translations with wrong word order often lead to misunderstanding and incomprehensibility. For instance, SMT-based Japanese-to-English translators tend to translate 'A because B' as 'B because A.' Thus, word order is the most important problem for distant language translation. However, conventional evaluation metrics do not significantly penalize such word order mistakes. Therefore, locally optimizing these metrics leads to inadequate translations. In this paper, we propose an automatic evaluation metric based on rank correlation coefficients modified with precision. Our meta-evaluation of the NTCIR-7 PATMT JE task data shows that this metric outperforms conventional metrics.

1 Introduction

Automatic evaluation of machine translation (MT) quality is essential to developing high-quality machine translation systems because human evaluation is time consuming, expensive, and irreproducible. If we have a perfect automatic evaluation metric, we can tune our translation system for the metric.

BLEU (Papineni et al., 2002b; Papineni et al., 2002a) showed high correlation with human judgments and is still used as the de facto standard automatic evaluation metric. However, Callison-Burch et al. (2006) argued that the MT community is overly reliant on BLEU by showing examples of poor performance. For Japanese-to-English (JE) translation, Echizen-ya et al. (2009) showed that the popular BLEU and NIST do not work well by using the system outputs of the NTCIR-7 PATMT (patent translation) JE task (Fujii et al., 2008). On the other hand, ROUGE-L (Lin and Hovy, 2003), Word Error Rate (WER), and IMPACT (Echizen-ya and Araki, 2007) worked better.

In these studies, Pearson's correlation coefficient and Spearman's rank correlation ρ with human evaluation scores are used to measure how closely an automatic evaluation method correlates with human evaluation. This evaluation of automatic evaluation methods is called **meta-evaluation**. In human evaluation, people judge the adequacy and the fluency of each translation.

Denoual and Lepage (2005) pointed out that BLEU assumes word boundaries, which is ambiguous in Japanese and Chinese. Here, we assume the word boundaries given by ChaSen, one of the standard morphological analyzers (http://chasen-legacy.sourceforge.jp/) following Fujii et al. (2008)

In JE translation, most Statistical Machine Translation (SMT) systems translate the Japanese sentence

(J0) *kare wa sono hon wo yonda node sekaishi ni kyoumi ga atta*

which means

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 944–952,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

(R0) he was interested in world history because he read the book

into an English sentence such as

(H0) he read the book because he was interested in world history

in which the cause and the effect are swapped. Why does this happen? The former half of (J0) means "He read the book," and the latter half means "(he) was interested in world history." The middle word "node" between them corresponds to "because." Therefore, SMT systems output sentences like (H0). On the other hand, Rule-based Machine Translation (RBMT) systems correctly give (R0).

In order to find (R0), SMT systems have to search a very large space because we cannot restrict its search space with a small distortion limit. Most SMT systems thus fail to find (R0).

Consequently, the global word order is essential for translation between distant language pairs, and wrong word order can easily lead to misunderstanding or incomprehensibility. Perhaps, some readers do not understand why we emphasize word order from this example alone. A few more examples will clarify what happens when SMT is applied to Japanese-to-English translation. Even the most famous SMT service available on the web failed to translate the following very simple sentence at the time of writing this paper.

Japanese: *meari wa jon wo koroshita.*
Reference: Mary killed John.
SMT output: John killed Mary.

Since it cannot translate such a simple sentence, it obviously cannot translate more complex sentences correctly.

Japanese: *bobu ga katta hon wo jon wa yonda.*
Reference: John read a book that Bob bought.
SMT output: Bob read the book John bought.

Another example is:

Japanese: *bobu wa meari ni yubiwa wo kau tameni, jon no mise ni itta.*
Reference: Bob went to John's store to buy a ring for Mary.
SMT output: Bob Mary to buy the ring, John went to the store.

In this way, this SMT service usually gives incomprehensible or misleading translations, and thus people prefer RBMT services. Other SMT systems also tend to make similar word order mistakes, and special care should be paid to the translation between distant language pairs such as Japanese and English.

Even Japanese people cannot solve this word order problem easily: It is well known that Japanese people are not good at speaking English.

From this point of view, conventional automatic evaluation metrics of translation quality disregard word order mistakes too much. Single-reference BLEU is defined by a geometrical mean of n-gram precisions p_n and is modified by Brevity Penalty (BP) $\min(1, \exp(1 - r/h))$, where r is the length of the reference and h is the length of the hypothesis.

$$\text{BLEU} = \text{BP} \times (p_1 p_2 p_3 p_4)^{1/4}.$$

Its range is [0, 1]. The BLEU score of (H0) with reference (R0) is $1.0 \times (11/11 \times 9/10 \times 6/9 \times 4/8)^{1/4} = 0.740$. Therefore, BLEU gives a very good score to this inadequate translation because it checks only n-grams and does not regard global word order.

Since (R0) and (H0) look similar in terms of fluency, **adequacy** is more important than fluency in the translation between distant language pairs.

Similarly, other popular scores such as NIST, PER, and TER (Snover et al., 2006) also give relatively good scores to this translation. NIST also considers only local word orders (n-grams). PER (Position-Independent Word Error Rate) was designed to disregard word order completely. TER (Snover et al., 2006) was designed to allow phrase movements without large penalties. Therefore, these standard metrics are not optimal for evaluating translation between distant language pairs.

In this paper, we propose an alternative automatic evaluation metric appropriate for distant language pairs. Our method is based on **rank correlation coefficients**. We use them to compare the word ranks in the reference with those in the hypothesis.

There are two popular rank correlation coefficients: Spearman's ρ and Kendall's τ (Kendall, 1975). In Isozaki et al. (2010), we used Kendall's τ to measure the effectiveness of our **Head Finalization** rule as a preprocessor for English-to-Japanese translation, but we measured the quality of translation by using conventional metrics.

It is not clear how well τ works as an automatic evaluation metric of translation quality. Moreover, Spearman's ρ might work better than Kendall's τ. As we discuss later, τ considers only the direction of the rank change, whereas ρ considers the distance of the change.

The first objective of this paper is to examine which is the better metric for distant language pairs. The second objective is to find improvements of these rank correlation-metrics.

Spearman's ρ is based on Pearson's correlation coefficients. Suppose we have two lists of numbers

$$\begin{aligned} \boldsymbol{x} &= [0.1, 0.4, 0.2, 0.6], \\ \boldsymbol{y} &= [0.9, 0.6, 0.2, 0.7]. \end{aligned}$$

To obtain Pearson's coefficients between $\boldsymbol{x}$ and $\boldsymbol{y}$, we use the raw values in these lists. If we substitute their ranks for their raw values, we get

$$\boldsymbol{x'} = [1, 3, 2, 4] \text{ and } \boldsymbol{y'} = [4, 2, 1, 3].$$

Then, Spearman's ρ between $\boldsymbol{x}$ and $\boldsymbol{y}$ is given by Pearson's coefficients between $\boldsymbol{x'}$ and $\boldsymbol{y'}$. This ρ can be rewritten as follows when there is no tie:

$$\rho = 1 - \frac{\sum_i d_i^2}{{}_{n+1}C_3}.$$

Here, d_i indicates the difference in the ranks of the i-th element. Rank distances are **squared** in this formula. Because of this square, we expect that ρ decreases drastically when there is an element that significantly changes in rank. But we are also afraid that ρ may be too severe for alternative good translations.

Since Pearson's correlation metric assumes linearity, nonlinear monotonic functions can change its score. On the other hand, Spearman's ρ and Kendall's τ uses ranks instead of raw evaluation scores, and simple application of monotonic functions cannot change them (use of other operations such as averaging sentence scores can change them).

2 Methodology

2.1 Word alignment for rank correlations

We have to determine word ranks to obtain rank correlation coefficients. Suppose we have:

(R1) `John hit Bob yesterday`
(H1) `Bob hit John yesterday`

The 1st word "John" in R1 becomes the **3**rd word in H1. The 2nd word "hit" in R1 becomes the **2**nd word in H1. The 3rd word "Bob" in R1 becomes the **1**st word in H1. The 4th word "yesterday" in R1 becomes the **4**th word in H1. Thus, we get H1's word order list [3, 2, 1, 4]. The number of all pairs of integers in this list is ${}_4C_2 = 6$. It has three increasing pairs: (3,4), (2,4), and (1,4). Since Kendall's τ is given by:

$$\tau = 2 \times \frac{\text{the number of increasing pairs}}{\text{the number of all pairs}} - 1,$$

H1's τ is $2 \times 3/6 - 1 = 0.0$.

In this case, we can obtain Spearman's ρ as follows: "John" moved by $d_1 = 2$ words, "hit" moved by $d_2 = 0$ words, "Bob" moved by $d_3 = 2$ words, and "yesterday" moved by $d_4 = 0$ words. Therefore, H1's ρ is $1 - (2^2 + 0^2 + 2^2 + 0^2)/{}_5C_3 = 0.2$.

Thus, τ considers only the direction of the movement, whereas ρ considers the distance of the movement. Both ρ and τ have the same range $[-1, 1]$. The main objective of this paper is to clarify which rank correlation is closer to human evaluation scores.

We have to consider the limitation of the rank correlation metrics. They are defined only when there is **one-to-one correspondence**. However, a reference sentence and a hypothesis sentence may have different numbers of words. They may have two or more occurrences of the same word in one sentence. Sometimes, a word in the reference does not appear in the hypothesis, or a word in the hypothesis does not appear in the reference. Therefore, we cannot calculate τ and ρ following the above definitions in general.

Here, we determine the correspondence of words between hypotheses and references as follows. First, we find one-to-one corresponding words. That is, we find words that appear in both sentences and only once in each sentence. Suppose we have:

(R2) `the boy read the book`
(H2) `the book was read by the boy`

By removing non-aligned words by one-to-one correspondence, we get:

(R3) `boy read book`
(H3) `book read boy`

Thus, we lost "`the`." We relax this one-to-one correspondence constraint by using one-to-one corresponding **bigrams**. (R2) and (H2) share "`the boy`" and "`the book`," and we can align these instances of "the" correctly.

(R4) the$_1$ boy$_2$ read$_3$ the$_4$ book$_5$
(H4) the$_4$ book$_5$ read$_3$ the$_1$ boy$_2$

Now, we have five aligned words, and H4's word order is represented by [4, 5, 3, 1, 2].

In returning to H0 and R0, we find that each of these sentences has eleven words. Almost all words are aligned by one-to-one correspondence but "he" is not aligned because it appears twice in each sentence. By considering one-to-one corresponding bigrams ("he was" and "he read"), "he" is aligned as follows.

(R5) he$_1$ was$_2$ interested$_3$ in$_4$ world$_5$ history$_6$ because$_7$ he$_8$ read$_9$ the$_{10}$ book$_{11}$
(H5) he$_8$ read$_9$ the$_{10}$ book$_{11}$ because$_7$ he$_1$ was$_2$ interested$_3$ in$_4$ world$_5$ history$_6$

H5's word order is [8, 9, 10, 11, 7, 1, 2, 3, 4, 5, 6]. The number of increasing pairs is: ${}_4C_2 = 6$ pairs in [8, 9, 10, 11] and ${}_6C_2 = 15$ pairs in [1, 2, 3, 4, 5, 6]. Then we obtain $\tau = 2 \times (6 + 15)/{}_{11}C_2 - 1 = -0.236$. On the other hand, $\sum_i d_i^2 = 5^2 \times 6 + 2^2 + 7^2 \times 4 = 350$, and we obtain $\rho = 1 - 350/{}_{12}C_3 = -0.591$.

Therefore, both Spearman's ρ and Kendall's τ give very bad scores to the misleading translation H0. This fact implies they are much better metrics than BLEU, which gave a good score to it. ρ is much lower than τ as we expected.

In general, we can use higher-order n-grams for this alignment, but here we use only unigrams and bigrams for simplicity. This algnment algorithm is given in Figure 1. Since some hypothesis words do not have corresponding reference words, the output integer list `worder` is sometimes shorter than the evaluated sentence. Therefore, we should not use $\texttt{worder}[i] - i$ as d_i directly. We have to renumber the list by rank as we did in Section 1.

```
Read a hypothesis sentence $h = h_1 h_2 \ldots h_m$
and its reference sentence $r = r_1 r_2 \ldots r_n$.
Initialize worder with an empty list.
For each word $h_i$ in $h$:
    • If $h_i$ appears only once each in $h$ and $r$, append $j$
      s.t. $r_j = h_i$ to worder.
    • Otherwise, if the bigram $h_i h_{i+1}$ appears only once
      each in $h$ and $r$, append $j$ s.t. $r_j r_{j+1} = h_i h_{i+1}$ to
      worder.
    • Otherwise, if the bigram $h_{i-1} h_i$ appears only once
      each in $h$ and $r$, append $j$ s.t. $r_{j-1} r_j = h_{i-1} h_i$ to
      worder.
Return worder.
```

Figure 1: Word alignment algorithm for rank correlation

2.2 Word order metrics and meta-evaluation metrics

These rank correlation metrics sometimes have negative values. In order to make them just like other automatic evaluation metrics, we normalize them as follows.

- Normalized Kendall's τ: NKT = $(\tau + 1)/2$.
- Normalized Spearman's ρ: NSR = $(\rho + 1)/2$.

Accordingly, NKT is 0.382 and NSR is 0.205.

These metrics are defined only when the number of aligned words is two or more. We define both NKT and NSR as zero when the number is one or less. Consequently, these normalized metrics have the same range [0, 1].

In order to avoid confusion, we use these abbreviations (NKT and NSR) when we use rank correlations as **word order metrics**, because these correlation metrics are also used in the machine translation community for **meta-evaluation**. For meta-evaluation, we use Spearman's ρ and Pearson's correlation coefficient and call them "Spearman" and "Pearson," respectively.

2.3 Overestimation problem

Since we measure the rank correlation of only corresponding words, these metrics will overestimate the correlation. For instance, a hypothesis sentence might have only two corresponding words among

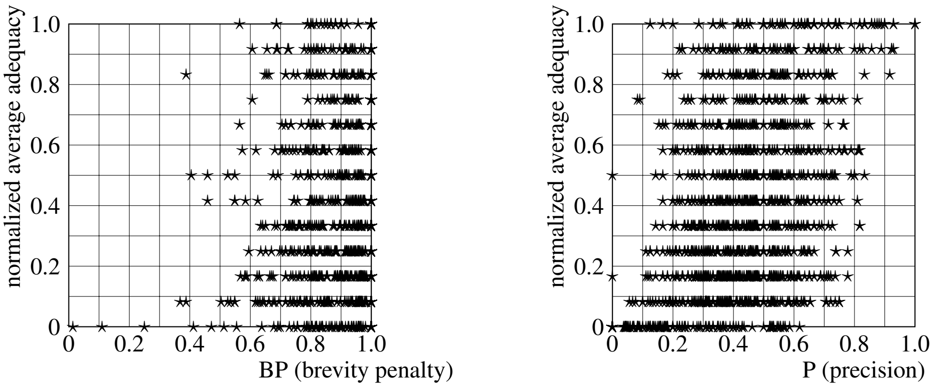

Figure 2: Scatter plots of normalized average adequacy with brevity penalty (left) and precision (right). (Each ⋆ corresponds to one sentence generated by one MT system)

dozens of words. In this case, these two words determine the score of the whole sentence. If the two words appear in their order in the reference, the whole sentence obtains the best score, NSR = NKT = 1.0, in spite of the fact that only two words matched.

Solving this overestimation problem is the second objective of this paper. BLEU uses "Brevity Penalty (BP)" (Section 1) to reduce the scores of too-short sentences. We can combine the above word order metrics with BP, e.g., NKT $\times$ BP and NSR $\times$ BP.

However, we cannot very much expect from this solution because BP scores do not correlate with human judgments well. The left graph of Figure 2 shows a scatter plot of BP and "normalized average adequacy." This graph has 15 (systems) $\times$ 100 (sentences) dots. Each dot ($\star$) corresponds to one sentence from one translation system.

In the NTCIR-7 data, three human judges gave five-point scores (1, 2, 3, 4, 5) for "adequacy" and "fluency" of each translated sentence. Although each system translated 1,381 sentences, only 100 sentences were evaluated by the judges.

For each translated sentence, we averaged three judges' adequacy scores and normalized this average x by $(x-1)/4$. This is our "normalized average adequacy," and the dots appears only at multiples of $1/3 \times 1/4$.

This graph shows that BP has very little correlation with adequacy, and we cannot expect BP to improve the meta-evaluation performance very much. Perhaps, BP's poor performance was caused by the fact that most MT systems output almost the same number of words, and if the number exceeds the length of the reference, BP=1.0 holds.

Therefore, we have to consider other modifiers for this overestimation problem. We can use other common metrics such as precision, recall, and F-measure to reduce the overestimation of NSR and NKT.

- Precision: $P = c/|h|$, where c is the number of corresponding words and $|h|$ is the number of words in the hypothesis sentence h.
- Recall: $R = c/r$, where $|r|$ is the number of words in the reference sentence r.
- F-measure: $F_\beta = (1+\beta^2)PR/(\beta^2 P + R)$, where β is a parameter.

In (R2)&(H2)'s case, precision is 5/7 = 0.714 and recall is 5/5 = 1.000.

Which metric should we use? Our preliminary experiments with NTCIR-7 data showed that **precision correlated best with adequacy** among these three metrics (P, R, and $F_{\beta=1}$). In addition, BLEU is essentially made for precision. Therefore, precision seems the most promising modifier.

The right graph of Figure 2 shows a scatter plot of precision and normalized average adequacy. The graph shows that precision has more correlation with adequacy than BP. We can observe that sentences with very small P values usually obtain very low adequacy scores but those with mediocre P values often obtain good adequacy scores.

If we multiply P directly by NSR or NKT, those sentences with mediocre P values will lose too much of their scores. The use of $\sqrt{x}$ will mitigate this problem. Since $\sqrt{P}$ is closer to 1.0 than P itself, multiplication of $\sqrt{P}$ instead of P itself will save these sentences. If we apply $\sqrt{x}$ twice ($\sqrt{\sqrt{P}} = \sqrt[4]{P}$), it will further save them. Therefore, we expect $\times\sqrt{P}$ and $\times\sqrt[4]{P}$ to work better than $\times P$. Now, we propose two new metrics:

$$\mathrm{NSR}P^{\alpha} \quad \text{and} \quad \mathrm{NKT}P^{\alpha},$$

where α is a parameter ($0 \leq \alpha \leq 1$).

3 Experiments

3.1 Meta-evaluation with NTCIR-7 data

In order to compare automatic translation evaluation methods, we use submissions to the NTCIR-7 Patent Translation (PATMT) task (Fujii et al., 2008). Fourteen MT systems participated in the Japanese-English intrinsic evaluation. There were two Rule-Based MT (RMBT) systems and one Example-based MT (EBMT) system. All other systems were Statistical MT (SMT) systems. The task organizers provided a baseline SMT system. These 15 systems translated 1,381 Japanese sentences into English. The organizers evaluated these translations by using BLEU and human judgments. In the human judgements, three experts independently evaluated 100 selected sentences in terms of '*adequacy*' and '*fluency*.'

For automatic evaluation, we used a single reference sentence for each of these 100 manually evaluated sentences. Echizen-ya et al. (2009) used multi-reference data, but their data is not publicly available yet.

For this meta-evaluation, we measured the *corpus-level* correlation between the human evaluation scores and the automatic evaluation scores. We simply averaged scores of 100 sentences for the proposed metrics. For existing metrics such as BLEU, we followed their definitions for corpus-level evaluation instead of simple averages of sentence-level scores. We used default settings for conventional metrics, but we tuned GTM (Melamed et al., 2007) with `-e` option. This option controls preferences on longer word runs. We also used the paraphrase database TERp (`http://www.umiacs.umd.edu/~snover/terp`) for METEOR (Banerjee and Lavie, 2005).

3.2 Meta-evaluation with WMT-07 data

We developed our metric mainly for automatic evaluation of translation quality for distant language pairs such as Japanese-English, but we also want to know how well the metric works for similar language pairs. Therefore, we also use the WMT-07 data (Callison-Burch et al., 2007) that covers only European language pairs. Callison-Burch et al. (2007) tried different human evaluation methods and showed detailed evaluation scores. The Europarl test set has 2,000 sentences, and The News Commentary test set has 2,007 sentences.

This data has different language pairs: Spanish, French, German ⇒ English. We exclude Czech-English because there were so few systems (See the footnote of p. 146 in their paper).

4 Results

4.1 Meta-evaluation with NTCIR-7 data

Table 1 shows the main results of this paper. The left part has corpus-level meta-evaluation with **adequacy**. Error metrics, WER, PER, and TER, have negative correlation coefficients, but we did not show their minus signs here.

Both NSR-based metrics and NKT-based metrics perform better than conventional metrics for this NTCIR PATMT JE translation data. As we expected, $\times$BP and $\times P^{(1/1)}$ performed badly. Spearman of BP itself is zero.

