(18 November 1932 – 14 September 2010)

Preface

Welcome to EMNLP 2010, Conference on Empirical Methods in Natural Language Processing! The conference is organized by SIGDAT, the Association for Computational Linguistics' special interest group on linguistic data and corpus-based approaches to NLP, and is held this year as a stand-alone conference at the MIT Stata Center, Massachusetts, USA on October 9-11. [1]

EMNLP 2010 received 500 submissions, a new record for the conference. The program committee was able to accept 125 papers in total (an acceptance rate of 25%). Among them, 70 of the papers (14%) were accepted for oral presentations, and 55 (11%) for poster presentations. The PC, which consists of 18 area chairs and 460 PC members from Asia, Europe, and North America, worked together to create a strong program with high quality oral and poster presentations and enlightening invited talks.

First and foremost, we would like to thank the authors who submitted their work to EMNLP 2010. The sheer number of submissions reflects how broad and active our field is. We are deeply indebted to the area chairs and the PC members for their hard work. They enabled us to make a wonderful program and to provide valuable feedback to the authors. We are very grateful to our invited speakers Kevin Knight, Andrew Ng and Amit Singhal, who kindly agreed to give talks at EMNLP. Many thanks to local arrangements chair, Regina Barzilay, who has made the conference smoothly held at the wonderful venue of MIT; the publications chair, Eric Fosler-Lussier, who put this volume together with assistance from Preethi Jyothi and Rohit Prabhavalkar; best paper award committee chair, Jason Eisner, who lead the effort of selecting the best papers. Special thanks to David Yarowsky and Ken Church of SIGDAT, as well as Jason Eisner, Philipp Koehn, Rada Mihalcea, who provided much valuable advice and assistance in the past months. David Yarowsky also worked on the important issues of invitation letters and travel grants. We are most grateful to Priscilla Rasmussen who helped us with various logistic and organizational aspects of the conference. Rich Gerber and the START team responded to our questions quickly, and helped us manage the large number of submissions smoothly; we would like to thank them as well.

To enhance the quality of the conference, the program committee made a number of new efforts and continued some existing good practices in PC management, paper selection, and conference participation.

First, a strict process for selecting PC members was set up. PC members were first nominated by the area chairs; PC co-chairs then carefully checked whether they were qualified as reviewers by looking at their publications and academic experience. Second, a best reviewer award was created for the first time in this conference. After the reviewing process, 86 outstanding PC members were selected as the "best reviewers" as noted in the proceedings: they submitted all the reviews on time, made detailed, constructive, and helpful comments, and actively participated in the paper discussion when necessary. These recipients were first nominated by the area chairs and then endorsed by the PC co-chairs. The awards are a recognition of the reviewers who really did hard work in reviews.

In paper selection, we created an author response period, as in the two previous EMNLP conferences. Authors were able to read and respond to the reviews of their papers before the program committee made a final decision. They were asked to correct factual errors in the reviews and answer questions

[1] Conference web site: http://www.lsi.upc.edu/events/emnlp2010/.

raised in the reviewer comments. In some cases, reviewers changed their scores in view of the authors' response; the area chairs read all responses carefully prior to making recommendations for acceptance. As PC co-chairs, we did our best effort in final paper selection. The area chairs made accept/reject suggestions to us on the papers in their areas. We carefully examined all the cases, discussing with the area chars the submissions on which we had divergent opinions. In some cases, the original suggestions by the area chairs were reversed after the discussions. The final paper selection was based on the consensus of the program committee. The accepted papers were further classified into oral and poster types, based on recommendations by the area chairs and discussions between the area chairs and us. Those papers that are suitable for presentations for the general audience (novel, inspiring, widely applicable, etc.) were selected as oral. After the paper notification, an independent committee for best paper awards led by Jason Eisner was created. From the candidates nominated by the PC, the committee performed independent reviews of the papers and made the best paper award selection, as listed in the proceedings.

Since EMNLP is held in the US, many participants needed visas to attend the conference. In order to help authors in the application for visas, a new procedure was implemented to anticipate the submission of invitation letters. The information on whether the authors needed a visa was collected at the paper submission time. The authors whose papers had average scores above a certain threshold were sent invitation letters by David Yarowsky, even before paper acceptance notification. In this way, the authors were given more time for their visa applications.

The success of a conference is really a result of the great efforts of everybody involved. We hope that you enjoy the conference at the fantastic building of MIT Stata Center!

Hang Li and Lluís Màrquez
EMNLP 2010 Program Co-Chairs

Program Co-chairs

Hang Li, Microsoft Research Asia
Lluís Màrquez, Technical University of Catalonia

Area Chairs

Eneko Agirre, University of the Basque Country
Kalina Bontcheva, University of Sheffield
Antal van den Bosch, Tilburg University
David Chiang, USC Information Sciences Institute
Jennifer Chu-Carroll, IBM Research
Evgeniy Gabrilovich, Yahoo! Research
Jianfeng Gao, Microsoft Research
Julio Gonzalo, UNED
Nancy Ide, Vassar College
Haizhou Li, Institute for Infocomm Research
Qun Liu, ICT, Chinese Academy of Sciences
Yusuke Miyao, National Institute of Informatics
Bo Pang, Yahoo! Research
Dragomir Radev, University of Michigan
Noah Smith, Carnegie Mellon University
Kristina Toutanova, Microsoft Research
Yoshimasa Tsuruoka, JAIST
Yi Zhang, University of California, Santa Cruz

Local Arrangements Chair

Regina Barzilay, Massachusetts Institute of Technology

Publications Chair

Eric Fosler-Lussier, The Ohio State University

Best Paper Award Committee

Jason Eisner, Johns Hopkins University (Chair)
Sharon Goldwater, University of Edinburgh Kevin Knight, University of Southern California
Dan Roth, University of Illinois, Urbana-Champaign
Ben Taskar, University of Pennsylvania
Jun'ichi Tsujii, University of Tokyo
Hanna Wallach, University of Massachusetts, Amherst

Reviewers

Hua Ai, Jan Alexandersson, Enrique Alfonseca, Enrique Amigó, Ion Androutsopoulos, Shlomo Argamon, Javier Artiles, Necip Fazil Ayan, Jing Bai, Collin Baker, Timothy Baldwin, Rafael Banchs, Carmen Banea, Shenghua Bao, Marco Baroni, Roberto Basili, Beata Beigman Klebanov, Núria Bel, Anja Belz, José-Miguel Benedí, Sabine Bergler, Mikhail Bilenko, John Blitzer, Phil Blunsom, Elizabeth Boschee, Jordan Boyd-Graber, SRK Branavan, Martin Braschler, Eric Breck, Christopher Brewster, Chris Brockett, Razvan Bunescu, Bill Byrne, Michael Cafarella, Aoife Cahill, Lynne Cahill, Chris Callison-Burch, Nicoletta Calzolari, Yunbo Cao, Claire Cardie, Andrew Carlson, Marine Carpuat, Xavier Carreras, John Carroll, Francisco Casacuberta, Asli Celikyilmaz, Joyce Chai, Raman Chandrasekar, Ming-Wei Chang, Yi Chang, Ciprian Chelba, Wenliang Chen, Colin Cherry, Jen-Tzung Chien, Hori Chiori, Yejin Choi, Ken Church, Massimiliano Ciaramita, Chris Cieri, Alex Clark, Stephen Clark, James Clarke, Paul Clough, Shay Cohen, Trevor Cohn, Nigel Collier, Michael Collins, Anna Corazza, Mark Core, Marta Costa-jussà, Josep M. Reviewers (continued)

Giuseppe Riccardi, Sebastian Riedel, Jason Riesa, Stefan Riezler, German Rigau, Ellen Riloff, Laura Rimell, Christoph Ringlstetter, Alan Ritter, Brian Roark, Mats Rooth, Barbara Rosario, Paolo Rosso, Antti-Veikko Rosti, Kenji Sagae, Horacio Saggion, Rajeev Sangal, Murat Saraclar, Ruhi Sarikaya, Anoop Sarkar, Manabu Sassano, Helmut Schmid, Lane Schwartz, Holger Schwenk, Hendra Setiawan, Burr Settles, Dou Shen, Libin Shen, Wade Shen, Shuming Shi, Luo Si, Advaith Siddharthan, Michel Simard, Khalil Sima'an, Matthew Snover, Ben Snyder, Marina Sokolova, Swapna Somasundaran, Youngin Song, Lucia Specia, Caroline Sporleder, Amanda Stent, Mark Stevenson, Veselin Stoyanov, Michael Strube, Jian Su, Keh-Yih Su, Eiichiro Sumita, Jun Sun, Maosong Sun, Mihai Surdeanu, Charles Sutton, Hisami Suzuki, Krysta Svore, Stan Szpakowicz, Idan Szpektor, Maite Taboada, Hiroya Takamura, Jie Tang, Joel Tetreault, Mariet Theune, Christoph Tillmann, Reut Tsarfaty, Benjamin Tsou, Hajime Tsukada, Dan Tufis, Gokhan Tur, Jordi Turmo, Raghavendra Udupa, Takehito Utsuro, Tim Van de Cruys, Josef van Genabith, Gertjan van Noord, Lucy Vanderwende, Vasudeva Varma, Olga Vechtomova, Ashish Venugopal, Juan Vilar, Andreas Vlachos, Stephen Wan, Xiaojun Wan, Dingding Wang, Haifeng Wang, Wei Wang, Xuanhui Wang, Ye-Yi Wang, Taro Watanabe, Bonnie Webber, Ralph Weischedel, Ji-Rong Wen, Jan Wiebe, Theresa Wilson, Shuly Wintner, Tak-Lam Wong, Dekai Wu, Fei Wu, Hua Wu, Fei Xia, Deyi Xiong, Gu Xu, Jinxi Xu, Peng Xu, Nianwen Xue, Xiaobing Xue, Hirofumi Yamamoto, Kazuhide Yamamoto, Hui Yang, Tao Yang, Roman Yangarber, Alexander Yates, Xing Yi, Scott Yih, Bei Yu, Kun Yu, François Yvon, Jun Zhao, Annie Zaenen, Fabio Massimo Zanzotto, Vanni Zavarella, Jakub Zavrel, Richard Zens, Torsten Zesch, Luke Zettlemoyer, ChengXiang Zhai, Duo Zhang, Hao Zhang, Hui Zhang, Min Zhang, Ying Zhang, Yue Zhang, Guodong Zhou, Jun Zhu, Imed Zitouni, Andreas Zollmann, Chengqing Zong

Secondary Reviewers

Sadaf Abdul-Rauf, Masayuki Asahara, Shen Bin, Yassine Benajiba, Shane Bergsma, Aditya Bhargava, Jiang Bian, Eduardo Blanco, Kristy Elizabeth Boyer, Pere R. Comas, Xiangyu Duan, Aaron Dunlop, Ji Fang, Yi Fang, Wei Gao, Edgar González, Charles Greenbacker, Eun Ha, Stefan Hahn, Zhongjun He, Yun Huang, Adrian Iftene, Tomoya Iwakura, Jiarong Jiang, Bilal Khaliq, Mi-Young Kim, Ioannis Korkontzelos, Sai Krishna, Gregor Leban, Sophia Yat Mei Lee, Shoushan Li, Shuguang Li, Changsong Liu, Shui Liu, Bin Lu, Cynthia Matuszek, Blaz Novak, Antoni Olivé, Elias Ponvert, Rob Phillips, Long Qiu, Longhua Qian, Rodrygo Santos, Kiran Sarvabhotla, Daniel Stein, Qi Su, György Szarvas, David Talbot, Diana Trandabăţ, Emily Tucker Prud'hommeaux, Damiano Spina Valenti, Cristina Vertan, Ying Xu, Shuang-Hong Yang, Limin Yao, Hui Zhang, Lanbo Zhang, Jiajun Zhang

Invited talks

"Why do we call it decoding?"

Kevin Knight, Information Sciences Institute, University of Southern California

The first natural language processing systems had a straightforward goal — decipher coded messages sent by the enemy. Sixty years later, we have many more applications! These include web search, question answering, summarization, speech recognition, and language translation. This talk explores connections between early decipherment research and today's work. We find that many ideas from the earlier era have become core to the field, while others still remain to be picked up and developed.

"Unsupervised feature learning and Deep Learning"

Andrew Ng, Computer Science Department, Stanford University

Machine learning has seen numerous successes, but applying learning algorithms today often means spending a long time laboriously hand-engineering the input feature representation. This is often true for learning in NLP, vision, audio, and many other problems. To address this, recently in machine learning there has been significant interest in unsupervised feature learning algorithms, including "deep learning" algorithms, that can automatically learn rich feature representations from unlabeled data. These algorithms build on such ideas as sparse coding, ICA, and deep belief networks, and have proved very effective for learning good feature representations in many problems. Since these algorithms mostly learn from unlabeled data, they also have the potential to learn from vastly increased amounts of data (since unlabeled data is cheap), and therefore perhaps also achieving vastly improved performance. In this talk, I'll survey the key ideas in this nascent area of unsupervised feature learning and deep learning. I'll outline a few algorithms, and describe a few successful applications of these ideas to problems in NLP, audio/speech, vision, and other problems.

"Challenges in running a commercial search engine"

Amit Singhal, Google, Inc.

These are exciting times for Information Retrieval and NLP. Web search engines have brought IR to the masses. It now affects the lives of hundreds of millions of people, and growing, as Internet search companies launch ever more products based on techniques developed in IR and NLP research.The real world poses unique challenges for search algorithms. They operate at unprecedented scales, and over a wide diversity of information. In addition, we have entered an unprecedented world of "Adversarial Information Retrieval." The lure of billions of dollars of commerce, guided by search engines, motivates all kinds of people to try all kinds of tricks to get their sites to the top of the search results. What techniques do people use to defeat IR algorithms? What are the evaluation challenges for a web search engine? How much impact has IR had on search engines? How does Google serve over 250 Million queries a day, often with sub-second response times? This talk will show that the world of algorithm and system design for commercial search engines can be described by two of Murphy's Laws: a) If anything can go wrong, it will, and b) If anything cannot go wrong, it will anyway.

Fred Jelinek Best Paper Award

The EMNLP-2010 Best Paper Award is named in memory of Fred Jelinek (18 Nov. 1932 - 14 Sept. 2010).

“Dual Decomposition for Parsing with Non-Projective Head Automata,”
Terry Koo, Alexander M. Rush, Michael Collins, Tommi Jaakkola and David Sontag

This paper introduces algorithms for non-projective parsing based on *dual decomposition*. We focus on parsing algorithms for *non-projective head automata*, a generalization of head-automata models to non-projective structures. The dual decomposition algorithms are simple and efficient, relying on standard dynamic programming and minimum spanning tree algorithms. They provably solve an LP relaxation of the non-projective parsing problem. Empirically the LP relaxation is very often tight: for many languages, exact solutions are achieved on over 98% of test sentences. The accuracy of our models is higher than previous work on a broad range of datasets.

Table of Contents

On Dual Decomposition and Linear Programming Relaxations for Natural Language Processing
Alexander M Rush, David Sontag, Michael Collins and Tommi Jaakkola 1

Self-Training with Products of Latent Variable Grammars
Zhongqiang Huang, Mary Harper and Slav Petrov 12

Utilizing Extra-Sentential Context for Parsing
Jackie Chi Kit Cheung and Gerald Penn 23

Turbo Parsers: Dependency Parsing by Approximate Variational Inference
Andre Martins, Noah Smith, Eric Xing, Pedro Aguiar and Mario Figueiredo 34

Holistic Sentiment Analysis Across Languages: Multilingual Supervised Latent Dirichlet Allocation
Jordan Boyd-Graber and Philip Resnik 45

Jointly Modeling Aspects and Opinions with a MaxEnt-LDA Hybrid
Xin Zhao, Jing Jiang, Hongfei Yan and Xiaoming Li 56

Summarizing Contrastive Viewpoints in Opinionated Text
Michael Paul, ChengXiang Zhai and Roxana Girju 66

Automatically Producing Plot Unit Representations for Narrative Text
Amit Goyal, Ellen Riloff and Hal Daume III 77

Handling Noisy Queries in Cross Language FAQ Retrieval
Danish Contractor, Govind Kothari, Tanveer Faruquie, L V Subramaniam and Sumit Negi 87

Learning the Relative Usefulness of Questions in Community QA
Razvan Bunescu and Yunfeng Huang 97

Positional Language Models for Clinical Information Retrieval
Florian Boudin, Jian-Yun Nie and Martin Dawes 108

Inducing Word Senses to Improve Web Search Result Clustering
Roberto Navigli and Giuseppe Crisafulli 116

Improving Translation via Targeted Paraphrasing
Philip Resnik, Olivia Buzek, Chang Hu, Yakov Kronrod, Alex Quinn and Benjamin B. Bederson
127

Soft Syntactic Constraints for Hierarchical Phrase-Based Translation Using Latent Syntactic Distributions
Zhongqiang Huang, Martin Cmejrek and Bowen Zhou 138

A Hybrid Morpheme-Word Representation for Machine Translation of Morphologically Rich Languages
Minh-Thang Luong, Preslav Nakov and Min-Yen Kan 148

”Poetic” Statistical Machine Translation: Rhyme and Meter
Dmitriy Genzel, Jakob Uszkoreit and Franz Och 158

Efficient Graph-Based Semi-Supervised Learning of Structured Tagging Models
Amarnag Subramanya, Slav Petrov and Fernando Pereira 167

Better Punctuation Prediction with Dynamic Conditional Random Fields
Wei Lu and Hwee Tou Ng 177

Joint Training and Decoding Using Virtual Nodes for Cascaded Segmentation and Tagging Tasks
Xian Qian, Qi Zhang, Yaqian Zhou, Xuanjing Huang and Lide Wu 187

Crouching Dirichlet, Hidden Markov Model: Unsupervised POS Tagging with Context Local Tag Generation
Taesun Moon, Katrin Erk and Jason Baldridge 196

Improving Gender Classification of Blog Authors
Arjun Mukherjee and Bing Liu 207

Negative Training Data Can be Harmful to Text Classification
Xiao-Li Li, Bing Liu and See-Kiong Ng 218

Modeling Organization in Student Essays
Isaac Persing, Alan Davis and Vincent Ng 229

Evaluating Models of Latent Document Semantics in the Presence of OCR Errors
Daniel Walker, William B. Lund and Eric K. Ringger 240

Translingual Document Representations from Discriminative Projections
John Platt, Kristina Toutanova and Wen-tau Yih 251

Storing the Web in Memory: Space Efficient Language Models with Constant Time Retrieval
David Guthrie and Mark Hepple 262

Efficient Incremental Decoding for Tree-to-String Translation
Liang Huang and Haitao Mi 273

Modeling Perspective Using Adaptor Grammars
Eric Hardisty, Jordan Boyd-Graber and Philip Resnik 284

Predicting the Semantic Compositionality of Prefix Verbs
Shane Bergsma, Aditya Bhargava, Hua He and Grzegorz Kondrak 293

Joint Inference for Bilingual Semantic Role Labeling
Tao Zhuang and Chengqing Zong 304

Automatic Discovery of Manner Relations and its Applications
Eduardo Blanco and Dan Moldovan 315

Tense Sense Disambiguation: A New Syntactic Polysemy Task
Roi Reichart and Ari Rappoport . . . 325

Improving Mention Detection Robustness to Noisy Input
Radu Florian, John Pitrelli, Salim Roukos and Imed Zitouni . . . 335

Clustering-Based Stratified Seed Sampling for Semi-Supervised Relation Classification
Longhua Qian and Guodong Zhou . . . 346

Unsupervised Discovery of Negative Categories in Lexicon Bootstrapping
Tara McIntosh . . . 356

Automatic Keyphrase Extraction via Topic Decomposition
Zhiyuan Liu, Wenyi Huang, Yabin Zheng and Maosong Sun . . . 366

Incorporating Content Structure into Text Analysis Applications
Christina Sauper, Aria Haghighi and Regina Barzilay . . . 377

Exploiting Conversation Structure in Unsupervised Topic Segmentation for Emails
Shafiq Joty, Giuseppe Carenini, Gabriel Murray and Raymond T. Ng . . . 388

A Semi-Supervised Approach to Improve Classification of Infrequent Discourse Relations Using Feature Vector Extension
Hugo Hernault, Danushka Bollegala and Mitsuru Ishizuka . . . 399

A Game-Theoretic Approach to Generating Spatial Descriptions
Dave Golland, Percy Liang and Dan Klein . . . 410

Facilitating Translation Using Source Language Paraphrase Lattices
Jinhua Du, Jie Jiang and Andy Way . . . 420

Mining Name Translations from Entity Graph Mapping
Gae-won You, Seung-won Hwang, Young-In Song, Long Jiang and Zaiqing Nie . . . 430

Non-Isomorphic Forest Pair Translation
Hui Zhang, Min Zhang, Haizhou Li and Eng Siong Chng . . . 440

Discriminative Instance Weighting for Domain Adaptation in Statistical Machine Translation
George Foster, Cyril Goutte and Roland Kuhn . . . 451

NLP on Spoken Documents Without ASR
Mark Dredze, Aren Jansen, Glen Coppersmith and Ken Church . . . 460

Fusing Eye Gaze with Speech Recognition Hypotheses to Resolve Exophoric References in Situated Dialogue
Zahar Prasov and Joyce Y. Chai . . . 471

Multi-Document Summarization Using A Search and Discriminative Learning*
Ahmet Aker, Trevor Cohn and Robert Gaizauskas . . . 482

A Multi-Pass Sieve for Coreference Resolution
Karthik Raghunathan, Heeyoung Lee, Sudarshan Rangarajan, Nate Chambers, Mihai Surdeanu, Dan Jurafsky and Christopher Manning 492

A Simple Domain-Independent Probabilistic Approach to Generation
Gabor Angeli, Percy Liang and Dan Klein 502

Title Generation with Quasi-Synchronous Grammar
Kristian Woodsend, Yansong Feng and Mirella Lapata 513

Automatic Analysis of Rhythmic Poetry with Applications to Generation and Translation
Erica Greene, Tugba Bodrumlu and Kevin Knight 524

Discriminative Word Alignment with a Function Word Reordering Model
Hendra Setiawan, Chris Dyer and Philip Resnik 534

Hierarchical Phrase-Based Translation Grammars Extracted from Alignment Posterior Probabilities
Adrià de Gispert, Juan Pino and William Byrne 545

Maximum Entropy Based Phrase Reordering for Hierarchical Phrase-Based Translation
Zhongjun He, Yao Meng and Hao Yu 555

Further Meta-Evaluation of Broad-Coverage Surface Realization
Dominic Espinosa, Rajakrishnan Rajkumar, Michael White and Shoshana Berleant 564

Two Decades of Unsupervised POS Induction: How Far Have We Come?
Christos Christodoulopoulos, Sharon Goldwater and Mark Steedman 575

We're Not in Kansas Anymore: Detecting Domain Changes in Streams
Mark Dredze, Tim Oates and Christine Piatko 585

A Fast Fertility Hidden Markov Model for Word Alignment Using MCMC
Shaojun Zhao and Daniel Gildea 596

Minimum Error Rate Training by Sampling the Translation Lattice
Samidh Chatterjee and Nicola Cancedda 606

Statistical Machine Translation with a Factorized Grammar
Libin Shen, Bing Zhang, Spyros Matsoukas, Jinxi Xu and Ralph Weischedel 616

Discriminative Sample Selection for Statistical Machine Translation
Sankaranarayanan Ananthakrishnan, Rohit Prasad, David Stallard and Prem Natarajan 626

Effects of Empty Categories on Machine Translation
Tagyoung Chung and Daniel Gildea 636

SCFG Decoding Without Binarization
Mark Hopkins and Greg Langmead 646

Example-Based Paraphrasing for Improved Phrase-Based Statistical Machine Translation
Aurélien Max 656

Combining Unsupervised and Supervised Alignments for MT: An Empirical Study
Jinxi Xu and Antti-Veikko Rosti 667

Top-Down Nearly-Context-Sensitive Parsing
Eugene Charniak 674

Improved Fully Unsupervised Parsing with Zoomed Learning
Roi Reichart and Ari Rappoport 684

Unsupervised Parse Selection for HPSG
Rebecca Dridan and Timothy Baldwin 694

Uptraining for Accurate Deterministic Question Parsing
Slav Petrov, Pi-Chuan Chang, Michael Ringgaard and Hiyan Alshawi 705

A Unified Framework for Scope Learning via Simplified Shallow Semantic Parsing
Qiaoming Zhu, Junhui Li, Hongling Wang and Guodong Zhou 714

A New Approach to Lexical Disambiguation of Arabic Text
Rushin Shah, Paramveer S. Dhillon, Mark Liberman, Dean Foster, Mohamed Maamouri and Lyle Ungar 725

What a Parser Can Learn from a Semantic Role Labeler and Vice Versa
Stephen Boxwell, Dennis Mehay and Chris Brew 736

Word Sense Induction & Disambiguation Using Hierarchical Random Graphs
Ioannis Klapaftis and Suresh Manandhar 745

Towards Conversation Entailment: An Empirical Investigation
Chen Zhang and Joyce Chai 756

The Necessity of Combining Adaptation Methods
Ming-Wei Chang, Michael Connor and Dan Roth 767

Training Continuous Space Language Models: Some Practical Issues
Hai Son Le, Alexandre Allauzen, Guillaume Wisniewski and François Yvon 778

Enhancing Domain Portability of Chinese Segmentation Model Using Chi-Square Statistics and Bootstrapping
Baobao Chang and Dongxu Han 789

Latent-Descriptor Clustering for Unsupervised POS Induction
Michael Lamar, Yariv Maron and Elie Bienenstock 799

A Probabilistic Morphological Analyzer for Syriac
Peter McClanahan, George Busby, Robbie Haertel, Kristian Heal, Deryle Lonsdale, Kevin Seppi and Eric Ringger 810

Lessons Learned in Part-of-Speech Tagging of Conversational Speech
Vladimir Eidelman, Zhongqiang Huang and Mary Harper 821

An Efficient Algorithm for Unsupervised Word Segmentation with Branching Entropy and MDL
Valentin Zhikov, Hiroya Takamura and Manabu Okumura 832

A Fast Decoder for Joint Word Segmentation and POS-Tagging Using a Single Discriminative Model
Yue Zhang and Stephen Clark 843

Simple Type-Level Unsupervised POS Tagging
Yoong Keok Lee, Aria Haghighi and Regina Barzilay 853

Classifying Dialogue Acts in One-on-One Live Chats
Su Nam Kim, Lawrence Cavedon and Timothy Baldwin 862

Resolving Event Noun Phrases to Their Verbal Mentions
Bin Chen, Jian Su and Chew Lim Tan 872

A Tree Kernel-Based Unified Framework for Chinese Zero Anaphora Resolution
Fang Kong and Guodong Zhou 882

Automatic Comma Insertion for Japanese Text Generation
Masaki Murata, Tomohiro Ohno and Shigeki Matsubara 892

Using Unknown Word Techniques to Learn Known Words
Kostadin Cholakov and Gertjan van Noord 902

WikiWars: A New Corpus for Research on Temporal Expressions
Pawel Mazur and Robert Dale 913

PEM: A Paraphrase Evaluation Metric Exploiting Parallel Texts
Chang Liu, Daniel Dahlmeier and Hwee Tou Ng 923

Assessing Phrase-Based Translation Models with Oracle Decoding
Guillaume Wisniewski, Alexandre Allauzen and François Yvon 933

Conference Program

Saturday, October 9, 2010

8:50–9:00 Opening Remarks

9:00–10:00 Invited talk: Kevin Knight, “Why do we call it decoding?”
CHAIR: HANG LI

10:00–10:30 Break

Session 1A: Syntactic Parsing and Machine Learning
CHAIR: XAVIER CARRERAS

10:30–10:55 *On Dual Decomposition and Linear Programming Relaxations for Natural Language Processing*
Alexander M Rush, David Sontag, Michael Collins and Tommi Jaakkola

10:55–11:20 *Self-Training with Products of Latent Variable Grammars*
Zhongqiang Huang, Mary Harper and Slav Petrov

11:20–11:45 *Utilizing Extra-Sentential Context for Parsing*
Jackie Chi Kit Cheung and Gerald Penn

11:45–12:10 *Turbo Parsers: Dependency Parsing by Approximate Variational Inference*
Andre Martins, Noah Smith, Eric Xing, Pedro Aguiar and Mario Figueiredo

Session 1B: Sentiment Analysis and Opinion Mining
CHAIR: HANNA WALLACH

10:30–10:55 *Holistic Sentiment Analysis Across Languages: Multilingual Supervised Latent Dirichlet Allocation*
Jordan Boyd-Graber and Philip Resnik

10:55–11:20 *Jointly Modeling Aspects and Opinions with a MaxEnt-LDA Hybrid*
Xin Zhao, Jing Jiang, Hongfei Yan and Xiaoming Li

11:20–11:45 *Summarizing Contrastive Viewpoints in Opinionated Text*
Michael Paul, ChengXiang Zhai and Roxana Girju

Saturday, October 9, 2010 (continued)

11:45–12:10 *Automatically Producing Plot Unit Representations for Narrative Text*
Amit Goyal, Ellen Riloff and Hal Daume III

Session 1C: Information Retrieval and Question Answering
CHAIR: JING JIANG

10:30–10:55 *Handling Noisy Queries in Cross Language FAQ Retrieval*
Danish Contractor, Govind Kothari, Tanveer Faruquie, L V Subramaniam and Sumit Negi

10:55–11:20 *Learning the Relative Usefulness of Questions in Community QA*
Razvan Bunescu and Yunfeng Huang

11:20–11:45 *Positional Language Models for Clinical Information Retrieval*
Florian Boudin, Jian-Yun Nie and Martin Dawes

11:45–12:10 *Inducing Word Senses to Improve Web Search Result Clustering*
Roberto Navigli and Giuseppe Crisafulli

12:10–14:10 Lunch

Session 2A: Machine Translation I
CHAIR: DANIEL MARCU

14:10–14:35 *Improving Translation via Targeted Paraphrasing*
Philip Resnik, Olivia Buzek, Chang Hu, Yakov Kronrod, Alex Quinn and Benjamin B. Bederson

14:35–15:00 *Soft Syntactic Constraints for Hierarchical Phrase-Based Translation Using Latent Syntactic Distributions*
Zhongqiang Huang, Martin Cmejrek and Bowen Zhou

15:00–15:25 *A Hybrid Morpheme-Word Representation for Machine Translation of Morphologically Rich Languages*
Minh-Thang Luong, Preslav Nakov and Min-Yen Kan

15:25–15:50 *”Poetic” Statistical Machine Translation: Rhyme and Meter*
Dmitriy Genzel, Jakob Uszkoreit and Franz Och

Saturday, October 9, 2010 (continued)

Session 2B: Tagging, Chunking and Segmentation
CHAIR: SHARON GOLDWATER

14:10–14:35 *Efficient Graph-Based Semi-Supervised Learning of Structured Tagging Models*
Amarnag Subramanya, Slav Petrov and Fernando Pereira

14:35–15:00 *Better Punctuation Prediction with Dynamic Conditional Random Fields*
Wei Lu and Hwee Tou Ng

15:00–15:25 *Joint Training and Decoding Using Virtual Nodes for Cascaded Segmentation and Tagging Tasks*
Xian Qian, Qi Zhang, Yaqian Zhou, Xuanjing Huang and Lide Wu

15:25–15:50 *Crouching Dirichlet, Hidden Markov Model: Unsupervised POS Tagging with Context Local Tag Generation*
Taesun Moon, Katrin Erk and Jason Baldridge

Session 2C: Text Mining
CHAIR: HAL DAUME III

14:10–14:35 *Improving Gender Classification of Blog Authors*
Arjun Mukherjee and Bing Liu

14:35–15:00 *Negative Training Data Can be Harmful to Text Classification*
Xiao-Li Li, Bing Liu and See-Kiong Ng

15:00–15:25 *Modeling Organization in Student Essays*
Isaac Persing, Alan Davis and Vincent Ng

15:25–15:50 *Evaluating Models of Latent Document Semantics in the Presence of OCR Errors*
Daniel Walker, William B. Lund and Eric K. Ringger

Saturday, October 9, 2010 (continued)

15:50–16:20 Break

Session 3A: Machine Learning for NLP
Chair: Noah Smith

16:20–16:45 *Translingual Document Representations from Discriminative Projections*
John Platt, Kristina Toutanova and Wen-tau Yih

16:45–17:10 *Storing the Web in Memory: Space Efficient Language Models with Constant Time Retrieval*
David Guthrie and Mark Hepple

17:10–17:35 *Efficient Incremental Decoding for Tree-to-String Translation*
Liang Huang and Haitao Mi

17:35–18:00 *Modeling Perspective Using Adaptor Grammars*
Eric Hardisty, Jordan Boyd-Graber and Philip Resnik

Session 3B: Semantics
Chair: Mark Steedman

16:20–16:45 *Predicting the Semantic Compositionality of Prefix Verbs*
Shane Bergsma, Aditya Bhargava, Hua He and Grzegorz Kondrak

16:45–17:10 *Joint Inference for Bilingual Semantic Role Labeling*
Tao Zhuang and Chengqing Zong

17:10–17:35 *Automatic Discovery of Manner Relations and its Applications*
Eduardo Blanco and Dan Moldovan

17:35–18:00 *Tense Sense Disambiguation: A New Syntactic Polysemy Task*
Roi Reichart and Ari Rappoport

Saturday, October 9, 2010 (continued)

Session 3C: Information Extraction
Chair: Ellen Riloff

16:20–16:45 *Improving Mention Detection Robustness to Noisy Input*
Radu Florian, John Pitrelli, Salim Roukos and Imed Zitouni

16:45–17:10 *Clustering-Based Stratified Seed Sampling for Semi-Supervised Relation Classification*
Longhua Qian and Guodong Zhou

17:10–17:35 *Unsupervised Discovery of Negative Categories in Lexicon Bootstrapping*
Tara McIntosh

17:35–18:00 *Automatic Keyphrase Extraction via Topic Decomposition*
Zhiyuan Liu, Wenyi Huang, Yabin Zheng and Maosong Sun

Sunday, October 10, 2010

9:00–10:00 Invited talk: Andrew Ng, “Unsupervised feature learning and Deep Learning”
Chair: David Yarowsky

10:00–10:30 Break

Session 4A: Discourse and Dialog
Chair: Rada Mihalcea

10:30–10:55 *Incorporating Content Structure into Text Analysis Applications*
Christina Sauper, Aria Haghighi and Regina Barzilay

10:55–11:20 *Exploiting Conversation Structure in Unsupervised Topic Segmentation for Emails*
Shafiq Joty, Giuseppe Carenini, Gabriel Murray and Raymond T. Ng

11:20–11:45 *A Semi-Supervised Approach to Improve Classification of Infrequent Discourse Relations Using Feature Vector Extension*
Hugo Hernault, Danushka Bollegala and Mitsuru Ishizuka

Sunday, October 10, 2010 (continued)

11:45–12:10 *A Game-Theoretic Approach to Generating Spatial Descriptions*
Dave Golland, Percy Liang and Dan Klein

Session 4B: Machine Translation II
Chair: Chris Quirk

10:30–10:55 *Facilitating Translation Using Source Language Paraphrase Lattices*
Jinhua Du, Jie Jiang and Andy Way

10:55–11:20 *Mining Name Translations from Entity Graph Mapping*
Gae-won You, Seung-won Hwang, Young-In Song, Long Jiang and Zaiqing Nie

11:20–11:45 *Non-Isomorphic Forest Pair Translation*
Hui Zhang, Min Zhang, Haizhou Li and Eng Siong Chng

11:45–12:10 *Discriminative Instance Weighting for Domain Adaptation in Statistical Machine Translation*
George Foster, Cyril Goutte and Roland Kuhn

Session 4C: NLP Applications
Chair: Manabu Okumura

10:30–10:55 *NLP on Spoken Documents Without ASR*
Mark Dredze, Aren Jansen, Glen Coppersmith and Ken Church

10:55–11:20 *Fusing Eye Gaze with Speech Recognition Hypotheses to Resolve Exophoric References in Situated Dialogue*
Zahar Prasov and Joyce Y. Chai

11:20–11:45 *Multi-Document Summarization Using A* Search and Discriminative Learning*
Ahmet Aker, Trevor Cohn and Robert Gaizauskas

11:45–12:10 *A Multi-Pass Sieve for Coreference Resolution*
Karthik Raghunathan, Heeyoung Lee, Sudarshan Rangarajan, Nate Chambers, Mihai Surdeanu, Dan Jurafsky and Christopher Manning

12:10–14:10 Lunch

Session 5A: Natural Language Generation
CHAIR: DRAGOMIR RADEV

14:10–14:35 *A Simple Domain-Independent Probabilistic Approach to Generation*
Gabor Angeli, Percy Liang and Dan Klein

14:35–15:00 *Title Generation with Quasi-Synchronous Grammar*
Kristian Woodsend, Yansong Feng and Mirella Lapata

15:00–15:25 *Automatic Analysis of Rhythmic Poetry with Applications to Generation and Translation*
Erica Greene, Tugba Bodrumlu and Kevin Knight

Session 5B: Machine Translation III
CHAIR: DAVID CHIANG

14:10–14:35 *Discriminative Word Alignment with a Function Word Reordering Model*
Hendra Setiawan, Chris Dyer and Philip Resnik

14:35–15:00 *Hierarchical Phrase-Based Translation Grammars Extracted from Alignment Posterior Probabilities*
Adrià de Gispert, Juan Pino and William Byrne

15:00–15:25 *Maximum Entropy Based Phrase Reordering for Hierarchical Phrase-Based Translation*
Zhongjun He, Yao Meng and Hao Yu

Session 5C: Language Resources
CHAIR: BENJAMIN TSOU

14:10–14:35 *Further Meta-Evaluation of Broad-Coverage Surface Realization*
Dominic Espinosa, Rajakrishnan Rajkumar, Michael White and Shoshana Berleant

14:35–15:00 *Two Decades of Unsupervised POS Induction: How Far Have We Come?*
Christos Christodoulopoulos, Sharon Goldwater and Mark Steedman

15:00–15:25 *We're Not in Kansas Anymore: Detecting Domain Changes in Streams*
Mark Dredze, Tim Oates and Christine Piatko

15:25–15:55 Break

Sunday, October 10, 2010 (continued)

15:55–17:30 **Session 6A: Poster Spotlights**
CHAIR: JASON EISNER

A Fast Fertility Hidden Markov Model for Word Alignment Using MCMC
Shaojun Zhao and Daniel Gildea

Minimum Error Rate Training by Sampling the Translation Lattice
Samidh Chatterjee and Nicola Cancedda

Statistical Machine Translation with a Factorized Grammar
Libin Shen, Bing Zhang, Spyros Matsoukas, Jinxi Xu and Ralph Weischedel

Discriminative Sample Selection for Statistical Machine Translation
Sankaranarayanan Ananthakrishnan, Rohit Prasad, David Stallard and Prem Natarajan

Effects of Empty Categories on Machine Translation
Tagyoung Chung and Daniel Gildea

SCFG Decoding Without Binarization
Mark Hopkins and Greg Langmead

Example-Based Paraphrasing for Improved Phrase-Based Statistical Machine Translation
Aurélien Max

Combining Unsupervised and Supervised Alignments for MT: An Empirical Study
Jinxi Xu and Antti-Veikko Rosti

Top-Down Nearly-Context-Sensitive Parsing
Eugene Charniak

Abstract

This paper introduces *dual decomposition* as a framework for deriving inference algorithms for NLP problems. The approach relies on standard dynamic-programming algorithms as oracle solvers for sub-problems, together with a simple method for forcing agreement between the different oracles. The approach provably solves a linear programming (LP) relaxation of the global inference problem. It leads to algorithms that are *simple*, in that they use existing decoding algorithms; *efficient*, in that they avoid exact algorithms for the full model; and often *exact*, in that empirically they often recover the correct solution in spite of using an LP relaxation. We give experimental results on two problems: 1) the combination of two lexicalized parsing models; and 2) the combination of a lexicalized parsing model and a trigram part-of-speech tagger.

1 Introduction

Dynamic programming algorithms have been remarkably useful for inference in many NLP problems. Unfortunately, as models become more complex, for example through the addition of new features or components, dynamic programming algorithms can quickly explode in terms of computational or implementational complexity.[1] As a result, efficiency of inference is a critical bottleneck for many problems in statistical NLP.

This paper introduces *dual decomposition* (Dantzig and Wolfe, 1960; Komodakis et al., 2007) as a framework for deriving inference algorithms in NLP. Dual decomposition leverages the observation that complex inference problems can often be decomposed into efficiently solvable sub-problems. The approach leads to inference algorithms with the following properties:

- The resulting algorithms are simple and efficient, building on standard dynamic-programming algorithms as oracle solvers for sub-problems,[2] together with a method for forcing agreement between the oracles.
- The algorithms provably solve a linear programming (LP) relaxation of the original inference problem.
- Empirically, the LP relaxation often leads to an exact solution to the original problem.

The approach is very general, and should be applicable to a wide range of problems in NLP. The connection to linear programming ensures that the algorithms provide a certificate of optimality when they recover the exact solution, and also opens up the possibility of methods that incrementally tighten the LP relaxation until it is exact (Sherali and Adams, 1994; Sontag et al., 2008).

The structure of this paper is as follows. We first give two examples as an illustration of the approach: 1) integrated parsing and trigram part-of-speech (POS) tagging; and 2) combined phrase-structure and dependency parsing. In both settings, it is possible to solve the integrated problem through an "intersected" dynamic program (e.g., for integration of parsing and tagging, the construction from Bar-Hillel et al. (1964) can be used). However, these methods, although polynomial time, are substantially less efficient than our algorithms, and are considerably more complex to implement.

Next, we describe exact polyhedral formulations for the two problems, building on connections between dynamic programming algorithms and marginal polytopes, as described in Martin et al. (1990). These allow us to precisely characterize the relationship between the exact formulations and the

[1] The same is true for NLP inference algorithms based on other exact combinatorial methods, for example methods based on minimum-weight spanning trees (McDonald et al., 2005), or graph cuts (Pang and Lee, 2004).

[2] More generally, other exact inference methods can be used as oracles, for example spanning tree algorithms for non-projective dependency structures.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 1–11,
MIT, Massachusetts, USA, 9-11 October 2010.

LP relaxations that we solve. We then give guarantees of convergence for our algorithms by showing that they are instantiations of Lagrangian relaxation, a general method for solving linear programs of a particular form.

Finally, we describe experiments that demonstrate the effectiveness of our approach. First, we consider the integration of the generative model for phrase-structure parsing of Collins (2003), with the second-order discriminative dependency parser of Koo et al. (2008). This is an interesting problem in its own right: the goal is to inject the high performance of discriminative dependency models into phrase-structure parsing. The method uses off-the-shelf decoders for the two models. We find three main results: 1) in spite of solving an LP relaxation, empirically the method finds an exact solution on over 99% of the examples; 2) the method converges quickly, typically requiring fewer than 10 iterations of decoding; 3) the method gives gains over a baseline method that forces the phrase-structure parser to produce the same dependencies as the first-best output from the dependency parser (the Collins (2003) model has an F1 score of 88.1%; the baseline method has an F1 score of 89.7%; and the dual decomposition method has an F1 score of 90.7%).

In a second set of experiments, we use dual decomposition to integrate the trigram POS tagger of Toutanova and Manning (2000) with the parser of Collins (2003). We again find that the method finds an exact solution in almost all cases, with convergence in just a few iterations of decoding.

Although the focus of this paper is on dynamic programming algorithms—both in the experiments, and also in the formal results concerning marginal polytopes—it is straightforward to use other combinatorial algorithms within the approach. For example, Koo et al. (2010) describe a dual decomposition approach for non-projective dependency parsing, which makes use of both dynamic programming and spanning tree inference algorithms.

2 Related Work

Dual decomposition is a classical method for solving optimization problems that can be decomposed into efficiently solvable sub-problems. Our work is inspired by dual decomposition methods for inference in Markov random fields (MRFs) (Wainwright et al., 2005a; Komodakis et al., 2007; Globerson and Jaakkola, 2007). In this approach, the MRF is decomposed into sub-problems corresponding to tree-structured subgraphs that together cover all edges of the original graph. The resulting inference algorithms provably solve an LP relaxation of the MRF inference problem, often significantly faster than commercial LP solvers (Yanover et al., 2006).

Our work is also related to methods that incorporate combinatorial solvers within loopy belief propagation (LBP), either for MAP inference (Duchi et al., 2007) or for computing marginals (Smith and Eisner, 2008). Our approach similarly makes use of combinatorial algorithms to efficiently solve sub-problems of the global inference problem. However, unlike LBP, our algorithms have strong theoretical guarantees, such as guaranteed convergence and the possibility of a certificate of optimality. These guarantees are possible because our algorithms directly solve an LP relaxation.

Other work has considered LP or integer linear programming (ILP) formulations of inference in NLP (Martins et al., 2009; Riedel and Clarke, 2006; Roth and Yih, 2005). These approaches typically use general-purpose LP or ILP solvers. Our method has the advantage that it leverages underlying structure arising in LP formulations of NLP problems. We will see that dynamic programming algorithms such as CKY can be considered to be very efficient solvers for particular LPs. In dual decomposition, these LPs—and their efficient solvers—can be embedded within larger LPs corresponding to more complex inference problems.

3 Background: Structured Models for NLP

We now describe the type of models used throughout the paper. We take some care to set up notation that will allow us to make a clear connection between inference problems and linear programming.

Our first example is weighted CFG parsing. We assume a context-free grammar, in Chomsky normal form, with a set of non-terminals N. The grammar contains all rules of the form $A \rightarrow B\ C$ and $A \rightarrow w$ where $A, B, C \in N$ and $w \in V$ (it is simple to relax this assumption to give a more constrained grammar). For rules of the form $A \rightarrow w$ we refer to A as the part-of-speech tag for w. We allow any non-terminal to be at the root of the tree.

Given a sentence with n words, $w_1, w_2, \ldots w_n$, a parse tree is a set of rule productions of the form $\langle A \rightarrow B\ C, i, k, j\rangle$ where $A, B, C \in N$, and $1 \leq i \leq k < j \leq n$. Each rule production represents the use of CFG rule $A \rightarrow B\ C$ where non-terminal A spans words $w_i \ldots w_j$, non-terminal B spans words $w_i \ldots w_k$, and non-terminal C spans words $w_{k+1} \ldots w_j$. There are $O(|N|^3 n^3)$ such rule productions. Each parse tree corresponds to a subset of these rule productions, of size $n - 1$, that forms a well-formed parse tree.[3]

We now define the *index set* for CFG parsing as

$$\mathcal{I} = \{\langle A \rightarrow B\ C, i, k, j\rangle \colon A, B, C \in N, \\ 1 \leq i \leq k < j \leq n\}$$

Each parse tree is a vector $y = \{y_r : r \in \mathcal{I}\}$, with $y_r = 1$ if rule r is in the parse tree, and $y_r = 0$ otherwise. Hence each parse tree is represented as a vector in $\{0, 1\}^m$, where $m = |\mathcal{I}|$. We use $\mathcal{Y}$ to denote the set of all valid parse-tree vectors; the set $\mathcal{Y}$ is a subset of $\{0, 1\}^m$ (not all binary vectors correspond to valid parse trees).

In addition, we assume a vector $\theta = \{\theta_r : r \in \mathcal{I}\}$ that specifies a weight for each rule production.[4] Each θ_r can take any value in the reals. The optimal parse tree is $y^* = \arg\max_{y \in \mathcal{Y}} \quad y \cdot \theta$ where $y \cdot \theta = \sum_r y_r \theta_r$ is the inner product between y and θ.

We use y_r and $y(r)$ interchangeably (similarly for θ_r and $\theta(r)$) to refer to the r'th component of the vector y. For example $\theta(A \rightarrow B\ C, i, k, j)$ is a weight for the rule $\langle A \rightarrow B\ C, i, k, j\rangle$.

We will use similar notation for other problems. As a second example, in POS tagging the task is to map a sentence of n words $w_1 \ldots w_n$ to a tag sequence $t_1 \ldots t_n$, where each t_i is chosen from a set T of possible tags. We assume a trigram tagger, where a tag sequence is represented through decisions $\langle (A, B) \rightarrow C, i\rangle$ where $A, B, C \in T$, and $i \in \{3 \ldots n\}$. Each production represents a transition where C is the tag of word w_i, and (A, B) are the previous two tags. The index set for tagging is

$$\mathcal{I}_{\text{tag}} = \{\langle (A, B) \rightarrow C, i\rangle \ : \ A, B, C \in T, 3 \leq i \leq n\}$$

Note that we do not need transitions for $i = 1$ or $i = 2$, because the transition $\langle (A, B) \rightarrow C, 3\rangle$ specifies the first three tags in the sentence.[5]

Each tag sequence is represented as a vector $z = \{z_r : r \in \mathcal{I}_{\text{tag}}\}$, and we denote the set of valid tag sequences, a subset of $\{0, 1\}^{|\mathcal{I}_{\text{tag}}|}$, as $\mathcal{Z}$. Given a parameter vector $\theta = \{\theta_r : r \in \mathcal{I}_{\text{tag}}\}$, the optimal tag sequence is $\arg\max_{z \in \mathcal{Z}} z \cdot \theta$.

As a modification to the above approach, we will find it convenient to introduce extended index sets for both the CFG and POS tagging examples. For the CFG case we define the extended index set to be $\mathcal{I}' = \mathcal{I} \cup \mathcal{I}_{\text{uni}}$ where

$$\mathcal{I}_{\text{uni}} = \{(i, t) : i \in \{1 \ldots n\}, t \in T\}$$

Here each pair (i, t) represents word w_i being assigned the tag t. Thus each parse-tree vector y will have additional (binary) components $y(i, t)$ specifying whether or not word i is assigned tag t. (Throughout this paper we will assume that the tag-set used by the tagger, T, is a subset of the set of non-terminals considered by the parser, N.) Note that this representation is over-complete, since a parse tree determines a unique tagging for a sentence: more explicitly, for any $i \in \{1 \ldots n\}$, $Y \in T$, the following linear constraint holds:

$$y(i, Y) = \sum_{k=i+1}^{n} \sum_{X, Z \in N} y(X \rightarrow Y\ Z, i, i, k) + \\ \sum_{k=1}^{i-1} \sum_{X, Z \in N} y(X \rightarrow Z\ Y, k, i-1, i)$$

We apply the same extension to the tagging index set, effectively mapping trigrams down to unigram assignments, again giving an over-complete representation. The extended index set for tagging is referred to as $\mathcal{I}'_{\text{tag}}$.

From here on we will make exclusive use of extended index sets for CFG parsing and trigram tagging. We use the set $\mathcal{Y}$ to refer to the set of valid parse structures under the extended representation;

[3] We do not require rules of the form $A \rightarrow w_i$ in this representation, as they are redundant: specifically, a rule production $\langle A \rightarrow B\ C, i, k, j\rangle$ implies a rule $B \rightarrow w_i$ iff $i = k$, and $C \rightarrow w_j$ iff $j = k + 1$.

[4] We do not require parameters for rules of the form $A \rightarrow w$, as they can be folded into rule production parameters. E.g., under a PCFG we define $\theta(A \rightarrow B\ C, i, k, j) = \log P(A \rightarrow B\ C \mid A) + \delta_{i,k} \log P(B \rightarrow w_i | B) + \delta_{k+1,j} \log P(C \rightarrow w_j | C)$ where $\delta_{x,y} = 1$ if $x = y$, 0 otherwise.

[5] As one example, in an HMM, the parameter $\theta((A, B) \rightarrow C, 3)$ would be $\log P(A | {*}{*}) + \log P(B | {*}A) + \log P(C | AB) + \log P(w_1 | A) + \log P(w_2 | B) + \log P(w_3 | C)$, where $*$ is the start symbol.

each $y \in \mathcal{Y}$ is a binary vector of length $|\mathcal{I}'|$. We similarly use $\mathcal{Z}$ to refer to the set of valid tag structures under the extended representation. We assume parameter vectors for the two problems, $\theta^{\text{cfg}} \in \mathbb{R}^{|\mathcal{I}'|}$ and $\theta^{\text{tag}} \in \mathbb{R}^{|\mathcal{I}'_{\text{tag}}|}$.

4 Two Examples

This section describes the dual decomposition approach for two inference problems in NLP.

4.1 Integrated Parsing and Trigram Tagging

We now describe the dual decomposition approach for integrated parsing and trigram tagging. First, define the set $\mathcal{Q}$ as follows:

$$\mathcal{Q} = \{(y, z) : y \in \mathcal{Y}, z \in \mathcal{Z}, \\ y(i,t) = z(i,t) \text{ for all } (i,t) \in \mathcal{I}_{uni}\} \quad (1)$$

Hence $\mathcal{Q}$ is the set of all (y, z) pairs that agree on their part-of-speech assignments. The integrated parsing and trigram tagging problem is then to solve

$$\max_{(y,z)\in\mathcal{Q}} \left(y \cdot \theta^{\text{cfg}} + z \cdot \theta^{\text{tag}} \right) \quad (2)$$

This problem is equivalent to

$$\max_{y\in\mathcal{Y}} \left(y \cdot \theta^{\text{cfg}} + g(y) \cdot \theta^{\text{tag}} \right)$$

where $g : \mathcal{Y} \rightarrow \mathcal{Z}$ is a function that maps a parse tree y to its set of trigrams $z = g(y)$. The benefit of the formulation in Eq. 2 is that it makes explicit the idea of maximizing over all pairs (y, z) under a set of agreement constraints $y(i,t) = z(i,t)$—this concept will be central to the algorithms in this paper.

With this in mind, we note that we have efficient methods for the inference problems of tagging and parsing alone, and that our combined objective almost separates into these two independent problems. In fact, if we drop the $y(i,t) = z(i,t)$ constraints from the optimization problem, the problem splits into two parts, each of which can be efficiently solved using dynamic programming:

$$(y^*, z^*) = (\arg\max_{y\in\mathcal{Y}} y \cdot \theta^{\text{cfg}}, \arg\max_{z\in\mathcal{Z}} z \cdot \theta^{\text{tag}})$$

Dual decomposition exploits this idea; it results in the algorithm given in figure 1. The algorithm optimizes the combined objective by repeatedly solving the two sub-problems separately—that is, it directly solves the harder optimization problem using an existing CFG parser and trigram tagger. After each iteration the algorithm adjusts the weights $u(i,t)$; these updates modify the objective functions for the two models, encouraging them to agree on the same POS sequence. In section 6.1 we will show that the variables $u(i,t)$ are Lagrange multipliers enforcing agreement constraints, and that the algorithm corresponds to a (sub)gradient method for optimization of a dual function. The algorithm is easy to implement: all that is required is a decoding algorithm for each of the two models, and simple additive updates to the Lagrange multipliers enforcing agreement between the two models.

```
Set $u^{(1)}(i,t) \leftarrow 0$ for all $(i,t) \in \mathcal{I}_{\text{uni}}$
for $k = 1$ to $K$ do
    $y^{(k)} \leftarrow \arg\max_{y\in\mathcal{Y}} \; (y \cdot \theta^{\text{cfg}} - \sum_{(i,t)\in\mathcal{I}_{\text{uni}}} u^{(k)}(i,t)y(i,t))$
    $z^{(k)} \leftarrow \arg\max_{z\in\mathcal{Z}} \; (z \cdot \theta^{\text{tag}} + \sum_{(i,t)\in\mathcal{I}_{\text{uni}}} u^{(k)}(i,t)z(i,t))$
    if $y^{(k)}(i,t) = z^{(k)}(i,t)$ for all $(i,t) \in \mathcal{I}_{\text{uni}}$ then
        return $(y^{(k)}, z^{(k)})$
    for all $(i,t) \in \mathcal{I}_{\text{uni}}$,
        $u^{(k+1)}(i,t) \leftarrow u^{(k)}(i,t) + \alpha_k(y^{(k)}(i,t) - z^{(k)}(i,t))$
return $(y^{(K)}, z^{(K)})$
```

Figure 1: The algorithm for integrated parsing and tagging. The parameters $\alpha_k > 0$ for $k = 1 \ldots K$ specify step sizes for each iteration, and are discussed further in the Appendix. The two $\arg\max$ problems can be solved using dynamic programming.

4.2 Integrating Two Lexicalized Parsers

Our second example problem is the integration of a phrase-structure parser with a higher-order dependency parser. The goal is to add higher-order features to phrase-structure parsing without greatly increasing the complexity of inference.

First, we define an index set for second-order unlabeled projective dependency parsing. The second-order parser considers first-order dependencies, as well as grandparent and sibling second-order dependencies (e.g., see Carreras (2007)). We assume that $\mathcal{I}_{\text{dep}}$ is an index set containing all such dependencies (for brevity we omit the details of this index set). For convenience we define an extended index set that makes explicit use of first-order dependencies, $\mathcal{I}'_{\text{dep}} = \mathcal{I}_{\text{dep}} \cup \mathcal{I}_{\text{first}}$, where

$$\mathcal{I}_{\text{first}} = \{(i,j) \ : \ i \in \{0 \dots n\}, j \in \{1 \dots n\}, i \neq j\}$$

Here (i,j) represents a dependency with head w_i and modifier w_j ($i = 0$ corresponds to the root symbol in the parse). We use $\mathcal{D} \subseteq \{0,1\}^{|\mathcal{I}'_{\text{dep}}|}$ to denote the set of valid projective dependency parses.

The second model we use is a lexicalized CFG. Each symbol in the grammar takes the form $A(h)$ where $A \in N$ is a non-terminal, and $h \in \{1 \dots n\}$ is an index specifying that w_h is the head of the constituent. Rule productions take the form $\langle A(a) \rightarrow B(b)\ C(c), i, k, j\rangle$ where $b \in \{i \dots k\}$, $c \in \{(k+1) \dots j\}$, and a is equal to b or c, depending on whether A receives its head-word from its left or right child. Each such rule implies a dependency (a,b) if $a = c$, or (a,c) if $a = b$. We take $\mathcal{I}_{\text{head}}$ to be the index set of all such rules, and $\mathcal{I}'_{\text{head}} = \mathcal{I}_{\text{head}} \cup \mathcal{I}_{\text{first}}$ to be the extended index set. We define $\mathcal{H} \subseteq \{0,1\}^{|\mathcal{I}'_{\text{head}}|}$ to be the set of valid parse trees.

The integrated parsing problem is then to find

$$(y^*, d^*) = \arg \max_{(y,d) \in \mathcal{R}} \left(y \cdot \theta^{\text{head}} + d \cdot \theta^{\text{dep}} \right) \quad (3)$$

where $\mathcal{R} = \{(y,d) : y \in \mathcal{H}, d \in \mathcal{D},$
$y(i,j) = d(i,j)$ for all $(i,j) \in \mathcal{I}_{\text{first}}\}$

This problem has a very similar structure to the problem of integrated parsing and tagging, and we can derive a similar dual decomposition algorithm. The Lagrange multipliers u are a vector in $\mathbb{R}^{|\mathcal{I}_{\text{first}}|}$ enforcing agreement between dependency assignments. The algorithm (omitted for brevity) is identical to the algorithm in figure 1, but with $\mathcal{I}_{\text{uni}}$, $\mathcal{Y}$, $\mathcal{Z}$, θ^{cfg}, and θ^{tag} replaced with $\mathcal{I}_{\text{first}}$, $\mathcal{H}$, $\mathcal{D}$, θ^{head}, and θ^{dep} respectively. The algorithm only requires decoding algorithms for the two models, together with simple updates to the Lagrange multipliers.

5 Marginal Polytopes and LP Relaxations

We now give formal guarantees for the algorithms in the previous section, showing that they solve LP relaxations of the problems in Eqs. 2 and 3.

To make the connection to linear programming, we first introduce the idea of *marginal polytopes* in section 5.1. In section 5.2, we give a precise statement of the LP relaxations that are being solved by the example algorithms, making direct use of marginal polytopes. In section 6 we will prove that the example algorithms solve these LP relaxations.

5.1 Marginal Polytopes

For a finite set $\mathcal{Y}$, define the set of all distributions over elements in $\mathcal{Y}$ as $\Delta = \{\alpha \in \mathbb{R}^{|\mathcal{Y}|} : \alpha_y \geq 0, \sum_{y \in \mathcal{Y}} \alpha_y = 1\}$. Each $\alpha \in \Delta$ gives a vector of marginals, $\mu = \sum_{y \in \mathcal{Y}} \alpha_y y$, where μ_r can be interpreted as the probability that $y_r = 1$ for a y selected at random from the distribution α.

The set of all possible marginal vectors, known as the *marginal polytope*, is defined as follows:

$$\mathcal{M} = \{\mu \in \mathbb{R}^m : \exists \alpha \in \Delta \text{ such that } \mu = \sum_{y \in \mathcal{Y}} \alpha_y y\}$$

$\mathcal{M}$ is also frequently referred to as the *convex hull* of $\mathcal{Y}$, written as $\text{conv}(\mathcal{Y})$. We use the notation $\text{conv}(\mathcal{Y})$ in the remainder of this paper, instead of $\mathcal{M}$.

For an arbitrary set $\mathcal{Y}$, the marginal polytope $\text{conv}(\mathcal{Y})$ can be complex to describe.[6] However, Martin et al. (1990) show that for a very general class of dynamic programming problems, the corresponding marginal polytope can be expressed as

$$\text{conv}(\mathcal{Y}) = \{\mu \in \mathbb{R}^m : A\mu = b, \mu \geq 0\} \quad (4)$$

where A is a $p \times m$ matrix, b is vector in $\mathbb{R}^p$, and the value p is linear in the size of a hypergraph representation of the dynamic program. Note that A and b specify a set of p linear constraints.

We now give an explicit description of the resulting constraints for CFG parsing:[7] similar constraints arise for other dynamic programming algorithms for parsing, for example the algorithms of Eisner (2000). The exact form of the constraints, and the fact that they are polynomial in number, is not essential for the formal results in this paper. However, a description of the constraints gives valuable intuition for the structure of the marginal polytope.

The constraints are given in figure 2. To develop some intuition, consider the case where the variables μ_r are restricted to be binary: hence each binary vector μ specifies a parse tree. The second constraint in Eq. 5 specifies that exactly one rule must be used at the top of the tree. The set of constraints in Eq. 6 specify that for each production of the form

[6] For any finite set $\mathcal{Y}$, $\text{conv}(\mathcal{Y})$ can be expressed as $\{\mu \in \mathbb{R}^m : A\mu \leq b\}$ where A is a matrix of dimension $p \times m$, and $b \in \mathbb{R}^p$ (see, e.g., Korte and Vygen (2008), pg. 65). The value for p depends on the set $\mathcal{Y}$, and can be exponential in size.

[7] Taskar et al. (2004) describe the same set of constraints, but without proof of correctness or reference to Martin et al. (1990).

$$\forall r \in \mathcal{I}',\ \mu_r \geq 0\ ;\quad \sum_{\substack{X,Y,Z \in N\\ k=1\ldots(n-1)}} \mu(X \rightarrow Y\ Z, 1, k, n) = 1 \tag{5}$$

$\forall X \in N$, $\forall (i,j)$ such that $1 \leq i < j \leq n$ and $(i,j) \neq (1,n)$:

$$\sum_{\substack{Y,Z \in N\\ k=i\ldots(j-1)}} \mu(X \rightarrow Y\ Z, i, k, j) = \sum_{\substack{Y,Z \in N\\ k=1\ldots(i-1)}} \mu(Y \rightarrow Z\ X, k, i-1, j) + \sum_{\substack{Y,Z \in N\\ k=(j+1)\ldots n}} \mu(Y \rightarrow X\ Z, i, j, k) \tag{6}$$

$$\forall Y \in T,\ \forall i \in \{1 \ldots n\}:\quad \mu(i,Y) = \sum_{\substack{X,Z \in N\\ k=(i+1)\ldots n}} \mu(X \rightarrow Y\ Z, i, i, k) + \sum_{\substack{X,Z \in N\\ k=1\ldots(i-1)}} \mu(X \rightarrow Z\ Y, k, i-1, i) \tag{7}$$

Figure 2: The linear constraints defining the marginal polytope for CFG parsing.

$\langle X \rightarrow Y\ Z, i, k, j\rangle$ in a parse tree, there must be exactly one production higher in the tree that generates (X, i, j) as one of its children. The constraints in Eq. 7 enforce consistency between the $\mu(i, Y)$ variables and rule variables higher in the tree. Note that the constraints in Eqs.(5–7) can be written in the form $A\mu = b$, $\mu \geq 0$, as in Eq. 4.

Under these definitions, we have the following:

Theorem 5.1 *Define $\mathcal{Y}$ to be the set of all CFG parses, as defined in section 4. Then*

$$\text{conv}(\mathcal{Y}) = \{\mu \in \mathbb{R}^m : \mu \textit{ satisifies Eqs.(5–7)}\}$$

Proof: This theorem is a special case of Martin et al. (1990), theorem 2.

The marginal polytope for tagging, $\text{conv}(\mathcal{Z})$, can also be expressed using linear constraints as in Eq. 4; see figure 3. These constraints follow from results for graphical models (Wainwright and Jordan, 2008), or from the Martin et al. (1990) construction.

As a final point, the following theorem gives an important property of marginal polytopes, which we will use at several points in this paper:

Theorem 5.2 *(Korte and Vygen (2008), page 66.) For any set $\mathcal{Y} \subseteq \{0,1\}^k$, and for any vector $\theta \in \mathbb{R}^k$,*

$$\max_{y \in \mathcal{Y}} y \cdot \theta = \max_{\mu \in \text{conv}(\mathcal{Y})} \mu \cdot \theta \tag{8}$$

$$\forall r \in \mathcal{I}'_{\text{tag}},\ \nu_r \geq 0\ ;\quad \sum_{X,Y,Z \in T} \nu((X,Y) \rightarrow Z, 3) = 1$$

$\forall X \in T, \forall i \in \{3 \ldots n-1\}$:

$$\sum_{Y,Z \in T} \nu((Y,Z) \rightarrow X, i) = \sum_{Y,Z \in T} \nu((Y,X) \rightarrow Z, i+1)$$

$\forall X \in T, \forall i \in \{3 \ldots n-2\}$:

$$\sum_{Y,Z \in T} \nu((Y,Z) \rightarrow X, i) = \sum_{Y,Z \in T} \nu((X,Y) \rightarrow Z, i+2)$$

$$\forall X \in T, \forall i \in \{3 \ldots n\}:\ \nu(i,X) = \sum_{Y,Z \in T} \nu((Y,Z) \rightarrow X, i)$$

$$\forall X \in T:\quad \nu(1,X) = \sum_{Y,Z \in T} \nu((X,Y) \rightarrow Z, 3)$$

$$\forall X \in T:\quad \nu(2,X) = \sum_{Y,Z \in T} \nu((Y,X) \rightarrow Z, 3)$$

Figure 3: The linear constraints defining the marginal polytope for trigram POS tagging.

The theorem states that for a linear objective function, maximization over a discrete set $\mathcal{Y}$ can be replaced by maximization over the convex hull $\text{conv}(\mathcal{Y})$. The problem $\max_{\mu \in \text{conv}(\mathcal{Y})} \mu \cdot \theta$ is a linear programming problem.