NKT performed slightly better than NSR. Perhaps, NSR penalized alternative good translations too much. However, one of the NSR-based metrics, NSR$P^{1/4}$, gave the **best Spearman score of 0.947**, and the difference between NSRP^{α} and NKTP^{α} was small. Modification with P led to this improvement.

NKT gave the best Pearson score of 0.922. However, Pearson measures linearity and we can change its score through a nonlinear monotonic function without changing Spearman very much. For instance, (NSR$P^{1/4})^{1.5}$ also has **Spearman of 0.947** but its **Pearson is 0.931**, which is better than NKT's 0.922. Thus, we think Spearman is a better **meta-**evaluation metric than Pearson.

Table 1: NTCIR-7 Meta-evaluation: correlation with human judgments (Spm = Spearman, Prs = Pearson)

human judge	**Adequacy**		Fluency	
eval\ meta-eval	Spm	Prs	Spm	Prs
P	0.615	0.704	0.672	0.876
R	0.436	0.669	0.461	0.854
$F_{\beta=1}$	0.525	0.692	0.543	0.871
BP	0.000	0.515	-0.007	0.742
NSR	0.904	0.906	0.869	0.910
NSR$P^{1/8}$	0.937	0.905	0.890	0.934
NSR$P^{1/4}$	**0.947**	0.900	0.901	0.944
NSR$P^{1/2}$	0.937	0.890	0.926	0.949
NSR$P^{1/1}$	0.883	0.872	0.883	0.939
NSR × BP	0.851	0.874	0.769	0.910
NKT	0.940	0.922	0.887	0.931
NKT$P^{1/8}$	0.940	0.913	0.908	0.944
NKT$P^{1/4}$	0.940	0.904	0.908	0.949
NKT$P^{1/2}$	0.929	0.890	0.897	0.949
NKT$P^{1/1}$	0.897	0.869	0.879	0.936
NKT × BP	0.829	0.878	0.726	0.918
ROUGE-L	0.903	0.874	0.889	0.932
ROUGE-S(4)	0.593	0.757	0.640	0.869
IMPACT	0.797	0.813	0.751	0.932
WER	0.894	0.822	0.836	0.926
TER	0.854	0.806	0.372	0.856
PER	0.375	0.642	0.393	0.842
METEOR(TERp)	0.490	0.708	0.508	0.878
GTM(-e 12)	0.618	0.723	0.601	0.850
NIST	0.343	0.661	0.372	0.856
BLEU	0.515	0.653	0.500	0.795

The right part of Table 1 shows correlation with fluency, but **adequacy is more important**, because our motivation is to provide a metric that is useful to reduce incomprehensible or misunderstanding outputs of MT systems. Again, the correlation-based metrics gave better scores than conventional metrics, and BP performed badly. NSR-based metrics proved to be as good as NKT-based metrics.

Meta-evaluation scores of the de facto standard BLEU is much lower than those of other metrics. Echizen-ya et al. (2009) reported that IMPACT performed very well for *sentence-level* evaluation of NTCIR-7 PATMT JE data. This *corpus-level* result also shows that IMPACT works better than BLEU, but ROUGE-L, WER, and our methods give better scores than IMPACT.

Table 2: WMT-07 meta-evaluation: Each source language has two columns: the left one is News Corpus and the right one is Europarl.

Spearman's ρ with human "rank"						
source	French		Spanish		German	
NSR	0.775	0.837	0.523	0.766	0.700	0.593
NSR$P^{1/8}$	0.821	0.857	0.786	0.595	0.400	0.685
NSR$P^{1/4}$	0.821	0.857	0.786	0.455	0.400	0.714
NSR$P^{1/2}$	0.821	0.857	0.786	0.347	0.400	0.714
NKT	0.845	0.857	0.607	0.838	0.700	0.630
NKT$P^{1/8}$	0.793	0.857	0.786	0.595	0.400	0.714
NKT$P^{1/4}$	0.793	0.857	0.786	0.524	0.400	0.714
NKT$P^{1/2}$	0.793	0.857	0.786	0.347	0.400	0.714
BLEU	0.786	0.679	0.750	0.595	0.400	0.821
WER	0.607	0.857	0.750	0.429	0.000	0.500
ROUGEL	0.893	0.739	0.786	0.707	0.700	0.857
ROUGES	0.883	0.679	0.786	0.690	0.400	0.929

4.2 Meta-evaluation with WMT-07 data

Callison-Burch et al. (2007) have performed different human evaluation methods for different language pairs and different corpora. Their Table 5 shows inter-annotator agreements for the human evaluation methods. According to their table, the "sentence ranking" (or "rank") method obtained better agreement than "adequacy." Therefore, we show Spearman's ρ for "rank." We used the scores given in their Tables 9, 10, and 11. (The "constituent" methods obtained the best inter-annotator agreement, but these methods focus on local translation quality and have nothing to do with global word order, which we are discussing here.)

Table 2 shows that our metrics designed for distant language pairs are comparable to conventional methods even for similar language pairs, but ROUGE-L and ROUGE-S performed better than ours for French News Corpus and German Europarl. BLEU scores in this table agree with those in Table 17 of Callison-Burch et al. (2007) within rounding errors.

After some experiments, we noticed that the use of R instead of P often gives better scores for WMT-07, but it degrades NTCIR-7 scores. We can extend our metric by F_β, weighted harmonic mean of P and R, or any other interpolation, but the introduction of new parameters into our metric makes it difficult to control. Improvement without new parameters is beyond the scope of this paper.

5 Discussion

It has come to our attention that Birch et al. (2010) has independently proposed an automatic evaluation method based on Kendall's τ. First, they started with Kendall's τ distance, which can be written as "$1 - \mathrm{NKT}$" in our terminology, and then subtracted it from one. Thus, their metric is nothing but NKT.

Then, they proposed application of the square root to get better Pearson by improving "the sensitivity to small reorderings." Since they used "Kendall's τ" and "Kendall's τ distance" interchangeably, it is not clear what they mean by "$\sqrt{\ }$ Kendall's τ," but perhaps they mean $1 - \sqrt{1 - \mathrm{NKT}}$ because $\sqrt{\mathrm{NKT}}$ is more insensitive to small reorderings. Table 3 shows the performance of these metrics for NTCIR-7 data. Pearson's correlation coefficient with adequacy was improved by $1 - \sqrt{1 - \mathrm{NKT}}$, but other scores were degraded in this experiment.

The difference between our method and Birch et al. (2010)'s method comes from the fact that we used Japanese-English translation data and Spearman's correlation for meta-evaluation, whereas they used Chinese-English translation data and only Pearson's correlation for meta-evaluation. Chinese word order is different from English, but Chinese is a Subject-Verb-Object (SVO) language and thus is much closer to English word order than Japanese, a typical SOV language.

We preferred NSR because it penalizes global word order mistakes much more than does NKT, and as discussed above, global word order mistakes often lead to incomprehensibility and misunderstanding.

On the other hand, they also tried Hamming distance, and summarized their experiments as follows:

> However, the Hamming distance seems to be more informative than Kendall's tau for small amounts of reordering.

This sentence and the introduction of the square root to NKT imply that Chinese word order is close to that of English, and they have to measure subtle word order mistakes.

Table 3: NTCIR-7 meta-evaluation: Effects of square root ($b(x) = 1 - \sqrt{1 - x}$)

	NKT	$\sqrt{\mathrm{NKT}}$	b(NKT)
Spearman w/ adequacy	0.940	0.940	0.922
Pearson w/ adequacy	0.922	0.817	0.941
Spearman w/ fluency	0.887	0.865	0.858
Pearson w/ fluency	0.931	0.917	0.833

In spite of these differences, the two groups independently recognized the usefulness of rank correlations for automatic evaluation of translation quality for distant language pairs.

In their WMT-2010 paper (Birch and Osborne, 2010), they multiplied NKT with the brevity penalty and interpolated it with BLEU for the WMT-2010 shared task. This fact implies that incomprehensible or misleading word order mistakes are rare in translation among European languages.

6 Conclusions

When Statistical Machine Translation is applied to distant language pairs such as Japanese and English, word order becomes an important problem. SMT systems often fail to find an appropriate translation because of a large search space. Therefore, they often output misleading or incomprehensible sentences such as "A because B" vs. "B because A." To penalize such inadequate translations, we presented an automatic evaluation method based on rank correlation. There were two questions for this approach. First, which correlation coefficient should we use: Spearman's ρ or Kendall's τ? Second, how should we solve the overestimation problem caused by the nature of one-to-one correspondence?

We answered these questions through our experiments using the NTCIR-7 PATMT JE translation data. For the first question, τ was slightly better than ρ, but ρ was improved by precision. For the second question, it turned out that BLEU's Brevity Penalty was counter-productive. A precision-based penalty gave a better solution. With this precision-based penalty, both ρ and τ worked well and they outperformed conventional methods for NTCIR-7 data. For similar language pairs, our method was comparable to conventional evaluation methods. Future work includes extension of the method so that it can outperform conventional methods even for similar language pairs.

Abstract

Electronic dictionaries covering all natural language levels are very relevant for the human use as well as for the automatic processing use, namely those constructed with respect to international standards. Such dictionaries are characterized by a complex structure and an important access time when using a querying system. However, the need of a user is generally limited to a part of such a dictionary according to his domain and expertise level which corresponds to a specialized dictionary. Given the importance of managing a unified dictionary and considering the personalized needs of users, we propose an approach for generating personalized views starting from a normalized dictionary with respect to Lexical Markup Framework LMF-ISO 24613 norm. This approach provides the re-use of already defined views for a community of users by managing their profiles information and promoting the materialization of the generated views. It is composed of four main steps: (i) the projection of data categories controlled by a set of constraints (related to the user's profiles), (ii) the selection of values with consistency checking, (iii) the automatic generation of the query's model and finally, (iv) the refinement of the view. The proposed approach was consolidated by carrying out an experiment on an LMF normalized Arabic dictionary.

1 Introduction

Electronic dictionaries are very useful in nowadays society, with the globalization and the increase of world communication and exchanges. There are clearly identified needs of dictionaries for human use as well as for automatic processing use.

Given the importance of having recourse to standards when constructing such lexical resources in order to promote the reuse and the fusion, the standardization committee ISO TC37/SC4 has recently validated the Lexical Markup Framework norm (LMF) project under the standard ISO 24 613 (Francopoulo and George 2008). LMF provides a common and shared representation of lexical objects that allows for the encoding of rich linguistic information, including among others morphological, syntactic, and semantic aspects. The LMF proposal is distinguished by the separate management of the hierarchical data structure (meta-model) and elementary linguistic descriptors (data categories) which promotes to cover several languages.

A normalized dictionary covers wide areas that include all lexical information of a given language and which are useful both for human use and for Natural Language Processing use in accordance with the kind of the user (linguist, lexicographer, developer, etc.), the level of the user (learner, expert, etc.) and the domain of the use (linguistic, medicine, biology, etc.). These dictionaries are characterized by a complex structure that supports the richness of natural languages. Therefore, dealing with a unique and complete dictionary is well for the manage task. However, such dictionaries are large and can be time consuming when querying their contents especially on the web. Moreover, displaying all details when some of which are not useful for the field of the query research is a

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 953–960,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

nuisance for the user. So, it will be interesting to reduce the displayed details according to the domain or to the expertise level of the user by generating personalized views (virtual or materialized) in order to appropriate the use of such dictionaries to the user needs.

The idea of creating document views is not a new concept but applying it on LMF normalized dictionaries is a new one. Indeed, it has been some attempts for dictionary creating in accordance to the TEI consortium (Véronis and Ide 1996) but the problem was the fact that created textual views (corresponding to the surface structure) or data base views (corresponding to the deep structure) were not customized. Others propositions are very interesting but they concern the ontology domain when dealing with the concept of point of view (Corby and al 2005).

In this paper, we propose an approach that favors the use of normalized dictionaries by generating virtual/materialized personalized views. This approach is based on the profiles information associated to user's community which helps to retrieve already defined views stored in a library of views. For the illustration, we use an Arabic LMF normalized dictionary (Baccar and al. 2008, Khemakhem and al., 2009) developed in the framework of an Arabic project supervised by the ALECSO (The Arab League Educational, Cultural and Scientific Organization) and founded by the University of King Abdul-Aziz in the Kingdom of Saudi Arabia[1]. An environment supporting the proposed approach was implemented. At present, it concerns the Arabic language.

The present paper is outlined as follows. We will start by giving an overview of projects that use LMF notably for the construction and the exploitation of electronic dictionaries. Then, we will present the foundation of the proposed approach related to the profile and the view concepts. After that, we will explain the different steps of the view's generating approach. Finally, we will bring back the experimentation that we carried out on a normalized Arabic dictionary using the proposed approach.

2 State of the art of projects using LMF

After the emergence of LMF, some projects were launched in order to construct or exploit electronic dictionaries in accordance with this norm. Among others we note LEXUS (Kirsch 2005) (Kemps-Snijders and al 2006), LIRICS (LIRICS 2005) and LMF-QL (Ben Abderrahmen and al 2007). All these labors have been recourse to Web service technology that favors to invoke, locally or afar, appropriate services for the management or the exploitation of a normalized dictionary.

LEXUS offers an interface permitting to the user to define formats of lexical bases with a perspective to enable the construction of lexical bases according to the LMF model. However, it does not allow the verification of the compliance between the model and the norm.

LIRICS proposes some APIs that focus especially on the management of lexical data base. These APIs offer the possibility to work on the structure of the LMF base by adding, modifying or deleting components of LMF model. However, there is no interface which facilitates the use of these APIs.

LMF-QL provides Web services to be used while developing lingware systems. These services offer the exploitation of a normalized lexical base without having any piece of information about its content and its structure. The results of these services may be personalized dictionaries given in an XML format. However, it covers only the morphological level.

Concerning the construction of personalized dictionaries using the works mentioned above, we can notice that the user must have an idea about the content of the desired dictionary and its structure. He must also have acquaintances with queries generation to satisfy his requirements.

Finally, we note an absence of works dealing with the generation of views starting from LMF standardized dictionary.

3 Foundation of the approach

An electronic dictionary can be used by many users who have different requirements. Indeed, by being a language learner, a researcher in linguistics or a teacher's, needs and uses are not the same. Therefore, it will be better to have a tool (editor) allowing generating a suitable view. The making of a view of the dictionary might be difficult for some kinds of users, so the recourse to user profiles may facilitate this task. One can note that the user profile is very important to guide the user through the retrieval and the reuse of existent views corresponding to his profile.

[1] www.almuajam.org

3.1 A user profile definition

Generally, all features characterizing a user or a group of users can be grouped under the term of a user profile. For electronic dictionaries, a user profile is a dataset that concerns a community of users of the dictionary.

Every profile is characterized by a category, a level of expertise and a field. Indeed, we classify the views of the dictionary according to a profile that is based on a selection of these three criteria. The formal representation of a profile is the following:

P : < K, L, F>

K: the kind of user: lexicographer, linguist, lingware system developer, etc.

L: the level of the expertise: beginner, student, expert, etc.

F: the field of user: medicine, sport, biology, general, etc.

3.2 A View definition

A view of a dictionary is a synthesis of a dictionary interrogation query. We can consider it as a specialized or lexical dictionary, supported by a query.

A dictionary view allows to filter some lexicographic information and to hide others that are useless for some users.

The formal representation of a view:

View : < D, P, C >

D: dictionary: each view is specific to a normalized dictionary.

P: profile of the view (see previous section).

C: it is a set of properties which characterizes the model of the view. Each property has the following representation:

C : <A, V, W>

A: attribute is a simple representation of a characteristic model. This characteristic may be a class (Lemma, Sense…), a feature (definition, pos, genre,…) or a relationship (RelatedForm, SenseRelation…) as indicated in Figure 3.

V: value: each attribute can have a set of values. For example, the values verb and noun for the attribute POS (Part Of Speech).

W: weight of a property. It may take the values 0 or 1.

- If the weight equals to 0, then this property is mandatory only for part of the lexical entry.
- If the weight equals to 1, then this property is mandatory for each lexical entry of this view.

3.3 Different types of views

There are two types of views:

- Virtual view: the results of this view are calculated upon request. In this case, interrogating queries of this view might generate a composed query that interrogates directly the principal dictionary (underlying).
- Materialized view (physical): a physical copy faithful to the view definition which is stored and maintained.

4 Proposed approach

In this section we describe the proposed approach through the detail that we will give for each one of its four steps. These steps are illustrated in Figure 1.

- Projection of the view model: includes the specification of data categories (linguistic information), controlled by constraints in order to build a suitable normalized and valid model. It can be started by already existing profiles.
- Selection and checkout of the coherence: concerns the specification of some values for data categories (DC) already specified. We use coherence rules to check the constancy knowing that there are strong dependencies between some DCs and values of other DCs (see section 4.2).
- Automatic generation of the model and the query: includes the model refinement and the checking of constraints by priority.
- Refinement of the view: involves the validation of a new view of dictionary, by adding the elements that are related to the lexical entries of this view.

4.1 Projection of the view model

The UML model of the dictionary is difficult to understand. So, we suggest a simpler representation which is more abstract. The choice can be started by already existing profiles in order to avoid views redundancy by the reuse of the previous ones and help users.

a. The specification of a profile

A user profile is a description that corresponds to a user community. We use the features of profile to filter the DCs. Indeed, we offer to the user only DCs that correspond to its field and its level based on the weight assigned to each DC. We assigned these weights according to a study on the needs of each user level. This study is based on the specific documents and dictionaries for each user level. By example for beginner level, we studied the school books to extract the information (root, schema,…) needed at this level.

It also facilitates and accelerates the task of needs specification and permits to avoid views redundancy. The projection phase is started by the specification of the user profile that requires the choice of its category, its level and its field. Then, if the user wants to consult the previous views of his profile, we display all the views associated to this profile. Otherwise, we offer the DCs specific to its field and its level.

b. Constraints

The abstraction of the model can hides relations between DCs. Indeed, during their specification there is a risk of having views with a non valid model. So, the DC specification must be controlled by constraints rules such as:

- If we select the field, the semantic class or the nature then the definition must be selected.
- If the relation between syntactic behaviors and senses is selected then the definition must be selected.

4.2 Selection and checkout of the coherence

Most of data categories use a list of values such as part-of-speech (pos), scheme, field, etc. Values specification of some DCs might influence the presence or the absence of the other DCs. For example, if the user has chosen DCs: pos, root, scheme, gender and number; then, he has fixed the value du pos =”particle” (it means that he needs only particles) and the value of the number =”singular”. In this case, we note an incoherence problem since the DC “number” is among particles characteristics but it concerns nouns. In this case, we must request the user to rectify the specifications. The selection must contain a checkout phase of coherence of DCs specified with the already existing data in the dictionary. This phase is based on coherence rules which ensure consistency between DCs and the specified values.

4.3 Automatic generation of the DTD and the query

We use the Document Type Definition (DTD) of the LMF norm and DC specifications of the model to automatically generate the DTD of the view. We use algorithms to generate DTD elements, respecting the order of the participating classes and ensuring classes relations.

The automatic generation of the query (i.e. using XQuery) involves two steps: the first one concern the specification of conditions for the selection of a lexical entry and its related information (i.e., semantic, syntactic). The second step permits the definition of an XML representation of a lexical entry. This step is based on the projection specified by the user and the priority order of DCs. There are DCs that influence the presence of the lexical entry and others that only influence the presence of the sense.

4.4 Refinement of the view

The steps of this phase depend on the type of the view. If it’s a virtual one, then it’s necessary to save the query already generated. This query will be used during the operation of this view. If it’s a materialized one, then query results are a part of the dictionary and must be saved for the operation of the view. The second case may give us a non valid XML base, especially when there are two lexical entries in relation and our query will select one of them that have an identifier of the other entry that is not selected. We recall that the lexical entries may have morphological links with other lexical entries and semantic links with other senses.

Indeed, after recording query‘s results, we move to the step of refinement. This step consists to valid the new personalized dictionary, adding lexical entries, senses and syntactic frame in relation with these results.