For parsing, this theorem implies that:

1. Weighted CFG parsing can be framed as a linear programming problem, of the form $\max_{\mu \in \text{conv}(\mathcal{Y})} \mu \cdot \theta$, where $\text{conv}(\mathcal{Y})$ is specified by a polynomial number of linear constraints.

2. Conversely, dynamic programming algorithms such as the CKY algorithm can be considered to be oracles that efficiently solve LPs of the form $\max_{\mu \in \text{conv}(\mathcal{Y})} \mu \cdot \theta$.

Similar results apply for the POS tagging case.

5.2 Linear Programming Relaxations

We now describe the LP relaxations that are solved by the example algorithms in section 4. We begin with the algorithm in Figure 1.

The original optimization problem was to find $\max_{(y,z) \in \mathcal{Q}} \left(y \cdot \theta^{\text{cfg}} + z \cdot \theta^{\text{tag}}\right)$ (see Eq. 2). By theorem 5.2, this is equivalent to solving

$$\max_{(\mu,\nu) \in \text{conv}(\mathcal{Q})} \left(\mu \cdot \theta^{\text{cfg}} + \nu \cdot \theta^{\text{tag}}\right) \tag{9}$$

To formulate our approximation, we first define:

$$\mathcal{Q}' = \{(\mu,\nu) : \mu \in \text{conv}(\mathcal{Y}), \nu \in \text{conv}(\mathcal{Z}),\ \mu(i,t) = \nu(i,t) \text{ for all } (i,t) \in \mathcal{I}_{\text{uni}}\}$$

The definition of $\mathcal{Q}'$ is very similar to the definition of $\mathcal{Q}$ (see Eq. 1), the only difference being that $\mathcal{Y}$ and $\mathcal{Z}$ are replaced by $\text{conv}(\mathcal{Y})$ and $\text{conv}(\mathcal{Z})$ respectively. Hence any point in $\mathcal{Q}$ is also in $\mathcal{Q}'$. It follows that any point in $\text{conv}(\mathcal{Q})$ is also in $\mathcal{Q}'$, because $\mathcal{Q}'$ is a convex set defined by linear constraints.

The LP relaxation then corresponds to the following optimization problem:

$$\max_{(\mu,\nu)\in\mathcal{Q}'} \left(\mu \cdot \theta^{\text{cfg}} + \nu \cdot \theta^{\text{tag}}\right) \tag{10}$$

$\mathcal{Q}'$ is defined by linear constraints, making this a linear program. Since $\mathcal{Q}'$ is an *outer bound* on $\text{conv}(\mathcal{Q})$, i.e. $\text{conv}(\mathcal{Q}) \subseteq \mathcal{Q}'$, we obtain the guarantee that the value of Eq. 10 always upper bounds the value of Eq. 9.

In Appendix A we give an example showing that in general $\mathcal{Q}'$ includes points that are not in $\text{conv}(\mathcal{Q})$. These points exist because the agreement between the two parts is now enforced in expectation ($\mu(i,t) = \nu(i,t)$ for $(i,t) \in \mathcal{I}_{\text{uni}}$) rather than based on actual assignments. This agreement constraint is weaker since different distributions over assignments can still result in the same first order expectations. Thus, the solution to Eq. 10 may be in $\mathcal{Q}'$ but not in $\text{conv}(\mathcal{Q})$. It can be shown that all such solutions will be *fractional*, making them easy to distinguish from $\mathcal{Q}$. In many applications of LP relaxations—including the examples discussed in this paper—the relaxation in Eq. 10 turns out to be *tight*, in that the solution is often integral (i.e., it is in $\mathcal{Q}$). In these cases, solving the LP relaxation *exactly* solves the original problem of interest.

In the next section we prove that the algorithm in Figure 1 solves the problem in Eq 10. A similar result holds for the algorithm in section 4.2: it solves a relaxation of Eq. 3, where $\mathcal{R}$ is replaced by

$$\mathcal{R}' = \{(\mu,\nu) : \mu \in \text{conv}(\mathcal{H}), \nu \in \text{conv}(\mathcal{D}),$$
$$\mu(i,j) = \nu(i,j) \text{ for all } (i,j) \in \mathcal{I}_{\text{first}}\}$$

6 Convergence Guarantees

6.1 Lagrangian Relaxation

We now show that the example algorithms solve their respective LP relaxations given in the previous section. We do this by first introducing a general class of linear programs, together with an optimization method, *Lagrangian relaxation*, for solving these LPs. We then show that the algorithms in section 4 are special cases of the general algorithm.

The linear programs we consider take the form

$$\max_{x_1\in X_1, x_2\in X_2} (\theta_1 \cdot x_1 + \theta_2 \cdot x_2) \quad \text{such that } Ex_1 = Fx_2$$

The matrices $E \in \mathbb{R}^{q\times m}$ and $F \in \mathbb{R}^{q\times l}$ specify q linear "agreement" constraints between $x_1 \in \mathbb{R}^m$ and $x_2 \in \mathbb{R}^l$. The sets X_1, X_2 are also specified by linear constraints, $X_1 = \{x_1 \in \mathbb{R}^m : Ax_1 = b, x_1 \geq 0\}$ and $X_2 = \left\{x_2 \in \mathbb{R}^l : Cx_2 = d, x_2 \geq 0\right\}$, hence the problem is an LP.

Note that if we set $X_1 = \text{conv}(\mathcal{Y})$, $X_2 = \text{conv}(\mathcal{Z})$, and define E and F to specify the agreement constraints $\mu(i,t) = \nu(i,t)$, then we have the LP relaxation in Eq. 10.

It is natural to apply Lagrangian relaxation in cases where the sub-problems $\max_{x_1\in X_1} \theta_1 \cdot x_1$ and $\max_{x_2\in X_2} \theta_2 \cdot x_2$ can be efficiently solved by combinatorial algorithms for any values of θ_1, θ_2, but where the constraints $Ex_1 = Fx_2$ "complicate" the problem. We introduce Lagrange multipliers $u \in \mathbb{R}^q$ that enforce the latter set of constraints, giving the Lagrangian:

$$L(u, x_1, x_2) = \theta_1 \cdot x_1 + \theta_2 \cdot x_2 + u \cdot (Ex_1 - Fx_2)$$

The dual objective function is

$$L(u) = \max_{x_1\in X_1, x_2\in X_2} L(u, x_1, x_2)$$

and the dual problem is to find $\min_{u\in\mathbb{R}^q} L(u)$.

Because X_1 and X_2 are defined by linear constraints, by strong duality we have

$$\min_{u\in\mathbb{R}^q} L(u) = \max_{x_1\in X_1, x_2\in X_2 : Ex_1=Fx_2} (\theta_1 \cdot x_1 + \theta_2 \cdot x_2)$$

Hence minimizing $L(u)$ will recover the maximum value of the original problem. This leaves open the question of how to recover the LP solution (i.e., the pair (x_1^*, x_2^*) that achieves this maximum); we discuss this point in section 6.2.

The dual $L(u)$ is convex. However, $L(u)$ is not differentiable, so we cannot use gradient-based methods to optimize it. Instead, a standard approach is to use a subgradient method. Subgradients are tangent lines that lower bound a function even at points of non-differentiability: formally, a subgradient of a convex function $L : \mathcal{R}^n \to \mathcal{R}$ at a point u is a vector g_u such that for all v, $L(v) \geq L(u) + g_u \cdot (v - u)$.

```
$u^{(1)} \leftarrow 0$
**for** $k = 1$ to $K$ **do**
    $x_1^{(k)} \leftarrow \arg\max_{x_1 \in X_1} (\theta_1 + (u^{(k)})^T E) \cdot x_1$
    $x_2^{(k)} \leftarrow \arg\max_{x_2 \in X_2} (\theta_2 - (u^{(k)})^T F) \cdot x_2$
    **if** $Ex_1^{(k)} = Fx_2^{(k)}$ **return** $u^{(k)}$
    $u^{(k+1)} \leftarrow u^{(k)} - \alpha_k (Ex_1^{(k)} - Fx_2^{(k)})$
**return** $u^{(K)}$
```

Figure 4: The Lagrangian relaxation algorithm.

By standard results, the subgradient for L at a point u takes a simple form, $g_u = Ex_1^* - Fx_2^*$, where

$$x_1^* = \arg \max_{x_1 \in X_1} (\theta_1 + (u^{(k)})^T E) \cdot x_1$$

$$x_2^* = \arg \max_{x_2 \in X_2} (\theta_2 - (u^{(k)})^T F) \cdot x_2$$

The beauty of this result is that the values of x_1^* and x_2^*, and by implication the value of the subgradient, can be computed using oracles for the two $\arg\max$ sub-problems.

Subgradient algorithms perform updates that are similar to gradient descent:

$$u^{(k+1)} \leftarrow u^{(k)} - \alpha_k g^{(k)}$$

where $g^{(k)}$ is the subgradient of L at $u^{(k)}$ and $\alpha_k > 0$ is the step size of the update. The complete subgradient algorithm is given in figure 4. The following convergence theorem is well-known (e.g., see page 120 of Korte and Vygen (2008)):

Theorem 6.1 *If* $\lim_{k \to \infty} \alpha_k = 0$ *and* $\sum_{k=1}^{\infty} \alpha_k = \infty$*, then* $\lim_{k \to \infty} L(u^{(k)}) = \min_u L(u)$.

The following proposition is easily verified:

Proposition 6.1 *The algorithm in figure 1 is an instantiation of the algorithm in figure 4,*[8] *with* $X_1 = \text{conv}(\mathcal{Y})$, $X_2 = \text{conv}(\mathcal{Z})$*, and the matrices* E *and* F *defined to be binary matrices specifying the constraints* $\mu(i,t) = \nu(i,t)$ *for all* $(i,t) \in \mathcal{I}_{uni}$.

Under an appropriate definition of the step sizes α_k, it follows that the algorithm in figure 1 defines a sequence of Lagrange multipliers $u^{(k)}$ minimizing a dual of the LP relaxation in Eq. 10. A similar result holds for the algorithm in section 4.2.

6.2 Recovering the LP Solution

The previous section described how the method in figure 4 can be used to minimize the dual $L(u)$ of the original linear program. We now turn to the problem of recovering a primal solution (x_1^*, x_2^*) of the LP. The method we propose considers two cases:

(Case 1) If $Ex_1^{(k)} = Fx_2^{(k)}$ at any stage during the algorithm, then simply take $(x_1^{(k)}, x_2^{(k)})$ to be the primal solution. In this case the pair $(x_1^{(k)}, x_2^{(k)})$ *exactly* solves the original LP.[9] If this case arises in the algorithm in figure 1, then the resulting solution is binary (i.e., it is a member of $\mathcal{Q}$), and the solution exactly solves the original inference problem.

(Case 2) If case 1 does not arise, then a couple of strategies are possible. (This situation could arise in cases where the LP is not tight—i.e., it has a fractional solution—or where K is not large enough for convergence.) The first is to define the primal solution to be the average of the solutions encountered during the algorithm: $\hat{x}_1 = \sum_k x_1^{(k)}/K$, $\hat{x}_2 = \sum_k x_2^{(k)}/K$. Results from Nedić and Ozdaglar (2009) show that as $K \to \infty$, these averaged solutions converge to the optimal primal solution.[10] A second strategy (as given in figure 1) is to simply take $(x_1^{(K)}, x_2^{(K)})$ as an approximation to the primal solution. This method is a heuristic, but previous work (e.g., Komodakis et al. (2007)) has shown that it is effective in practice; we use it in this paper.

In our experiments we found that in the vast majority of cases, case 1 applies, after a small number of iterations; see the next section for more details.

7 Experiments

7.1 Integrated Phrase-Structure and Dependency Parsing

Our first set of experiments considers the integration of Model 1 of Collins (2003) (a lexicalized phrase-structure parser, from here on referred to as Model

[8] with the caveat that it returns $(x_1^{(k)}, x_2^{(k)})$ rather than $u^{(k)}$.

[9] We have that $\theta_1 \cdot x_1^{(k)} + \theta_2 \cdot x_2^{(k)} = L(u^{(k)}, x_1^{(k)}, x_2^{(k)}) = L(u^{(k)})$, where the last equality is because $x_1^{(k)}$ and $x_2^{(k)}$ are defined by the respective $\arg\max$'s. Thus, $(x_1^{(k)}, x_2^{(k)})$ and $u^{(k)}$ are primal and dual optimal.

[10] The resulting fractional solution can be projected back to the set $\mathcal{Q}$, see (Smith and Eisner, 2008; Martins et al., 2009).

Itn.	1	2	3	4	5-10	11-20	20-50	**
Dep	43.5	20.1	10.2	4.9	14.0	5.7	1.4	0.4
POS	58.7	15.4	6.3	3.6	10.3	3.8	0.8	1.1

Table 1: Convergence results for Section 23 of the WSJ Treebank for the dependency parsing and POS experiments. Each column gives the percentage of sentences whose *exact* solutions were found in a given range of subgradient iterations. ** is the percentage of sentences that did not converge by the iteration limit (K=50).

1),[11] and the 2nd order discriminative dependency parser of Koo et al. (2008). The inference problem for a sentence x is to find

$$y^* = \arg\max_{y \in \mathcal{Y}} (f_1(y) + \gamma f_2(y)) \qquad (11)$$

where $\mathcal{Y}$ is the set of all lexicalized phrase-structure trees for the sentence x; $f_1(y)$ is the score (log probability) under Model 1; $f_2(y)$ is the score under Koo et al. (2008) for the dependency structure implied by y; and $\gamma > 0$ is a parameter dictating the relative weight of the two models.[12] This problem is similar to the second example in section 4; a very similar dual decomposition algorithm to that described in section 4.2 can be derived.

We used the Penn Wall Street Treebank (Marcus et al., 1994) for the experiments, with sections 2-21 for training, section 22 for development, and section 23 for testing. The parameter γ was chosen to optimize performance on the development set.

We ran the dual decomposition algorithm with a limit of $K = 50$ iterations. The dual decomposition algorithm returns an exact solution if case 1 occurs as defined in section 6.2; we found that of 2416 sentences in section 23, case 1 occurred for 2407 (99.6%) sentences. Table 1 gives statistics showing the number of iterations required for convergence. Over 80% of the examples converge in 5 iterations or fewer; over 90% converge in 10 iterations or fewer.

	Precision	Recall	F$_1$	Dep
Model 1	88.4	87.8	88.1	91.4
Koo08 Baseline	89.9	89.6	89.7	93.3
DD Combination	91.0	90.4	90.7	93.8

Table 2: Performance results for Section 23 of the WSJ Treebank. Model 1: a reimplementation of the generative parser of (Collins, 2002). Koo08 Baseline: Model 1 with a hard restriction to dependencies predicted by the discriminative dependency parser of (Koo et al., 2008). DD Combination: a model that maximizes the joint score of the two parsers. Dep shows the unlabeled dependency accuracy of each system.

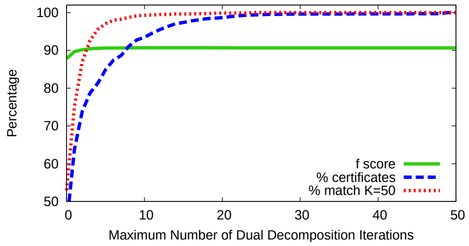

Figure 5: Performance on the parsing task assuming a fixed number of iterations K. f-score: accuracy of the method. % certificates: percentage of examples for which a certificate of optimality is provided. % match: percentage of cases where the output from the method is identical to the output when using $K = 50$.

We compare the accuracy of the dual decomposition approach to two baselines: first, Model 1; and second, a naive integration method that enforces the hard constraint that Model 1 must only consider dependencies seen in the first-best output from the dependency parser. Table 2 shows all three results. The dual decomposition method gives a significant gain in precision and recall over the naive combination method, and boosts the performance of Model 1 to a level that is close to some of the best single-pass parsers on the Penn treebank test set. Dependency accuracy is also improved over the Koo et al. (2008) model, in spite of the relatively low dependency accuracy of Model 1 alone.

Figure 5 shows performance of the approach as a function of K, the maximum number of iterations of dual decomposition. For this experiment, for cases where the method has not converged for $k \leq K$, the output from the algorithm is chosen to be the $y^{(k)}$ for $k \leq K$ that maximizes the objective function in Eq. 11. The graphs show that values of K less than 50 produce almost identical performance to $K = 50$, but with fewer cases giving certificates of optimality (with $K = 10$, the f-score of the method is 90.69%; with $K = 5$ it is 90.63%).

[11] We use a reimplementation that is a slight modification of Collins Model 1, with very similar performance, and which uses the TAG formalism of Carreras et al. (2008).

[12] Note that the models f_1 and f_2 were trained separately, using the methods described by Collins (2003) and Koo et al. (2008) respectively.

	Precision	Recall	F_1	POS Acc
Fixed Tags	88.1	87.6	87.9	96.7
DD Combination	88.7	88.0	88.3	97.1

Table 3: Performance results for Section 23 of the WSJ. Model 1 (Fixed Tags): a baseline parser initialized to the best tag sequence of from the tagger of Toutanova and Manning (2000). DD Combination: a model that maximizes the joint score of parse and tag selection.

7.2 Integrated Phrase-Structure Parsing and Trigram POS tagging

In a second experiment, we used dual decomposition to integrate the Model 1 parser with the Stanford max-ent trigram POS tagger (Toutanova and Manning, 2000), using a very similar algorithm to that described in section 4.1. We use the same training/dev/test split as in section 7.1. The two models were again trained separately.

We ran the algorithm with a limit of $K = 50$ iterations. Out of 2416 test examples, the algorithm found an exact solution in 98.9% of the cases. Table 1 gives statistics showing the speed of convergence for different examples: over 94% of the examples converge to an exact solution in 10 iterations or fewer. In terms of accuracy, we compare to a baseline approach of using the first-best tag sequence as input to the parser. The dual decomposition approach gives 88.3 F1 measure in recovering parse-tree constituents, compared to 87.9 for the baseline.

8 Conclusions

We have introduced dual-decomposition algorithms for inference in NLP, given formal properties of the algorithms in terms of LP relaxations, and demonstrated their effectiveness on problems that would traditionally be solved using intersections of dynamic programs (Bar-Hillel et al., 1964). Given the widespread use of dynamic programming in NLP, there should be many applications for the approach.

There are several possible extensions of the method we have described. We have focused on cases where two models are being combined; the extension to more than two models is straightforward (e.g., see Komodakis et al. (2007)). This paper has considered approaches for MAP inference; for closely related methods that compute approximate marginals, see Wainwright et al. (2005b).

A Fractional Solutions

We now give an example of a point $(\mu, \nu) \in \mathcal{Q}' \backslash \text{conv}(\mathcal{Q})$ that demonstrates that the relaxation $\mathcal{Q}'$ is strictly larger than $\text{conv}(\mathcal{Q})$. Fractional points such as this one can arise as solutions of the LP relaxation for worst case instances, preventing us from finding an exact solution.

Recall that the constraints for $\mathcal{Q}'$ specify that $\mu \in \text{conv}(\mathcal{Y})$, $\nu \in \text{conv}(\mathcal{Z})$, and $\mu(i,t) = \nu(i,t)$ for all $(i,t) \in \mathcal{I}_{\text{uni}}$. Since $\mu \in \text{conv}(\mathcal{Y})$, μ must be a convex combination of 1 or more members of $\mathcal{Y}$; a similar property holds for ν. The example is as follows. There are two possible parts of speech, A and B, and an additional non-terminal symbol X. The sentence is of length 3, $w_1\ w_2\ w_3$. Let ν be the convex combination of the following two tag sequences, each with probability 0.5: $w_1/A\ w_2/A\ w_3/A$ and $w_1/A\ w_2/B\ w_3/B$. Let μ be the convex combination of the following two parses, each with probability 0.5: $(X(A\ w_1)(X(A\ w_2)(B\ w_3)))$ and $(X(A\ w_1)(X(B\ w_2)(A\ w_3)))$. It can be verified that $\mu(i,t) = \nu(i,t)$ for all (i,t), i.e., the marginals for single tags for μ and ν agree. Thus, $(\mu,\nu) \in \mathcal{Q}'$.

To demonstrate that this fractional point is *not* in $\text{conv}(\mathcal{Q})$, we give parameter values such that this fractional point is optimal and all integral points (i.e., actual parses) are suboptimal. For the tagging model, set $\theta(AA \rightarrow A, 3) = \theta(AB \rightarrow B, 3) = 0$, with all other parameters having a negative value. For the parsing model, set $\theta(X \rightarrow A\ X, 1, 1, 3) = \theta(X \rightarrow A\ B, 2, 2, 3) = \theta(X \rightarrow B\ A, 2, 2, 3) = 0$, with all other rule parameters being negative. For this objective, the fractional solution has value 0, while all integral points (i.e., all points in $\mathcal{Q}$) have a negative value. By Theorem 5.2, the maximum of any linear objective over $\text{conv}(\mathcal{Q})$ is equal to the maximum over $\mathcal{Q}$. Thus, $(\mu,\nu) \notin \text{conv}(\mathcal{Q})$.

B Step Size

We used the following step size in our experiments. First, we initialized α_0 to equal 0.5, a relatively large value. Then we defined $\alpha_k = \alpha_0 * 2^{-\eta_k}$, where η_k is the number of times that $L(u^{(k')}) > L(u^{(k'-1)})$ for $k' \leq k$. This learning rate drops at a rate of $1/2^t$, where t is the number of times that the dual increases from one iteration to the next. See Koo et al. (2010) for a similar, but less aggressive step size used to solve a different task.

Abstract

We study self-training with products of latent variable grammars in this paper. We show that increasing the quality of the automatically parsed data used for self-training gives higher accuracy self-trained grammars. Our generative self-trained grammars reach F scores of 91.6 on the WSJ test set and surpass even discriminative reranking systems without self-training. Additionally, we show that multiple self-trained grammars can be combined in a product model to achieve even higher accuracy. The product model is most effective when the individual underlying grammars are most diverse. Combining multiple grammars that were self-trained on disjoint sets of unlabeled data results in a final test accuracy of 92.5% on the WSJ test set and 89.6% on our Broadcast News test set.

1 Introduction

The latent variable approach of Petrov et al. (2006) is capable of learning high accuracy context-free grammars directly from a raw treebank. It starts from a coarse treebank grammar (Charniak, 1997), and uses latent variables to refine the context-free assumptions encoded in the grammar. A hierarchical split-and-merge algorithm introduces grammar complexity gradually, iteratively splitting (and potentially merging back) each observed treebank category into a number of increasingly refined latent subcategories. The Expectation Maximization (EM) algorithm is used to train the model, guaranteeing that each EM iteration will increase the training likelihood. However, because the latent variable grammars are not explicitly regularized, EM keeps fitting the training data and eventually begins overfitting (Liang et al., 2007). Moreover, EM is a local method, making no promises regarding the final point of convergence when initialized from different random seeds. Recently, Petrov (2010) showed that substantial differences between the learned grammars remain, even if the hierarchical splitting reduces the variance across independent runs of EM.

In order to counteract the overfitting behavior, Petrov et al. (2006) introduced a linear smoothing procedure that allows training grammars for 6 split-merge (SM) rounds without overfitting. The increased expressiveness of the model, combined with the more robust parameter estimates provided by the smoothing, results in a nice increase in parsing accuracy on a held-out set. However, as reported by Petrov (2009) and Huang and Harper (2009), an additional 7th SM round actually hurts performance.

Huang and Harper (2009) addressed the issue of data sparsity and overfitting from a different angle. They showed that self-training latent variable grammars on their own output can mitigate data sparsity issues and improve parsing accuracy. Because the capacity of the model can grow with the size of the training data, latent variable grammars are able to benefit from the additional training data, even though it is not perfectly labeled. Consequently, they also found that a 7th round of SM training was beneficial in the presence of large amounts of training data. However, variation still remains in their self-trained grammars and they had to use a held-out set for model selection.

The observation of variation is not surprising; EM's tendency to get stuck in local maxima has been studied extensively in the literature, resulting in various proposals for model selection methods (e.g., see

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 12–22,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

Burnham and Anderson (2002)). What is perhaps more surprising is that the different latent variable grammars seem to capture complementary aspects of the data. Petrov (2010) showed that a simple randomization scheme produces widely varying grammars. Quite serendipitously, these grammars can be combined into an unweighted product model that substantially outperforms the individual grammars.

In this paper, we combine the ideas of self-training and product models and show that both techniques provide complementary effects. We hypothesize that the main factors contributing to the final accuracy of the product model of self-trained grammars are (i) the accuracy of the grammar used to parse the unlabeled data for retraining (single grammar versus product of grammars) and (ii) the diversity of the grammars that are being combined (self-trained grammars trained using the same automatically labeled subset or different subsets). We conduct a series of analyses to develop an understanding of these factors, and conclude that both dimensions are important for obtaining significant improvements over the standard product models.

2 Experimental Setup

2.1 Data

We conducted experiments in two genres: newswire text and broadcast news transcripts. For the newswire studies, we used the standard setup (sections 02-21 for training, 22 for development, and 23 for final test) of the WSJ Penn Treebank (Marcus et al., 1999) for supervised training. The BLLIP corpus (Charniak et al., 2000) was used as a source of unlabeled data for self-training the WSJ grammars. We ignored the parse trees contained in the BLLIP corpus and retained only the sentences, which are already segmented and tokenized for parsing (e.g., contractions are split into two tokens and punctuation is separated from the words). We partitioned the 1,769,055 BLLIP sentences into 10 equally sized subsets[1].

For broadcast news (BN), we utilized the Broadcast News treebank from Ontonotes (Weischedel et al., 2008) together with the WSJ Penn Treebank for supervised training, because their combination results in better parser models compared to using the limited-sized BN corpus alone (86.7 F vs. 85.2 F). The files in the Broadcast News treebank represent news stories collected during different time periods with a diversity of topics. In order to obtain a representative split of train-test-development sets, we divided them into blocks of 10 files sorted by alphabetical filename order. We used the first file in each block for development, the second for test, and the remaining files for training. This training set was then combined with the entire WSJ treebank. We also used 10 equally sized subsets from the Hub4 CSR 1996 utterances (Garofolo et al., 1996) for self-training. The Hub 4 transcripts are markedly noisier than the BLLIP corpus is, in part because it is harder to sentence segment, but also because it was produced by human transcription of spoken language.

The treebanks were pre-processed differently for the two genres. For newswire, we used a slightly modified version of the WSJ treebank: empty nodes and function labels were deleted and auxiliary verbs were replaced with AUXB, AUXG, AUXZ, AUXD, or AUXN to represent infinitive, progressive, present, past, or past participle auxiliaries[2]. The targeted use of the broadcast models is for parsing broadcast news transcripts for language models in speech recognition systems. Therefore, in addition to applying the transformations used for newswire, we also replaced symbolic expressions with verbal forms (e.g., $5 was replaced with five dollars) and removed punctuation and case. The Hub4 data was segmented into utterances, punctuation was removed, words were down-cased, and contractions were tokenized for parsing. Table 1 summarizes the data set sizes used in our experiments, together with average sentence length and standard deviation.

2.2 Scoring

Parses from all models are compared with respective gold standard parses using SParseval bracket scoring (Roark et al., 2006). This scoring tool pro-

[1] We corrected some of the most egregious sentence segmentation problems in this corpus, and so the number of sentences is different than if one simply pulled the fringe of the trees. It was not uncommon for a sentence split to occur on abbreviations, such as Adm.

[2] Parsing accuracy is marginally affected. The average over 10 SM6 grammars with the transformation is 90.5 compared to 90.4 F without it, a 0.1% average improvement.

Genre	Statistics	Train	Dev	Test	Unlabeled

duces scores that are identical to those produced by EVALB for WSJ. For Broadcast News, SParseval applies Charniak and Johnson's (Charniak and Johnson, 2001) scoring method for EDITED nodes[3]. Using this method, BN scores were slightly (.05-.1) lower than if EDITED constituents were treated like any other, as in EVALB.

2.3 Latent Variable Grammars

We use the latent variable grammar (Matsuzaki et al., 2005; Petrov et al., 2006) implementation of Huang and Harper (2009) in this work. Latent variable grammars augment the observed parse trees in the treebank with a latent variable at each tree node. This effectively splits each observed category into a set of latent subcategories. An EM-algorithm is used to fit the model by maximizing the joint likelihood of parse trees and sentences. To allocate the grammar complexity only where needed, a simple split-and-merge procedure is applied. In every split-merge (SM) round, each latent variable is first split in two and the model is re-estimated. A likelihood criterion is used to merge back the least useful splits (50% merge rate for these experiments). This iterative refinement proceeds for 7 rounds, at which point parsing performance on a held-out set levels off and training becomes prohibitively slow.

Since EM is a local method, different initializations will result in different grammars. In fact, Petrov (2010) recently showed that this EM-algorithm is very unstable and converges to widely varying local maxima. These local maxima correspond to different high quality latent variable grammars that have captured different types of patterns in the data. Because the individual models' mistakes are independent to some extent, multiple grammars can be effectively combined into an unweighted product model of much higher accuracy. We build upon this line of work and investigate methods to exploit products of latent variable grammars in the context of self-training.

3 Self-training Methodology

Different types of parser self-training have been proposed in the literature over the years. All of them involve parsing a set of unlabeled sentences with a baseline parser and then estimating a new parser by combining this automatically parsed data with the original training data. McClosky et al. (2006) presented a very effective method for self-training a two-stage parsing system consisting of a first-stage generative lexicalized parser and a second-stage discriminative reranker. In their approach, a large amount of unlabeled text is parsed by the two-stage system and the parameters of the first-stage lexicalized parser are then re-estimated taking the counts from the automatically parsed data into consideration.

More recently Huang and Harper (2009) presented a self-training procedure based on an EM-algorithm. They showed that the EM-algorithm that is typically used to fit a latent variable grammar (Matsuzaki et al., 2005; Petrov et al., 2006) to a treebank can also be used for self-training on automatically parsed sentences. In this paper, we investigate self-training with products of latent variable grammars. We consider three training scenarios:

ST-Reg Training Use the best single grammar to

[3] Non-terminal subconstituents of EDITED nodes are removed so that the terminal constituents become immediate children of a single EDITED node, adjacent EDITED nodes are merged, and they are ignored for span calculations of the other constituents.

Regular	Best	Average	Product
SM6	90.8	90.5	92.0
SM7	90.4	90.1	92.2

Table 2: Performance of the regular grammars and their products on the WSJ development set.

ST-Reg	Best	Average	Product
SM6	91.5	91.2	92.0
SM7	91.6	91.5	92.4

Table 3: Performance of the ST-Reg grammars and their products on the WSJ development set.

parse a single subset of the unlabeled data and train 10 self-trained grammars using this single set.

ST-Prod Training Use the product model to parse a single subset of the unlabeled data and train 10 self-trained grammars using this single set.

ST-Prod-Mult Training Use the product model to parse all 10 subsets of the unlabeled data and train 10 self-trained grammars, each using a different subset.

The resulting grammars can be either used individually or combined in a product model.

These three conditions provide different insights. The first experiment allows us to investigate the effectiveness of product models for standard self-trained grammars. The second experiment enables us to quantify how important the accuracy of the baseline parser is for self-training. Finally, the third experiment investigates a method for injecting some additional diversity into the individual grammars to determine whether a product model is most successful when there is more variance among the individual models.

Our initial experiments and analysis will focus on the development set of WSJ. We will then follow up with an analysis of broadcast news (BN) to determine whether the findings generalize to a second, less structured type of data. It is important to construct grammars capable of parsing this type of data accurately and consistently in order to support structured language modeling (e.g., (Wang and Harper, 2002; Filimonov and Harper, 2009)).

4 Newswire Experiments

In this section, we compare single grammars and their products that are trained in the standard way with gold WSJ training data, as well as the three self-training scenarios discussed in Section 3. We report the F scores of both SM6 and SM7 grammars on the development set in order to evaluate the effect of model complexity on the performance of the self-trained and product models. Note that we use 6th round grammars to produce the automatic parse trees for the self-training experiments. Parsing with the product of the 7th round grammars is slow and requires a large amount of memory (32GB). Since we had limited access to such machines, it was infeasible for us to parse all of the unlabeled data with the SM7 product grammars.

4.1 Regular Training

We begin by training ten latent variable models initialized with different random seeds using the gold WSJ training set. Results are presented in Table 2. The best F score attained by the individual SM6 grammars on the development set is 90.8, with an average score of 90.5. The product of grammars achieves a significantly improved accuracy at 92.0[4]. Notice that the individual SM7 grammars perform worse on average (90.1 vs. 90.5) due to overfitting, but their product achieves higher accuracy than the product of the SM6 grammars (92.2 vs. 92.0). We will further investigate the causes for this effect in Section 5.

4.2 ST-Reg Training

Given the ten SM6 grammars from the previous subsection, we can investigate the three self-training methods. In the first regime (ST-Reg), we use the best single grammar (90.8 F) to parse a single subset of the BLLIP data. We then train ten grammars from different random seeds, using an equally weighted combination of the WSJ training set with this single set. These self-trained grammars are then combined into a product model. As reported in Table 3,

[4] We use Dan Bikel's randomized parsing evaluation comparator to determine the significance ($p < 0.05$) of the difference between two parsers' outputs.

ST-Prod	Best	Average	Product
SM6	91.7	91.4	92.2
SM7	91.9	91.7	92.4

Table 4: Performance of the ST-Prod grammars and their products on the WSJ development set.

ST-Prod-Mult	Best	Average	Product
SM6	91.7	91.4	92.5
SM7	91.8	91.7	92.8

Table 5: Performance of the ST-Prod-Mult grammars and their products on the WSJ development set.

thanks to the use of additional automatically labeled training data, the individual SM6 ST-Reg grammars perform significantly better than the individual SM6 grammars (91.2 vs. 90.5 on average), and the individual SM7 ST-Reg grammars perform even better, achieving a high F score of 91.5 on average.

The product of ST-Reg grammars achieves significantly better performance over the individual grammars, however, the improvement is much smaller than that obtained by the product of regular grammars. In fact, the product of ST-Reg grammars performs quite similarly to the product of regular grammars despite the higher average accuracy of the individual grammars. This may be caused by the fact that self-training on the same data tends to reduce the variation among the self-trained grammars. We will show in Section 5 that the diversity among the individual grammars is as important as average accuracy for the performance attained by the product model.

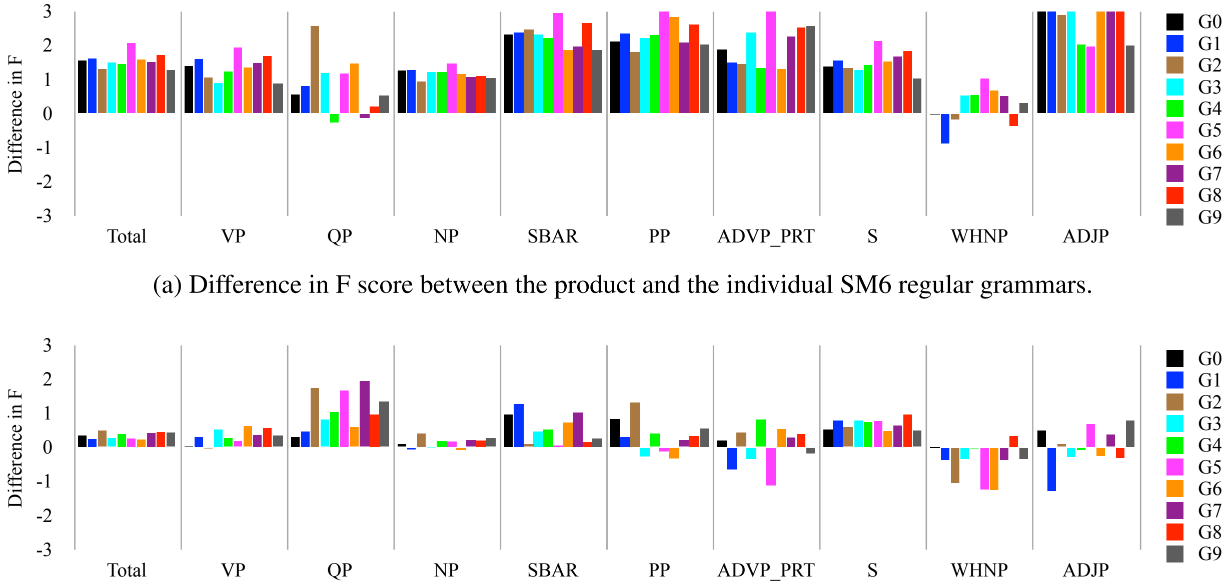
4.3 ST-Prod Training

Since products of latent variable grammars perform significantly better than individual latent variable grammars, it is natural to try using the product model for parsing the unlabeled data. To investigate whether the higher accuracy of the automatically labeled data translates into a higher accuracy of the self-trained grammars, we used the product of 6th round grammars to parse the same subset of the unlabeled data as in the previous experiment. We then trained ten self-trained grammars, which we call ST-Prod grammars. As can be seen in Table 4, using the product of the regular grammars for labeling the self-training data results in improved individual ST-Prod grammars when compared with the ST-Reg grammars, with 0.2 and 0.3 improvements for the best SM6 and SM7 grammars, respectively. Interestingly, the best individual SM7 ST-Prod grammar (91.9 F) performs comparably to the product of the regular grammars (92.0 F) that was used to label the BLLIP subset used for self-training. This is very useful for practical reasons because a single grammar is faster to parse with and requires less memory than the product model.

The product of the SM6 ST-Prod grammars also achieves a 0.2 higher F score compared to the product of the SM6 ST-Reg grammars, but the product of the SM7 ST-Prod grammars has the same performance as the product of the SM7 ST-Reg grammars. This could be due to the fact that the ST-Prod grammars are no more diverse than the ST-Reg grammars, as we will show in Section 5.

4.4 ST-Prod-Mult Training

When creating a product model of regular grammars, Petrov (2010) used a different random seed for each model and conjectured that the effectiveness of the product grammars stems from the resulting diversity of the individual grammars. Two ways to systematically introduce bias into individual models are to either modify the feature sets (Baldridge and Osborne, 2008; Smith and Osborne, 2007) or to change the training distributions of the individual models (Breiman, 1996). Petrov (2010) attempted to use the second method to train individual grammars on either disjoint or overlapping subsets of the treebank, but observed a performance drop in individual grammars resulting from training on less data, as well as in the performance of the product model. Rather than reducing the amount of gold training data (or having treebank experts annotate more data to support the diversity), we employ the self-training paradigm to train models using a combination of the same gold training data with different sets of the self-labeled training data. This approach also allows us to utilize a much larger amount of low-cost self-labeled data than can be used to train one model by partitioning the data into ten subsets and then training ten models with a different subset. Hence, in



(a) Difference in F score between the product and the individual SM6 regular grammars.

(b) Difference in F score between the product of SM6 regular grammars and the individual SM7 ST-Prod-Mult grammars.

Figure 1: Difference in F scores between various individual grammars and representative product grammars.

the third self-training experiment, we use the product of the regular grammars to parse all ten subsets of the unlabeled data and train ten grammars, which we call ST-Prod-Mult grammars, each using a different subset.

As shown in Table 5, the individual ST-Prod-Mult grammars perform similarly to the individual ST-Prod grammars. However, the product of the ST-Prod-Mult grammars achieves significantly higher accuracies than the product of the ST-Prod grammars, with 0.3 and 0.4 improvements for SM6 and SM7 grammars, respectively, suggesting that the use of multiple self-training subsets plays an important role in model combination.

5 Analysis

We conducted a series of analyses to develop an understanding of the factors affecting the effectiveness of combining self-training with product models.

5.1 What Has Improved?

Figure 1(a) depicts the difference between the product and the individual SM6 regular grammars on overall F score, as well as individual constituent F scores. As can be observed, there are significant variations among the individual grammars, and the product of the regular grammars improves almost all categories, with a few exceptions (some individual grammars do better on QP and WHNP constituents).

Figure 1(b) shows the difference between the product of the SM6 regular grammars and the individual SM7 ST-Prod-Mult grammars. Self-training dramatically improves the quality of single grammars. In most of the categories, some individual ST-Prod-Mult grammars perform comparably or slightly better than the product of SM6 regular grammars used to automatically label the unlabeled training set.

5.2 Overfitting vs. Smoothing

Figure 2(a) and 2(b) depict the learning curves of the regular and the ST-Prod-Mult grammars. As more latent variables are introduced through the iterative SM training algorithm, the modeling capacity of the grammars increases, leading to improved performance. However, the performance of the regular grammars drops after 6 SM rounds, as also previously observed in (Huang and Harper, 2009; Petrov, 2009), suggesting that the regular SM7 grammars have overfit the relatively small-sized gold training data. In contrast, the performance of the self-trained grammars continues to improve in the 7th SM round. Huang and Harper (2009) argued that the additional self-labeled training data adds a smoothing effect to the grammars, supporting an increase in model complexity without overfitting.

Although the performance of the individual grammars, both regular and self-trained, varies significantly and the product model consistently helps, there is a non-negligible difference between the improvement achieved by the two product models over their component grammars. The regular product model improves upon its individual grammars more than the ST-Prod-Mult product does in the later SM rounds, as illustrated by the relative error reduction curves in figures 2(a) and (b). In particular, the product of the SM7 regular grammars gains a remarkable 2.1% absolute improvement over the average performance of the individual regular SM7 grammars and 0.2% absolute over the product of the regular SM6 grammars, despite the fact that the individual regular SM7 grammars perform worse than the SM6 grammars. This suggests that the product model is able to effectively exploit less smooth, overfit grammars. We will examine this issue further in the next subsection.

5.3 Diversity

From the perspective of Products of Experts (Hinton, 1999) or Logarithmic Opinion Pools (Smith et al., 2005), each individual expert learns complementary aspects of the training data and the veto power of product models enforces that the joint prediction of their product has to be licensed by all individual experts. One possible explanation of the observation in the previous subsection is that with the addition of more latent variables, the individual grammars become more deeply specialized on certain aspects of the training data. This specialization leads to greater diversity in their prediction preferences, especially in the presence of a small training set. On the other hand, the self-labeled training set size is much larger, and so the specialization process is therefore slowed down.

Petrov (2010) showed that the individually learned grammars are indeed very diverse by looking at the distribution of latent annotations across the treebank categories, as well as the variation in overall and individual category F scores (see Figure 1). However, these measures do not directly relate to the diversity of the prediction preferences of the grammars, as we observed similar patterns in the regular and self-trained models.

Given a sentence s and a set of grammars $\mathcal{G} = \{G_1, \cdots, G_n\}$, recall that the decoding algorithm of the product model (Petrov, 2010) searches for the best tree T such that the following objective function is maximized:

$$\sum_{r \in T} \sum_{G \in \mathcal{G}} \log p(r|s, G)$$

where $\log p(r|s, G)$ is the log posterior probability of rule r given sentence s and grammar G. The power of the product model comes directly from the diversity in $\log p(r|s, G)$ among individual grammars. If there is little diversity, the individual grammars would make similar predictions and there would be little or no benefit from using a product model. We use the average empirical variance of the log posterior probabilities of the rules among the learned grammars over a held-out set S as a proxy of the diversity among the grammars:

$$\frac{\sum\limits_{s \in S} \sum\limits_{G \in \mathcal{G}} \sum\limits_{r \in \mathcal{R}(G,s)} p(r|s, G)\text{VAR}(\log(p(r|s, \mathcal{G})))}{\sum\limits_{s \in S} \sum\limits_{G \in \mathcal{G}} \sum\limits_{r \in \mathcal{R}(G,s)} p(r|s, G)}$$

where $\mathcal{R}(G, s)$ represents the set of rules extracted from the chart when parsing sentence s with grammar G, and $\text{VAR}(\log(p(r|s, \mathcal{G})))$ is the variance of $\log(p(r|s, G))$ among all grammars $G \in \mathcal{G}$.

Note that the average empirical variance is only an approximation of the diversity among grammars. In particular, this measure tends to be biased to produce larger numbers when the posterior probabilities of rules tend to be small, because small differences in probability produce large changes in the log scale. This happens for coarser grammars produced in early SM stages when there is more uncertainty about what rules to apply, with the rules remaining in the parsing chart having low probabilities overall.

As shown in Figure 2(c), the average variances all start at a high value and then drop, probably due to the aforementioned bias. However, as the SM iteration continues, the average variances increase despite the bias. More interestingly, the variance

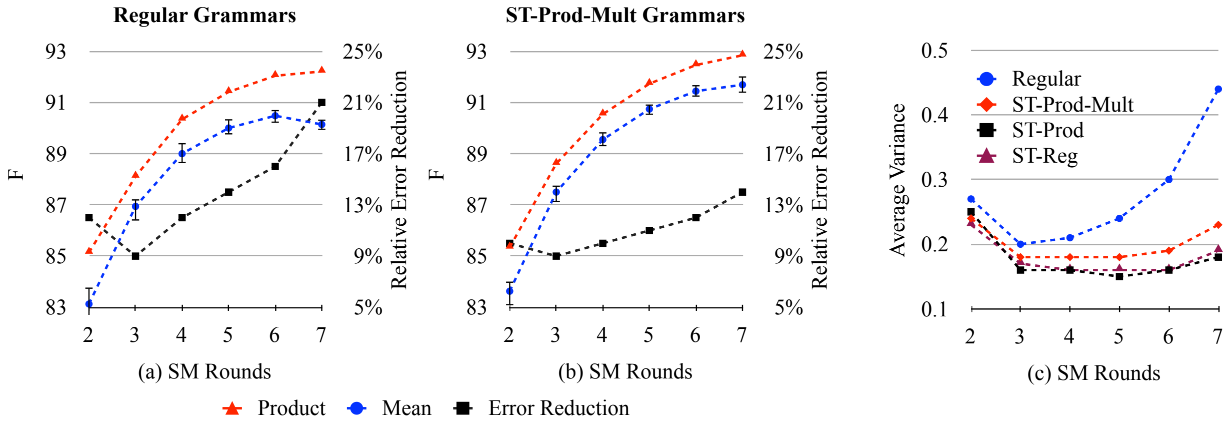


Figure 2: Learning curves of the individual regular (a) and ST-Prod-Mult (b) grammars (average performance, with minimum and maximum values indicated by bars) and their products before and after self-training on the WSJ development set. The relative error reductions of the products are also reported. (c) The measured average empirical variance among the grammars trained on WSJ.

among the regular grammars grows at a much faster speed and is consistently greater when compared to the self-trained grammars. This suggests that there is more diversity among the regular grammars than among the self-trained grammars, and explains the greater improvement obtained by the regular product model. It is also important to note that there is more variance among the ST-Prod-Mult grammars, which were trained on disjoint self-labeled training data, and a greater improvement in their product model relative to the ST-Reg and ST-Prod grammars, further supporting the diversity hypothesis. Last but not the least, the trend seems to indicate that the variance of the self-trained grammars would continue increasing if EM training was extended by a few more SM rounds, potentially resulting in even better product models. It is currently impractical to test this due to the dramatic increase in computational requirements for an SM8 product model, and so we leave it for future work.

5.4 Generalization to Broadcast News

We conducted the same set of experiments on the broadcast news data set. While the development set results in Table 6 show similar trends to the WSJ results, the benefits from the combination of self-training and product models appear even more pronounced here. The best single ST-Prod-Mult grammar (89.2 F) alone is able to outperform the product of SM7 regular grammars (88.9 F), and their product achieves another 0.7 absolute improvement, resulting in a significantly better accuracy at 89.9 F.

Model	Rounds	Best	Product
Regular	SM6	87.1	88.6
	SM7	87.1	88.9
ST-Prod	SM6	88.5	89.0
	SM7	89.0	89.6
ST-Prod-Mult	SM6	88.8	89.5
	SM7	**89.2**	**89.9**

Table 6: F-score for various models on the BN development set.

Figure 3 shows again that the benefits of self-training and product models are complementary and can be stacked. As can be observed, the self-trained grammars have increasing F scores as the split-merge rounds increase, while the regular grammars have a slight decrease in F score after round 6. In contrast to the newswire models, it appears that the individual ST-Prod-Mult grammars trained on broadcast news always perform comparably to the product of the regular grammars at all SM rounds, including the product of SM7 regular grammars. This is noteworthy, given that the ST-Prod-Mult grammars are trained on the output of the worse performing product of the SM6 regular grammars. One

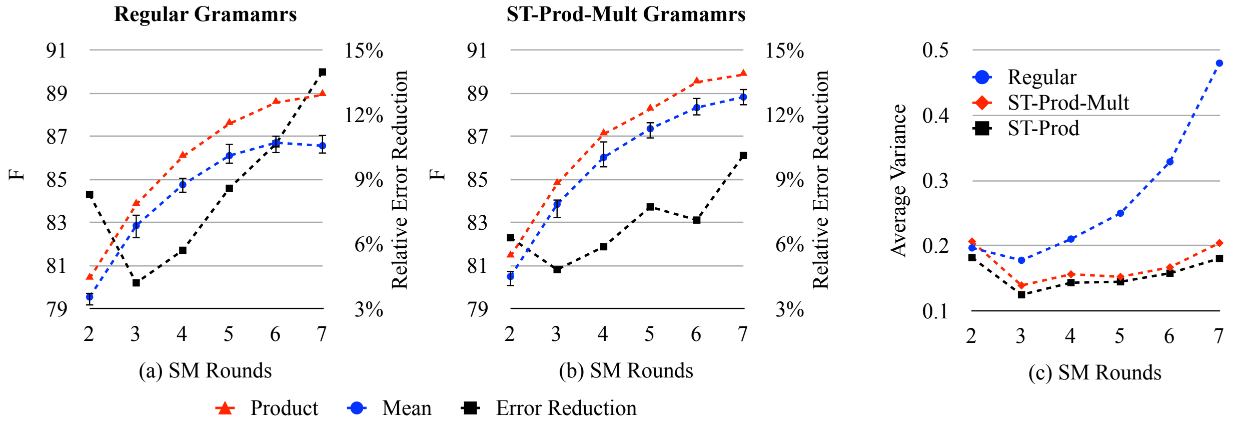

Figure 3: Learning curves of the individual regular (a) and ST-Prod-Mult (b) grammars (average performance, with minimum and maximum values indicated by bars) and their products before and after self-training on the BN development set. The relative error reductions of the products are also reported. (c) The measured average empirical variance among the grammars trained on BN.

possible explanation is that we used more unlabeled data for self-training the broadcast news grammars than for the newswire grammars. The product of the ST-Prod-Mult grammars provides further and significant improvement in F score.

6 Final Results

We evaluated the best single self-trained grammar (SM7 ST-Prod), as well as the product of the SM7 ST-Prod-Mult grammars on the WSJ test set. Table 7 compares these two grammars to a large body of related work grouped into single parsers (SINGLE), discriminative reranking approaches (RE), self-training (SELF), and system combinations (COMBO).

Our best single grammar achieves an accuracy that is only slightly worse (91.6 vs. 91.8 in F score) than the product model in Petrov (2010). This is made possible by self-training on the output of a high quality product model. The higher quality of the automatically parsed data results in a 0.3 point higher final F score (91.6 vs. 91.3) over the self-training results in Huang and Harper (2009), which used a single grammar for parsing the unlabeled data. The product of the self-trained ST-Prod-Mult grammars achieves significantly higher accuracies with an F score of 92.5, a 0.7 improvement over the product model in Petrov (2010).

Type	Parser	LP	LR	EX
SINGLE	Charniak (2000)	89.9	89.5	37.2
	Petrov and Klein (2007)	90.2	90.1	36.7
	Carreras et al. (2008)	91.4	90.7	-
RE	Charniak and Johnson (2005)	91.8	91.2	44.8
	Huang (2008)	92.2	91.2	43.5
SELF	Huang and Harper (2009)[8]	91.6	91.1	40.4
	McClosky et al. (2006)	92.5	92.1	45.3

	Zhang et al. (2009)	93.3	92.0	-
	This Paper Best Single	91.8	91.4	40.3
	Best Product	92.7	92.2	43.1

Table 7: Final test set accuracies on WSJ.

Although our models are based on purely generative PCFG grammars, our best product model performs competitively to the self-trained two-step discriminative reranking parser of McClosky et al. (2006), which makes use of many non-local reranking features. Our parser also performs comparably to other system combination approaches (Sagae and Lavie, 2006; Fossum and Knight, 2009; Zhang et al., 2009) with higher recall and lower precision,

[8] Our ST-Reg grammars are trained in the same way as in Huang and Harper (2009) except that we keep all unary rules. The reported numbers are from the best single ST-Reg grammar in this work.

but again without using a discriminative reranking step. We expect that replacing the first-step generative parsing model in McClosky et al. (2006) with a product of latent variable grammars would give even higher parsing accuracies.

On the Broadcast News test set, our best performing single and product grammars (bolded in Table 6) obtained F scores of 88.7 and 89.6, respectively. While there is no prior work using our setup, we expect these numbers to set a high baseline.

7 Conclusions and Future Work

We evaluated methods for self-training high accuracy products of latent variable grammars with large amounts of genre-matched data. We demonstrated empirically on newswire and broadcast news genres that very high accuracies can be achieved by training grammars on disjoint sets of automatically labeled data. Two primary factors appear to be determining the efficacy of our self-training approach. First, the accuracy of the model used for parsing the unlabeled data is important for the accuracy of the resulting single self-trained grammars. Second, the diversity of the individual grammars controls the gains that can be obtained by combining multiple grammars into a product model. Our most accurate single grammar achieves an F score of 91.6 on the WSJ test set, rivaling discriminative reranking approaches (Charniak and Johnson, 2005) and products of latent variable grammars (Petrov, 2010), despite being a single generative PCFG. Our most accurate product model achieves an F score of 92.5 without the use of discriminative reranking and comes close to the best known numbers on this test set (Zhang et al., 2009).

In future work, we plan to investigate additional methods for increasing the diversity of our self-trained models. One possibility would be to utilize more unlabeled data or to identify additional ways to bias the models. It would also be interesting to determine whether further increasing the accuracy of the model used for automatically labeling the unlabeled data can enhance performance even more. A simple but computationally expensive way to do this would be to parse the data with an SM7 product model.

Finally, for this work, we always used products of 10 grammars, but we sometimes observed that subsets of these grammars produce even better results on the development set. Finding a way to select grammars from a grammar pool to achieve high performance products is an interesting area of future study.

Utilizing Extra-sentential Context for Parsing

Abstract

Syntactic consistency is the preference to reuse a syntactic construction shortly after its appearance in a discourse. We present an analysis of the WSJ portion of the Penn Treebank, and show that syntactic consistency is pervasive across productions with various left-hand side nonterminals. Then, we implement a reranking constituent parser that makes use of extra-sentential context in its feature set. Using a linear-chain conditional random field, we improve parsing accuracy over the generative baseline parser on the Penn Treebank WSJ corpus, rivalling a similar model that does not make use of context. We show that the context-aware and the context-ignorant rerankers perform well on different subsets of the evaluation data, suggesting a combined approach would provide further improvement. We also compare parses made by models, and suggest that context can be useful for parsing by capturing structural dependencies between sentences as opposed to lexically governed dependencies.

1 Introduction

Recent corpus linguistics work has produced evidence of syntactic consistency, the preference to reuse a syntactic construction shortly after its appearance in a discourse (Gries, 2005; Dubey et al., 2005; Reitter, 2008). In addition, experimental studies have confirmed the existence of syntactic priming, the psycholinguistic phenomenon of syntactic consistency[1]. Both types of studies, however, have limited the constructions that are examined to particular syntactic constructions and alternations. For instance, Bock (1986) and Gries (2005) examine specific constructions such as the passive voice, dative alternation and particle placement in phrasal verbs, and Dubey et al. (2005) deal with the internal structure of noun phrases. In this work, we extend these results and present an analysis of the distribution of all syntactic productions in the Penn Treebank WSJ corpus. We provide evidence that syntactic consistency is a widespread phenomenon across productions of various types of *LHS* nonterminals, including all of the commonly occurring ones.

Despite this growing evidence that the probability of syntactic constructions is not independent of the extra-sentential context, current high-performance statistical parsers (e.g. (Petrov and Klein, 2007; McClosky et al., 2006; Finkel et al., 2008)) rely solely on intra-sentential features, considering the particular grammatical constructions and lexical items within the sentence being parsed. We address this by implementing a reranking parser which takes advantage of features based on the context surrounding the sentence. The reranker outperforms the generative baseline parser, and rivals a similar model that does not make use of context. We show that the context-aware and the context-ignorant models perform well on different subsets of the evaluation data, suggesting a feature set that combines the two models would provide further improvement. Analysis of the rerankings made provides cases where contextual information has clearly improved parsing per-

[1] Whether or not corpus-based studies of consistency have any bearing on syntactic priming as a reality in the human mind is a subject of debate. See (Pickering and Branigan, 1999) and (Gries, 2005) for opposing viewpoints.

formance, indicating the potential of extra-sentential contextual information to aid parsing, especially for structural dependencies between sentences, such as parallelism effects.

2 Syntactic Consistency in the Penn Treebank WSJ

Syntactic consistency has been examined by Dubey et al. (2005) for several English corpora, including the WSJ, Brown, and Switchboard corpora. They have provided evidence that syntactic consistency exists not only within coordinate structures, but also in a variety of other contexts, such as within sentences, between sentences, within documents, and between speaker turns in the Switchboard corpus. However, their analysis rests on a selected number of constructions concerning the internal structure of noun phrases. We extend their result here to arbitrary syntactic productions.

There have also been studies into syntactic consistency that consider all syntactic productions in dialogue corpora (Reitter, 2008; Buch and Pietsch, 2010). These studies find an inverse correlation between the probability of the appearance of a syntactic structure and the distance since its last occurrence, which indicates syntactic consistency. These studies, however, do not provide consistency results on subsets of production-types, such as by production LHS as our study does, so the implications that can be drawn from them for improving parsing are less apparent.

We adopt the measure used by Dubey et al. (2005) to quantify syntactic consistency, *adaptation probability*. This measure originates in work on lexical priming (Church, 2000), and quantifies the probability of a target word or construction w appearing in a "primed" context. Specifically, four frequencies are calculated, based on whether the target construction appears in the previous context (the prime set), and whether the construction appears after this context (the target set):

$$\begin{aligned} f_{p,\neg t}(w) &= \text{\# of times } w \text{ in prime set only} \\ f_{\neg p,t}(w) &= \text{\# of times } w \text{ in target set only} \\ f_{\neg p,\neg t}(w) &= \text{\# of times } w \text{ in neither set} \\ f_{p,t}(w) &= \text{\# of times } w \text{ in both sets} \end{aligned}$$

We also define N to be the sum of the four fre-

Table 1: Weighted average by production frequency among non-singleton production-types of prior and positive adaptation probabilities, and the ratio between them. The columns on the right show the number of production-types for which the positive adaptation probability is significantly greater than, not different from, or less than the prior probability. We exclude *LHS*s with a weighted average prior of less than 0.005, due to the small sample size.

quencies. Then, we define the *prior* and the *positive adaptation* probability of a construction as follows (See also Figure 1):

$$\begin{aligned} prior(w) &= \frac{f_{p,t}(w) + f_{\neg p,t}(w)}{N} \\ pos\_adapt(w) &= \frac{f_{p,t}(w)}{f_{p,t}(w) + f_{p,\neg t}(w)} \end{aligned}$$

A positive adaptation probability that is greater than the prior probability would be interpreted as evidence for syntactic consistency for that construction. We conduct χ^2 tests for statistical significance testing. We analyze the Penn Treebank WSJ corpus according this schema for all productions that occur in sections 2 to 22. These are the standard training and development sets for training parsers. We did not analyze section 23 in order not to use its characteristics in designing our reranking parser so that we can use this section as our evaluation test set. Our analysis focuses on the consistency of rules between sentences, so we take the previous sentence within the same article as the prime set, and the current sentence as the target set in calculating the probabilities given above. The raw data from which we produced our analysis are available at `http://www.cs.toronto.edu/~jcheung/wsj_parallelism_data.txt`.

We first present results for consistency in all the production-types[2], grouped by the *LHS* of the production. Table 1 shows the weighted average prior and positive adaptation probabilities for productions by *LHS*, where the weighting is done by the number of occurrence of that production. Production-types that only occur once are removed. It also shows the number of production-types in which the positive adaptation probability is statistically significantly greater than, not significantly different from, and significantly lower than the prior probability.

Quite remarkably, very few production-types are significantly less likely to reoccur compared to the prior probability. Also note the wide variety of *LHS*s for which there is a large number of production-types that are consistent to a significant degree. While a large number of production-types appears not to be significantly more likely to occur in a primed context, this is due to the large number of production-types which only appear a few times. Frequently occurring production-types mostly exhibit syntactic consistency.

We show this in Figure 2, in which we put non-singleton production-types into ten bins by fre-

[2] That is, all occurrences of a production with a particular *LHS* and *RHS*.

Table 2: Some instances of consistency effects of productions. All productions' pos_adapt probability is significantly greater than its $prior$ probability at $p < 10^{-6}$.

quency and calculated the proportion of production-types in that bin for which the positive adaptation probability is significantly greater than the prior. It is clear that the most frequently occurring production-types are also the ones most likely to exhibit evidence of syntactic consistency.

Table 2 shows the breakdown of the prior and positive adaptation calculation components for the ten most frequent production-types and the ten most consistent (by the ratio pos_adapt / $prior$) productions among the top decile of production-types. Note that all of these production-types are consistent to a statistically significant degree. Interestingly, many of the most consistent production-types have NP as the *LHS*, but overall, productions with many different *LHS* parents exhibit consistency.

3 A Context-Aware Reranker

Having established evidence for widespread syntactic consistency in the WSJ corpus, we now investigate incorporating extra-sentential context into a statistical parser. The first decision to make is whether to incorporate the context into a generative or a discriminative parsing model.

Employing a generative model would allow us to train the parser in one step, and one such parser which incorporates the previous context has been implemented by Dubey et al. (2006). They implement a PCFG, learning the production probabilities by a variant of standard PCFG-MLE probability estimation that conditions on whether a rule has recently occurred in the context or not:

$$P(RHS|LHS, Prime) = \frac{c(LHS \rightarrow RHS, Prime)}{c(LHS, Prime)}$$

LHS and *RHS* represent the left-hand side and right-hand side of a production, respectively. *Prime* is a binary variable which is `True` if and only if the current production has occurred in the prime set (the previous sentence). *c* represents the frequency count.

The drawback of such a system is that it doubles the state space of the model, and hence likely increases the amount of data needed to train the parser to a comparable level of performance as a more compact model, or would require elaborate smoothing. Dubey et al. (2006) find that this system performs worse than the baseline PCFG-MLE model, dropping F1 from 73.3% to 71.6%[3].

We instead opt to incorporate the extra-sentential context into a discriminative reranking parser, which naturally allows additional features to be incorporated into the statistical model. Many discriminative models of constituent parsing have been proposed in recent literature. They can be divided into two broad categories–those that rerank the N-best outputs of a generative parser, and those that make all parsing decisions using the discriminative model. We choose to implement an N-best reranking parser so that we can utilize state-of-the-art generative parsers to ensure a good selection of candidate parses to feed into our reranking module. Also, fully discriminative models tend to suffer from efficiency problems, though recent models have started to overcome this problem (Finkel et al., 2008).

Our approach is similar to N-best reranking parsers such as Charniak and Johnson (2005) and Collins and Koo (2005), which implement a variety of features to capture within-sentence lexical and structural dependencies. It is also similar to work which focuses on coordinate noun phrase parsing (e.g. (Hogan, 2007; Kübler et al., 2009)) in that we also attempt to exploit syntactic parallelism, but in a between-sentence setting rather than in a within-sentence setting that only considers coordination.

As evidence of the potential of an N-best reranking approach with respect to extra-sentential context, we considered the 50-best parses in the development set produced by the generative parser, and categorized each into one of nine bins depending on whether this candidate parse exhibits more, less, or the same amount of rule overlap with the previous correct parse than the generative baseline, and whether the candidate parse has a better, worse, or the same F1 measure than the generative baseline (Table 3). We find that a larger percentage of candidate parses which share more productions with the previous parse are better than the generative baseline parse than for the other categories, and this difference is statistically significant (χ^2 test).

	Overlap		
	less	*equal*	*more*
worse F1	32519 (81.8%)	7224 (69.3%)	17280 (75.4%)
equal F1	1023 (2.6%)	1674 (16.1%)	540 (2.4%)
better F1	6224 **(15.7%)**	1527 **(14.6%)**	5106 **(22.3%)**

Table 3: Correlation between rule overlap and F1 compared to the generative baseline for the 50-best parses in the development set.

3.1 Conditional Random Fields

For our statistical reranker, we implement a linear-chain conditional random field (CRF). CRFs are a very flexible class of graphical models which have been used for various sequence and relational labelling tasks (Lafferty et al., 2001). They have been used for tree labelling, in XML tree labelling (Jousse et al., 2006) and semantic role labelling tasks (Cohn and Blunsom, 2005). They have also been used for shallow parsing (Sha and Pereira, 2003), and full constituent parsing (Finkel et al., 2008; Tsuruoka et al., 2009). We exploit the flexibility of CRFs by incorporating features that depend on extra-sentential context.

In a linear-chain CRF, the conditional probability of a sequence of labels **y** = $y_{\{t=1...T\}}$ given a sequence of observed output **x** = $x_{\{t=1...T\}}$ and weight vector $\boldsymbol{\theta}$ = $\theta_{\{k=1...K\}}$ is given as follows:

$$P(\mathbf{y}|\mathbf{x}) = \frac{1}{Z} exp(\sum_{t=1}^{T} \sum_{k} \theta_k f_k(y_{t-1}, y_t, \mathbf{x}, t))$$

[3] A similar model which conditions on whether productions have previously occurred *within the same sentence*, however, improves F1 to 73.6%.

where Z is the partition function. The feature functions $f_k(y_{t-1}, y_t, \mathbf{x}, t)$ can depend on two neighbouring parses, the sentences in the sequence, and the position of the sentence in the sequence. Since our feature functions do not depend on the words or the time-step within the sequence, however, we will write $f_k(y_{t-1}, y_t)$ from now on.

We treat each document in the corpus as one CRF sequence, and each sentence as one time-step in the sequence. The label sequence then is the sequence of parses, and the outputs are the sentences in the document. Since there is a large number of parses possible for each sentence and correspondingly many possible states for each label variable, we restrict the possible label state-space by extracting the N-best parses from a generative parser, and rerank over the sequences of candidate parses thus provided. We use the generative parser of Petrov and Klein (2007), a state-splitting parser that uses an EM algorithm to find splits in the nonterminal symbols to maximize training data likelihood. We use the 20-best parses, with an oracle F1 of 94.96% on section 23.