5 Experimentation

5.1 The normalized Arabic dictionary

In order to experiment our approach, we are going to use the normalized Arabic interactive dictionary containing more than 38000 lexical entries and developed in the framework of an Arabic project[2] supervised by the ALECSO. This dictionary is modeled according to the meta-model proposed by LMF[3] (ISO 24613) and uses data categories generated by the DCR[4] norm (ISO 12620). The dictionary pattern is composed of classes selected from the kernel or from one of its extensions (morphological, semantic, syntactic, MRD) in order to see a dictionary covering most of new dictionary’s needs (Baccar and al 2008). Since there are many information that can be classified in multi extensions in the same time, the norm’s editor have chosen to put them in one of these extensions. For this reason, we did not use only Machine Readable Dictionary (MRD) extension. This pattern valorizes derivation phenomenon in Arabic language and neutralizes the differences between lexicographical schools, ensuring language evolution. In fact, we have considered

[2] www.almuajam.org/

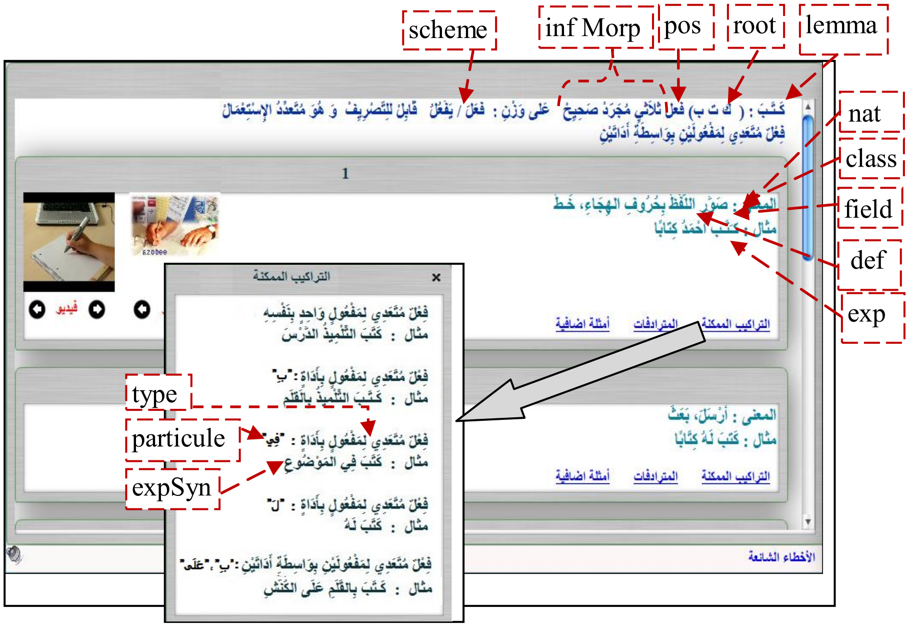
[3] www.lexicalmarkupframework.org/

[4] www.isocat.org/

roots (ك ت ب “k t b”), derived forms (كَتَبَ “kataba” (write), كَاتِب ”kâtib” (writer)), invariable words (إنَّ ”inna” (indeed), حَتَّى “hattâ” (in order)) and non-Arab origin words (كَمْبِيُوتَر “computer”, أَنْتَرْنَات “internet”) as lexical entries that can have morphological relations (i.e., RelatedForm relation).

In addition, this dictionary is rich with semantic information (i.e., definitions, examples, subject field, semantic class) and syntactic information (i.e., subcategorisation frame). It ensures the link between senses and their possible syntactic behaviors.

The Figure 2, given below, shows a part of the lexical entry “كَتَبَ” ”kataba” (write) which gives an idea about the structure of this dictionary.



كَتَبَ : (كَ ت ب) فعلٌ ثلاثي مُجَرَّدٌ صَحِيحٌ على وَزْنِ : فَعَلَ / يَفعُلُ قابِلٌ للتَّصرِيفِ و هُوَ مُتَعَدِّدُ الإستِعمَالِ

pos : part of speech
nat : nature
class : class
field : field
exp : example for a sense
inf Morp : Morphlogical piece of information
def : definition
expSyn : example of using a type
type : type of a syntactic frame

Figure 2. Example of a lexical entry of the normalized Arabic dictionary.

In this Figure, we highlight some properties of the used dictionary such as:

- The diversity of information: morphology, semantics, syntax, image, video, etc.
- The sense relations (i.e., synonym) link two senses and not two lexical entries
- The precision of the syntactic behavior. Indeed, each syntactic behavior has a type; the particles needed an example and its definition.
- The structure of a lexical entry varies according to its part of speech

5.2 Experiment of the approach

We illustrate in this section the generation process of a personalized dictionary view. We have setup a computing system online, that allows the user to make his view of the dictionary in the format of an interactive Web page (so independent of all material or software owner) in which he will be able to define, create and enhance his personal view.

Before starting the generation of the view, the user must specify his profile. If the views are associated with this profile, we will display their description to reuse the existing views and to avoid redundancy.

مثال : كَتَبَ لَهُ كِتَابًا

الأخطاء الشائعة

Figure 7. Displayed results of query applied on a generated view.

6 Conclusion

The construction of specialized dictionaries is an old concept. However, it has not been used after the publication of LMF standard in spite of the complexity and the richness of normalized dictionaries. In this paper, we proposed an approach allowing the generation of specialized and personalized views of dictionaries according to users' profiles in order to benefit from the management of a unique dictionary and give appropriate services.

A Practical experiment was carried out on a normalized Arabic dictionary using an appropriate tool that permits to manage users' profiles and views' generation. We successfully performed some empirical illustrations starting from the normalized dictionary.

In the future, we will consider the experimentation of the developed tool in the generation of various personalized views both in virtual and materialized versions. Also, we plan to put up our system on the Web. Also, we plan to experiment our approach on others languages.

Generating Confusion Sets for Context-Sensitive Error Correction

Alla Rozovskaya and Dan Roth
University of Illinois at Urbana-Champaign
Urbana, IL 61801
{rozovska,danr}@illinois.edu

Abstract

In this paper, we consider the problem of generating candidate corrections for the task of correcting errors in text. We focus on the task of correcting errors in preposition usage made by non-native English speakers, using discriminative classifiers. The standard approach to the problem assumes that the set of candidate corrections for a preposition consists of all preposition choices participating in the task. We determine likely preposition confusions using an annotated corpus of non-native text and use this knowledge to produce smaller sets of candidates.

We propose several methods of restricting candidate sets. These methods exclude candidate prepositions that are not observed as valid corrections in the annotated corpus and take into account the likelihood of each preposition confusion in the non-native text. We find that restricting candidates to those that are observed in the non-native data improves both the precision and the recall compared to the approach that views all prepositions as possible candidates. Furthermore, the approach that takes into account the likelihood of each preposition confusion is shown to be the most effective.

1 Introduction

We address the problem of generating candidate corrections for the task of correcting context-dependent mistakes in text, mistakes that involve confusing valid words in a language. A well-studied instance of this problem – context-sensitive spelling errors – has received a lot of attention in natural language research (Golding and Roth, 1999; Carlson et al., 2001; Carlson and Fette, 2007; Banko and Brill, 2001). The context-sensitive spelling correction task addresses the problem of correcting spelling mistakes that result in legitimate words, such as confusing *their* and *there* or *your* and *you're*. In this task, a *candidate set* or a *confusion set* is defined that specifies a list of confusable words, e.g., {*their, there*} or {*cite, site, sight*}. Each occurrence of a confusable word in text is represented as a vector of features derived from a small context window around the target. A classifier is trained on text assumed to be error-free, replacing each target word occurrence (e.g. *their*) with a *confusion set* consisting of {*their, there*}, thus generating both positive and negative examples, respectively, from the same context. Given a text to correct, for each word in text that belongs to the confusion set the classifier predicts the most likely candidate in the confusion set.

More recently, work in error correction has taken an interesting turn and focused on correcting errors made by English as a Second Language (ESL) learners, with a special interest given to errors in article and preposition usage. These mistakes are some of the most common mistakes for non-native English speakers of all proficiency levels (Dalgish, 1985; Bitchener et al., 2005; Leacock et al., 2010). Approaches to correcting these mistakes have adopted the methods of the context-sensitive spelling correction task. A system is usually trained on well-formed native English text (Izumi et al., 2003; Eeg-Olofsson and Knuttson, 2003; Han et al., 2006; Felice and Pulman, 2008; Gamon et al., 2008; Tetreault

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 961–970,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

and Chodorow, 2008; Elghaari et al., 2010; Tetreault et al., 2010), but several works incorporate into training error-tagged data (Gamon, 2010; Han et al., 2010) or error statistics (Rozovskaya and Roth, 2010b). The classifier is then applied to non-native text to predict the correct article/preposition in context. The possible candidate selections include the set of all articles or all prepositions.

While in the article correction task the candidate set is small (a, *the*, no article), systems for correcting preposition errors, even when they consider the most common prepositions, may include between 9 to 34 preposition classes. For each preposition in the non-native text, every other candidate in the confusion set is viewed as a potential correction. This approach, however, does not take into account that writers do not make mistakes randomly: Not all candidates are equally likely given the preposition chosen by the author and errors may depend on the first language (L1) of the writer. In this paper, we define *L1-dependent candidate sets* for the preposition correction task (Section 4.1). L1-dependent candidate sets reflect preposition confusions observed with the speakers of the first language L1. We propose methods of enforcing L1-dependent candidate sets in training and testing.

We consider mistakes involving the top ten English prepositions. As our baseline system, we train a multi-class classifier in *one-vs-all* approach, which is a standard approach to multi-class classification. In this approach, a separate binary classifier for each preposition p_i, $1 \leq i \leq 10$, is trained, s.t. all p_i examples are positive examples for the classifier and all other nine classes act as negative examples. Thus, for each preposition p_i in non-native text there are ten[1] possible prepositions that the classifier can propose as corrections for p_i.

We contrast this baseline method to two methods that enforce L1-dependent candidate sets in training. First, we train a separate classifier for each preposition p_i on the prepositions that belong to *L1-dependent candidate set* of p_i. In this setting, the negative examples for p_i are those that belong to *L1-dependent candidate set* of p_i.

The second method of enforcing *L1-dependent candidate sets* in training is to train on native data with artificial preposition errors in the spirit of Rozovskaya and Roth (2010b), where the errors mimic the error rates and error patterns of the non-native text. This method requires more knowledge, since it uses a distribution of errors from an error-tagged corpus.

We also propose a method of enforcing *L1-dependent candidate sets* in testing, through the use of a confidence threshold. We consider two ways of applying a threshold: (1) the standard way, when a correction is proposed only if the classifier's confidence is sufficiently high and (2) L1-dependent threshold, when a correction is proposed only if it belongs to *L1-dependent candidate set*.

We show that the methods of restricting candidate sets to L1-dependent confusions improve the preposition correction system. We demonstrate that restricting candidate sets to those prepositions that are confusable in the data by L1 writers is beneficial, when compared to a system that assumes an unrestricted candidate set by considering as valid corrections all prepositions participating in the task. Furthermore, we find that the most effective method is the one that uses knowledge about the likelihoods of preposition confusions in the non-native text introduced through artificial errors in training.

The rest of the paper is organized as follows. First, we describe related work on error correction. Section 3 presents the ESL data and statistics on preposition errors. Section 4 describes the methods of restricting candidate sets in training and testing. Section 5 describes the experimental setup. We present and discuss the results in Section 6. The key findings are summarized in Table 5 and Fig. 1 in Section 6. We conclude with a brief discussion of directions for future work.

2 Related Work

Work in text correction has focused primarily on correcting context-sensitive spelling errors (Golding and Roth, 1999; Banko and Brill, 2001; Carlson et al., 2001; Carlson and Fette, 2007) and mistakes made by ESL learners, especially errors in article and preposition usage.

Roth (1998) takes a unified approach to resolving semantic and syntactic ambiguities in natural lan-

[1] This includes the preposition p_i itself. If proposed by the classifier, it would not be flagged as an error.

guage by treating several related problems, including word sense disambiguation, word selection, and context-sensitive spelling correction as instances of the disambiguation task. Given a *candidate set* or a *confusion set* of confusable words, the task is to select the most likely candidate in context. Examples of confusion sets are $\{$*sight, site, cite*$\}$ for context-sensitive spelling correction, $\{$*among, between*$\}$ for word selection, or a set of prepositions for the preposition correction problem.

Each occurrence of a candidate word in text is represented as a vector of features. A classifier is trained on a large corpus of error-free text. Given text to correct, for each word in text that belongs to the confusion set the classifier is used to predict the most likely candidate in the confusion set given the word's context.

In the same spirit, models for correcting ESL errors are generally trained on well-formed native text. Han et al. (2006) train a maximum entropy model to correct article mistakes. Chodorow et. al (2007), Tetreault and Chodorow (2008), and De Felice and Pulman (2008) train a maximum entropy model and De Felice and Pulman (2007) train a voted perceptron algorithm to correct preposition errors. Gamon et al. (2008) train a decision tree model and a language model to correct errors in article and preposition usage. Bergsma et al. (2009) propose a Naïve Bayes algorithm with web-scale N-grams as features, for preposition selection and context-sensitive spelling correction.

The set of valid candidate corrections for a target word includes all words in the confusion set. For the preposition correction task, the entire set of prepositions considered for the task is viewed as the set of possible corrections for each preposition in non-native text. Given a preposition with its surrounding context, the model selects the most likely preposition from the set of all candidates, where the set of candidates consists of nine (Felice and Pulman, 2008), 12 (Gamon, 2010), or 34 (Tetreault et al., 2010; Tetreault and Chodorow, 2008) prepositions.

2.1 Using Error-tagged Data in Training

Several recent works explore ways of using annotated non-native text when training error correction models.

One way to incorporate knowledge about which confusions are likely with ESL learners into the error correction system is to train a model on error-tagged data. Preposition confusions observed in the non-native text can then be included in training, by using the preposition chosen by the author (the *source* preposition) as a feature. This is not possible with a system trained on native data, because each *source* preposition is always the correct preposition.

Han et al. (2010) train a model on partially annotated Korean learner data. The error-tagged model trained on one million prepositions obtains a slightly higher recall and a significant improvement in precision (from 0.484 to 0.817) over a model fives times larger trained on well-formed text.

Gamon (2010) proposes a hybrid system for preposition and article correction, by incorporating the scores of a language model and class probabilities of a maximum entropy model, both trained on native data, into a meta-classifier that is trained on a smaller amount of annotated ESL data. The meta-classifier outperforms by a large margin both of the native models, but it requires large amounts of expensive annotated data, especially in order to correct preposition errors, where the problem complexity is much larger.

Rozovskaya and Roth (2010b) show that by introducing into native training data artificial article errors it is possible to improve the performance of the article correction system, when compared to a classifier trained on native data. In contrast to Gamon (2010) and Han et al. (2010) that use annotated data for training, the system is trained on native data, but the native data are transformed to be more like L1 data through artificial article errors that mimic the error rates and error patterns of non-native writers. This method is cheaper, since obtaining error statistics requires much less annotated data than training. Moreover, the training data size is not restricted by the amount of the error-tagged data available. Finally, the *source* article of the writer can be used in training as a feature, in the exact same way as with the models trained on error-tagged data, providing knowledge about which confusions are likely. Unlike article errors, preposition errors lend themselves very well to a study of confusion sets because the set of prepositions participating in the task is a lot bigger than the set of article choices.

3 ESL Data

3.1 Preposition Errors in Learner Data

Preposition errors are one of the most common mistakes that non-native speakers make. In the Cambridge Learner Corpus[2] (CLC), which contains data by learners of different first language backgrounds and different proficiency levels, preposition errors account for about 13.5% of all errors and occur on average in 10% of all sentences (Leacock et al., 2010). Similar error rates have been reported for other annotated ESL corpora, e.g. (Izumi et al., 2003; Rozovskaya and Roth, 2010a; Tetreault et al., 2010). Learning correct preposition usage in English is challenging for learners of all first language backgrounds (Dalgish, 1985; Bitchener et al., 2005; Gamon, 2010; Leacock et al., 2010).

3.2 The Annotated Corpus

We use data from an annotated corpus of essays written by ESL students. The essays were fully corrected and error-tagged by native English speakers. For each preposition used incorrectly by the author, the annotator also indicated the correct preposition choice. Rozovskaya and Roth (2010a) provide a detailed description of the annotation of the data.

The annotated data include sentences by speakers of five first language backgrounds: Chinese, Czech, Italian, Russian, and Spanish. The Czech, Italian, Russian and Spanish data come from the International Corpus of Learner English (ICLE, (Granger et al., 2002)), which is a collection of essays written by advanced learners of English. The Chinese data is a part of the Chinese Learners of English corpus (CLEC, (Gui and Yang, 2003)) that contains essays by students of all levels of proficiency. Table 1 shows preposition statistics based on the annotated data.

The combined data include 4185 prepositions, 8.4% of which were judged to be incorrect by the annotators. Table 1 demonstrates that the error rates in the Chinese speaker data, for which different proficiency levels are available, are 2 or 3 times higher than the error rates in other language groups. The data for other languages come from very advanced learners and, while there are also proficiency differences among advanced speakers, their error rates are much lower.

Source language	Total preps.	Incorrect preps.	Error rate
Chinese	953	144	15.1%
Czech	627	28	4.5%
Italian	687	43	6.3%
Russian	1210	85	7.0%
Spanish	708	52	7.3%
All	4185	352	8.4%

Table 1: **Statistics on prepositions in the ESL data.** Column *Incorrect* denotes the number of prepositions judged to be incorrect by the native annotators. Column *Error rate* denotes the proportion of prepositions used incorrectly.

We would also like to point out that we take as the *baseline*[3] for the task the accuracy of the non-native data, or the proportion of prepositions used correctly. Using the error rate numbers shown in Table 1, the baseline for Chinese speakers is thus 84.9%, and for all the data combined it is 91.6%.

3.3 Preposition Errors and L1

We focus on *preposition confusion* errors, mistakes that involve an incorrectly selected preposition[4]. We consider ten most frequent prepositions in English: *on, from, for, of, about, to, at, in, with,* and *by*[5].

We mentioned in Section 2 that not all preposition confusions are equally likely to occur and preposition errors may depend on the first language of the writer. Han et al. (2010) show that preposition errors in the annotated corpus by Korean learners are not evenly distributed, some confusions occurring more often than others. We also observe that confusion frequencies differ by L1. This is consistent with other studies, which show that learners' errors are influenced by their first language (Lee and Seneff, 2008; Leacock et al., 2010).

[2] http://www.cambridge.org/elt

[3] It is argued in Rozovskaya and Roth (2010b) that the most frequent class baselines are not relevant for error correction tasks. Instead, the error rate in the data need to be considered, when determining the baseline.

[4] We do not address errors of missing or extraneous prepositions.

[5] It is common to restrict the systems that detect errors in preposition usage to the top prepositions. In the CLC corpus, the usage of the ten most frequent prepositions accounts for 82% of all preposition errors (Leacock et al., 2010).

4 Methods of Improving Candidate Sets

In this section, we describe methods of restricting candidate sets according to the first language of the writer. For the preposition correction task, the standard approach considers all prepositions participating in the task as valid corrections for every preposition in the non-native data.

In Section 3.3, we pointed out that (1) not all preposition confusions are equally likely to occur and (2) preposition errors may depend on the first language of the writer. The methods of restricting confusion sets proposed in this work use knowledge about which prepositions are confusable based on the data by speakers of language L1.

We refer to the preposition originally chosen by the author in the non-native text as the *source* preposition, and *label* denotes the correct preposition choice, as chosen by the annotator. Consider, for example, the following sentences from the annotated corpus.

1. We ate **by*/with** our hands .
2. To tell the truth , time spent in jail often changes prisoners **to*/for** the worse.
3. And the problem that immediately appeared was that men were unable to cope **with** the new woman image .

In example 1, the annotator replaced *by* with *with*; *by* is the *source* preposition and *with* is the *label*. In example 2, *to* is the *source* and *for* is the *label*. In example 3, the preposition *with* is judged as correct. Thus, *with* is both the *source* and the *label*.

4.1 L1-Dependent Confusion Sets

Let source preposition p_i denote a preposition that appears in the data by speakers of L1. Let *ConfSet* denote the set of all prepositions that the system can propose as a correction for source preposition p_i. We define two types of confusion sets *ConfSet*. An unrestricted confusion set *AllConfSet* includes all ten prepositions. *L1-dependent confusion set L1ConfSet*(p_i) is defined as follows:

Definition $L1ConfSet(p_i) = \{p_j | \exists$ a sentence in which an L1 writer replaced preposition p_j with p_i $\}$

For example, in the Spanish speaker data, *from* is used incorrectly in place of *of* and *for*. Then for Spanish speakers, *L1ConfSet*(from)={from, of, for}.

Source prep. p_i	***L1ConfSet***(p_i)
on	{on, about, of, to, at, in, with, by}
by	{with, by, in}
from	{of, from, for}

Table 2: L1-dependent confusion sets for three prepositions based on data by Chinese speakers.

Table 2 shows for Chinese speakers three prepositions and their L1-dependent confusion sets.

We now describe methods of enforcing *L1-dependent confusion sets* in training and testing.

4.2 Enforcing L1-dependent Confusion Sets in Training

We propose two methods of enforcing L1-dependent confusion sets in training. They are contrasted to the typical method of training a multi-class 10-way classifier, where each class corresponds to one of the ten participating prepositions.

First, we describe the typical training setting.

NegAll Training proceeds in a standard way of training a multi-class classifier (*one-vs-all* approach) on all ten prepositions using well-formed native English data. For each preposition p_i, p_i examples are positive and the other nine prepositions are negative examples.

We now describe two methods of enforcing L1-dependent confusion sets in training.

NegL1 This method explores the difference between training with nine types as negative examples and (fewer than nine) L1-dependent negative examples.

For every preposition p_i, we train a classifier using only examples that are in *L1ConfSet*(p_i). In contrast to *NegAll*, for each source preposition, the negative examples are not all other nine types, but only those that belong in *L1ConfSet*(p_i). For each language L1, we train ten classifiers, one for each source preposition. For source preposition p_i in test, we consult the classifier for p_i. In this model, the confusion set for source p_i is restricted through training, since for source p_i, the possible candidate replacements are only those that the classifier sees in training, and they are all in *L1ConfSet*(p_i).

Training data	**Negative examples**	
	NegAll	**NegL1**
Clean	NegAll-Clean	NegL1-Clean
ErrorL1	NegAll-ErrorL1	-

Table 3: Training conditions that result in unrestricted (All) and L1-dependent training paradigms.

ErrorL1 This method restricts the candidate set to *L1ConfSet*(p_i) by generating artificial preposition errors in the spirit of Rozovskaya and Roth (2010b). The training data are thus no longer well-formed or *clean*, but augmented with L1 error statistics. Specifically, each preposition p_i in training is replaced with a different preposition p_j with probability *probConf*, s.t.

$$probConf = prob(p_i|p_j) \qquad (1)$$

Suppose 10% of all source prepositions *to* in the Russian speaker data correspond to label *for*. Then *for* is replaced with *to* with probability 0.1.

The classifier uses in training the source preposition as a feature, which cannot be done when training on well-formed text, as discussed in Section 2.1. By providing the source preposition as a feature, we enforce L1-dependent confusion sets in training, because the system learns which candidate corrections occur with source preposition p_i. An important distinction of this approach is that it does not simply provide L1-dependent confusion sets in training: Because errors are generated using L1 writers' error statistics, the likelihood of each candidate correction is also provided. This approach is also more knowledge-intensive, as it requires annotated data to obtain error statistics.

It should be noted that this method is orthogonal to the *NegAll* and *NegL1* methods of training described above and can be used in conjunction with each of them, only that it transforms the training data to account in a more natural way for ESL writing.

We combine the proposed methods *NegAll*, *NegL1* with the *Clean* or *ErrorL1* methods and create three training approaches shown in Table 3.

4.3 Restricting Confusion Sets in Testing

To reduce the number of false alarms, correction systems generally use a threshold on the confidence of the classifier, following (Carlson et al., 2001), and propose a correction only when the confidence of the classifier is above the threshold. We show in Section 5 that the system trained on data with artificial errors performs competitively even without a threshold. The other systems use a threshold. We consider two ways of applying a threshold[6]:

1. **ThreshAll** A correction for source preposition p_i is proposed only when the confidence of the classifier exceeds the threshold. For each preposition in the non-native data, this method considers *all* candidates as valid corrections.

2. **ThreshL1Conf** A correction for source preposition p_i is proposed only when the confidence of the classifier exceeds the empirically found threshold and the preposition proposed as a correction for p_i is in the confusion set *L1ConfSet*(p_i).

5 Experimental Setup

In this section, we describe experiments with L1-dependent confusion sets. Combining the three training conditions shown in Table 3 with the two ways of thresholding described in Section 4.3, we build four systems[7]:

1. **NegAll-Clean-ThreshAll** This system assumes both in training and in testing stages that all preposition confusions are possible. The system is trained as a multi-class 10-way classifier, where for each preposition p_i, all other nine prepositions are negative examples. In testing, when applying the threshold, all prepositions are considered as valid corrections.

2. **NegAll-Clean-ThreshL1** This system is trained exactly as *NegAll-Clean-ThreshAll* but in testing only corrections that belong

[6] Thresholds are found empirically: We divide the evaluation data into three equal parts and to each part apply the threshold, which is optimized on the other two parts of the data.

[7] In testing, it is not possible to consider a confusion set larger than the one used in training. Therefore, *ThreshAll* is only possible with *NegAll* training condition.

to *L1ConfSet*(p_i) are considered as valid corrections for p_i.

3. **NegL1-Clean-ThreshL1** For each preposition p_i, a separate classifier is trained on the prepositions that are in *L1ConfSet*(p_i), where p_i examples are positive and a set of (fewer than nine) p_i-dependent prepositions are negative. Only corrections that belong to *L1ConfSet*(p_i) are considered as valid corrections for p_i.[8] Ten p_i-dependent classifiers for each L1 are trained.

4. **NegAll-ErrorL1-NoThresh** A system is trained as a multi-class 10-way classifier with artificial preposition errors that mimic the errors rates and confusion patterns of the non-native text. For each L1, an L1-dependent system is trained. This system does not use a threshold. We discuss this in more detail below.

The system *NegAll-Clean-ThreshAll* is our *baseline* system. It assumes both in training and in testing that all preposition confusions are possible.

All of the systems are trained on the same set of word and part-of-speech features using the same set of training examples. Features are extracted from a window of eight words around the preposition and include words, part-of-speech tags and conjunctions of words and tags of lengths two, three, and four. Training data are extracted from English Wikipedia and the New York Times section of the Gigaword corpus (Linguistic Data Consortium, 2003).

In each training paradigm, we follow a discriminative approach, using an online learning paradigm and making use of the Averaged Perceptron Algorithm (Freund and Schapire, 1999) – we use the regularized version in Learning Based Java[9] (LBJ, (Rizzolo and Roth, 2007)). While classical Perceptron comes with generalization bound related to the margin of the data, Averaged Perceptron also comes with a PAC-like generalization bound (Freund and Schapire, 1999). This linear learning algorithm is known, both theoretically and experimentally, to be among the best linear learning approaches and is competitive with SVM and Logistic Regression, while being more efficient in training. It also has been shown to produce state-of-the-art results on many natural language applications (Punyakanok et al., 2008).

6 Results and Discussion

Table 4 shows performance of the four systems by the source language. For each source language, the methods that restrict candidate sets in training or testing outperform the baseline system *NegAll-Clean-ThreshAll* that does not restrict candidate sets. The *NegAll-ErrorL1-NoThresh* system performs better than the other three systems for all languages, except for Italian. In fact, for the Czech speaker data, all systems other than *NegAll-ErrorL1-NoThresh*, have a precision and a recall of 0, since no errors are detected[10].

Source lang.	System	Acc.	P	R
CH	*NegAll-Clean-ThreshAll*	84.78	47.58	11.46
	NegAll-Clean-ThreshL1	84.84	48.05	15.28
	NegL1-Clean-ThreshL1	84.94	50.87	11.46

CZ	*NegAll-Clean-ThreshAll*	94.74	0.00	0.00
	NegAll-Clean-ThreshL1	94.98	0.00	0.00
	NegL1-Clean-ThreshL1	94.66	0.00	0.00
	NegAll-ErrorL1-NoThresh	95.85	**75.00**	**10.71**
	`Baseline`	95.53		
IT	*NegAll-Clean-ThreshAll*	93.23	26.14	8.14
	NegAll-Clean-ThreshL1	94.03	**51.59**	**18.60**
	NegL1-Clean-ThreshL1	93.16	35.00	16.28
	NegAll-ErrorL1-NoThresh	93.60	44.95	10.47
	`Baseline`	93.74		
RU	*NegAll-Clean-ThreshAll*	92.73	31.11	3.53
	NegAll-Clean-ThreshL1	93.02	48.81	8.24
	NegL1-Clean-ThreshL1	92.44	34.42	8.82
	NegAll-ErrorL1-NoThresh	93.14	**52.38**	**12.94**
	`Baseline`	92.98		
SP	*NegAll-Clean-ThreshAll*	91.95	26.14	5.77
	NegAll-Clean-ThreshL1	92.02	28.64	5.77
	NegL1-Clean-ThreshL1	92.44	40.00	7.69
	NegAll-ErrorL1-NoThresh	93.71	**77.50**	**19.23**
	`Baseline`	92.66		

Table 4: **Performance results for the 4 systems**. All systems, except for *NegAll-ErrorL1-NoThresh*, use a threshold, which is optimized for accuracy on the development set. *Baseline* denotes the percentage of prepositions used correctly in the data. The baseline allows us to evaluate the systems with respect to accuracy, the percentage of prepositions, on which the prediction of the system is the same as the label. Averaged results over 2 runs.

[8] *ThreshAll* is not possible with this training option, as the system never proposes a correction that is not in *L1ConfSet*(p_i).

[9] LBJ code is available at `http://cogcomp.cs.illinois.edu/page/software`

[10] The Czech data set is the smallest and contains a total of 627 prepositions and only 28 errors.

The *NegAll-ErrorL1-NoThresh* system does not use a threshold. However, as shown in Fig. 1, it is possible to increase the precision of the *NegAll-ErrorL1-NoThresh* system by applying a threshold, at the expense of a lower recall.

While the ordering of the systems with respect to quality is not consistent from Table 4, due to modest test data sizes, Table 5 and Fig. 1 show results for the models on all data combined and thus give a better idea of how the systems compare against each other.

Table 5 shows performance results for all data combined. Both *NegAll-Clean-ThreshL1* and *NegL1-Clean-ThreshL1* achieve a better precision and recall over the system with an unrestricted candidate set *NegAll-Clean-ThreshAll*. Recall that both of the systems restrict candidate sets, the former at testing stage, the latter by training a separate classifier for each source preposition. *NegAll-Clean-ThreshL1* performs slightly better than *NegL1-Clean-ThreshL1*. We hypothesize that the *NegAll-Clean-ThreshAll* performance may be affected because the classifiers for different source prepositions contain different number of classes, depending on the size of *L1ConfSet* confusion sets, which makes it more difficult to find a unified threshold. The best performing system overall is *NegAll-ErrorL1-NoThresh*. While *NegAll-Clean-ThreshL1* and *NegL1-Clean-ThreshL1* restrict candidate sets, *NegAll-ErrorL1-NoThresh* also provides information about the likelihood of each confusion, which benefits the classifier. The differences between *NegAll-ErrorL1-ThreshL1* and each of the other three systems are statistically significant[11] (McNemar's test, $p < 0.01$). The table also demonstrates that the results on the correction task may vary widely. For example, the recall varies by language between 10.47% and 27.43% for the *NegAll-ErrorL1-NoThresh system*. The highest recall numbers are obtained for Chinese speakers. These speakers also have the highest error rate, as we noted in Section 3.

System	Acc.	P	R
NegAll-Clean-ThreshAll	90.90	31.11	7.95
NegAll-Clean-ThreshL1	91.11	37.82	12.78
NegL1-Clean-ThreshL1	90.97	34.34	9.66
NegAll-ErrorL1-NoThresh	92.23	**58.47**	**19.60**

Table 5: **Comparison of the performance of the 4 systems on all data combined**. All systems, except for *NegAll-ErrorL1-NoThresh*, use a threshold, which is optimized for accuracy on the development set. The differences between *NegAll-ErrorL1-ThreshL1* and each of the other three systems are statistically significant (McNemar's test, $p < 0.01$).

Finally, Fig. 1 shows precision/recall curves for the systems[12]. The curves are obtained by varying a decision threshold for each system. Before we examine the differences between the models, it should be noted that in error correction tasks precision is favored over recall due to the low level of error.

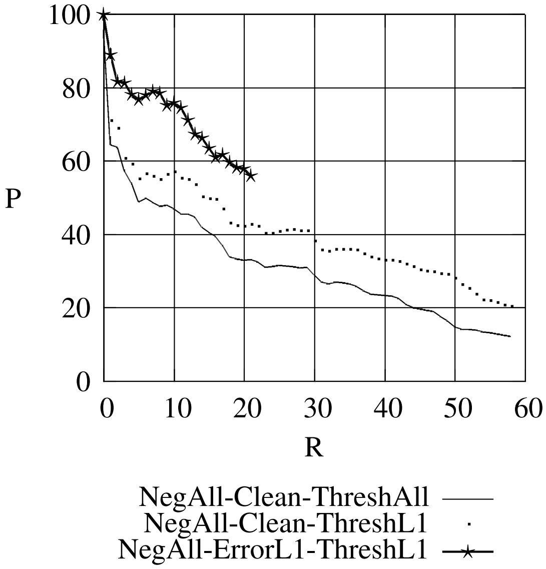

Figure 1: Precision and recall (%) for three models: *NegAll-Clean-ThreshAll*, *NegAll-Clean-ThreshL1*, and *NegAll-ErrorL1-ThreshL1*.

The curves demonstrate that *NegAll-Clean-ThreshL1* and *NegAll-ErrorL1-ThreshL1* are superior to the baseline system *NegAll-Clean-ThreshAll*: on the same recall points, the precision for both systems is consistently better than for the base-

[11] Tests of statistical significance compare the combined results from all language groups for each model. For example, to compare the model *NegAll-Clean-ThreshAll* to *NegAll-ErrorL1-NoThresh*, we combine the results from the five language-specific models *NegAll-ErrorL1-NoThresh* and compare them to the results on the combined data from the five language groups achieved by the model *NegAll-Clean-ThreshAll*.

[12] *NegL1-Clean-ThreshL1* is not shown, since it is similar in its behavior to *NegAll-Clean-ThreshL1*.

line model[13]. Moreover, while restricting candidate sets improves the results, providing information to the classifier about the likelihoods of different confusions is more helpful, which is reflected in the precision differences between *NegAll-Clean-ThreshL1* and *NegAll-ErrorL1-ThreshL1*. In fact, *NegAll-ErrorL1-ThreshL1* achieves a higher precision compared to the other systems, even when no threshold is used (Tables 4 and 5). This is because, unlike the other models, this system does not tend to propose too many false alarms.

6.1 Comparison to Other Systems

It is difficult to compare performance to other systems, since training and evaluation are not performed on the same data, and results may vary widely depending on the first language and proficiency level of the writer. However, in Table 6 we list several systems and their performance on the task. Tetreault et al. (2010) train on native data and obtain a precision of 48.6% and a recall of 22.5% with top 34 prepositions on essays from the Test of English as a Foreign Language exams. Han et al. (2010) obtain a precision of 81.7% and a recall of 13.2% using a model trained on partially error-tagged data by Korean speakers on top ten prepositions. A model trained on 2 million examples from clean text achieved on the same data set a precision of 46.3% and a recall of 11.6%.

Gamon (2010) shows precision/recall curves on the combined task of detecting missing, extraneous and confused prepositions. For recall points 10% and 20%, precisions of 55% and 40%, respectively, are obtained. For our data, a recall of 10% corresponds to a precision of 46% for the worst-performing model and 78% for the best-performing model. For 20% recall, we obtain a precision of 33% for the worst-performing model and 58% for the best-performing model. We would like to emphasize that these comparisons should be interpreted with caution.

7 Conclusion and Future Work

In this paper, we proposed methods for improving candidate sets for the task of detecting and correcting errors in text. To correct errors in preposition usage made by non-native speakers of English, we proposed L1-dependent confusion sets that determine valid candidate corrections using knowledge about preposition confusions observed in the non-native text. We found that restricting candidates to those that are observed in the non-native data improves both the precision and the recall compared to a classifier that considers as possible candidates the set of all prepositions. Furthermore, the approach that takes into account the likelihood of each preposition confusion is shown to be the most effective.

System	**Training Data**	**P**	**R**
Tetreault et al., 2010	native; 34 preps.	48.6	22.5
Han et al., 2010	partially error-tagged; 10 preps.	81.7	13.2
Han et al., 2010	native; 10 preps.	46.3	11.6
Gamon, 2010	native; 12 preps.+ extraneous+missing	33.0	10.0
Gamon, 2010	native+error-tagged; 12 preps.+ extraneous+missing	55.0	10.0
NegAll-Clean-ThreshAll	native; 10 preps.	46.0	10.0
NegAll-ErrorL1-ThreshL1	native with L1 error statistics; 10 preps.	78.0	10.0

Table 6: **Comparison to other systems**. Please note that a direct comparison is not possible, since the systems are trained and evaluated on different data sets. Gamon (2010) also considers missing and extraneous preposition errors.

The methods proposed in this paper make use of select characteristics that the error-tagged data can provide. We would also like to compare the proposed methods to the quality of a model trained on error-tagged data. Improving the system is also in our future work, but orthogonal to the current contribution.

Acknowledgments

Abstract

Confidence-Weighted linear classifiers (CW) and its successors were shown to perform well on binary and multiclass NLP problems. In this paper we extend the CW approach for sequence learning and show that it achieves state-of-the-art performance on four noun phrase chucking and named entity recognition tasks. We then derive few algorithmic approaches to estimate the prediction's correctness of each label in the output sequence. We show that our approach provides a reliable relative correctness information as it outperforms other alternatives in ranking label-predictions according to their error. We also show empirically that our methods output close to absolute estimation of error. Finally, we show how to use this information to improve active learning.

1 Introduction

In the past decade structured classification has seen much interest by the machine learning community. After the introduction of conditional random fields (CRFs) (Lafferty et al., 2001), and maximum margin Markov networks (Taskar et al., 2003), which are batch algorithms, new online method were introduced. For example the passive-aggressive algorithm was adapted to chunking (Shimizu and Haas, 2006), parsing (McDonald et al., 2005b), learning preferences (Wick et al., 2009) and text segmentation (McDonald et al., 2005a). These new online algorithms are fast to train and simple to implement, yet they generate models that output merely a prediction with no additional information, as opposed to probabilistic models like CRFs or HMMs.

In this work we fill this gap proposing few alternatives to compute confidence in the output of discriminative non-probabilistic algorithms. As before, our algorithms output the highest-scoring labeling. However, they also compute additional labelings, that are used to compute the *per word* confidence in its labelings. We build on the recently introduced confidence-weighted learning (Dredze et al., 2008; Crammer et al., 2009b) and induce a distribution over labelings from the distribution maintained over weight-vectors.

We show how to compute confidence estimates in the label predicted per word, such that the confidence reflects the probability that the label is not correct. We then use this confidence information to rank all labeled words (in all sentences). This can be thought of as a retrieval of the erroneous words, which can than be passed to human annotator for an examination, either to correct these mistakes or as a quality control component. Next, we show how to apply our techniques to active learning over sequences. We evaluate our methods on four NP chunking and NER datasets and demonstrate the usefulness of our methods. Finally, we report the performance of obtained by CW-like adapted to sequence prediction, which are comparable with current state-of-the-art algorithms.

2 Confidence-Weighted Learning

Consider the following online binary classification problem that proceeds in rounds. On the ith round the online algorithm receives an input $\boldsymbol{x}_i \in \mathbb{R}^d$ and

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 971–981,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

applies its current rule to make a prediction $\hat{y}_i \in \mathcal{Y}$, for the binary set $\mathcal{Y} = \{-1, +1\}$. It then receives the correct label $y_i \in \mathcal{Y}$ and suffers a loss $\ell(y_i, \hat{y}_i)$. At this point, the algorithm updates its prediction rule with the pair $(\boldsymbol{x}_i, y_i)$ and proceeds to the next round. A summary of online algorithms can be found in (Cesa-Bianchi and Lugosi, 2006).

Online confidence-weighted (CW) learning (Dredze et al., 2008; Crammer et al., 2008), generalized the passive-aggressive (PA) update principle to multivariate Gaussian distributions over the weight vectors - $\mathcal{N}(\boldsymbol{\mu}, \Sigma)$ - for binary classification. The mean $\boldsymbol{\mu} \in \mathbb{R}^d$ contains the current estimate for the best weight vector, whereas the Gaussian covariance matrix $\Sigma \in \mathbb{R}^{d \times d}$ captures the confidence in this estimate. More precisely, the diagonal elements $\Sigma_{p,p,}$ capture the confidence in the value of the corresponding weight $\boldsymbol{\mu}_p$; the smaller the value of $\Sigma_{p,p,}$ is, the more confident is the model in the value of $\boldsymbol{\mu}_p$. The off-diagonal elements $\Sigma_{p,q}$ for $p \neq q$ capture the correlation between the values of $\boldsymbol{\mu}_p$ and $\boldsymbol{\mu}_q$. When the data is of large dimension, such as in natural language processing, a model that maintains a full covariance matrix is not feasible and we back-off to diagonal covariance matrices.

CW classifiers are trained according to a PA rule that is modified to track differences in Gaussian distributions. At each round, the new mean and covariance of the weight vector distribution is chosen to be the solucion of an optimization problem (see (Crammer et al., 2008) for details). This particular CW rule may over-fit by construction. A more recent alternative scheme called AROW (adaptive regularization of weight-vectors) (Crammer et al., 2009b) replaces the guaranteed prediction at each round with the a more relaxed objective (see (Crammer et al., 2009b)). AROW has been shown to perform well in practice, especially for noisy data where CW severely overfits.

The solution for the updates of CW and AROW share the same general form,

$$\boldsymbol{\mu}_{i+1} = \boldsymbol{\mu}_i + \alpha_i \Sigma_i y_i \boldsymbol{x}_i \; ; \; \Sigma_{i+1}^{-1} = \Sigma_{i+1}^{-1} + \beta_i \boldsymbol{x}_i \boldsymbol{x}_i^\top \; , \quad (1)$$

where the difference between CW and AROW is the specific instance-dependent rule used to set the values of α_i and β_i.