To learn the weight vector, we employ a stochastic gradient ascent method on the conditional log likelihood, which has been shown to perform well for parsing tasks (Finkel et al., 2008). In standard gradient ascent, the conditional log likelihood with a L2 regularization term for a Gaussian prior for a training corpus of N sequences is

$$\begin{aligned} L(\boldsymbol{\theta}) = & \sum_{i=1}^{N} \sum_{t,k} \theta_k f_k(y_{t-1}^{(i)}, y_t^{(i)}) \\ & - \sum_{i=1}^{N} log\ Z^{(i)} - \sum_{k} \frac{\theta_k^2}{2\sigma^2} \end{aligned}$$

And the partial derivatives with respect to the weights are

$$\begin{aligned} \frac{\partial L}{\partial \theta_k} = & \sum_{i=1}^{N} \sum_{t} f_k(y_{t-1}^{(i)}, y_t^{(i)}) \\ & - \sum_{i=1}^{N} \sum_{t} \sum_{y,y'} f_k(y, y') P(y, y' | \mathbf{x}^{(i)}) \\ & - \sum_{k} \frac{\theta_k}{\sigma^2} \end{aligned}$$

The first term is the feature counts in the training data, and the second term is the feature expectations according to the current weight vector. The third term corresponds to the penalty to non-zero weight values imposed by regularization. The probabilities in the second term can be efficiently calculated by the CRF-version of the forward-backward algorithm.

In standard gradient ascent, we update the weight vector after iterating through the whole training corpus. Because this is computationally expensive, we instead use stochastic gradient ascent, which approximates the true gradient by the gradient calculated from a single sample from the training corpus. We thus do not have to sum over the training set in the above expressions. We also employ a learning rate multiplier on the gradient. Thus, the weight update for the ith encountered training sequence during training is

$$\begin{aligned} \boldsymbol{\theta} &= \boldsymbol{\theta} + \alpha_i \nabla L_{stochastic}(\boldsymbol{\theta}) \\ \alpha_i &= \eta \frac{\tau \times N}{\tau \times N + i} \end{aligned}$$

The learning rate function is modelled on the one used by Finkel et al. (2008). It is designed such that α_i is halved after τ passes through the training set.

We train the model by iterating through the training set in a randomly permuted order, updating the weight vector after each sequence. The parameters η, τ, and σ are tuned to the development set. The final settings we use are $\eta = 0.08$, $\tau = 5$, and $\sigma = 50$. We use sections 2–21 of the Penn Treebank WSJ for training, 22 for development, and 23 for testing. We conduct 20-fold cross validation to generate the N-best parses for the training set, as is standard for N-best rerankers.

To rerank, we do inference with the linear-chain CRF for the most likely sequence of parses using the Viterbi algorithm.

3.2 Feature Functions

We experiment with various feature functions that depend on the syntactic and lexical parallelism between y_{t-1} and y_t. We use the occurrence of a rule in y_t that occurred in y_{t-1} as a feature. Based on the results of the corpus analysis, the first representation

Generative	89.70

Table 4: Development set (section 22) results of various models that we trained. Italicized are the models we use for the test set.

we tried was to simply enumerate the (non-lexical) productions in y_t along with whether that production is found in y_{t-1}. However, we found that our most successful feature function is to consider overlaps in partial structures of productions.

Specifically, we decompose a tree into all of the nonlexical vertically and horizontally markovized subtrees. Each of the subtrees in y_t marked by whether that same subtree occurs in the previous tree is a feature. The simple production representation corresponds to a vertical markovization of 1 and a horizontal markovization of infinite. We found that a vertical markovization of 1 and a horizontal markovization of 2 produced the best results on our data. We will call this model the `phrasal` model.

This schema so far only considers local substructures of parse trees, without being informed by the lexical information found in the leaves of the tree. We try another schema which considers the POS tag sequences found in each subtree. A feature then is the node label of the root of the subtree with the POS tag sequence it dominates, again decomposed into sequences of length 2 by markovization. We will call this model the `lexical` model.

To extract features from this sequence, we consider the substructures in the second parse, and mark whether they are found in the first parse as well. We add edge markers to mark the beginning and end of constituents. See Figure 3 for an example of features extracted by the two models.

We will consider various ways of combining the two schemata above in the next section. In addition, we also add a feature corresponding to the scaled log probability of a parse tree derived from the generative parsing baseline. Scaling is necessary because of the large differences in the magnitude of the log probability for different sentences. The scaling formula that we found to work best is to scale the maximum log probability among the N-best candidate parses to be 1.0 and the minimum to be 0.0.

3.3 Results

We train the two models which make use of extra-sentential context described in the previous section, and use the model to parse the development and test set. We also trained a model which combines both sets of features, but we found that we get better performance by training the two models separately, then averaging the models by computing the respective averages of their features' weights. Thus, we use the model-averaged version of the models that consider context in the test set experiments. The generative parser forms the first baseline method to which we compare our results. We also train a reranker which makes use of the same features as we described above, but without marking whether each substructure occurs in the previous sentence. This is thus a reranking method which does not make use of the previous context. Again, we tried model averaging, but this produces less accurate parses on the

development set, so we use the jointly trained model on the test set. We will refer to this model as the context-ignorant or $-$Context model, as opposed to the previous context-aware or $+$Context model. The results of these experiments on the development set are shown in Table 4.

PARSEVAL results[4] on the development and test set are presented in Tables 5 and 6. We see that the reranked models outperform the generative baseline model in terms of F1, and that the reranked model that uses extra-sentential context outperforms the version that does not use extra-sentential context in the development set, but not in the test set. Using Bikel's randomized parsing evaluation comparator[5], we find that both reranking models outperform the baseline generative model to statistical significance for recall and precision. The context-ignorant reranker outperforms the context-aware reranker on recall ($p < 0.01$), but not on precision ($p = 0.42$). However, the context-aware model has the highest exact match scores in both the development and the test set.

The F1 result suggests two possibilities–either the context-aware model captures the same information as the context-ignorant model, but less effectively, or the two models capture different information about the parses. Two pieces of evidence point to the latter possibility. First, if the context-aware model were truly inferior, then we would expect it to outperform the context-ignorant model on almost no sentences. Otherwise, we would expect them to do well on different sentences. Table 7 shows that the context-aware model outperforms the context-ignorant model on nearly as many trees in the test section as the reverse. Second, if we hypothetically had an oracle that could determine whether the context-ignorant or the context-aware model would be more accurate on a sentence and if the two models were complementary to each other, we would expect to achieve a gain in F1 over the generative baseline which is roughly the sum of the gain achieved by each model separately. This is indeed the case, as we are able to achieve F1s of 91.23% and 90.89% on sections 22 and 23 respectively, roughly twice the improvement that the individual models obtain.

System	*Baseline*	*Best*	*Imp. (rel.)*
Dubey et al. (2006)	73.3	73.6	0.3 (1.1%)
Hogan (2007)	89.4	89.6	0.2 (1.9%)
This work	**89.5**	**89.9**	**0.4 (3.8%)**

Table 8: A comparison of parsers specialized to exploit intra- or extra-sentential syntactic parallelism on section 23 in terms of the generative baseline they compare themselves against, the best F1 their non-baseline models achieve, and the absolute and relative improvements.

aware model achieves over the generative baseline to that of other systems specialized to exploit intra- or extra-sentential parallelism. We achieve a greater improvement despite the fact that our generative baseline provides a higher level of performance, and is presumably thus more difficult to improve upon (Table 8). These systems do not compare themselves against a reranked model that does not use parallelism as we do in this work.

During inference, the Viterbi algorithm recovers the most probable sequence of parses, and this means that we are relying on the generative parser to provide the context (i.e. the previous parses) when analyzing any given sentence. We do another type of oracle analysis in which we provide the parser with the correct, manually annotated parse tree of the previous sentence when extracting features for the current sentence during training and parsing. This "perfect context" model achieves F1s of 90.42% and 90.00% on sections 22 and 23 respectively, which is comparable to the best results of our reranking models. This indicates that the lack of perfect contextual information is not a major obstacle to further improving parsing performance.

3.4 Analysis

We now analyze several specific cases in the development set in which the reranker makes correct use of contextual information. They concretely illustrate how context can improve parsing performance, and confirm our initial intuition that extra-sentential context can be useful for parsing. The sentence in (3) and (4) is one such case.

(3) *Generative/Context-ignorant*: (S (S A BMA spokesman said "runaway medical costs" have made health insurance "a significant challenge) ," and (S margins also have been pinched ...) (. .))

(4) *Context-aware*: (S (NP A BMA spokesman) (VP said "runaway medical costs" have made health insurance "a significant challenge," and margins also have been pinched ...) (. .))

The baseline and the context-ignorant models parse the sentence as a conjunction of two S clauses, misanalyzing the scope of what is said by the BMA spokesman to the first part of the conjunct. By analyzing the features and feature weight values extracted from the parse sequence, we determined that the context-aware reranker is able to correct the analysis of the scoping due to a parallelism in the syntactic structure. Specifically, the substructure $S \rightarrow VP.$ is present in both this sentence and the previous sentence of the reranked sequence, which also contains a reporting verb.

(5) (S (NP BMA Corp., Kansas City, Mo.,) (VP said it's weighing "strategic alternatives" ... and is contacting possible buyers ...) (. .))

As a second example, consider the following sentence.

(6) *Generative/Context-ignorant*: To achieve maximum liquidity and minimize price volatility, (NP either all markets) (VP should be open to trading or none).

(7) *Context-aware*: To achieve maximum liquidity and minimize price volatility, (CC either) (S (NP all markets) should be open to trading or none).

The original generative and context-ignorant parses posit that "either all markets" is a noun phrase, which is incorrect. Syntactic parallelism corrects this for two reasons. First, the reranker prefers a determiner to start an NP in a consistent context, as both surround sentences also contain this substructure. Also, the previous sentence also contains a conjunction CC followed by a S node under a S node, which the reranker prefers.

While these examples show contextual features to be useful for parsing coordinations, we also found context-awareness to be useful for other types of structural ambiguity such as PP attachment ambiguity. Notice that the method we employ to correct coordination errors is different from previous approaches which usually rely on lexical or syntactic similarity between conjuncts rather than between sentences. Our approach can thus broaden the range of sentences that can be usefully reranked. For example, there is little similarity between conjuncts to avail of in the second example (Sentences 6 and 7).

Based on these analyses, it appears that context awareness provides a source of information for parsing which is not available to context-ignorant parsers. We should thus consider integrating both types of features into the reranking parser to build on the advantages of each. Specifically, within-sentence features are most appropriate for lexical dependencies and some structural dependencies. Extra-sentential features, on the other hand, are appropriate for capturing the syntactic consistency effects as we have demonstrated in this paper.

4 Conclusions

In this paper, we have examined evidence for syntactic consistency between neighbouring sentences. First, we conducted a corpus analysis of the Penn Treebank WSJ, and shown that parallelism exists between sentences for productions with a variety of *LHS* types, generalizing previous results for noun phrase structure. Then, we explored a novel source of features for parsing informed by the extra-sentential context. We improved on the parsing accuracy over a generative baseline parser, and rival a similar reranking model that does not rely on extra-sentential context. By examining the subsets of the evaluation data on which each model performs best and also individual cases, we argue that context allows a type of structural ambiguity resolution not available to parsers which only rely on intra-sentential context.

Abstract

We present a unified view of two state-of-the-art non-projective dependency parsers, both approximate: the loopy belief propagation parser of Smith and Eisner (2008) and the relaxed linear program of Martins et al. (2009). By representing the model assumptions with a factor graph, we shed light on the optimization problems tackled in each method. We also propose a new aggressive online algorithm to learn the model parameters, which makes use of the underlying variational representation. The algorithm does not require a learning rate parameter and provides a single framework for a wide family of convex loss functions, including CRFs and structured SVMs. Experiments show state-of-the-art performance for 14 languages.

1 Introduction

Feature-rich discriminative models that break locality/independence assumptions can boost a parser's performance (McDonald et al., 2006; Huang, 2008; Finkel et al., 2008; Smith and Eisner, 2008; Martins et al., 2009; Koo and Collins, 2010). Often, inference with such models becomes computationally intractable, causing a demand for understanding and improving approximate parsing algorithms.

In this paper, we show a formal connection between two recently-proposed approximate inference techniques for non-projective dependency parsing: loopy belief propagation (Smith and Eisner, 2008) and linear programming relaxation (Martins et al., 2009). While those two parsers are differently motivated, we show that both correspond to inference in a factor graph, and both optimize objective functions over local approximations of the marginal polytope. The connection is made clear by writing the explicit declarative optimization problem underlying Smith and Eisner (2008) and by showing the factor graph underlying Martins et al. (2009). The success of both approaches parallels similar approximations in other fields, such as statistical image processing and error-correcting coding. Throughtout, we call these *turbo parsers*.[1]

Our contributions are not limited to dependency parsing: we present a general method for inference in factor graphs with hard constraints (§2), which extends some combinatorial factors considered by Smith and Eisner (2008). After presenting a geometric view of the variational approximations underlying message-passing algorithms (§3), and closing the gap between the two aforementioned parsers (§4), we consider the problem of learning the model parameters (§5). To this end, we propose an aggressive online algorithm that generalizes MIRA (Crammer et al., 2006) to arbitrary loss functions. We adopt a family of losses subsuming CRFs (Lafferty et al., 2001) and structured SVMs (Taskar et al., 2003; Tsochantaridis et al., 2004). Finally, we present a technique for including features not attested in the training data, allowing for richer models without substantial runtime costs. Our experiments (§6) show state-of-the-art performance on dependency parsing benchmarks.

[1] The name stems from "turbo codes," a class of high-performance error-correcting codes introduced by Berrou et al. (1993) for which decoding algorithms are equivalent to running belief propagation in a graph with loops (McEliece et al., 1998).

2 Structured Inference and Factor Graphs

Denote by $\mathcal{X}$ a set of input objects from which we want to infer some hidden structure conveyed in an output set $\mathcal{Y}$. Each input $x \in \mathcal{X}$ (e.g., a sentence) is associated with a set of candidate outputs $\mathcal{Y}(x) \subseteq \mathcal{Y}$ (e.g., parse trees); we are interested in the case where $\mathcal{Y}(x)$ is a large structured set.

Choices about the *representation* of elements of $\mathcal{Y}(x)$ play a major role in algorithm design. In many problems, the elements of $\mathcal{Y}(x)$ can be represented as discrete-valued vectors of the form $\mathbf{y} = \langle y_1, \ldots, y_I \rangle$, each y_i taking values in a label set $\mathcal{Y}_i$. For example, in unlabeled dependency parsing, I is the number of candidate dependency arcs (quadratic in the sentence length), and each $\mathcal{Y}_i = \{0, 1\}$. Of course, the y_i are highly interdependent.

Factor Graphs. Probabilistic models like CRFs (Lafferty et al., 2001) assume a factorization of the conditional distribution of Y,

$$\Pr(Y = \mathbf{y} \mid X = x) \ \propto \ \textstyle\prod_{C \in \mathcal{C}} \Psi_C(x, \mathbf{y}_C), \quad (1)$$

where each $C \subseteq \{1, \ldots, I\}$ is a *factor*, $\mathcal{C}$ is the set of factors, each $\mathbf{y}_C \triangleq \langle y_i \rangle_{i \in C}$ denotes a partial output assignment, and each Ψ_C is a nonnegative *potential function* that depends on the output only via its restriction to C. A *factor graph* (Kschischang et al., 2001) is a convenient representation for the factorization in Eq. 1: it is a bipartite graph $\mathcal{G}_x$ comprised of variable nodes $\{1, \ldots, I\}$ and factor nodes $C \in \mathcal{C}$, with an edge connecting the ith variable node and a factor node C iff $i \in C$. Hence, the factor graph $\mathcal{G}_x$ makes explicit the direct dependencies among the variables $\{y_1, \ldots, y_I\}$.

Factor graphs have been used for several NLP tasks, such as dependency parsing, segmentation, and co-reference resolution (Sutton et al., 2007; Smith and Eisner, 2008; McCallum et al., 2009).

Hard and Soft Constraint Factors. It may be the case that valid outputs are a *proper* subset of $\mathcal{Y}_1 \times \cdots \times \mathcal{Y}_I$—for example, in dependency parsing, the entries of the output vector $\mathbf{y}$ must jointly define a spanning tree. This requires *hard constraint factors* that rule out forbidden partial assignments by mapping them to zero potential values. See Table 1 for an inventory of hard constraint factors used in this paper. Factors that are not of this special kind are called *soft factors*, and have strictly positive potentials. We thus have a partition $\mathcal{C} = \mathcal{C}_{\text{hard}} \cup \mathcal{C}_{\text{soft}}$.

We let the soft factor potentials take the form $\Psi_C(x, \mathbf{y}_C) \triangleq \exp(\boldsymbol{\theta}^\top \boldsymbol{\phi}_C(x, \mathbf{y}_C))$, where $\boldsymbol{\theta} \in \mathbb{R}^d$ is a vector of parameters (shared across factors) and $\boldsymbol{\phi}_C(x, \mathbf{y}_C)$ is a local feature vector. The conditional distribution of Y (Eq. 1) thus becomes log-linear:

$$\Pr_{\boldsymbol{\theta}}(\mathbf{y}|x) = Z_x(\boldsymbol{\theta})^{-1} \exp(\boldsymbol{\theta}^\top \boldsymbol{\phi}(x, \mathbf{y})), \quad (2)$$

where $Z_x(\boldsymbol{\theta}) \triangleq \sum_{\mathbf{y}' \in \mathcal{Y}(x)} \exp(\boldsymbol{\theta}^\top \boldsymbol{\phi}(x, \mathbf{y}'))$ is the *partition function*, and the features decompose as:

$$\boldsymbol{\phi}(x, \mathbf{y}) \triangleq \textstyle\sum_{C \in \mathcal{C}_{\text{soft}}} \boldsymbol{\phi}_C(x, \mathbf{y}_C). \quad (3)$$

Dependency Parsing. Smith and Eisner (2008) proposed a factor graph representation for dependency parsing (Fig. 1). The graph has $O(n^2)$ variable nodes (n is the sentence length), one per candidate arc $a \triangleq \langle h, m \rangle$ linking a head h and modifier m. Outputs are binary, with $y_a = 1$ iff arc a belongs to the dependency tree. There is a hard factor TREE connected to all variables, that constrains the overall arc configurations to form a spanning tree. There is a unary soft factor per arc, whose log-potential reflects the score of that arc. There are also $O(n^3)$ pairwise factors; their log-potentials reflect the scores of *sibling* and *grandparent* arcs. These factors create loops, thus calling for approximate inference. Without them, the model is arc-factored, and exact inference in it is well studied: finding the most probable parse tree takes $O(n^3)$ time with the Chu-Liu-Edmonds algorithm (McDonald et al., 2005),[2] and computing posterior marginals for all arcs takes $O(n^3)$ time via the matrix-tree theorem (Smith and Smith, 2007; Koo et al., 2007).

Message-passing algorithms. In general factor graphs, both inference problems—obtaining the most probable output (the MAP) $\text{argmax}_{\mathbf{y} \in \mathcal{Y}(x)} \Pr_{\boldsymbol{\theta}}(\mathbf{y}|x)$, and computing the marginals $\Pr_{\boldsymbol{\theta}}(Y_i = y_i|x)$—can be addressed with the belief propagation (BP) algorithm (Pearl, 1988), which iteratively passes messages between variables and factors reflecting their local "beliefs."

[2] There is a faster but more involved $O(n^2)$ algorithm due to Tarjan (1977).

A general binary factor: $\Psi_C(v_1, \dots, v_n) = \begin{cases} 1 & v_1, \dots, v_n \in \mathcal{S}_C \\ 0 & \text{otherwise,} \end{cases}$ where $\mathcal{S}_C \subseteq \{0,1\}^n$. • Message-induced distribution: $\boldsymbol{\omega} \triangleq \langle m_{j \to C} \rangle_{j=1,\dots,n}$ • Partition function: $Z_C(\boldsymbol{\omega}) \triangleq \sum_{\langle v_1,\dots,v_n\rangle \in \mathcal{S}_C} \prod_{i=1}^n m_{i\to C}^{v_i}$ • Marginals: $\text{MARG}_i(\boldsymbol{\omega}) \triangleq \Pr_{\boldsymbol{\omega}}\{V_i = 1 \mid \langle V_1, \dots, V_n\rangle \in \mathcal{S}_C\}$ • Max-marginals: $\text{MAX-MARG}_{i,b}(\boldsymbol{\omega}) \triangleq \max_{\mathbf{v}\in\mathcal{S}_C} \Pr_{\boldsymbol{\omega}}(\mathbf{v} \mid v_i = b)$ • Sum-prod.: $m_{C\to i} = m_{i\to C}^{-1} \cdot \text{MARG}_i(\boldsymbol{\omega})/(1 - \text{MARG}_i(\boldsymbol{\omega}))$ • Max-prod.: $m_{C\to i} = m_{i\to C}^{-1} \cdot \text{MAX-MARG}_{i,1}(\boldsymbol{\omega})/\text{MAX-MARG}_{i,0}(\boldsymbol{\omega})$ • Local agreem. constr.: $\mathbf{z} \in \text{conv}\, \mathcal{S}_C$, where $\mathbf{z} = \langle \tau_i(1) \rangle_{i=1}^n$ • Entropy: $H_C = \log Z_C(\boldsymbol{\omega}) - \sum_{i=1}^n \text{MARG}_i(\boldsymbol{\omega}) \log m_{i\to C}$
TREE $\Psi_{\text{TREE}}(\langle y_a \rangle_{a\in A}) = \begin{cases} 1 & \mathbf{y} \in \mathcal{Y}_{\text{tree}} \text{ (i.e., } \{a \in A \mid y_a = 1\} \text{ is a directed spanning tree)} \\ 0 & \text{otherwise,} \end{cases}$ where A is the set of candidate arcs. • Partition function $Z_{\text{tree}}(\boldsymbol{\omega})$ and marginals $\langle \text{MARG}_a(\boldsymbol{\omega}) \rangle_{a\in A}$ computed via the matrix-tree theorem, with $\boldsymbol{\omega} \triangleq \langle m_{a\to\text{TREE}} \rangle_{a\in A}$ • Sum-prod.: $m_{\text{TREE}\to a} = m_{a\to\text{TREE}}^{-1} \cdot \text{MARG}_a(\boldsymbol{\omega})/(1 - \text{MARG}_a(\boldsymbol{\omega}))$ • Max-prod.: $m_{\text{TREE}\to a} = m_{a\to\text{TREE}}^{-1} \cdot \text{MAX-MARG}_{a,1}(\boldsymbol{\omega})/\text{MAX-MARG}_{a,0}(\boldsymbol{\omega})$, where $\text{MAX-MARG}_{a,b}(\boldsymbol{\omega}) \triangleq \max_{\mathbf{y}\in\mathcal{Y}_{\text{tree}}} \Pr_{\boldsymbol{\omega}}(\mathbf{y} \mid y_a = b)$ • Local agreem. constr.: $\mathbf{z} \in \mathcal{Z}_{\text{tree}}$, where $\mathcal{Z}_{\text{tree}} \triangleq \text{conv}\, \mathcal{Y}_{\text{tree}}$ is the arborescence polytope • Entropy: $H_{\text{tree}} = \log Z_{\text{tree}}(\boldsymbol{\omega}) - \sum_{a\in A} \text{MARG}_a(\boldsymbol{\omega}) \log m_{a\to\text{TREE}}$
XOR (“one-hot”) $\Psi_{\text{XOR}}(v_1, \dots, v_n) = \begin{cases} 1 & \sum_{i=1}^n v_i = 1 \\ 0 & \text{otherwise.} \end{cases}$ • Sum-prod.: $m_{\text{XOR}\to i} = \left(\sum_{j\neq i} m_{j\to\text{XOR}}\right)^{-1}$ • Max-prod.: $m_{\text{XOR}\to i} = \left(\max_{j\neq i} m_{j\to\text{XOR}}\right)^{-1}$ • Local agreem. constr.: $\sum_i z_i = 1$, $z_i \in [0,1], \forall i$ • $H_{\text{XOR}} = -\sum_i (m_{i\to\text{XOR}}/\sum_j m_{j\to\text{XOR}}) \log(m_{i\to\text{XOR}}/\sum_j m_{j\to\text{XOR}})$
OR $\Psi_{\text{OR}}(v_1, \dots, v_n) = \begin{cases} 1 & \sum_{i=1}^n v_i \geq 1 \\ 0 & \text{otherwise.} \end{cases}$ • Sum-prod.: $m_{\text{OR}\to i} = \left(1 - \prod_{j\neq i}(1 + m_{j\to\text{OR}})^{-1}\right)^{-1}$ • Max-prod.: $m_{\text{OR}\to i} = \max\{1, \min_{j\neq i} m_{j\to\text{OR}}^{-1}\}$ • Local agreem. constr.: $\sum_i z_i \geq 1$, $z_i \in [0,1], \forall i$
OR-WITH-OUTPUT $\Psi_{\text{OR-OUT}}(v_1, \dots, v_n) = \begin{cases} 1 & v_n = \bigvee_{i=1}^{n-1} v_i \\ 0 & \text{otherwise.} \end{cases}$ • Sum-prod.: $m_{\text{OR-OUT}\to i} = \begin{cases} \left(1 - (1 - m_{n\to\text{OR-OUT}}^{-1}) \prod_{j\neq i,n}(1 + m_{j\to\text{OR-OUT}})^{-1}\right)^{-1} & i < n \\ \prod_{j\neq n}(1 + m_{j\to\text{OR-OUT}}) - 1 & i = n. \end{cases}$ • Max-prod.: $m_{\text{OR-OUT}\to i} = \begin{cases} \min\left\{m_{n\to\text{OR-OUT}} \prod_{j\neq i,n} \max\{1, m_{j\to\text{OR-OUT}}\}, \max\{1, \min_{j\neq i,n} m_{j\to\text{OR-OUT}}^{-1}\}\right\} & i < n \\ \prod_{j\neq n} \max\{1, m_{j\to\text{OR-OUT}}\} \min\{1, \max_{j\neq n} m_{j\to\text{OR-OUT}}\} & i = n. \end{cases}$

Table 1: Hard constraint factors, their potentials, messages, and entropies. The top row shows expressions for a general binary factor: each outgoing message is computed from incoming *marginals* (in the sum-product case), or *max-marginals* (in the max-product case); the entropy of the factor (see §3) is computed from these marginals and the partition function; the local agreement constraints (§4) involve the *convex hull* of the set $\mathcal{S}_C$ of allowed configurations (see footnote 5). The TREE, XOR, OR and OR-WITH-OUTPUT factors allow tractable computation of all these quantities (rows 2–5). Two of these factors (TREE and XOR) had been proposed by Smith and Eisner (2008); we provide further information (max-product messages, entropies, and local agreement constraints). Factors OR and OR-WITH-OUTPUT are novel to the best of our knowledge. This inventory covers many cases, since the above formulae can be extended to the case where some inputs are *negated*: just replace the corresponding messages by their reciprocal, v_i by $1 - v_i$, etc. This allows building factors NAND (an OR factor with negated inputs), IMPLY (a 2-input OR with the first input negated), and XOR-WITH-OUTPUT (an XOR factor with the last input negated).

In sum-product BP, the messages take the form:[3]

$$M_{i\to C}(y_i) \propto \prod_{D\neq C} M_{D\to i}(y_i) \tag{4}$$

$$M_{C\to i}(y_i) \propto \sum_{\mathbf{y}_C\sim y_i} \Psi_C(\mathbf{y}_C) \prod_{j\neq i} M_{j\to C}(y_j). \tag{5}$$

In max-product BP, the summation in Eq. 5 is replaced by a maximization. Upon convergence, variable and factor beliefs are computed as:

$$\tau_i(y_i) \propto \prod_C M_{C\to i}(y_i) \tag{6}$$

$$\tau_C(\mathbf{y}_C) \propto \Psi_C(\mathbf{y}_C) \prod_i M_{i\to C}(y_i). \tag{7}$$

BP is exact when the factor graph is a tree: in the sum-product case, the beliefs in Eqs. 6–7 correspond to the true marginals, and in the max-product case, maximizing each $\tau_i(y_i)$ yields the MAP output. In graphs with loops, BP is an approximate method, not guaranteed to converge, nicknamed *loopy* BP. We highlight a variational perspective of loopy BP in §3; for now we consider algorithmic issues. Note that computing the factor-to-variable messages for each factor C (Eq. 5) requires a summation/maximization over exponentially many configurations. Fortunately, for all the hard constraint factors in rows 3–5 of Table 1, this computation can be done in linear time (and polynomial for the TREE factor)—this extends results presented in Smith and Eisner (2008).[4]

[3] We employ the standard $\sim$ notation, where a summation/maximization indexed by $\mathbf{y}_C \sim y_i$ means that it is over all $\mathbf{y}_C$ with the i-th component held fixed and set to y_i.

[4] The insight behind these speed-ups is that messages on binary-valued potentials can be expressed as $M_{C\to i}(y_i) \propto$

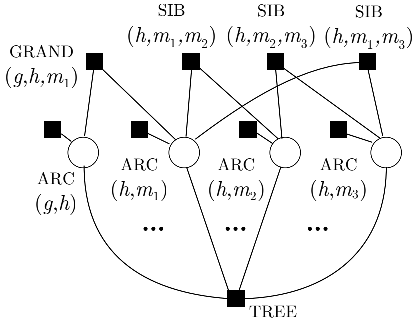

Figure 1: Factor graph corresponding to the dependency parsing model of Smith and Eisner (2008) with sibling and grandparent features. Circles denote variable nodes, and squares denote factor nodes. Note the loops created by the inclusion of pairwise factors (GRAND and SIB).

In Table 1 we present closed-form expressions for the factor-to-variable message ratios $m_{C\to i} \triangleq M_{C\to i}(1)/M_{C\to i}(0)$ in terms of their variable-to-factor counterparts $m_{i\to C} \triangleq M_{i\to C}(1)/M_{i\to C}(0)$; these ratios are all that is necessary when the variables are binary. Detailed derivations are presented in an extended version of this paper (Martins et al., 2010b).

3 Variational Representations

Let $\mathcal{P}_x \triangleq \{\Pr_{\boldsymbol{\theta}}(.|x) \mid \boldsymbol{\theta} \in \mathbb{R}^d\}$ be the family of all distributions of the form in Eq. 2. We next present an alternative parametrization for the distributions in $\mathcal{P}_x$ in terms of factor marginals. We will see that each distribution can be seen as a point in the so-called *marginal polytope* (Wainwright and Jordan, 2008); this will pave the way for the variational representations to be derived next.

Parts and Output Indicators. A *part* is a pair $\langle C, \mathbf{y}_C\rangle$, where C is a soft factor and $\mathbf{y}_C$ a partial output assignment. We let $\mathcal{R} = \{\langle C, \mathbf{y}_C\rangle \mid C \in \mathcal{C}_{\text{soft}}, \mathbf{y}_C \in \prod_{i\in C}\mathcal{Y}_i\}$ be the set of all parts. Given an output $\mathbf{y}' \in \mathcal{Y}(x)$, a part $\langle C, \mathbf{y}_C\rangle$ is said to be *active* if it locally matches the output, i.e., if $\mathbf{y}_C = \mathbf{y}'_C$. Any output $\mathbf{y}' \in \mathcal{Y}(x)$ can be mapped to a $|\mathcal{R}|$-dimensional binary vector $\boldsymbol{\chi}(\mathbf{y}')$ indicating which parts are active, i.e., $[\boldsymbol{\chi}(\mathbf{y}')]_{\langle C,\mathbf{y}_C\rangle} = 1$ if $\mathbf{y}_C = \mathbf{y}'_C$ and 0 otherwise; $\boldsymbol{\chi}(\mathbf{y}')$ is called the *output indicator vector*. This mapping allows decoupling the feature vector in Eq. 3 as the product of an input matrix and an output vector:

$$\boldsymbol{\phi}(x,\mathbf{y}) = \sum_{C\in\mathcal{C}_{\text{soft}}} \boldsymbol{\phi}_C(x,\mathbf{y}_C) = \mathbf{F}(x)\boldsymbol{\chi}(\mathbf{y}), \qquad (8)$$

where $\mathbf{F}(x)$ is a d-by-$|\mathcal{R}|$ matrix whose columns contain the part-local feature vectors $\boldsymbol{\phi}_C(x,\mathbf{y}_C)$. Observe, however, that not every vector in $\{0,1\}^{|\mathcal{R}|}$ corresponds necessarily to a valid output in $\mathcal{Y}(x)$.

Marginal Polytope. Moving to vector representations of outputs leads naturally to a geometric view of the problem. The *marginal polytope* is the convex hull[5] of all the "valid" output indicator vectors:

$$\mathcal{M}(\mathcal{G}_x) \triangleq \text{conv}\{\boldsymbol{\chi}(\mathbf{y}) \mid \mathbf{y} \in \mathcal{Y}(x)\}.$$

Note that $\mathcal{M}(\mathcal{G}_x)$ only depends on the factor graph $\mathcal{G}_x$ and the hard constraints (i.e., it is independent of the parameters $\boldsymbol{\theta}$). The importance of the marginal polytope stems from two facts: (i) each vertex of $\mathcal{M}(\mathcal{G}_x)$ corresponds to an output in $\mathcal{Y}(x)$; (ii) each point in $\mathcal{M}(\mathcal{G}_x)$ corresponds to a vector of marginal probabilities that is realizable by some distribution (not necessarily in $\mathcal{P}_x$) that factors according to $\mathcal{G}_x$.

Variational Representations. We now describe formally how the points in $\mathcal{M}(\mathcal{G}_x)$ are linked to the distributions in $\mathcal{P}_x$. We extend the "canonical overcomplete parametrization" case, studied by Wainwright and Jordan (2008), to our scenario (common in NLP), where arbitrary features are allowed and the parameters are *tied* (shared by all factors). Let $H(\Pr_{\boldsymbol{\theta}}(.|x)) \triangleq -\sum_{\mathbf{y}\in\mathcal{Y}(x)} \Pr_{\boldsymbol{\theta}}(\mathbf{y}|x)\log\Pr_{\boldsymbol{\theta}}(\mathbf{y}|x)$ denote the *entropy* of $\Pr_{\boldsymbol{\theta}}(.|x)$, and $E_{\boldsymbol{\theta}}[.]$ the expectation under $\Pr_{\boldsymbol{\theta}}(.|x)$. The component of $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{G}_x)$ indexed by part $\langle C, \mathbf{y}_C\rangle$ is denoted $\mu_C(\mathbf{y}_C)$.

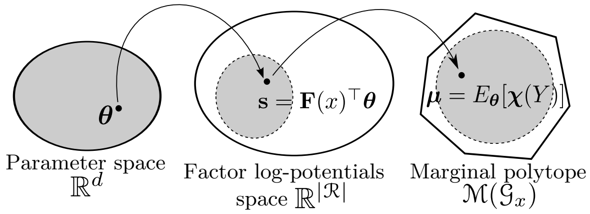
Proposition 1. *There is a map coupling each distribution* $\Pr_{\boldsymbol{\theta}}(.|x) \in \mathcal{P}_x$ *to a unique* $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{G}_x)$ *such that* $E_{\boldsymbol{\theta}}[\boldsymbol{\chi}(Y)] = \boldsymbol{\mu}$. *Define* $H(\boldsymbol{\mu}) \triangleq H(\Pr_{\boldsymbol{\theta}}(.|x))$ *if some* $\Pr_{\boldsymbol{\theta}}(.|x)$ *is coupled to* $\boldsymbol{\mu}$, *and* $H(\boldsymbol{\mu}) = -\infty$ *if no such* $\Pr_{\boldsymbol{\theta}}(.|x)$ *exists. Then:*

1. *The following variational representation for the log-partition function (mentioned in Eq. 2) holds:*

$$\log Z_x(\boldsymbol{\theta}) = \max_{\boldsymbol{\mu}\in\mathcal{M}(\mathcal{G}_x)} \boldsymbol{\theta}^\top \mathbf{F}(x)\boldsymbol{\mu} + H(\boldsymbol{\mu}). \qquad (9)$$

$\Pr\{\Psi_C(Y_C) = 1|Y_i = y_i\}$ and $M_{C\to i}(y_i) \propto \max_{\Psi_C(\mathbf{y}_C)=1}\Pr\{Y_C = \mathbf{y}_C|Y_i = y_i\}$, respectively for the sum-product and max-product cases; these probabilities are induced by the messages in Eq. 4: for an event $A \subseteq \prod_{i\in C}\mathcal{Y}_i$, $\Pr\{Y_C \in A\} \triangleq \sum_{\mathbf{y}_C}\mathbb{I}(\mathbf{y}_C \in A)\prod_{i\in C} M_{i\to C}(y_i)$.

[5] The convex hull of $\{\mathbf{z}_1, \ldots, \mathbf{z}_k\}$ is the set of points that can be written as $\sum_{i=1}^k \lambda_i \mathbf{z}_i$, where $\sum_{i=1}^k \lambda_i = 1$ and each $\lambda_i \geq 0$.



$\boldsymbol{\theta}$
$\mathbf{s} = \mathbf{F}(x)^\top\boldsymbol{\theta}$
$\boldsymbol{\mu} = E_{\boldsymbol{\theta}}[\boldsymbol{\chi}(Y)]$
Parameter space $\mathbb{R}^d$
Factor log-potentials space $\mathbb{R}^{|\mathcal{R}|}$
Marginal polytope $\mathcal{M}(\mathcal{G}_x)$

Figure 2: Dual parametrization of the distributions in $\mathcal{P}_x$. Our parameter space (left) is first linearly mapped to the space of factor log-potentials (middle). The latter is mapped to the marginal polytope $\mathcal{M}(\mathcal{G}_x)$ (right). In general only a subset of $\mathcal{M}(\mathcal{G}_x)$ is reachable from our parameter space. Any distribution in $\mathcal{P}_x$ can be parametrized by a vector $\boldsymbol{\theta} \in \mathbb{R}^d$ or by a point $\boldsymbol{\mu} \in \mathcal{M}(\mathcal{G}_x)$.

2. *The problem in Eq. 9 is convex and its solution is attained at the factor marginals, i.e., there is a maximizer $\bar{\boldsymbol{\mu}}$ s.t. $\bar{\mu}_C(\mathbf{y}_C) = \Pr_{\boldsymbol{\theta}}(Y_C = \mathbf{y}_C|x)$ for each $C \in \mathcal{C}$. The gradient of the log-partition function is $\nabla \log Z_x(\boldsymbol{\theta}) = \mathbf{F}(x)\bar{\boldsymbol{\mu}}$.*

3. *The MAP $\hat{\mathbf{y}} \triangleq \operatorname{argmax}_{\mathbf{y}\in\mathcal{Y}(x)} \Pr_{\boldsymbol{\theta}}(\mathbf{y}|x)$ can be obtained by solving the linear program*

$$\hat{\boldsymbol{\mu}} \triangleq \boldsymbol{\chi}(\hat{\mathbf{y}}) = \operatorname*{argmax}_{\boldsymbol{\mu}\in\mathcal{M}(\mathcal{G}_x)} \boldsymbol{\theta}^\top \mathbf{F}(x)\boldsymbol{\mu}. \tag{10}$$

A proof of this proposition can be found in Martins et al. (2010a). Fig. 2 provides an illustration of the dual parametrization implied by Prop. 1.

4 Approximate Inference & Turbo Parsing

We now show how the variational machinery just described relates to message-passing algorithms and provides a common framework for analyzing two recent dependency parsers. Later (§5), Prop. 1 is used constructively for learning the model parameters.

4.1 Loopy BP as a Variational Approximation

For general factor graphs with loops, the marginal polytope $\mathcal{M}(\mathcal{G}_x)$ cannot be compactly specified and the entropy term $H(\boldsymbol{\mu})$ lacks a closed form, rendering exact optimizations in Eqs. 9–10 intractable. A popular *approximate* algorithm for marginal inference is sum-product loopy BP, which passes messages as described in §2 and, upon convergence, computes beliefs via Eqs. 6–7. Were loopy BP exact, these beliefs would be the true marginals and hence a point in the marginal polytope $\mathcal{M}(\mathcal{G}_x)$. However, this need not be the case, as elucidated by Yedidia et al. (2001) and others, who first analyzed loopy BP from a variational perspective. The following two approximations underlie loopy BP:

- The marginal polytope $\mathcal{M}(\mathcal{G}_x)$ is approximated by the *local polytope* $\mathcal{L}(\mathcal{G}_x)$. This is an *outer* bound; its name derives from the fact that it only imposes *local agreement constraints* $\forall i, y_i \in \mathcal{Y}_i, C \in \mathcal{C}$:

$$\textstyle\sum_{y_i} \tau_i(y_i) = 1, \ \sum_{\mathbf{y}_C \sim y_i} \tau_C(\mathbf{y}_C) = \tau_i(y_i). \tag{11}$$

  Namely, it is characterized by $\mathcal{L}(\mathcal{G}_x) \triangleq \{\boldsymbol{\tau} \in \mathbb{R}_+^{|\mathcal{R}|} \mid \text{Eq. 11 holds } \forall i, y_i \in \mathcal{Y}_i, C \in \mathcal{C}\}$. The elements of $\mathcal{L}(\mathcal{G}_x)$ are called *pseudo-marginals*. Clearly, the true marginals satisfy Eq. 11, and therefore $\mathcal{M}(\mathcal{G}_x) \subseteq \mathcal{L}(\mathcal{G}_x)$.

- The entropy H is replaced by its *Bethe approximation* $H_{\text{Bethe}}(\boldsymbol{\tau}) \triangleq \sum_{i=1}^{I}(1 - d_i)H(\boldsymbol{\tau}_i) + \sum_{C\in\mathcal{C}} H(\boldsymbol{\tau}_C)$, where $d_i = |\{C \mid i \in C\}|$ is the number of factors connected to the ith variable, $H(\boldsymbol{\tau}_i) \triangleq -\sum_{y_i} \tau_i(y_i) \log \tau_i(y_i)$ and $H(\boldsymbol{\tau}_C) \triangleq -\sum_{\mathbf{y}_C} \tau_C(\mathbf{y}_C) \log \tau_C(\mathbf{y}_C)$.

Any stationary point of sum-product BP is a local optimum of the variational problem in Eq. 9 with $\mathcal{M}(\mathcal{G}_x)$ replaced by $\mathcal{L}(\mathcal{G}_x)$ and H replaced by H_{Bethe} (Yedidia et al., 2001). Note however that multiple optima may exist, since H_{Bethe} is not necessarily concave, and that BP may not converge.

Table 1 shows closed form expressions for the local agreement constraints and entropies of some hard-constraint factors, obtained by invoking Eq. 7 and observing that $\tau_C(\mathbf{y}_C)$ must be zero if configuration $\mathbf{y}_C$ is forbidden. See Martins et al. (2010b).

4.2 Two Dependency Turbo Parsers

We next present our main contribution: a formal connection between two recent approximate dependency parsers, which at first sight appear unrelated. Recall that (i) Smith and Eisner (2008) proposed a factor graph (Fig. 1) in which they run loopy BP, and that (ii) Martins et al. (2009) approximate parsing as the solution of a linear program. Here, we fill the blanks in the two approaches: we derive explicitly the variational problem addressed in (i) and we provide the underlying factor graph in (ii). This puts the two approaches side-by-side as approximate methods for marginal and MAP inference. Since both rely on "local" approximations (in the sense of Eq. 11) that ignore the loops in their graphical models, we dub them *turbo parsers* by analogy with error-correcting turbo decoders (see footnote 1).

Turbo Parser #1: Sum-Product Loopy BP. The factor graph depicted in Fig. 1—call it $\mathcal{G}_x$—includes pairwise soft factors connecting sibling and grandparent arcs.[6] We next characterize the local polytope $\mathcal{L}(\mathcal{G}_x)$ and the Bethe approximation H_{Bethe} inherent in Smith and Eisner's loopy BP algorithm.

Let A be the set of candidate arcs, and $P \subseteq A^2$ the set of pairs of arcs that have factors. Let $\boldsymbol{\tau} = \langle \boldsymbol{\tau}_A, \boldsymbol{\tau}_P \rangle$ with $\boldsymbol{\tau}_A = \langle \tau_a \rangle_{a \in A}$ and $\boldsymbol{\tau}_P = \langle \tau_{ab} \rangle_{\langle a,b \rangle \in P}$. Since all variables are binary, we may write, for each $a \in A$, $\tau_a(1) = z_a$ and $\tau_a(0) = 1 - z_a$, where z_a is a variable constrained to $[0,1]$. Let $\mathbf{z}_A \triangleq \langle z_a \rangle_{a \in A}$; the local agreement constraints at the TREE factor (see Table 1) are written as $\mathbf{z}_A \in \mathcal{Z}_{\text{tree}}(x)$, where $\mathcal{Z}_{\text{tree}}(x)$ is the *arborescence polytope*, i.e., the convex hull of all incidence vectors of dependency trees (Martins et al., 2009). It is straightforward to write a contingency table and obtain the following local agreement constraints at the pairwise factors:

$$\begin{aligned} \tau_{ab}(1,1) &= z_{ab}, & \tau_{ab}(0,0) &= 1 - z_a - z_b + z_{ab} \\ \tau_{ab}(1,0) &= z_a - z_{ab}, & \tau_{ab}(0,1) &= z_b - z_{ab}. \end{aligned}$$

Noting that all these pseudo-marginals are constrained to the unit interval, one can get rid of all variables τ_{ab} and write everything as

$$\begin{aligned} &z_a \in [0,1], \quad z_b \in [0,1], \quad z_{ab} \in [0,1], \\ &z_{ab} \leq z_a, \quad\;\; z_{ab} \leq z_b, \quad\;\; z_{ab} \geq z_a + z_b - 1, \end{aligned} \tag{12}$$

inequalities which, along with $\mathbf{z}_A \in \mathcal{Z}_{\text{tree}}(x)$, define the local polytope $\mathcal{L}(\mathcal{G}_x)$. As for the factor entropies, start by noting that the TREE-factor entropy H_{tree} can be obtained in closed form by computing the marginals $\bar{\mathbf{z}}_A$ and the partition function $Z_x(\boldsymbol{\theta})$ (via the matrix-tree theorem) and recalling the variational representation in Eq. 9, yielding $H_{\text{tree}} = \log Z_x(\boldsymbol{\theta}) - \boldsymbol{\theta}^\top \mathbf{F}(x)\bar{\mathbf{z}}_A$. Some algebra allows writing the overall Bethe entropy approximation as:

$$H_{\text{Bethe}}(\boldsymbol{\tau}) = H_{\text{tree}}(\mathbf{z}_A) - \sum_{\langle a,b \rangle \in P} I_{a;b}(z_a, z_b, z_{ab}), \tag{13}$$

where we introduced the mutual information associated with each pairwise factor, $I_{a;b}(z_a, z_b, z_{ab}) = \sum_{y_a, y_b} \tau_{ab}(y_a, y_b) \log \frac{\tau_{ab}(y_a,y_b)}{\tau_a(y_a)\tau_b(y_b)}$. The approximate variational expression becomes $\log Z_x(\boldsymbol{\theta}) \approx$

$$\begin{aligned} \max_{\mathbf{z}} \quad & \boldsymbol{\theta}^\top \mathbf{F}(x)\mathbf{z} + H_{\text{tree}}(\mathbf{z}_A) - \sum_{\langle a,b \rangle \in P} I_{a;b}(z_a, z_b, z_{ab}) \\ \text{s.t.} \quad & z_{ab} \leq z_a, \quad z_{ab} \leq z_b, \\ & z_{ab} \geq z_a + z_b - 1, \quad \forall \langle a,b \rangle \in P, \\ & \mathbf{z}_A \in \mathcal{Z}_{\text{tree}}, \end{aligned} \tag{14}$$

whose maximizer corresponds to the beliefs returned by the Smith and Eisner's loopy BP algorithm (if it converges).

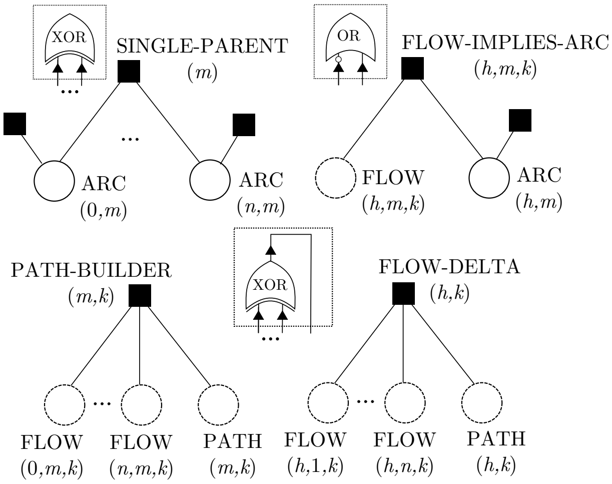


Figure 3: Details of the factor graph underlying the parser of Martins et al. (2009). Dashed circles represent auxiliary variables. See text and Table 1.

Turbo Parser #2: LP-Relaxed MAP. We now turn to the concise integer LP formulation of Martins et al. (2009). The formulation is exact but NP-hard, and so an LP relaxation is made there by dropping the integer constraints. We next construct a factor graph $\mathcal{G}'_x$ and show that the LP relaxation corresponds to an optimization of the form in Eq. 10, with the marginal polytope $\mathcal{M}(\mathcal{G}'_x)$ replaced by $\mathcal{L}(\mathcal{G}'_x)$.

$\mathcal{G}'_x$ includes the following auxiliary variable nodes: *path variables* $\langle p_{ij} \rangle_{i=0,\ldots,n,j=1,\ldots,n}$, which indicate whether word j descends from i in the dependency tree, and *flow variables* $\langle f_a^k \rangle_{a \in A, k=1,\ldots,n}$, which evaluate to 1 iff arc a "carries flow" to k, i.e., iff there is a path from the root to k that passes through a. We need to seed these variables imposing

$$p_{0k} = p_{kk} = 1, \forall k, \quad f^h_{\langle h,m \rangle} = 0, \forall h, m; \tag{15}$$

i.e., any word descends from the root and from itself, and arcs leaving a word carry no flow to that

[6] Smith and Eisner (2008) also proposed other variants with more factors, which we omit for brevity.

word. This can be done with unary hard constraint factors. We then replace the TREE factor in Fig. 1 by the factors shown in Fig. 3:

- $O(n)$ XOR factors, each connecting all arc variables of the form $\{\langle h,m\rangle\}_{h=0,\ldots,n}$. These ensure that each word has exactly one parent. Each factor yields a local agreement constraint (see Table 1):
$$\textstyle\sum_{h=0}^{n} z_{\langle h,m\rangle} = 1, \quad m \in \{1,\ldots,n\} \qquad (16)$$
- $O(n^3)$ IMPLY factors, each expressing that if an arc carries flow, then that arc *must* be active. Such factors are OR factors with the first input negated, hence, the local agreement constraints are:
$$f_a^k \leq z_a, \quad a \in A, k \in \{1,\ldots,n\}. \qquad (17)$$
- $O(n^2)$ XOR-WITH-OUTPUT factors, which impose the constraint that each path variable p_{mk} is active if and only if exactly one incoming arc in $\{\langle h,m\rangle\}_{h=0,\ldots,n}$ carries flow to k. Such factors are XOR factors with the last input negated, and hence their local constraints are:
$$p_{mk} = \textstyle\sum_{h=0}^{n} f_{\langle h,m\rangle}^k, \quad m,k \in \{1,\ldots,n\} \quad (18)$$
- $O(n^2)$ XOR-WITH-OUTPUT factors to impose the constraint that words don't consume other words' commodities; i.e., if $h \neq k$ and $k \neq 0$, then there is a path from h to k iff exactly one outgoing arc in $\{\langle h,m\rangle\}_{m=1,\ldots,n}$ carries flow to k:
$$p_{hk} = \textstyle\sum_{m=1}^{n} f_{\langle h,m\rangle}^k, \ h,k \in \{0,\ldots,n\}, \ k \notin \{0,h\}. \qquad (19)$$

$\mathcal{L}(\mathcal{G}'_x)$ is thus defined by the constraints in Eq. 12 and 15–19. The approximate MAP problem, that replaces $\mathcal{M}(\mathcal{G}'_x)$ by $\mathcal{L}(\mathcal{G}'_x)$ in Eq. 10, thus becomes:

$$\begin{array}{ll} \max_{\mathbf{z},\mathbf{f},\mathbf{p}} & \boldsymbol{\theta}^\top \mathbf{F}(x)\mathbf{z} \\ \text{s.t.} & \text{Eqs. 12 and 15–19 are satisfied.} \end{array} \qquad (20)$$

This is exactly the LP relaxation considered by Martins et al. (2009) in their multi-commodity flow model, for the configuration with siblings and grandparent features.[7] They also considered a configuration with non-projectivity features—which fire if an arc is non-projective.[8] That configuration can also be obtained here if variables $\{n_{\langle h,m\rangle}\}$ are added to indicate non-projective arcs and OR-WITH-OUTPUT hard constraint factors are inserted to enforce $n_{\langle h,m\rangle} = z_{\langle h,m\rangle} \wedge \bigvee_{\min(h,m)<j<\min(h,m)} \neg p_{hj}$. Details are omitted for space.

In sum, although the approaches of Smith and Eisner (2008) and Martins et al. (2009) look very different, in reality both are variational approximations emanating from Prop. 1, respectively for marginal and MAP inference. However, they operate on distinct factor graphs, respectively Figs. 1 and 3.[9]

5 Online Learning

Our learning algorithm is presented in Alg. 1. It is a generalized online learner that tackles ℓ_2-regularized empirical risk minimization of the form

$$\min_{\boldsymbol{\theta}\in\mathbb{R}^d} \tfrac{\lambda}{2}\|\boldsymbol{\theta}\|^2 + \tfrac{1}{m}\textstyle\sum_{i=1}^{m} L(\boldsymbol{\theta}; x_i, \mathbf{y}_i), \qquad (21)$$

where each $\langle x_i, \mathbf{y}_i\rangle$ is a training example, $\lambda \geq 0$ is the regularization constant, and $L(\boldsymbol{\theta}; x, \mathbf{y})$ is a nonnegative convex loss. Examples include the logistic loss used in CRFs ($-\log \Pr_{\boldsymbol{\theta}}(\mathbf{y}|x)$) and the hinge loss of structured SVMs ($\max_{\mathbf{y}'\in\mathcal{Y}(x)} \boldsymbol{\theta}^\top(\boldsymbol{\phi}(x,\mathbf{y}') - \boldsymbol{\phi}(x,\mathbf{y})) + \ell(\mathbf{y}',\mathbf{y})$ for some cost function ℓ). These are both special cases of the family defined in Fig. 4, which also includes the structured perceptron's loss ($\beta \to \infty$, $\gamma = 0$) and the softmax-margin loss of Gimpel and Smith (2010; $\beta = \gamma = 1$).

Alg. 1 is closely related to stochastic or online gradient descent methods, but with the key advantage of not needing a learning rate hyperparameter. We sketch the derivation of Alg. 1; full details can be found in Martins et al. (2010a). On the tth round, one example $\langle x_t, \mathbf{y}_t\rangle$ is considered. We seek to solve

$$\begin{array}{ll} \min_{\boldsymbol{\theta},\xi} & \frac{\lambda m}{2}\|\boldsymbol{\theta} - \boldsymbol{\theta}_t\|^2 + \xi \\ \text{s.t.} & L(\boldsymbol{\theta}; x_t, \mathbf{y}_t) \leq \xi, \quad \xi \geq 0, \end{array} \qquad (23)$$

[7] To be precise, the constraints of Martins et al. (2009) are recovered after eliminating the path variables, via Eqs. 18–19.

[8] An arc $\langle h,m\rangle$ is non-projective if there is some word in its span not descending from h (Kahane et al., 1998).

[9] Given what was just exposed, it seems appealing to try max-product loopy BP on the factor graph of Fig. 1, or sum-product loopy BP on the one in Fig. 3. Both attempts present serious challenges: the former requires computing messages sent by the tree factor, which requires $O(n^2)$ calls to the Chu-Liu-Edmonds algorithm and hence $O(n^5)$ time. No obvious strategy seems to exist for simultaneous computation of all messages, unlike in the sum-product case. The latter is even more challenging, as standard sum-product loopy BP has serious issues in the factor graph of Fig. 3; we construct in Martins et al. (2010b) a simple example with a very poor Bethe approximation. This might be fixed by using other variants of sum-product BP, e.g., ones in which the entropy approximation is concave.

$$L_{\beta,\gamma}(\boldsymbol{\theta}; x, \mathbf{y}) \triangleq \tfrac{1}{\beta} \log \textstyle\sum_{\mathbf{y}' \in \mathcal{Y}(x)} \exp \left[\beta \Big(\boldsymbol{\theta}^\top \big(\boldsymbol{\phi}(x, \mathbf{y}') - \boldsymbol{\phi}(x, \mathbf{y}) \big) + \gamma \ell(\mathbf{y}', \mathbf{y}) \Big) \right] \tag{22}$$

Figure 4: A family of loss functions including as particular cases the ones used in CRFs, structured SVMs, and the structured perceptron. The hyperparameter β is the analogue of the inverse temperature in a Gibbs distribution, while γ scales the cost. For any choice of $\beta > 0$ and $\gamma \geq 0$, the resulting loss function is convex in $\boldsymbol{\theta}$, since, up to a scale factor, it is the composition of the (convex) log-sum-exp function with an affine map.

Algorithm 1 Aggressive Online Learning

```
1:  Input: ${\{\langle x_i, \mathbf{y}_i \rangle\}}_{i=1}^m$, $\lambda$, number of epochs $K$
2:  Initialize $\boldsymbol{\theta}_1 \leftarrow \mathbf{0}$; set $T = mK$
3:  for $t = 1$ to $T$ do
4:      Receive instance $\langle x_t, \mathbf{y}_t \rangle$ and set $\boldsymbol{\mu}_t = \boldsymbol{\chi}(\mathbf{y}_t)$
5:      Solve Eq. 24 to obtain $\bar{\boldsymbol{\mu}}_t$ and $L_{\beta,\gamma}(\boldsymbol{\theta}_t, x_t, \mathbf{y}_t)$
6:      Compute $\nabla L_{\beta,\gamma}(\boldsymbol{\theta}_t, x_t, \mathbf{y}_t) = \mathbf{F}(x_t)(\bar{\boldsymbol{\mu}}_t - \boldsymbol{\mu}_t)$
7:      Compute $\eta_t = \min \left\{ \frac{1}{\lambda m}, \frac{L_{\beta,\gamma}(\boldsymbol{\theta}_t; x_t, \mathbf{y}_t)}{\|\nabla L_{\beta,\gamma}(\boldsymbol{\theta}_t; x_t, \mathbf{y}_t)\|^2} \right\}$
8:      Return $\boldsymbol{\theta}_{t+1} = \boldsymbol{\theta}_t - \eta_t \nabla L_{\beta,\gamma}(\boldsymbol{\theta}_t; x_t, \mathbf{y}_t)$
9:  end for
10: Return the averaged model $\bar{\boldsymbol{\theta}} \leftarrow \frac{1}{T} \sum_{t=1}^T \boldsymbol{\theta}_t$.
```

which trades off conservativeness (stay close to the most recent solution $\boldsymbol{\theta}_t$) and correctness (keep the loss small). Alg. 1's lines 7–8 are the result of taking the first-order Taylor approximation of L around $\boldsymbol{\theta}_t$, which yields the lower bound $L(\boldsymbol{\theta}; x_t, \mathbf{y}_t) \geq L(\boldsymbol{\theta}_t; x_t, \mathbf{y}_t) + (\boldsymbol{\theta} - \boldsymbol{\theta}_t)^\top \nabla L(\boldsymbol{\theta}_t; x_t, \mathbf{y}_t)$, and plugging that linear approximation into the constraint of Eq. 23, which gives a simple Euclidean projection problem (with slack) with a closed-form solution.

The online updating requires evaluating the loss and computing its gradient. Both quantities can be computed using the variational expression in Prop. 1, for any loss $L_{\beta,\gamma}(\boldsymbol{\theta}; x, \mathbf{y})$ in Fig. 4.[10] Our only assumption is that the cost function $\ell(\mathbf{y}', \mathbf{y})$ can be written as a sum over factor-local costs; letting $\boldsymbol{\mu} = \boldsymbol{\chi}(\mathbf{y})$ and $\boldsymbol{\mu}' = \boldsymbol{\chi}(\mathbf{y}')$, this implies $\ell(\mathbf{y}', \mathbf{y}) = \mathbf{p}^\top \boldsymbol{\mu}' + q$ for some $\mathbf{p}$ and q which are constant with respect to $\boldsymbol{\mu}'$.[11] Under this assumption, $L_{\beta,\gamma}(\boldsymbol{\theta}; x, \mathbf{y})$ becomes expressible in terms of the log-partition function of a distribution whose log-potentials are set to $\beta(\mathbf{F}(x)^\top \boldsymbol{\theta} + \gamma \mathbf{p})$. From Eq. 9 and after some algebra, we finally obtain $L_{\beta,\gamma}(\boldsymbol{\theta}; x, \mathbf{y}) =$

$$\max_{\boldsymbol{\mu}' \in \mathcal{M}(\mathcal{G}_x)} \boldsymbol{\theta}^\top \mathbf{F}(x)(\boldsymbol{\mu}' - \boldsymbol{\mu}) + \frac{1}{\beta} H(\boldsymbol{\mu}') + \gamma(\mathbf{p}^\top \boldsymbol{\mu}' + q). \tag{24}$$

Let $\bar{\boldsymbol{\mu}}$ be a maximizer in Eq. 24; from the second statement of Prop. 1 we obtain $\nabla L_{\beta,\gamma}(\boldsymbol{\theta}; x, \mathbf{y}) = \mathbf{F}(x)(\bar{\boldsymbol{\mu}} - \boldsymbol{\mu})$. When the inference problem in Eq. 24 is intractable, approximate message-passing algorithms like loopy BP still allow us to obtain approximations of the loss $L_{\beta,\gamma}$ and its gradient.

For the hinge loss, we arrive precisely at the max-loss variant of 1-best MIRA (Crammer et al., 2006). For the logistic loss, we arrive at a new online learning algorithm for CRFs that resembles stochastic gradient descent but with an automatic step size that follows from our variational representation.

Unsupported Features. As datasets grow, so do the sets of features, creating further computational challenges. Often only "supported" features—those observed in the training data—are included, and even those are commonly eliminated when their frequencies fall below a threshold. Important information may be lost as a result of these expedient choices. Formally, the *supported feature set* is $\mathcal{F}_{\text{supp}} \triangleq \bigcup_{i=1}^m \operatorname{supp} \boldsymbol{\phi}(x_i, \mathbf{y}_i)$, where $\operatorname{supp} \mathbf{u} \triangleq \{j \mid u_j \neq 0\}$ denotes the *support* of vector $\mathbf{u}$. $\mathcal{F}_{\text{supp}}$ is a subset of the *complete* feature set, comprised of those features that occur in some candidate output, $\mathcal{F}_{\text{comp}} \triangleq \bigcup_{i=1}^m \bigcup_{\mathbf{y}'_i \in \mathcal{Y}(x_i)} \operatorname{supp} \boldsymbol{\phi}(x_i, \mathbf{y}'_i)$. Features in $\mathcal{F}_{\text{comp}} \setminus \mathcal{F}_{\text{supp}}$ are called *unsupported*.

Sha and Pereira (2003) have shown that training a CRF-based shallow parser with the complete feature set may improve performance (over the supported one), at the cost of 4.6 times more features. Dependency parsing has a much higher ratio (around 20 for bilexical word-word features, as estimated in the Penn Treebank), due to the quadratic or faster growth of the number of parts, of which only a few are active in a legal output. We propose a simple strategy for handling $\mathcal{F}_{\text{comp}}$ efficiently, which can be applied for those losses in Fig. 4 where $\beta = \infty$. (e.g., the structured SVM and perceptron). Our procedure is the following: keep an active set $\mathcal{F}$ contain-

[10] Our description also applies to the (non-differentiable) hinge loss case, when $\beta \rightarrow \infty$, if we replace all instances of "the gradient" in the text by "a subgradient."

[11] For the Hamming cost, this holds with $\mathbf{p} = \mathbf{1} - 2\boldsymbol{\mu}$ and $q = \mathbf{1}^\top \boldsymbol{\mu}$. See Taskar et al. (2006) for other examples.

Table 2: Unlabeled attachment scores, ignoring punctuation. The leftmost columns show the performance of arc-factored and second-order models for the CRF and SVM losses, after 10 epochs with $1/(\lambda m) = 0.001$ (tuned on the English Non-Proj. dev.-set). The rightmost columns refer to a model to which non-projectivity features were added, trained under the SVM loss, that handles the *complete* feature set. Shown is the total number of features instantiated, the multiplicative factor w.r.t. the number of supported features, and the accuracies (in parenthesis, we display the difference w.r.t. a model trained with the supported features only). Entries marked with † are the highest reported in the literature, to the best of our knowledge, beating (sometimes slightly) McDonald et al. (2006), Martins et al. (2008), Martins et al. (2009), and, in the case of English Proj., also the third-order parser of Koo and Collins (2010), which achieves 93.04% on that dataset (their experiments in Czech are not comparable, since the datasets are different).

ing all features that have been instantiated in Alg. 1. At each round, run lines 4–5 as usual, using only features in $\mathcal{F}$. Since the other features have not been used before, they have a zero weight, hence can be ignored. When $\beta = \infty$, the variational problem in Eq. 24 consists of a MAP computation and the solution corresponds to one output $\hat{\mathbf{y}}_t \in \mathcal{Y}(x_t)$. Only the parts that are active in $\hat{\mathbf{y}}_t$ but not in $\mathbf{y}_t$, or vice-versa, will have features that might receive a nonzero update. Those parts are reexamined for new features and the active set $\mathcal{F}$ is updated accordingly.

6 Experiments

We trained non-projective dependency parsers for 14 languages, using datasets from the CoNLL-X shared task (Buchholz and Marsi, 2006) and two datasets for English: one from the CoNLL-2008 shared task (Surdeanu et al., 2008), which contains non-projective arcs, and another derived from the Penn Treebank applying the standard head rules of Yamada and Matsumoto (2003), in which all parse trees are projective.[12] We implemented Alg. 1, which handles any loss function $L_{\beta,\gamma}$.[13] When $\beta < \infty$, Turbo Parser #1 and the loopy BP algorithm of Smith and Eisner (2008) is used; otherwise, Turbo Parser #2 is used and the LP relaxation is solved with CPLEX. In both cases, we employed the same pruning strategy as Martins et al. (2009).

Two different feature configurations were first tried: an arc-factored model and a model with second-order features (siblings and grandparents). We used the same arc-factored features as McDonald et al. (2005) and second-order features that conjoin words and lemmas (at most two), parts-of-speech tags, and (if available) morphological information; this was the same set of features as in Martins et al. (2009). Table 2 shows the results obtained in both configurations, for CRF and SVM loss functions. While in the arc-factored case performance is similar, in second-order models there seems to be a consistent gain when the SVM loss is used. There are two possible reasons: first, SVMs take the cost function into consideration; second, Turbo Parser #2 is less approximate than Turbo Parser #1, since only the marginal polytope is approximated (the entropy function is not involved).

[12] We used the provided train/test splits for all datasets. For English, we used the standard test partitions (section 23 of the Wall Street Journal). We did not exploit the fact that some datasets only contain projective trees and have unique roots.