Algorithm 1 Sequence Labeling CW/AROW

```
Input: Joint feature mapping $\mathbf{\Phi}(\boldsymbol{x}, \boldsymbol{y}) \in \mathbb{R}^d$
       Initial variance $a > 0$
       Tradeoff Parameter $r > 0$ (AROW)
    or Confidence parameter $\phi$ (CW)
Initialize: $\boldsymbol{\mu}_0 = \mathbf{0}$ , $\Sigma_0 = aI$
for $i = 1, 2 \ldots$ do
    Get $\boldsymbol{x}_i \in \mathcal{X}$
    Predict best labeling
        $\hat{\boldsymbol{y}}_i = \arg\max_{\boldsymbol{z}} \boldsymbol{\mu}_{i-1} \cdot \mathbf{\Phi}(\boldsymbol{x}_i, \boldsymbol{z})$
    Get correct labeling $\boldsymbol{y}_i \in \mathcal{Y}^{|\boldsymbol{x}_i|}$
    Define $\mathbf{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} = \mathbf{\Phi}(\boldsymbol{x}, \boldsymbol{y}_i) - \mathbf{\Phi}(\boldsymbol{x}, \hat{\boldsymbol{y}}_i)$
    Compute $\alpha_i$ and $\beta_i$ (Eq. (3) for CW ; Eqs. (4),$\beta_i = 1/r$) for AROW)
    Set $\boldsymbol{\mu}_i = \boldsymbol{\mu}_{i-1} + \alpha_i \Sigma_{i-1} \mathbf{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}$
    Set $\Sigma_i^{-1} = \Sigma_{i-1}^{-1} + \beta_i \mathbf{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \mathbf{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}^\top$
end for
```

3 Sequence Labeling

In the sequence labeling setting, instances $\boldsymbol{x}$ belong to a general input space $\mathcal{X}$ and conceptually are composed of a finite number n of components, such as words of a sentence. The number of components $n = |\boldsymbol{x}|$ varies between instances. Each part of an instance is labelled from a finite set $\mathcal{Y}$, $|\mathcal{Y}| = K$. That is, a labeling of an entire instance belongs to the product set $\boldsymbol{y} \in \mathcal{Y} \times \mathcal{Y} \ldots \mathcal{Y}$ (n times).

We employ a general approach (Collins, 2002; Crammer et al., 2009a) to generalize binary classification and use a joined feature mapping of an instance $\boldsymbol{x}$ and a labeling $\boldsymbol{y}$ into a common vector space, $\mathbf{\Phi}(\boldsymbol{x}, \boldsymbol{y}) \in \mathbb{R}^d$.

Given an input instance $\boldsymbol{x}$ and a model $\boldsymbol{\mu} \in \mathbb{R}^d$ we predict the labeling with the highest score, $\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{z}} \boldsymbol{\mu} \cdot \mathbf{\Phi}(\boldsymbol{x}, \boldsymbol{z})$. A brute-force approach evaluates the value of the score $\boldsymbol{\mu} \cdot \mathbf{\Phi}(\boldsymbol{x}, \boldsymbol{z})$ for each possible labeling $\boldsymbol{z} \in \mathcal{Y}^n$, which is not feasible for large values of n. Instead, we follow standard factorization and restrict the joint mapping to be of the form, $\mathbf{\Phi}(\boldsymbol{x}, \boldsymbol{y}) = \sum_{p=1}^{n} \mathbf{\Phi}(\boldsymbol{x}, y_p) + \sum_{q=2}^{n} \mathbf{\Phi}(\boldsymbol{x}, y_q, y_{q-1})$. That is, the mapping is a sum of mappings, each taking into consideration only a label of a single part, or two consecutive parts. The time required to compute the $\max$ operator is linear in n and quadratic in K using the dynamic-programming Viterbi algorithm.

After the algorithm made a prediction, it uses the current labeled instance $(\boldsymbol{x}_i, \boldsymbol{y}_i)$ to update the model. We now define the update rule both for a version of CW and for AROW for strucutred learning, staring with CW. Given the input parameter ϕ of CW we denote by $\phi' = 1 + \phi^2/2, \phi'' = 1 + \phi^2$. We follow a similar argument as in the single update of (Crammer et al., 2009a, sec. 5.1) to sequence labeling by a reduction to binary classification. We first define the difference between the feature vector associated with the current labeling $\boldsymbol{y}_i$ and the feature vector associated with some labeling $\boldsymbol{z}$ to be, $\boldsymbol{\Delta}_{i,\boldsymbol{y},\boldsymbol{z}} = \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{y}_i) - \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{z})$, and in particular, when we use the prediction $\hat{\boldsymbol{y}}_i$ we get, $\boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} = \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{y}_i) - \boldsymbol{\Phi}(\boldsymbol{x}, \hat{\boldsymbol{y}}_i)$. The CW update is,

$$\begin{aligned} \boldsymbol{\mu}_i &= \boldsymbol{\mu}_{i-1} + \alpha_i \Sigma_{i-1} \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \\ \Sigma_i^{-1} &= \Sigma_{i-1}^{-1} + \beta_i \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}^\top , \end{aligned} \tag{2}$$

where the two scalars α_i and β_i are set using the update rule defined by (Crammer et al., 2008) for binary classification,

$$v_i = \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}^\top \Sigma_{i-1} \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \ , \ m_i = \boldsymbol{\mu}_{i-1} \cdot \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \tag{3}$$

$$\alpha_i = \max\left\{0, \frac{1}{v_i \phi''} \left(-m_i \phi' + \sqrt{m_i^2 \frac{\phi^4}{4} + v_i \phi^2 \phi''} \right) \right\}$$

$$\beta_i = \frac{\alpha_i \phi}{\sqrt{v_i^+}} \quad , \quad v_i^+ = \frac{1}{4} \left(-\alpha_i v_i \phi + \sqrt{\alpha_i^2 v_i^2 \phi^2 + 4 v_i} \right)^2$$

We turn our attention and describe a modification of AROW for sequence prediction. Replacing the binary-hinge loss in (Crammer et al., 2009b, Eqs. (1,2)) the first one with the corresponding multi-class hinge loss for structured problems we obtain, $\frac{1}{2} (\boldsymbol{\mu}_i - \boldsymbol{\mu})^\top \Sigma_i^{-1} (\boldsymbol{\mu}_i - \boldsymbol{\mu}) + \frac{1}{2r} (\max \{0, \max_{\boldsymbol{z} \neq \boldsymbol{y}} \{d(\boldsymbol{y}, \boldsymbol{z}) - \boldsymbol{\mu} \cdot (\boldsymbol{\Delta}_{i,\boldsymbol{y},\boldsymbol{z}})\}\})^2$, where, $d(\boldsymbol{y}, \boldsymbol{z}) = \sum_{q=1}^{|\boldsymbol{x}|} 1_{y_q \neq z_q}$, is the hamming distance between the two label sequences $\boldsymbol{y}$ and $\boldsymbol{z}$. The last equation is hard to optimize since the max operator is enumerating over exponential number of possible labellings $\boldsymbol{z}$. We thus approximate the enumeration over all possible $\boldsymbol{z}$ with the predicted label sequence $\hat{y}_i$ and get, $\frac{1}{2} (\boldsymbol{\mu}_i - \boldsymbol{\mu})^\top \Sigma_i^{-1} (\boldsymbol{\mu}_i - \boldsymbol{\mu}) + \frac{1}{2r} \left(\max \left\{ 0, d(\boldsymbol{y}_i, \hat{\boldsymbol{y}}_i) - \boldsymbol{\mu} \cdot \left(\boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \right) \right\} \right)^2$. Computing the optimal value of the last equation we get an update of the form of the first equation of Eq. (2) where

$$\alpha_i = \frac{\max \left\{ 0, d(\boldsymbol{y}_i, \hat{\boldsymbol{y}}_i) - \boldsymbol{\mu}_{i-1} \cdot \left(\boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}} \right) \right\}}{r + \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}^\top \Sigma_{i-1} \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}} . \tag{4}$$

Dataset	Sentences	Words	Features

Table 2: Averaged F-measure of methods. Statistical significance (t-test) are with respect to AROW, where * indicates 0.001 and ** indicates 0.01

We proceed with the confidence paramters in (Crammer et al., 2009b, Eqs. (1,2)), which takes into considiration the change of confidence due to the update. The effective features vector that is used to update the mean parameters is $\boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}$, and thus the structured update is, $\frac{1}{2} \log \left(\frac{\det \Sigma_i}{\det \Sigma} \right) + \frac{1}{2} \mathrm{Tr} \left(\Sigma_{i-1}^{-1} \Sigma \right) + \frac{1}{2r} \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}^\top \Sigma \boldsymbol{\Delta}_{i,\boldsymbol{y},\hat{\boldsymbol{y}}}$. Solving the above equation we get an update of the form of the second term of Eq. (2) where $\beta_i = \frac{1}{r}$. The pseudo-code of CW and AROW for sequence problems appears in Alg. 1.

4 Evaluation

For the experiments described in this paper we used four large sequential classification datasets taken from the CoNLL-2000, 2002 and 2003 shared tasks: noun-phrase (NP) chunking (Kim et al., 2000), and named-entity recognition (NER) in Spanish, Dutch (Tjong and Sang, 2002) and English (Tjong et al., 2003). The properties of the four datasets are summarized in Table 1. We followed the feature generation process of (Sha and Pereira, 2003).

Although our primary goal is estimating confidence in prediction and not the actual performance itself, we first report the results of using AROW and CW for sequence learning. We compared the performance CW and AROW of Alg. 1 with two standard online baseline algorithms: Averaged-Perceptron algorithm and 5-best PA (the value of five was shown to be optimal for various tasks (Crammer et al., 2005)). The update rule described in Alg. 1 assumes a full covariance matrix, which is not feasible in our

setting. Three options are possible: compute a full Σ and then take its diagonal elements; compute a full inverse Σ, take its diagonal elements and then compute its inverse; assume that Σ is diagonal and compute the optimal update for this choice. We found the first method to work best, and thus employ it from now on.

The hyper parameters (r for AROW, ϕ for CW, C for PA) were tuned for each task by a single run over a random split of the data into a three-fourths training set and a one-fourth test set. We used parameter averaging with all methods.

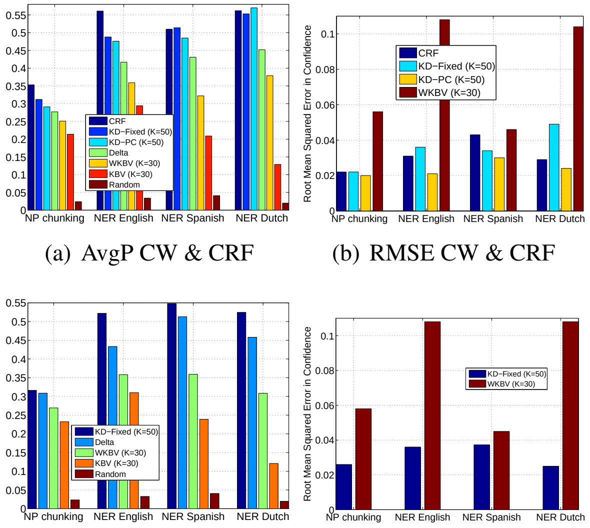
For each of the four datasets we used 10-fold cross validation. All algorithms (Perceptron, PA, CW and AROW) are online, and as mentioned above work in rounds. For each of the ten folds, each of the four algorithm performed ten (10) iterations over the training set and the performance (Recall, Precision and F-measure) was evaluated on the test set after each iteration.

The F-measure of the four algorithms after 10 iterations over the four datasets is summarized in Table 2. The general trend is that AROW slightly outperforms CW, which is better than PA that is better than the Perceptron. The difference between AROW and the Perceptron is significant, and between AROW and PA is significant in two datasets. The difference between AROW and CW is not significant although it is consistent.

We further investigate the convergence properties of the algorithms in Fig. 1. The figure shows the recall and precision results after each training round averaged across the 10 folds. Each panel summarizes the results on a single dataset, and in each panel a single set of connected points corresponds to one algorithm. Points in the left-bottom of the plot correspond to early iterations and points in the right-top correspond to later iterations. Long segments indicate a big improvement in performance between two consecutive iterations.

Few points are in order. First, high (in the y-axis) values indicate better precision and right (in the x-axis) values indicate better recall. Second, the performance of all algorithms is converging in about 10 iterations as indicated by the fact the points in the top-right of the plot are close to each other. Third, the long segments in the bottom-left for the Perceptron algorithm indicate that this algorithm benefits more from more than one pass compared with the other. Fourth, on the three NER datasets after 10 iterations AROW gets slightly higher precision values than CW, while CW gets slightly higher recall values than AROW. This is indicated by the fact that the top-right red square is left and above to the top-right blue circle. Finally, in two datasets, PA get slightly better recall than CW and AROW, but paying in terms of precision and overall F-measure performance.

In addition to online algorithms we also compared the performance of CW with the CRF algo-



(a) AvgP CW & CRF (b) RMSE CW & CRF

(c) AvgP PA (d) RMSE PA

Figure 2: Two left panels: average precision of rankings of the words of the test-set according to confidence in the prediction of seven methods (left to right bars in each group): CRF, KD-Fixed, KD-PC, Delta, WKBV, KBV and random ordering, when training with the CW algorithm (top) and the PA algorithm (bottom). Two right panels: The root-mean-squared-error of four methods that output absolute valued confidence: CRF, KD-Fixed, KD-PC and WKBV.

rithm which is a batch algorithm. We used Mallet toolkit (McCallum, 2002) for CRF implementation. For feature generation we used a combination of standard methods provided with Mallet toolkit (called pipes). We chose a combination yielding a feature set that is close as possible to the feature set we used in our system but it was not a perfect match, CRF generated about 20% fewer features in all datasets. Nevertheless, any other combination of pipes we tried only hurt CRF performance. The precision, recall, F-measure and percentage of mislabeled words of CW algorithm compared with CRF measured over a single split of the data into a three-fourths training set and a one-fourth test set is summarized in Table 3. We see that in three of the four datasets CW outperforms CRF and in one dataset CRF performs better. Some of the performance differences may be due to the differences in features.

5 Confidence in the Prediction

Most large-margin-based training algorithms output models that their prediction is a single labeling of the input, with no additional confidence information about the correctness of that prediction. This situation is acceptable when the output of the system is used anyway, irrespectively of its quality. This situation is not acceptable when the output of the system is used as an input of another system that is sensitive to correctness of the specific prediction or that integrates various input sources. In such cases, additional confidence information about the correctness of these feeds for specific input can be used to improve the total output quality. Another case where such information is useful, is when there is additional agent that is validating the output of the system. The confidence information can be used to direct the check into small number of suspected predictions as opposed to random check, which may miss errors if their rate is small.

Some methods only provide *relative* confidence information. This information can be used to *rank* all predictions according to their confidence score, which can be used to direct a quality control component to detect errors in the prediction. Note, the confidence score is meaningless by itself and in fact, any monotonic transformation of the confidence scores yield equivalent confidence information. Other methods are providing confidence in the predicted output as an *absolute* information, that is, the probability of a prediction to be correct. We refer to these probabilistic outputs in a frequentists approach. When taking a large set of events (predictions) with similar probability confidence value ν of being correct, we expect that about ν fraction of the predictions in the group will be correct.

Algorithms: All of our methods to evaluate confidence, except two (Delta and CRF below), share the same conceptual approach and work in two stages. First, a method generates a set of K possible labelings for the input sentence (instead of a single prediction). Then, the confidence in a predicted labeling for a specific word is defined to be the proportion of labelings which are consistent with the predicted label. Formally, let $\boldsymbol{z}^{(i)}$ for $i = 1 \ldots K$ be the K labelings for some input $\boldsymbol{x}$, and let $\hat{\boldsymbol{y}}$ be the actual prediction for the input. (We do not assume that $\hat{\boldsymbol{y}} = \boldsymbol{z}^{(i)}$ for some i). The confidence in the label $\hat{y}_p$ of word $p = 1 \ldots |\boldsymbol{x}|$ is defined to be

$$\nu_p = |\{i \,:\, \hat{y}_p = z_p^{(i)}\}|/K \,. \qquad (5)$$

Figure 3: Total number of detected erroneous words vs. the number of ranked words (top panels), and relative to the Delta method (bottom panels). In other words, the lines in the bottom panels are the number of *additional* erroneous words detected compared to Delta method. All methods builds on the same weight-vector except CRF (see text).

We tried four approaches to generate the set of K possible labelings. The first method is valid only for methods that induce a probability distribution over predicted labels. In this case, we draw K labelings from this distribution. Specifically, we exploit the Gaussian distribution over weight vectors $\boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)$ maintained by AROW and CW, by inducing a distribution over labelings given an input. The algorithm samples K weight vectors according to this Gaussian distribution and outputs the best labeling with respect to each weight vector. Formally, we define the set $Z = \{\boldsymbol{z}^{(i)} : \boldsymbol{z}^{(i)} = \arg\max_{\boldsymbol{z}} \boldsymbol{w} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{z}) \text{ where } \boldsymbol{w} \sim \mathcal{N}(\boldsymbol{\mu}, \Sigma)\}$

The predictions of algorithms that use the mean weight vector $\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{z}} \boldsymbol{\mu} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{z})$ are invariant to the value of the input Σ (as noted by (Crammer et al., 2008)). However for the purpose of confidence estimation the specific value of Σ has a huge affect. Small eigenvalue of Σ yield that all the elements of Z will be the same, while large values yield random elements in the set, ignoring the input.

One possible simple option is to run the algorithm few times, with few possible initializations of Σ and choose one using the training set. However since the actual predictions of all these versions is the same (invariance to scaling, see (Crammer et al., 2008)) in practice we run the algorithm once initializing $\Sigma = I$. Then, after the training is completed, we try few scalings of the final covariance $s\Sigma$ for some positive scalar s, and choose the best value s using the training set. We refer to this method as KD-PC for K-Draws by Parameters Confidence.

The second method to estimate confidence follows the same conceptual steps, except that we used an isotropic covariance matrix, $\Sigma = sI$ for some positive scale information s. As before, the value of s was tuned on the training set. We denote this method KD-Fixed for K Draws by Fixed Standard Deviation. This method is especially appealing, since it can be used in combination with training algorithms that do *not* maintain confidence information, such as the Perceptron or PA.

Our third and fourth methods are deterministic and do not involve a stochastic process. We modified the Viterbi algorithm to output the K distinct labelings with highest score (computed using the mean weight vector in case of CW or AROW). The third method assigns uniform importance to each of the K labelings ignoring the actual score values. We call this method KBV, for K-best Viterbi. We thus propose the fourth method in which we define an importance weight ω_i to each labeling $\boldsymbol{z}^{(i)}$ and evaluate confidence using the weights, $\nu_p = \left(\sum_{i \text{ s.t. } \hat{y}_p = z_p^{(i)}} \omega_i\right) / \left(\sum_i \omega_i\right)$, where we set the weights to be their score value clipped at zero from below $\omega_i = \max\{0, \boldsymbol{\mu} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{z}^{(i)})\}$. (In practice, top score was always positive.) We call this method WKBV for weighted K-best Viterbi.

In addition to these four methods we propose a fifth method that is based on the margin and does not share the same conceptual structure of the previous methods. This method provide confidence score that is only relative and not absolute, namely its output can be used to compare the confidence in two labelings, yet there is no semantics defined over the scores. Given an input sentence to be labeled $\boldsymbol{x}$ and a model we define the confidence in the prediction associated with the pth word to be the difference in the highest score and the closest score, where we set the label of that word to anything but the label with the highest score. Formally, as before we define the best labeling $\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{z}} \boldsymbol{\mu} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{z})$, then the score of word p is defined to be, $\boldsymbol{\mu} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, \hat{\boldsymbol{y}}) - \max_{u \neq \hat{y}_p} \boldsymbol{\mu} \cdot \boldsymbol{\Phi}(\boldsymbol{x}, \boldsymbol{z}_{|z_p=u})$, where we define the labeling $\boldsymbol{z}_{|z_p=u}$ to be the labeling that agrees with $\boldsymbol{z}$ on all words, except the pth word, where we define its label to be u. We refer to this method as Delta where the confidence information is a difference, aka as delta, between two score values.

Finally, as an additional baseline, we used a sixth method based on the confidence values for single words produced by CRF model. We considered the marginal probability of the word p to be assigned the predicted label $\hat{y}_p$ to be the confide value, this probability is calculated using the forward-backwards algorithm. This method is close in spirit to the Delta method as the later can be thought of computing marginals (in score, rather than probability). It also close to the K-Draws methods, as both CRF and K-Draws induce a distribution over labels. For CRF we can compute the marginals explicitly, while for the Gaussian models generated by CW (or AROW) the marginals can not be computed expliclity, and thus a sample based estimation (K-Draws) is used.

Experimental Setting: We evaluate the above methods as follows. We trained a classifier using the CW algorithm running for ten (10) iterations on three-fourth of the data and applied it to the remaining one-fourth to get a labeling of the test set. There are between $49K - 54K$ words to be labeled in all tasks, except NER Dutch where there are about $74K$ words. The fraction of words for which the trained model makes a mistake ranges between 2% (for NER Dutch) to 4.1% for NER Spanish.

We set the value of the hyper parameter ϕ to its optimal value obtained in the experiments reported in the previous section. The size of K of the number of labelings used in the four first methods (KD-PC, KD-Fixed, KBV, WKBV) and the weighting scalar s used in KD-PC and KD-Fixed were tuned for each dataset on a single evaluation on subset of the training set according to the best measured average precision. For the parameter s we tried about 20 values in the range 0.01 to 1.0, and for the number of labels K we tried the values in $10, 20 \ldots 80$. The optimal values are $K = 50$ for KD-PC and KD-Fixed, and $K = 30$ for KBV and WKBV. We noticed that KD-PC and KD-Fixed were robust to larger values of K, while the performance of KBV and WKBV was degraded significantly for large values of K.

We also trained CRF on the same training sets and applied it to label and assign confidence values to all the words in the test sets. The fraction of mislabeled words produced by the CRF model and the CW model is summarized in Table 3.

Relative Confidence: For each of the datasets, we first trained a model using the CW algorithm and applied each of the confidence methods on the output, ranking from low to high all the words of the test set according to the confidence in the prediction associated with them. Ideally, the top ranked words are the ones for which the classifier made a mistake on. This task can be thought of as a retrieval task of the erroneous words.

The average precision is the average of the precision values computed at all ranks of erroneous words. The average precision for ranking the words of the test-set according the confidence in the prediction of seven methods appears in the top-left panel of Fig. 2. (left to right bars in each group : CRF, KD-Fixed, KD-PC, Delta, WKBV, KBV and random ordering.) We see that when ordering the words randomly, the average precision is about the frequency of erroneous word, which is the lowest average precision. Next are the two methods based on the best Viterbi labelings, where the weighted approach outperforming the non-weighted version. Thus, taking the actual score value into consideration improves the ability to detect erroneous words. Next in performance is Delta, the margin-induced method. The

Figure 4: Predicted error in each bin vs. the actual frequency of mistakes in each bin. Best performance is obtained by methods close to the line $y = x$ (black line) for four tasks. Four methods are compared: weighted K-Viterbi (WKBV), K-draws PC (KD-PC) and K-draws fixed covariance (KD-Fixed) and CRF.

two best performing among the CW based methods are KD-Fixed and KD-PC, where the former is better in three out of four datasets. When compared to CRF we see that in two cases CRF outperforms the K-Draws based methods and in the other two cases it performs equally. We found the relative success of KD-Fixed compared to KD-PC surprising, as KD-Fixed does not take into consideration the actual uncertainty in the parameters learned by CW, and in fact replaced it with a *fixed* value across all features. Since this method does not need to assume a confidence-based learning approach we repeated the experiment, training a model with the passive-aggressive algorithm, rather than CW. All confidence estimation methods can be used except the KD-PC, which does take the confidence information into consideration. The results appear in the bottom-left panel of Fig. 2, and basically tell the same story, KD-Fixed outperform the margin based method (Delta), and the Viterbi based methods (KBV, WKBV).

To better understand the behavior of the various methods we plot the total number of detected erroneous words vs. the number of ranked words (first $5,000$ ranked words) in the top panels of Fig. 3. The bottom panels show the relative additional number of words each methods detects on top of the margin-based Delta method. Clearly, KD-Fixed and KD-PC detect erroneous words better than the other CW based methods, finding about 100 more words than Delta (when ranking $5,000$ words) which is about 8% of the total number of erroneous words.

Regarding CRF, it outperforms the K-Draws methods in NER English and NP chunking datasets, finding about 150 more words, CRF performed equally for NER Dutch, and performed worse for NER Spanish finding about 80 less words. We emphasize that all methods *except CRF* were based on the same exact weight vector, ranking the same predations, while CRF used an alternative weight vector that yields different number of erroneous words.

In details, we observe some correlation between the percentage or erroneous words in the entire set and the number of erroneous words detected among the first $5,000$ ranked words. For NP chunking and NER English datasets, CRF has more erroneous words compared to CW and it detects more erroneous words compared to K-Draws. For NER Dutch dataset CRF and CW have almost same number of erroneous words and almost same number of erroneous words detected, and finally in NER Spanish dataset CRF has fewer erroneous words and it detected less erroneous words. In other words, where there are more erroneous words to find (e.g. CRF in NP chunking), the task of ranking erroneous words is easier, and vice-versa.

We hypothesize that part of the performance differences we see between the K-Draws and CRF methods is due to the difference in the number of erroneous words in the ranked set.

This ranking view can be thought of marking suspected words to be evaluated manually by a human annotator. Although in general it may be hard for a human to annotate a single word with no need to annotate its close neighbor, this is not the case here. As the neighbor words are already labeled, and pretty reliably, as mentioned above.

Absolute Confidence: Our next goal is to evaluate how reliable are the *absolute* confidence values output by the proposed methods. As before, the confidence estimation methods (KD-PC, KD-Fixed, KBV, WKBV and CRF) were applied on the entire set of predicted labels. (Delta method is omitted as the confidence score it produces is not in $[0, 1]$).

For each of the four datasets and the five algorithms we grouped the words according to the value of their confidence. Specifically, we used twenty (20) bins dividing uniformly the confidence range into intervals of size 0.05. For each bin, we computed the fraction of words predicted correctly from the words assigned to that bin. Ultimately, the value of the computed frequency should be about the center value of the interval of the bin. Formally, bin indexed j contains words with confidence value in the range $[(j-1)/20, j/20)$ for $j = 1 \ldots 20$. Let b_j be the center value of bin j, that is $b_j = j/20 - 1/40$. The frequency of correct words in bin j, denoted by c_j is the fraction of words with confidence $\nu \in [(j-1)/20, j/20)$ that their assigned label is correct. Ultimately, these two values should be the same, $b_j = c_j$, meaning that the confidence information is a good estimator of the frequency of correct labels. Methods for which $c_j > b_j$ are too pessimistic, predicting too high frequency of erroneous labels, while methods for which $c_j < b_j$ are too optimistic, predicting too low frequency of erroneous words.

The results are summarized in Fig 4, one panel per dataset, where we plot the value of the center-of-bin b_j vs. the frequency of correct prediction c_j, connecting the points associated with a single algorithm. Four algorithms are shown: KD-PC, KD-Fixed, WKBV and CRF. We omit the results of the KBV approach - they were substantially inferior to all other methods. Best performance is obtained when the resulting line is close to the line $y = x$.

From the plots we observe that WKBV is too pessimistic as its corresponding line (blue square) is above the line $y = x$. CRF method is too optimistic, its corresponding line is below the line $y = x$. The KD-Fixed method is too pessimistic on NER-Dutch and too optimistic on NER-English. The best method is KD-PC which, surprisingly, tracks the line $x = y$ pretty closely. We hypothesis that its superiority is because it makes use of the uncertainty information captured in the covariance matrix Σ which is part of the Gaussian distribution.

Finally, these bins plots does not reflect the fact that different bins were not populated uniformly, the bins with higher values were more heavily populated. We thus plot in the top-right of Fig. 2 the root mean-square error in predicting the bin center value given by $\sqrt{\left(\sum_j n_j (b_j - c_j)^2\right) / \left(\sum_j n_j\right)}$, where n_j is the number of words in the jth bin. We observed a similar trend to the one appeared in the previous figure. WKBV is the least-performing method, then KD-Fixed and CRF, and then KD-PC which achieved lowest RMSE in all four datasets. Similar plot but when using PA for training appear in the bottom-right panel of Fig. 2. In this case we also see that KD-Fixed is better than WKBV, even though both methods were not trained with an algorithm that takes uncertainty information into consideration, like CW.

The success of KD-PC and KD-Fixed in evaluating confidence led us to experiment with using similar techniques for inference. Given an input sentence, the inference algorithm samples K times from the Gaussian distribution and output the best labeling according to each sampled weight vector. Then the algorithm predicts for each word the most frequent label. We found this method inferior to inference with the mean parameters. This approach differs from the one used by (Crammer et al., 2009a), as they output the most frequent labeling in a set, while the predicted label of our algorithm may not even belong to the set of predictions.

6 Active Learning

Encouraged by the success of the KD-PC and KD-Fixed algorithms in estimating the confidence in the prediction we apply these methods to the task of active learning. In active learning, the algorithm is given a large set of unlabeled data and a small set of labeled data and works in iterations. On each iteration, the overall labeled data at this point is used to build a model, which is then used to choose new subset of examples to be annotated.

In our setting, we have a large set of unlabeled sentences and start with a small set of 50 annotated sentences. The active learning algorithm is then using the CW algorithm to build a model, which in turn is used to rank sentences. The new data items are then annotated and accumulated to the set of labeled data points, ready for the next round. Many active learning algorithms are first computing a prediction for each of the unlabeled-data examples, which is then used to choose new examples to be labeled. In our case the goal is to label sentences, which are expensive to label. We thus applied the following setting. First, we chose a subset of 9K sentences as unlabeled training set, and another subset of size 3K for evaluation. After obtaining a model, the algorithm labels random $1,000$ sentences and chose a subset of 10 sentences using the active learning rule, which we will define shortly. After repeating this process 10 times we then evaluate the current model using the test data and proceed to choose new unlabeled examples to be labeled. Each method was applied to pick $5,000$ sentences to be labeled.

In the previous section, we used the confidence estimation algorithms to choose individual *words* to be annotated by a human. This setting is realistic since most words in each sentence were already classified (correctly). However, when moving to active learning, the situation changes. Now, all the words in a sentence are not labeled, thus a human may need to label additional words than the one in target, in order to label the target word. We thus experimented with the following protocol. On each iteration, the algorithm defines the score of an entire sentence to be the score of the least confident word in the sentence. Then the algorithm chooses the least confident sentence, breaking ties by favoring shorter sentences (assuming they contain relatively more informative words to be labeled than long sentences).

We evaluated five methods, KD-PC and KD-Fixed mentioned above. The method that ranks a sentence by the difference in score between the top- and second-best labeling, averaged over the length of sentence, denoted by MinMargin (Tong and Koller, 2001). A similar approach, motivated by (Dredze and Crammer, 2008), normalizes MinMargin score using the confidence information extracted from the Gaussian covariance matrix, we call this method MinConfMargin. Finally, We also evaluated an approach that picks random sentences to be labeled, denoted by RandAvg (averaged 5 times).

The averaged cumulative F-measure vs. number of words labeled is presented in Figs. 5,6. We can see that for short horizon (small number of sentences) the MinMargin is worse (in three out of four data sets), while MinConfMargin is worse in NP Chunking. Then there is no clear winner, but the KD-Fixed seems to be the best most of the time. The bottom panels show the results for more than $10k$ training words. Here, the random method performing the worst, while KD-PC and KD-Fixed are the best, and as shown in (Dredze and Crammer, 2008), MinConfMargin outperforming MinMargin.

Related Work: Most previous work has focused on confidence estimation for an entire example or some fields of an entry (Culotta and McCallum, 2004) using CRFs. (Kristjansson et al., 2004) show the utility of confidence estimation is extracted fields of an interactive information extraction system by high-lighting low confidence fields for the user. (Scheffer et al., 2001) estimate confidence of single token label in HMM based information extraction system by a method similar to the Delta method we used. (Ueffing and Ney, 2007) propose several methods for word level confidence estimation for the task of machine translation. One of the methods they use is very similar to the weighted and non-weighted K-best Viterbi methods we used with the proper adjustments to the machine translation task.

Abstract

In state-of-the-art approaches to information extraction (IE), dependency graphs constitute the fundamental data structure for syntactic structuring and subsequent knowledge elicitation from natural language documents. The top-performing systems in the BioNLP 2009 Shared Task on Event Extraction all shared the idea to use dependency structures generated by a variety of parsers — either directly or in some converted manner — and optionally modified their output to fit the special needs of IE. As there are systematic differences between various dependency representations being used in this competition, we scrutinize on different encoding styles for dependency information and their possible impact on solving several IE tasks. After assessing more or less established dependency representations such as the *Stanford* and *CoNLL-X* dependencies, we will then focus on trimming operations that pave the way to more effective IE. Our evaluation study covers data from a number of constituency- and dependency-based parsers and provides experimental evidence which dependency representations are particularly beneficial for the event extraction task. Based on empirical findings from our study we were able to achieve the performance of 57.2% F-score on the development data set of the BioNLP Shared Task 2009.

1 Introduction

Relation and event extraction are among the most demanding semantics-oriented NLP challenge tasks (both in the newspaper domain such as for ACE[1], as well as in the biological domain such as for BioCreative[2] or the BioNLP Shared Task[3]), comparable in terms of analytical complexity with recent efforts directed at opinion mining (e.g., NTCIR-7[4] or TREC Blog tracks[5]) or the recognition of textual entailment.[6] The most recent *BioNLP 2009 Shared Task on Event Extraction* (Kim et al., 2009) required, for a sample of 260 MEDLINE abstracts, to determine all mentioned events — to be chosen from a given set of nine event types, including *"Localization"*, *"Binding"*, *"Gene Expression"*, *"Transcription"*, *"Protein Catabolism"*, *"Phosphorylation"*, *"Positive Regulation"*, *"Negative Regulation"*, and (unspecified) *"Regulation"* — and link them appropriately with *a priori* supplied protein annotations. The demands on text analytics to deal with the complexity of this Shared Task in terms of relation diversity and specificity are unmatched by former challenges.

For relation extraction in the biomedical domain (the focus of our work), a stunning convergence towards dependency-based syntactic representation structures is witnessed by the performance results of the top-performing systems in the *BioNLP'09*

Shared Task on Event Extraction.[7] Regarding the fact that dependency representations were always viewed as a vehicle to represent fundamental semantic relationships already at the syntactic level, this is not a great surprise. Yet, dependency grammar is not a monolithic, consensually shaped and well-defined linguistic theory. Accordingly, associated parsers tend to vary in terms of dependency pairing or structuring (which pairs of words join in a dependency relation?) and dependency typing (how are dependency relations for a particular pair labelled?).

Depending on the type of dependency theory or parser being used, various representations emerge (Miyao et al., 2007). In this paper, we explore these different representations of the dependency graphs and try, first, to pinpoint their effects on solving the overall event extraction task and, second, to further enhance the potential of JREX, a high-performance relation and event extractor developed at the JULIE Lab (Buyko et al., 2009).

2 Related Work

In the biomedical domain, the focus has largely been on binary relations, in particular protein-protein interactions (PPIs). Accordingly, the biomedical NLP community has developed various PPI-annotated corpora (e.g., LLL (Nédellec, 2005), AIMED (Bunescu et al., 2005), BIOINFER (Pyysalo et al., 2007)). PPI extraction does clearly not count as a solved problem, and a deeper look at its biological and representational intricacies is certainly worthwhile. The GENIA event corpus (Kim et al., 2008) and the BioNLP 2009 Shared Task data (Kim et al., 2009) contain such detailed annotations of PPIs (amongst others).

The BioNLP Shared Task was a first step towards the extraction of specific pathways with precise information about the molecular events involved. In that task, 42 teams participated and 24 of them submitted final results. The winner system, TURKU (Björne et al., 2009), achieved with 51.95% F-score the milestone result in that competition followed by the JULIELab system (Buyko et al., 2009) which peaked at 46.7% F-score. Only recently, an extension of the TURKU system, the TOKYO system, has been realized (Miwa et al., 2010). TOKYO system's event extraction capabilities are based on the TURKU system, yet TURKU's manually crafted rule system for post-processing and the combination of extracted trigger-argument relations is replaced by a machine learning approach in which rich features collected from classification steps for triggers and arguments are re-combined. TOKYO achieves an overall F-score of 53.29% on the test data, thus outperforming TURKU by 1.34 percentage points.

The three now top-performing systems, TOKYO, TURKU and JULIELab, all rely on dependency graphs for solving the event extraction tasks. While the TURKU system exploits the Stanford dependencies from the McClosky-Charniak parser (Charniak and Johnson, 2005), and the JULIELab system uses the CoNLL-like dependencies from the GDep parser (Sagae and Tsujii, 2007),[8] the TOKYO system overlays the Shared Task data with two parsing representations, *viz.* Enju PAS structure (Miyao and Tsujii, 2002) and GDep parser dependencies. Obviously, one might raise the question as to what extent the performance of these systems depends on the choice of the parser and its output representations. Miyao et al. (2008) already assessed the impact of different parsers for the task of biomedical relation extraction (PPI). Here we perform a similar study for the task of event extraction and focus, in particular, on the impact of various dependency representations such as Stanford and CoNLL'X dependencies and additional trimming procedures.

For the experiments on which we report here, we performed experiments with the JULIELab system. Our main goal is to investigate into the crucial role of proper representation structures for dependency graphs so that the performance gap from Shared Task results between the best-performing TOKYO system and the JULIELab system be narrowed.

3 Event Extraction

3.1 Objective

Event extraction is a complex task that can be subdivided into a number of subtasks depending on

[7] `www-tsujii.is.s.u-tokyo.ac.jp/GENIA/SharedTask/results/results-master.html`

[8] The GDep parser has been trained on the GENIA Treebank pre-official version of the version 1.0 converted with the script available from `http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html`

whether the focus is on the event itself or on the arguments involved:

Event trigger identification deals with the large variety of alternative verbalizations of the same event type, e.g., whether the event is expressed in a verbal or in a nominalized form ("*A is expressed*" as well as "*the expression of A*" both refer to the same event type, *viz.* $Expression(A)$). Since the same trigger may stand for more than one event type, event trigger ambiguity has to be resolved as well.

Event trigger disambiguation selects the correct event name from the set of alternative event triggers.

Argument identification is concerned with finding all necessary participants in an event, i.e., the arguments of the relation.

Argument ordering assigns each identified participant its functional role within the event, mostly $Agent$ and $Patient$.

3.2 JULIELab System

The JULIELab solution can best be characterized as a single-step learning approach for event detection as the system does not separate the overall learning task into independent event trigger and event argument learning subtasks.[9] The JULIELab system incorporates manually curated dictionaries and machine learning (ML) methodologies to sort out associated event triggers and arguments on dependency graph structures. For argument extraction, the JULIELab system uses two ML-based approaches, a feature-based and a kernel-based one. Given that methodological framework, the JULIELab team scored on 2nd rank among 24 competing teams, with 45.8% precision, 47.5% recall and 46.7% F-score on all 3,182 events. After the competition, this system was updated and achieved 57.6% precision, 45.7% recall and 51.0% F-score (Buyko et al., 2010) using modified dependency representations from the MST parser (McDonald et al., 2005). In this study, we perform event extraction experiments with various dependency representations that allow us to measure their effects on the event extraction task and to increase the overall JULIELab system performance in terms of F-score.

4 Dependency Graph Representations

In this section, we focus on representation formats of dependency graphs. In Section 4.1, we introduce fundamental notions underlying dependency parsing and consider established representation formats for dependency structures as generated by various parsers. In Section 4.2, we account for selected trimming operations for dependency graphs to ease IE.

4.1 Dependency Structures: Representation Issues

Dependency parsing, in the past years, has increasingly been recognized as an alternative to long-prevailing constituency-based parsing approaches, particularly in semantically-oriented application scenarios such as information extraction. Yet even under purely methodologically premises, it has gained wide-spread attention as witnessed by recent activities performed as part of the "CoNLL Shared Tasks on Multilingual Dependency Parsing" (Buchholz and Marsi, 2006).

In a nutshell, in dependency graphs of sentences, nodes represent single words and edges account for head-modifier relations between single words. Despite this common understanding, concrete syntactic representations often differ markedly from one dependency theory/parser to the other. The differences fall into two main categories: dependency pairing or structuring (which pairs of words join in a dependency relation?) and dependency typing (how are dependency relations for a particular pair labelled?).

The CoNLL'X dependencies, for example, are defined by 54 relation types,[10] while the Stanford scheme (de Marneffe et al., 2006) incorporates 48 types (so called grammatical relations or Stanford dependencies). The Link Grammar Parser (Sleator and Temperley, 1991) employs a particularly fine-grained repertoire of dependency relations adding up to 106 types, whereas the well-known MINIPAR parser (Lin, 1998) relies on 59 types. Differences in dependency structure are at least as common as differences in dependency relation typing (see below).

[9] The JULIELab system considers all relevant lexical items as potential event triggers which might represent an event. Only those event triggers that can eventually be connected to arguments, finally, represent a true event.

[10] Computed by using the conversion script on WSJ data (accessible via `http://nlp.cs.lth.se/pennconverter/`; see also Johansson and Nugues (2007) for additional information). From the GENIA corpus, using this script, we could only extract 29 CoNLL dependency relations.