[13] The code is available at `http://www.ark.cs.cmu.edu/TurboParser`.

β	1	1	1	1	3	5	∞
γ	0 (CRF)	1	3	5	1	1	1 (SVM)
ARC-F.	90.15	90.41	90.38	90.53	90.80	90.83	90.66
2 ORD.	91.08	91.85	91.89	91.51	92.04	91.98	91.79

Table 3: Varying β and γ: neither the CRF nor the SVM is optimal. Results are UAS on the English Non-Projective dataset, with λ tuned with dev.-set validation.

The loopy BP algorithm managed to converge for nearly all sentences (with message damping). The last three columns show the beneficial effect of unsupported features for the SVM case (with a more powerful model with non-projectivity features). For most languages, unsupported features convey helpful information, which can be used with little extra cost (on average, 2.5 times more features are instantiated). A combination of the techniques discussed here yields parsers that are in line with very strong competitors—for example, the parser of Koo and Collins (2010), which is exact, third-order, and constrains the outputs to be projective, does not outperform ours on the projective English dataset.[14]

Finally, Table 3 shows results obtained for different settings of β and γ. Interestingly, we observe that higher scores are obtained for loss functions that are "between" SVMs and CRFs.

7 Related Work

There has been recent work studying efficient computation of messages in combinatorial factors: bipartite matchings (Duchi et al., 2007), projective and non-projective arborescences (Smith and Eisner, 2008), as well as high order factors with count-based potentials (Tarlow et al., 2010), among others. Some of our combinatorial factors (OR, OR-WITH-OUTPUT) and the analogous entropy computations were never considered, to the best of our knowledge.

Prop. 1 appears in Wainwright and Jordan (2008) for canonical overcomplete models; we adapt it here for models with shared features. We rely on the variational interpretation of loopy BP, due to Yedidia et al. (2001), to derive the objective being optimized by Smith and Eisner's loopy BP parser.

Independently of our work, Koo et al. (2010) recently proposed an efficient dual decomposition method to solve an LP problem similar (but not equal) to the one in Eq. 20,[15] with excellent parsing performance. Their parser is also an instance of a turbo parser since it relies on a local approximation of a marginal polytope. While one can also use dual decomposition to address our MAP problem, the fact that our model does not decompose as nicely as the one in Koo et al. (2010) would likely result in slower convergence.

8 Conclusion

We presented a unified view of two recent approximate dependency parsers, by stating their underlying factor graphs and by deriving the variational problems that they address. We introduced new hard constraint factors, along with formulae for their messages, local belief constraints, and entropies. We provided an aggressive online algorithm for training the models with a broad family of losses.

There are several possible directions for future work. Recent progress in message-passing algorithms yield "convexified" Bethe approximations that can be used for marginal inference (Wainwright et al., 2005), and provably convergent max-product variants that solve the relaxed LP (Globerson and Jaakkola, 2008). Other parsing formalisms can be handled with the inventory of factors shown here—among them, phrase-structure parsing.

A. were supported by the FET programme (EU FP7), under the SIMBAD project (contract 213250).

[14] This might be due to the fact that Koo and Collins (2010) trained with the perceptron algorithm and did not use unsupported features. Experiments plugging the perceptron loss ($\beta \to \infty, \gamma \to 0$) into Alg. 1 yielded worse performance than with the hinge loss.

[15] The difference is that the model of Koo et al. (2010) includes features that depend on *consecutive* siblings—making it decompose into subproblems amenable to dynamic programming—while we have factors for *all pairs* of siblings.

Abstract

In this paper, we develop multilingual supervised latent Dirichlet allocation (MLSLDA), a probabilistic generative model that allows insights gleaned from one language's data to inform how the model captures properties of other languages. MLSLDA accomplishes this by jointly modeling two aspects of text: how multilingual concepts are clustered into thematically coherent topics and how topics associated with text connect to an observed regression variable (such as ratings on a sentiment scale). Concepts are represented in a general hierarchical framework that is flexible enough to express semantic ontologies, dictionaries, clustering constraints, and, as a special, degenerate case, conventional topic models. Both the topics and the regression are discovered via posterior inference from corpora. We show MLSLDA can build topics that are consistent across languages, discover sensible bilingual lexical correspondences, and leverage multilingual corpora to better predict sentiment.

Sentiment analysis (Pang and Lee, 2008) offers the promise of automatically discerning how people feel about a product, person, organization, or issue based on what they write online, which is potentially of great value to businesses and other organizations. However, the vast majority of sentiment resources and algorithms are limited to a single language, usually English (Wilson, 2008; Baccianella and Sebastiani, 2010). Since no single language captures a majority of the content online, adopting such a limited approach in an increasingly global community risks missing important details and trends that might only be available when text in multiple languages is taken into account.

Up to this point, multiple languages have been addressed in sentiment analysis primarily by transferring knowledge from a resource-rich language to a less rich language (Banea et al., 2008), or by ignoring differences in languages via translation into English (Denecke, 2008). These approaches are limited to a view of sentiment that takes place through an English-centric lens, and they ignore the potential to share information between languages. Ideally, learning sentiment cues holistically, *across* languages, would result in a richer and more globally consistent picture.

In this paper, we introduce Multilingual Supervised Latent Dirichlet Allocation (MLSLDA), a model for sentiment analysis on a multilingual corpus. MLSLDA discovers a consistent, unified picture of sentiment across multiple languages by learning "topics," probabilistic partitions of the vocabulary that are consistent in terms of both meaning and relevance to observed sentiment. Our approach makes few assumptions about available resources, requiring neither parallel corpora nor machine translation.

The rest of the paper proceeds as follows. In Section 1, we describe the probabilistic tools that we use to create consistent topics bridging across languages and the MLSLDA model. In Section 2, we present the inference process. We discuss our set of semantic bridges between languages in Section 3, and our experiments in Section 4 demonstrate that this approach functions as an effective multilingual topic model, discovers sentiment-biased topics, and uses multilingual corpora to make better sentiment predictions across languages. Sections 5 and 6 discuss related research and discusses future work, respectively.

1 Predictions from Multilingual Topics

As its name suggests, MLSLDA is an extension of Latent Dirichlet allocation (LDA) (Blei et al., 2003), a modeling approach that takes a corpus of unannotated documents as input and produces two outputs, a set of "topics" and assignments of documents to topics. Both the topics and the assignments are probabilistic: a topic is represented as a probability distribution over words in the corpus, and each document is assigned a probability distribution over all the topics. Topic models built on the foundations of LDA are appealing for sentiment analysis because the learned topics can cluster together sentiment-bearing words, and because topic distributions are a parsimonious way to represent a document.[1]

LDA has been used to discover latent structure in text (e.g. for discourse segmentation (Purver et al., 2006) and authorship (Rosen-Zvi et al., 2004)). MLSLDA extends the approach by ensuring that this latent structure — the underlying topics — is consistent across languages. We discuss multilingual topic modeling in Section 1.1, and in Section 1.2 we show how this enables supervised regression regardless of a document's language.

1.1 Capturing Semantic Correlations

Topic models posit a straightforward generative process that creates an observed corpus. For each document d, some distribution θ_d over unobserved topics is chosen. Then, for each word position in the document, a topic z is selected. Finally, the word for that position is generated by selecting from the topic indexed by z. (Recall that in LDA, a "topic" is a distribution over words).

In monolingual topic models, the topic distribution is usually drawn from a Dirichlet distribution. Using Dirichlet distributions makes it easy to specify sparse priors, and it also simplifies posterior inference because Dirichlet distributions are conjugate to multinomial distributions. However, drawing topics from Dirichlet distributions will not suffice if our vocabulary includes multiple languages. If we are working with English, German, and Chinese at the same time, a Dirichlet prior has no way to favor distributions z such that $p(\text{good}|z)$, $p(\text{gut}|z)$, and $p(\text{hǎo}|z)$ all tend to be high at the same time, or low at the same time. More generally, the structure of our model must encourage topics to be consistent across languages, and Dirichlet distributions cannot encode correlations between elements.

One possible solution to this problem is to use the multivariate normal distribution, which can produce correlated multinomials (Blei and Lafferty, 2005), in place of the Dirichlet distribution. This has been done successfully in multilingual settings (Cohen and Smith, 2009). However, such models complicate inference by not being conjugate.

Instead, we appeal to tree-based extensions of the Dirichlet distribution, which has been used to induce correlation in semantic ontologies (Boyd-Graber et al., 2007) and to encode clustering constraints (Andrzejewski et al., 2009). The key idea in this approach is to assume the vocabularies of all languages are organized according to some shared semantic structure that can be represented as a tree. For concreteness in this section, we will use WordNet (Miller, 1990) as the representation of this multilingual semantic bridge, since it is well known, offers convenient and intuitive terminology, and demonstrates the full flexibility of our approach. However, the model we describe generalizes to any tree-structured representation of multilingual knowledge; we discuss some alternatives in Section 3.

WordNet organizes a vocabulary into a rooted, directed acyclic graph of nodes called synsets, short for "synonym sets." A synset is a child of another synset if it satisfies a hyponomy relationship; each child "is a" more specific instantiation of its parent concept (thus, hyponomy is often called an "isa" relationship). For example, a "dog" is a "canine" is an "animal" is a "living thing," etc. As an approximation, it is not unreasonable to assume that WordNet's structure of meaning is language independent, i.e. the concept encoded by a synset can be realized using terms in different languages that share the same meaning. In practice, this organization has been used to create many alignments of international WordNets to the original English WordNet (Ordan and Wintner, 2007; Sagot and Fišer, 2008; Isahara et al., 2008).

Using the structure of WordNet, we can now describe a generative process that produces a distribution over a multilingual vocabulary, which encourages correlations between words with similar mean-

[1] The latter property has also made LDA popular for information retrieval (Wei and Croft, 2006)).

ings regardless of what language each word is in. For each synset h, we create a multilingual word distribution for that synset as follows:

1. Draw transition probabilities $\beta_h \sim \text{Dir}(\tau_h)$
2. Draw stop probabilities $\omega_h \sim \text{Dir}(\kappa_h)$
3. For each language l, draw emission probabilities for that synset $\phi_{h,l} \sim \text{Dir}(\pi_{h,l})$.

For conciseness in the rest of the paper, we will refer to this generative process as *multilingual Dirichlet hierarchy*, or MULTDIRHIER$(\boldsymbol{\tau}, \boldsymbol{\kappa}, \boldsymbol{\pi})$.[2] Each observed token can be viewed as the end result of a sequence of visited synsets λ. At each node in the tree, the path can end at node i with probability $\omega_{i,1}$, or it can continue to a child synset with probability $\omega_{i,0}$. If the path continues to another child synset, it visits child j with probability $\beta_{i,j}$. If the path ends at a synset, it generates word k with probability $\phi_{i,l,k}$.[3] The probability of a word being emitted from a path with visited synsets r and final synset h in language l is therefore

$$p(w, \lambda = r, h | l, \boldsymbol{\beta}, \boldsymbol{\omega}, \boldsymbol{\phi}) = \left(\prod_{(i,j) \in r} \beta_{i,j} \omega_{i,0} \right) (1 - \omega_{h,1}) \phi_{h,l,w}. \quad (1)$$

Note that the stop probability ω_h is independent of language, but the emission $\phi_{h,l}$ is dependent on the language. This is done to prevent the following scenario: while synset A is highly probable in a topic and words in language 1 attached to that synset have high probability, words in language 2 have low probability. If this could happen for many synsets in a topic, an entire language would be effectively silenced, which would lead to inconsistent topics (e.g. Topic 1 is about baseball in English and about travel in German). Separating path from emission helps ensure that topics are consistent across languages.

Having defined topic distributions in a way that can preserve cross-language correspondences, we now use this distribution within a larger model that can discover cross-language patterns of use that predict sentiment.

1.2 The MLSLDA Model

We will view sentiment analysis as a regression problem: given an input document, we want to predict a real-valued observation y that represents the sentiment of a document. Specifically, we build on supervised latent Dirichlet allocation (SLDA, (Blei and McAuliffe, 2007)), which makes predictions based on the topics expressed in a document; this can be thought of projecting the words in a document to low dimensional space of dimension equal to the number of topics. Blei et al. showed that using this latent topic structure can offer improved predictions over regressions based on words alone, and the approach fits well with our current goals, since word-level cues are unlikely to be identical across languages. In addition to text, SLDA has been successfully applied to other domains such as social networks (Chang and Blei, 2009) and image classification (Wang et al., 2009). The key innovation in this paper is to extend SLDA by creating topics that are globally consistent across languages, using the bridging approach above.

We express our model in the form of a probabilistic generative latent-variable model that generates documents in multiple languages *and* assigns a real-valued score to each document. The score comes from a normal distribution whose sum is the dot product between a regression parameter η that encodes the influence of each topic on the observation and a variance σ^2. With this model in hand, we use statistical inference to determine the distribution over latent variables that, given the model, best explains observed data.

The generative model is as follows:

1. For each topic $i = 1 \dots K$, draw a topic distribution $\{\boldsymbol{\beta}_i, \boldsymbol{\omega}_i, \boldsymbol{\phi}_i\}$ from MULTDIRHIER$(\boldsymbol{\tau}, \boldsymbol{\kappa}, \boldsymbol{\pi})$.
2. For each document $d = 1 \dots M$ with language l_d:
   (a) Choose a distribution over topics $\theta_d \sim \text{Dir}(\alpha)$.

[2] Variables τ_h, $\pi_{h,l}$, and κ_h are hyperparameters. Their mean is fixed, but their magnitude is sampled during inference (i.e. $\frac{\tau_{h,i}}{\sum_k \tau_{h,k}}$ is constant, but $\tau_{h,i}$ is not). For the bushier bridges, (e.g. dictionary and flat), their mean is uniform. For GermaNet, we took frequencies from two balanced corpora of German and English: the British National Corpus (University of Oxford, 2006) and the Kern Corpus of the Digitales Wörterbuch der Deutschen Sprache des 20. Jahrhunderts project (Geyken, 2007). We took these frequencies and propagated them through the multilingual hierarchy, following LDAWN's (Boyd-Graber et al., 2007) formulation of information content (Resnik, 1995) as a Bayesian prior. The variance of the priors was initialized to be 1.0, but could be sampled during inference.

[3] Note that the language and word are taken as given, but the path through the semantic hierarchy is a latent random variable.

    (b) For each word in the document $n = 1 \ldots N_d$, choose a topic assignment $z_{d,n} \sim \mathrm{Mult}\left(\theta_d\right)$ and a path $\lambda_{d,n}$ ending at word $w_{d,n}$ according to Equation 1 using $\{\boldsymbol{\beta}_{z_{d,n}}, \boldsymbol{\omega}_{z_{d,n}}, \boldsymbol{\phi}_{z_{d,n}}\}$.

3. Choose a response variable from $y \sim \mathrm{Norm}\left(\eta^\top \bar{z}, \sigma^2\right)$, where $\bar{z_d} \equiv \frac{1}{N}\sum_{n=1}^{N} z_{d,n}$.

Crucially, note that the topics are not independent of the sentiment task; the regression encourages terms with similar effects on the observation y to be in the same topic. The consistency of topics described above allows the same regression to be done for the entire corpus regardless of the language of the underlying document.

2 Inference

Finding the model parameters most likely to explain the data is a problem of statistical inference. We employ stochastic EM (Diebolt and Ip, 1996), using a Gibbs sampler for the E-step to assign words to paths and topics. After randomly initializing the topics, we alternate between sampling the topic and path of a word $(z_{d,n}, \lambda_{d,n})$ and finding the regression parameters η that maximize the likelihood. We jointly sample the topic and path conditioning on all of the other path and document assignments in the corpus, selecting a path and topic with probability

$$\begin{aligned} p(z_n = k, \lambda_n = r | \boldsymbol{z}_{-n}, \boldsymbol{\lambda}_{-n}, w_n, \eta, \sigma, \Theta) = \\ p(y_d | \boldsymbol{z}, \eta, \sigma) p(\lambda_n = r | z_n = k, \boldsymbol{\lambda}_{-n}, w_n, \boldsymbol{\tau}, \boldsymbol{\kappa}, \boldsymbol{\pi}) \\ p(z_n = k | \boldsymbol{z}_{-n}, \alpha). \qquad (2) \end{aligned}$$

Each of these three terms reflects a different influence on the topics from the vocabulary structure, the document's topics, and the response variable. In the next paragraphs, we will expand each of them to derive the full conditional topic distribution.

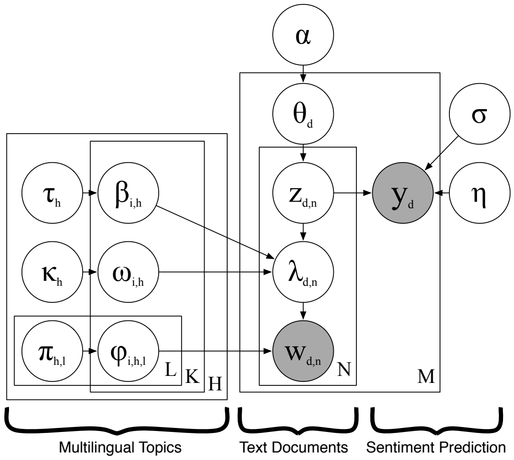

Figure 1: Graphical model representing MLSLDA. Shaded nodes represent observations, plates denote replication, and lines show probabilistic dependencies.

As discussed in Section 1.1, the structure of the topic distribution encourages terms with the same meaning to be in the same topic, even across languages. During inference, we marginalize over possible multinomial distributions β, ω, and ϕ, using the observed transitions from i to j in topic k; $T_{k,i,j}$, stop counts in synset i in topic k, $O_{k,i,0}$; continue counts in synsets i in topic k, $O_{k,i,1}$; and emission counts in synset i in language l in topic k, $F_{k,i,l}$. The probability of taking a path r is then

$$p(\lambda_n = r | z_n = k, \boldsymbol{\lambda}_{-n}) = \underbrace{\prod_{(i,j)\in r}\left(\frac{B_{k,i,j}+\tau_{i,j}}{\sum_{j'} B_{k,i,j'}+\tau_{i,j}}\frac{O_{k,i,1}+\omega_i}{\sum_{s\in 0,1} O_{k,i,s}+\omega_{i,s}}\right)}_{\text{Transition}} \underbrace{\frac{O_{k,r_{end},0}+\omega_{r_{end}}}{\sum_{s\in 0,1} O_{k,r_{end},s}+\omega_{r_{end},s}}\frac{F_{k,r_{end},w_n}+\pi_{r_{end},l}}{\sum_{w'} F_{r_{end},w'}+\pi_{r_{end},w'}}}_{\text{Emission}}. \qquad (3)$$

Equation 3 reflects the *multilingual* aspect of this model. The conditional topic distribution for SLDA (Blei and McAuliffe, 2007) replaces this term with the standard Multinomial-Dirichlet. However, we believe this is the first published SLDA-style model using MCMC inference, as prior work has used variational inference (Blei and McAuliffe, 2007; Chang and Blei, 2009; Wang et al., 2009).

Because the observed response variable depends on the topic assignments of a document, the conditional topic distribution is shifted toward topics that explain the observed response. Topics that move the predicted response $\hat{y}_d$ toward the true y_d will be favored. We drop terms that are constant across all topics for the effect of the response variable,

$$p(y_d|\boldsymbol{z}, \eta, \sigma) \propto \underbrace{\exp\left[\frac{1}{\sigma^2}\left(y_d - \frac{\sum_{k'} N_{d,k'}\eta_{k'}}{\sum_{k'} N_{d,k'}}\right)\frac{\eta_{z_k}}{\sum_{k'} N_{d,k'}}\right]}_{\text{Other words' influence}} \underbrace{\exp\left[\frac{-\eta_{z_k}^2}{2\sigma^2 \sum_{k'} N_{d,k'}^2}\right]}_{\text{This word's influence}}. \quad (4)$$

The above equation represents the *supervised* aspect of the model, which is inherited from SLDA.

Finally, there is the effect of the topics already assigned to a document; the conditional distribution favors topics already assigned in a document,

$$p(z_n = k|\boldsymbol{z}_{-n}, \alpha) = \frac{T_{d,k} + \alpha_k}{\sum_{k'} T_{d,k'} + \alpha_{k'}}. \quad (5)$$

This term represents the *document* focus of this model; it is present in all Gibbs sampling inference schemes for LDA (Griffiths and Steyvers, 2004).

Multiplying together Equations 3, 4, and 5 allows us to sample a topic using the conditional distribution from Equation 2, based on the topic and path of the other words in all languages. After sampling the path and topic for each word in a document, we then find new regression parameters η that maximize the likelihood conditioned on the current state of the sampler. This is simply a least squares regression using the topic assignments $\bar{z}_d$ to predict y_d.

Prediction on documents for which we don't have an observed y_d is equivalent to marginalizing over y_d and sampling topics for the document from Equations 3 and 5. The prediction for y_d is then the dot product of η and the empirical topic distribution $\bar{z}_d$.

We initially optimized all hyperparameters using slice sampling. However, we found that the regression variance σ^2 was not stable. Optimizing σ^2 seems to balance between modeling the language in the documents and the prediction, and thus is sensitive to documents' length. Given this sensitivity, we did not optimize σ^2 for our prediction experiments in Section 4, but instead kept it fixed at 0.25. We leave optimizing this variable, either through cross validation or adapting the model, to future work.

3 Bridges Across Languages

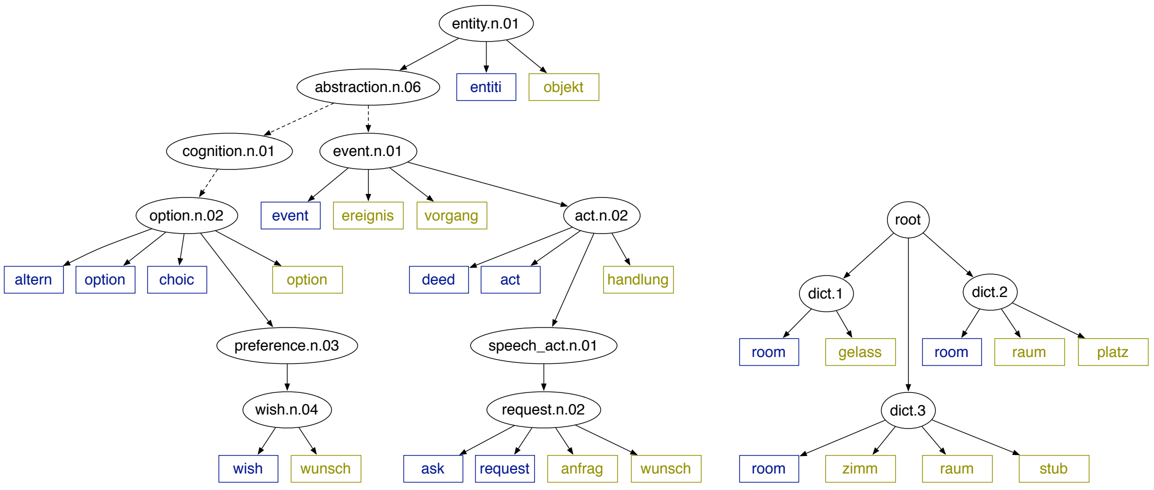
In Section 1.1, we described connections across languages as offered by semantic networks in a general way, using WordNet as an example. In this section, we provide more specifics, as well as alternative ways of building semantic connections across languages.

Flat First, we can consider a degenerate mapping that is nearly equivalent to running SLDA independently across multiple languages, relating topics only based on the impact on the response variable. Consider a degenerate tree with only one node, with all words in all languages associated with that node. This is consistent with our model, but there is really no shared semantic space, as all emitted words must come from this degenerate "synset" and the model only represents the output distribution for this single node.

WordNet We took the alignment of GermaNet to WordNet 1.6 (Kunze and Lemnitzer, 2002) and removed all synsets that were had no mapped German words. Any German synsets that did not have English translations had their words mapped to the lowest extant English hypernym (e.g. "beinbruch," a broken leg, was mapped to "fracture"). We stemmed all words to account for inflected forms not being present (Porter and Boulton, 1970). An example of the paths for the German word "wunsch" (wish, request) is shown in Figure 2(a).

Dictionaries A dictionary can be viewed as a many to many mapping, where each entry e_i maps one or more words in one language $\boldsymbol{s}_i$ to one or more words $\boldsymbol{t}_i$ in another language. Entries were taken from an English-German dictionary (Richter, 2008) a Chinese-English dictionary (Denisowski, 1997), and a Chinese-German dictionary (Hefti, 2005). As with WordNet, the words in entries for English and German were stemmed to improve coverage. An example for German is shown in Figure 2(b).

Algorithmic Connections In addition to hand-curated connections across languages, one could also consider automatic means of mapping across languages, such as using edit distance or local context (Haghighi et al., 2008; Rapp, 1995) or using a lexical translation table obtained from parallel text (Melamed, 1998). While we experimented



(a) GermaNet (b) Dictionary

Figure 2: Two methods for constructing multilingual distributions over words. On the left, paths to the German word "wunsch" in GermaNet are shown. On the right, paths to the English word "room" are shown. Both English and German words are shown; some internal nodes in GermaNet have been omitted for space (represented by dashed lines). Note that different senses are denoted by different internal paths, and that internal paths are distinct from the per-language expression.

with these techniques, constructing appropriate hierarchies from these resources required many arbitrary decisions about cutoffs and which words to include. Thus, we do not consider them in this paper.

4 Experiments

We evaluate MLSLDA on three criteria: how well it can discover consistent topics across languages for matching parallel documents, how well it can discover sentiment-correlated word lists from non-aligned text, and how well it can predict sentiment.

4.1 Matching on Multilingual Topics

We took the 1996 documents from the Europarl corpus (Koehn, 2005) using three bridges: GermaNet, dictionary, and the uninformative flat matching.[4] The model is unaware that the translations of documents in one language are present in the other language. Note that this does not use the supervised framework (as there is no associated response variable for Europarl documents); this experiment is to demonstrate the effectiveness of the multilingual aspect of the model. To test whether the topics learned by the model are consistent across languages, we represent each document using the probability distribution θ_d over topic assignments. Each θ_d is a vector of length K and is a language-independent representation of the document.

For each document in one language, we computed the Hellinger distance between it and all of the documents in the other language and sorted the documents by decreasing distance. The translation of the document is somewhere in that set; the higher the normalized rank (the percentage of documents with a rank lower than the translation of the document), the better the underlying topic model connects languages.

We compare three bridges against what is to our knowledge the only other topic model for unaligned text, Multilingual Topics for Unaligned Text (Boyd-Graber and Blei, 2009).[5]

[4] For English and German documents in all experiments, we removed stop words (Loper and Bird, 2002), stemmed words (Porter and Boulton, 1970), and created a vocabulary of the most frequent 5000 words per language (this vocabulary limit was mostly done to ensure that the dictionary-based bridge was of manageable size). Documents shorter than fifty content words were excluded.

[5] The bipartite matching was initialized with the dictionary weights as specified by the Multilingual Topics for Unaligned Text algorithm. The matching size was limited to 250 and the bipartite matching was only updated on the initial iteration then held fixed. This yielded results comparable to when the matching

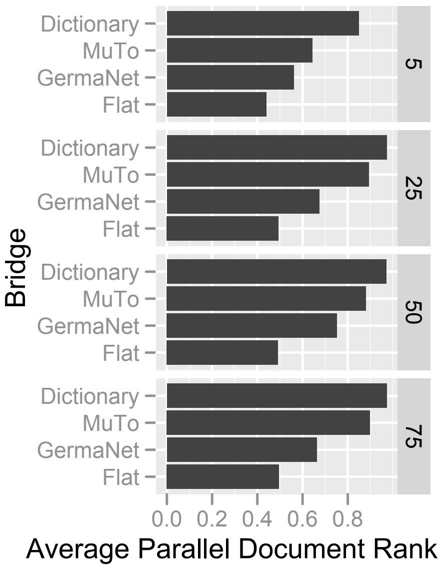


Figure 3: Average rank of paired translation document recovered from the multilingual topic model. Random guessing would yield 0.5; MLSLDA with a dictionary based matching performed best.

Figure 3 shows the results of this experiment. The dictionary-based bridge had the best performance on the task, ranking a large proportion of documents (0.95) below the translated document once enough topics were available. Although GermaNet is richer, its coverage is incomplete; the dictionary structure had a much larger vocabulary and could build a more complete multilingual topics. Using comparable input information, this more flexible model performed better on the matching task than the existing multilingual topic model available for unaligned text. The degenerate flat bridge did no better than the baseline of random guessing, as expected.

4.2 Qualitative Sentiment-Correlated Topics

One of the key tasks in sentiment analysis has been the collection of lists of words that convey sentiment (Wilson, 2008; Riloff et al., 2003). These resources are often created using or in reference to resources like WordNet (Whitelaw et al., 2005; Baccianella and Sebastiani, 2010). MLSLDA provides a method for extracting topical and sentiment-correlated word lists from multilingual corpora. If a WordNet-like resource is used as the bridge, the resulting topics are distributions over synsets, not just over words.

As our demonstration corpus, we used the Amherst Sentiment Corpus (Constant et al., 2009), as it has documents in multiple languages (English, Chinese, and German) with numerical assessments of sentiment (number of stars assigned to the review). We segmented the Chinese text (Tseng et al., 2005) and used a classifier trained on character n-grams to remove English-language documents that were mixed in among the Chinese and German language reviews.

Figure 4 shows extracted topics from German-English and German-Chinese corpora. MLSLDA is able to distinguish sentiment-bearing topics from content bearing topics. For example; in the German-English corpus, “food” and “children” topics are not associated with a consistent sentiment signal, while “religion” is associated with a more negative sentiment. In contrast, in the German-Chinese corpus, the “religion/society” topic is more neutral, and the gender-oriented topic is viewed more negatively. Negative sentiment-bearing topics have reasonable words such as “pages,” “kǒng pà” (Chinese for “I'm afraid that . . . ”) and “tuo” (Chienese for “discard”), and positive sentiment-bearing topics have reasonable words such as “great,” “good,” and “juwel” (German for “jewel”).

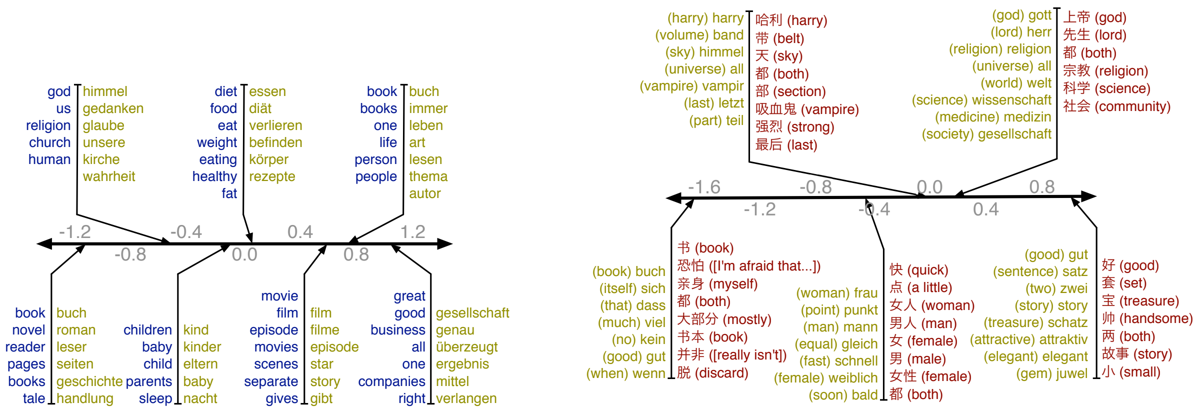
The qualitative topics also betray some of the weaknesses of the model. For example, in one of the negative sentiment topics, the German word “gut” (good) is present. Because topics are distributions over words, they can encode the presence of negations like “kein” (no) and “nicht” (not), but not collocations like “nicht gut.” More elaborate topic models that can model local syntax and collocations (Johnson, 2010) provide options for addressing such problems.

We do not report the results for sentiment prediction for this corpus because the baseline of predicting a positive review is so strong; most algorithms do extremely well by always predicting a positive review, ours included.

4.3 Sentiment Prediction

We gathered 330 film reviews from a German film review site (Vetter et al., 2000) and combined them with a much larger English film review corpus of over

was updated more frequently.



(a) German / English

(b) German / Chinese

Figure 4: Topics, along with associated regression coefficient η from a learned 25-topic model on German-English (left) and German-Chinese (right) documents. Notice that theme-related topics have regression parameter near zero, topics discussing the number of pages have negative regression parameters, topics with "good," "great," "hǎo" (good) and "überzeugt" (convinced) have positive regression parameters. For the German-Chinese corpus, note the presence of "gut" (good) in one of the negative sentiment topics, showing the difficulty of learning collocations.

Train	Test	GermaNet	Dictionary	Flat
DE	DE	73.8	24.8	92.2
EN	DE	7.44	2.68	18.3
EN + DE	DE	**1.17**	**1.46**	**1.39**

Table 1: Mean squared error on a film review corpus. All results are on the same German test data, varying the training data. Over-fitting prevents the model learning on the German data alone; adding English data to the mix allows the model to make better predictions.

5000 film reviews (Pang and Lee, 2005) to create a multilingual film review corpus.[6]

The results for predicting sentiment in German documents with 25 topics are presented in Table 1. On a small monolingual corpus, prediction is very poor. The model over-fits, especially when it has the entire vocabulary to select from. The slightly better performance using GermaNet and a dictionary as topic priors can be viewed as basic feature selection, removing proper names from the vocabulary to prevent over-fitting.

One would expect that prediction improves with a larger training set. For this model, such an improvement is seen even when the training set includes *no* documents in the target language. Note that even the degenerate flat bridge across languages provides useful information. After introducing English data, the model learns to prefer smaller regression parameters (this can be seen as a form of regularization).

Performance is best when a reasonably large corpus is available including some data in the target language. For each bridge, performance improves dramatically, showing that MLSLDA is successfully able to incorporate information learned from both languages to build a single, coherent picture of how sentiment is expressed in both languages. With the GermaNet bridge, performance is better than both the degenerate and dictionary based bridges, showing that the model is sharing information both through the multilingual topics and the regression parameters. Performance on English prediction is comparable to previously published results on this dataset (Blei and McAuliffe, 2007); with enough data, a monolingual model is no longer helped by adding additional multilingual data.

[6] We followed Pang and Lee's method for creating a numerical score between 0 and 1 from a star rating. We then converted that to an integer by multiplying by 100; this was done because initial data preprocessing assumed integer values (although downstream processing did not assume integer values). The German movie review corpus is available at `http://www.umiacs.umd.edu/~jbg/static/downloads_and_media.html`

5 Relationship to Previous Research

The advantages of MLSLDA reside largely in the assumptions that it makes and does not make: documents need not be parallel, sentiment is a normally distributed document-level property, words are exchangeable, and sentiment can be predicted as a regression on a K-dimensional vector.

By not assuming parallel text, this approach can be applied to a broad class of corpora. Other multilingual topic models require parallel text, either at the document (Ni et al., 2009; Mimno et al., 2009) or word-level (Kim and Khudanpur, 2004; Zhao and Xing, 2006). Similarly, other multilingual sentiment approaches also require parallel text, often supplied via automatic translation; after the translated text is available, either monolingual analysis (Denecke, 2008) or co-training is applied (Wan, 2009). In contrast, our approach requires fewer resources for a language: a dictionary (or similar knowledge structure relating words to nodes in a graph) and comparable text, instead of parallel text or a machine translation system.

Rather than viewing one language through the lens of another language, MLSLDA views all languages through the lens of the topics present in a document. This is a modeling decision with pros and cons. It allows a language agnostic decision about sentiment to be made, but it restricts the expressiveness of the model in terms of sentiment in two ways. First, it throws away information important to sentiment analysis like syntactic constructions (Greene and Resnik, 2009) and document structure (McDonald et al., 2007) that may impact the sentiment rating. Second, a single real number is not always sufficient to capture the nuances of sentiment. Less critically, assuming that sentiment is normally distributed is not true of all real-world corpora; review corpora often have a skew toward positive reviews. We standardize responses by the mean and variance of the training data to partially address this issue, but other response distributions are possible, such as generalized linear models (Blei and McAuliffe, 2007) and vector machines (Zhu et al., 2009), which would allow more traditional classification predictions.

Other probabilistic models for sentiment classification view sentiment as a word level feature. Some models use sentiment word lists, either given or learned from a corpus, as a prior to seed topics so that they attract other sentiment bearing words (Mei et al., 2007; Lin and He, 2009). Other approaches view sentiment or perspective as a perturbation of a log-linear topic model (Lin et al., 2008). Such techniques could be combined with the multilingual approach presented here by using distributions over words that not only bridge different languages but also encode additional information. For example, the vocabulary hierarchies could be structured to encourage topics that encourage correlation among similar sentiment-bearing words (e.g. clustering words associated with price, size, etc.). Future work could also more rigorously validate that the multilingual topics discovered by MLSLDA are sentiment-bearing via human judgments.

In contrast, MLSLDA draws on techniques that view sentiment as a regression problem based on the topics used in a document, as in supervised latent Dirichlet allocation (SLDA) (Blei and McAuliffe, 2007) or in finer-grained parts of a document (Titov and McDonald, 2008). Extending these models to multilingual data would be more straightforward.

6 Conclusions

MLSLDA is a "holistic" statistical model for multilingual corpora that does not require parallel text or expensive multilingual resources. It discovers connections across languages that can recover latent structure in parallel corpora, discover sentiment-correlated word lists in multiple languages, and make accurate predictions across languages that improve with more multilingual data, as demonstrated in the context of sentiment analysis.

More generally, MLSLDA provides a formalism that can be used to incorporate the many insights of topic modeling-driven sentiment analysis to multilingual corpora by tying together word distributions across languages. MLSLDA can also contribute to the development of word list-based sentiment systems: the topics discovered by MLSLDA can serve as a first-pass means of sentiment-based word lists for languages that might lack annotated resources.

MLSLDA also can be viewed as a sentiment-informed multilingual word sense disambiguation (WSD) algorithm. When the multilingual bridge is an explicit representation of sense such as WordNet, part of the generative process is an explicit assignment of every word to sense (the path latent variable λ); this is discovered during inference. The dictionary-based technique may be viewed as a disambiguation via a transfer dictionary. How sentiment prediction impacts the implicit WSD is left to future work.

Better capturing local syntax and meaningful collocations would also improve the model's ability to predict sentiment and model multilingual topics, as would providing a better mechanism for representing words not included in our bridges. We intend to develop such models as future work.

Abstract

Discovering and summarizing opinions from online reviews is an important and challenging task. A commonly-adopted framework generates structured review summaries with aspects and opinions. Recently topic models have been used to identify meaningful review aspects, but existing topic models do not identify aspect-specific opinion words. In this paper, we propose a MaxEnt-LDA hybrid model to jointly discover both aspects and aspect-specific opinion words. We show that with a relatively small amount of training data, our model can effectively identify aspect and opinion words simultaneously. We also demonstrate the domain adaptability of our model.

1 Introduction

With the dramatic growth of opinionated user-generated content, consumers often turn to online product reviews to seek advice while companies see reviews as a valuable source of consumer feedback. How to automatically understand, extract and summarize the opinions expressed in online reviews has therefore become an important research topic and gained much attention in recent years (Pang and Lee, 2008). A wide spectrum of tasks have been studied under review mining, ranging from coarse-grained document-level polarity classification (Pang et al., 2002) to fine-grained extraction of opinion expressions and their targets (Wu et al., 2009). In particular, a general framework of summarizing reviews of a certain product is to first identify different aspects (a.k.a. features) of the given product and then extract specific opinion expressions for each aspect. For example, aspects of a restaurant may include *food*, *staff*, *ambience* and *price*, and opinion expressions for *staff* may include *friendly*, *rude*, etc. Because of the practicality of this structured summary format, it has been adopted in several previous studies (Hu and Liu, 2004; Popescu and Etzioni, 2005; Brody and Elhadad, 2010) as well as some commercial systems, e.g. the "scorecard" feature at Bing shopping[1].

Different approaches have been proposed to identify aspect words and phrases from reviews. Previous methods using frequent itemset mining (Hu and Liu, 2004) or supervised learning (Jin and Ho, 2009; Jin et al., 2009; Wu et al., 2009) have the limitation that they do not group semantically related aspect expressions together. Supervised learning also suffers from its heavy dependence on training data. In contrast, unsupervised, knowledge-lean topic modeling approach has been shown to be effective in automatically identifying aspects and their representative words (Titov and McDonald, 2008; Brody and Elhadad, 2010). For example, words such as *waiter*, *waitress*, *staff* and *service* are grouped into one aspect.

We follow this promising direction and extend existing topic models to jointly identify both aspect and opinion words, especially aspect-specific opinion words. Current topic models for opinion mining, which we will review in detail in Section 2, still lack this ability. But separating aspect and opinion words can be very useful. Aspect-specific opinion words can be used to construct a domain-dependent senti-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 56–65,
MIT, Massachusetts, USA, 9-11 October 2010.

ment lexicon and applied to tasks such as sentiment classification. They can also provide more informative descriptions of the product or service being reviewed. For example, using more specific opinion words such as *cozy* and *romantic* to describe the *ambience* aspect in a review summary is more meaningful than using generic words such as *nice* and *great*. To the best of our knowledge, Brody and Elhadad (2010) are the first to study aspect-specific opinion words, but their opinion word detection is performed outside of topic modeling, and they only consider adjectives as possible opinion words.

In this paper, we propose a new topic modeling approach that can automatically separate aspect and opinion words. A novelty of this model is the integration of a discriminative maximum entropy (MaxEnt) component with the standard generative component. The MaxEnt component allows us to leverage arbitrary features such as POS tags to help separate aspect and opinion words. Because the supervision relies mostly on non-lexical features, although our model is no longer fully unsupervised, the number of training sentences needed is relatively small. Moreover, training data can also come from a different domain and yet still remain effective, making our model highly domain adaptive. Empirical evaluation on large review data sets shows that our model can effectively identify both aspects and aspect-specific opinion words with a small amount of training data.

2 Related Work

Pioneered by the work of Hu and Liu (2004), review summarization has been an important research topic. There are usually two major tasks involved, namely, aspect or feature identification and opinion extraction. Hu and Liu (2004) applied frequent itemset mining to identify product features without supervision, and considered adjectives collocated with feature words as opinion words. Jin and Ho (2009), Jin et al. (2009) and Wu et al. (2009) used supervised learning that requires hand-labeled training sentences to identify both aspects and opinions. A common limitation of these methods is that they do not group semantically related aspect expressions together. Furthermore, supervised learning usually requires a large amount of training data in order to perform well and is not easily domain adaptable.

Topic modeling provides an unsupervised and knowledge-lean approach to opinion mining. Titov and McDonald (2008) show that global topic models such as LDA (Blei et al., 2003) may not be suitable for detecting rateable aspects. They propose multi-grain topic models for discovering local rateable aspects. However, they do not explicitly separate aspect and opinion words. Lin and He (2009) propose a joint topic-sentiment model, but topic words and sentiment words are still not explicitly separated. Mei et al. (2007) propose to separate topic and sentiment words using a positive sentiment model and a negative sentiment model, but both models capture general opinion words only. In contrast, we model *aspect-specific* opinion words as well as general opinion words.

Recently Brody and Elhadad (2010) propose to detect aspect-specific opinion words in an unsupervised manner. They take a two-step approach by first detecting aspect words using topic models and then identifying aspect-specific opinion words using polarity propagation. They only consider adjectives as opinion words, which may potentially miss opinion words with other POS tags. We try to jointly capture both aspect and opinion words within topic models, and we allow non-adjective opinion words.

Another line of related work is about how to incorporate useful features into topic models (Zhu and Xing, 2010; Mimno and McCallum, 2008). Our MaxEnt-LDA hybrid bears similarity to these recent models but ours is designed for opinion mining.

3 Model Description

Our model is an extension of LDA (Blei et al., 2003) but captures both aspect words and opinion words. To model the aspect words, we use a modified version of the multi-grain topic models from (Titov and McDonald, 2008). Our model is simpler and yet still produces meaningful aspects. Specifically, we assume that there are T aspects in a given collection of reviews from the same domain, and each review document contains a mixture of aspects. We further assume that each sentence (instead of each word as in standard LDA) is assigned to a single aspect, which is often true based on our observation.

To understand how we model the opinion words, let us first look at two example review sentences from the restaurant domain:

The food was tasty.
The waiter was quite friendly.

We can see that there is a strong association of *tasty* with *food* and similarly of *friendly* with *waiter*. While both *tasty* and *friendly* are specific to the restaurant domain, they are each associated with only a single aspect, namely *food* and *staff*, respectively. Besides these aspect-specific opinion words, we also see general opinion words such as *great* in the sentence "*The food was great!*" These general opinion words are shared across aspects, as opposed to aspect-specific opinion words which are used most commonly with their corresponding aspects. We therefore introduce a general opinion model and T aspect-specific opinion models to capture these different opinion words.

3.1 Generative Process

We now describe the generative process of the model. First, we draw several multinomial word distributions from a symmetric Dirichlet prior with parameter β: a background model $\phi^{\mathcal{B}}$, a general aspect model $\phi^{\mathcal{A},g}$, a general opinion model $\phi^{\mathcal{O},g}$, T aspect models $\{\phi^{\mathcal{A},t}\}_{t=1}^{T}$ and T aspect-specific opinion models $\{\phi^{\mathcal{O},t}\}_{t=1}^{T}$. All these are multinomial distributions over the vocabulary, which we assume has V words. Then for each review document d, we draw a topic distribution $\theta^d \sim \text{Dir}(\alpha)$ as in standard LDA. For each sentence s in document d, we draw an aspect assignment $z_{d,s} \sim \text{Multi}(\theta^d)$.

Now for each word in sentence s of document d, we have several choices: The word may describe the specific aspect (e.g. *waiter* for the *staff* aspect), or a general aspect (e.g. *restaurant*), or an opinion either specific to the aspect (e.g. *friendly*) or generic (e.g. *great*), or a commonly used background word (e.g. *know*). To distinguish between these choices, we introduce two indicator variable, $y_{d,s,n}$ and $u_{d,s,n}$, for the nth word $w_{d,s,n}$. We draw $y_{d,s,n}$ from a multinomial distribution over $\{0, 1, 2\}$, parameterized by $\pi^{d,s,n}$. $y_{d,s,n}$ determines whether $w_{d,s,n}$ is a background word, aspect word or opinion word. We will discuss how to set $\pi^{d,s,n}$ in Section 3.2. We draw $u_{d,s,n}$ from a Bernoulli distribution over $\{0, 1\}$ parameterized by p, which in turn is drawn from a symmetric Beta(γ). $u_{d,s,n}$ determines whether $w_{d,s,n}$ is general or aspect-specific. We then draw $w_{d,s,n}$ as follows:

$$w_{d,s,n} \sim \begin{cases} \text{Multi}(\phi^{\mathcal{B}}) & \text{if } y_{d,s,n} = 0 \\ \text{Multi}(\phi^{\mathcal{A},z_{d,s}}) & \text{if } y_{d,s,n} = 1, u_{d,s,n} = 0 \\ \text{Multi}(\phi^{\mathcal{A},g}) & \text{if } y_{d,s,n} = 1, u_{d,s,n} = 1 \\ \text{Multi}(\phi^{\mathcal{O},z_{d,s}}) & \text{if } y_{d,s,n} = 2, u_{d,s,n} = 0 \\ \text{Multi}(\phi^{\mathcal{O},g}) & \text{if } y_{d,s,n} = 2, u_{d,s,n} = 1 \end{cases}.$$

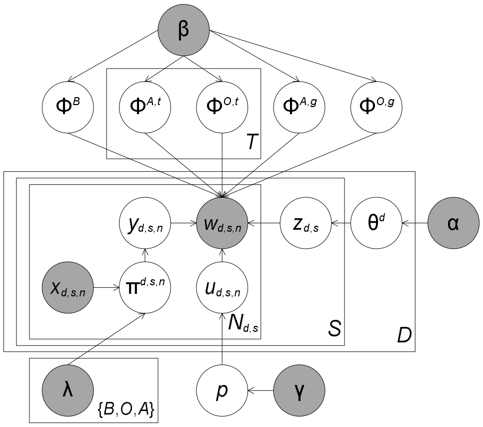

Figure 1: The plate notation of our model.

Figure 1 shows our model using the plate notation.

3.2 Setting π with a Maximum Entropy Model

A simple way to set $\pi^{d,s,n}$ is to draw it from a symmetric Dirichlet prior. However, as suggested in (Mei et al., 2007; Lin and He, 2009), fully unsupervised topic models are unable to identify opinion words well. An important observation we make is that aspect words and opinion words usually play different syntactic roles in a sentence. Aspect words tend to be nouns while opinion words tend to be adjectives. Their contexts in sentences can also be different. But we do not want to use strict rules to separate aspect and opinion words because there are also exceptions. E.g. verbs such as *recommend* can also be opinion words.

In order to use information such as POS tags to help discriminate between aspect and opinion words, we propose a novel idea as follows: We set $\pi^{d,s,n}$ using a maximum entropy (MaxEnt) model applied to a feature vector $\boldsymbol{x}_{d,s,n}$ associated with $w_{d,s,n}$. $\boldsymbol{x}_{d,s,n}$ can encode any arbitrary features we think may be discriminative, e.g. previous, current and next POS tags. Formally, we have

$$p(y_{d,s,n} = l|\boldsymbol{x}_{d,s,n}) = \pi_l^{d,s,n} = \frac{\exp\left(\lambda_l \cdot \boldsymbol{x}_{d,s,n}\right)}{\sum_{l'=0}^{2} \exp\left(\lambda_{l'} \cdot \boldsymbol{x}_{d,s,n}\right)},$$

where $\{\lambda_l\}_{l=0}^{2}$ denote the MaxEnt model weights and can be learned from a set of training sentences with labeled background, aspect and opinion words. This MaxEnt-LDA hybrid model is partially inspired by (Mimno and McCallum, 2008).

As for the features included in $\boldsymbol{x}$, currently we use two types of simple features: (1) lexical features which include the previous, the current and the next words $\{\mathrm{w}_{i-1}, \mathrm{w}_i, \mathrm{w}_{i+1}\}$, and (2) POS tag features which include the previous, the current and the next POS tags $\{\mathrm{POS}_{i-1}, \mathrm{POS}_i, \mathrm{POS}_{i+1}\}$.

3.3 Inference

We use Gibbs sampling to perform model inference. Due to the space limit, we leave out the derivation details and only show the sampling formulas. Note that the MaxEnt component is trained first independently of the Gibbs sampling procedure, that is, in Gibbs sampling, we assume that the λ parameters are fixed.

We use $\boldsymbol{w}$ to denote all the words we observe in the collection, $\boldsymbol{x}$ to denote all the feature vectors for these words, and $\boldsymbol{y}$, $\boldsymbol{z}$ and $\boldsymbol{u}$ to denote all the hidden variables. First, given the assignment of all other hidden variables, to sample a value for $z_{d,s}$, we use the following formula:

$$
\begin{aligned}
& P(z_{d,s} = t | \boldsymbol{z}_{\neg(d,s)}, \boldsymbol{y}, \boldsymbol{u}, \boldsymbol{w}, \boldsymbol{x}) \propto \frac{c^{d}_{(t)} + \alpha}{c^{d}_{(\cdot)} + T\alpha} \\
& \times \left(\frac{\Gamma\left(c^{\mathcal{A},t}_{(\cdot)} + V\beta\right)}{\Gamma\left(c^{\mathcal{A},t}_{(\cdot)} + n^{\mathcal{A},t}_{(\cdot)} + V\beta\right)} \cdot \prod_{v=1}^{V} \frac{\Gamma\left(c^{\mathcal{A},t}_{(v)} + n^{\mathcal{A},t}_{(v)} + \beta\right)}{\Gamma\left(c^{\mathcal{A},t}_{(v)} + \beta\right)} \right) \\
& \times \left(\frac{\Gamma\left(c^{\mathcal{O},t}_{(\cdot)} + V\beta\right)}{\Gamma\left(c^{\mathcal{O},t}_{(\cdot)} + n^{\mathcal{O},t}_{(\cdot)} + V\beta\right)} \cdot \prod_{v=1}^{V} \frac{\Gamma\left(c^{\mathcal{O},t}_{(v)} + n^{\mathcal{O},t}_{(v)} + \beta\right)}{\Gamma\left(c^{\mathcal{O},t}_{(v)} + \beta\right)} \right).
\end{aligned}
$$

Here $c^{d}_{(t)}$ is the number of sentences assigned to aspect t in document d, and $c^{d}_{(\cdot)}$ is the number of sentences in document d. $c^{\mathcal{A},t}_{(v)}$ is the number of times word v is assigned as an *aspect* word to aspect t, and $c^{\mathcal{O},t}_{(v)}$ is the number of times word v is assigned as an *opinion* word to aspect t. $c^{\mathcal{A},t}_{(\cdot)}$ is the total number of times any word is assigned as an aspect word to aspect t, and $c^{\mathcal{O},t}_{(\cdot)}$ is the total number of times any word is assigned as an opinion word to aspect t. All these counts represented by a c variable exclude sentence s of document d. $n^{\mathcal{A},t}_{(v)}$ is the number of times word v is assigned as an aspect word to aspect t in sentence s of document d, and similarly, $n^{\mathcal{O},t}_{(v)}$ is the number of times word v is assigned as an opinion word to aspect t in sentence s of document d.

Then, to jointly sample values for $y_{d,s,n}$ and $u_{d,s,n}$, we have

$$
\begin{aligned}
& P(y_{d,s,n} = 0 | \boldsymbol{z}, \boldsymbol{y}_{\neg(d,s,n)}, \boldsymbol{u}_{\neg(d,s,n)}, \boldsymbol{w}, \boldsymbol{x}) \\
\propto\; & \frac{\exp(\lambda_0 \cdot \boldsymbol{x}_{d,s,n})}{\sum_{l'} \exp(\lambda_{l'} \cdot \boldsymbol{x}_{d,s,n})} \cdot \frac{c^{\mathcal{B}}_{(w_{d,s,n})} + \beta}{c^{\mathcal{B}}_{(\cdot)} + V\beta}, \\
& P(y_{d,s,n} = l, u_{d,s,n} = b | \boldsymbol{z}, \boldsymbol{y}_{\neg(d,s,n)}, \boldsymbol{u}_{\neg(d,s,n)}, \boldsymbol{w}, \boldsymbol{x}) \\
\propto\; & \frac{\exp(\lambda_l \cdot \boldsymbol{x}_{d,s,n})}{\sum_{l'} \exp(\lambda_{l'} \cdot \boldsymbol{x}_{d,s,n})} \cdot g(w_{d,s,n}, z_{d,s}, l, b),
\end{aligned}
$$

where the function $g(v, t, l, b)$ $(1 \le v \le V, 1 \le t \le T, l \in \{1, 2\}, b \in \{0, 1\})$ is defined as follows:

$$
g(v,t,l,b) = \begin{cases}
\frac{c^{\mathcal{A},t}_{(v)} + \beta}{c^{\mathcal{A},t}_{(\cdot)} + V\beta} \cdot \frac{c_{(0)} + \gamma}{c_{(\cdot)} + 2\gamma} & \text{if } l = 1, b = 0 \\
\frac{c^{\mathcal{O},t}_{(v)} + \beta}{c^{\mathcal{O},t}_{(\cdot)} + V\beta} \cdot \frac{c_{(0)} + \gamma}{c_{(\cdot)} + 2\gamma} & \text{if } l = 2, b = 0 \\
\frac{c^{\mathcal{A},g}_{(v)} + \beta}{c^{\mathcal{A},g}_{(\cdot)} + V\beta} \cdot \frac{c_{(1)} + \gamma}{c_{(\cdot)} + 2\gamma} & \text{if } l = 1, b = 1 \\
\frac{c^{\mathcal{O},g}_{(v)} + \beta}{c^{\mathcal{O},g}_{(\cdot)} + V\beta} \cdot \frac{c_{(1)} + \gamma}{c_{(\cdot)} + 2\gamma} & \text{if } l = 2, b = 1.
\end{cases}.
$$

Here the various c variables denote various counts excluding the nth word in sentence s of document d. Due to space limit, we do not give full explanation here.

4 Experiment Setup

To evaluate our MaxEnt-LDA hybrid model for jointly modeling aspect and opinion words, we used a restaurant review data set previously used in (Ganu et al., 2009; Brody and Elhadad, 2010) and a hotel review data set previously used in (Baccianella et al., 2009). We removed stop words and used the Stanford POS Tagger[2] to tag the two data sets. Only reviews that have no more than 50 sentences were used. We also kept another version of the data which includes the stop words for the purpose of extracting the contextual features included in $\boldsymbol{x}$. Some details of the data sets are given in Table 1.

For our hybrid model, we ran 500 iterations of Gibbs sampling. Following (Griffiths and Steyvers, 2004), we fixed the Dirichlet priors as follows: $\alpha =$

[2] http://nlp.stanford.edu/software/tagger.shtml

data set	restaurant	hotel
#tokens	1,644,923	1,097,739
#docs	52,574	14,443

DVD player	180	3024

Table 2: Some statistics of the labeled training data.

$50/T$, $\beta = 0.1$ and $\gamma = 0.5$. We also experimented with other settings of these priors and did not notice any major difference. For MaxEnt training, we tried three labeled data sets: one that was taken from the restaurant data set and manually annotated by us[3], and two from the annotated data set used in (Wu et al., 2009). Note that the latter two were used for testing domain adaptation in Section 6.3. Some details of the training sets are shown in Table 2.

In our preliminary experiments, we also tried two variations of our MaxEnt-LDA hybrid model. (1) The first is a fully unsupervised model where we used a uniform Dirichlet prior for π. We found that this unsupervised model could not separate aspect and opinion words well. (2) The second is a bootstrapping version of the MaxEnt-LDA model where we used the predicted values of y as pseudo labels and re-trained the MaxEnt model iteratively. We found that this bootstrapping procedure did not boost the overall performance much and even hurt the performance a little in some cases. Due to the space limit we do not report these experiments here.

5 Evaluation

In this section we report the evaluation of our model. We refer to our MaxEnt-LDA hybrid model as *ME-LDA*. We also implemented a local version of the standard LDA method where each sentence is treated as a document. This is the model used in (Brody and Elhadad, 2010) to identify aspects, and we refer to this model as *LocLDA*.

Food	Staff	Order Taking	Ambience
chocolate	service	wait	room
dessert	food	waiter	dining
cake	staff	wait	tables
cream	**excellent**	order	bar
ice	**friendly**	minutes	place
desserts	**attentive**	seated	decor
coffee	**extremely**	waitress	scene
tea	waiters	reservation	space
bread	**slow**	asked	area
cheese	**outstanding**	told	table

Table 4: Sample aspects of the restaurant domain using LocLDA. Note that the words in bold are opinion words which are mixed with aspect words.

5.1 Qualitative Evaluation

For each of the two data sets, we show four sample aspects identified by ME-LDA in Table 3 and Table 5. Because the hotel domain is somehow similar to the restaurant domain, we used the labeled training data from the restaurant domain also for the hotel data set. From the tables we can see that generally aspect words are quite coherent and meaningful, and opinion words correspond to aspects very well. For comparison, we also applied LocLDA to the restaurant data set and present the aspects in Table 4. We can see that ME-LDA and LocLDA give similar aspect words. The major difference between these two models is that ME-LDA can sperate aspect words and opinion words, which can be very useful. ME-LDA is also able to separate general opinion words from aspect-specific ones, giving more informative opinion expressions for each aspect.

5.2 Evaluation of Aspects Identification

We also quantitatively evaluated the quality of the automatically identified aspects. Ganu et al. (2009) provide a set of annotated sentences from the restaurant data set, in which each sentence has been assigned one or more labels from a gold standard label set $\mathcal{S}$ = {Staff, Food, Ambience, Price, Anecdote, Misc}. To evaluate the quality of our aspect identification, we chose from the gold standard labels three major aspects, namely *Staff*, *Food* and *Ambience*. We did not choose the other aspects because (1) *Price* is often mixed with other aspects such as *Food*, and (2) *Anecdote* and *Misc* do not show clear

[3] We randomly selected 46 sentences for manual annotation.

Food		Staff		Order Taking		Ambience		General
Aspect	Opinion	Aspect	Opinion	Aspect	Opinion	Aspect	Opinion	Opinion
chocolate	good	service	friendly	table	seated	room	small	good

Table 5: Sample aspects and opinion words of the hotel domain using ME-LDA.

patterns in either word usage or writing styles, making it even hard for humans to identify them. Brody and Elhadad (2010) also only used these three aspects for quantitative evaluation. To avoid ambiguity, we used only the single-labeled sentences for evaluation. About 83% of the labeled sentences have a single label, which confirms our observation that a sentence usually belongs to a single aspect.

Aspect	Method	Precision	Recall	F-1
Staff	LocLDA	0.804	0.585	0.677
	ME-LDA	0.779	0.540	0.638
Food	LocLDA	0.898	0.648	0.753
	ME-LDA	0.874	0.787	0.828
Ambience	LocLDA	0.603	0.677	0.638
	ME-LDA	0.773	0.558	0.648

Table 6: Results of aspects identification on restaurant.

We first ran ME-LDA and LocLDA each to get an inferred aspect set $\mathcal{T}$. Following (Brody and Elhadad, 2010), we set the number of aspects to 14 in both models. We then manually mapped each inferred aspect to one of the six gold standard aspects, i.e., we created a mapping function $f(t) : \mathcal{T} \rightarrow \mathcal{S}$. For sentence s of document d, we first assign it to an inferred aspect as follows:

$$t^* = \arg\max_{t \in \mathcal{T}} \sum_{n=1}^{N_{d,s}} \log P(w_{d,s,n}|t).$$

We then assign the gold standard aspect $f(t^*)$ to this sentence. We then calculated the F-1 score of the three aspects: *Staff*, *Food* and *Ambience*. The results are shown in Table 6. Generally ME-LDA has given competitive results compared with LocLDA. For *Food* and *Ambience* ME-LDA outperformed LocLDA, while for *Staff* ME-LDA is a little worse than LocLDA. Note that ME-LDA is not designed to compete with LocLDA for aspect identification.

5.3 Evaluation of Opinion Identification

Since the major advantage of ME-LDA is its ability to separate aspect and opinion words, we further quantitatively evaluated the quality of the aspect-specific opinion words identified by ME-LDA. Brody and Elhadad (2010) has constructed a gold standard set of aspect-specific opinion words for the restaurant data set. In this gold standard set, they manually judged eight out of the 14 automatically inferred aspects they had: $\mathcal{J}$ = {Ambiance, Staff, Food-Main Dishes, Atmosphere-Physical, Food-Baked Goods, Food-General, Drinks, Service}. Each word is assigned a polarity score ranging from -2.0 to 2.0 in each aspect. We used their gold standard words whose polarity scores are not equal to zero. Because their gold standard only includes adjectives, we also manually added more opinion words into the gold standard set. To do so, we took the top 20 opinion words returned by our method and two baseline methods, pooled them together, and manually judged them. We use precision at n (P@n), a commonly used metric in information retrieval, for evaluation. Because top words are more important in opinion models, we set n to 5, 10 and 20. For both ME-LDA and BL-1 below, we again manually mapped each automatically inferred aspect to one of the gold standard aspects.

Since LocLDA does not identify aspect-specific opinion words, we consider the following two baseline methods that can identify aspect-specific opinion words:

BL-1: In this baseline, we start with all adjectives as candidate opinion words, and use mutual information (MI) to rank these candidates. Specifically, given an aspect t, we rank the candidate words according to the following scoring function:

$$\text{Score}_{\text{BL-1}}(w,t) = \sum_{v \in \mathcal{V}_t} p(w,v) \log \frac{p(w,v)}{p(w)p(v)},$$

where $\mathcal{V}_t$ is the set of the top-100 frequent aspect words from $\phi^{A,t}$.

BL-2: In this baseline, we first use LocLDA to learn a topic distribution for each sentence. We then assign a sentence to the aspect with the largest probability and hence get sentence clusters. We manually map these clusters to the eight gold standard aspects. Finally, for each aspect we rank adjectives by their frequencies in the aspect and treat these as aspect-specific opinion words.

Method	P@5	P@10	P@20
ME-LDA	$0.825^{*,\diamond}$	0.700^{*}	0.569^{*}
BL-1	0.400	0.450	0.469
BL-2	0.725	0.650	0.563

Table 7: Average P@n of aspect-specific opinion words on restaurant. * and $\diamond$ indicate that the improvement hypothesis is accepted at confidence level 0.9 respectively for BL-1 and BL-2.

The basic results in terms of the average precision at n over the eight aspects are shown in Table 7. We can see that ME-LDA outperformed the two baselines consistently. Especially, for P@5, ME-LDA gave more than 100% relative improvement over BL-1. The absolute value of 0.825 for P@5 also indicates that top opinion words discovered by our model are indeed meaningful.

5.4 Evaluation of the Association between Opinion Words and Aspects

The evaluation in the previous section shows that our model returns good opinion words for each aspect. It does not, however, directly judge how *aspect-specific* those opinion words are. This is because the gold standard created by (Brody and Elhadad, 2010) also includes general opinion words. E.g. *friendly* and *good* may both be judged to be opinion words for the *staff* aspect, but the former is more specific than the latter. We suspect that BL-2 has comparable performance with ME-LDA for this reason. So we further evaluated the association between opinion words and aspects by directly looking at how easy it is to infer the corresponding aspect by only looking at an aspect-specific opinion word. We selected four aspects for evaluation: *Ambiance*, *Staff*, *Food-Main Dishes* and *Atmosphere-Physical* . We chose these four aspects because they are quite different from each other and thus manual judgments on these four aspects can be more objective. For each aspect, similar to the pooling strategy in IR, we pooled the top 20 opinion words identified by BL-1, BL-2 and ME-LDA. We then asked two human assessors to assign an association score to each of these words as follows: If the word is closely associated with an aspect, a score of 2 is given; if it is marginally as-

Metrics	Dataset	BL-2	ME-LDA
nDCG@5	Restaurant	0.647	0.764
	Hotel	0.782	0.820
nDCG@10	Restaurant	0.781	0.897
	Hotel	0.722	0.789

Table 8: Average nDCG performance of BL-2 and ME-LDA. Because only four aspects were used for evaluation, we did not perform statistical significance test. We found that in all cases ME-LDA outperformed BL-2 for either all aspects or three out of four aspects.

sociated with an aspect, a score of 1 is given; otherwise, 0 is given. We calculated the Kappa statistics of agreement, and we got a quite high Kappa value of 0.8375 and 0.7875 respectively for the restaurant data set and the hotel data set. Then for each word in an aspect, we took the average of the scores of the two assessors. We used an nDCG-like metric to compare the performance of our model and of BL-2. The metric is defined as follows:

$$\text{nDCG@}k(t, \mathcal{M}) = \frac{\sum_{i=1}^{k} \frac{\text{Score}(\mathcal{M}_{t,i})}{\log_2(i+1)}}{\text{iDCG@}k(t)},$$

where $\mathcal{M}_{t,i}$ is the ith aspect-specific opinion word inferred by method $\mathcal{M}$ for aspect t, Score($\mathcal{M}_{t,i}$) is the association score of this word, and iDCG@$k(t)$ is the score of the ideal DCG measure at k for aspect t, that is, the maximum DCG score assuming an ideal ranking. We chose $k = 5$ and $k = 10$. The average nDCG over the four aspects are presented in Table 8. We can see that ME-LDA outperformed BL-2 quite a lot for the restaurant data set, which conforms to our hypothesis that ME-LDA generates aspect-specific opinion words of stronger association with aspects. For the hotel data set, ME-LDA outperformed a little. This may be due to the fact that we used the restaurant training data for the hotel data set.