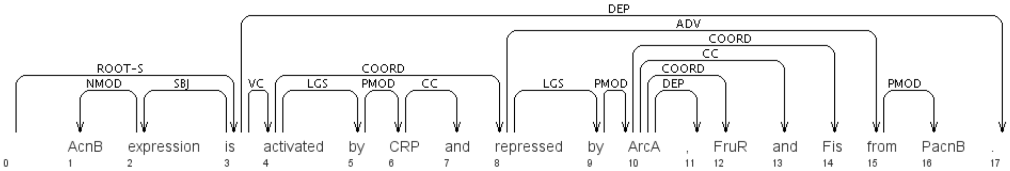

Figure 1: Example of CoNLL 2008 dependencies, as used in most of the native dependency parsers.

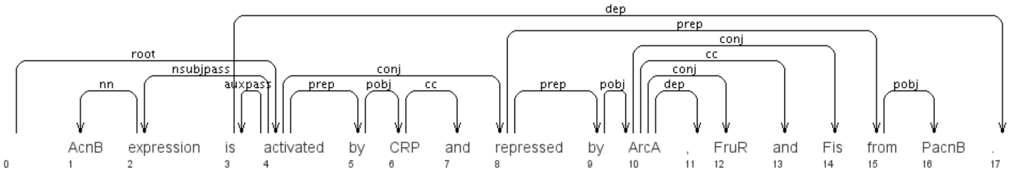

Figure 2: Stanford dependencies, *basic* conversion from Penn Treebank.

In general, dependency graphs can be generated by syntactic parsers in two ways. First, native dependency parsers output CoNLL'X or Stanford dependencies dependent on which representation format they have been trained on.[11] Second, in a derivative dependency mode, the output of constituency-based parsers, e.g., phrase structure representations, is subsequently converted either into CoNLL'X or Stanford dependencies using Treebank conversion scripts (see below). In the following, we provide a short description of these two established dependency graph representations:

- **CoNLL'X dependencies (CD).** This dependency tree format was used in the CoNLL'X Shared Tasks on multi-lingual dependency parsing (see Figure 1). It has been adopted by most native dependency parsers and was originally obtained from Penn Treebank (PTB) trees using constituent-to-dependency conversion (Johansson and Nugues, 2007). It differs slightly in the number and types of dependencies being used from various CoNLL rounds (e.g., CoNLL'08 provided a dependency type for representing appositions).[12]

- **Stanford dependencies (SD).** This format was proposed by de Marneffe et al. (2006) for semantics-sensitive applications using dependency representations, and can be obtained using the Stanford tools[13] from PTB trees. The Stanford format is widely used in the biomedical domain (e.g., by Miyao et al. (2008) or Clegg and Shepherd (2005)).

There are systematic differences between CoNLL'X and Stanford dependencies, e.g., as far as the representation of passive constructions, the position of auxiliary and modal verbs, or coordination representation is concerned. In particular, the representation of the *passive* construction and the role of the auxiliary verb therein may have considerable effects for semantics-sensitive tasks. While in SD the subject of the passive construction is represented by a special `nsubj` dependency label, in CD we find the same subject label as for active constructions `SUB(J)`. On CoNLL'08 data, the logical subject is marked by the `LGS` dependency edge that connects the passive-indicating preposition *"by"* with the logical subject of the sentence.

The representation of *active* constructions are similar in CD and SD though besides the role of auxiliary and modal verbs. In the Stanford dependency representation scheme, rather than taking auxiliaries to be the heads in passive or tense constructions, main verbs are assigned this grammatical function (see Figure 2). The CoNLL'X represen-

[11] We disregard in this study other dependency representations such as MINIPAR and LINK GRAMMAR representations.

[12] For the differences between CoNLL'07 and CoNLL'08 representations, cf. `http://nlp.cs.lth.se/software/treebank_converter/`

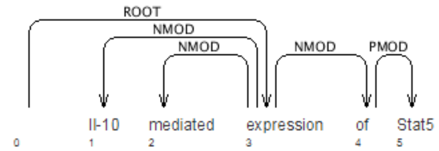

Figure 3: Noun phrase representation in CoNLL'X dependency trees.

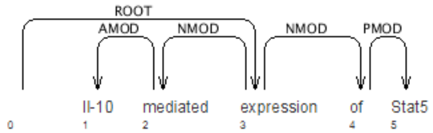

Figure 4: Trimming procedure *noun phrase* on CoNLL'X dependency trees.

tation scheme is completely different in that auxiliaries – much in common with standard dependency theory – are chosen to occupy the role of the governor (see Figure 1). From the perspective of relation extraction, however, the Stanford scheme is certainly closer to the desired predicate-argument structure representations than the CoNLL scheme.

4.2 Dependency Graph Modifications in Detail

Linguistic intuition suggests that the closer a dependency representation is to the format of the targeted semantic representation, the more likely will it support the semantic application. This idea is directly reflected in the Stanford dependencies which narrow the distance between nodes in the dependency graph by collapsing procedures (the so-called *collapsed* mode of phrase structure conversion). An example of collapsing is the conversion of "*expression* $\xrightarrow{\text{nmod}}$ *in* $\xrightarrow{\text{pmod}}$ *cells*" to "*expression* $\xrightarrow{\text{prep\_in}}$ *cells*". An extension of collapsing is the re-structuring of coordinations with sharing the dependency relations of conjuncts (the so-called *ccprocessed* mode of phrase structure conversion).

According to the Stanford scheme, Buyko et al. (2009) proposed collapsing scenarios on CoNLL'X dependency graphs. Their so-called *trimming* operations treat three syntactic phenomena, *viz.* coordinations (*coords*), auxiliaries/modals (*auxiliaries*), and prepositions (*preps*). For coordinations, they propagate the dependency relation of the first conjunct to all the other conjuncts within the coordination. For auxiliaries/modals, they prune the auxiliaries/modals as governors from the dependency graph and propagate the dependency relations of these nodes to the main verbs. Finally, for prepositions, they collapse a pair of typed dependencies into a single typed dependency (as illustrated above).

For the following experiments, we extended the trimming procedures and propose the re-structuring of noun phrases with action adjectives to make the dependency representation even more compact for semantic interpretation. The original dependency representation of the noun phrase selects the rightmost noun as the head of the NP and thus all remaining elements are its dependents (see Figure 3). For the noun phrases containing action adjectives (mostly verb derivations) this representation does not reflect the true semantic relations between the elements. For example, in *"IL-10 mediated expression"* it is *"IL-10"* that mediates the expression. Therefore, we re-structure the dependency graph by changing the head of *"IL-10"* from *"expression"* to *"mediated"*. Our re-coding heuristics selects, first, all the noun phrases containing action adjectives ending with *"-ed"*, *"-ing"*, *"-ible"* suffixes and with words such as *"dependent"*, *"specific"*, *"like"*. In the second step, we re-structure the noun phrase by encoding the adjective as the head of all the nouns preceding this adjective in the noun phrase under scrutiny (see Figure 4).

5 Experiments and Results

In this section, we describe the experiments and results related to event extraction tasks based on alternative dependency graph representations. For our experiments, we selected the following top-performing parsers — the first three phrase structure based and thus the origin of derivative dependency structures, the last three fully dependency based for making native dependency structures available:

- **C+J**, Charniak and Johnson's reranking parser (Charniak and Johnson, 2005), with the WSJ-trained parsing model.

- **M+C**, Charniak and Johnson's reranking parser (Charniak and Johnson, 2005), with the self-trained biomedical parsing model from McClosky (2010).

- **Bikel**, Bikel's parser (Bikel, 2004) with the WSJ-trained parsing model.

- **GDep** (Sagae and Tsujii, 2007), a native dependency parser.

- **MST** (McDonald et al., 2005), another native dependency parser.

- **MALT** (Nivre et al., 2007), yet another native dependency parser.

The native dependency parsers were re-trained on the GENIA Treebank (Tateisi et al., 2005) conversions.[14] These conversions,[15] i.e., Stanford *basic*, CoNLL'07 and CoNLL'08 were produced with the currently available conversion scripts. For the Stanford dependency conversion, we used the Stanford parser tool,[16] for CoNLL'07 and CoNLL'08 we used the treebank-to-CoNLL conversion scripts[17] available from the CoNLL'X Shared Task organizers.

The phrase structure based parsers were applied with already available models, i.e., the Bikel and C+J parsers as trained on the WSJ corpus, and M+C as trained on the GENIA Treebank corpus. For our experiments, we converted the prediction results of the phrase structure based parsers into five dependency graph representations, *viz.* Stanford *basic*, Stanford *collapsed*, Stanford *ccprocessed*, CoNLL'07 and CoNLL'08, using the same scripts as for the conversion of the GENIA Treebank.

The JULIELab event extraction system was re-trained on the Shared Task data enriched with different outputs of syntactic parsers as described above. The results for the event extraction task are represented in Table 1. Due to the space limitation of this paper we provide the summarized results of important event extraction sub-tasks only, i.e., results for basic events (*Gene Expression*, *Transcription*, *Localization*, *Protein Catabolism*) are summarized under SVT-TOTAL; regulatory events are summarized under REG-TOTAL; the overall extraction results are listed in ALL-TOTAL (see Table 1).

Obviously, the event extraction system trained on various dependency representations indeed produces truly different results. The differences in terms of F-score come up to 2.4 percentage points for the SVT-TOTAL events (cf. the MALT parser, difference between SD *basic* (75.6% F-score) and CoNLL'07 (78.0% F-score)), up to 3.6 points for REG-TOTAL (cf. the M+C parser, difference between SD *ccprocessed* (40.9% F-score) and CoNLL'07 (44.5% F-score)) and up to 2.5 points for ALL-TOTAL (cf. the M+C parser, difference between SD *ccprocessed* (52.8% F-score) and CoNLL'07 (55.3% F-score)).

The top three event extraction results on the development data based on different syntactic parsers results are achieved with M+C parser – CoNLL'07 representation (55.3% F-score), MST parser – CoNLL'08 representation (54.6% F-score) and MALT parser – CoNLL'08 representation (53.8% F-score) (see Table 1, ALL-TOTAL). Surprisingly, both the CoNLL'08 and CoNLL'07 formats clearly outperform Stanford representations on all event extraction tasks. Stanford dependencies seem to be useful here only in the *basic* mode. The *collapsed* and *ccprocessed* modes produce even worse results for the event extraction tasks.

Our second experiment focused on trimming operations on CoNLL'X dependency graphs. Here we performed event extraction after the trimming of the dependency trees as described in Section 4.2 in different modes: *coords* – re-structuring coordinations; *preps* – collapsing of prepositions; *auxiliaries* – propagating dependency relations of auxiliars and modals to main verbs; *noun phrase* – re-structuring noun phrases containing action adjectives. Our second experiment showed that the extraction of selected events can profit in particular from the trimming procedures *coords* and *auxiliaries*, but there is no evidence for a general trimming configuration for the overall event extraction task.

In Table 2 we summarize the best configurations we found for the events in focus. It is quite evident that the CoNLL'08 and CoNLL'07 dependencies modified for auxiliaries and coordinations are the best configurations for four events (out of nine). For three events no modifications are necessary and

[14] For the training of dependency parsers, we used from the available Stanford conversion variants only Stanford *basic*. The *collapsed* and *ccprocessed* variants do not provide dependency trees and are not recommended for training native dependency parsers.

only one event profits from trimming of prepositions (*Protein Catabolism*). Only the *Binding* event profits significantly from noun phrase modifications (see Table 3). The increase in F-score for trimming procedures is 4.1 percentage points for *Binding* events.

In our final experiment we connected the best configurations for each of the BioNLP'09 events as presented in Table 2. The overall event extraction results of this final configuration are presented in Tables 4 and 5. We achieved an increase of 1.9 percentage points F-score in the overall event extraction compared to the best-performing single parser configuration (M+C, CoNLL'07) (see Table 4, ALL-TOTAL). The reported results on the development data outperform the results of the TOKYO system by 2.6 percentage points F-score for all basic events including *Binding* events (see Table 4, EVT-TOTAL) and by 0.9 percentage points in the overall event extraction task (see Table 4, ALL-TOTAL).

On the test data we achieved an F-score similar to the current JULIELab system trained on modified CoNLL'07 dependencies from the MST parser (see Table 5, ALL-TOTAL).[18] The results on the official test data reveal that the performance differences between various parsers may play a much smaller role than the proper choice of dependency representations.[19] Our empirical findings that the best performance results could only be achieved by event-specific dependency graph configurations reveal that the syntactic representations of different semantic events vary considerably at the level of dependency graph complexity and that the automatic prediction of such syntactic structures can vary from one dependency parser to the other.

6 Discussion

The evaluation results from Table 1 show that an increased F-score is basically due to a better performance in terms of precision. For example, the M+C evaluation results in the Stanford *basic* mode provide an increased precision by 2 percentage points compared to the Stanford *ccprocessed* mode. Therefore, we focus here on the analysis of false positives that the JULIELab system extracts in various modes.

For the first analysis we took the outputs of the systems based on the M+C parsing results. We scrutinized on the Stanford *basic* and *ccprocessed* false positives (fps) and we compared the occurrences of dependency labels in two data sets, namely the intersection of false positives from both system modes (set *A*) and the false positives produced only by the system with a worse performance (set *B*, *ccprocessed* mode). About 70% of all fps are contained in set *A*. Our analysis revealed that some dependency labels have a higher occurrence in set *B*, e.g., `nsubjpass, prep_on, prep_with, prep_in, prep_for, prep_as`. Some dependency labels occur only in set *B* such as `agent`, `prep_unlike, prep_upon`. It seems that collapsing some prepositions, such as *"with"*, *"in"*, *"for"*, *"as"*, *"on"*, *"unlike"*, *"upon"*, does not have a positive effect on the extraction of argument structures. In a second step, we compared the Stanford *basic* and CoNLL'07 false positive sets. The fps of both systems have an intersection of about 70%. We also compared the intersection of fps between two outputs (set *A*) and the set of additional fps of the system with worse results (Stanford *basic* mode, set *B*). The dependency labels such as `abbrev, dep, nsubj, nsubjpass` have a higher occurrence in set *B* than in set *A*. This analysis renders evidence that the distinction of `nsubj` and `nsubjpass` does not seem to have been properly learned for event extraction.

For the second analysis round we took the outputs of the MST parsing results. As in the previous experiments, we compared false positives from two mode outputs, here the CoNLL'07 mode and the CoNLL'07 modified for *auxiliaries* and *coordinations* mode. The fps have an intersection of 75%. The dependency labels such as `VC, SUBJ, COORD`, and `IOBJ` occur more frequently in the additional false positives from the CoNLL'07 mode than in the intersection of false positives from both system outputs. Obviously, the trimming of auxiliary and coordination structures has a direct positive effect on the argument extraction reducing false positive numbers especially with corresponding dependency labels in shortest dependency paths.

Our analysis of false positives shows that the distinction between active and passive subject labels,

[18] The current JULIELab system uses event-specific trimming procedures on CoNLL'07 dependencies determined on the development data set (see Buyko et al. (2010)).

[19] Trimmed CoNLL dependencies are used in both system configurations.

abbreviation labels, as well as collapsing prepositions in the Stanford dependencies, could not have been properly learned, which consequently leads to an increased rate of false positives. The trimming of auxiliary structures and the subsequent coordination collapsing on CoNLL'07 dependencies has indeed event-specific positive effects on the event extraction.

The main focus of this work has been on the evaluation of effects of different dependency graph representations on the IE task achievement (here the task of event extraction). But we also targeted the task-oriented evaluation of top-performing syntactic parsers. The results of this work indicate that the GENIA-trained parsers, i.e., M+C parser, the MST, MALT and GDep, are a reasonable basis for achieving state-of-the art performance in biomedical event extraction.

But the choice of the most suitable parser should also take into account its performance in terms of parsing time. Cer et al. (2010) and Miyao et al. (2008) showed in their experiments that native dependency parsers are faster than constituency-based parsers. When it comes to scaling event extraction to huge biomedical document collections, such as MEDLINE, the selection of a parser is mainly influenced by its run-time performance. MST, MALT and GDep parsers or the M+C parser with reduced reranking (Cer et al., 2010) would thus be an appropriate choice for large-scale event extraction under these constraints.[20]

7 Conclusion

In this paper, we investigated the role different dependency representations may have on the accomplishment of the event extraction task as exemplified by biological events. Different representation formats (mainly, Stanford *vs.* CoNLL) were then experimentally compared employing different parsers (Bikel, Charniak+Johnson, GDep, MST, MALT), both constituency based (for the derivative dependency mode) as well as dependency based (for the native dependency mode), considering different training scenarios (newspaper *vs.* biology domain).

From our experiments we draw the conclusion that the dependency graph representation has a crucial impact on the level of achievement of IE task requirements. Surprisingly, the CoNLL'X dependencies outperform the Stanford dependencies for four from six parsers. With additionally trimmed CoNLL'X dependencies we could achieve an F-score of 50.9% on the official test data and an F-score of 57.2% on the official development data of the BioNLP Shared Task on Event Extraction (see Table 5, ALL-TOTAL).

[20] For large-scale experiments an evaluation of the M+C with reduced reranking should be provided.

Abstract

The research question treated in this paper is centered on the idea of exploiting rich resources of one language to enhance the performance of a mention detection system of another one. We successfully achieve this goal by projecting information from one language to another via a parallel corpus. We examine the potential improvement using various degrees of linguistic information in a statistical framework and we show that the proposed technique is effective even when the target language model has access to a significantly rich feature set. Experimental results show up to 2.4F improvement in performance when the system has access to information obtained by projecting mentions from a resource-rich-language mention detection system via a parallel corpus.

1 Introduction

The task of identifying and classifying entity textual references in open-domain texts, i.e. the *Mention Detection* (MD) task, has become one of the most important subtasks of Information Extraction (IE). It might intervene both as one step to structure natural language texts or as a text enrichment preprocessing step to help other Natural Language Processing (NLP) applications reach higher accuracy. Similarly to the Automatic Content Extraction (ACE) [1] nomenclature, we consider that a mention can be either named (e.g., John, Chicago), nominal (e.g., president, activist) or pronominal (e.g., he, she). It has also a specific class which describes the type of the entity it refers to. For instance, in the sentence:

Michael Bloomberg, the Mayor of NYC, declared his war on tobacco and sugary drinks in the city.

we find the mentions 'Michael Bloomberg', 'Mayor' and 'his' of the same person entity. Their types are named, nominal and pronominal, respectively. 'NYC' and 'city', on the other hand, are mentions of the same geopolitical (GPE) entity of type named and nominal, respectively. Consequently, MD is a more general and complex task than the well known Named Entity Recognition (NER) task which aims solely at the identification and classification of the named mentions.

The difficulty of the MD task is directly related to the nature of the language and the linguistic resources available, i.e. it is easier to build accurate MD systems for languages with a simple morphology and a high amount of linguistic resources. For this reason, we explore the idea of using an MD system, which has been designed and built for a resource-rich language (RRL), to help enhance the performance of an MD system in a target language (TL). More specifically, the goal of the research work we present in this paper is to employ the richness of English, in terms of natural language resources, to raise the accuracy of MD systems in other languages. For instance, an English MD system might achieve a performance of $F_{\beta=1}$-measure=82.7 (Zitouni and Florian, 2009) when it resorts to a rich set of features extracted from diverse resources, namely: part-of-speech, chunk information, syntactic parse trees, word sense information, WordNet information and information from the output of other mention detection classifiers. In this paper, our research question revolves around investigating an adequate approach to use such a system to the benefit of other languages such as Arabic, Chinese, French or Spanish MD systems, which also

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 993–1001,
MIT, Massachusetts, USA, 9-11 October 2010.

have annotated resources but not of the same quantity and/or quality as English.

In this paper, we have targeted English and Arabic as the RRL and TL, respectively, because:

1. We have a very competitive English MD system;
2. The linguistic resources available for the Arabic language allow a simulation of different TL richness levels; and
3. The use of two languages of an utterly different nature makes the extrapolation of the results to other languages possible.

Our hypothesis might be expressed as follows: using an MD system resorting to a rich feature set (i.e. the RRL MD system) to boost a MD system performance in a TL can be very beneficial if the "donor" system surpasses its TL counterpart in terms of resources. To test this hypothesis, we have projected MD tags from RRL to TL via a parallel corpus, and then extracted several linguistic features about the automatically tagged words. Thereafter, we have conducted experiments adding these new features to the TL baseline MD system. In order to have a complete picture on the impact of these new features, we have used TL baseline systems resorting to a varied amount of features, starting with a case employing only lexical information to a case where we use all the resources we could gather for the TL. Experiments show that the gain is always statistically significant and it reaches its maximum when only very basic features are used in the baseline TL MD system.

2 Mention Detection

Similarly to classical NLP tasks, such as Base Phrase Chunking (Ramshaw and Marcus, 1999) (BPC) or NER (Tjong Kim Sang, 2002), we formulate the MD task as a sequence classification problem, i.e. the classifier assigns to each token in the text a label indicating whether it starts a specific mention, is inside a specific mention, or is outside any mentions. It also assigns to every non outside mention a class to specify its type: e.g., person, organization, location, etc. In this study, we chose the Maximum Entropy Markov Model (MEMM henceforth) approach because it can easily integrate arbitrary types of information in order to make a classification decision. To train our models, we have used the *Sequential Conditional Generalized Iterative Scaling* (SCGIS) technique (Goodman, 2002). This techniques uses a *Gaussian prior* for regularization (Chen and Rosenfeld, 2000). The features used by our MD systems can be divided into the following categories:

1- *Lexical*: these are token n-grams directly neighboring the current token on both sides, i.e. left and right. Empirical results have shown that the optimal span is $n = 3$.

2- *Syntactic*: they consist of the outcomes of several Part-Of-Speech (POS) taggers and BPCs trained on different corpora and different tag-sets in order to provide the MD system with a wider variety of information. Our model uses the POS and BPC information appearing in window of 5 (current, two previous, and two next) jointly with the tokens.

Both the English and the Arabic MD systems have access to lexical and syntactic features. The former one, however, also employs a set of features obtained from the output of other MD classifiers. In order to provide the MD system with complementary information, these classifiers are trained on different datasets annotated for different mention types, e.g. dates or occupation references (not used in our task).

3 Annotation, Projection and Feature Extraction

We remind the reader that our main goal is to use an RRL MD system to enhance the performance of an MD system in another language, i.e. the TL. In order to achieve this goal, we propose an approach that uses an RRL-to-TL parallel corpus to bridge between these two languages. This approach performs in three main steps, namely: annotation, projection and feature extraction. In this section, we describe in details each of these steps.

3.1 Annotation

This first step consists of MD tagging of the RRL side of the parallel corpus. Because in our case study we have chosen English as the RRL, we have used an accurate English MD system to perform the annotation step. Our English MD system achieves an F-measure of 82.7 (Zitouni and Florian, 2009) and has achieved significantly competitive results at the ACE evaluation campaign.

3.2 Projection

Once the RRL side of the parallel corpus is accurately augmented with MD tags, the projection step comes to transfer those tags to the TL side, Arabic in our case study, using the word alignment information. We illustrate the projection step with a relevant example. Let consider the following MD tagged English sentence:

*Bill/***B-PER-NAM** *Clinton/***I-PER-NAM** *is visiting North/***B-GPE-NAM** *Korea/***I-GPE-NAM** *today*

where "*Bill Clinton*" is a named person mention and "*North Korea*" is a named geopolitical entity (GPE) one. A potential Arabic translation of this sentence would be:

بيل كلينتون يزور كوريا الشمالية اليوم

which might be transliterated as:

byl klyntwn yzwr kwryA Al$mAlyA Alywm

After projecting the English mentions to the Arabic text, we obtain the following:

*byl/***B-PER-NAM** *klyntwn/***I-PER-NAM** *yzwr kwryA/***B-GPE-NAM** *Al$mAlyp/***I-GPE-NAM** *Alywm*

This tagged version of the Arabic text is provided to the third module of the process responsible on feature extraction (see Subsection 3.3). It is, however, pertinent to point out that the example we have used for illustration is relatively simple in the sense that almost all English and Arabic words have a 1-to-1 mapping. In real world translation (both human and automatic), one should expect to see 1-to-n, n-to-1 mappings as well as unmapped words on both sides of the parallel corpus rather frequently.

As stated by (Klementiev and Roth, 2006), the projection of NER tags is easier in comparison to projecting other types of annotations such as POS-tags and BPC[2], mainly because:

1. *Not all the words are mentions*: once we have projected the tags of the mentions from the RRL to TL side, the rest of tokens are simply considered as outside any mentions. This is different from the POS-tag and BPC where all the words are assigned a tag and thus when a word is unmapped, further processing is required (Yarowsky et al., 2001);

2. *In case of a 1-to-n mapping, the target n words are assigned the same class*: for instance, let consider the English GPE named mention "North-Korea". The segmented version of its Arabic translation would be "كوريا ال شمالية" (kwrya Al $mAlyp). The projection process consists in simply assigning the same class, i.e. GPE, to all Arabic tokens. The problem takes another dimension, however, in the case of propagating the POS-tags, because "North" is a NNP aligned with the determinant (DET) "Al" and the NNP "$mAlyp". Additional processing is needed to handle this difference of tags on the two sides.

3. *In case of n-to-1 mapping, the TL side word is simply assigned the class propagated from the RRL side*. For instance, if on the English side we have the named person multi-word mention "Ben Moussa", translated into the one-word mention بنموسى (bnmwsY) on the Arabic side, then projection consists of simply assigning the person named tag to the Arabic word.

However, in our research study, new challenges arose because our RRL data are automatically annotated, which is different from what has been reported in the research works we have mentioned before, i.e. (Yarowsky et al., 2001) and (Klementiev and Roth, 2006), where gold annotated data were used. In order to relax the impact of the noise introduced by the English MD system, we :

1. *use mention "splits" to filter annotation errors:* We assume that when a sequence of tokens is tagged as a mention on the RRL side, its TL counterpart should be an uninterrupted sequence of tokens as well. When the RRL MD system captures incorrectly the span of a mention, e.g. in the sentence "*Dona Karan international reputation of ...*", the RRL MD system might mistakenly tag "Dona Karan international" as an organization mention instead of tagging "Dona Karan" as a person mention. It is possible to detect this type of errors on the TL side because "dwnA kArAn" (Dona Karan) is distant from "Al EAlmyp" (international), i.e. they do not form an uninterrupted token sequence. We use this "split" in the mentions as information in order to not use these mentions in the feature extraction step (see Subsection 3.3).

2. *do not use the projected mentions directly for training:* Instead, we use these tags as additional features to our TL baseline model and allow our MEMM classifier to weigh them according to their relevance to each mention type.

3.3 Feature Extraction

At this point, the parallel corpus should be annotated with mentions on both of its sides. Where the RRL side is tagged using the English MD system during the annotation step (c.f section 3.1) while the TL side is annotated by the propagation of these MD tags via the parallel corpus in the projection step (c.f. section 3.2). In this third step, the goal is to extract pertinent linguistic features of the automatically tagged TL corpus to enhance MD model in the TL. The explored features are as follows:

[2] The claim is also valid for MD because it is the same type of annotation.

1. **Gazetteers:** we group mentions by class in different dictionaries. During both training and decoding, when we encounter a token or a sequence of tokens that is part of a dictionary, we fire its corresponding class; the feature is fired only when we find a complete match between sequence of tokens in the text and in the dictionary.
2. **Model-based features:** it consists of building a model on the automatically tagged TL side of the parallel corpus. The output of this model is used as a feature to enhance MD model in the target language. However, it is also possible to use this model to directly tag text in the TL. This would be useful in cases where we do not have any TL annotated data.
3. **n-gram context features:** it consists of using the annotated corpus in the TL to collect n-gram tokens surrounding a mention. We organize those contexts by mention type and we use them to tag tokens which appear in the same context in both the training and decoding sets. These tags will be used as additional feature in the MD model. For instance, if we consider that the person mention صدام حسين (SdAm Hsyn - Sadam Husein) appears in the following sentence: صرح أمس أن صدام حسين يترأس نظاما فاشلا which might be transliterated as: *SrH Ams An SdAm Hsyn ytrAs nZAmA fA$lA* and translated to English as: *declared yesterday that Sadam Husein governs a failed system*
the context n-grams that would be extracted are:

. **Left n-grams:** W_{-1}=أن (An - that), W_{-2}=أمس أن (Ams An - yesterday that), etc.

. **Right n-grams:** W_{+1}=يترأس (ystrAs - governs), W_{+2}=يترأس نظاما (ytrAs nZAmA - governs a system), etc.

. **Left and right n-grams:** a joint of the two previous features, W_{-i} and W_{+i}.

For both training and test data we create a new feature stream where we indicate that a token sequence is a mention if it appears in the same n-gram context.

4. **Head-word based features:** it considers that the lexical context in which the mention appeared is the sequence of the parent sub-trees head words in a parse-tree. For instance, if we consider the sentence which we have used in the previous example, the corresponding parse tree is shown in Figure 1.

The parent sub-tree heads of 'SdAm Hsyn' are marked with h_i on the tree. Similarly to the other features, in both training and decoding sets, we create a new feature stream where we tag those token sequences which appear with the same n first parent sub-tree head words as a person mention in the annotated TL data.

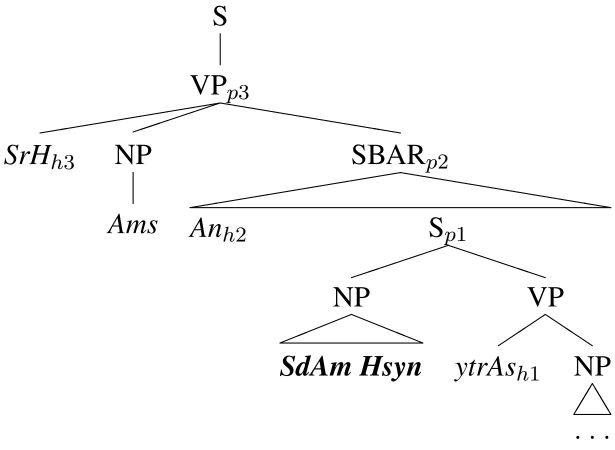

Figure 1: Parse tree

5. **Parser-based features:** it attempts to use the syntactic environment in which a mention might appear. In order to do so, for each mention in the target language corpus we consider only labels of the parent non-terminals .We mark parent non-terminal labels of 'SdAm Hsyn' on the tree with p_i. Similarly to the features described above, we create during both training and test a new feature stream where we indicate the token sequences which appear in the same parent non-terminal labels.

Gazetteers and model-based features are the most natural and expected kind of features that one would extract from the automatically MD tagged version of the TL text. Our motivation of using n-gram context features, on one hand, and the head-word based and parse-based features on the other is to: (i) contrast the impact of local and global context features; and (ii) experiment the possibility of employing both of them jointly in order to test their complementarity.

4 The Target Language Mention Detection System

- The Arabic language: In our research study, we have intentionally chosen a TL which is differs from English in its strategy in forming words and sentences. By doing so, we are seeking to avoid obtaining results which are biased by the similarity of the employed languages. For this reason, we have chosen Arabic as a TL.

Due to its Semitic origins, the Arabic language is both *derivational*, i.e. it uses a templatic strategy to form a word, and *highly inflectional*, i.e. additional affixes might be added to a word in order to obtain further meaning. Whereas the former characteristic is common in most languages, the latter, however, results in increasing *sparseness* in data and consequently forming an obstacle to achieve a high performance for most of the NLP tasks (Diab et al., 2004; Benajiba et al., 2008; Zitouni et al., 2005; Zitouni and Florian, 2008). From a NLP viewpoint, especially the supervised tasks such as the one we are dealing with in this paper, this implies that a huge amount of training data is necessary in order to build a robust model. In our study, to tackle the data sparseness problem, we have performed the *word segmentation*. This segmentation pre-processing step consists of separating the normal white-space delimited words into prefixes, stems, and suffixes. Thus, from a modeling viewpoint, the unit of analysis becomes the segments. We use a technique similar to the one introduced in (Lee et al., 2003) for segmentation with an accuracy of 98%.

- The Arabic MD system: Our Arabic MD system employs the same technique presented in Section 2. Compared to English MD model, Arabic MD system has access to morphological information (Stem) as we will explain next. Features used by the Arabic MD system are divided in three categories:

1. Lexical: Similar to the lexical features used by our English MD system (c.f. section 2);

2. Stem: This feature has been introduced in (Zitouni et al., 2005) as stem n-grams spanning the current stem; both preceding and following it. If the current token x_i is a stem, stem n-gram features contain the previous $n-1$ stems and the following $n-1$ stems. Stem n-gram features represent a lexical generalization that reduce data sparseness;

3. Syntactic: it consists of the output of POS taggers and the BPCs.

As we describe with more details in the experiments section (see Section 6), once we have extracted the new features from the parallel corpus, we contrast their impact with the level of richness in features of the TL MD system, i.e. we measure the impact of each feature f_i when the TL MD system uses: (i) only lexical features; (ii) both lexical and stem features; and (iii) lexical, stem and syntactic features.

5 Evaluation Data

Experiments are conducted on the Arabic ACE 2007 data. There are 379 Arabic documents and almost $98,000$ words. We find seven classes of mentions: Person (PER), Organization (ORG), Geo-Political Entity (GPE), Location (LOC), Facility (FAC), Vehicle (VEH) and Weapon (WEA). Since the evaluation test sets are not publicly available, we have split the publicly available *training* corpus into an 85%/15% data split. We use 323 documents ($80,000$ words) for training and 56 documents ($18,000$ words) as a test set. This results in $17,634$ mentions ($7,816$ named, $8,831$ nominal and 987 pronominal) for training and $3,566$ for test ($1,673$ named, $1,682$ nominal and 211 pronominal). To facilitate future comparisons with work presented here, and to simulate a realistic scenario, the splits are created based on article dates: the test data is selected as the latest 15% of the data in chronological order, in each of the covered genres (newswire and webblog). Performance on the ACE data is usually evaluated using a special-purpose measure, i.e. the ACE value metric. However, given that we are interested in the mention detection task only, we decided to use the more intuitive and popular (un-weighted) F-measure, the harmonic mean of precision and recall.

6 Experiments and Results

As we have stated earlier, our main goal is to investigate how an MD model of a TL might benefit from additional information about the mentions obtained by propagation from an RRL. In our research study we have chosen Arabic as the TL and English as the RRL. The English MD system we use has access to a large set of information (Zitouni and Florian, 2009) and has achieved a performance of 82.7F on ACE'07 data. In order to simulate different levels of resource-richness for the TL, we have employed four baseline systems which use different feature-sets. Following we present these feature-sets ranked from the resource-poorest to the resource-richest one: 1- $Lex.$: lexical features; 2- $Stem.$: $Lex.$ + stem features; and 3- $Syntac.$: $Stem.$ + syntactic features.

For each of these baseline systems, we study the impact of features extracted from the parallel corpus (c.f. Section 3) separately. We report the following results:

1- $Base.$: baseline system *without* the use of parallel-data extracted features;

2- $n-Lex.$: $Base.+$ n-gram context features;

	$Lex.$	$Stem$	$Syntac$
$Base.$	74.14	74.47	75.53
$n - Lex.$	74.71	75.25	76.20
$n - Head$	74.63	75.29	75.93
$n - Pars.$	75.32	75.19	75.74
Gaz	74.90	74.79	75.66
$Model$	74.60	75.50	76.22
$Comb.$	**76.01**	**76.74**	**77.18**

Table 1: Obtained results when the features were extracted from a hand-aligned parallel corpus

3- $n - Head$: $Base.$ + head-word based features;
4- $n - Pars.$: $Base.$ + parser-related features;
5- $Gaz.$: $Base.$ + automatically extracted gazetteers from the parallel corpus;
6- $Model$: $Base.$ + output of model trained on the Arabic part of the parallel corpus;
7- $Comb.$: combination of all the above.
In the rest of the paper, to measure whether the improvement in performance of a system using features from parallel data over baseline is statistically significant or not, we use the stratified bootstrap re-sampling significance test (Noreen, 1989) used in the NER shared task of CoNLL-2002[3]. We consider results as statistically significant when $p < 0.02$.

6.1 Hand-aligned Data

In our first experiment-set, we use a hand-aligned English-to-Arabic parallel corpus of approximately one million words. After tagging the Arabic side by projection we obtain 86.5K mentions. As we have previously mentioned, in order to generate the model-based feature, $Model$, we have trained a model on the Arabic side of the parallel corpus. This model achieved an F-measure of 57.7F. This shows the performance that might be achieved when *no human annotated data* is available in the TL.

Results in Table 1 show that a significant improvement is obtained when the TL is poor in resources; for instance an improvement of $\sim$1.9 points was achieved when the TL used only lexical features. The use of $n - Pars.$ features alone yielded 1.2 points of improvement. when the TL model uses a rich feature-set, we still can obtain $\sim$1.7 points improvement. When the TL baseline model employs the $Syntac$ feature-set, the greatest improvement is obtained when we add the model-based feature. Improvement obtained by the system using $Comb.$ features is statistically significant compared to the baseline model. This system also outperforms systems using the new feature set separately across the board. According to our error-analysis, the significant amount of Arabic mentions observed in the parallel corpus, where many of them do not appear in the training corpus, has significantly helped the $Lex.$, $Stem$ and $Syntac$ MD models to capture new mentions and/or correct the type assigned. Some of the relevant examples in our data are: (i) the facility mention مبنى بلفور (mbnY blfwr - Belvoir Building); (ii) the GPE mention كابول (kAbwl - Kabul); and (iii) the person mention البعثيّين (AlbEvyyn - the Baathists). These mentions have only been tagged correctly when we have added the new extracted features to our model.
In other words, the error-analysis clearly points out that one possible way to get further improvement is to increase the parallel data in order to increase the number of matches between (1) *the number of mentions which are wrongly tagged by the TL MD model* and (2) *the number of mentions in the TL side of the parallel corpus*. The second parameter can be, indirectly, increased by increasing the size of the parallel data. Getting 10 or 20 times more of parallel data that is hand-aligned is expensive and requires several months of human/hours work. For this reason we opted for using an unsupervised approach by selecting a parallel corpus that is automatically aligned as we discuss in the next section.

6.2 Automatically-aligned Data

We have used for this experiment-set an Arabic-to-English parallel data of 22 million words. The data in this corpus is automatically aligned using a technique presented in (Ittycheriah and Roukos, 2005). The alignment is one-to-many with a performance around 87 F-measure.

Because we are dealing with a large amount of data and the word alignment is done automatically, meaning more noise, we have used the English MD model confidence for additional filtering. Such filtering consists in keeping, from the parallel corpus, only sentences which have all tokens tagged with a confidence greater than α. In this paper, we use a value of $\alpha = 0.94$, which results in a corpus of 17 million words. We notice that a lower value of α results in a radical increase in noise. Because of space limitation, we will report results only with this value of α.

Table 2 shows the obtained results for parallel-

	$Lex.$	$Stem$	$Syntac$
$Base.$	74.14	74.47	75.53
$n - Lex.$	74.27	74.74	75.24
$n - Head.$	74.07	74.95	75.33
$n - Pars.$	75.62	75.22	76.02
Gaz	73.96	74.11	74.94
$Model$	74.87	75.12	75.76
$Comb.$	**75.56**	**75.93**	**76.46**

Table 2: Obtained results when the features were extracted from a automatically-aligned parallel corpus

data based features using the 17M subset. Differently from experiments using hand-aligned data, the best results have been obtained when we have used the parser-based feature, i.e. $n - Pars.$ On one hand, the overall behavior is comparable to the one obtained when using the 1M hand-aligned parallel data (see Table 1), i.e. (i) the greatest improvement has been obtained when the TL uses a poor feature-set; and (ii) when the TL baseline model is rich in resources, we still obtain 0.45 points absolute improvement when using $n - Pars.$ On the other hand, features extracted from automatically-aligned data, in comparison with the ones extracted from the hand aligned data, have helped the MD model to correct many of the TL baseline model false negatives. This has been observed when the TL baseline system uses a rich feature set as well. A side effect of the noisy word alignment, however, was an increase in the number of false positives. For instance, the word مستحضرات (mstHDrAt - preparations) which appeared in the following sentence:

عدم السماح لمستحضرات أخرى

which might be transliterated as:

Edm AlsmAH lmstHDrAt AxrY

and translated to English as:

not to allow other preparations

has been tagged as an organization mention because it has been mistakenly aligned, in the parallel corpus, with the word كاو, *KO*, in the sentence:

شركة كاو الكبرى للّمستحضرات التجميلية

meaning:

The big cosmetics company KO.

In order to validate our results, we run our experiments on a blind test-set. We have selected the latest 5% of each genre of the hand-aligned data and they have been manually annotated by a human. The blind test-set consists of 51,781 tokens of which 6,481 are mentions. Table 3 shows the distribution of these mentions over the different classes. The results are shown in Table 4. These results confirm the conclusions we have deduced from the ones previously presented in Table 2, i.e.: (i) the highest improvement is obtained when the TL is resource-scarce.

Class	Num. of mentions
FAC	285
GPE	2,145
LOC	239
ORG	1,135
PER	2,474
VEH	65
WEA	138

Table 3: Distribution over the classes of the blind test mentions

	$Lex.$	$Stem$	$Syntac$
$Base.$	74.26	73.54	73.61
$n - Lex.$	74.04	73.72	73.83
$n - Head$	74.14	73.64	73.83
$n - Pars.$	74.32	74.18	74.32
Gaz	71.49	72.13	73.39
$Model$	**75.01**	**74.66**	**74.78**