6 Further Analysis of MaxEnt

In this section, we perform some further evaluation and analysis of the MaxEnt component in our model.

6.1 Feature Selection

Previous studies have shown that simple POS features and lexical features can be very effective for discovering aspect words and opinion words (Hu and Liu, 2004; Jin et al., 2009; Wu et al., 2009; Brody and Elhadad, 2010). for POS features, since we observe that aspect words tend to be nouns while opinion words tend to be adjectives but sometimes also verbs or other part-of-speeches, we can expect that POS features should be quite useful. As for lexical features, words from a sentiment lexicon can also be helpful in discovering opinion words.

Methods	Average F-1
LocLDA	0.690
ME-LDA + $\mathcal{A}$	0.631
ME-LDA + $\mathcal{B}$	0.695
ME-LDA + $\mathcal{C}$	0.705

Table 9: Comparison of the average F-1 using different feature sets for aspect identification on restaurant.

However, lexical features are more diverse so presumably we need more training data in order to detect useful lexical features. Lexical features are also more domain-dependent. On the other hand, we hypothesize that POS features are more effective when the amount of training data is small and/or the training data comes from a different domain. We therefore compare the following three sets of features:

- $\mathcal{A}$: w_{i-1}, w_i, w_{i+1}
- $\mathcal{B}$: POS_{i-1}, POS_i, POS_{i+1}
- $\mathcal{C}$: $\mathcal{A} + \mathcal{B}$

We show the comparison of the performance in Table 9 using the average F-1 score defined in Section 5.2 for aspect identification, and in Table 10 using the average P@n measure defined in Section 5.3 for opinion identification. We can see that Set $\mathcal{B}$ plays the most important part, which conforms to our hypothesis that POS features are very important in opinion mining. In addition, we can see that Set $\mathcal{C}$ performs a bit better than Set $\mathcal{B}$, which indicates that some lexical features (e.g., general opinion words) may also be helpful. Note that here the training data is from the same domain as the test data, and therefore lexical features are likely to be useful.

6.2 Examine the Size of Labeled Data

As we have seen, POS features play the major role in discriminating between aspect and opinion words. Because there are much fewer POS features than word features, we expect that we do not need many

Methods	P@5	P@10	P@20
BL-2	0.725	0.650	0.563
ME-LDA + $\mathcal{A}$	0.150	0.200	0.231
ME-LDA + $\mathcal{B}$	0.775	0.688	0.569
ME-LDA + $\mathcal{C}$	0.825	0.700	0.569

Method	F-1
LocalLDA	0.690
ME-LDA + 10	0.629
ME-LDA + 20	0.692
ME-LDA + 30	0.691
ME-LDA + 40	0.726
ME-LDA + 46	0.705

Table 11: Average F-1 with differen sizes of training data on restaurant.

labeled sentences to learn the POS-based patterns. We now examine the sensitivity of the performance with respect to the amount of labeled data. We generated four smaller training data sets with 10, 20, 30 and 40 sentences each from the whole training data set we have, which consists of 46 labeled sentences. The results are shown in Table 11 and Table 12. We can see that generally the performance stays above BL when the number of training sentences is 20 or more. This indicates that our model needs only a relatively small number of high-quality training sentences to achieve good results.

6.3 Domain Adaption

Since we find that the MaxEnt supervision relies more on POS features than lexical features, we also hypothesize that if the training sentences come from a different domain the performance can still remain relatively high. To test this hypothesis, we tried two quite different training data sets, one from the *cell phone* domain and the other from the *DVD player* domain, both used in (Wu et al., 2009).

Method	P@5	P@10	P@20
BL-2	0.725	0.650	0.563
ME-LDA + 10	0.700	0.563	0.488
ME-LDA + 20	0.875	0.650	0.600
ME-LDA + 30	0.825	0.700	0.569
ME-LDA + 40	0.825	0.688	0.581

restaurant + $\mathcal{C}$	0.705
cell phone + $\mathcal{B}$	0.662
cell phone + $\mathcal{C}$	0.629
DVD player + $\mathcal{B}$	0.686
DVD player + $\mathcal{C}$	0.635

Table 13: Average F-1 performance for domain adaption on restaurant.

Method	P@5	P@10	P@20
restaurant + $\mathcal{B}$	0.775	0.688	0.569
restaurant + $\mathcal{C}$	0.825	0.700	0.569
cell phone + $\mathcal{B}$	0.775	0.675	0.588
cell phone + $\mathcal{C}$	0.750	0.688	0.594
DVD player + $\mathcal{B}$	0.775	0.713	0.575
DVD player + $\mathcal{C}$	0.825	0.663	0.588

Table 14: Average P@n of aspect-specific opinion words for domain adaption on restaurant.

We consider two feature sets defined in Section 6.1 for domain adaption, namely $\mathcal{B}$ and $\mathcal{C}$. The results are shown in Table 13 and Table 14.

For aspect identification, using out-of-domain training data performed worse than using in-domain training data, but the absolute performance is still decent. And interestingly, we can see that using $\mathcal{B}$ is better than using $\mathcal{C}$, indicating that lexical features may hurt the performance in the cross-domain setting. It suggests that lexical features are not easily adaptable across domains for aspect identification.

For opinion identification, we can see that there is no clear difference between using out-of-domain training data and using in-domain training data, which may indicate that our opinion identification component is robust in domain adaption. Also, we cannot easily tell whether $\mathcal{B}$ has advantage over $\mathcal{C}$ for opinion identification. One possible reason may be that those general opinion words are useful across domains, so lexical features may still be useful for domain adaption.

7 Conclusions

In this paper, we presented a topic modeling approach that can jointly identify aspect and opinion words, using a MaxEnt-LDA hybrid. We showed that by incorporating a supervised, discriminative maximum entropy model into an unsupervised, generative topic model, we could leverage syntactic features to help separate aspect and opinion words. We evaluated our model on two large review data sets from the restaurant and the hotel domains. We found that our model was competitive in identifying meaningful aspects compared with previous models. Most importantly, our model was able to identify meaningful opinion words strongly associated with different aspects. We also demonstrated that the model could perform well with a relatively small amount of training data or with training data from a different domain.

Our model provides a principled way to jointly model both aspects and opinions. One of the future directions we plan to explore is to use this model to help sentence-level extraction of specific opinions and their targets, which previously was only tackled in a fully supervised manner. Another direction is to extend the model to support polarity classification.

Abstract

This paper presents a two-stage approach to summarizing multiple contrastive viewpoints in opinionated text. In the first stage, we use an unsupervised probabilistic approach to model and extract multiple viewpoints in text. We experiment with a variety of lexical and syntactic features, yielding significant performance gains over bag-of-words feature sets. In the second stage, we introduce *Comparative LexRank*, a novel random walk formulation to score sentences and pairs of sentences from opposite viewpoints based on both their representativeness of the collection as well as their contrastiveness with each other. Experimental results show that the proposed approach can generate informative summaries of viewpoints in opinionated text.

1 Introduction

The amount of opinionated text available online has been growing rapidly, increasing the need for systems that can summarize opinions expressed in such text so that a user can easily digest them. In this paper, we study how to summarize opinionated text in a such a way that highlights contrast between multiple viewpoints, which is a little-studied task.

Usually, online opinionated text is generated by multiple people, and thus often contains multiple viewpoints about an issue or topic. A viewpoint/perspective refers to "a mental position from which things are viewed" (cf. WordNet). An opinion is usually expressed in association with a particular viewpoint, even though the viewpoint is usually not explicitly given; for example, a blogger that is in favor of a policy would likely look at the positive aspects of the policy (i.e., positive viewpoint), while someone against the policy would likely emphasize the negative aspects (i.e., negative viewpoint). Moreover, in an opinionated text with diverse opinions, the multiple viewpoints taken by opinion holders are often "contrastive", leading to opposite polarities. Indeed, such contrast in opinions may be a main driving force behind many online discussions.

Futhermore, opinions regarding news events and other short-term issues may quickly emerge and disappear. Such opinions may reflect many different types of viewpoints which cannot be modeled by current systems. For this reason, we believe that a viewpoint summarization system would benefit from the ability to extract unlabeled viewpoints without supervision. Even if such clustering has inaccuracies, it could still be a useful starting point for human editors to select representative excerpts.

Thus, given a set of opinionated documents about a topic, we aim at automatically extracting and summarizing the multiple contrastive viewpoints implicitly expressed in the opinionated text to facilitate digestion and comparison of different viewpoints. Specifically, we will generate two types of multi-view summaries: macro multi-view summary and micro multi-view summary. A macro multi-view summary would contain multiple sets of sentences, each representing a different viewpoint; these different sets of sentences can be compared to understand the difference of multiple viewpoints at the "macro level." A micro multi-view summary would contain a set of pairs of contrastive sentences (each pair

MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

consists of two sentences representing two different viewpoints), making it easy to understand the difference between two viewpoints at the "micro level."

Although opinion summarization has been extensively studied (e.g., (Liu et al., 2005; Hu and Liu, 2004; Hu and Liu, 2006; Zhuang et al., 2006)), existing work has not attempted to generate our envisioned contrastive macro and micro multi-view summaries in an unsupervised way, which is the goal of our work. For example, Hu and Liu (2006) rank sentences based on their dominant sentiment according to the polarity of adjectives occuring near a product feature in a sentence. A contradiction occurs when two sentences are highly unlikely to be simultaneously true (cf. (Marneffe et al., 2008)). Although little work has been done on contradiction detection, there are a few notable approaches (Harabagiu et al., 2006; Marneffe et al., 2008; Kim and Zhai, 2009).

The closest work to ours is perhaps that of Lerman and McDonald (2009) who present an approach to contrastive summarization. They add an objective to their summarization model such that the summary model for one set of text is different from the model for the other set. The idea is to highlight the key differences between the sets, however this is a different type of contrast than the one we study here – our goal is instead to make the summaries *similar* to each other, to contrast how the same information is conveyed through different viewpoints.

In this paper, we propose a two-stage approach to solving this novel summarization problem, which will be explained in the following two sections.

2 Modeling Viewpoints

The first challenge to be solved in order to generate a contrastive summary of multiple viewpoints is to model and extract these viewpoints which are hidden in text. In this paper we propose to solve this challenge by employing the Topic-Aspect Model (TAM) (Paul and Girju, 2010), which is an extension of the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) for jointly modeling topics and viewpoints in text. While most existing work on such topic models (including TAM) has taken a topic model as a generative model for word tokens in text, we propose to take TAM as a generative model for more complex linguistic features extracted from text. These are more discriminative than single word tokens and can improve the accuracy of extracting multiple viewpoints as we will show in the experimental results' section. Below we first give a brief introduction to TAM and then present the proposed set of features.

2.1 Topic-Aspect Model (TAM)

LDA-style probabilistic topic models of document content (Blei et al., 2003) have been shown to offer state-of-the-art summarization quality. Such models also provide a framework for adding additional structure to a summarization model (Haghighi and Vanderwende, 2009). In our case, we want to add more structure to a model to incorporate the notion of viewpoint/perspective into our summaries.

When it comes to extracting viewpoints, recent research suggests that it may be beneficial to model both topics and perspectives, as sentiment may be expressed differently depending on the issue involved (Brody and Elhadad, 2010; Paul and Girju, 2010). For example, let's consider a set of product reviews for a home theater system. Content topics in this data might include things like sound quality, usability, etc., while the viewpoints might be the positive and negative sentiments. A word like *speakers*, for instance depends on the sound topic but not a viewpoint, while *good* would be an example of a word that depends on a viewpoint but not any particular topic. A word like *loud* would depend on both (since it would be considered positive sentiment only in the context of the sound quality topic), while a word like *think* depends on neither.

We make use of a recent model, the Topic-Aspect Model (Paul and Girju, 2010), which can model such behavior with or without supervision. Under this model, a document has a mixture over topics as well as a mixture over viewpoints. The two mixtures are drawn independently of each other, and thus can be thought of as two separate clustering dimensions. A word is associated with variables denoting its topic and viewpoint assignments, as well as two binary variables to denote if the word depends on the topic and if the word depends on the viewpoint. A word may depend on the topic, the viewpoint, both, or neither, as in the above example.

The generative process for a document d under this model can be briefly described as follows. For each word in a document:

1. Sample a topic z from $P(z|d)$ and a viewpoint v from $P(v|d)$.
2. Sample a "level" $\ell \in \{0,1\}$ from $P(\ell|d)$. This determines if the word will depend on the topic (topical level) or not (background level).
3. Sample a "route" $r \in \{0,1\}$ from $P(r|\ell,z)$. This determines if the word will depend on the viewpoint.
4. Sample a word w from $P(w|z,v,r,\ell)$.

The probabilities are multinomial/binomial distributions with Dirichlet/Beta priors, and thus this model falls under the standard LDA framework. The number of topics and number of viewpoints are parameters that must be specified. Inference can be done with Gibbs sampling (Paul and Girju, 2010).

TAM naturally gives us a very rich output to use in a viewpoint summarization application. If we are doing unsupervised viewpoint extraction, we can use the output of the model to compute $P(v|sentence)$ which could be used to generate summaries that contain only excerpts that strongly highlight one viewpoint over another. Similarly, we could use the learned topic mixtures to generate topic-specific summaries. Futhermore, the variables r and ℓ tell us if a word is dependent on the viewpoint and topic, and we could use this information to focus on sentences that contain informative content words. Note that without supervision, TAM's clustering is based only on co-occurrences and the patterns it captures may or may not correspond with the viewpoints we wish to extract. Nonetheless, we show in this research that it can indeed find meaningful viewpoints with reasonable accuracy on certain data sets. Although we do not explore this in this paper, additional information about the viewpoints could be added to TAM by defining priors on the distributions to further improve the accuracy of viewpoint discovery.

2.2 Features

Previous work with TAM used only bag of words features, which may not be the best features for capturing viewpoints. For example, "Israel attacked Palestine" and "Palestine attacked Israel" are identical excerpts in an exchangable bag of words representation, yet one is more likely to come from the perspective of a Palestinian and the other from an Israeli. In this subsection, we will propose a variety of feature sets. We evaluate the utility of these features to the task of modeling viewpoints by measuring the accuracy of unsupervised clustering.

2.2.1 Words

We have experimented with simple bag of words features as baseline approaches, both with and without removing stop words, and found that the accuracy of clustering by viewpoint is better when retaining all words. This supports the observation that common function words may have important psychological properties (Chung and Pennebaker, 2007). Thus, we do not do any stop word removal for any of our other feature sets. We find that we get better results by stemming the words, so we apply Porter's stemmer to all of our features described.

2.2.2 Dependency Relations

It has been shown that using syntactic information can improve the accuracy of sentiment models (Joshi and Rosé, 2009). Thus, instead of representing documents as a bag of words, we will experiment with using features returned by a dependency parser. For this, we used the Stanford parser[1], which returns dependency tuples of the form $\texttt{rel}(a,b)$ where $\texttt{rel}$ is some dependency relation and a and b are tokens of a sentence. We can use these specific tuples as features, referred here as the *full-tuple* representation.

One problem with this representation is that we are using very specific information and it is harder for learning algorithms to find patterns due to the lack of redundancy. One solution is to generalize these features and rewrite a tuple $\texttt{rel}(a,b)$ as two tuples: $\texttt{rel}(a,*)$ and $\texttt{rel}(*,b)$ (Greene and Resnik, 2009; Joshi and Rosé, 2009). We will refer to this as the *split-tuple* representation.

2.2.3 Negation

If a word w_i appears in the head of a $\texttt{neg}$ relation, then we would like this to be reflected in other dependency tuples in which w_i occurs. For a tuple $\texttt{rel}(w_i,w_j)$, if either w_i or w_j is negated, then we simply rewrite it as $\neg\texttt{rel}(w_i,w_j)$.

An alternative would be to rewrite the individual word w_i as $\neg w_i$. However in our experiments this representation produced worse accuracies, perhaps because this produces less redundancy.

[1] http://nlp.stanford.edu/software/

2.2.4 Polarity

We also hypothesize that lexical polarity information may improve our model. If we are using the *full-tuple* representation, then a tuple becomes more general by replacing the specific word with a $+$ or $-$. In the case that both words are polarity words, we use two tuples, replacing only one word at a time rather than replacing both words with their polarity signs. To determine the polarity of a word, we simply use the Subjectivity Clues lexicon (Wilson et al., 2005) and as polarity values, *positive* (+), *negative* (-), and *neutral* (*). Under our *split-tuple* representation, this becomes more specific by replacing the $*$ with the polarity sign. For example, the tuple $\texttt{amod}(idea, good)$ would be represented as $\texttt{amod}(idea, +)$ and $\texttt{amod}(*, good)$. We collapse negated features to flip the polarity sign such that $\neg\texttt{rel}(a, +)$ becomes $\texttt{rel}(a, -)$.

2.2.5 Generalized Relations

We also experimented with backing off the relations themselves. Since the Stanford dependencies can be organized in a hierarchy[2], we will represent the relations at more generalized levels in the hierarchy. For example, both a direct object and an indirect object are a type of object. For a relation $\texttt{rel}$, we define $\texttt{R}_{\texttt{rel}}$ as the relation above $\texttt{rel}$ in the hierarchy – for example, $\texttt{R}_{\texttt{dobj}} = \texttt{obj}$. We make an exception for neg which has its own important properties that we wish to retain, so we let $\texttt{R}_{\texttt{neg}} = \texttt{neg}$. Thus, when using these features, we rewrite $\texttt{rel}(a, b)$ as $\texttt{R}_{\texttt{rel}}(a, b)$.

3 Multi-Viewpoint Summarization

As a computation problem, extractive multi-viewpoint summarization would take as input a set of candidate excerpts[3] $X = \{x_1, x_2, ..., x_{|X|}\}$ with k viewpoints and generate two types of multi-view contrastive summaries: 1) A macro contrastive summary S_{macro} consists of k disjoint sets of excerpts, $X_1, X_2, ..., X_k \subset X$ with each X_i containing representative sentences of the i-th view (i.e., $S_{macro} = (X_1, ..., X_k)$). The number of excerpts in each X_i can be empirically set based on application needs. 2) A micro contrastive summary S_{micro} consists of a set of excerpt pairs, each containing two excerpts from two different viewpoints, i.e., $S_{micro} = \{(s_1, t_1), ..., (s_n, t_n)\}$ where $s_i \in X$ and $t_i \in X$ are two comparable excerpts representing two different viewpoints. n is the length of the summary, which can be set empirically based on application needs. Note that both macro and micro summaries can reveal contrast between different viewpoints, though at different granularity levels.

To generate macro and micro summaries based on the probabilistic assignment of excerpts to viewpoints given by TAM, we propose a novel extension to the LexRank algorithm (Erkan and Radev, 2004), a graph-based method for scoring representative excerpts to be used in a summary. Our key idea is to modify the definition of the jumping probability in the random walk model so that it would favor excerpts that represent a viewpoint well and encourage jumping to an excerpt comparable with the current one but from a different viewpoint. As a result, the stationary distribution of the random walk model would capture representative contrastive excerpts and allow us to generate both macro and micro contrastive summaries within a unified framework. We now describe this novel summarization algorithm (called Comparative LexRank) in detail.

3.1 Comparative LexRank

LexRank is a PageRank-like algorithm (Page et al., 1998), where we define a random walk model on top of a graph that has sentences to be summarized as nodes and edges placed between two sentences that are similar to each other. We can then score all the sentences based on the expected probability of a random walker visiting each sentence. We use the short-hand $P(x_j|x_i)$ to denote the probability of being at node x_j at a time t given that the walker was at x_i at time $t-1$. The jumping probability from node x_i to node x_j is given by:

$$P(x_j|x_i) = \frac{sim(x_i, x_j)}{\sum_{j' \in X} sim(x_i, x_{j'})} \quad (1)$$

where sim is a content similarity function defined on two sentence/excerpt nodes.

Our extension is mainly to modify this jumping probability in two ways so as to favor visiting contrastive representative opinions from multiple view-

[2] The complete hierarchy can be found in the Stanford dependencies manual (Marneffe and Manning, 2008).

[3] An "excerpt" refers to the smallest unit of text that will make up our summary such as a sentence.

points. The first modification is to make it favor jumping to a good representative excerpt x of any viewpoint v (i.e., with high probability $p(v|x)$ according to the TAM model). The second modification is to further favor jumping between two excerpts that can potentially form a good contrastive pair for use in generating a micro contrastive summary.

Specifically, under our model, the random walker first decides whether to jump to a sentence of the same viewpoint or to a sentence of a different viewpoint. We define this decision as a binary variable $z \in \{0, 1\}$. Intuitively, if we can force the random walker to move back and forth between viewpoints, then the final scores will favor sentences that are similar across both viewpoints.

We define two different modified similarity functions for the two possible values of z. The first one, sim_0 (corresponding to $z = 0$) scales the similarity by the likelihood that the two x's represent the same viewpoint, and the second one, sim_1 (for $z = 1$) scales the similarity by the likelihood that the x's come from different viewpoints.

$$\begin{aligned} sim_0(x_i, x_j) &= sim(x_i, x_j) \sum_{m=1}^{k} P(v = m|x_i)P(v = m|x_j) \\ sim_1(x_i, x_j) &= sim(x_i, x_j) \times \\ &\sum_{m_1, m_2 \in [1,k], m_1 \neq m_2} P(v = m_1|x_i)P(v = m_2|x_j) \end{aligned}$$

where $P(v|x)$ denotes the probability that the excerpt x belongs to the viewpoint v, and in general, can be obtained through any multi-viewpoint model. A special case of this is when the labels for viewpoints are known, in which case $P(v|x) = 1$ for the correct label and 0 for the others.

In our experiments, $P(v|x)$ comes from the output of TAM, and we define $sim(x_i, x_j)$ as the cosine between the vectors x_i and x_j, although again any similarity function could be used. The conditional transition probability from x_i to x_j given z is then:

$$P(x_j|x_i, z) = \frac{sim_z(x_i, x_j)}{\sum_{j' \in X} sim_z(x_i, x_{j'})} \quad (2)$$

Using λ to denote $P(z = 0)$ and marginalizing across z, we have the transition probability:

$$P(x_j|x_i) = \lambda P(x_j|x_i, z = 0) + (1 - \lambda)P(x_j|x_i, z = 1)$$

The stationary distribution of the random walk gives us a scoring of the excerpts to be used in our summary. It is also possible to score *pairs* of excerpts that contrast each other. We define the score for a pair (x_i, x_j) as the probability of being at x_i and transitioning to x_j or vice versa, where x_i and x_j are of opposite viewpoints. Specifically:

$$P(x_i)P(x_j|x_i, z = 1) + P(x_j)P(x_i|x_j, z = 1) \quad (3)$$

3.2 Summary Generation

The final summary should be a set of excerpts that have a high relevance score according to our scoring algorithm, but are not redundant among each other. Many techniques could be used to accomplish this (Carbonell and Goldstein, 1998; McDonald, 2007), but we use a simple greedy approach: at each step of the summary generation algorithm, we add the excerpt with the highest relevance score as long as the excerpt's redundancy score – the cosine similarity between the candidate and the current summary – is under some threshold δ. This is repeated until the summary reaches a user-supplied length limit.

Macro contrastive summarization: A macro-level summary consists of independent summaries for each viewpoint, which we generate by first using the random walk stationary distribution across all of the data to rank the excerpts. We then separate the top-ranked excerpts into two disjoint sets according to their viewpoint based on whichever gives a greater value of $P(v|x)$, and finally remove redundancy and produce the summary according to our method described above. We refer to this as *macro contrastive summarization*, because the summaries will contrast each other in that they have related content, but the excerpts in the summaries are not explicitly aligned with each other.

Micro contrastive summarization: A candidate excerpt for a micro-level summary will consist of a pair (x_i, x_j) with the pairwise relevance score defined in Equation 3. We can then rank these pairs and remove redundancy. It is possible that both x_i and x_j in a high-scoring pair may belong to the same viewpoint; such a case would be filtered out since we are mainly interested in including contrastive pairs in our summary. We refer to this as *micro contrastive summarization*, because the summaries will allow us to see contrast at the level of individual excerpts from different viewpoints.

4 Experiments and Evaluation

4.1 Experimental Setup

Evaluation of multi-view summarization is challenging as there is no existing data set we can use. We leverage the resources on the Web and created two data sets in the domain of political opinion.

Our first dataset is a set of 948 verbatim responses to a Gallup® phone survey about the 2010 U.S. healthcare bill (Jones, 2010), conducted March 4-7, 2010. Responses in this set tend to be short and often incomplete or otherwise ill-formed and informal sentences. Respondants indicate if they are 'for' or 'against' the bill, and there is a roughly even mix of the two viewpoints (45% for and 48% against).

We also use the Bitterlemons corpus, a collection of 594 editorials about the Israel-Palestine conflict. This dataset is fully described in (Lin et al., 2006) and has been used in other perspective modeling literature (Lin et al., 2008; Greene and Resnik, 2009). The style of this data differs substantially from the healthcare data in that documents in this set tend to be long and verbose articles with well-formed sentences. It again contains a fairly even mixture of two different perspectives: 312 articles from Israeli authors and 282 articles from Palestinian authors.

Moreover, for the healthcare data set, manually extracted opinion polls are available on the Web, which we further leverage to construct gold standard summaries to evaluate our method quantitatively. The data and test sets are available at `http://apfel.ai.uiuc.edu/resources.html`.

4.2 Stage One: Modeling Viewpoints

The main research question we want to answer in modeling viewpoints is whether richer feature sets would lead to better accuracy than word features. We used our various feature sets as input to TAM and measured the accuracy of clustering documents by viewpoint. This evaluation serves both to measure how accurately this type of clustering can be done, as well as to measure which types of features are important for modeling viewpoints.

We found that the clustering accuracy is improved if we measure the accuracy of only the subset of documents such that $P(v|doc)$ is greater than some threshold (we used 0.8). Thus, the accuraries presented in this section are measured using this confidence threshold. We will use this approach for the summarization task as well, as it ensures we are only summarizing documents where we have high confidence about their viewpoint membership.

There are several parameters to set for TAM. Since our focus is on comparing linguistic features with word features, we simply set these parameters to some reasonable values: We used Dirichlet pseudo-counts of 80.0 for $P(\ell = 0)$, 20.0 for $P(\ell = 1)$, uniform pseudo-counts of 5.0 for $P(x)$, 0.1 for the topic and aspect mixtures, and 0.01 for the word distributions. We tell the model to use 2 viewpoints as well as 5 topics for the healthcare corpus and 8 topics for the Bitterlemons corpus.

There is high variance in the accuracies depending on how the Gibbs samplers were initialized. We thus repeated the experiments many times to obtain relatively confident measures – 200 times for the healthcare set and 50 times for the Bitterlemons set, with 2000 iterations each time. A natural way to select a model is to choose the model that gives the highest likelihood to its input. To evaluate how well this selection strategy would work, we measured the correlation between accuracy and likelihood.

The results are shown in Table 1. We can make several observations. (1) In all cases, the proposed linguistic features yield higher accuracy than the word features, supporting our hypothesis that for viewpoint modeling, applying TAM to these features improves performance over using simple word features. Since virtually all existing work on topic models assumes word tokens as data to be modeled, our results suggest that it would be interesting to explore applying generative topic models to complex features for other tasks as well. This may be because by adding additional complex features to the observed data, we artificially inflate the data likelihood to emphasize modeling co-occurrences of such features, which effectively biases the model to capture a certain perspective of co-occurrences.

(2) The increase is substantially greater for the Bitterlemons corpus, which may be due to the fact that the parsing accuracy is likely better because the language is formal. The *split-tuple* representation is very significantly better for the healthcare corpus, but it is not clear which is better for the Bitterlemons corpus. It is also not clear how the generalized relations affect the performance.

	Healthcare Corpus					*Bitterlemons Corpus*				
Feature Set	**Mean**	**Med**	**Max**	**MaxLL**	**Corr**	**Mean**	**Med**	**Max**	**MaxLL**	**Corr**
bag of words	61.12 +/- 0.76%	61.01	72.17	52.92	0.187	68.22 +/- 3.31%	69.26	88.27	84.94	0.39
- no stopwords	60.58 +/- 0.79%	60.50	72.18	62.58	0.154	61.29 +/- 3.05%	57.69	91.34	82.91	0.33
full-tuples	62.42 +/- 0.88%	62.47	74.04	63.37	0.201	80.89 +/- 3.45%	85.40	94.07	92.10	0.34
+ negation	63.67 +/- 0.81%	64.54	74.07	69.25	0.338	80.60 +/- 3.88%	88.07	95.61	91.32	0.66
+ neg. + polarity	63.16 +/- 0.94%	64.46	74.05	67.8	0.455	82.53 +/- 3.55%	86.64	94.44	91.16	0.31
gen. full-tuples	63.80 +/- 0.73%	64.35	73.29	71.70	0.254	76.62 +/- 4.09%	84.56	94.53	84.56	0.25
split-tuples	68.32 +/- 0.90%	70.74	77.80	76.57	0.646	77.14 +/- 3.64%	81.29	92.99	88.13	0.30
+ negation	68.00 +/- 0.91%	69.11	79.73	76.14	0.187	83.53 +/- 3.05%	87.71	95.00	95.00	0.12
+ neg. + polarity	65.11 +/- 1.05%	65.35	78.59	67.22	0.159	81.24 +/- 3.37%	83.44	95.03	88.55	0.08
gen. split-tuples	69.31 +/- 0.83%	70.69	77.90	73.90	0.653	76.69 +/- 4.36%	83.78	93.60	91.67	0.09

Table 1: The clustering accuracy with TAM using a variety of feature sets. These results were averaged over 200 randomly-initialized Gibbs sampling procedures for the healthcare set, and 50 procedures for the Bitterlemons set. The 95% confidence interval using a standard t-test is also given. *Max* refers to the maximum accuracy obtained over the 200 or 50 instances. *MaxLL* refers to the clustering accuracy using the model that yielded the highest corpus log-likelihood as defined by TAM. *Corr* refers to the Pearson correlation coefficient between accuracy and log-likelihood.

(3) It appears that adding polarity helps the *full-tuple* features (by making them more general) but hurts the *split-tuple* features (by making them more specific). Negation significantly improves the *full-tuple* features in the Bitterlemons corpus, but it is not clear if it helps in the other cases. It should be noted that capturing negation and polarity is a very complex and difficult task, and it is not expected that our simple approaches will accurately capture these properties. Nonetheless, it seems that these simple features may help in certain cases.

4.3 Stage Two: Summarizing Viewpoints

For the second stage (i.e., the Comparative LexRank algorithm), we mainly want to evaluate the quality of the generated contrastive multi-viewpoint summary and study the effectiveness of our extension to the standard LexRank. Below we present extensive evaluation of our summarization method on the healthcare data. We do not have an evaluation set with which to compute quantitative metrics on the Bitterlemons corpus, so we will instead perform a simple qualitative evaluation in the last subsection.

4.3.1 Gold Standard Summaries

The responses to the Gallup healthcare poll are described in an article[4] which gives a table of the main responses found in the data along with their prominence in the data. In a way, this represents an expert human-generated summary of our database, and we will use this as a gold standard macro contrastive summary against which the representativeness of a multi-viewpoint contrastive summary can be evaluated. The reasons given in this table will be used verbatim as our reference set, excluding the other/no-reason/no-opinion reasons. A sample of this table is shown in Table 2.

We also want to develop a reference set for micro contrastive summaries, where we are mainly interested in evaluating contrastiveness. To do this, we asked 3 annotators to identify contrastive pairs in the “main reasons” table described above. Each pair must contain one reason from the ‘for’ side and one reason from the ’against’ side, though we do not require a one-to-one alignment; that is, multiple pairs may contain the same reason. We take the set of pairs that were identified as being contrastive by at least 2 annotators to be our gold set of contrastive pairs. Because these pairs come from the gold summary, they are still representative of the collection as a whole, rather than fine-grained contrasts.

The macro reference set contains 9 ‘for’ reasons and 15 ‘against’ reasons. The micro reference set contains 13 annotator-identified pairs composed of 9 unique ‘for’ reasons and 8 unique ‘against’ reasons.

4.3.2 Baseline Approaches

Graph-based algorithms: The standard LexRank algorithm can also be used to score pairs of sentences according to Equation 3. We will thus compare our new LexRank extension to the unmodified form of this algorithm. When $\lambda = 1$, the random walk model only transitions to sentences within the same viewpoint, and thus in this case our modified algorithm produces the same ranking as the unmodified LexRank. This will be our first baseline.

[4] http://www.gallup.com/poll/126521/Favor-Oppose-Obama-Healthcare-Plan.aspx

For		*Against*	
People need health insurance/Too many uninsured	29%	Will raise costs of insurance/Make it less affordable	20%
System is broken/Needs to be fixed	18%	Does not address real problems	19%
Costs are out of control/Would help control costs	12%	Need more information/clarity on how system would work	8%
Moral responsibility to provide/Obligation/Fair	12%	Against big government/Too much government involvement	8%

Table 2: Some of the top reasons given along with their prominence in the healthcare data, as analyzed by Gallup. This is a sample of what will serve as our gold set. The highlighted cells show an example of a contrastive pair identified by our annotators.

Model-based algorithms: We will also compare against the approach of Lerman and McDonald (2009) who introduce their contrastiveness objective into a model-based summarization algorithm. The basic form of this algorithm is to select a set of sentences S_m to minimize the KL-divergence between the models of the summary S_m and the entire collection X_m for a viewpoint m. The objective function is: $-\sum_{m=1}^{k} KL(L(S_m)||L(X_m))$ where L is an arbitrary language model. We define $L(A)$ simply as the unigram distribution over words in the collection A, a method also evaluated by Haghighi and Vanderwende (2009). This is the fairest comparison to our LexRank experiments, where sentences are also represented as unigrams. (We do not do any modeling with TAM in our quantitative evaluation.)

Lerman and McDonald introduce an additional term to maximize the KL-divergence between the summary of one viewpoint and the collection of the opposite viewpoint, so that each viewpoint's summary is dissimilar to the other viewpoints. We borrow this idea but instead do the opposite so that the viewpoints' summaries are more (rather than less) similar to each other. This contrastive version of our model-based baseline is formulated as:

$$-\sum_{m_1=1}^{k} KL(L(S_{m_1})||L(X_{m_1})) + \left(\frac{1}{k-1}\sum_{m_2\in[1,k],m_1\neq m_2} KL(L(S_{m_1})||L(X_{m_2}))\right)$$

Our summary generation algorithm is to iteratively add excerpts to the summary in a greedy fashion, selecting the excerpt with the highest score in each iteration. Note that this approach only generates macro-level summaries, leaving us with the LexRank baseline for micro-level summaries.

4.3.3 Metrics

We will evaluate our summaries using a variant of the standard ROUGE evaluation metric (Lin, 2004).

Recall that we have two different evaluation sets – one that contains all of the reasons for each viewpoint, and one that consists only of aligned pairs of excerpts. Since the same excerpt may appear in multiple pairs, there would be significant redundancy in our reference summary if we were to include every pair. Thus, we will restrict a contrastive reference summary to exclude overlapping pairs, and we will have many reference sets for all possible combinations of pairs. There is only one reference set for the representativeness criterion.

Our reference summaries have a unique property in that the summaries have already been annotated with the prominence of the different reasons in the data. A good summary should capture the more prominent statements, so we will include this in our scoring function. We thus augment the basic ROUGE n-gram recall score by weighting the n-gram counts in the reference summary according to this percentage. This is a generalization of the standard ROUGE formula where this percentage would be uniform.

For evaluating the macro-level summaries, we will score the summaries for the two viewpoints separately, given a reference set Ref_i and a candidate summary C_i for a viewpoint $v = i$. The final score is a combination of the scores for both viewpoints, i.e. $S_{rep} = 0.5S(Ref_i, C_i) + 0.5S(Ref_j, C_j)$ where $S(Ref, C)$ is our ROUGE-based scoring metric. It would also be interesting to measure how well a viewpoint's summary matches the gold summary of the *opposite* viewpoint, which will give insights into how well the Comparative LexRank algorithm makes the two summaries similar to each other. We will measure this as the inverse of the above metric, i.e. $S_{opp} = 0.5S(Ref_i, C_j) + 0.5S(Ref_j, C_i)$.

Finally, to score the micro-level comparative summaries (recall that this gives explicitly-aligned pairs of excerpts), we will concatenate each pair (x_i, x_j) as a single excerpt, and use these as the excerpts in our reference and candidate summaries. The scoring function is then $S_p = S(Ref_{pairs}, C_{pairs})$. Note that we have multiple reference summaries for the

λ	S_{rep}**-1**	S_{opp}**-1**	S_{rep}**-2**	S_{opp}**-2**	S_p**-1**	S_p**-2**
0.0	**.425**	**.416**	.083	.060	.309	.036
0.2	**.410**	**.423**	.082	**.065**	.285	.044
0.5	**.419**	**.434**	.085	**.072**	**.386**	.044
0.8	**.410**	.324	**.095**	.028	**.367**	**.062**
1.0	.354	.240	.070	.006	.322	.057
MB	.362	.246	.089	.003		
MC	.347	.350	.054	.059		

Table 3: Our evaluation scores for various values of λ. Smaller values of λ favor greater contrastiveness. Note that $\lambda = 1$ should be considered a baseline, because at this value the algorithm ignores the contrastiveness and it becomes a standard summarization problem. MB and MC refer to our model-based baselines described in Subsection 4.3.2. Bold scores are significant over all baselines according to a paired t-test.

micro-level evaluation due to overlapping pairs in the evaluation set. In this case, the ROUGE score is defined as the maximum score among all possible reference summaries (Lin, 2004).

We measure both unigram (removing stop words, denoted S-1) and bigram (retaining stop words, denoted S-2) recall, stemming words in all cases.

4.3.4 Evaluation Results

In order to evaluate our Comparative LexRank algorithm by itself, in this subsection we will not use the output of TAM as part of our summarization input, and will assign excerpts fixed values of $P(v|x) = 1$ for the correct label and 0 otherwise. We constructed our sentence vectors with unigrams (removing stop words) and no IDF weighting.

We set the PageRank damping factor (Erkan and Radev, 2004) to 0.01 and tried combinations of the redundancy threshold $\delta \in \{0.01, 0.05, 0.1, 0.2\}$ with different values of λ, the parameter which controls the level of contrastiveness. For each value of λ, we optimized δ on the original data set according to $S_{rep} \times S_{opp}$ so that we can directly compare these scores, and then we tuned δ separately for S_p. The summary length is 6 excerpts. To obtain more robust results, we repeated the experiment 100 times on random half-size subsets of our data. The scores shown in Table 3 are averaged across these trials.

In general, increasing λ increases S_{rep}, which suggests that tuning λ behaves as expected, and high- and mid-range λ values indeed produce summaries where the summaries of the two viewpoints are more similar to each other. Similarly, mid-range λ values produce substantially higher values of S_p-1, the unigram ROUGE scores for the micro contrastive summary, although there is not a large difference between the bigram scores. An example of our micro-level output is shown in Table 4.

As for our model-based baseline, we show results for both the basic algorithm (denoted MB) in addition to the contrastive modification (denoted MC). We see that the contrastive modification behaves as expected and produces much higher scores for S_{opp}, however, this method does not outperform our LexRank algorithm. It is interesting to note that in almost all cases where a contrastive objective is introduced, the scores for the opposite viewpoint S_{opp} increase without decreasing the S_{rep} scores, suggesting that contrastiveness can be introduced into a multi-view summarization problem without diminishing the overall quality of the summary. It is admittedly difficult to make generalizations about these methods from experiments with only one data set, but we have at least some evidence that our algorithm works as intended.

4.4 Unsupervised Summarization

So far we have focused on evaluating our viewpoint clustering models and our multi-view summarization algorithms separately. We will finally show how these two stages might work in tandem in unsupervised summarization of the Bitterlemons corpus.

Without a gold set, it is difficult to perform an extensive automatic evaluation as we did with the healthcare data. Instead we will perform a simple qualitative evaluation to see if the algorithm appears to achieve its goal. Thus, we asked 8 people to guess if each viewpoint's summary was written by Israeli or Palestinian authors. To diversify the summaries, for each annotator we randomly split each summary into two equal-sized subsets of the sentence set. Thus each person was asked to label four different summaries, which were presented in a random order. If humans can correctly identify the viewpoints, then this would suggest both that the TAM accurately clustered documents by viewpoint and the summarization algorithm is selecting sentences that coherently represent the viewpoints.

We first ran TAM on our data using the same procedure and parameters as in Subsection 4.2 using the *full-tuple* features. We repeated this 10 times and used the model that gave the highest data likelihood as our model for summarization input. We then gen-

For the Healthcare Bill	*Against the Healthcare Bill*
the government already provides half of the healthcare dollars in the united states [...] [they] might as well spend their dollars smarter	government is too much involvement.
my kids are uninsured.	a lot of people will be getting it that should be getting it on their own, and my kids will be paying a lot of taxes.
so everybody would have it and afford it.	we cannot afford it.
because of my family.	i don't know enough about it and i don't know where exactly it's going to put my family.
because i have no health insurance and i need it.	because i have health insurance.
cost of healthcare is so high.	high costs.

Table 4: An example of our *micro-level* contrastive summarization output on the healthcare data, using $\delta = 0.05$ and $\lambda = 0.5$.

erated macro contrastive summaries of our data for the two viewpoints with 6 sentences per viewpoint. We used unigram sentence vectors with IDF weighting. We used $\lambda = 0.5$ and $\delta = 0.1$, which gave the highest score at this λ value on the healthcare data.

Only one of these sentences was clustered incorrectly by TAM. The human judges correctly labeled 78% of the summary sets, suggesting that our system accurately selected some sentences that could be recognized as belonging to the viewpoints, but is not perfect. Unsupervised micro-level summaries were less coherent. Many of the sentences are mislabeled, and the ones that are correctly labeled are not representative of the collection.

This is not surprising, and indeed exposes the challenge inherent in our problem definition: clustering documents based on similarity and then highlighting sentences with high similarity but opposite cluster membership are almost conflicting objectives for an unsupervised learner. Such contrastive pairs are perhaps the most difficult data points to model. A good test of a viewpoint model may be whether it can capture the nuanced properties of the viewpoints needed to contrast them at the micro level.

5 Discussion

The properties of the text which we attempt to summarize in our work are related to the concept of *framing* from political science (Chong and Druckman, 2010), which is defined as "an interpretation or evaluation of an issue, event, or person that emphasizes certain of its features or consequences" focusing on "certain features and implications of the issue – rather than others." For example, someone in favor of the healthcare bill might focus on the benefits and someone against the bill might focus on the cost.

However, our approach is different in that our contrastive objective encourages the summaries to include each point as addressed by all viewpoints, rather than each viewpoint selectively emphasizing only certain points. In a sense, this makes our summary more like a live debate, where one side must directly respond to a point raised by the other side. For example, someone in favor of healthcare reform might cite the high cost of the current system, but someone against this might counter-argue that the proposed system in the new bill has its own high costs (as seen in the last row of Table 4). The idea is to show how both sides address the same issues.

Thus, we can say that we are summarizing the key arguments/issues/points from different opinions. Futhermore, our models and algorithms are defined very generally, and while we tested their viability in the domain of political opinion, they may also be useful for many other comparative tasks.

In conclusion, we have presented steps toward a two-stage system that can automatically extract and summarize viewpoints in opinionated text. First, we have shown that accuracy of clustering documents by viewpoint can be enhanced by using simple but rich dependency features. This can be done within the framework of existing probabilistic topic models without altering the models simply by using a "bag of features" representation of documents.

Second, we have introduced *Comparative LexRank*, an extension of the LexRank algorithm that aims to generate contrastive summaries both at the macro and micro level. The algorithm presented is general enough that it can be applied to any number of viewpoints, and can accomodate input where the viewpoints are either given fixed labels, or given probabilistic assignments. The tradeoff between contrast and representation can flexibly be tuned to an application's needs.

Abstract

In the 1980s, plot units were proposed as a conceptual knowledge structure for representing and summarizing narrative stories. Our research explores whether current NLP technology can be used to automatically produce plot unit representations for narrative text. We create a system called AESOP that exploits a variety of existing resources to identify affect states and applies "projection rules" to map the affect states onto the characters in a story. We also use corpus-based techniques to generate a new type of affect knowledge base: verbs that impart positive or negative states onto their patients (e.g., being eaten is an undesirable state, but being fed is a desirable state). We harvest these "patient polarity verbs" from a Web corpus using two techniques: co-occurrence with Evil/Kind Agent patterns, and bootstrapping over conjunctions of verbs. We evaluate the plot unit representations produced by our system on a small collection of Aesop's fables.

1 Introduction

In the 1980s, plot units (Lehnert, 1981) were proposed as a knowledge structure for representing narrative stories and generating summaries. Plot units are fundamentally different from the story representations that preceded them because they focus on the affect states of characters and the tensions between them as the driving force behind interesting and cohesive stories. Plot units were used in narrative summarization studies, both in computer science and psychology (Lehnert et al., 1981), but previous computational models of plot units relied on tremendous amounts of manual knowledge engineering.

The last few decades have seen tremendous advances in NLP and the emergence of many resources that could be useful for plot unit analysis. So we embarked on a project to see whether plot unit representations can be generated automatically using current NLP technology. We created a system called AESOP that uses a variety of resources to identify words that correspond to positive, negative, and mental *affect states*. AESOP uses *affect projection rules* to map the affect states onto the characters in the story based on verb argument structure. Additionally, affect states are inferred based on syntactic properties, and causal and cross-character links are created using simple heuristics.

Affect states often arise from actions that produce good or bad states for the character that is acted upon. For example, *"the cat ate the mouse"* produces a negative state for the mouse because being eaten is bad. Similarly, *"the man fed the dog"* produces a positive state for the dog because being fed is generally good. Knowledge about the effects of actions (i.e., state changes) on patients is not readily available in existing semantic resources. We create a new type of lexicon consisting of *patient polarity verbs (PPVs)* that impart positive or negative states on their patients. These verbs reflect world knowledge about desirable/undesirable states for animate beings; for example, being *fed*, *paid* or *adopted* are generally desirable states, while being *eaten*, *chased* or *hospitalized* are generally undesirable states.

We automatically generate a lexicon of "patient polarity verbs" from a Web corpus using two tech-

The Father and His Sons

(s1) A father had a family of sons who were perpetually quarreling among themselves. (s2) When he failed to heal their disputes by his exhortations, he determined to give them a practical illustration of the evils of disunion; and for this purpose he one day told them to bring him a bundle of sticks. (s3) When they had done so, he placed the faggot into the hands of each of them in succession, and ordered them to break it in pieces. (s4) They tried with all their strength, and were not able to do it. (s5) He next opened the faggot, took the sticks separately, one by one, and again put them into his sons' hands, upon which they broke them easily. (s6) He then addressed them in these words: "My sons, if you are of one mind, and unite to assist each other, you will be as this faggot, uninjured by all the attempts of your enemies; but if you are divided among yourselves, you will be broken as easily as these sticks."

(b) Plot Unit Analysis for "Father and Sons" Fable

Figure 1: Sample Fable and Plot Unit Representation

niques: patterns that identify co-occurrence with stereotypically evil or kind agents, and a bootstrapping algorithm that learns from conjunctions of verbs. We evaluate the plot unit representations produced by our system on a small collection of fables.

2 Overview of Plot Units

Plot unit structures consist of *affect states* for each character, and links defining the relationships between them. Plot units include three types of affect states: positive (+), negative (-), and mental (M). Affect states can be connected by *causal links* and *cross-character* links, which explain how the narrative hangs together. Causal links exist between affect states for the same character and have four types: motivation (m), actualization (a), termination (t) and equivalence (e). Cross-character links indicate that a single event affects multiple characters. For instance, if one character *requests* something of another, then each character is assigned an M state and a cross-character link connects the states.

To see a concrete example of a plot unit representation, a short fable, "The Father and His Sons," is shown in Figure 1(a) and our annotation of its plot unit structure is shown in Figure 1(b). In this fable, there are two characters, the "Father" and (collectively) the "Sons", who go through a series of affect states depicted chronologically in the two columns.

The first affect state ($a1$) is produced from sentence #1 ($s1$) and is a negative state for the sons because they are quarreling. This state is *shared* by the father (via a cross-character link) who has a negative annoyance state ($a2$). The father decides that he wants to stop the sons from quarreling, which is a mental event ($a3$). The causal link from $a2$ to $a3$ with an m label indicates that his annoyed state "motivated" this decision. His first attempt is by exhortations ($a4$). The first M ($a3$) is connected to the second M ($a4$) with an m (motivation) link, which represents subgoaling. The father's overall goal is to stop the quarreling ($a3$), and to do so he creates a subgoal of exhorting the sons to stop ($a4$). The exhortations fail, which produces a negative state ($a5$) for the father. The a causal link indicates an "actualization", representing the failure of his plan ($a4$).

This failure motivates a new subgoal: teach the sons a lesson ($a6$). At a high level, this subgoal has two parts, indicated by the two gray regions ($a7 - a10$ and $a11 - a14$). The first gray region begins with a cross-character link (M to M), which indicates a request (in this case, to break a bundle of sticks). The sons fail at this, which upsets them ($a9$) but pleases the father ($a10$). The second gray region depicts the second part of the father's subgoal; he makes a second request ($a11$ to $a12$) to separate the bundle and break the sticks, which the sons successfully do, making them happy ($a13$) and the father happy ($a14$) as well. This latter structure (the second gray region) is an HONORED REQUEST plot unit structure. At the end, the father's plan succeeds ($a15$) which is an actualization (a link) of his goal to teach the sons a lesson ($a6$).

3 Where Do Affect States Come From?

We briefly overview the variety of situations that can be represented by affect states in plot units.

Direct Expressions of Emotion: Affect states can correspond to positive/negative emotional states, as have been studied in the realm of sentiment analysis. For example, *"Max was disappointed"* produces a negative affect state for Max, and *"Max was pleased"* produces a positive affect state for Max.

Situational Affect States: Positive and negative affect states can represent good and bad situational states that characters find themselves in. These states do not represent emotion, but indicate whether a situation (state) is good or bad for a character based on world knowledge. e.g., *"The wolf had a bone stuck in his throat."* produces a negative affect state for the wolf. Similarly, *"The woman recovered her sight."* produces a positive affect state for the woman.

Plans and Goals: The existence of a plan or goal is represented as a mental state (M). Plans and goals can be difficult to detect automatically and can be revealed in many ways, such as:

- **Direct expressions of plans/goals:** a plan/goal may be explicitly stated (e.g., *"John wants food"*).
- **Speech acts:** a plan or goal may be revealed through a speech act. For example, *"the wolf asked an eagle to extract the bone"* is a directive speech act that indicates the wolf's plan to resolve its negative state (having a bone stuck). This example illustrates how a negative state (bone stuck) can motivate a mental state (plan). When a speech act involves multiple characters, it produces multiple mental states.
- **Inferred plans/goals:** plans and goals are sometimes inferred from actions. e.g., *"the lion hunted deer"* implies that the lion has a plan to obtain food. Similarly, *"the serpent spat poison at John"* implies that the serpent wants to kill John.
- **Plan/Goal completion:** Plans and goals produce +/- affect states when they succeed or fail. For example, if the eagle successfully extracts the bone from the wolf's throat, then both the wolf and the eagle will have positive affect states because both were successful in their respective goals.

We observed that situational and plan/goal states often originate from an action. When a character is acted upon (the *patient* of a verb), then the character may be in a positive or negative state depending upon whether the action was good or bad for them based on world knowledge. For example, being *fed*, *paid* or *adopted* is generally desirable, but being *chased*, *eaten*, or *hospitalized* is usually undesirable. Consequently, we decided to create a lexicon of *patient polarity verbs* that produce positive or negative states for their patients. In Section 4.2, we present two methods for automatically harvesting these verbs from a Web corpus.

4 AESOP: Automatically Generating Plot Unit Representations

Our system, AESOP, automatically creates plot unit representations for narrative text. AESOP has four main steps: affect state recognition, character identification, affect state projection, and link creation. During affect state recognition, AESOP identifies words that may be associated with positive, negative, and mental states. AESOP then identifies the main characters in the story and applies *affect projection rules* to map the affect states onto these characters. During this process, some additional affect states are inferred based on verb argument structure. Finally, AESOP creates cross-character links and causal links between affect states. We also present two corpus-based methods to automatically produce a new resource for affect state recognition: a *patient polarity verb lexicon*.

4.1 Plot Unit Creation

4.1.1 Recognizing Affect States

The basic building blocks of plot units are *affect states* which come in three flavors: positive, negative, and mental. In recent years, many publicly available resources have been created for sentiment analysis and other types of semantic knowledge. We considered a wide variety of resources and ultimately decided to experiment with five resources that most closely matched our needs:

- FrameNet (Baker et al., 1998): We manually identified 87 frame classes that seem to be associated with affect: 43 mental classes (e.g., COMMUNICATION and NEEDING), 22 positive classes (e.g., ACCOMPLISHMENT and SUPPORTING), and 22 negative classes (e.g., CAUSE HARM and PROHIBIT-

ING). We use the verbs listed for these classes to produce M, +, and - affect states.

• MPQA Lexicon (Wilson et al., 2005b): We used the words listed as having positive or negative sentiment polarity to produce +/- states, when they occur with the designated part-of-speech.

• OpinionFinder (Wilson et al., 2005a) (Version 1.4) : We used the +/- labels assigned by its contextual polarity classifier (Wilson et al., 2005b) to create +/- states and the MPQASD tags produced by its Direct Subjective and Speech Event Identifier (Choi et al., 2006) to produce mental (M) states.

• Semantic Orientation Lexicon (Takamura et al., 2005): We used the words listed as having positive or negative polarity to produce +/- affect states, when they occur with the designated part-of-speech.

• Speech Act Verbs: We used 228 speech act verbs from (Wierzbicka, 1987) to produce M states.

4.1.2 Identifying the Characters

For the purposes of this work, we made two simplifying assumptions: (1) There are only two characters per fable[1], and (2) Both characters are mentioned in the fable's title. The problem of coreference resolution for fables is somewhat different than for other genres, primarily because the characters are often animals (e.g., *he=owl*). So we hand-crafted a simple rule-based coreference system. First, we apply heuristics to determine number and gender based on word lists, WordNet (Miller, 1990) and part-of-speech tags. If no determination of a character's gender or number can be made, we employ a process of elimination. Given the two character assumption, if one character is known to be male, but there are female pronouns in the fable, then the other character is assumed to be female. The same is done for number agreement. Finally, if there is only one character between a pronoun and the beginning of a document, then we resolve the pronoun with that character and the character assumes the gender and number of the pronoun. Lastly, WordNet provides some additional resolutions by exploiting hypernym relations, for instance, linking *peasant* with *man*.

4.1.3 Mapping Affect States onto Characters

Plot unit representations are not just a set of affect states, but they are structures that capture the chronological ordering of states for each character as the narrative progresses. Consequently, every affect state needs to be attributed to a character. Since most plots revolve around events, we use verb argument structure as the primary means for projecting affect states onto characters.

We developed four *affect projection rules* that orchestrate how affect states are assigned to the characters. We used the Sundance parser (Riloff and Phillips, 2004) to produce a shallow parse of each sentence, which includes syntactic chunking, clause segmentation, and active/passive voice recognition. We normalized the verb phrases with respect to active/passive voice to simplify the rules. We made the assumption that the Subject of the VP is its AGENT and the Direct Object of the VP is its PATIENT.[2] The rules only project affect states onto AGENTS and PATIENTS that refer to a character in the story. The four projection rules are presented below.

1. AGENT **VP** : This rule applies when the VP has no PATIENT or the PATIENT corefers with the AGENT. All affect tags assigned to the VP are projected onto the AGENT. Example: *"Mary **laughed** (+)"* projects a + affect state onto Mary.

2. **VP** PATIENT : This rule applies when the VP has no agent, which is common in passive voice constructions. All affect tags assigned to the VP are projected onto the PATIENT. Example: *"John was **rewarded** (+)*, projects a + affect state onto John.

3. AGENT **VP** PATIENT : This rules applies when both an AGENT and PATIENT are present, do not corefer, and at least one of them is a character. If the PATIENT is a character, then all affect tags associated with the VP are projected onto the PATIENT. If the AGENT is a character and the VP has an M tag, then we also project an M tag onto the AGENT (representing a shared, cross-character mental state).

4. AGENT **VERB1** to **VERB2** PATIENT : This rule has two cases: (a) If the AGENT and PATIENT refer to the same character, then we apply Rule #1. Example: *"Bo decided to teach himself..."* (b) If the AGENT and PATIENT are different, then we apply Rule #1 to **VERB1** and Rule #2 to **VERB2**.

Finally, if an adverb or adjectival phrase has affect, then that affect is mapped onto the preceding VP and the rules above are applied. For all of the

[1] We only selected fables that had two main characters.

[2] This is not always correct, but worked ok in our fables.

rules, if a clause contains a negation word, then we flip the polarity of all words in that clause.

4.1.4 Inferring Affect States

Recognizing plans and goals depends on world knowledge and inference, and is beyond the scope of this paper. However, we identified two cases where affect states often can be inferred based on syntactic properties. The first case involves verb phrases (VPs) that have both an AGENT and PATIENT, which corresponds to projection rule #3. If the VP has polarity, then rule #3 assigns that polarity to the PATIENT, not the AGENT. For example, *"John killed Paul"* imparts negative polarity on Paul, but not necessarily on John. Unless we are told otherwise, one assumes that John *intentionally* killed Paul, and so in a sense, John accomplished his goal. Consequently, this action should produce a positive affect state for John. We capture this notion of accomplishment as a side effect of projection rule #3: if the VP has +/- polarity, then we produce an *inferred positive state* for the AGENT.

The second case involves infinitive verb phrases of the form: "AGENT VERB1 TO VERB2 PATIENT" (e.g., *"Susan tried to warn Mary"*). The infinitive VP construction suggests that the AGENT has a goal or plan that is being put into motion (e.g., *tried to, wanted to, attempted to, hoped to*, etc.). To capture this intuition, in rule #4 if VERB1 does not already have an affect state assigned to it then we produce an *inferred mental state* for the AGENT.

4.1.5 Causal and Cross-Character Links

Our research is focused primarily on creating affect states for characters, but plot unit structures also include *cross-character links* to connect states that are shared across characters and *causal links* between states for a single character. As an initial attempt to create complete plot units, AESOP produces links using simple heuristics. A cross-character link is created when two characters in a clause have affect states that originated from the same word. A causal link is created between each pair of (chronologically) consecutive affect states for the same character. Currently, AESOP only produces forward causal links (*motivation (m)*, *actualization (a)*) and does not produce backward causal links (*equivalence (e)*, *termination (t)*). For forward links, the causal syntax only allows for five cases: $M \xrightarrow{m} M$, $+ \xrightarrow{m} M$, $- \xrightarrow{m} M$, $M \xrightarrow{a} +$, $M \xrightarrow{a} -$. So when AESOP produces a causal link between two affect states, the order and types of the two states uniquely determine which label it gets (m or a).

4.2 Generating PPV Lexicons

During the course of this research, we identified a gap in currently available knowledge: we are not aware of existing resources that identify verbs which produce a desirable/undesirable state for their patients even though the verb itself does not carry polarity. For example, the verb *eat* describes an action that is generally neutral, but being eaten is clearly an undesirable state. Similarly, the verb *fed* does not have polarity, but being fed is a desirable state for the patient. In the following sections, we try to fill this gap by using corpus-based techniques to automatically acquire a *Patient Polarity Verb (PPV) Lexicon*.

4.2.1 PPV Harvesting with Evil/Kind Agents

The key idea behind our first approach is to identify verbs that frequently occur with evil or kind agents. Our intuition was that an "evil" agent will typically perform actions that are bad for the patient, while a "kind" agent will typically perform actions that are good for the patient.

We manually identified 40 stereotypically evil agent words, such as *monster*, *villain*, *terrorist*, and *murderer*, and 40 stereotypically kind agent words, such as *hero*, *angel*, *benefactor*, and *rescuer*. We searched the Google Web $1T$ N-gram corpus to identify verbs that co-occur with these words as probable agents. For each agent term, we applied the pattern "* by [a,an,the] AGENT" and extracted the matching N-grams. Then we applied a part-of-speech tagger to each N-gram and saved the words that were tagged as verbs (i.e., the words in the * position).[3] This process produced 811 negative (evil agent) PPVs and 1362 positive (kind agent) PPVs.

4.2.2 PPV Bootstrapping over Conjunctions

Our second approach for acquiring PPVs is based on an observation from sentiment analysis research that conjoined adjectives typically have the same polarity (e.g. (Hatzivassiloglou and McKeown, 1997)).

[3] The POS tagging quality is undoubtedly lower than if tagging complete sentences but it seemed reasonable.

Our hypothesis was that conjoined verbs often share the same polarity as well (e.g., *"abducted and killed"* or *"rescued and rehabilitated"*). We exploit this idea inside a bootstrapping algorithm to iteratively learn verbs that co-occur in conjunctions.

Bootstrapping begins with 10 negative and 10 positive PPV seeds. First, we extracted triples of the form *"w1 and w2"* from the Google Web $1T$ N-gram corpus that had frequency ≥ 100 and were lower case. We separated each conjunction into two parts: a primary VERB ("$w1$") and a CONTEXT ("$and\ w2$"), and created a copy of the conjunction with the roles of $w1$ and $w2$ reversed. For example, *"rescued and adopted"* produces:

VERB="rescued" CONTEXT="and adopted"
VERB="adopted" CONTEXT="and rescued"

Next, we applied the Basilisk bootstrapping algorithm (Thelen and Riloff, 2002) to learn PPVs. Basilisk identifies semantically similar words based on their co-occurrence with seeds in contextual patterns. Basilisk was originally designed for semantic class induction using lexico-syntactic patterns, but has also been used to learn subjective and objective nouns (Riloff et al., 2003).

Basilisk first identifies the pattern contexts that are most strongly associated with the seed words. Words that occur in those contexts are labeled as *candidates* and scored based on the strength of their contexts. The top 5 candidates are selected and the bootstrapping process repeats. Basilisk produces a *lexicon* of learned words as well as a ranked list of pattern contexts. Since we bootstrapped over verb conjunctions, we also extracted new PPVs from the contexts. We ran the bootstrapping process to create a lexicon of 500 words, and we collected verbs from the top 500 contexts as well.

5 Evaluation

Plot unit analysis of narrative text is enormously complex – the idea of creating gold standard plot unit annotations seemed like a monumental task. So we began with relatively simple and constrained texts that seemed appropriate: fables. Fables have two desirable attributes: (1) they have a small cast of characters, and (2) they typically revolve around a moral, which is exemplified by a short and concise plot. Even so, fables are challenging for NLP due to anthropomorphic characters, flowery language, and sometimes archaic vocabulary.

We collected 34 Aesop's fables from a web site[4], choosing fables that have a true plot (some only contain quotes) and exactly two characters. We divided them into a development set of 11 stories, a tuning set of 8 stories, and a test set of 15 stories.

Creating a gold standard was itself a substantial undertaking, and training non-experts to produce them did not seem feasible in the short term. So the authors discussed and iteratively refined manual annotations for the development and tuning sets until we produced similar results and had a common understanding of the task. Then two authors independently created annotations for the test set, and a third author adjudicated the differences.

5.1 Evaluation Procedure

For evaluation, we used recall (R), precision (P), and F-measure (F). In our gold standard, each affect state is annotated with the set of clauses that could legitimately produce it. In most cases (75%), we were able to ascribe the existence of a state to precisely one clause. During evaluation, the system-produced affect states must be generated from the correct clause. However, for affect states that could be ascribed to multiple clauses in a sentence, the evaluation was done at the sentence level. In this case, the system-produced affect state must come from the sentence that contains one of those clauses.

Coreference resolution is far from perfect, so we created gold standard coreference annotations for our fables and used them for most of our experiments. This allowed us to evaluate our approach without coreference mistakes factoring in. In Section 5.5, we re-evaluate our final results using automatic coreference resolution.

5.2 Evaluation of Affect States using External Resources

Our first set of experiments evaluates the quality of the affect states produced by AESOP using only the external resources. The top half of Table 1 shows the results for each resource independently. FrameNet produced the best results, yielding much higher recall than any other resource. The bottom half of Ta-

Table 2: Evaluation results for AESOP with PPVs. The # in parentheses is the # of gold affect states.

ble 1 shows the results when combining FrameNet with other resources. In terms of F score, the only additive benefit came from the Semantic Orientation Lexicon, which produced a better balance of recall and precision and an F score gain of +2.

5.3 Evaluation of Affect States using PPVs

Our second set of experiments evaluates the quality of the automatically generated PPV lexicons. The top portion of Table 2 shows the results for the negative PPVs. The PPVs harvested by the Evil Agent patterns produced the best results, yielding recall and precision of .46 for negative states. Note that M and + states are also generated from the negative PPVs because they are inferred during affect projection (Section 4.1.4). The polarity of a negative PPV can also be flipped by negation to produce a + state.

Basilisk's negative PPVs achieved similar precision but lower recall. We see no additional recall and some precision loss when the Evil Agent and Basilisk PPV lists are combined. The precision drop is likely due to redundancy, which creates spurious affect states. If two different words have negative polarity but refer to the same event, then only one negative affect state should be generated. But AESOP will generate two affect states, so one will be spurious.

The middle section of Table 2 shows the results for the positive PPVs. Both positive PPV lexicons were of dubious quality, so we tried to extract a high-quality subset of each list. For the Kind Agent PPVs, we computed the ratio of the frequency of the verb with Evil Agents versus Kind Agents and only saved verbs with an Evil:Kind ratio (θ) > 1, which yielded 1203 PPVs. For the positive Basilisk PPVs, we used only the top 100 lexicon and top 100 context verbs, which yielded 164 unique verbs. The positive PPVs did generate several correct affect states (including a - state when a positive PPV was negated), but also many spurious states.

The bottom section of Table 2 shows the impact of the learned PPVs when combined with FrameNet and the Semantic Orientation Lexicon (SOLex). Adding the Evil Agent PPVs improved AESOP's F score from 39% to 44%, mainly due to a +8 recall gain. The recall of the - states increased from 22% to 46% with no loss of precision. Interestingly, if we remove SOLex and use only FrameNet with our PPVs, precision increases from 46% to 49% and recall only drops by -1. Finally, the last row of Table

2 shows that adding Basilisk's positive PPVs produces a small recall boost (+2) with a slight drop in precision (-1).

Evaluating the impact of PPVs on plot unit structures is an indirect way of assessing their quality because creating plot units involves many steps. Also, our test set is small so many verbs will never appear. To directly measure the quality of our PPVs, we recruited 3 people to manually review them. We developed annotation guidelines that instructed each annotator to judge whether a verb is generally *good* or *bad* for its patient, assuming the patient is animate. They assigned each verb to one of 6 categories: × (not a verb), 2 (always good), 1 (usually good), 0 (neutral, mixed, or requires inanimate patient), -1 (usually bad), -2 (always bad). Each annotator labeled 250 words: 50 words randomly sampled from each of our 4 PPV lexicons[5] (Evil Agent PPVs, Kind Agent PPVs, Positive Basilisk PPVs, and Negative Basilisk PPVs) plus 50 verbs labeled as neutral in the MPQA lexicon.

First, we measured agreement based on three groupings: *negative* (-2 and -1), *neutral* (0), or *positive* (1 and 2). We computed κ scores to measure inter-annotator agreement for each pair of annotators.[6], but the κ scores were relatively low because the annotators had trouble distinguishing the positive cases from the neutral ones. So we re-computed agreement using two groupings: *negative* (-2 and -1) and *not-negative* (0 through 2), and obtained κ scores of .69, .71, and .74. We concluded that people largely agree on whether a verb is bad for the patient, but they do not necessarily agree if a verb is good for the patient. One possible explanation is that many "bad" verbs represent physical harm or danger: these verbs are both plentiful and easy to recognize. In contrast, "good" verbs are often more abstract and open to interpretation (e.g., is being "envied" or "feared" a good thing?).

We used the labels produced by the two annotators with the highest κ score to measure the accuracy of our PPVs. Both the Evil Agent and Negative Basilisk PPVs were judged to be 72.5% accurate, averaged over the judges. The Kind Agent PPVs were only about 39% accurate, while the Positive Basilisk PPVs were nearly 50% accurate. These results are consistent with our impressions that the negative PPVs are of relatively high quality, while the positive PPVs are mixed. Some examples of learned PPVs that were not present in our other resources are:

- : censor, chase, fire, orphan, paralyze, scare, sue
+ : accommodate, harbor, nurse, obey, respect, value

5.4 Evaluation of Links

We represented each link as a 5-tuple ⟨*src-clause*, *src-state*, *tgt-clause*, *tgt-state*, *link-type*⟩, where source/target denotes the direction of the link, the source/target-states are the affect state type (+,-,M) and *link-type* is one of 3 types: actualization (a), motivation (m), or cross-character (xchar). A system-produced link is considered correct if *all* 5 elements of the tuple match the human annotation.

	Gold Aff States			*System Aff States*		
Links	*R*	*P*	*F*	*R*	*P*	*F*
xchar (56)	.79	.85	.82	.18	.43	.25
a (51)	.90	.94	.92	.04	.07	.05
m (26)	1.0	.57	.72	.15	.10	.12

Table 3: Link results; parentheses show # of gold links.

The second column of Table 3 shows the performance of AESOP when using gold standard affect states. Our simple heuristics for creating links work surprisingly well for xchar and a links when given perfect affect states. However, these heuristics produce relatively low precision for m links, albeit with 100% recall. This reveals that m links primarily do connect adjacent states, but we need to be more discriminating when connecting them. The third column of Table 3 shows the results when using system-generated affect states. We see that performance is much lower. This is not particularly surprising, since AESOP's F-score is 45%, so over half of the individual states are wrong, which means that less than a quarter of the pairs are correct. From that perspective, the xchar link performance is reasonable, but the causal a and m links need improvement.

5.5 Analysis

We performed additional experiments to evaluate some assumptions and components. First, we created a *Baseline* system that is identical to AESOP

[5] The top-ranked Evil/Kind Agent PPV lists ($\theta > 1$) which yields 1203 kind PPVs, and 477 evil PPVs, the top 164 positive Basilisk verbs, and the 678 (unique) negative Basilisk verbs.

[6] We discarded words labeled as not a verb.

except that it does not use the affect projection rules. Instead, it naively projects every affect state in a clause onto every character in that clause. The first two rows of the table below show that AESOP's precision is double the Baseline, with nearly the same recall. This illustrates the importance of the projection rules for mapping affect states onto characters.

	R	*P*	*F*
Baseline	.44	.24	.31
AESOP, gold coref	.43	.48	.45
AESOP, gold coref, infstates	.39	.48	.43
AESOP, auto coref, infstates	.24	.56	.34

Our gold standard includes *pure inference affect states* that are critical to the plot unit structure but come from world knowledge outside the story itself. Of 157 affect states in our test set, 14 were pure inference states. We ignored these states in our previous experiments because our system has no way to generate them. The third row of the table shows that including them lowers recall by -4. Generating pure inferences is an interesting challenge, but they seem to be a relatively small part of the problem.

The last row of the table shows AESOP's performance when we use our automated coreference resolver (Section 4.1.2) instead of gold standard coreference annotations. We see a -15 recall drop coupled with a +8 precision gain. We were initially puzzled by the precision gain but believe that it is primarily due to the handling of quotations. Our gold standard includes annotations for characters mentioned in quotations, but our automated coreference resolver ignores quotations. Most fables end with a moral, which is often a quote that may not mention the plot. Consequently, AESOP generates more spurious affect states from the quotations when using the gold standard annotations.

6 Related Work and Conclusions

Our research is the first effort to fully automate the creation of plot unit structures. Other preliminary work has begun to look at plot unit modelling for single character stories (Appling and Riedl, 2009). More generally, our work is related to research in narrative story understanding (e.g., (Elson and McKeown, 2009)), automatic affect state analysis (Alm, 2009), and automated learning of scripts (Schank and Abelson, 1977) and other conceptual knowledge structures (e.g., (Mooney and DeJong, 1985; Fujiki et al., 2003; Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009; Kasch and Oates, 2010)). Our work benefitted from prior research in creating semantic resources such as FrameNet (Baker et al., 1998) and sentiment lexicons and classifiers (e.g., (Takamura et al., 2005; Wilson et al., 2005b; Choi et al., 2006)). We showed that *affect projection rules* can effectively assign affect states to characters. This task is similar to, but not the same as, associating opinion words with their targets or topics (Kim and Hovy, 2006; Stoyanov and Cardie, 2008). Some aspects of affect state identification are closely related to Hopper and Thompson's (1980) theory of transitivity. In particular, their notions of *aspect* (has an action completed?), benefit and harm (how much does an object gain/lose from an action?) and volition (did the subject make a conscious choice to act?).

AESOP produces affect states with an F score of 45%. Identifying *positive* states appears to be more difficult than negative or mental states. Our system's biggest shortcoming currently seems to hinge around identifying plans and goals. This includes the M affect states that initiate plans, the +/- completion states, as well as their corresponding links. We suspect that the relatively low recall on positive affect states is due to our inability to accurately identify successful plan completions. Finally, these results are based on fables; plot unit analysis of other types of texts will pose additional challenges.

Abstract

Recent times have seen a tremendous growth in mobile based data services that allow people to use Short Message Service (SMS) to access these data services. In a multilingual society it is essential that data services that were developed for a specific language be made accessible through other local languages also. In this paper, we present a service that allows a user to query a Frequently-Asked-Questions (FAQ) database built in a local language (Hindi) using Noisy SMS English queries. The inherent noise in the SMS queries, along with the language mismatch makes this a challenging problem. We handle these two problems by formulating the query similarity over FAQ questions as a combinatorial search problem where the search space consists of combinations of dictionary variations of the noisy query and its top-N translations. We demonstrate the effectiveness of our approach on a real-life dataset.

1 Introduction

There has been a tremendous growth in the number of new mobile subscribers in the recent past. Most of these new subscribers are from developing countries where mobile is the primary information device. Even for users familiar with computers and the internet, the mobile provides unmatched portability. This has encouraged the proliferation of information services built around SMS technology. Several applications, traditionally available on Internet, are now being made available on mobile devices using SMS. Examples include SMS short code services. Short codes are numbers where a short message in a predesignated format can be sent to get specific information. For example, to get the closing stock price of a particular share, the user has to send a message IBMSTOCKPR. Other examples are search (Schusteritsch et al., 2005), access to Yellow Page services (Kopparapu et al., 2007), Email [1], Blog [2] , FAQ retrieval [3] etc. The SMS-based FAQ retrieval services use human experts to answer SMS questions.

Recent studies have shown that instant messaging is emerging as the preferred mode of communication after speech and email.[4] Millions of users of instant messaging (IM) services and short message service (SMS) generate electronic content in a dialect that does not adhere to conventional grammar, punctuation and spelling standards. Words are intentionally compressed by non-standard spellings, abbreviations and phonetic transliteration are used. Typical question answering systems are built for use with languages which are free from such errors. It is difficult to build an automated question answering system around SMS technology. This is true even for questions whose answers are well documented like in a Frequently-Asked-Questions (FAQ) database. Unlike other automatic question answering systems that focus on searching answers from a given text collection, Q&A archive (Xue et al., 2008) or the Web (Jijkoun et al., 2005), in a FAQ database the questions and answers are already pro-

Figure 1: Sample SMS queries with Hindi FAQs

vided by an expert. The main task is then to identify the best matching question to retrieve the relevant answer (Sneiders, 1999) (Song et al., 2007). The high level of noise in SMS queries makes this a difficult problem (Kothari et al., 2009). In a multilingual setting this problem is even more formidable. Natural language FAQ services built for users in one language cannot be accessed in another language. In this paper we present a FAQ-based question answering system over a SMS interface that solves this problem for two languages. We allow the FAQ to be in one language and the SMS query to be in another.

Multi-lingual question answering and information retrieval has been studied in the past (Sekine and Grishman, 2003)(Cimiano et al., 2009). Such systems resort to machine translation so that the search can be performed over a single language space. In the two language setting, it involves building a machine translation system engine and using it such that the question answering system built for a single language can be used.

Typical statistical machine translation systems use large parallel corpora to learn the translation probabilities (Brown et al., 2007). Traditionally such corpora have consisted of news articles and other well written articles. Since the translation systems are not trained on SMS language they perform very poorly when translating noisy SMS language. Parallel corpora comprising noisy sentences in one language and clean sentences in another language are not available and it would be hard to build such large parallel corpora to train a machine translation system. There exists some work to remove noise from SMS (Choudhury et al., 2007) (Byun et al., 2008) (Aw et al., 2006) (Neef et al., 2007) (Kobus et al., 2008). However, all of these techniques require an aligned corpus of SMS and conventional language for training. Such data is extremely hard to create. Unsupervised techniques require huge amounts of SMS data to learn mappings of non-standard words to their corresponding conventional form (Acharyya et al., 2009).

Removal of noise from SMS without the use of parallel data has been studied but the methods used are highly dependent on the language model and the degree of noise present in the SMS (Contractor et al., 2010). These systems are not very effective if the SMSes contain grammatical errors (or the system would require large amounts of training data in the language model to be able to deal with all possible types of noise) in addition to misspellings etc. Thus, the translation of a cleaned SMS, into a second language, will not be very accurate and it would not give good results if such a translated SMS is used to query an FAQ collection.

Token based noise-correction techniques (such as those using edit-distance, LCS etc) cannot be directly applied to handle the noise present in the SMS query. These noise-correction methods return a list of candidate terms for a given noisy token (E.g. ’gud’ $->$ ’god’,’good’,’guide’) . Considering all these candidate terms and their corresponding translations drastically increase the search space for any multi-lingual IR system. Also , naively replacing the noisy token in the SMS query with the top matching candidate term gives poor performance as shown by our experiments. Our algorithm handles these and related issues in an efficient manner.

In this paper we address the challenges arising when building a cross language FAQ-based question answering system over an SMS interface. Our method handles noisy representation of questions in a source language to retrieve answers across target languages. The proposed method does not require hand corrected data or an aligned corpus for explicit SMS normalization to mitigate the effects of noise. It also works well with grammatical noise. To the best of our knowledge we are the first to address issues in noisy SMS based cross-language FAQ retrieval. We propose an efficient algorithm that can handle noise in the form of lexical and semantic corruptions in the source language.

2 Problem formulation

Consider an input SMS S^e in a source language e. We view S^e as a sequence of n tokens $S^e = s_1, s_2, \ldots, s_n$. As explained in the introduction, the input is bound to have misspellings and other lexical and semantic distortions. Also let Q^h denote the set of questions in the FAQ corpus of a target language h. Each question $Q^h \in \mathcal{Q}^h$ is also viewed as a sequence of tokens. We want to find the question $\hat{Q^h}$ from the corpus $\mathcal{Q}^h$ that best matches the SMS S^e.

The matching is assisted by a source dictionary $\mathcal{D}^e$ consisting of clean terms in e constructed from a general English dictionary and a domain dictionary of target language $\mathcal{D}^h$ built from all the terms appearing in $\mathcal{Q}^h$. For a token s_i in the SMS input, term t_e in dictionary $\mathcal{D}^e$ and term t_h in dictionary $\mathcal{D}^h$ we define a *cross-lingual similarity measure* $\alpha(t_h, t_e, s_i)$ that measures the extent to which term s_i matches t_h using the clean term t_e. We consider t_h a *cross lingual variant* of s_i if for any t_e the cross language similarity measure $\alpha(t_h, t_e, s_i) > \epsilon$. We denote this as $t_h \sim s_i$.

We define a weight function $\omega(t_h, t_e, s_i)$ using the *cross lingual similarity measure* and the *inverse document frequency* (idf) of t_h in the target language FAQ corpus. We also define a scoring function to assign a score to each question in the corpus $\mathcal{Q}^h$ using the weight function. Consider a question $Q^h \in \mathcal{Q}^h$. For each token s_i, the scoring function chooses the term from Q^h having the maximum weight using possible clean representations of s_i; then the weight of the n chosen terms are summed up to get the score. The score measures how closely the question in FAQ matches the noisy SMS string S^e using the composite weights of individual tokens.

$$\text{Score}(Q^h) = \sum_{i=1}^{n} \max_{t_h \in Q^h, t_e \in \mathcal{D}^e \text{ \& } t_h \sim s_i} \omega(t_h, t_e, s_i)$$

Our goal is to efficiently find the question $\hat{Q^h}$ having the maximum score.

3 Noise removal from queries

In order to process the noisy SMS input we first have to map noisy tokens in S^e to the possible correct lexical representations. We use a similarity measure to map the noisy tokens to their clean lexical representations.

3.1 Similarity Measure

For a term $t_e \in \mathcal{D}^e$ and token s_i of the SMS input S^e, the similarity measure $\gamma(t_e, s_i)$ between them is

$$\gamma(t_e, s_i) = \begin{cases} \frac{LCSRatio(t_e,s_i)}{EditDistance_{SMS}(t_e,s_i)} & \textit{if } t_e \textit{ and } s_i \textit{ share same starting character *} \\ 0 & \textit{otherwise} \end{cases} \tag{1}$$

Where $LCSRatio(t_e, s_i) = \frac{length(LCS(t_e,s_i))}{length(t_e)}$ and $LCS(t_e, s_i)$ is the *Longest common subsequence* between t_e and s_i.
** The intuition behind this measure is that people typically type the first few characters of a word in an SMS correctly. This way we limit the possible variants for a particular noisy token*

The *Longest Common Subsequence Ratio* (LCSRatio) (Melamed et al., 1999) of two strings is the ratio of the length of their LCS and the length of the longer string. Since in the SMS scenario, the dictionary term will always be longer than the SMS token, the denominator of LCSRatio is taken as the length of the dictionary term.

The $EditDistance_{SMS}$ (Figure 2) compares the Consonant Skeletons (Prochasson et al., 2007) of the dictionary term and the SMS token. If the Levenshtein distance between consonant skeletons is small then $\gamma(t_e, s_i)$ will be high. The intuition behind using $EditDistance_{SMS}$ can be explained through an example. Consider an SMS token "gud" whose most likely correct form is "good". The longest common subsequence for "good" and "guided" with "gud" is "gd". Hence the two dictionary terms "good" and "guided" have the same LCSRatio of 0.5 w.r.t "gud", but the $EditDistance_{SMS}$ of "good" is 1 which is less than that of "guided", which has $EditDistance_{SMS}$ of 2 w.r.t "gud". As a result the similarity measure between "gud" and "good" will be higher than that of "gud" and "guided". Higher the *LCSRatio* and lower the $EditDistance_{SMS}$, higher will be the similarity measure. Hence, for a given SMS token "byk", the similarity measure of word "bike" is higher than that of "break".

4 Cross lingual similarity

Once we have potential candidates which are the likely disambiguated representations of the noisy

```
Procedure $EditDistance_{SMS}(t_e, s_i)$
Begin
  return $LevenshteinDistance(CS(s_i), CS(t_e)) + 1$
End

Procedure CS (t): // Consonant Skeleton Generation
Begin
  Step 1. remove consecutive repeated characters in $t$
    // ($fall \rightarrow fal$)
  Step 2. remove all vowels in $t$
    //($painting \rightarrow pntng, threat \rightarrow thrt$)
  return $t$
End
```

Figure 2: $EditDistance_{SMS}$

term, we map these candidates to appropriate terms in the target language. We use a statistical dictionary to achieve this cross lingual mapping.

4.1 Statistical Dictionary

In order to build a statistical dictionary we use the statistical translation model proposed in (Brown et al., 2007). Under IBM model 2 the translation probability of source language sentence $\bar{e} = \{t_e^1, \ldots, t_e^j, \ldots, t_e^m\}$ and a target language sentence $\bar{h} = \{t_h^1, \ldots, t_h^i, \ldots, t_e^l\}$ is given by

$$Pr(\bar{h}|\bar{e}) = \phi(l|m) \prod_{i=1}^{l} \sum_{j=0}^{m} \tau(t_h^i|t_e^j) a(j|i, m, l). \tag{2}$$

Here the word translation model $\tau(t_h|t_e)$ gives the probability of translating the source term to target term and the alignment model $a(j|i, m, l)$ gives the probability of translating the source term at position i to a target position j. This model is learnt using an aligned parallel corpus.

Given a clean term t_e^i in source language we get all the corresponding terms $\mathcal{T} = \{t_h^1, \ldots, t_h^k, \ldots\}$ from the target language such that word translation probability $\tau(t_h^k|t_e^i) > \varepsilon$. We rank these terms according to the probability given by the word translation model $\tau(t_h|t_e)$ and consider only those target terms that are part of domain dictionary i.e. $t_h^k \in \mathcal{D}^h$.

4.2 Cross lingual similarity measure

For each term s_i in SMS input query, we find all the clean terms t_e in source dictionary $\mathcal{D}^e$ for which similarity measure $\gamma(t_e, s_i) > \phi$. For each of these term t_e, we find the cross lingual similar terms $\mathcal{T}_{t_e}$ using the word translation model. We compute the cross lingual similarity measure between these terms as

$$\alpha(s_i, t_e, t_h) = \gamma(t_e, s_i).\tau(t_h, t_e) \tag{3}$$

The measure selects those terms in target language that have high probability of being translated from a noisy term through one or more valid clean terms.

4.3 Cross lingual similarity weight

We combine the idf and the cross lingual similarity measure to define the cross lingual weight function $\omega(t_h, t_e, s_i)$ as

$$\omega(t_h, t_e, s_i) = \alpha(t_h, t_e, s_i).idf(t_h) \tag{4}$$

By using idf we give preference to terms that are highly discriminative. This is necessary because queries are distinguished from each other using informative words. For example for a given noisy token "bck" if a word translation model produces a translation output "wapas" (as in came back) or "peet" or "qamar" (as in back pain) then idf will weigh "peet" more as it is relatively more discriminative compared to "wapas" which is used frequently.

5 Pruning and matching

In this section we describe our search algorithm and the preprocessing needed to find the best question $\hat{Q}^h$ for a given SMS query.

5.1 Indexing

Our algorithm operates at a token level and its corresponding cross lingual variants. It is therefore necessary to be able to retrieve all questions $Q_{t_h}^h$ that contain a given target language term t_h. To do this efficiently we index the questions in FAQ corpus using *Lucene*[5]. Each question in FAQ is treated as a document. It is tokenized using whitespace as delimiter before indexing.

[5] http://lucene.apache.org/java/docs/

The cross lingual similarity weight calculation requires the *idf* for a given term t_h. We query on this index to determine the number of documents f that contain t_h. The *idf* of each term in $\mathcal{D}^h$ is precomputed and stored in a hashtable with t_h as the key. The cross lingual similarity measure calculation requires the word translation probability for a given term t_e. For every t_e in dictionary D^e, we store $\mathcal{T}_{t_e}$ in a hashmap that contains a list of terms in the target language along with their statistically determined translation probability $\tau(t_h|t_e) > \varepsilon$, where $t_h \in \mathcal{D}^h$.

Since the query and the FAQs use terms from different languages, the computation of IDF becomes a challenge (Pirkola, 1998) (Oard et al., 2007). Prior work uses a bilingual dictionary for translations for calculating the IDF. We on the other hand rely on a statistical dictionary that has translation probabilities. Applying the method suggested in the prior work on a statistical dictionary leads to errors as the translations may themselves be inaccurate.

We therefore calculate IDFs for target language term (translation) and use it in the weight measure calculation. The method suggested by Oard et al (Oard et al., 2007) is more useful in retrieval tasks for multiple documents, while in our case we need to retrieve a specific document (FAQ).

5.2 List Creation

Given an SMS input string S^e, we tokenize it on white space and replace any occurrence of digits to their string based form (e.g. 4get, 2day) to get a series of n tokens $s_1, s_2, \ldots, s_n$. A list L_i^e is created for each token s_i using terms in the monolingual dictionary D^e. The list for a single character SMS token is set to *null* as it is most likely to be a stop word. A term t_e from D^e is included in L_i^e if it satisfies the threshold condition

$$\gamma(t_e, s_i) > \phi \tag{5}$$

The threshold value ϕ is determined experimentally. For every $t_e \in L_i^e$ we retrieve $\mathcal{T}_{t_e}$ and then retrieve the *idf* scores for every $t_h \in \mathcal{T}_{t_e}$. Using the word translation probabilities and the idf score we compute the cross lingual similarity weight to create a new list L_i^h. A term t_h is included in the list only if

$$\tau(t_h|t_e) > 0.1 \tag{6}$$

This probability cut-off is used to prevent poor quality translations from being included in the list.

If more than one term t_e has the same translation t_h, then t_h can occur more than once in a given list. If this happens, then we remove repetitive occurrences of t_h and assign it a weight equal to the maximum weight amongst all occurrences in the list, multiplied by the number of times it occurs. The terms t_h in L_i^h are sorted in decreasing order of their similarity weights. Henceforth, the term “list” implies a sorted list.

For example given a SMS query “hw mch ds it cst to stdy in india” as shown in Fig. 3, for each token we create a list of possible correct dictionary words by dictionary look up. Thus for token “cst” we get dictionary words lik “cost, cast, case, close”. For each dictionary word we get a set of possible words in Hindi by looking at statistical translation table. Finally we merged the list obtained to get single list of Hindi words. The final list is ranked according to their similarity weights.

5.3 Search algorithm

Given S^e containing n tokens, we create n sorted lists $L_1^h, L_2^h, \ldots, L_n^h$ containing terms from the domain dictionary and sorted according to their cross lingual weights as explained in the previous section. A naive approach would be to query the index using each term appearing in all L_i^h to build a *Collection set* $\mathcal{C}$ of questions. The best matching question $\hat{Q}^h$ will be contained in this collection. We compute the score of each question in $\mathcal{C}$ using $Score(Q)$ and the question with highest score is treated as $\hat{Q}^h$. However the naive approach suffers from high runtime cost.

Inspired by the Threshold Algorithm (Fagin et al., 2001) we propose using a pruning algorithm that maintains a much smaller *candidate set* $\mathcal{C}$ of questions that can potentially contain the maximum scoring question. The algorithm is shown in Figure 4. The algorithm works in an iterative manner. In each iteration, it picks the term that has maximum weight among all the terms appearing in the lists $L_1^h, L_2^h, \ldots, L_n^h$. As the lists are sorted in the descending order of the weights, this amounts to picking the maximum weight term amongst the first terms of the n lists. The chosen term t_h is queried to find the set Q_{t_h}. The set Q_{t_h} is added to the candi-

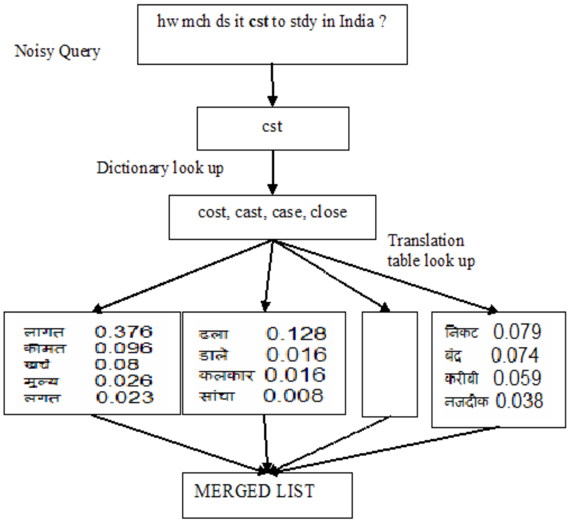

Figure 3: List creation

date set $\mathcal{C}$. For each question $Q \in Q_{t_h}$, we compute its score $Score(Q)$ and keep it along with Q. After this the chosen term t_h is removed from the list and the next iteration is carried out. We stop the iterative process when a thresholding condition is met and focus only on the questions in the candidate set $\mathcal{C}$. The thresholding condition guarantees that the candidate set $\mathcal{C}$ contains the maximum scoring question $\hat{Q}^h$. Next we develop this thresholding condition.

Let us consider the end of an iteration. Suppose Q is a question not included in $\mathcal{C}$. At best, Q will include the current top-most tokens $L_1^h[1], L_2^h[1], \ldots, L_n^h[1]$ from every list. Thus, the upper bound UB on the score of Q is

$$\text{Score}(Q) \leq \sum_{i=0}^{n} \omega(L_i^h[1]).$$

Let Q^* be the question in $\mathcal{C}$ having the maximum score. Notice that if $Q^* \geq$ UB, then it is guaranteed that any question not included in the candidate set $\mathcal{C}$ cannot be the maximum scoring question. Thus, the condition "$Q^* \geq$ UB" serves as the termination criterion. At the end of each iteration, we check if the termination condition is satisfied and if so, we can stop the iterative process. Then, we simply pick the question in $\mathcal{C}$ having the maximum score and return it.

```
Procedure Search Algorithm
Input: SMS $S = s_1, s_2, \ldots, s_n$
Output: Maximum scoring question $\hat{Q}^h$.
Begin
  $\forall s_i$, construct $L_i^e$ for which $\gamma(s_i, t_e) > \epsilon$
    // $L_i$ lists variants of $s_i$
  Construct lists $L_1^h, L_2^h, \ldots, L_n^h$ //(see Section 5.2).
    // $L_i^h$ lists cross lingual variants of $s_i$ in decreasing
    //order of weight.
  Candidate list $\mathcal{C} = \emptyset$.
  repeat
    $j^* = \text{argmax}_i \omega(L_i^h[1])$
    $t_h^* = L_{j^*}^h[1]$
      // $t_h^*$ is the term having maximum weight among
      // all terms appearing in the $n$ lists.
    Delete $t_h^*$ from the list $L_{j^*}^h$.
    Retrieve $Q_{t_h^*}$ using the index
      // $Q_{t_h^*}$: the set of all questions in $\mathcal{Q}^h$
      //having the term $t_h^*$
    For each $Q \in Q_{t_h^*}$
      Compute Score($Q$) and
      add $Q$ with its score into $\mathcal{C}$
    UB = $\sum_{i=1}^{n} \omega(L_i^h[1])$
    $\widehat{Q} = \text{argmax}_{Q \in \mathcal{C}} \text{Score}(Q)$.
    if Score($\widehat{Q}$) $\geq$ UB, then
        // Termination condition satisfied
      Output $\widehat{Q}$ and exit.
  forever
End
```

Figure 4: Search Algorithm with Pruning

6 Experiments

To evaluate our system we used noisy English SMS queries to query a collection of $10,000$ Hindi FAQs. These FAQs were collected from websites of various government organizations and other online resources. These FAQs are related to railway reservation, railway enquiry, passport application and health related issues. For our experiments we asked 6 human evaluators, proficient in both English and Hindi, to create English SMS queries based on the general topics that our FAQ collection dealt with. We found 60 SMS queries created by the evaluators, had answers in our FAQ collection and we designated these as the in-domain queries. To measure the effectiveness of our system in handling out of domain queries we used a total of 380 SMSes part of which were taken from the NUS corpus (How et al.,

whch metro statn z nr pragati maidan ?
dus metro goes frm airpot 2 new delhi rlway statn?
is dere any special metro pas 4 delhi uni students?
whn is d last train of delhi metro?
whr r d auto stands N delhi?

Figure 5: Sample SMS queries

2005) and the rest from the "out-of-domain" queries created by the human evaluators. Thus the total SMS query data size was 440. Fig 5 shows some of the sample queries.

Our objective was to retrieve the correct Hindi FAQ response given a noisy English SMS query. A given English SMS query was matched against the list of indexed FAQs and the best matching FAQ was returned by the Pruning Algorithm described in Section 5. A score of 1 was assigned if the retrieved answer was indeed the response to the posed SMS query else we assigned a score of 0. In case of out of domain queries a score of 1 was assigned if the output was NULL else we assigned a score of 0.

6.1 Translation System

We used the Moses toolkit (Koehn et al., 2007) to build an English-Hindi statistical machine translation system. The system was trained on a collection of $150,000$ English and Hindi parallel sentences sourced from a publishing house. The $150,000$ sentences were on a varied range of subjects such as news, literature, history etc. Apart from this the training data also contained an aligned parallel corpus of English and Hindi FAQs. The FAQs were collected from government websites on topics such as health, education, travel services etc.

Since an MT system trained solely on a collection of sentences would not be very accurate in translating questions, we trained the system on an English-Hindi parallel question corpus. As it was difficult to find a large collection of parallel text consisting of questions, we created a small collection of parallel questions using 240 FAQs and multiplied them to create a parallel corpus of $50,000$ sentences. This set was added to the training data and this helped familiarize the language model and phrase tables used by the MT systems to questions. Thus in total the MT system was trained on a corpus of $200,000$ sentences.

Experiment 1 and 2 form the baseline against which we evaluated our system. For our experiments the lexical translation probabilities generated by Moses toolkit were used to build the word translation model. In Experiment 1 the threshold ϕ described in Equation 5 is set to 1. In Experiment 2 and 3 this is set to 0.5. The Hindi FAQ collection was indexed using Lucene and a domain dictionary D^h was created from the Hindi words in the FAQ collection.

6.2 System Evaluation

We perform three sets of experiments to show how each stage of the algorithm contributes in improving the overall results.

6.2.1 Experiment 1

For Experiment 1 the threshold ϕ in Equation 5 is set to 1 i.e. we consider only those tokens in the query which belong to the dictionary. This setup illustrates the case when no noise handling is done. The results are reported in Figure 6.

6.2.2 Experiment 2

For Experiment 2 the noisy SMS query was cleaned using the following approach. Given a noisy token in the SMS query it's similarity (Equation 1) with each word in the Dictionary is calculated. The noisy token is replaced with the Dictionary word with the maximum similarity score. This gives us a clean English query.

For each token in the cleaned English SMS query, we create a list of possible Hindi translations of the token using the statistical translation table. Each Hindi word was assigned a weight according to Equation 4. The Pruning algorithm in Section 5 was then applied to get the best matching FAQ.

6.2.3 Experiment 3

In this experiment, for each token in the noisy English SMS we obtain a list of possible English variations. For each English variation a corresponding set of Hindi words from the statistical translation table was obtained. Each Hindi word was assigned a weight according to Equation 4. As described in Section 5.2, all Hindi words obtained from English variations of a given SMS token are merged to create

	Experiment 1	Experiment 2	Experiment 3
MRR Score	0.41	0.68	0.83

Table 1: MRR Scores

	F1 Score
Expt 1 (Baseline 1)	0.23
Expt 2 (Baseline 2)	0.68
Expt 3 (Proposed Method)	0.72

Table 2: F1 Measure

a list of Hindi words sorted in terms of their weight. The Pruning algorithm as described in Section 5 was then applied to get the best matching FAQ.

We evaluated our system using two different criteria. We used MRR (Mean reciprocal rank) and the best matching accuracy. Mean reciprocal rank is used to evaluate a system by producing a list of possible responses to a query, ordered by probability of correctness. The reciprocal rank of a query response is the multiplicative inverse of the rank of the first correct answer. The mean reciprocal rank is the average of the reciprocal ranks of results for a sample of queries Q.

$$MRR = 1/|Q| \sum_{i=1}^{Q} 1/rank_i \tag{7}$$

Best match accuracy can be considered as a special case of MRR where the size of the ranked list is 1. As the SMS based FAQ retrieval system will be used via mobile phones where screen size is a major constraint it is crucial to have the correct result on the top. Hence in our settings the best match accuracy is a more relevant and stricter performance evaluation measure than MRR.

Table 1 compares the MRR scores for all three experiments. Our method reports the highest MRR of 0.83. Figure 6 shows the performance using the strict evaluation criterion of the top result returned being correct.

We also experimented with different values of the threshold for Score(Q) (Section 5.3). The ROC curve for various threshold is shown in Figure 7. The result for both in-domain and out-of-domain queries for the three experiments are shown in Figure 6 for Score(Q) = 8. The F1 Score for experiments 1, 2 and 3 are shown in Table 2.

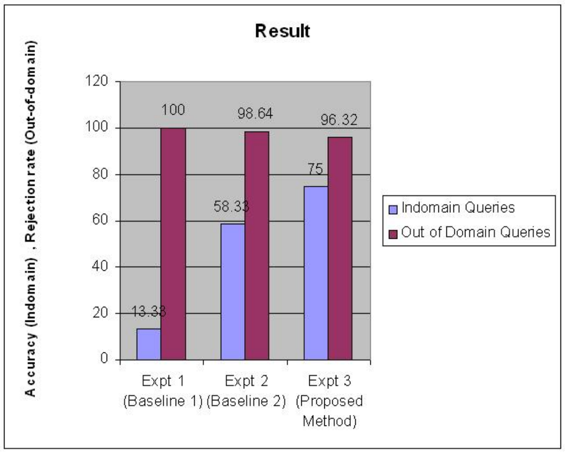

Figure 6: Comparison of results

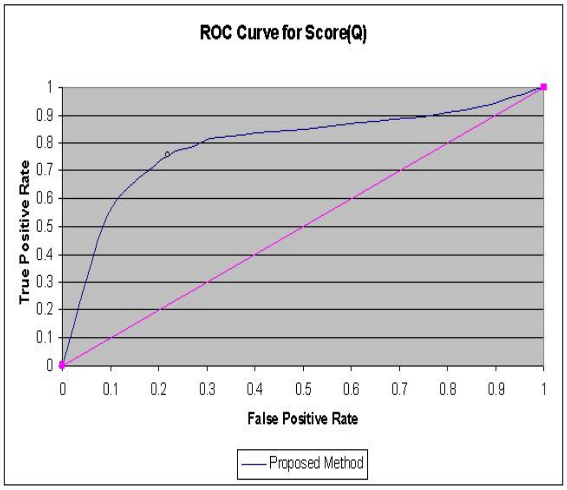

Figure 7: ROC Curve for $Score(Q)$

6.3 Measuring noise level in SMS queries

In order to quantify the level of noise in the collected SMS data, we built a character-level language model(LM) using the questions in the FAQ data-set (vocabulary size is 70) and computed the perplexity of the language model on the noisy and the cleaned SMS test-set. The perplexity of the LM on a corpus gives an indication of the average number of bits needed per n-gram to encode the corpus. Noise re-

		Cleaned SMS	Noisy SMS
English FAQ collection	bigram	16.64	55.19
	trigram	9.75	69.41

Table 3: Perplexity for Cleaned and Noisy SMS

sults in the introduction of many previously unseen n-grams in the corpus. Higher number of bits are needed to encode these improbable n-grams which results in increased perplexity. From Table 3 we can see the difference in perplexity for noisy and clean SMS data for the English FAQ data-set. Large perplexity values for the SMS dataset indicates a high level of noise.

For each noisy SMS query e.g. “hw 2 prvnt typhd” we manually created a clean SMS query “how to prevent typhoid”. A character level language model using the questions in the clean English FAQ dataset was created to quantify the level of noise in our SMS dataset. We computed the perplexity of the language model on clean and noisy SMS queries.

7 Conclusion

There has been a tremendous increase in information access services using SMS based interfaces. However, these services are limited to a single language and fail to scale for multilingual QA needs. The ability to query a FAQ database in a language other than the one for which it was developed is of great practical significance in multilingual societies. Automatic cross-lingual QA over SMS is challenging because of inherent noise in the query and the lack of cross language resources for noisy processing. In this paper we present a cross-language FAQ retrieval system that handles the inherent noise in source language to retrieve FAQs in a target language. Our system does not require an end-to-end machine translation system and can be implemented using a simple dictionary which can be static or constructed statistically using a moderate sized parallel corpus. This side steps the problem of building full fledged translation systems but still enabling the system to be scaled across multiple languages quickly. We present an efficient algorithm to search and match the best question in the large FAQ corpus of target language for a noisy input question. We have demonstrated the effectiveness of our approach on a real life FAQ corpus.

Abstract

We present a machine learning approach for the task of ranking previously answered questions in a question repository with respect to their relevance to a new, unanswered reference question. The ranking model is trained on a collection of question groups manually annotated with a partial order relation reflecting the relative utility of questions inside each group. Based on a set of meaning and structure aware features, the new ranking model is able to substantially outperform more straightforward, unsupervised similarity measures.

1 Introduction

Open domain Question Answering (QA) is one of the most complex and challenging tasks in natural language processing. In general, a question answering system may need to integrate knowledge coming from a wide variety of linguistic processing tasks such as syntactic parsing, semantic role labeling, named entity recognition, and anaphora resolution (Prager, 2006). State of the art implementations of these linguistic analysis tasks are still limited in their performance, with errors that compound and propagate into the final performance of the QA system (Moldovan et al., 2002). Consequently, the performance of open domain QA systems has yet to arrive at a level at which it would become a feasible alternative to the current paradigms for information access based on keyword searches.

Recently, community-driven QA sites such as Yahoo! Answers and WikiAnswers [1] have established a new approach to question answering that shifts the inherent complexity of open domain QA from the computer system to volunteer contributors. The computer is no longer required to perform a deep linguistic analysis of questions and generate corresponding answers, and instead acts as a mediator between users submitting questions and volunteers providing the answers.

An important objective in community QA is to minimize the time elapsed between the submission of questions by users and the subsequent posting of answers by volunteer contributors. One useful strategy for minimizing the response latency is to search the QA repository for similar questions that have already been answered, and provide the corresponding ranked list of answers, if such a question is found. The success of this approach depends on the definition and implementation of the question-to-question similarity function. In the simplest solution, the system searches for previously answered questions based on exact string matching with the reference question. Alternatively, sites such as WikiAnswers allow the users to mark questions they think are rephrasings ("alternate wordings", or paraphrases) of existing questions. These question clusters are then taken into account when performing exact string matching, therefore increasing the likelihood of finding previously answered questions that are semantically equivalent to the reference question.

In order to lessen the amount of work required from the contributors, an alternative approach is to build a system that automatically finds rephrasings of questions, especially since question rephrasing

[1] answers.yahoo.com, wiki.answers.com

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 97–107,
MIT, Massachusetts, USA, 9-11 October 2010.

seems to be computationally less demanding than question answering. According to previous work in this domain, a question is considered a rephrasing of a reference question Q_0 if it uses an alternate wording to express an identical information need. For example, Q_0 and Q_1 below are rephrasings of each other, and consequently they are expected to have the same answer.

Q_0 What should I feed my turtle?

Q_1 What do I feed my pet turtle?

Paraphrasings of a new question cannot always be found in the community QA repository. We believe that computing a ranked list of existing questions that at least partially address the original information need could also be useful to the user, at least until other users volunteer to give an exact answer to the original, unanswered reference question. For example, in the absence of any additional information about the reference question Q_0, the expected answers to questions Q_2 and Q_3 below may be seen as partially overlapping in information content with the expected answer for the reference question Q_0. An answer to question Q_4, on the other hand, is less likely to benefit the user, even though it has a significant lexical overlap with the reference question.

Q_2 What kind of fish should I feed my turtle?

Q_3 What do you feed a turtle that is the size of a quarter?

Q_4 What kind of food should I feed a turtle dove?

In this paper, we propose a supervised learning approach to the question ranking problem, a generalization of the question paraphrasing problem in which questions are ranked in a partial order based on the relative information overlap between their expected answers and the expected answer of the reference question. Underlying the question ranking task is the expectation that the user who submits a reference question will find the answers of the highly ranked questions to be more useful than the answers associated with the lower ranked questions. For the reference question Q_0 above, the learned ranking model is expected to produce a partial order in which Q_1 is ranked higher than Q_2, Q_3 and Q_4, whereas Q_2 and Q_3 are ranked higher than Q_4.

2 Partially Ordered Datasets for Question Ranking

In order to enable the evaluation of question ranking approaches, we have previously created a dataset of 60 groups of questions (Bunescu and Huang, 2010b). Each group consists of a reference question (e.g. Q_0 above) that is associated with a partially ordered set of questions (e.g. Q_1 to Q_4 above). For each reference questions, its corresponding partially ordered set is created from questions in Yahoo! Answers and other online repositories that have a high cosine similarity with the reference question. Out of the 26 top categories in Yahoo! Answers, the 60 reference questions span a diverse set of categories. Figure 1 lists the 20 categories covered, where each category is shown with the number of corresponding reference questions between parentheses.

```
   Travel (10), Computers & Internet (6),
    Beauty & Style (5), Entertainment &
Music (5), Food & Drink (5), Health (5),
      Arts & Humanities (3), Cars &
Transportation (3), Consumer Electronics
 (3), Pets (3), Family & Relationships
    (2), Science & Mathematics (2),
 Education & Reference (1), Environment
 (1), Local Businesses (1), Pregnancy &
 Parenting (1), Society & Culture (1),
     Sports (1), Yahoo! Products (1)
```

Figure 1: The 20 categories represented in the dataset.

Inside each group, the questions are manually annotated with a partial order relation, according to their utility with respect to the reference question. We use the notation $\langle Q_i \succ Q_j | Q_r \rangle$ to encode the fact that question Q_i is *more useful than* question Q_j with respect to the reference question Q_r. Similarly, $\langle Q_i = Q_j \rangle$ will be used to express the fact that questions Q_i and Q_j are reformulations of each other (the reformulation relation is independent of the reference question). The partial ordering among the questions Q_0 to Q_4 above can therefore be expressed concisely as follows: $\langle Q_0 = Q_1 \rangle$, $\langle Q_1 \succ Q_2 | Q_0 \rangle$, $\langle Q_1 \succ Q_3 | Q_0 \rangle$, $\langle Q_2 \succ Q_4 | Q_0 \rangle$, $\langle Q_3 \succ Q_4 | Q_0 \rangle$. Note that we do not explicitly annotate the relation $\langle Q_1 \succ Q_4 | Q_0 \rangle$, since it can be inferred based on the transitivity of the *more useful than* relation: $\langle Q_1 \succ Q_2 | Q_0 \rangle \wedge \langle Q_2 \succ Q_4 | Q_0 \rangle \Rightarrow \langle Q_1 \succ Q_4 | Q_0 \rangle$.

REFERENCE QUESTION (Q_r)

Q_5 What's a nice summer camp to go to in Florida?

PARAPHRASING QUESTIONS ($\mathcal{P}$)

Q_6 What camps are good for a vacation during the summer in FL?
Q_7 What summer camps in FL do you recommend?

USEFUL QUESTIONS ($\mathcal{U}$)

Q_8 Does anyone know a good art summer camp to go to in FL?
Q_9 Are there any good artsy camps for girls in FL?
Q_{10} What are some summer camps for like singing in Florida?
Q_{11} What is a good cooking summer camp in FL?
Q_{12} Do you know of any summer camps in Tampa, FL?
Q_{13} What is a good summer camp in Sarasota FL for a 12 year old?
Q_{14} Can you please help me find a surfing summer camp for beginners in Treasure Coast, FL?
Q_{15} Are there any acting summer camps and/or workshops in the Orlando, FL area?
Q_{16} Does anyone know any volleyball camps in Miramar, FL?
Q_{17} Does anyone know about any cool science camps in Miami?
Q_{18} What's a good summer camp you've ever been to?

NEUTRAL QUESTIONS ($\mathcal{N}$)

Q_{19} What's a good summer camp in Canada?
Q_{20} What's the summer like in Florida?

Table 1: A question group.

Also note that no relation is specified between Q_2 and Q_3, and similarly no relation can be inferred between these two questions. This reflects our belief that, in the absence of any additional information regarding the user or the "turtle" referenced in Q_0, we cannot compare questions Q_2 and Q_3 in terms of their usefulness with respect to Q_0.

Table 1 shows another reference question Q_5 from our dataset, together with its annotated group of questions Q_6 to Q_{20}. In order to make the annotation process easier and reproducible, we have divided it into two levels of annotation. During the first annotation stage, each question group is partitioned manually into 3 subgroups of questions:

- $\mathcal{P}$ is the set of *paraphrasing* questions.
- $\mathcal{U}$ is the set of *useful* questions.
- $\mathcal{N}$ is the set of *neutral* questions.

A question is deemed useful if its expected answer may overlap in information content with the expected answer of the reference question. The expected answer of a neutral question, on the other hand, should be irrelevant with respect to the reference question. Let Q_r be the reference question, $Q_p \in \mathcal{P}$ a paraphrasing question, $Q_u \in \mathcal{U}$ a useful question, and $Q_n \in \mathcal{N}$ a neutral question. Then the following relations are assumed to hold among these questions:

1. $\langle Q_p \succ Q_u | Q_r \rangle$: a *paraphrasing* question is more useful than a *useful* question.
2. $\langle Q_u \succ Q_n | Q_r \rangle$: a *useful* question is more useful than a *neutral* question.

Note that as long as these relations hold between the 3 types of questions, the names of the subgroups and their definitions are irrelevant with respect to the implied set of *more useful than* relations, since only the implied ternary relations will be used for training and evaluating question ranking approaches. We also assume that, by transitivity, the following ternary relations also hold: $\langle Q_p \succ Q_n | Q_r \rangle$, i.e. a *paraphrasing* question is more useful than a *neutral* question. Furthermore, if $Q_{p_1}, Q_{p_2} \in \mathcal{P}$ are two paraphrasing questions, this implies $\langle Q_{p_1} = Q_{p_2} | Q_r \rangle$.

For the vast majority of questions, the first annotation stage is straightforward and non-controversial. In the second annotation stage, we perform a finer annotation of relations between questions in the middle group $\mathcal{U}$. Table 1 shows two such relations (using indentation): $\langle Q_8 \succ Q_9 | Q_5 \rangle$ and $\langle Q_8 \succ Q_{10} | Q_5 \rangle$. Question Q_8 would have been a rephrasing of the reference question, were it not for the noun "art" modifying the focus noun phrase "summer camp". Therefore, the information content of the answer to Q_8 is strictly subsumed in the information content associated with the answer to Q_5. Similarly, in Q_9 the focus noun phrase is further specialized through the prepositional phrase "for girls". Therefore, (an answer to) Q_9 is less *useful* to Q_5 than (an answer to) Q_8, i.e. $\langle Q_8 \succ Q_9 | Q_5 \rangle$. Furthermore, the focus "art summer camp" in Q_8 conceptually subsumes the focus "summer camps for singing" in Q_{10}, therefore $\langle Q_8 \succ Q_{10} | Q_5 \rangle$.

We call this dataset *simple* since most of the reference questions are shorter than the other questions in their group. We have also created a *complex* version of the same dataset, by selecting as the reference question in each group a longer question from the same group. For example, if Q_0 were a reference question, it would be replaced with a more complex question, such as Q_2, or Q_3. The annotation is redone to reflect the relative usefulness relations with respect to the new reference questions. We believe that the new *complex* dataset is closer to the actual distribution of questions in community QA repositories: unanswered questions tend to be more specific (longer), whereas general questions (shorter) are more likely to have been answered already. Each dataset is annotated by two annotators, leading to a total of 4 datasets: Simple$_1$, Simple$_2$, Complex$_1$, and Complex$_2$.

Table 2 presents the following statistics on the two types of datasets (Simple, Complex) for each annotator (1, 2): the total number of paraphrasings ($\mathcal{P}$), the total number of useful questions ($\mathcal{U}$), the total number of neutral questions ($\mathcal{N}$), the total number of *more useful than* ordered pairs encoded in the dataset, either explicitly or through transitivity, and the Inter-Annotator Agreement (ITA). We compute the ITA as the *precision* (*P*) and *recall* (*R*) with respect to the *more useful than* ordered pairs encoded in one annotation ($Pairs_1$) relative to the ordered pairs encoded in the other annotation ($Pairs_2$).

Dataset	$\mathcal{P}$	$\mathcal{U}$	$\mathcal{N}$	Pairs	ITA
Simple$_1$	164	775	594	11015	*P*: 76.6
Simple$_2$	134	778	621	10436	*R*: 81.6
Complex$_1$	103	766	664	10654	*P*: 71.3
Complex$_2$	89	730	714	9979	*R*: 81.3

Table 2: Dataset statistics.

$$P = \frac{|Pairs_1 \cap Pairs_2|}{Pairs_1} \quad R = \frac{|Pairs_1 \cap Pairs_2|}{Pairs_2}$$

The statistics in Table 2 indicate that the second annotator was in general more conservative in tagging questions as paraphrases or useful questions.

3 Unsupervised Methods for Question Ranking

An ideal question ranking method would take an arbitrary triplet of questions Q_r, Q_i and Q_j as input, and output an ordering between Q_i and Q_j with respect to the reference question Q_r, i.e. one of $\langle Q_i \succ Q_j | Q_r \rangle$, $\langle Q_i = Q_j | Q_r \rangle$, or $\langle Q_j \succ Q_i | Q_r \rangle$. One approach is to design a *usefulness* function $u(Q_i, Q_r)$ that measures how useful question Q_i is for the reference question Q_r, and define the *more useful than* ($\succ$) relation as follows:

$$\langle Q_i \succ Q_j | Q_r \rangle \Leftrightarrow u(Q_i, Q_r) > u(Q_j, Q_r)$$

If we define $I(Q)$ to be the *information need* associated with question Q, then $u(Q_i, Q_r)$ could be defined as a measure of the relative overlap between $I(Q_i)$ and $I(Q_r)$. Unfortunately, the information need is a concept that, in general, is defined only intensionally and therefore it is difficult to measure. For lack of an operational definition of the information need, we will approximate $u(Q_i, Q_r)$ directly as a measure of the similarity between Q_i and Q_r. The similarity between two questions can be seen as a special case of text-to-text similarity, consequently one possibility is to use a general text-to-text similarity function such as *cosine similarity* in the vector space model (Baeza-Yates and Ribeiro-Neto, 1999):

$$cos(Q_i, Q_r) = \frac{Q_i^T Q_r}{\|Q_i\| \|Q_r\|}$$

Here, Q_i and Q_r denote the corresponding *tf*×*idf* vectors.

As a measure of question similarity, one major drawback of cosine similarity is that it is oblivious of the meanings of words in each question. This particular problem is illustrated by the three questions below. Q_{22} and Q_{23} have the same cosine similarity with Q_{21}, they are therefore indistinguishable in terms of their usefulness to the reference question Q_{21}, even though we expect Q_{22} to be more useful than Q_{23} (a place that sells hydrangea often sells other types of plants too, possibly including cacti).

Q_{21} Where can I buy a hydrangea?

Q_{22} Where can I buy a cactus?

Q_{23} Where can I buy an iPad?

To alleviate the lexical chasm, we can redefine $u(Q_i, Q_r)$ to be the similarity measure proposed by (Mihalcea et al., 2006) as follows:

$$mcs(Q_i, Q_r) = \frac{\sum_{w \in \{Q_i\}} maxSim(w, Q_r) * idf(w)}{\sum_{w \in \{Q_i\}} idf(w)} + \frac{\sum_{w \in \{Q_r\}} maxSim(w, Q_i) * idf(w)}{\sum_{w \in \{Q_r\}} idf(w)}$$

Since scaling factors are immaterial for ranking, we have ignored the normalization constant contained in the original measure. For each word $w \in Q_i$, $maxSim(w, Q_r)$ computes the maximum semantic similarity between w and any word $w_r \in Q_r$. The similarity scores are weighted by the corresponding *idf*'s, and normalized. A similar score is computed for each word $w \in Q_r$. The score computed by $maxSim$ depends on the actual function used to compute the word-to-word semantic similarity. In this paper, we evaluated four of the knowledge-based measures explored in (Mihalcea et al., 2006): *wup* (Wu and Palmer, 1994), *res* (Resnik, 1995), *lin* (Lin, 1998), and *jcn* (Jiang and Conrath, 1997).

4 Supervised Learning for Question Ranking

Cosine similarity, henceforth referred as *cos*, treats questions as bags-of-words. The meta-measure proposed in (Mihalcea et al., 2006), henceforth called *mcs*, treats questions as bags-of-concepts. Both *cos* and *mcs* ignore the syntactic relations between the words in a question, and therefore may miss important structural information. In the next three sections we describe a set of structural features that we believe are relevant for judging question similarity. These and other types of features will be integrated in an SVM model for ranking, as described later in Section 4.4.

4.1 Matching the Focus Words

If we consider the question Q_{24} below as reference, question Q_{26} will be deemed more useful than Q_{25} when using *cos* or *mcs* because of the higher relative lexical and conceptual overlap with Q_{24}. However, this is contrary to the actual ordering $\langle Q_{25} \succ Q_{26} | Q_{24} \rangle$, which reflects the fact that Q_{25}, which expects the same answer type as Q_{24}, should be deemed more useful than Q_{26}, which has a different answer type.

Q_{24} What are some good thriller *movies*?

Q_{25} What are some thriller *movies* with happy ending?

Q_{26} What are some good *songs* from a thriller movie?

The analysis above shows the importance of using the answer type when computing the similarity between two questions. However, instead of relying exclusively on a predefined hierarchy of answer types, we identify the *question focus* of a question, defined as the set of maximal noun phrases in the question that corefer with the expected answer (Bunescu and Huang, 2010a). Focus nouns such as *movies* and *songs* provide more discriminative information than general answer types such as *products*. We use answer types only for questions such as Q_{27} or Q_{28} below that lack an explicit question focus. In such cases, an artificial question focus is created from the answer type (e.g. *location* for Q_{27}, or *method* for Q_{28}).

Q_{27} *Where* can I buy a good coffee maker?

Q_{28} *How* do I make a pizza?

Let f_i and f_r be the focus words corresponding to questions Q_i and Q_r. We introduce a focus feature ϕ_f, and set its value to be equal with the similarity between the focus words:

$$\phi_f(Q_i, Q_r) = wsim(f_i, f_r) \qquad (1)$$

We use *wsim* to denote a generic word meaning similarity measure (e.g. *wup*, *res*, *lin* or *jcn*). When computing the focus feature, the non-focus word "movie" in Q_{26} will not be compared with the focus word "movies" in Q_{24}, and therefore Q_{26} will have a lower value for this feature than Q_{25}, i.e. $\phi_f(Q_{26}, Q_{24}) < \phi_f(Q_{25}, Q_{24})$.

4.2 Matching the Main Verbs

In addition to the question focus, the *main verb* of a question can also provide key information in estimating question-to-question similarity. We define the main verb to be the content verb that is highest in the dependency tree of the question, e.g. *buy* for Q_{27}, or *make* for Q_{28}. If the question does not contain a content verb, the main verb is defined to be the highest verb in the dependency tree, as for example *are* in Q_{24} to Q_{26}. The utility of a question's main verb in judging its similarity to other questions can be seen more clearly in the questions below, where Q_{29} is the reference:

Q_{29} How can I *transfer* music from iTunes to my iPod?

Q_{30} How can I *upload* music to my iPod?

Q_{31} How can I *play* music in iTunes?

The fact that *upload*, as the main verb of Q_{30}, is more semantically related to *transfer* is essential in deciding that $\langle Q_{30} \succ Q_{31} | Q_{29} \rangle$, i.e. Q_{30} is more useful than Q_{31} to Q_{29}.

Let v_i and v_r be the main verbs corresponding to questions Q_i and Q_r. We introduce a main verb feature ϕ_v as follows:

$$\phi_v(Q_i, Q_r) = wsim(v_i, v_r) \qquad (2)$$

If Q_{29} is considered as reference question, it is expected that the main verb feature for question Q_{30} will have a higher value than the main verb feature for Q_{31}, i.e. $\phi_f(Q_{31}, Q_{29}) < \phi_f(Q_{30}, Q_{29})$.

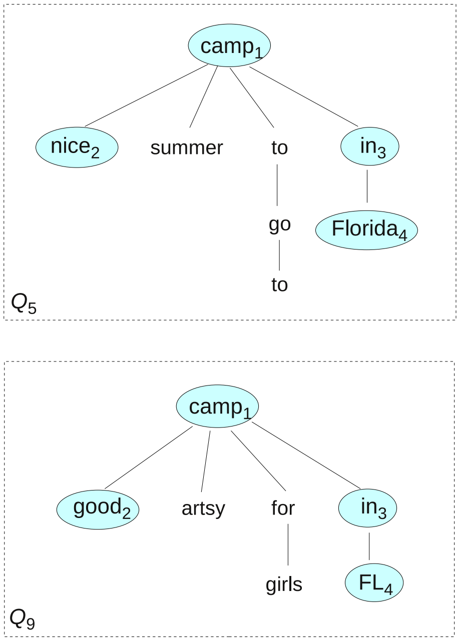

Figure 2: Matched dependency trees.

4.3 Matching the Dependency Trees

The question focus and the main verb are only two of the nodes in the syntactic dependency tree of a question. In general, all the words in a question are important when judging its semantic similarity with another question. We therefore propose a more general feature that exploits the dependency structure of the question and, in doing so, it also considers all the words in the question, like *cos* and *mcs*. For any given question we initially ignore the direction of the dependency arcs and change the question dependency tree to be rooted at the focus word, as illustrated in Figure 2 for questions Q_5 and Q_9. Interrogative patterns such as "What is" or "Are there any" are automatically eliminated from the dependency trees. We define the dependency tree similarity between two questions Q_i and Q_r to be a function of similarities $wsim(v_i, v_r)$ computed between aligned nodes $v_i \in Q_i$ and $v_r \in Q_r$. The nodes of two dependency trees are aligned through a function $\texttt{MaxMatch}(u_i.\mathcal{C},\ u_r.\mathcal{C})$ that takes two sets of children nodes as arguments, one from Q_i and one from Q_r, and finds the maximum weighted bipartite matching between $u_i.\mathcal{C}$ and $u_r.\mathcal{C}$. Given two children nodes $v_i \in u_i.\mathcal{C}$ and $v_r \in u_r.\mathcal{C}$, the weight of a potential matching between v_i and v_r is defined simply as $wsim(v_i, v_r)$. MaxMatch($u_i.\mathcal{C}$, $u_r.\mathcal{C}$) is furthermore constrained to match only nodes that have compatible part-of-speech tags (e.g. nouns are matched to nouns, verbs are matched to verbs), and children nodes that have the same head-modifier relationship with their parents (i.e. they are both heads, or they are both dependents of their parents). Table 3 shows the recursive algorithm used for finding a matching between two question dependency trees rooted at the focus words. The initial arguments of the algorithm are the two focus words $u_i = f_i$ and $u_r = f_r$. Thus, the pair (f_i, f_r) is the first pair of nodes to be added to the matching $\mathcal{M}$ in step 1. In the next step, we compute the maximum weighted matching between the children nodes $u_i.\mathcal{C}$ and $u_r.\mathcal{C}$, and recursively call the matching algorithm on pairs of matched nodes (v_i, v_r) from $\mathcal{M}$. The algorithm stops when MaxMatch returns an empty matching, which may happen when reaching leaf nodes, or when no pair of children nodes has compatible POS tags, or child-parent dependencies. Figure 2 shows the results of applying the tree matching algorithm on questions Q_5 and Q_9. Matched nodes share the same index and are shown in circles, whereas unmatched nodes are shown in italics.

```
TreeMatch($u_i, u_r$)
[In]: Two dependency tree nodes $u_i$, $u_r$.
[Out]: A set of node pairs $\mathcal{M}$.
1. set $\mathcal{M} \leftarrow \{(u_i, u_r)\}$
2. for each $(v_i, v_r) \in$ MaxMatch($u_i.\mathcal{C}, u_r.\mathcal{C}$):
3.     set $\mathcal{M} \leftarrow \mathcal{M} \cup$ TreeMatch($v_i, v_r$)
4. return $\mathcal{M}$
```

Table 3: Dependency Tree Matching.

We introduce a new feature $\phi_t(Q_i, Q_r)$ whose value is defined as the dependency tree similarity between questions Q_i and Q_r. Once the optimum matching $\mathcal{M}(Q_i, Q_r)$ between dependency trees has been found, $\phi_t(Q_i, Q_r)$ is computed as the normalized sum of the similarities between pairs of matched nodes v_i and v_r, as shown in Equations 3 and 4 below. When computing the similarity between two matched nodes, we factor in the similarities between corresponding pairs of words on the paths $f_i \rightsquigarrow v_i$, $f_r \rightsquigarrow v_r$ between the focus words f_i, f_r and the nodes v_i, v_r, as shown in Equation 5. This has the effect of reducing the importance of words that are farther away from the focus word in the dependency tree.

$$\phi_t(Q_i, Q_r) = \frac{sim(Q_i, Q_r)}{\sqrt{sim(Q_i, Q_i) sim(Q_r, Q_r)}} \tag{3}$$

$$sim(Q_i, Q_r) = \sum_{(v_i, v_r) \in \mathcal{M}(Q_i, Q_r)} sim(f_i \rightsquigarrow v_i, f_r \rightsquigarrow v_r) \tag{4}$$

$$sim(u_1 \rightsquigarrow u_n, v_1 \rightsquigarrow v_n) = \prod_{i=1}^{n} wsim(u_i, v_i) \tag{5}$$

If the word similarity function is normalized and defined to return 1 for identical words, the normalizer in Equation 3 becomes equivalent with $\sqrt{|Q_i||Q_r|}$. Thus, words that are left unmatched implicitly decrease the dependency tree similarity.

4.4 An SVM Model for Ranking Questions

We consider learning a *usefulness* function $u(Q_i, Q_r)$ of the following general, linear form:

$$u(Q_i, Q_r) = \mathbf{w}^T \phi(Q_i, Q_r) \tag{6}$$

The vector $\phi(Q_i, Q_r)$ is defined to contain the following generic features:

1. $\phi_f(Q_i, Q_r)$ = the semantic similarity between focus words, as described in Section 4.1.
2. $\phi_v(Q_i, Q_r)$ = the semantic similarity between main verbs, as described in Section 4.2.
3. $\phi_t(Q_i, Q_r)$ = the semantic similarity between the dependency trees, as described in Section 4.3.
4. $cos(Q_i, Q_r)$ = the cosine similarity between the two questions, as described in Section 3.
5. $mcs(Q_i, Q_r)$ = the bag-of-concepts similarity between the two questions, as described in Section 3.

Each of the generic features ϕ_f, ϕ_v, ϕ_t, and mcs corresponds to four actual features, one for each possible choice of the word similarity function $wsim$ (i.e. *wup*, *res*, *lin* or *jcn*). An additional pair of features is targeted at questions containing locations:

6. $\phi_l(Q_i, Q_r)$ = 1 if both questions contain locations, 0 otherwise.

7. $\phi_d(Q_i, Q_r)$ = the normalized geographical distance between the locations in Q_i and Q_r, 0 if $\phi_l(Q_i, Q_r)$ = 0.

Given two location names, we first find their latitude and longitude using Google Maps, and then compute the spherical distance between them using the *haversine formula*.

The corresponding parameters $\mathbf{w}$ will be trained on pairs from one of the partially ordered datasets described in Section 2. We use the kernel version of the large-margin ranking approach from (Joachims, 2002) which solves the optimization problem in Figure 3 below. The aim of this formulation is to find a weight vector $\mathbf{w}$ such that 1) the number of ranking constraints $u(Q_i, Q_r) \geq u(Q_j, Q_r)$ from the training data $\mathcal{D}$ that are violated is minimized, and 2) the ranking function $u(Q_i, Q_r)$ generalizes well beyond the training data. The learned $\mathbf{w}$ is a linear combination of the feature vectors $\phi(Q_i, Q_r)$, which makes it possible to use kernels.

minimize:
$$J(w, \xi) = \frac{1}{2}\|\mathbf{w}\|^2 + C\sum \xi_{rij}$$
subject to:
$$\mathbf{w}^T\phi(Q_i, Q_r) - \mathbf{w}^T\phi(Q_j, Q_r) \geq 1 - \xi_{rij}$$
$$\xi_{rij} \geq 0$$
$$\forall Q_r, Q_i, Q_j \in \mathcal{D}, \langle Q_i \succ Q_j | Q_r\rangle$$

Figure 3: SVM ranking optimization problem.

5 Experimental Evaluation

We use the four question ranking datasets described in Section 2 to evaluate the three similarity measures cos, mcs, and ϕ_t, as well as the SVM ranking model. We report one set of results for each of the four word similarity measures *wup*, *res*, *lin* or *jcn*. Each question similarity measure is evaluated in terms of its accuracy on the set of ordered pairs, and the performance is averaged between the two annotators for the *Simple* and *Complex* datasets. If $\langle Q_i \succ Q_j | Q_r\rangle$ is a relation specified in the annotation, we consider the tuple $\langle Q_i, Q_j, Q_r\rangle$ correctly classified if and only if $u(Q_i, Q_r) > u(Q_j, Q_r)$, where u is the question similarity measure. We used the SVM^{light} [2] implementation of ranking SVMs, with a cubic kernel and the standard parameters. The SVM ranking model was trained and tested using 10-fold cross-validation, and the overall accuracy was computed by averaging over the 10 folds.

We used the NLTK [3] implementation of the four similarity measures *wup*, *res*, *lin* or *jcn*. The *idf* values for each word were computed from frequency counts over the entire Wikipedia. For each question, the *focus* is identified automatically by an SVM tagger trained on a separate corpus of 2,000 questions manually annotated with focus information (Bunescu and Huang, 2010a). The SVM tagger uses a combination of lexico-syntactic features and a quadratic kernel to achieve a 93.5% accuracy in a 10-fold cross validation evaluation on the 2,000 questions. The head-modifier dependencies were derived automatically from the syntactic parse tree using the head finding rules from (Collins, 1999). The syntactic tree is obtained using Spear [4], a syntactic parser which comes pre-trained on an additional treebank of questions. The *main verb* of a question is identified deterministically using a breadth first traversal of the dependency tree.

The overall accuracy results presented in Table 4 show that the SVM ranking model obtains by far the best performance on both datasets, a substantial 10% higher than *cos*, which is the best performing unsupervised method. The random baseline – assigning a random similarity value to each pair of questions – results in 50% accuracy. Even though its use of word senses was expected to lead to superior results, *mcs* does not perform better than *cos* on this dataset. Our implementation of *mcs* did however perform better than *cos* on the Microsoft paraphrase corpus (Dolan et al., 2004). One possible reason for this behavior is that *mcs* seems to be less resilient than *cos* to differences in question length. Whereas the Microsoft paraphrase corpus was specifically designed such that "the length of the shorter of the two sentences, in words, is at least 66% that of the longer" (Dolan and Brockett, 2005), the question ranking datasets place no constraints on the lengths of the

Table 5: Ablation results.

questions. However, even though by themselves the meaning aware mcs and the structure-and-meaning aware ϕ_t do not outperform the bag-of-words cos, they do help in increasing the performance of the SVM ranking model, as can be inferred from the corresponding columns in Table 5. The table shows the results of ablation experiments in which all but one type of features are used. The results indicate that all types of features are useful, with significant contributions being brought especially by cos and the focus related features $\phi_{f,t}$.

The measures investigated in this paper are all compositional and reduce the similarity computations to word level. The following question patterns illustrate the need to design more complex similarity measures that take into account the context of every word in the question:

P_1 Where can I find a job around ⟨*City* ⟩?

P_2 What are some famous people from ⟨*City* ⟩?

P_3 What is the population of ⟨*City* ⟩?

Below are three instantiations of the first question pattern:

Q_{32} Where can I find a job around Anaheim, CA?

Q_{33} Where can I find a job around Los Angeles?

Q_{34} Where can I find a job around Vista, CA?

If we take Q_{32} as reference question, the fact that the distance between Los Angeles and Anaheim is smaller than the distance between Vista and Anaheim leads the ranking system to rank Q_{33} as more useful than Q_{34} with respect to Q_{32}, which is the expected result. The preposition "around" from the city context in the first pattern is a good indicator that proximity relations are relevant in this case. When the same three cities are used for instantiating the other two patterns, it can be seen that the proximity relations are no longer as relevant for judging the relative usefulness of questions.

6 Future Work

We plan to integrate context dependent word similarity measures into a more robust question utility function. We also plan to make the dependency tree matching more flexible in order to account for paraphrase patterns that may differ in their syntactic structure. The questions that are posted on community QA sites often contain spelling or grammatical errors. Consequently, we will work on interfacing the question ranking system with a separate module aimed at fixing orthographic and grammatical errors.

7 Related Work

The question rephrasing subtask has spawned a diverse set of approaches. (Hermjakob et al., 2002) derive a set of phrasal patterns for question reformulation by generalizing surface patterns acquired automatically from a large corpus of web documents. The focus of the work in (Tomuro, 2003) is on deriving reformulation patterns for the interrogative part of a question. In (Jeon et al., 2005), word translation probabilities are trained on pairs of semantically similar questions that are automatically extracted from an FAQ archive, and then used in a language model that retrieves question reformulations. (Jijkoun and de Rijke, 2005) describe an FAQ question retrieval system in which weighted combinations of similarity functions corresponding to questions, existing answers, FAQ titles and pages are computed using a vector space model. (Zhao et al., 2007) exploit the Encarta logs to automatically extract clusters containing question paraphrases and further train a perceptron to recognize question paraphrases inside each cluster based on a combination of lexical, syntactic and semantic similarity features. More recently, (Bernhard and Gurevych, 2008) evaluated various string similarity measures and vector space based similarity measures on the task of retrieving question paraphrases from the WikiAnswers repository. The aim of the question search task presented in (Duan et al., 2008) is to return questions that are semantically equivalent or close to the queried question, and is therefore similar to our question ranking task. Their approach is evaluated on a dataset in which questions are categorized either as relevant or irrelevant. Our formulation of question ranking is more general, and in particular subsumes the annotation of binary question categories such as relevant vs. irrelevant, or paraphrases vs. non-paraphrases. Moreover, we are able to exploit the annotated utility relations as supervision in a learning for ranking approach, whereas (Duan et al., 2008) use the annotated dataset to tune the 3 parameters of a mostly unsupervised approach. The question ranking task was first formulated in (Bunescu and Huang, 2010b), where an initial version of the dataset was also described. In this paper, we introduce 4 versions of the dataset, a more general meaning and structure aware similarity measure, and a supervised model for ranking that substantially outperforms the previously proposed utility measures.

8 Conclusion

We presented a supervised learning approach to the question ranking task in which previously known questions are ordered based on their relative utility with respect to a new, reference question. We created four versions of a dataset of 60 groups of questions [5], each annotated with a partial order relation reflecting the relative utility of questions inside each group. An SVM ranking model was trained on the dataset and evaluated together with a set of simpler, unsupervised question-to-question similarity models. Experimental results demonstrate the importance of using structure and meaning aware features when computing the relative usefulness of questions.

Abstract

The PECO framework is a knowledge representation for formulating clinical questions. Queries are decomposed into four aspects, which are Patient-Problem (P), Exposure (E), Comparison (C) and Outcome (O). However, no test collection is available to evaluate such framework in information retrieval. In this work, we first present the construction of a large test collection extracted from systematic literature reviews. We then describe an analysis of the distribution of PECO elements throughout the relevant documents and propose a language modeling approach that uses these distributions as a weighting strategy. In our experiments carried out on a collection of 1.5 million documents and 423 queries, our method was found to lead to an improvement of 28% in MAP and 50% in P@5, as compared to the state-of-the-art method.

1 Introduction

In recent years, the volume of health and biomedical literature available in electronic form has grown exponentially. MEDLINE, the authoritative repository of citations from the medical and bio-medical domain, contains more than 18 million citations. Searching for clinically relevant information within this large amount of data is a difficult task that medical professionals are often unable to complete in a timely manner. A better access to clinical evidence represents a high impact application for physicians.

Evidence-Based Medicine (EBM) is a widely accepted paradigm for medical practice (Sackett et al., 1996). EBM is defined as the conscientious, explicit and judicious use of current best evidence in making decisions about patient care. Practice EBM means integrating individual clinical expertise with the best available external clinical evidence from systematic research. It involves tracking down the best evidence from randomized trials or meta-analyses with which to answer clinical questions. Richardson et al. (1995) identified the following four aspects as the key elements of a well-built clinical question:

- **Patient-problem**: what are the patient characteristics (e.g. age range, gender, etc.)? What is the primary condition or disease?
- **Exposure-intervention**: what is the main intervention (e.g. drug, treatment, duration, etc.)?
- **Comparison**: what is the exposure compared to (e.g. placebo, another drug, etc.)?
- **Outcome**: what are the clinical outcomes (e.g. healing, morbidity, side effects, etc.)?

These elements are known as the PECO elements. Physicians are educated to formulate their clinical questions in respect to this structure. For example, in the following question: "*In patients of all ages with Parkinson's disease, does a Treadmill training compared to no training allows to increase the walking distance*?" one can identify the following elements:

- **P**: Patients of all ages with Parkinson's disease
- **E**: Treadmill training
- **C**: No treadmill training
- **O**: Walking distance

In spite of this well-defined question structure, physicians still use keyword-based queries when they search for clinical evidence. An explanation of

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 108–115,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

that is the almost total absence of PECO search interfaces. PubMed[1], the most used search interface, does not allow users to formulate PECO queries yet. For the previously mentioned clinical question, a physician would use the query "*Treadmill* AND *Parkinson's disease*". There is intuitively much to gain by using a PECO structured query in the retrieval process. This structure specifies the role of each concept in the desired documents, which is a clear advantage over a keyword-based approach. One can for example differentiate two queries in which a disease would be a patient condition or a clinical outcome. This conceptual decomposition of queries is also particularly useful in a sense that it can be used to balance the importance of each element in the search process.

Another important factor that prevented researchers from testing approaches to clinical information retrieval (IR) based on PECO elements is the lack of a test collection, which contains a set of documents, a set of queries and the relevance judgments. The construction of such a test collection is costly in manpower. In this paper, we take advantage of the systematic reviews about clinical questions from Cochrane. Each Cochrane review examines in depth a clinical question and survey all the available relevant publications. The reviews are written for medical professionals. We transformed them into a TREC-like test collection, which contains 423 queries and 8926 relevant documents extracted from MEDLINE. In a second part of this paper, we present a model integrating the PECO framework in a language modeling approach to IR. An intuitive method would try to annotate the concepts in documents into PECO categories. One can then match the PECO elements in the query to the elements detected in documents. However, as previous studies have shown, it is very difficult to automatically annotate accurately PECO elements in documents. To by-pass this issue, we propose an alternative that relies on the observed positional distribution of these elements in documents. We will see that different types of element have different distributions. By weighting words according to their positions, we can indirectly weigh the importance of different types of element in search. As we will show in this paper, this approach turns out to be highly effective.

This paper is organized as follows. We first briefly review the previous work, followed by a description of the test collection we have constructed. Next, we give the details of the method we propose and present our experiments and results. Lastly, we conclude with a discussion and directions for further work.

2 Related work

The need to answer clinical questions related to a patient care using IR systems has been well studied and documented (Hersh et al., 2000; Niu et al., 2003; Pluye et al., 2005). There are a limited but growing number of studies trying to use the PECO elements in the retrieval process. (Demner-Fushman and Lin, 2007) is one of the few such studies, in which a series of knowledge extractors is used to detect PECO elements in documents. These elements are later used to re-rank a list of retrieved citations from PubMed. Results reported indicate that their method can bring relevant citations into higher-ranking positions, and from these abstracts generate responses that answer clinicians' questions. This study demonstrates the value of the PECO framework as a method for structuring clinical questions. However, as the focus has been put on the post-retrieval step (for question-answering), it is not clear whether PECO elements are useful at the retrieval step. Intuitively, the integration of PECO elements in the retrieval process can also lead to higher retrieval effectiveness.

The most obvious scenario for testing this would be to recognize PECO elements in documents prior to indexing. When a PECO-structured query is formulated, it is matched against the PECO elements in the documents (Dawes et al., 2007). Nevertheless, the task of automatically identifying PECO elements is a very difficult one. There are two major reasons for that. First, previous studies have indicated that there is a low to moderate agreement rate among humans for annotating PECO elements. This is due to the lack of standard definition for the element' boundaries (e.g. can be words, phrases or sentences) but also to the existence of several levels of annotation. Indeed, there are a high number

[1] `www.pubmed.gov`

of possible candidates for each element and one has to choose if it is a main element (i.e. playing a major role in the clinical study) or secondary elements. Second is the lack of sufficient annotated data that can be used to train automatic tagging tools.

Despite all these difficulties, several efficient detection methods have been proposed (Demner-Fushman and Lin, 2007; Chung, 2009). Nearly all of them are however restricted to a coarse-grain annotation level (i.e. tagging entire sentences as describing one element). This kind of coarser-grain identification is more robust and more feasible than the one at concept level, and it could be sufficient in the context of IR. In fact, for IR purposes, what is the most important is to correctly weight the words in documents and queries. From this perspective, an annotation at the sentence level may be sufficient. Notwithstanding, experiments conducted using a collection of documents that were annotated at a sentence-level only showed a small increase in retrieval accuracy (Boudin et al., 2010b) compared to a traditional bag-of-words approach.

More recently, Boudin et al. (2010a) proposed an alternative to the PECO detection issue that relies on assigning different weights to words according to their positions in the document. A location-based weighting strategy is used to emphasize the most informative parts of documents. They show that a large improvement in retrieval effectiveness can be obtained this way and indicate that the weights learned automatically are correlated to the observed distribution of PECO elements in documents. In this work, we propose to go one step further in this direction by analyzing the distribution of PECO elements in a large number of documents and define the positional probabilities of PECO elements accordingly. These probabilities will be integrated in the document language model.

3 Construction of the test collection

Despite the increasing use of search engines by medical professionals, there is no standard test collection for evaluating clinical IR. Constructing such a resource from scratch would require considerable time and money. One way to overcome this obstacle is to use already available systematic reviews. Systematic reviews try to identify, appraise, select and synthesize all high quality research evidence relevant to a clinical question. The best-known source of systematic reviews in the healthcare domain is the Cochrane collaboration[2]. It consists of a group of over 15,000 specialists who systematically identify and review randomized trials of the effects of treatments. In particular, a review contains a reference section, listing all the relevant studies to the clinical question. These references can be considered as relevant documents. In our work, we propose to use these reviews as a way to semi-automatically build a test collection. As the reviews are made by specialists in the area independently from our study, we can avoid bias in our test collection.

We gathered a subset of Cochrane systematic reviews and asked a group of annotators, one professor and four Master students in family medicine, to create PECO-structured queries corresponding to the clinical questions. As clinical questions answered in these reviews cover various aspects of one topic, multiple variants of precise PECO queries were generated for each review. Moreover, in order to be able to compare a PECO-based search strategy to a real world scenario, this group have also provided the keyword-based queries that they would have used to search with PubMed. Below is an example of queries generated from the systematic review about "*Aspirin with or without an antiemetic for acute migraine headaches in adults*":

Keyword-based query

[aspirin and migraine]

PECO-structured queries

1. [adults 18 years or more with migraine]$^{\mathrm{P}}$
   [aspirin alone]$^{\mathrm{E}}$
   [placebo]$^{\mathrm{C}}$
   [pain free]$^{\mathrm{O}}$
2. [adults 18 years or more with migraine]$^{\mathrm{P}}$
   [aspirin plus an antiemetic]$^{\mathrm{E}}$
   [placebo]$^{\mathrm{C}}$
   [pain free]$^{\mathrm{O}}$
3. [adults 18 years or more with migraine]$^{\mathrm{P}}$
   [aspirin plus metoclopramide]$^{\mathrm{E}}$
   [active comparator]$^{\mathrm{C}}$
   [use of rescue medication]$^{\mathrm{O}}$

[2] www.cochrane.org

All the citations included in the "References" section of the systematic review were extracted and selected as relevant documents. These citations were manually mapped to PubMed unique identifiers (PMID). This is a long process that was undertaken by two different workers to minimize the number of errors. At this step, only articles published in journals referenced in PubMed are considered (e.g. conference proceedings are not included).

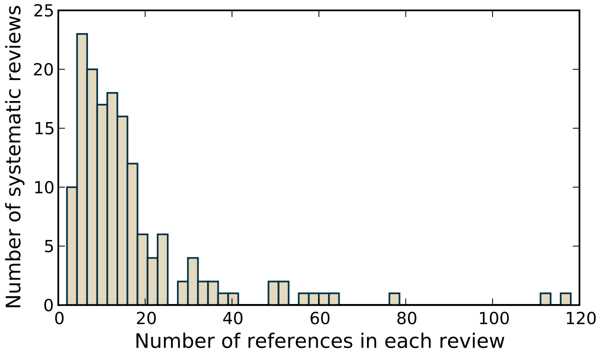

Figure 1: Histogram of the number of queries versus the number of relevant documents.

We selected in sequential order from the set of new systematic reviews[3] and processed 156 Cochrane reviews. There was no restriction about the topics covered or the number of included references. The resulting test collection is composed of 423 queries and 8926 relevant citations (2596 different citations). This number reduces to 8138 citations once we remove the citations without any text in the abstract (i.e. certain citations, especially old ones, only contain a title). Figure 1 shows the statistics derived from the number of relevant documents by query. In this test collection, the average number of documents per query is approximately 19 while the average length of a document is 246 words.

4 Distribution of PECO elements

The observation that PECO elements are not evenly distributed throughout the documents is not new. In fact, most existing tagging methods used location-based features. This information turns out to be very useful because of the standard structure of medical citations. Actually, many scientific journals explicitly recommend authors to write their abstracts in compliance to the ordered rhetorical structure: Introduction, Methods, Results and Discussion. These rhetorical categories are highly correlated to the distributions of PECO elements, as some elements are more likely to occur in certain categories (e.g. clinical outcomes are more likely to appear in the conclusion). The position is thus a strong indicator of whether a text segment contains a PECO element or not.

To the best of our knowledge, the first analysis of the distribution of PECO elements in documents was described in(Boudin et al., 2010a). A small collection of manually annotated abstracts was used to compute the probability that a PECO element occurs in a specific part of the documents. This study is however limited by the small number of annotated documents (approximately 50 citations) and the moderate agreement rate among human annotators. Here we propose to use our test collection to compute more reliable statistics.

The idea is to use the pairs of PECO-structured query and relevant document, assuming that if a document is relevant then it should contain the same elements as the query. Of course, this is obviously not always the case. Errors can be introduced by synonyms or homonyms and relevant documents may not contain all of the elements described in the query. But, with more than 8100 documents, it is quite safe to say that this method produce fairly reliable results. Moreover, a filtering process is applied to queries removing all non-informative words (e.g. stopwords, numbers, etc.) from being counted.

There are several ways to look at the distribution of PECO elements in documents. One can use the rhetorical structure of abstracts to do that. However, the high granularity level of such analysis would make it less precise for IR purposes. Furthermore, most of the citations available in PubMed are devoid of explicitly marked sections. It is possible to automatically detect these sections but only with a non-negligible error rate (McKnight and Srinivasan, 2003). In our study, we chose to use a fixed number of partitions by dividing documents into parts of equal length. This choice is motivated by its repeatability and ease to implement, but also for comparison with previous studies.

We divided each relevant document into 10 parts of equal length on a word level (from P1 to P10). We

[3] http://mrw.interscience.wiley.com/cochrane/cochrane_clsysrev_new_fs.html

computed statistics on the number of query words that occur in each of these parts. For each PECO element, the distribution of query words among the parts of the documents is not uniform (Figure 2). We observe distinctive distributions, especially for Patient-Problem and Exposure elements, indicating that first and last parts of the documents have higher chance to contain these elements. This gives us a clear and robust indication on which specific parts should be enhanced when searching for a given element. Our proposed model will exploit the typical distributions of PECO elements in documents.

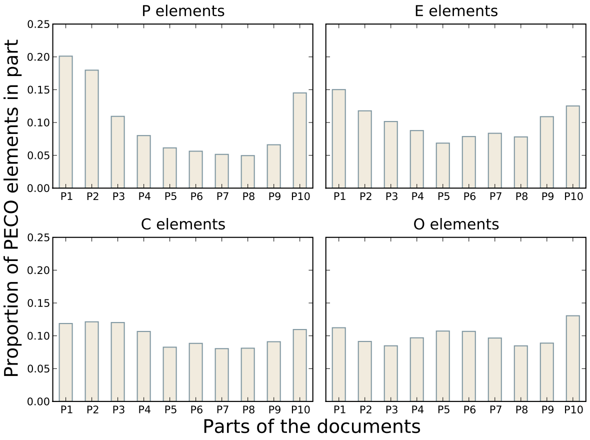

Figure 2: Distribution of each PECO element throughout the different parts of the documents.

5 Retrieval Method

In this work, we use the language modeling approach to information retrieval. This approach assumes that queries and documents are generated from some probability distribution of text (Ponte and Croft, 1998). Under this assumption, ranking a document D as relevant to a query Q is seen as estimating $P(Q|D)$, the probability that Q was generated by the same distribution as D. A typical way to score a document D as relevant to a query Q is to compute the Kullback-Leibler divergence between their respective language models:

$$\mathrm{score}(Q, D) = \sum_{w \in Q} P(w|Q) \cdot \log P(w|D) \qquad (1)$$

Under the traditional bag-of-words assumption, i.e. assuming that there is no need to model term dependence, a simple estimate for $P(w|Q)$ can be obtained by computing Maximum Likelihood Estimation (MLE). It is calculated as the number of times the word w appears in the query Q, divided by its length:

$$P(w|Q) = \frac{\mathrm{count}(w, Q)}{|Q|}$$

A similar method is employed for estimating $P(w|D)$. Bayesian smoothing using Dirichlet priors is however applied to the maximum likelihood estimator to compensate for data sparseness (i.e. smoothing probabilities to remove zero estimates). Given μ the prior parameter and $\mathcal{C}$ the collection of documents, $P(w|D)$ is computed as:

$$P(w|D) = \frac{\mathrm{count}(w, D) + \mu \cdot P(w|\mathcal{C})}{|D| + \mu}$$

5.1 Model definition

In our model, we propose to use the distribution of PECO elements observed in documents to emphasize the most informative parts of the documents. The idea is to get rid of the problem of precisely detecting PECO elements by using a positional language model. To integrate position, we estimate a series of probabilities that constraints the word counts to a specific part of the documents instead of the entire document. Each document D is ranked by a weighted linear interpolation. Given a document D divided in 10 parts $p \in [P1, P2 \cdots P10]$, $P(w|D)$ in equation 1 is redefined as:

$$\begin{aligned} P'(w|D) = \alpha \cdot P(w|D) + \beta \cdot P_{\mathrm{title}}(w|D) \\ + \gamma \cdot \sum_{p_i \in D} \sigma_e \cdot P_{p_i}(w|D) \end{aligned} \qquad (2)$$

where the σ_e weights for each type of element e are empirically fixed to the values of the distribution of PECO elements observed in documents. We then redefine the scoring function to integrate the PECO query formulation. The idea is to use the PECO structure as a way to balance the importance of each element in the retrieval step. The final scoring function is defined as:

$$\mathrm{score}_{\mathrm{final}}(Q, D) = \sum_{e \in \mathrm{PECO}} \delta_e \cdot \mathrm{score}(Q_e, D)$$

In our model, there are a total of 7 weighting parameters, 4 corresponding to the PECO elements in queries (δ_P, δ_E, δ_C and δ_O) and 3 for the document language models (α, β and γ). These parameters will be determined by cross-validation.

6 Results

In this section, we first describe the details of our experimental protocol. Then, we present the results obtained by our model on the constructed test collection.

6.1 Experimental settings

As a collection of documents, we gathered 1.5 millions of citations from PubMed. We used the following constraints: citations with an abstract, human subjects, and belonging to one of the following publication types: randomized control trials, reviews, clinical trials, letters, editorials and meta-analyses. The set of queries and relevance judgments described in Section 3 is used to evaluate our model. Relevant documents were, if not already included, added to the collection. Because each query is generated from a systematic literature review completed at a time t, we placed an additional restriction on the publication date of the retrieved documents: only documents published before time t are considered. Before indexing, each citation is pre-processed to extract its title and abstract text and then converted into a TREC-like document format. Abstracts are divided into 10 parts of equal length (the ones containing less than 10 words are discarded). The following fields are marked in each document: title, P1, P2 $\cdots$ P10. The following evaluation measures are used:

- Precision at rank n (P@n): precision computed on the n topmost retrieved documents.
- Mean Average Precision (MAP): average of precision measures computed at the point of each relevant document in the ranked list.
- Number of relevant documents retrieved

All retrieval tasks are performed using an "out-of-the-shelf" version of the Lemur toolkit[4]. We use the embedded tokenization algorithm along with the standard Porter stemmer. The number of retrieved documents is set to 1000 and the Dirichlet prior smoothing parameter to $\mu = 2000$. In all our experiments, we use the KL divergence scoring function (equation 1) as baseline. Statistical significance is computed using the well-known Student's t-test. To determine reasonable weights and avoid overtuning the parameters, we use a 10-fold cross-validation optimizing the MAP values.

6.2 Experiments

We first investigated the impact of using PECO-structured queries on the retrieval performance. As far as we know, no quantitative evaluation of the increase or decrease of performance in comparison with a keyword-based search strategy has been reported. Schardt et al. (2007) presented a comparison between PubMed and a PECO search interface but failed to demonstrate any significant difference between the two search protocols. The larger number of words in PECO-structured queries, on average 18.8 words per query compared to 4.3 words for keyword queries, should capture more aspects of the information need. But, it may also be a disadvantage due to the fact that more noise can be brought in, causing query-drift issues.

We propose two baselines using the keyword-based queries. The first baseline (named Baseline-1) uses keyword queries with the traditional language modeling approach. This is one of the state-of-the-art approaches in current IR research. This retrieval model considers each word in a query as an equal, independent source of information. In the second baseline (named Baseline-2), we consider multiword phrases. In our test collection, queries are often composed of multiword phrases such as "*low back pain*" or "*early pregnancy*". It is clear that finding the exact phrase "*heart failure*" is a much stronger indicator of relevance than just finding "*heart*" and "*failure*" scattered within a document. The Indri operator `#1` is used to perform phrase-based retrieval. Phrases are already indicated in queries by the conjunction and (e.g. *vaccine and hepatitis B*). A simple regular expression is used to recognize the phrases.

Results are presented in Table 1. As expected, phrase-based retrieval leads to some increase in retrieval precision (P@5). However, the number of

[4] www.lemurproject.org

relevant documents retrieved is decreased. This is due to the fact that we use exact phrase matching that can reduce query coverage. One solution would be to use unordered window features (Indri operator `#uwn`) that would require words to be close together but not necessarily in an exact sequence order (Metzler and Croft, 2005).

The PECO queries use PECO-structured queries as a bag of words. We observe that PECO queries do not enhance the average precision but increase the P@5 significantly. The number of relevant documents retrieved is also larger. These results indicate that formulating clinical queries according to the PECO framework enhance the retrieval effectiveness.

Model	**MAP**	**P@5**	**#rel. ret.**
Baseline-1	**0.129**	0.151	5369
Baseline-2	0.128	0.161*	4645
PECO-queries	0.126	**0.172***	**5433**

Table 1: Comparing the performance measures of keyword-based and PECO-structured queries in terms of MAP, precision at 5 and number of relevant documents retrieved (#rel. ret.). ($*$: t.test $<$ 0.05)

In a second series of experiments, we evaluated the model we proposed in Section 5 . We compared two variants of our model. The first variant (named Model-1) uses a global σ_e distribution fixed according to the average distribution of all PECO elements (i.e. the observed probability that a PECO element occurs in a document' part, no matter which element it is). The second variant (named Model-2) uses a differentiated σ_e distribution for each type of PECO element. The idea is to see if, given the fact that PECO elements have different distributions in documents, using an adapted weight distribution for each element can improve the retrieval effectiveness.

Previous studies have shown that assigning a different weight to each PECO element in the query leads to better results (Demner-Fushman and Lin, 2007; Boudin et al., 2010a). In order to compare our model with a similar method, we defined another baseline (named Baseline-3) by fixing the parameters $\beta = 0$ and $\gamma = 0$ in equation 2. We performed a grid search (from 0 to 1 by step of 0.1) to find the optimal δ weights. Regarding the last three parameters in our full models, namely α, β and γ, we conducted a second grid search to find their optimal values. Performance measures obtained in 10-fold cross-validation (optimizing the MAP measure) by these models are presented in Table 2.

A significant improvement is obtained by the Baseline-3 over the keyword-based approach (Baseline-2). The PECO decomposition of queries is particularly useful to balance the importance of each element in the scoring function. We observe a large improvement in retrieval effectiveness for both models over the two baselines. This strongly indicates that a weighting scheme based on the word position in documents is effective. These results support our assumption that the distribution of PECO elements in documents can be used to weight words in the document language model.

However, we do not observe meaningful differences between Model-1 and Model-2. This tend to suggest that a global distribution is likely more robust for IR purposes than separate distributions for each type of element. Another possible reason is that our direct mapping from positional distribution to probabilities may not be the most appropriate. One may think about using a different transformation, or performing some smoothing. We will leave this for our future work.

7 Conclusion

This paper first presented the construction of a test collection for evaluating clinical information retrieval. From a set of systematic reviews, a group of annotators were asked to generate structured clinical queries and collect relevance judgments. The resulting test collection is composed of 423 queries and 8926 relevant documents. This test collection provides a basis for researchers to experiment with PECO-structured queries in clinical IR. The test collection introduced in this paper, along with the manual given to the group of annotators, will be available for download[5].

In a second step, this paper addressed the problem of using the PECO framework in clinical IR. A straightforward idea is to identify PECO elements in documents and use the elements in the retrieval process. However, this approach does not work well be-

[5] http://www-etud.iro.umontreal.ca/~boudinfl/pecodr/

Model	**MAP**	**% rel.**	**P@5**	**% rel.**	**#rel. ret.**

Baseline-3	0.144	+12.5%*	0.196	+21.7%†	5780
Model-1	0.164	+28.1%†	0.241	+49.7%†	5768
Model-2	0.163	+27.3%†	0.240	+49.1%†	5770

Table 2: 10-fold cross validation scores for the Baseline-2, Baseline-3 and the two variants of our proposed model (Model-1 and Model-2). Relative increase over the Baseline-2 is given, #rel. ret. is the number of relevant documents retrieved. ($\dagger$: t.test < 0.01, $*$: t.test < 0.05)

cause of the difficulty to automatically detect these elements. Instead, we proposed a less demanding approach that uses the distribution of PECO elements in documents to re-weight terms in the document model. The observation of variable distributions in our test collection led us to believe that the position information can be used as a robust indicator of the presence of a PECO element. This strategy turns out to be promising. On a data set composed of 1.5 million citations extracted with PubMed, our best model obtains an increase of 28% for MAP and nearly 50% for P@5 over the classical language modeling approach.

In future work, we intend to expand our analysis of the distribution of PECO elements to a larger number of citations. One way to do that would be to automatically extract PubMed citations that contain structural markers associated to PECO categories (Chung, 2009).

Inducing Word Senses to Improve Web Search Result Clustering

Roberto Navigli and **Giuseppe Crisafulli**

Abstract

In this paper, we present a novel approach to Web search result clustering based on the automatic discovery of word senses from raw text, a task referred to as Word Sense Induction (WSI). We first acquire the senses (i.e., meanings) of a query by means of a graph-based clustering algorithm that exploits cycles (triangles and squares) in the co-occurrence graph of the query. Then we cluster the search results based on their semantic similarity to the induced word senses. Our experiments, conducted on datasets of ambiguous queries, show that our approach improves search result clustering in terms of both clustering quality and degree of diversification.

1 Introduction

Over recent years increasingly huge amounts of text have been made available on the Web. Popular search engines such as Yahoo! and Google usually do a good job at retrieving a small number of relevant results from such an enormous collection of Web pages (i.e. retrieving with high precision, low recall). However, current search engines are still facing the lexical ambiguity issue (Furnas et al., 1987) – i.e. the linguistic property owing to which any particular word may convey different meanings. In a recent study (Sanderson, 2008) – conducted using WordNet (Miller et al., 1990) and Wikipedia as sources of ambiguous words – it was reported that around 3% of Web queries and 23% of the most frequent queries are ambiguous. Examples include: "buy B-52" (a cocktail? a bomber? a DJ workstation? tickets for a band?), "Alexander Smith quotes" (the novelist? the poet?), "beagle search" (dogs? the Linux search tool? the landing spacecraft?).

Ambiguity is often the consequence of the low number of query words entered on average by Web users (Kamvar and Baluja, 2006). While average query length is increasing – it is now estimated at around 3 words per query[1] – many search engines such as Google have already started to tackle the query ambiguity issue by reranking and diversifying their results, so as to prevent Web pages that are similar to each other from ranking too high on the list.

In the past few years, Web clustering engines (Carpineto et al., 2009) have been proposed as a solution to the lexical ambiguity issue in Web Information Retrieval. These systems group search results, by providing a cluster for each specific aspect (i.e., meaning) of the input query. Users can then select the cluster(s) and the pages therein that best answer their information needs. However, many Web clustering engines group search results on the basis of their lexical similarity. For instance, consider the following snippets returned for the *beagle search* query:

1. *Beagle* is a *search* tool that ransacks your...

2. ...the *beagle* disappearing in *search* of game...

3. *Beagle* indexes your files and *searches*...

While snippets 1 and 3 both concern the Linux search tool, they do not have any content word in

common except our query words. As a result, they will most likely be assigned to two different clusters.

In this paper we present a novel approach to Web search result clustering which is based on the automatic discovery of word senses from raw text – a task referred to as Word Sense Induction (WSI). At the core of our approach is a graph-based algorithm that exploits cycles in the co-occurrence graph of the input query to detect the query's meanings. Our experiments on two datasets of ambiguous queries show that our WSI approach boosts search result clustering in terms of both clustering quality and degree of diversification.

2 Related Work

Web directories. A first, historical solution to query ambiguity is that of Web directories, that is taxonomies providing categories to which Web pages are manually assigned (e.g., the Open Directory Project – `http://dmoz.org`). Given a query, search results are organized by category. This approach has three main weaknesses: first, it is static, thus it needs manual updates to cover new pages; second, it covers only a small portion of the Web; third, it classifies Web pages based on coarse categories. This latter feature of Web directories makes it difficult to distinguish between instances of the same kind (e.g., pages about artists with the same surname classified as `Arts:Music:Bands and Artists`). While methods for the automatic classification of Web documents have been proposed (e.g., (Liu et al., 2005b; Xue et al., 2008)) and some problems have been effectively tackled (Bennett and Nguyen, 2009), these approaches are usually supervised and still suffer from relying on a predefined taxonomy of categories.

Semantic Information Retrieval (SIR). A different direction consists of associating explicit semantics (i.e., word senses or concepts) with queries and documents, that is, performing Word Sense Disambiguation (WSD, see Navigli (2009)). SIR is performed by indexing and/or searching concepts rather than terms, thus potentially coping with two linguistic phenomena: expressing a single meaning with different words (*synonymy*) and using the same word to express various different meanings (*polysemy*). Over the years, different methods for SIR have been proposed (Krovetz and Croft, 1992; Voorhees, 1993; Mandala et al., 1998; Gonzalo et al., 1999; Kim et al., 2004; Liu et al., 2005a, inter alia). However, contrasting results have been reported on the benefits of these techniques: it has been shown that WSD has to be very accurate to benefit Information Retrieval (Sanderson, 1994) – a result that was later debated (Gonzalo et al., 1999; Stokoe et al., 2003). Also, it has been reported that WSD has to be very precise on minority senses and uncommon terms, rather than on frequent words (Krovetz and Croft, 1992; Sanderson, 2000).

SIR relies on the existence of a reference dictionary to perform WSD (typically, WordNet) and thus suffers from its static nature and its inherent paucity of most proper nouns. This latter problem is particularly important for Web searches, as users tend to retrieve more information about named entities (e.g., singers, artists, cities) than concepts (e.g., abstract information about singers or artists).

Search Result Clustering. A more popular approach to query ambiguity is that of search result clustering. Typically, given a query, the system starts from a flat list of text snippets returned from one or more commonly-available search engines and clusters them on the basis of some notion of textual similarity. At the root of the clustering approach lies van Rijsbergen's (1979) cluster hypothesis: "closely associated documents tend to be relevant to the same requests", whereas documents concerning different meanings of the input query are expected to belong to different clusters.

Approaches to search result clustering can be classified as data-centric or description-centric (Carpineto et al., 2009). The former focus more on the problem of data clustering than on presenting the results to the user. A pioneering example is Scatter/Gather (Cutting et al., 1992), which divides the dataset into a small number of clusters and, after the selection of a group, performs clustering again and proceeds iteratively. Developments of this approach have been proposed which improve on cluster quality and retrieval performance (Ke et al., 2009). Other data-centric approaches use agglomerative hierarchical clustering (e.g., LASSI (Yoelle Maarek and Pelleg, 2000)), rough sets (Ngo and Nguyen, 2005) or exploit link information (Zhang et al., 2008).

Description-centric approaches are, instead, more focused on the description to produce for each cluster of search results. Among the most popular and successful approaches are those based on suffix trees (Zamir et al., 1997; Zamir and Etzioni, 1998), including later developments (Crabtree et al., 2005; Bernardini et al., 2009). Other methods in the literature are based on formal concept analysis (Carpineto and Romano, 2004), singular value decomposition (Osinski and Weiss, 2005), spectral clustering (Cheng et al., 2005), spectral geometry (Liu et al., 2008), link analysis (Gelgi et al., 2007), and graph connectivity measures (Di Giacomo et al., 2007). Search result clustering has also been viewed as a supervised salient phrase ranking task (Zeng et al., 2004).

Diversification. Another recent research topic dealing with the query ambiguity issue is diversification, which aims to rerank top search results based on criteria that maximize their diversity. One of the first examples of diversification algorithms is based on the use of similarity functions to measure the diversity among documents and between document and query (Carbonell and Goldstein, 1998). Other techniques use conditional probabilities to determine which document is most different from higher-ranking ones (Chen and Karger, 2006) or use affinity ranking (Zhang et al., 2005), based on topic variance and coverage. More recently, an algorithm called Essential Pages (Swaminathan et al., 2009) has been proposed to reduce information redundancy and return Web pages that maximize coverage with respect to the input query.

Word Sense Induction (WSI). In contrast to the above approaches, we perform WSI to dynamically acquire an inventory of senses of the input query. Instead of performing clustering on the basis of the surface similarity of Web snippets, we use our induced word senses to group snippets. Very little work on this topic exists: vector-based WSI was successfully shown to improve bag-of-words ad-hoc Information Retrieval (Schütze and Pedersen, 1995) and preliminary studies (Udani et al., 2005; Chen et al., 2008) have provided interesting insights into the use of WSI for Web search result clustering. A more recent attempt at automatically identifying query meanings is based on the use of hidden topics (Nguyen et al., 2009). However, in this approach topics – estimated from a universal dataset – are query-independent and thus their number needs to be established beforehand. In contrast, we aim to cluster snippets based on a dynamic and finer-grained notion of sense.

3 Approach

Web search result clustering is usually performed in three main steps:

1. Given a query q, a search engine (e.g., Yahoo!) is used to retrieve a list of results $R = (r_1, \dots, r_n)$;

2. A clustering $\mathcal{C} = (C_0, C_1, \dots, C_m)$ of the results in R is obtained by means of a clustering algorithm;

3. The clusters in $\mathcal{C}$ are optionally labeled with an appropriate algorithm (e.g., see Zamir and Etzioni (1998) and Carmel et al. (2009)) for visualization purposes.

Our key idea is to improve step 2 by means of a Word Sense Induction algorithm: given a query q, we first dynamically induce, from a text corpus, the set of word senses of q (Section 3.1); next, we cluster the Web results on the basis of the word senses previously induced (Section 3.2).

3.1 Word Sense Induction

Word Sense Induction algorithms are unsupervised techniques aimed at automatically identifying the set of senses denoted by a word. These methods induce word senses from text by clustering word occurrences based on the idea that a given word – used in a specific sense – tends to co-occur with the same neighbouring words (Harris, 1954). Several approaches to WSI have been proposed in the literature (see Navigli (2009) for a survey), ranging from clustering based on context vectors (e.g., Schütze (1998)) to word clustering (e.g., Lin (1998)) and co-occurrence graphs (e.g., Widdows and Dorow (2002)).

Successful approaches such as HyperLex (Véronis, 2004) – a graph algorithm based on the identification of hubs in co-occurrence graphs – have to cope with a high number of parameters to be tuned (Agirre et al., 2006). To deal with this issue we propose two variants of a simple, yet effective, graph-based algorithm for WSI, that we describe hereafter. The algorithm consists of two steps: graph construction and identification of word senses.

3.1.1 Graph construction

Given a target query q, we build a co-occurrence graph $G_q = (V, E)$ such that V is a set of context words related to q and E is the set of undirected edges, each denoting a co-occurrence between pairs of words in V. To determine the set of co-occurring words V, we use the Google Web1T corpus (Brants and Franz, 2006), a large collection of n-grams ($n = 1, \dots, 5$) – i.e., windows of n consecutive tokens – occurring in one terabyte of Web documents. First, for each content word w we collect the total number $c(w)$ of its occurrences and the number of times $c(w, w')$ that w and w' occur together in any 5-gram (we include inflected forms in the count); second, we use the Dice coefficient to determine the strength of co-occurrence between w and w':

$$Dice(w, w') = \frac{2c(w, w')}{c(w) + c(w')}. \qquad (1)$$

The rationale behind Dice is that dividing by the sum of total counts of the two words drastically decreases the ranking of words that tend to co-occur frequently with many other words (e.g., *new*, *old*, *nice*, etc.).

The graph $G_q = (V, E)$ is built as follows:

- Our initial vertex set $V^{(0)}$ contains all the content words from the snippet results of query q (excluding stopwords); then, we add to $V^{(0)}$ the highest-ranking words co-occurring with q in the Web1T corpus, i.e., those words w for which $Dice(q, w) \geq \delta$ (the threshold δ is established experimentally, see Section 4.1). We set $V := V^{(0)}$ and $E := \emptyset$.

- For each word $w \in V^{(0)}$, we select the highest ranking words co-occurring with w in Web1T, that is those words w' for which $Dice(w, w') \geq \delta$. We add each of these words to V (note that some w' might already be in $V^{(0)}$) and the corresponding edge $\{w, w'\}$ to E with weight $Dice(w, w')$. Finally, we remove disconnected vertices.

3.1.2 Identification of word senses

The main idea behind our approach is that edges in the co-occurrence graph participating in cycles are likely to connect vertices (i.e., words) belonging to the same meaning component. Specifically, we focus on cycles of length 3 and 4, called respectively triangles and squares in graph theory.

For each edge e, we calculate the ratio of triangles in which e participates:

$$\mathit{Tri}(e) = \frac{\text{\# triangles } e \text{ participates in}}{\text{\# triangles } e \text{ could participate in}} \qquad (2)$$

where the numerator is the number of cycles of length 3 in which $e = \{w, w'\}$ participates, and the denominator is the total number of neighbours of w and w'. Similarly, we define a measure $Sqr(e)$ of the ratio of squares (i.e., cycles of length 4) an edge e participates in to the number of possible squares e could potentially participate in:

$$\mathit{Sqr}(e) = \frac{\text{\# squares } e \text{ participates in}}{\text{\# squares } e \text{ could participate in}} \qquad (3)$$

where the numerator is the number of squares containing e and the denominator is the number of possible distinct pairs of neighbours of w and w'. If no triangle (or square) exists for e, the value of the corresponding function is set to 0.

In order to disconnect the graph and determine the meaning components, we remove all the edges whose *Tri* (or *Sqr*) value is below a threshold σ. The resulting connected components represent the word senses induced for the query q. Notice that the number of senses is dynamically chosen based on the co-occurrence graph and the algorithm's thresholds.

Our triangular measure is the edge counterpart of the clustering coefficient (or curvature) for vertices, previously used to perform WSI (Widdows and Dorow, 2002). However, it is our hunch that measuring the ratio of squares an edge participates in provides a stronger clue of how important that edge is within a meaning component. In Section 4, we will corroborate this idea with our experiments.

3.1.3 An example

As an example, let $q = \textit{beagle}$. Two steps are performed:

1. **Graph construction.** We build the co-occurrence graph $G_{beagle} = (V, E)$, an excerpt of which is shown in Figure 1(a).

2. **Identification of word senses.** We calculate the *Sqr* values of each edge in the graph. The edges e whose $\mathit{Sqr}(e) < \sigma$ are removed (we assume $\sigma = 0.25$). For instance, *Sqr*({ *dog, breed* }) = $\frac{1}{2}$, as the edge participates in the square *dog – breed – puppy – canine – dog*, but it could also have participated in the potential square *dog – breed – puppy – search – dog*. In fact, the other neighbours of *dog* are *canine*, *puppy* and *search*, and the other neighbour of *breed* is *puppy*, thus the square can only be closed by connecting *puppy* to either *canine* or *search*. In our example, the only edges whose *Sqr* is below σ are: { *dog, puppy* }, { *dog, search* } and { *linux, mission* } (they participate in no square). We remove these edges and select the resulting connected components as the senses of the query *beagle* (shown in Figure 1(b)). Note that, if we selected triangles as our pruning measure, we should also remove the following edges { *search, index* }, { *index, linux* }, { *linux, system* } and { *system, search* }. In fact, these edges do not participate in any triangle (while they do participate in a square). As a result, we would miss the computer science sense of the query.

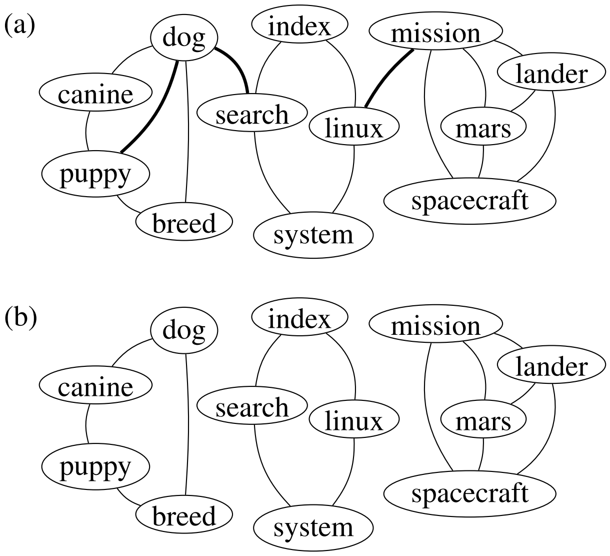

Figure 1: The *beagle* example: (a) graph construction, "weak" edges (according to *Sqr*) drawn in bold, (b) the word senses induced after edge removal.

3.2 Clustering of Web results

Given our query q, we submit it to a search engine, which returns a list of relevant search results $R = (r_1, \dots, r_n)$. We process each result r_i by considering the corresponding text snippet and transforming it to a bag of words b_i (we apply tokenization, stopwords and target word removal, and lemmatization[2]). For instance, given the snippet:

"the *beagle* is a breed of medium-sized dog",

we produce the following bag of words:

{ *breed*, *medium*, *size*, *dog* }.

As a result of the above processing, we obtain a list of bags of words $B = (b_1, \dots, b_n)$. Now, our aim is to cluster our Web results R, i.e., the corresponding bags of words B. To this end, rather than considering the interrelationships between them (as is done in traditional search result clustering), we intersect each bag of words $b_i \in B$ with the sense clusters $\{S_1, \dots, S_m\}$ acquired as a result of our Word Sense Induction algorithm (cf. Section 3.1). The sense cluster with the largest intersection with b_i is selected as the most likely meaning of r_i. Formally:

$$\mathit{Sense}(r_i) = \begin{cases} \underset{j=1,\dots,m}{\operatorname{argmax}} |b_i \cap S_j| & \text{if} \max\limits_j |b_i \cap S_j| > 0 \\ 0 & \text{else} \end{cases} \tag{4}$$

where 0 denotes that no sense is assigned to result r_i, as the intersection is empty for all senses S_j. Otherwise the function returns the index of the sense having the largest overlap with b_i – the bag of words associated with the search result r_i. As a result of sense assignment for each $r_i \in R$, we obtain a clustering $\mathcal{C} = (C_0, C_1, \dots, C_m)$ such that:

$$C_j = \{r_i \in R : \mathit{Sense}(r_i) = j\}, \tag{5}$$

that is, C_j contains the search results classified with the j-th sense of query q (C_0 includes unassigned results). Finally, we sort the clusters in our clustering $\mathcal{C}$ based on their "quality". For each cluster $C_j \in \mathcal{C} \setminus \{C_0\}$, we determine its similarity with

[2] We use the WordNet lemmatizer.

the corresponding meaning S_j by calculating the following formula:

$$avgsim(C_j, S_j) = \frac{\sum_{r_i \in C_j} sim(r_i, S_j)}{|C_j|}. \quad (6)$$

The formula determines the average similarity between the search results in cluster C_j and the corresponding sense cluster S_j. The similarity between a search result r_i and S_j is determined as the normalized overlap between its bag of words b_i and S_j:

$$sim(r_i, S_j) = sim(b_i, S_j) = \frac{|b_i \cap S_j|}{|b_i|}. \quad (7)$$

Finally, we rank the elements r_i within each cluster C_j by their similarity $sim(r_i, S_j)$. We note that the ranking and optimality of clusters can be improved with more sophisticated techniques (Crabtree et al., 2005; Kurland, 2008; Kurland and Domshlak, 2008; Lee et al., 2008, inter alia). However, this is outside the scope of this paper.

4 Experiments

4.1 Experimental Setup

Test Sets. We conducted our experiments on two datasets:

- AMBIENT (AMBIguous ENTries), a recently released dataset which contains 44 ambiguous queries[3]. The sense inventory for the meanings (i.e., subtopics)[4] of queries is given by Wikipedia disambiguation pages. For instance, given the *beagle* query, its disambiguation page in Wikipedia provides the meanings of dog, Mars lander, computer search service, beer brand, etc. The top 100 Web results of each query returned by the Yahoo! search engine were tagged with the most appropriate query senses according to Wikipedia (amounting to 4400 sense-annotated search results). To our knowledge, this is currently the largest dataset of ambiguous queries available on-line. Other datasets, such as those from the TREC competitions, are not focused on distiguishing the subtopics of a query.

dataset	queries	queries by length				avg. polys.
		1	2	3	4	
AMBIENT	44	35	6	3	0	17.9
MORESQUE	114	0	47	36	31	6.7

Table 1: Statistics on the datasets of ambiguous queries.

- MORESQUE (MORE Sense-tagged QUEry results), a new dataset of 114 ambiguous queries which we developed as a complement to AMBIENT following the guidelines provided by its authors. In fact, our aim was to study the behaviour of Web search algorithms on queries of different lengths, ranging from 1 to 4 words. However, the AMBIENT dataset is composed mostly of single-word queries. MORESQUE provides dozens of queries of length 2, 3 and 4, together with the 100 top results from Yahoo! for each query annotated as in the AMBIENT dataset (overall, we tagged 11,400 snippets). We decided to carry on using Yahoo! mainly for homogeneity reasons.

We report the statistics on the composition of the two datasets in Table 1. Given that the snippets could possibly be annotated with more than one Wikipedia subtopic, we also determined the average number of subtopics per snippet. This amounted to 1.01 for AMBIENT and 1.04 for MORESQUE for snippets with at least one subtopic annotation (51% and 53% of the respective datasets). We can thus conclude that multiple subtopic annotations are infrequent.

Parameters. Our graph-based algorithms have two parameters: the Dice threshold δ for graph construction (Section 3.1.1) and the threshold σ for edge removal (Section 3.1.2). The best parameters, used throughout our experiments, were ($\delta = 0.00033, \sigma = 0.45$) with triangles and ($\delta = 0.00033, \sigma = 0.33$) with squares. The parameter values were obtained as a result of tuning on a small in-house development dataset. The dataset was built by automatically identifying monosemous words and creating pseudowords following the scheme proposed by Schütze (1998).

Systems. We compared Triangles and Squares against the best systems reported by Bernardini et al. (2009, cf. Section 2):

[3] `http://credo.fub.it/ambient`

[4] In the following, we use the terms *subtopic* and *word sense* interchangeably.

- **Lingo** (Osinski and Weiss, 2005): a Web clustering engine implemented in the Carrot^2 open-source framework[5] that clusters the most frequent phrases extracted using suffix arrays.

- **Suffix Tree Clustering (STC)** (Zamir and Etzioni, 1998): the original Web search clustering approach based on suffix trees.

- **KeySRC** (Bernardini et al., 2009): a state-of-the-art Web clustering engine built on top of STC with part-of-speech pruning and dynamic selection of the cut-off level of the clustering dendrogram.

- **Essential Pages (EP)** (Swaminathan et al., 2009): a recent diversification algorithm that selects fundamental pages which maximize the amount of information covered for a given query.

- **Yahoo!**: the original search results returned by the Yahoo! search engine.

The first three of the above are Web search result clustering approaches, whereas the last two produce lists of possibly diversified results (cf. Section 2).

4.2 Experiment 1: Clustering Quality

Measure. While assessing the quality of clustering is a notably hard problem, given a gold standard $\mathcal{G}$ we can calculate the **Rand index** (RI) of a clustering $\mathcal{C}$, a common quality measure in the literature, determined as follows (Rand, 1971; Manning et al., 2008):

$$\text{RI}(\mathcal{C}) = \frac{\sum_{(w,w')\in\mathcal{W}\times\mathcal{W},w\neq w'} \delta(w,w')}{|\{(w,w')\in\mathcal{W}\times\mathcal{W} : w \neq w'\}|} \quad (8)$$

where $\mathcal{W}$ is the union set of all the words in $\mathcal{C}$ and $\delta(w,w') = 1$ if any two words w and w' are in the same cluster both in $\mathcal{C}$ and in the gold standard $\mathcal{G}$ or they are in two different clusters in both $\mathcal{C}$ and $\mathcal{G}$, otherwise $\delta(w,w') = 0$. In other words, we calculate the percentage of word pairs that are in the same configuration in both $\mathcal{C}$ and $\mathcal{G}$. For the gold standard $\mathcal{G}$ we use the clustering induced by the sense annotations provided in our datasets for each snippet (i.e., each cluster contains the snippets manually associated with a particular Wikipedia subtopic). Similarly to what was done in Section 3.2, untagged results are grouped together in a special cluster of $\mathcal{G}$.

System	AMBIENT	MORESQUE	All
Squares	72.59	65.41	67.28
Triangles	66.13	64.47	64.93
Lingo	62.75	52.68	55.49
STC	61.48	51.52	54.29
KeySRC	66.49	55.82	58.78

Table 2: Results by Rand index (percentages).

Results. The results of all systems on the AMBIENT and MORESQUE datasets according to the average Rand index are shown in Table 2[6]. In accordance with previous results in the literature, KeySRC performed generally better than the other search result clustering systems, especially on smaller queries. Our Word Sense Induction systems, Squares and Triangles, outperformed all other systems by a large margin, thus showing a higher clustering quality (with the exception of KeySRC performing better than Triangles on AMBIENT). Interestingly, all clustering systems perform more poorly on longer queries (i.e., on the MORESQUE dataset), however our WSI systems, and especially Triangles, are more robust across query lengths. Compared to Triangles, the Squares algorithm performs better, confirming our hunch that Squares is a more solid graph pattern.

4.3 Experiment 2: Diversification

Measure. Search result clustering can also be used to diversify the top results returned by a search engine. Thus, for each query q, one natural way of measuring a system's performance is to calculate the **subtopic recall-at-K** (Zhai et al., 2003) given by the number of different subtopics retrieved for q in the top K results returned:

$$\text{S-recall@K} = \frac{|\bigcup_{i=1}^{K} subtopics(r_i)|}{M} \quad (9)$$

where $subtopics(r_i)$ is the set of subtopics manually assigned to the search result r_i and M is the number of subtopics for query q (note that in our experiments M is the number of subtopics occurring in the 100 results retrieved for q, so S-recall@100 = 1). However, this measure is only suitable for systems returning ranked lists (such as Yahoo! and EP). Given

[6] For reference systems we used the implementations of Bernardini et al. (2009) and Osinski and Weiss (2005).

System	K=3	K=5	K=10	K=15	K=20
Squares	51.9	63.4	75.8	83.3	87.4
Triangles	50.8	62.4	75.2	82.7	86.6
Yahoo!	49.2	60.0	72.9	78.5	82.7
EP	40.6	53.2	68.6	77.2	83.3
KeySRC	44.3	55.8	72.0	79.1	83.2

Table 3: S-recall@K on all queries (percentages).

a clustering $\mathcal{C} = (C_0, C_1, \ldots, C_m)$, we flatten it to a list as follows: we add to the initially empty list the first element of each cluster C_j ($j = 1, \ldots, m$); then we iterate the process by selecting the second element of each cluster C_j such that $|C_j| \geq 2$, and so on. The remaining elements returned by the search engine, but not included in any cluster of $\mathcal{C} \setminus \{C_0\}$, are appended to the bottom of the list in their original order. Note that the elements are selected from each cluster according to their internal ranking (e.g., for our algorithms we use Formula 7 introduced in Section 3.2).

Results. For the sake of clarity and to save space, we selected the best systems from our previous experiment, namely Squares, Triangles and KeySRC, and compared their output with the original snippet list returned by Yahoo! and the output of the EP diversification algorithm (cf. Section 4.1).

The S-recall@K (with $K = 3, 5, 10, 15, 20$) calculated on AMBIENT+MORESQUE is reported in Table 3. Squares and Triangles show the highest degree of diversification, with a subtopic recall greater than all other systems, and with Squares consistently performing better than Triangles. It is interesting to observe that KeySRC performs worse than Yahoo! with low values of K and generally better with higher values of K.

Given that the two datasets complement each other in terms of query lengths (with AMBIENT having queries of length $\leq$ 2 and MORESQUE with many queries of length $\geq$ 3), we studied the S-recall@K trend for the two datasets. The results are shown in Figures 2 and 3. While KeySRC does not show large differences in the presence of short and long ambiguous queries, our graph-based algorithms do. For instance, as soon as $K = 3$ the Squares algorithm obtains S-recall values of 37% and 57.5% on AMBIENT and MORESQUE, respectively. The difference decreases as K increases, but is still significant when K = 10. We hypothesize that, because they are less ambiguous, longer queries are easier to diversify with the aid of WSI. However, we note that, even with low values of K, Squares and Triangles obtain higher S-recall than the other systems (with KeySRC competing on AMBIENT when $K \leq$ 15). Finally, we observe that – with low values of K – the Squares algorithm performs significantly better than Triangles on shorter queries, and only slightly better on longer ones.

5 Discussion

Results. Our results show that our graph-based algorithms are able to consistently produce clusters of better quality than all other systems tested in our experiments. The results on S-recall@K show that our approach can also be used effectively as a diversification technique, performing better than a very recent proposal such as Essential Pages. The latter outperforms Yahoo! and KeySRC when $K \geq 30$ on AMBIENT, whereas on MORESQUE it performs generally worse until higher values of K are reached. If we analyze the entire dataset of 158 queries by length, EP works best after examining at least 20 results on 1- and 2-word ambiguous queries, whereas on longer queries a larger number of documents (≥ 30) needs to be analyzed before surpassing Yahoo! performance.

The above considerations might not seem intuitive at first glance, as the average polysemy of longer queries is lower (17.9 on AMBIENT vs. 6.7 on MORESQUE according to our gold standard). However, we note that while the kind of ambiguity of 1-word queries is generally coarser (e.g., *beagle* as dog vs. lander vs. search tool), with longer queries we often encounter much finer sense distinctions (e.g., *Across the Universe* as song by The Beatles vs. a 2007 film based on the song vs. a Star Trek novel vs. a rock album by Trip Shakespeare, etc.). Word Sense Induction is able to deal better with this latter kind of ambiguity as discriminative words become part of the meanings acquired.

Performance issues. Inducing word senses from the query graph comes at a higher computational cost than other non-semantic clustering techniques. Indeed, the most time-consuming phase of our approach is the construction of the query graph, which requires intensive querying of our database of co-occurrences calculated from the Web1T corpus. While graphs can be precomputed or cached, previously unseen queries will still require the construction of new graphs. Instead, triangles and squares, as well as the resulting connected components, can be calculated on the fly.

6 Conclusions

In this paper we have presented a novel approach to Web search result clustering. Our key idea is to induce senses for the target query automatically by means of a graph-based algorithm focused on the notion of cycles. The results of a Web search engine are then mapped to the query senses and clustered accordingly.

The paper provides three novel contributions. First, we show that WSI boosts the quality of search result clustering and improves the diversification of the snippets returned as a flat list. We provide a clear indication on the usefulness of a loose notion of sense to cope with ambiguous queries. This is in contrast to research on Semantic Information Retrieval, which has obtained contradictory and often inconclusive results. The main advantage of WSI lies in its dynamic production of word senses that cover both concepts (e.g., *beagle* as a breed of dog) and instances (e.g., *beagle* as a specific instance of a space lander). In contrast, static dictionaries such as WordNet – typically used in Word Sense Disambiguation – by their very nature encode mainly concepts. Second, we propose two simple, yet effective, graph algorithms to induce the senses of our queries. The best performing approach is based on squares (cycles of length 4), a novel graph pattern in WSI. Third, we contribute a new dataset of 114 ambiguous queries and 11,400 sense-annotated snippets which complements an existing dataset of ambiguous queries[7]. Given the lack of ambiguous query datasets available (Sanderson, 2008), we hope our new dataset will be useful in future comparative experiments. Finally, we note that our approach needed very little tuning. Moreover, its requirement of a Web corpus of n-grams is not a stringent one, as such corpora are available for several languages and can be produced for any language of interest.

As regards future work, we intend to combine our clustering algorithm with a cluster labeling algorithm. We also aim to implement a number of Word Sense Induction algorithms and compare them in the same evaluation framework with more Web search and Web clustering engines. Finally, it should be possible to use precisely the same approach presented in this paper for document clustering, by grouping the contexts in which the target query occurs – and we will also experiment on this in the future.

Acknowledgments

We thank Google for providing the Web1T corpus for research purposes. We also thank Massimiliano D'Amico for producing the output of KeySRC and EP, and Stanislaw Osinski and Dawid Weiss for their

Abstract

Targeted paraphrasing is a new approach to the problem of obtaining cost-effective, reasonable quality translation that makes use of simple and inexpensive human computations by monolingual speakers in combination with machine translation. The key insight behind the process is that it is possible to spot likely translation errors with only monolingual knowledge of the target language, and it is possible to generate alternative ways to say the same thing (i.e. paraphrases) with only monolingual knowledge of the source language. Evaluations demonstrate that this approach can yield substantial improvements in translation quality.

1 Introduction

For most of the world's languages, the availability of translation is limited to two possibilities: high quality at high cost, via professional translators, and low quality at low cost, via machine translation (MT). The spectrum between these two extremes is very poorly populated, and at any point on the spectrum the ready availability of translation is limited to only a small fraction of the world's languages. There is, of course, a long history of technological assistance to translators, improving cost effectiveness using translation memory (Laurian, 1984; Bowker and Barlow, 2004) or other interactive tools to assist translators (Esteban et al., 2004; Khadivi et al., 2006). And there is a recent and rapidly growing interest in crowdsourcing with non-professional translators, which can be remarkably effective (Munro, 2010). However, all these alternatives face a central availability bottleneck: they require the participation of humans with bilingual expertise.

In this paper, we report on a new exploration of the middle ground, taking advantage of a virtually unutilized resource: speakers of the source and target language who are *effectively monolingual*, i.e. who each only know one of the two languages relevant for the translation task. The solution we are proposing has the potential to provide a more cost effective approach to translation in scenarios where machine translation *would* be considered acceptable to use, if only it were generally of high enough quality. This would clearly exclude tasks like translation of medical reports, business contracts, or literary works, where the validation of a qualified bilingual translator is absolutely necessary. However, it does include a great many real-world scenarios, such as following news reports in another country, reading international comments about a product, or generating a decent first draft translation of a Wikipedia page for Wikipedia editors to improve.

The use of monolingual participants in a human-machine translation process is not entirely new. Callison-Burch et al. (2004) pioneered the exploration of monolingual post-editing within the MT community, an approach extended more recently to provide richer information to the user by Albrecht et al. (2009) and Koehn (2009). There have also been at least two independently developed human-machine translation frameworks that employ an iterative protocol involving monolinguals on both the source and target side. Morita and Ishida (2009) describe a system in which target and source language speakers perform editing of MT output to improve fluency and adequacy, respectively; they utilize source-side paraphrasing at a course grain level, although their approach is limited to requests to paraphrase the entire sentence when the translation cannot be understood.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 127–137,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

Bederson et al. (2010) describe a similar protocol in which cross-language communication is enhanced by metalinguistic communication in the user interface. Shahaf and Horvitz (2010) use machine translation as a specific instance of a general game-based framework for combining a range of machine and human capabilities.

We call the technique used here *targeted paraphrasing*. In a nutshell, target-language monolinguals identify parts of an initial machine translation that don't appear to be right, and source-language monolinguals provide the MT system with alternative phrasings that might lead to better translations; these are then passed through MT again and the best scoring hypothesis is selected as the final translation. This technique can be viewed as compatible with the richer protocol- and game-based approaches, but it is considerably simpler; in Sections 2 through 4 we describe the method and present evaluation results on Chinese-English translation. Unlike other approaches, the technique also offers clear opportunities to replace human participation with machine components if the latter are up to the task; we discuss this in Section 5 before wrapping up in Section 6 with conclusions and directions for future work.

2 Targeted Paraphrasing

The starting point for our approach is an observation: the source sentence provided as input to an MT system is just one of many ways in which the meaning could have been expressed, and for any given MT system, some forms of expression are easier to translate than others. The same basic observation has been applied quite fruitfully over the past several years to deal with statistical MT challenges involving segmentation, morphological analysis, and more recently, source language word order (Dyer, 2007; Dyer et al., 2008; Dyer and Resnik, 2010). Here we apply it to the surface expression of meaning.

For example, consider the following real example of translation from English to French by an automatic MT system:

- **Source:** Polls indicate Brown, a state senator, and Coakley, Massachusetts' Attorney General, are locked in a virtual tie to fill the late Sen. Ted Kennedy's Senate seat.

- **System:** Les sondages indiquent Brown, un sénateur d'état, et Coakley, Massachusetts' Procureur général, sont enfermés dans une cravate virtuel à remplir le regretté sénateur Ted Kennedy's siège au Sénat.

A French speaker can look at this automatic translation and see immediately that the underlined parts are wrong, even without knowing the intended source meaning. We can identify the spans in the source English sentence that are responsible for these badly translated French spans, and change them to alternative expressions with the same meaning (e.g. changing *Massachusetts' Attorney General* to *the Attorney General of Massachusetts*); if we do so and then use the same MT system again, we obtain a translation that is still imperfect (e.g. *cravate* means necktie), but is more acceptable:

- **System:** Les sondages indiquent que Brown, un sénateur d'état, et Coakley, le procureur général du Massachusetts, sont enfermés dans une cravate virtuel pourvoir le siége au Sénat de Sen. Ted Kennedy, qui est décédé récemment.

Operationally, then, translation with targeted paraphrasing includes the following steps.

Initial machine translation. For this paper, we use the Google Translate Research API, which, among other advantages, provides word-level alignments between the source text and its output. In principle, however, any automatic translation system can be used in this role, potentially at some cost to quality, by performing *post hoc* target-to-source alignment.

Identification of mistranslated spans. This step identifies parts of the source sentence that lead to ungrammatical, nonsensical, or apparently incorrect translations on the target side. In the experiments of Sections 3 and 4, this step is performed by having monolingual target speakers identify likely error spans on the target side, as in the French example above, and projecting those spans back to the source spans that generated them using word alignments as the bridge (Hwa et al., 2005; Yarowsky et al., 2001). In Section 5, we describe a heuristic but effective method for performing this fully automatically. Du et al. (2010), in this proceedings, explore the use of source paraphrases *without* targeting apparent mistranslations, using lattice translation (Dyer et al., 2008) to efficiently represent and decode the resulting very large space of paraphrase alternatives.

Source paraphrase generation. This step generates alternative expressions for the source spans identified in the previous step. In this paper, it is performed by monolingual source speakers who perform the paraphrase task: the speaker is given a sentence with a phrase span marked, and is asked to replace the marked text with a different way of saying the same thing, so that the resulting sentence still makes sense and means the same thing as the original sentence. To illustrate in English, someone seeing *John and Mary took a European vacation this summer* might supply the paraphrase *Mary went on a European*, verifying that the resulting *John and Mary went on a European vacation this summer* preserves the original meaning. This step can also be fully automated (Max, 2009) by taking advantage of bilingual phrase-table pivoting (Bannard and Callison-Burch, 2005); see Max (2010), in these proceedings, for a related approach in which the paraphrases of a source phrase are used to refine the estimated probability distribution over its possible target phrases.

Generating sentential source paraphrases. For each sentence, there may be multiple paraphrased spans. These are multiplied out to provide full-sentence paraphrases. For example, if two non-overlapping source spans are each paraphrased in three ways, we generate 9 sentential source paraphrases, each of which represents an alternative way of expressing the original sentence.

Machine translation of alternative sentences. The alternative source sentences, produced via paraphrase, are sent through the same MT system, and a single-best translation hypothesis is selected, e.g. on the basis of the translation system's model score. In principle, one could also combine the alternatives into a lattice representation and decode to find the best path using lattice translation (Dyer et al., 2008); cf. Du et al. (2010). One could also present translation alternatives to a target speaker for selection, similarly to Callison-Burch et al. (2004).

Notice that with the exception of the initial translation, each remaining step in this pipeline can involve either human participation or fully automatic processing. The targeted paraphrasing framework therefore defines a rich set of intermediate points on the spectrum between fully automatic and fully human translation, of which we explore only a few in this paper.

3 Pilot Study

In order to assess the potential of our approach, we conducted a small pilot study, using eleven sentences in simplified Chinese selected from the article on "Water" in Chinese Wikipedia (http://zh.wikipedia.org/zh-cn/%E6%B0%B4). This article was chosen because its topic is well known in both English-speaking and Chinese-speaking populations. The first five sentences were taken from the first paragraph of the article. The other six sentences were taken from a randomly-chosen paragraph in the article. As a preprocessing step, we removed any parenthetical items from the input sentences, e.g. "(H$_2$0)". The shortest sentence in this set has 12 Chinese characters, the longest has 54.[1]

Human participation in this task was accomplished using Amazon Mechanical Turk, an online marketplace that enables human performance of small "human intelligence tasks" (HITs) in return for micropayments. For each sentence, after we translated it automatically (using Google Translate), three English-speaking Mechanical Turk workers ("Turkers") on the target side performed identification of mistranslated spans. Each span identified was projected back to its corresponding source span, and three Chinese-speaking Turkers were asked to provide paraphrases of each source span. These tasks were easy to perform (no more than around 30 seconds to complete on average) and inexpensive (less than $1 for the entire pilot study).[2] The Chinese source span paraphrases were then used to construct full-sentence paraphrases, which were retranslated, once again by Google Translate, to produce the output of the targeted paraphrasing translation process.

[1] Note that this page is *not* a translation of the corresponding English Wikipedia page or vice versa.

[2] The four English-speaking Turkers were recruited through the normal Mechanical Turk mechanism. The three Chinese-speaking Turkers were recruited offline by the authors in order to quickly obtain results, although they participated as full-fledged Turkers.

The initial translation outputs from Google Translate (GT) and the results of the targeted paraphrasing translation process (TP) were evaluated according to widely used critera of fluency and adequacy. Fluency ratings were obtained on a 5-point scale from three native English speakers without knowledge of Chinese. Translation adequacy ratings were obtained from three native Chinese speakers who are also fluent in English; they assessed adequacy of English sentences by comparing the communicated meaning to the Chinese source sentences.

Fluency was rated on the following scale:

1. Unintelligible: nothing or almost nothing of the sentence is comprehensible.
2. Barely intelligible: only a part of the sentence (less than 50%) is understandable.
3. Fairly intelligible: the major part of the sentence passes.
4. Intelligible: all the content of the sentence is comprehensible, but there are errors of style and/or of spelling, or certain words are missing.
5. Very intelligible: all the content of the sentence is comprehensible. There are no mistakes.

Adequacy was rated on the following scale:

1. None of the meaning expressed in the reference sentence is expressed in the sentence.
2. Little of the reference sentence meaning is expressed in the sentence.
3. Much of the reference sentence meaning is expressed in the sentence.
4. Most of the reference sentence meaning is expressed in the sentence.
5. All meaning expressed in the reference sentence appears in the sentence.

For each GT output, we averaged across the ratings of the alternative TP to produce average TP fluency and adequacy scores. The average GT output ratings, measuring the pure machine translation baseline, were 2.36 for fluency and 2.91 for adequacy. Averaging across the TP outputs, these rose to 3.32 and 3.49, respectively.

One could argue that a more sensible evaluation is not to *average* across alternative TP outputs, but rather to simulate the behavior of a target-language speaker who simply chooses the one translation among the alternatives that seems most fluent. If we select the most fluent TP output for each source sentence according to the English-speakers' average fluency ratings, we obtain average test set ratings of 3.58 for fluency and 3.73 for adequacy. Those are respective gains of 0.82 and 1.21 over the baseline initial MT output, each on a 5-point scale.

Figure 1 shows a selection of outputs: we present the two cases where the most fluent TP alternative shows the greatest gain in average fluency rating (best gain +2.67); two cases near the median gain in average fluency (median +1); and the worst two cases with respect to effect on average fluency rating (worst -0.33). The table accurately conveys a qualitative impression corresponding to the quantitative results: the overall quality of translations appears to be improved by our process consistently, despite the absence of any bilingual input in the improvements.

4 Chinese-English Evaluation

As a followup to our pilot study, we conducted an evaluation using Chinese-English test data taken from the NIST MT'08 machine translation evaluation, in order to obtain fully automatic translation evaluation scores. We report on results for 49 sentences of the 1,357 in this data set. These underwent the same targeted paraphrasing process as in the pilot study, with the addition of a basic step to filter out cheaters: we disregarded as invalid any responses consisting purely of ASCII characters (signifying a non-Chinese response) or responses that were identical to the original source text.

Target English speakers identified 115 potential mistranslation spans, or 2.3 spans per sentence, that yielded at least one source paraphrase on the source Chinese side. Chinese speakers provided 138 valid paraphrases. The entire cost for the human tasks in this experiment was $5.06, or a bit under $0.11 per sentence on average.[3]

Table 1 reports on the results, evaluating in standard fashion using BLEU with the four English MT'08 references for each Chinese sentence. Since the targeted paraphrasing translation process (TP) produces multiple hypotheses — one automatic translation output per sentential paraphrases — we selected the single best output for each sentence by

[3] Invalid paraphrase responses were rejected, i.e. zero-cost.

Condition	Fluency	Adequacy	Sentence
GT	1.33	2.33	Water play life evolve into important to use.
TP	4.00	4.33	Water in the evolution of life played an important role.
GT	1.33	2.67	Human civilization from the source of the majority of large rivers in the domain.
TP	3.33	4.67	Most of the origin of human civilization in river basin.
GT	2.33	3.00	In human daily life, the water in drinking, cleaning, washing and other side to make use of an indispensable.
TP	3.67	3.33	In human daily life, water for drinking, cleaning, washing and other essential role.
GT	2.00	2.33	Eastern and Western ancient Pak prime material view of both the water regarded as a kind of basic groups into the elements, water is the Chinese ancient five rows of a; the West ancient four elements that also have water.
TP	3.00	3.33	East and West in ancient concept of simple substances regarded water as a basic component elements. Among them, the five elements of water is one of ancient China; Western ancient four elements that also have water.
GT	4.00	4.00	Early cities will generally be in the water side of the establishment, in order to solve irrigation, drinking and sewage problems.
TP	4.67	4.33	Early cities are generally built near the water to solve the irrigation, drinking and sewage problems.
GT	3.0	3.33	Human very early on began to produce a water awareness.
TP	2.67	3.00	Man long ago began to understand the water produced.

Figure 1: Original Google Translate output (GT) for the pilot study in Section 3, together with translations produced by the targeted paraphrase translation process (TP), selected to show a range from strong to weak improvements in fluency.

Condition	BLEU
GT (baseline)	28.33
GT n-best oracle	28.47
TP one-best	30.01
TP oracle	30.79
Human upper bound	49.41

Table 1: Results on a 49-sentence subset of the NIST MT'08 Chinese-English test set

selecting the highest scoring English translation, according to the translation score delivered with each output by the Google Translate Research API. (The original translation was, of course, included among the candidates for selection.) This yielded an improvement of 1.68 BLEU points on the 49-sentence test set (TP one-best).

One could argue that this result is simply a result of having more hypotheses to choose from, not a result of the targeted paraphrasing process itself. In order to rule out this possibility, we generated $(n+1)$-best Google translations, setting n for each sentence to match the number of alternative translations generated via targeted paraphrasing. We then chose the best translation for each sentence, among the $(n+1)$-best Google hypotheses, via oracle selection, using the TERp metric (Snover et al., 2009) to evaluate each hypothesis against the reference translations.[4] The resulting BLEU score for the full set showed negligible improvement (GT n-best oracle).

We did a similar oracle-best calculation using TERp for targeted paraphrasing (TP oracle). The result shows a potential gain of 2.46 BLEU points over the baseline, if the best scoring alternative from the targeted paraphrasing process were always chosen.

In addition to aggregate scoring using BLEU, we also looked at oracle results on a per-sentence basis using TERp (since BLEU more appropriate to use at the document level, not the sentence level). Identifying the best sentential paraphrase alternative using TERp as an oracle, we find that the TERp score would improve for 32 of the 49 test sentences, 65.3%. For those 32 sentences, the average gain is 8.36 TERp points.[5] A fairer measure is the average obtained when scoring zero gain for the 17 sentences where no improvement was obtained; taking these into account, i.e. assuming an oracle who chooses the original translation if none of the paraphrase-based alternatives are better, the average improvement over the entire set of 49 sentences is 5.46 TERp points.

Although we have obtained results on only a small subset of the full NIST MT'08 test set, our automatic evaluation confirms the qualitative impressions in Figure 1 and the subjective ratings results obtained in our pilot study in Section 3. The TP oracle results establish that by taking advantage of monolingual human speakers, it is possible to obtain quite substantial gains in translation quality. The TP one-best results demonstrate that the majority of that oracle gain is obtained in automatic hypothesis selection, simply by selecting the paraphrase-based alternative translation with the highest translation score.

The last line in Table 1 shows a human upper bound computed using the reference translations via cross validation; that is, for each of the four reference translations, we evaluate it as a hypothesized translation using the other three references as ground truth; these four scores were then averaged. The value of this upper bound is quite consistent with the bound computed similarly by Callison-Burch (2009).

5 English-Chinese Evaluation

As we noted in Section 2, the targeted paraphrasing translation process defines a set of human-machine combinations that do not require bilingual expertise. The previous section described human identification of mistranslated spans on the target side, human generation of paraphrases for problematic sub-sentential spans on the source side, and both automatic hypothesis selection and human selection (via fluency ratings, in Section 3).

In this section, we take a step toward more automated processing, replacing human identification of mistranslated spans with an a fully automatic method.[6] The idea behind our automatic error identification is straightforward: if the source sentence

[4] An "oracle" telling us which variant is best is not available in the real world, of course, but in situations like this one, oracle studies are often used to establish the magnitude of the potential gain (Och et al., 2004).

[5] "Gains" refer to a lower score: since TERp is an error measure, lower is better.

[6] This section contains material we originally reported in Buzek et al. (2010).

GT: WTO chief negotiator on behalf of the United States to propose substantial reduction of agricultural subsidies, Kai Fa countries substantially reduce industrial products import tariffs to Dapo ?? Doha Round of negotiations deadlock.

Figure 2: Random sample of 5 items from study in Section 4: original Google translation (GT), results of targeted paraphrasing translation process (TP), and a human reference translation.

is translated to the target and then back-translated, a comparison of the result with the original is likely to identify places where the translation process encountered difficulty.[7] Briefly, we automatically translate source F to target E, then back-translate to produce F' in the source language. We compare F and F' using TERp — which, in addition to its use as an evaluation metric, is a form of string-edit distance that identifies various categories of differences between two sentences. When at least two consecutive edits are found, we flag their smallest containing syntactic constituent as a potential source of translation difficulty.[8]

In more detail, we posit that if an area of backtranslation F' has many edits relative to original sentence F, then that area probably comes from parts of the target translation that did not represent the desired meaning in F very well. We only consider consecutive edits in certain of the TERp edit categories, specifically, deletions (D), insertions (I), and shifts (S); the two remaining categories, matches (M) and paraphrases (P), indicate that the words are identical or that the original meaning was preserved. Furthermore, we assume that while a single D, S, or I edit might be fairly meaningless, a string of at least two of those types of edits is likely to represent a substantive problem in the translation.

In order to identify reasonably meaningful paraphrase units based on potential errors, we rely on a source language constituency parser. Using the parse, we find the smallest constituent of the sentence containing all of the tokens in a particular error string. At times, these constituents can be quite large, even the entire sentence. To weed out these cases, we restrict constituent length to no more than 7 tokens.

For example, given

F **The most recent probe to visit Jupiter** was the Pluto-bound New Horizons spacecraft in late February 2007.

E La investigación más reciente fue la visita de Júpiter a Plutón de la envolvente sonda New Horizons a fines de febrero de 2007.

F' The latest research visit Jupiter was the Pluto-bound New Horizons spacecraft in late February 2007.

spans in the the bolded phrase in F would be identified, based on the TERp alignment and smallest containing constituent as shown in Figure 3.

In order to evaluate this approach, we again use NIST MT08 data, this time going in the English-to-Chinese direction since we are assuming source language resources not currently available for Chinese.[9] We used English reference 0 as the source sentence, and the original Chinese sentence as the target.[10]

The data set comprises 1,357 sentence pairs. Using the above described algorithm to automatically identify possible problem areas in the translation, with the Google Translate API providing both the translation and back-translation, we generated 1,780 potential error spans in 1,006 of the sentences, and, continuing the targeted paraphrasing process, we obtained up to three source paraphrases per span, for the problemantic spans in 1,000 of those sentences. (For six sentences, no paraphrases weres suggested for any of the problematic spans.) These yielded full-sentence paraphrase alternatives for the 1,000 sentences, which we again evaluated via an oracle study.

For this study we used the TER metric (Snover et al., 2006) rather than TERp. Comparing with the GT output, we find that TP yields a better-translated paraphrase sentence is available in 313 of the 1000 cases, or 31.3%, and for those 313 cases, TER for the oracle-best paraphrase alternative improves on the TER for the original sentence by 12.16 TER points. Also taking into account the cases where there is no improvement over the baseline, the average TER score improves by 3.8 points. The cost for human tasks in this study — just paraphrases, since identifying problematic spans was done automatically — was $117.48, or a bit under $0.12 per sentence.

[7] Exactly the same insight is behind the "source-side pseudo-referencebased feature" employed by Soricut and Echihabi (2010) in their system for predicting the trustworthiness of translations.

[8] It is possible that the difficulty so identified involves back-translation only, not translation in the original direction. If that is the case, then more paraphrasing will be done than necessary, but the quality of the TP process's output should not suffer.

[9] The Stanford parser (Klein and Manning, 2002), which we use to identify source syntactic constituents, exists for both English and Chinese, but TERp uses English resources such as WordNet in order to capture acceptable variants of expression for the same meaning. Matt Snover (personal communication) is working on extension of TERp to other languages.

[10] We chose reference 0 because on inspection these references seemed most reflective of native English grammar and usage.

6 Conclusions and Future Work

In this paper we have focused on a relatively less-explored space on the spectrum between high quality and low cost translation: sharing the burden of the translation task among a fully automatic system and *monolingual* human participants, without requiring human bilingual expertise. The monolingual participants in this framework perform straightforward tasks: they identify parts of sentences in their language that seem to have errors, they provide sub-sentential paraphrases in context, and they judge the fluency of sentences they are presented with (or, in a variant still to be explored, they simply select which target sentence they like the best). Unlike other proposals for exploiting monolingual speakers in human-machine collaborative translation, the human steps here are amenable to automation, and in addition to evaluating a mostly-human variant of our targeted paraphrasing translation framework, we also assessed a version in which the identification of mistranslated spans (to be paraphrased) is done automatically.

Our experimentation yielded a consistent pattern of results, supporting the conclusion that targeted paraphrasing can lead to significant improvements in translation, via several different measures. First, a very small pilot study for Chinese-English translation in Wikipedia provided preliminary validation that translation fluency and accuracy can be improved quite significantly for a set of fairly chosen test sentences, according to human ratings. Second, a small experiment in Chinese-English translation using standard NIST test sentences suggested the potential for dramatic gains using the BLEU and TERp scores, with oracle improvements of 2.46 points and 5.46 points, respectively. In addition, a non-oracle experiment, selecting the best hypothesis according to the MT system's model score, yielded a gain of nearly 1.7 BLEU points. And third, in a large scale evaluation of the approach using English-Chinese translation of 1,000 sentences, this time automating the step of identifying potentially mistranslated parts of source sentences, the oracle results demonstrated that a gain of nearly 4 TER points is available.

These initial studies leave considerable room for future work. One important step will be to better characterize the relationship between cost and quality in quantitative terms: how much does it cost to obtain how much quality improvement, and how does that compare with typical professional translation costs of $0.25 per word? This question is closely connected with the dynamics of crowdsourcing platforms such as Mechanical Turk — the cost *per sentence* in these experiments works out to be around $0.12, but translation on a large scale will involve a complicated ecosystem of workers and cheaters, tasks and motivations and incentives (Quinn and Bederson, 2009). A related crowdsourcing issue requiring further study is the availability of monolingual human participants for a range of language pairs, in order to validate the argument that drawing on monolingual human participation will significantly reduce the severity of the availability bottleneck. And, of course, in the upper bound in Table 1 makes quite clear the crucial value added by bilingual translators, when they are available; we hope to explore whether the targeted paraphrasing translation pipeline can improve the productivity of post-editing by bilinguals, making it easier to move toward the upper bound in a cost-effective way.

Another set of issues concerns the underlying translation technology. A reviewer correctly notes that the value of the approach taken here is likely to vary depending upon the quality of the underlying translation system, and the approach may break down at the extrema, when the baseline translation is either already very good or completely awful. We chose to use Google Translate for its wide availability and the fact that it represents a state of the art baseline to beat; however, in future work we plan to substitute our own statistical MT systems, which will permit us to experiment across a range of translation model and language model LM training set sizes, and therefore to vary quality while keeping other system details constant. More directly connected to research in machine translation, this framework provides a variety of opportunities for improving fully automatic statistical MT systems. We plan to implement a fully automatic targeted paraphrasing translation pipeline, using the automated methods discussed when introducing the pipeline in Section 2, including translation of targeted paraphrase lattices (cf. (Max, 2010; Du et al., 2010)). Finally, we intend to explore the application of our approach in scenarios involving less-common languages, by using a more common language as a pivot or bridge (Habash and Hu, 2009).

Soft Syntactic Constraints for Hierarchical Phrase-based Translation Using Latent Syntactic Distributions

Abstract

In this paper, we present a novel approach to enhance hierarchical phrase-based machine translation systems with linguistically motivated syntactic features. Rather than directly using treebank categories as in previous studies, we learn a set of linguistically-guided latent syntactic categories automatically from a source-side parsed, word-aligned parallel corpus, based on the hierarchical structure among phrase pairs as well as the syntactic structure of the source side. In our model, each X nonterminal in a SCFG rule is decorated with a real-valued feature vector computed based on its distribution of latent syntactic categories. These feature vectors are utilized at decoding time to measure the similarity between the syntactic analysis of the source side and the syntax of the SCFG rules that are applied to derive translations. Our approach maintains the advantages of hierarchical phrase-based translation systems while at the same time naturally incorporates soft syntactic constraints.

1 Introduction

In recent years, syntax-based translation models (Chiang, 2007; Galley et al., 2004; Liu et al., 2006) have shown promising progress in improving translation quality, thanks to the incorporation of phrasal translation adopted from the widely used phrase-based models (Och and Ney, 2004) to handle local fluency and the engagement of synchronous context-free grammars (SCFG) to handle non-local phrase reordering. Approaches to syntax-based translation models can be largely categorized into two classes based on their dependency on annotated corpus (Chiang, 2007). Linguistically syntax-based models (e.g., (Yamada and Knight, 2001; Galley et al., 2004; Liu et al., 2006)) utilize structures defined over linguistic theory and annotations (e.g., Penn Treebank) and guide the derivation of SCFG rules with explicit parsing on at least one side of the parallel corpus. Formally syntax-based models (e.g., (Wu, 1997; Chiang, 2007)) extract synchronous grammars from parallel corpora based on the hierarchical structure of natural language pairs without any explicit linguistic knowledge or annotations. In this work, we focus on the hierarchical phrase-based models of Chiang (2007), which is formally syntax-based, and always refer the term SCFG, from now on, to the grammars of this model class.

On the one hand, hierarchical phrase-based models do not suffer from errors in syntactic constraints that are unavoidable in linguistically syntax-based models. Despite the complete lack of linguistic guidance, the performance of hierarchical phrase-based models is competitive when compared to linguistically syntax-based models. As shown in (Mi and Huang, 2008), hierarchical phrase-based models significantly outperform tree-to-string models (Liu et al., 2006; Huang et al., 2006), even when attempts are made to alleviate parsing errors using either forest-based decoding (Mi et al., 2008) or forest-based rule extraction (Mi and Huang, 2008).

On the other hand, when properly used, syntactic constraints can provide invaluable benefits to improve translation quality. The tree-to-string models of Mi and Huang (2008) can actually signif-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 138–147,
MIT, Massachusetts, USA, 9-11 October 2010.

icantly outperform hierarchical phrase-based models when using forest-based rule extraction together with forest-based decoding. Chiang (2010) also obtained significant improvement over his hierarchical baseline by using syntactic parse trees on both source and target sides to induce fuzzy (not exact) tree-to-tree rules and by also allowing syntactically mismatched substitutions.

In this paper, we augment rules in hierarchical phrase-based translation systems with novel syntactic features. Unlike previous studies (e.g., (Zollmann and Venugopal, 2006)) that directly use explicit treebank categories such as NP, NP/PP (NP missing PP from the right) to annotate phrase pairs, we induce a set of latent categories to capture the syntactic dependencies inherent in the hierarchical structure of phrase pairs, and derive a real-valued feature vector for each X nonterminal of a SCFG rule based on the distribution of the latent categories. Moreover, we convert the equality test of two sequences of syntactic categories, which are either identical or different, into the computation of a similarity score between their corresponding feature vectors. In our model, two *symbolically different* sequences of syntactic categories could have a high similarity score in the feature vector representation if they are *syntactically similar*, and a low score otherwise. In decoding, these feature vectors are utilized to measure the similarity between the syntactic analysis of the source side and the syntax of the SCFG rules that are applied to derive translations. Our approach maintains the advantages of hierarchical phrase-based translation systems while at the same time naturally incorporates soft syntactic constraints. To the best of our knowledge, this is the first work that applies real-valued syntactic feature vectors to machine translation.

The rest of the paper is organized as follows. Section 2 briefly reviews hierarchical phrase-based translation models. Section 3 presents an overview of our approach, followed by Section 4 describing the hierarchical structure of aligned phrase pairs and Section 5 describing how to induce latent syntactic categories. Experimental results are reported in Section 6, followed by discussions in Section 7. Section 8 concludes this paper.

2 Hierarchical Phrase-Based Translation

An SCFG is a synchronous rewriting system generating source and target side string pairs simultaneously based on a context-free grammar. Each synchronous production (i.e., rule) rewrites a nonterminal into a pair of strings, γ and α, where γ (or α) contains terminal and nonterminal symbols from the source (or target) language and there is a one-to-one correspondence between the nonterminal symbols on both sides. In particular, the hierarchical model (Chiang, 2007) studied in this paper explores hierarchical structures of natural language and utilize only a unified nonterminal symbol X in the grammar,

$$X \rightarrow \langle \gamma, \alpha, \sim \rangle$$

where $\sim$ is the one-to-one correspondence between X's in γ and α, and it can be indicated by underscripted co-indexes. Two example English-to-Chinese translation rules are represented as follows:

$$X \rightarrow \langle \text{give the pen to me}, \text{钢笔 给 我} \rangle \quad (1)$$

$$X \rightarrow \langle \text{give } X_1 \text{ to me}, X_1 \text{ 给 我} \rangle \quad (2)$$

The SCFG rules of hierarchical phrase-based models are extracted automatically from corpora of word-aligned parallel sentence pairs (Brown et al., 1993; Och and Ney, 2000). An aligned sentence pair is a tuple (E, F, A), where $E = e_1 \cdots e_n$ can be interpreted as an English sentence of length n, $F = f_1 \cdots f_m$ its translation of length m in a foreign language, and A a set of links between words of the two sentences. Figure 1 (a) shows an example of aligned English-to-Chinese sentence pair. Widely adopted in phrase-based models (Och and Ney, 2004), a pair of consecutive sequences of words from E and F is a *phrase pair* if all words are aligned only within the sequences and not to any word outside. We call a sequence of words a *phrase* if it corresponds to either side of a phrase pair, and a *non-phrase* otherwise. Note that the boundary words of a phrase pair may not be aligned to any other word. We call the phrase pairs with all boundary words aligned *tight* phrase pairs (Zhang et al., 2008). A tight phrase pair is the minimal phrase pair among all that share the same set of alignment links. Figure 1 (b) highlights the tight phrase pairs in the example sentence pair.

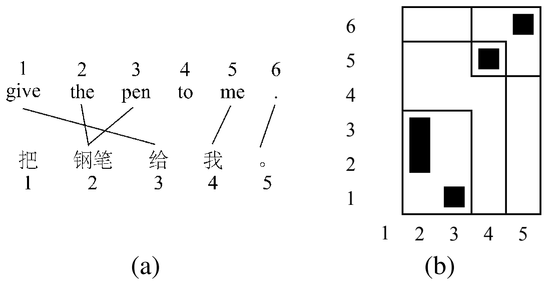

Figure 1: An example of word-aligned sentence pair (a) with tight phrase pairs marked in a matrix representation (b).

The extraction of SCFG rules proceeds as follows. In the first step, all phrase pairs below a maximum length are extracted as phrasal rules. In the second step, abstract rules are extracted from tight phrase pairs that contain other tight phrase pairs by replacing the sub phrase pairs with co-indexed X-nonterminals. Chiang (2007) also introduced several requirements (e.g., there are at most two nonterminals at the right hand side of a rule) to safeguard the quality of the abstract rules as well as keeping decoding efficient. In our example above, rule (2) can be extracted from rule (1) with the following sub phrase pair:

$$X \rightarrow \langle \text{the pen}, \text{钢笔} \rangle$$

The use of a unified X nonterminal makes hierarchical phrase-based models flexible at capturing non-local reordering of phrases. However, such flexibility also comes at the cost that it is not able to differentiate between different syntactic usages of phrases. Suppose rule $X \rightarrow \langle \text{I am reading } X_1, \cdots \rangle$ is extracted from a phrase pair with *I am reading a book* on the source side where X_1 is abstracted from the noun phrase pair . If this rule is used to translate *I am reading the brochure of a book fair*, it would be better to apply it over the entire string than over sub-strings such as *I ... the brochure of*. This is because the nonterminal X_1 in the rule was abstracted from a noun phrase on the source side of the training data and would thus be better (more informative) to be applied to phrases of the same type. Hierarchical phrase-based models are not able to distinguish syntactic differences like this.

Zollmann and Venugopal (2006) attempted to address this problem by annotating phrase pairs with treebank categories based on automatic parse trees. They introduced an extended set of categories (e.g., NP+V for *she went* and DT\NP for *great wall*, an noun phrase with a missing determiner on the left) to annotate phrase pairs that do not align with syntactic constituents. Their hard syntactic constraint requires that the nonterminals should match exactly to rewrite with a rule, which could rule out potentially correct derivations due to errors in the syntactic parses as well as to data sparsity. For example, NP cannot be instantiated with phrase pairs of type DT+NN, in spite of their syntactic similarity. Venugopal et al. (2009) addressed this problem by directly introducing soft syntactic preferences into SCFG rules using preference grammars, but they had to face the computational challenges of large preference vectors. Chiang (2010) also avoided hard constraints and took a soft alternative that directly models the cost of mismatched rule substitutions. This, however, would require a large number of parameters to be tuned on a generally small-sized held-out set, and it could thus suffer from over-tuning.

3 Approach Overview

In this work, we take a different approach to introduce linguistic syntax to hierarchical phrase-based translation systems and impose soft syntactic constraints between derivation rules and the syntactic parse of the sentence to be translated. For each phrase pair extracted from a sentence pair of a source-side parsed parallel corpus, we abstract its syntax by the sequence of highest root categories, which we call a *tag sequence*, that exactly[1] dominates the syntactic tree fragments of the source-side phrase. Figure 3 (b) shows the source-side parse tree of a sentence pair. The tag sequence for “the pen” is simply “NP” because it is a noun phrase, while phrase “give the pen” is dominated by a verb followed by a noun phrase, and thus its tag sequence is “VBP NP”.

Let $TS = \{ts_1, \cdots, ts_m\}$ be the set of all tag sequences extracted from a parallel corpus. The syntax of each X nonterminal[2] in a SCFG rule can be then

[1] In case of a non-tight phrase pair, we only abstract and compare the syntax of the largest tight part.

[2] There are three X nonterminals (one on the left and two on the right) for binary abstract rules, two for unary abstract rules, and one for phrasal rules.

Tag Sequence	Probability
NP	0.40
DT NN	0.35
DT NN NN	0.25

Table 1: The distribution of tag sequences for X_1 in $X \rightarrow \langle$I am reading $X_1, \cdots\rangle$.

characterized by the distribution of tag sequences $\vec{P}_X(TS) = (p_X(ts_1), \cdots, p_X(ts_m))$, based on the phrase pairs it is abstracted from. Table 1 shows an example distribution of tag sequences for X_1 in $X \rightarrow \langle$I am reading $X_1, \cdots\rangle$.

Instead of directly using tag sequences, as we discussed their disadvantages above, we represent each of them by a real-valued feature vector. Suppose we have a collection of n latent syntactic categories $\mathcal{C} = \{c_1, \cdots, c_n\}$. For each tag sequence ts, we compute its distribution of latent syntactic categories $\vec{P}_{ts}(\mathcal{C}) = (p_{ts}(c_1), \cdots, p_{ts}(c_n))$. For example, $\vec{P}_{\text{``NP VP''}}(\mathcal{C}) = \{0.5, 0.2, 0.3\}$ means that the latent syntactic categories c_1, c_2, and c_3 are distributed as $p(c_1) = 0.5$, $p(c_2) = 0.2$, and $p(c_3) = 0.3$ for tag sequence "NP VP". We further convert the distribution to a normalized feature vector $\vec{F}(ts)$ to represent tag sequence ts:

$$\begin{aligned}\vec{F}(ts) &= (f_1(ts), \cdots, f_n(ts)) \\ &= \frac{(p_{ts}(c_1), \cdots, p_{ts}(c_n))}{\|(p_{ts}(c_1), \cdots, p_{ts}(c_n))\|}\end{aligned}$$

The advantage of using real-valued feature vectors is that the degree of similarity between two tag sequences ts and ts' in the space of the latent syntactic categories $\mathcal{C}$ can be simply computed as a dot-product[3] of their feature vectors:

$$\vec{F}(ts) \cdot \vec{F}(ts') = \sum_{1 \leq i \leq n} f_i(ts) f_i(ts')$$

which computes a syntactic similarity score in the range of 0 (totally syntactically different) to 1 (completely syntactically identical).

Similarly, we can represent the syntax of each X nonterminal in a rule with a feature vector $\vec{F}(X)$, computed as the sum of the feature vectors of tag sequences weighted by the distribution of tag sequences of the nonterminal X:

$$\vec{F}(X) = \sum_{ts \in TS} p_X(ts) \vec{F}(ts)$$

Now we can impose soft syntactic constraints using these feature vectors when a SCFG rule is used to translate a parsed source sentence. Given that a X nonterminal in the rule is applied to a span with tag sequence[4] ts as determined by a syntactic parser, we can compute the following syntax similarity feature:

$$\text{SynSim}(X, ts) = -\log(\vec{F}(ts) \cdot \vec{F}(X))$$

Except that it is computed on the fly, this feature can be used in the same way as the regular features in hierarchical translation systems to determine the best translation, and its feature weight can be tuned in the same way together with the other features on a held-out data set.

In our approach, the set of latent syntactic categories is automatically induced from a source-side parsed, word-aligned parallel corpus based on the hierarchical structure among phrase pairs along with the syntactic parse of the source side. In what follows, we will explain the two critical aspects of our approach, i.e., how to identify the hierarchical structures among all phrase pairs in a sentence pair, and how to induce the latent syntactic categories from the hierarchy to syntactically explain the phrase pairs.

4 Alignment-based Hierarchy

The aforementioned abstract rule extraction algorithm of Chiang (2007) is based on the property that a tight phrase pair can contain other tight phrase pairs. Given two non-disjoint tight phrase pairs that share at least one common alignment link, there are only two relationships: either one completely includes another or they do not include one another but have a non-empty overlap, which we call a non-trivial overlap. In the second case, the intersection, differences, and union of the two phrase pairs are

[3] Other measures such as KL-divergence in the probability space are also feasible.

[4] A normalized uniform feature vector is used for tag sequences (of parsed test sentences) that are not seen on the training corpus.

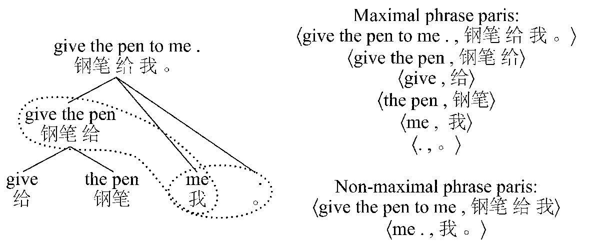

Figure 2: A decomposition tree of tight phrase pairs with all tight phrase pairs listed on the right. As highlighted, the two non-maximal phrase pairs are generated by consecutive sibling nodes.

also tight phrase pairs (see Figure 1 (b) for example), and the two phrase pairs, as well as their intersection and differences, are all sub phrase pairs of their union.

Zhang et al. (2008) exploited this property to construct a hierarchical decomposition tree (Bui-Xuan et al., 2005) of phrase pairs from a sentence pair to extract all phrase pairs in linear time. In this paper, we focus on learning the syntactic dependencies along the hierarchy of phrase pairs. Our hierarchy construction follows Heber and Stoye (2001).

Let $\mathcal{P}$ be the set of tight phrase pairs extracted from a sentence pair. We call a sequentially-ordered list[5] $L = (p_1, \cdots, p_k)$ of unique phrase pairs $p_i \in \mathcal{P}$ a *chain* if every two successive phrase pairs in L have a non-trivial overlap. A chain is *maximal* if it can not be extended to its left or right with other phrase pairs. Note that any sub-sequence of phrase pairs in a chain generates a tight phrase pair. In particular, chain L generates a tight phrase pair $\tau(L)$ that corresponds exactly to the union of the alignment links in $p \in L$. We call the phrase pairs generated by maximal chains *maximal* phrase pairs and call the other phrase pairs *non-maximal*. Non-maximal phrase pairs always overlap non-trivially with some other phrase pairs while maximal phrase pairs do not, and it can be shown that any non-maximal phrase pair can be generated by a sequence of maximal phrase pairs. Note that the largest tight phrase pair that includes all alignment links in A is also a maximal phrase pair.

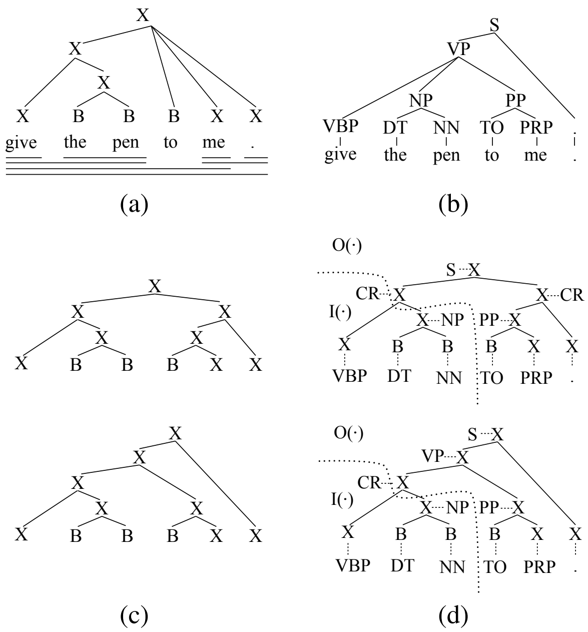

Figure 3: (a) decomposition tree for the English side of the example sentence pair with all phrases underlined, (b) automatic parse tree of the English side, (c) two example binarized decomposition trees with syntactic emissions in depicted in (d), where the two dotted curves give an example I(·) and O(·) that separate the forest into two parts.

Lemma 1 *Given two different maximal phrase pairs p_1 and p_2, exactly one of the following alternatives is true: p_1 and p_2 are disjoint, p_1 is a sub phrase pair of p_2, or p_2 is a sub phrase pair of p_1.*

A direct outcome of Lemma 1 is that there is an unique decomposition tree $T = (N, E)$ covering all of the tight phrase pairs of a sentence pair, where N is the set of maximal phrase pairs and E is the set of edges that connect between pairs of maximal phrase pairs if one is a sub phrase pair of another. All of the tight phrase pairs of a sentence pair can be extracted directly from the nodes of the decomposition tree (these phrase pairs are maximal), or generated by sequences of consecutive sibling nodes[6] (these phrase pairs are non-maximal). Figure 2 shows the decomposition tree as well as all of the tight phrase pairs that can be extracted from the example sentence pair in Figure 1.

We focus on the source side of the decomposition tree, and expand it to include all of the non-phrase

[5] The phrase pairs can be sequentially ordered first by the boundary positions of the source-side phrase and then by the boundary positions of the target-side phrase.

[6] Unaligned words may be added.

single words within the scope of the decomposition tree as frontiers and attach each as a child of the lowest node that contains the word. We then abstract the trees nodes with two symbol, X for phrases, and B for non-phrases, and call the result the *decomposition tree* of the source side phrases. Figure 3 (a) depicts such tree for the English side of our example sentence pair. We further recursively binarize[7] the decomposition tree into a binarized decomposition forest such that all phrases are directly represented as nodes in the forest. Figure 3 (c) shows two of the many binarized decomposition trees in the forest.

The binarized decomposition forest compactly encodes the hierarchical structure among phrases and non-phrases. However, the coarse abstraction of phrases with X and non-phrases with B provides little information on the constraints of the hierarchy. In order to bring in syntactic constraints, we annotate the nodes in the decomposition forest with syntactic observations based on the automatic syntactic parse tree of the source side. If a node aligns with a constituent in the parse tree, we add the syntactic category (e.g., NP) of the constituent as an emitted observation of the node, otherwise, it crosses constituent boundaries and we add a designated crossing category CR as its observation. We call the resulting forest a *syntactic decomposition forest*. Figure 3 (d) shows two syntactic decomposition trees of the forest based on the parse tree in Figure 3 (b). We will next describe how to learn finer-grained X and B categories based on the hierarchical syntactic constraints.

5 Inducing Latent Syntactic Categories

If we designate a unique symbol S as the new root of the syntactic decomposition forests introduced in the previous section, it can be shown that these forests can be generated by a probabilistic context-free grammar $G = (V, \Sigma, S, \mathcal{R}, \phi)$, where

- $V = \{S, X, B\}$ is the set of nonterminals,
- Σ is the set of terminals comprising treebank categories plus the CR tag (the crossing category),
- $S \in V$ is the unique start symbol,
- $\mathcal{R}$ is the union of the set of production rules each rewriting a nonterminal to a sequence of nonterminals and the set of emission rules each generating a terminal from a nonterminal,
- and ϕ assigns a probability score to each rule $r \in R$.

Such a grammar can be derived from the set of syntactic decomposition forests extracted from a source-side parsed parallel corpus, with rule probability scores estimated as the relative frequencies of the production and emission rules.

The X and B nonterminals in the grammar are coarse representations of phrase and non-phrases and do not carry any syntactic information at all. In order to introduce syntax to these nonterminals, we incrementally split[8] them into a set of latent categories $\{X_1, \cdots, X_n\}$ for X and another set $\{B_1, \cdots, B_n\}$ for B, and then learn a set of rule probabilities[9] ϕ on the latent categories so that the likelihood of the training forests are maximized. The motivation is to let the latent categories learn different preferences of (emitted) syntactic categories as well as structural dependencies along the hierarchy so that they can carry syntactic information. We call them *latent syntactic categories*. The learned X_i's represent syntactically-induced finer-grained categories of phrases and are used as the set of latent syntactic categories $\mathcal{C}$ described in Section 3. In related research, Matsuzaki et al. (2005) and Petrov et al. (2006) introduced latent variables to learn finer-grained distinctions of treebank categories for parsing, and Huang et al. (2009) used a similar approach to learn finer-grained part-of-speech tags for tagging. Our method is in spirit similar to these approaches.

Optimization of grammar parameters to maximize the likelihood of training forests can be achieved

[7] The intermediate binarization nodes are also labeled as either X or B based on whether they exactly cover a phrase or not.

[8] We incrementally split each nonterminal to 2, 4, 8, and finally 16 categories, with each splitting followed by several EM iterations to tune model parameters. We consider 16 an appropriate number for latent categories, not too small to differentiate between different syntactic usages and not too large for the extra computational and storage costs.

[9] Each binary production rule is now associated with a 3-dimensional matrix of probabilities, and each emission rule associated with a 1-dimensional array of probabilities.

by a variant of Expectation-Maximization (EM) algorithm. Recall that our decomposition forests are fully binarized (except the root). In the hypergraph representation (Huang and Chiang, 2005), the hyperedges of our forests all have the same format[10] $\langle (V, W), U \rangle$, meaning that node U expands to nodes V and W with production rule $U \to VW$. Given a forest F with root node R, we denote $e(U)$ the emitted syntactic category at node U and LR(U) (or PL(W), or PR(V))[11] the set of node pairs (V, W) (or (U, V), or (U, W)) such that $\langle (V, W), U \rangle$ is a hyperedge of the forest. Now consider node U, which is either S, X, or B, in the forest. Let U_x be the latent syntactic category[12] of node U. We define I(U_x) the part of the forest (includes $e(U)$ but not U_x) inside U, and O(U_x) the other part of the forest (includes U_x but not $e(U)$) outside U, as illustrated in Figure 3 (d). The inside-outside probabilities are defined as:

$$\begin{aligned} \mathrm{P}_{\mathrm{IN}}(U_x) &= P(\mathrm{I}(U_x)|U_x) \\ \mathrm{P}_{\mathrm{OUT}}(U_x) &= P(\mathrm{O}(U_x)|S) \end{aligned}$$

which can be computed recursively as:

$$\begin{aligned} \mathrm{P}_{\mathrm{IN}}(U_x) &= \sum_{(V,W)\in \mathrm{LR}(U)} \sum_{y,z} \begin{matrix} \phi(U_x \to e(U)) \\ \times \phi(U_x \to V_y W_z) \\ \times \mathrm{P}_{\mathrm{IN}}(V_y)\mathrm{P}_{\mathrm{IN}}(W_z) \end{matrix} \\ \mathrm{P}_{\mathrm{OUT}}(U_x) &= \sum_{(V,W)\in \mathrm{PL(U)}} \sum_{y,z} \begin{matrix} \phi(V_y \to e(V)) \\ \times \phi(V_y \to W_z U_x) \\ \times \mathrm{P}_{\mathrm{OUT}}(V_y)\mathrm{P}_{\mathrm{IN}}(W_z) \end{matrix} \\ &+ \sum_{(V,W)\in \mathrm{PR(U)}} \sum_{y,z} \begin{matrix} \phi(V_y \to e(V)) \\ \times \phi(V_y \to U_x W_z) \\ \times \mathrm{P}_{\mathrm{OUT}}(V_y)\mathrm{P}_{\mathrm{IN}}(W_z) \end{matrix} \end{aligned}$$

In the E-step, the posterior probability of the occurrence of production rule[13] $U_x \to V_y W_z$ is computed as:

$$P(U_x \to V_y W_z|F) = \frac{\begin{matrix} \phi(U_x \to e(U)) \\ \times \phi(U_x \to V_y W_z) \\ \times \mathrm{P}_{\mathrm{OUT}}(U_x)\mathrm{P}_{\mathrm{IN}}(V_y)\mathrm{P}_{\mathrm{IN}}(W_w) \end{matrix}}{\mathrm{P}_{\mathrm{IN}}(R)}$$

In the M-step, the expected counts of rule $U_x \to V_y W_z$ for all latent categories V_y and W_z are accumulated together and then normalized to obtain an update of the probability estimation:

$$\phi(U_x \to V_y W_z) = \frac{\#(U_x \to V_y W_z)}{\sum\limits_{(V',W')} \sum\limits_{y,z} \#(U_x \to V_y W_z)}$$

Recall that each node U labeled as X in a forest is associated with a phrase whose syntax is abstracted by a tag sequence. Once a grammar is learned, for each such node with a corresponding tag sequence ts in forest F, we compute the posterior probability that the latent category of node U being X_i as:

$$P(X_i|ts) = \frac{\mathrm{P}_{\mathrm{OUT}}(U_i)\mathrm{P}_{\mathrm{IN}}(U_i)}{\mathrm{P}_{\mathrm{IN}}(R)}$$

This contributes $P(X_i|ts)$ evidence that tag sequence ts belongs to a X_i category. When all of the evidences are computed and accumulated in $\#(X_i, ts)$, they can then be normalized to obtain the probability that the latent category of ts is X_i:

$$p_{ts}(X_i) = \frac{\#(X_i, ts)}{\sum_i \#(X_i, ts)}$$

As described in Section 3, the distributions of latent categories are used to compute the syntactic feature vectors for the SCFG rules.

6 Experiments

We conduct experiments on two tasks, English-to-German and English-to-Chinese, both aimed for speech-to-speech translation. The training data for the English-to-German task is a filtered subset of the Europarl corpus (Koehn, 2005), containing ∼300k parallel bitext with ∼4.5M tokens on each side. The dev and test sets both contain 1k sentences with one reference for each. The training data for the English-to-Chinese task is collected from transcription and human translation of conversations in travel domain. It consists of ∼500k parallel bitext with ∼3M tokens[14] on each side. Both dev and test sets contain ∼1.3k sentences, each with two references. Both

[10] The hyperedge corresponding to the root node has a different format because it is unary, but it can be handled similarly. When clear from context, we use the same variable to present both a node and its label.

[11] LR stands for the left and right children, PL for the parent and left children, and PR for the parent and right children.

[12] We never split the start symbol S, and denote $S_0 = S$.

[13] The emission rules can be handled similarly.

[14] The Chinese sentences are automatically segmented into words. However, BLEU scores are computed at character level for tuning and evaluation.

corpora are also preprocessed with punctuation removed and words down-cased to make them suitable for speech translation.

The baseline system is our implementation of the hierarchical phrase-based model of Chiang (2007), and it includes basic features such as rule and lexicalized rule translation probabilities, language model scores, rule counts, etc. We use 4-gram language models in both tasks, and conduct minimum-error-rate training (Och, 2003) to optimize feature weights on the dev set. Our baseline hierarchical model has 8.3M and 9.7M rules for the English-to-German and English-to-Chinese tasks, respectively.

The English side of the parallel data is parsed by our implementation of the Berkeley parser (Huang and Harper, 2009) trained on the combination of Broadcast News treebank from Ontonotes (Weischedel et al., 2008) and a speechified version of the WSJ treebank (Marcus et al., 1999) to achieve higher parsing accuracy (Huang et al., 2010). Our approach introduces a new syntactic feature and its feature weight is tuned in the same way together with the features in the baseline model. In this study, we induce 16 latent categories for both X and B nonterminals.

Our approach identifies $\sim$180k unique tag sequences for the English side of phrase pairs in both tasks. As shown by the examples in Table 2, the syntactic feature vector representation is able to identify similar and dissimilar tag sequences. For instance, it determines that the sequence of "DT JJ NN" is syntactically very similar to "DT ADJP NN" while very dissimilar to "NN CD VP". Notice that our latent categories are learned automatically to maximize the likelihood of the training forests extracted based on alignment and are not explicitly instructed to discriminate between syntactically different tag sequences. Our approach is not guaranteed to always assign similar feature vectors to syntactically similar tag sequences. However, as the experimental results show below, the latent categories are able to capture some similarities among tag sequences that are beneficial for translation.

Table 3 and 4 report the experimental results on the English-to-German and English-to-Chinese tasks, respectively. The addition of the syntax feature achieves a statistically significant improvement ($p \leq 0.01$) of 0.6 in BLEU on the test set of the English-to-German task. This improvement is substantial given that only one reference is used for each test sentence. On the English-to-Chinese task, the syntax feature achieves a smaller improvement of 0.41 BLEU on the test set. One potential explanation for the smaller improvement is that the sentences on the English-to-Chinese task are much shorter, with an average of only 6 words per sentence, compared to 15 words in the English-to-German task. The hypothesis space of translating a longer sentence is much larger than that of a shorter sentence. Therefore, there is more potential gain from using syntax features to rule out unlikely derivations of longer sentences, while phrasal rules might be adequate for shorter sentences, leaving less room for syntax to help as in the case of the English-to-Chinese task.

7 Discussions

The incorporation of the syntactic feature into the hierarchical phrase-based translation system also brings in additional memory load and computational cost. In the worst case, our approach requires storing one feature vector for each tag sequence and one feature vector for each nonterminal of a SCFG rule, with the latter taking the majority of the extra memory storage. We observed that about 90% of the X nonterminals in the rules only have one tag sequence, and thus the required memory space can be significantly reduced by only storing a pointer to the feature vector of the tag sequence for these nonterminals. Our approach also requires computing one dot-product of two feature vectors for each nonterminal when a SCFG rule is applied to a source span.

This cost can be reduced, however, by caching the dot-products of the tag sequences that are frequently accessed.

There are other successful investigations to impose soft syntactic constraints to hierarchical phrase-based models by either introducing syntax-based rule features such as the prior derivation model of Zhou et al. (2008) or by imposing constraints on translation spans at decoding time, e.g., (Marton and Resnik, 2008; Xiong et al., 2009; Xiong et al., 2010). These approaches are all orthogonal to ours and it is expected that they can be combined with our approach to achieve greater improvement.

This work is an initial effort to investigate latent syntactic categories to enhance hierarchical phrase-based translation models, and there are many directions to continue this line of research. First, while the current approach imposes soft syntactic constraints between the parse structure of the source sentence and the SCFG rules used to derive the translation, the real-valued syntactic feature vectors can also be used to impose soft constraints between SCFG rules when rule rewrite occurs. In this case, target side parse trees could also be used alone or together with the source side parse trees to induce the latent syntactic categories. Second, instead of using single parse trees during both training and decoding, our approach is likely to benefit from exploring parse forests as in (Mi and Huang, 2008). Third, in addition to the treebank categories obtained by syntactic parsing, lexical cues directly available in sentence pairs could also to explored to guide the learning of latent categories. Last but not the least, it would be interesting to investigate discriminative training approaches to learn latent categories that directly optimize on translation quality.

8 Conclusion

We have presented a novel approach to enhance hierarchical phrase-based machine translation systems with real-valued linguistically motivated feature vectors. Our approach maintains the advantages of hierarchical phrase-based translation systems while at the same time naturally incorporates soft syntactic constraints. Experimental results showed that this approach improves the baseline hierarchical phrase-based translation models on both English-to-German and English-to-Chinese tasks. We will continue this line of research and exploit better ways to learn syntax and apply syntactic constraints to machine translation.

Abstract

We propose a language-independent approach for improving statistical machine translation for morphologically rich languages using a hybrid morpheme-word representation where the basic unit of translation is the morpheme, but word boundaries are respected at all stages of the translation process. Our model extends the classic phrase-based model by means of (1) word boundary-aware morpheme-level phrase extraction, (2) minimum error-rate training for a morpheme-level translation model using word-level BLEU, and (3) joint scoring with morpheme- and word-level language models. Further improvements are achieved by combining our model with the classic one. The evaluation on English to Finnish using *Europarl* (714K sentence pairs; 15.5M English words) shows statistically significant improvements over the classic model based on BLEU and human judgments.

1 Introduction

The fast progress of statistical machine translation (SMT) has boosted translation quality significantly. While research keeps diversifying, *the word* remains the atomic token-unit of translation. This is fine for languages with limited morphology like English and French, or no morphology at all like Chinese, but it is inadequate for morphologically rich languages like Arabic, Czech or Finnish (Lee, 2004; Goldwater and McClosky, 2005; Yang and Kirchhoff, 2006).

There has been a line of recent SMT research that incorporates morphological analysis as part of the translation process, thus providing access to the information within the individual words. Unfortunately, most of this work either relies on language-specific tools, or only works for very small datasets.

Below we propose a language-independent approach to SMT of morphologically rich languages using a hybrid morpheme-word representation where the basic unit of translation is the morpheme, but word boundaries are respected at all stages of the translation process. We use unsupervised morphological analysis and we incorporate its output into the process of translation, as opposed to relying on pre-processing and post-processing only as has been done in previous work.

The remainder of the paper is organized as follows. Section 2 reviews related work. Sections 3 and 4 present our morphological and phrase merging enhancements. Section 5 describes our experiments, and Section 6 analyzes the results. Finally, Section 7 concludes and suggests directions for future work.

2 Related Work

Most previous work on morphology-aware approaches relies heavily on language-specific tools, e.g., the *TreeTagger* (Schmid, 1994) or the *Buckwalter* Arabic Morphological Analyzer (Buckwalter, 2004), which hampers their portability to other languages. Moreover, the prevalent method for incorporating morphological information is by heuristically-driven pre- or post-processing. For example, Sadat and Habash (2006) use different combinations of Arabic pre-processing schemes

for Arabic-English SMT, whereas Oflazer and El-Kahlout (2007) post-processes Turkish morpheme-level translations by re-scoring n-best lists with a word-based language model. These systems, however, do not attempt to incorporate their analysis as part of the decoding process, but rather rely on models designed for word-token translation.

We should also note the importance of the translation direction: it is much harder to translate from a morphologically poor to a morphologically rich language, where morphological distinctions not present in the source need to be generated in the target language. Research in translating into morphologically rich languages, has attracted interest for languages like *Arabic* (Badr et al., 2008), *Greek* (Avramidis and Koehn, 2008), *Hungarian* (Novák, 2009; Koehn and Haddow, 2009), *Russian* (Toutanova et al., 2008), and *Turkish* (Oflazer and El-Kahlout, 2007). These approaches, however, either only succeed in enhancing the performance for small bi-texts (Badr et al., 2008; Oflazer and El-Kahlout, 2007), or improve only modestly for large bi-texts[1].

3 Morphological Enhancements

We present a morphologically-enhanced version of the classic phrase-based SMT model (Koehn et al., 2003). We use a hybrid morpheme-word representation where the basic unit of translation is the morpheme, but word boundaries are respected at all stages of the translation process. This is in contrast with previous work, where morphological enhancements are typically performed as pre-/post-processing steps only.

In addition to changing the basic translation token unit from a word to a morpheme, our model extends the phrase-based SMT model with the following:

1. word boundary-aware morpheme-level phrase extraction;
2. minimum error-rate training for a morpheme-level model using word-level BLEU;
3. joint scoring with morpheme- and word-level language models.

We first introduce our morpheme-level representation, and then describe our enhancements.

3.1 Morphological Representation

Our morphological representation is based on the output of an unsupervised morphological analyzer. Following Virpioja et al. (2007), we use *Morfessor*, which is trained on raw tokenized text (Creutz and Lagus, 2007). The tool segments words into morphemes annotated with the following labels: PRE (prefix), STM (stem), SUF (suffix). Multiple prefixes and suffixes can be proposed for each word; word compounding is allowed as well. The output can be described by the following regular expression:

$$\texttt{WORD} = (\ \texttt{PRE*}\ \ \texttt{STM}\ \ \texttt{SUF*}\ )^{+}$$

For example, uncarefully is analyzed as

un/PRE+ care/STM+ ful/SUF+ ly/SUF

The above token sequence forms the input to our system. We keep the PRE/STM/SUF tags as part of the tokens, and distinguish between care/STM+ and care/STM. Note also that the “+” sign is appended to each nonfinal tag so that we can distinguish word-internal from word-final morphemes.

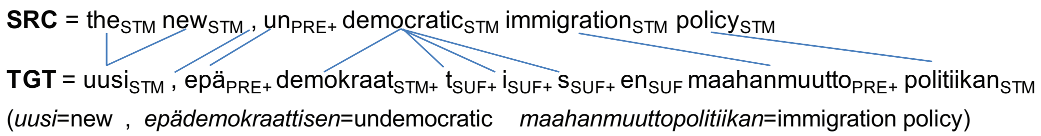
3.2 Word Boundary-aware Phrase Extraction

The core translation structure of a phrase-based SMT model is the *phrase table*, which is learned from a bilingual parallel sentence-aligned corpus, typically using the alignment template approach (Och and Ney, 2004). It contains a set of bilingual phrase pairs, each associated with five scores: forward and backward phrase translation probabilities, forward and backward lexicalized translation probabilities, and a constant phrase penalty.

The maximum phrase length n is normally limited to seven words; higher values of n increase the table size exponentially without actually yielding performance benefit (Koehn et al., 2003). However, things are different when translating with morphemes, for two reasons: (1) morpheme-token phrases of length n can span less than n words; and (2) morpheme-token phrases may only partially span words.

The first point means that morpheme-token phrase pairs span fewer word tokens, and thus cover a smaller context, which may result in fewer total extracted pairs compared to a word-level approach. Figure 1 shows a case where three Finnish words consist of nine morphemes. Previously, this issue was addressed by simply increasing the value of n when using morphemes, which is of limited help.

[1] Avramidis and Koehn (2008) improved by 0.15 BLEU over a 18.05 English-Greek baseline; Toutanova et al. (2008) improved by 0.72 BLEU over a 36.00 English-Russian baseline.



SRC = the$_{STM}$ new$_{STM}$, un$_{PRE+}$ democratic$_{STM}$ immigration$_{STM}$ policy$_{STM}$
TGT = uusi$_{STM}$, epä$_{PRE+}$ demokraat$_{STM+}$ t$_{SUF+}$ i$_{SUF+}$ s$_{SUF+}$ en$_{SUF}$ maahanmuutto$_{PRE+}$ politiikan$_{STM}$
(uusi=new , epädemokraattisen=undemocratic maahanmuuttopolitiikan=immigration policy)

Figure 1: **Example of English-Finnish bilingual fragments morphologically segmented by *Morfessor*.** Solid links represent IBM Model 4 alignments at the morpheme-token level. Translation glosses for Finnish are given below.

The second point is more interesting: morpheme-level phrases may span words partially, making them potentially usable in translating unknown inflected forms of known source language words, but also creates the danger of generating sequences of morphemes that are not legal target language words.

For example, let us consider the phrase in Figure 1: $\mathtt{un}_{\mathtt{PRE+}}$ $\mathtt{democratic}_{\mathtt{STM}}$. The original algorithm will extract the spurious phrase $\mathtt{epä}_{\mathtt{PRE+}}$ $\mathtt{demokraat}_{\mathtt{STM+}}$ $\mathtt{t}_{\mathtt{SUF+}}$ $\mathtt{i}_{\mathtt{SUF+}}$ $\mathtt{s}_{\mathtt{SUF+}}$, beside the correct one that has $\mathtt{en}_{\mathtt{SUF}}$ appended at the end. Such a spurious phrase does not generally help in translating unknown inflected forms, especially for morphologically-rich languages that feature multiple affixes, but negatively affects the translation model in terms of complexity and quality.

We solve both problems by modifying the phrase-pair extraction algorithm so that morpheme-token phrases can extend longer than n, as long as they span n words or less. We further require that word boundaries be respected[2], i.e., morpheme-token phrases span a sequence of whole words. This is a fair extension of the morpheme-token system with respect to a word-token one since both are restricted to span up to n word-tokens.

3.3 Morpheme-Token MERT Optimizing Word-Token BLEU

Modern phrase-based SMT systems use a log-linear model with the following typical feature functions: language model probabilities, word penalty, distortion cost, and the five parameters from the phrase table. Their weights are set by optimizing BLEU score (Papineni et al., 2001) directly using minimum error rate training (MERT), as suggested by Och (2003).

In previous work, phrase-based SMT systems using morpheme-token input/output naturally performed MERT at the morpheme-token level as well. This is not optimal since the final expected system output is a sequence of words, not morphemes. The main danger is that optimizing a morpheme-token BLEU score could lead to a suboptimal weight for the word penalty feature function: this is because the brevity penalty of BLEU is calculated with respect to the number of morphemes, which may vary for sentences with an identical number of words.

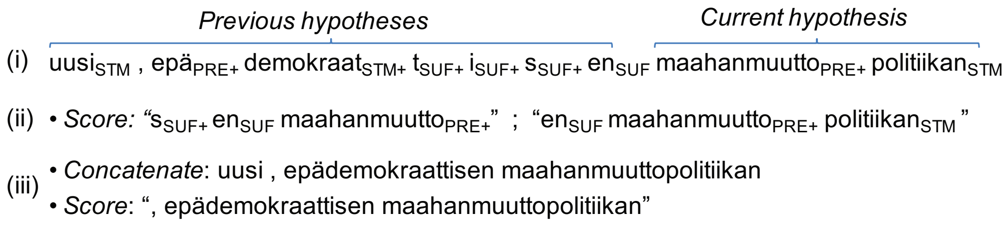
This motivates us to perform MERT at the word-token level, although our input consists of morphemes. In particular, for each iteration of MERT, as soon as the decoder generates a morpheme-token translation for a sentence, we convert it into a word-token sequence, which is used to calculate BLEU. We thus achieve MERT optimization at the word-token level while translating a morpheme-token input and generating a morpheme-token output.

3.4 Scoring with Twin Language Models

An SMT system that takes morpheme-token input and generates morpheme-token output should naturally use a morpheme-token language model (LM). This has the advantage of alleviating the problem of data sparseness, especially when translating into a morphologically rich language, since the LM would be able to handle some new unseen inflected forms of known words. On the negative side, a morpheme-token LM spans fewer word-tokens and thus has a more limited word "horizon" compared to one operating at the word level. As with the maximum phrase length, mechanically increasing the order of the morpheme-token LM has a limited impact.

In order to address the issue in a more principled manner, we enhance our model with a second LM that works at the word-token level. This LM is used together with the morpheme-token LM, which is achieved by using two separate feature functions in the log-linear SMT model: one for each LM. We further had to modify the Moses decoder so that

[2] This means that we miss the opportunity to generate new wordforms for known baseforms, but removes the problem of proposing nonwords in the target language.



Previous hypotheses
Current hypothesis
(i) uusi_{STM} , epä_{PRE+} demokraat_{STM+} t_{SUF+} i_{SUF+} s_{SUF+} en_{SUF} $\text{maahanmuutto}_{PRE+}$ politiikan_{STM}
(ii) • Score: "s_{SUF+} en_{SUF} $\text{maahanmuutto}_{PRE+}$" ; "$\text{en}_{SUF}$ $\text{maahanmuutto}_{PRE+}$ politiikan_{STM} "
(iii) • Concatenate: uusi , epädemokraattisen maahanmuuttopolitiikan
• Score: ", epädemokraattisen maahanmuuttopolitiikan"

Figure 2: **Scoring with twin LMs.** Shown are: (i) The current state of the decoding process with the target phrases covered by the current partial hypotheses. (ii, iii) Scoring with 3-gram morpheme-token and 3-gram word-token LMs, respectively. For the word-token LM, the morpheme-token sequence is concatenated into word-tokens before scoring.

it can be enhanced with an appropriate word-token "view" on the partial morpheme-level hypotheses[3].

The interaction of the twin LMs is illustrated in Figure 2. The word-token LM can capture much longer phrases and more complete contexts such as ", *epädemokraattisen maahanmuuttopolitiikan*" compared to the morpheme-token LM.

Note that scoring with two LMs that see the output sequence as different numbers of tokens is not readily offered by the existing SMT decoders. For example, the phrase-based model in Moses (Koehn et al., 2007) allows scoring with multiple LMs, but assumes they use the same token granularity, which is useful for LMs trained on different monolingual corpora, but cannot handle our case. While the factored translation model (Koehn and Hoang, 2007) in Moses does allow scoring with models of different granularity, e.g., lemma-token and word-token LMs, it requires a 1:1 correspondence between the tokens in the different factors, which clearly is not our case.

Note that scoring with twin LMs is conceptually superior to n-best re-scoring with a word-token LM, e.g., (Oflazer and El-Kahlout, 2007), since it is tightly integrated into decoding: it scores partial hypotheses and influenced the search process directly.

4 Enriching the Translation Model

Another general strategy for combining evidence from the word-token and the morpheme-token representations is to build two separate SMT systems and then combine them. This can be done as a post-processing system combination step; see (Chen et al., 2009a) for an overview of such approaches. However, for phrase-based SMT systems, it is theoretically more appealing to combine their phrase tables since this allows the translation models of both systems to influence the hypothesis search directly.

We now describe our phrase table combination approach. Note that it is orthogonal to the work presented in the previous section, which suggests combining the two (which we will do in Section 5).

4.1 Building a Twin Translation Model

Figure 3 shows a general scheme of our twin translation model. First, we tokenize the input at different granularities: (1) morpheme-token and (2) word-token. We then build separate phrase tables (PT) for the two inputs: a word-token PT_w and a morpheme-token PT_m. Second, we re-tokenize PT_w at the morpheme level, thus obtaining a new phrase table $PT_{w\rightarrow m}$, which is of the same granularity as PT_m. Finally, we merge $PT_{w\rightarrow m}$ and PT_m, and we input the resulting phrase table to the decoder.

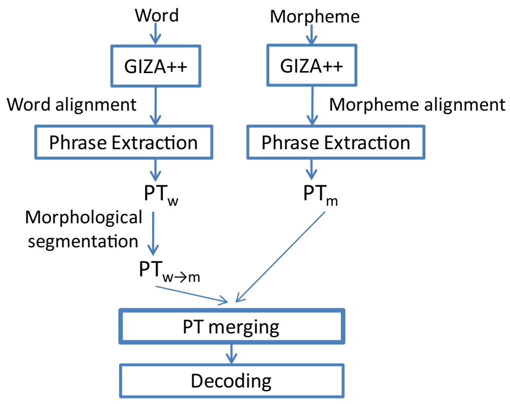


Figure 3: **Building a twin phrase table (PT).** First, separate PTs are generated for different input granularities: word-token and morpheme-token. Second, the word-token PT is retokenized at the morpheme-token level. Finally, the two PTs are merged and used by the decoder.

[3] We use the term "hypothesis" to collectively refer to the following (Koehn, 2003): the *source phrase* covered, the corresponding *target phrase*, and most importantly, a *reference to the previous hypothesis* that it extends.

4.2 Merging and Normalizing Phrase Tables

Below we first describe the two general phrase table combination strategies used in previous work: (1) direct merging using additional feature functions, and (2) phrase table interpolation. We then introduce our approach.

Add-feature methods. The first line of research on phrase table merging is exemplified by (Niehues et al., 2009; Chen et al., 2009b; Do et al., 2009; Nakov and Ng, 2009). The idea is to select one of the phrase tables as primary and to add to it all non-duplicating phrase pairs from the second table together with their associated scores. For each entry, features can be added to indicate its origin (whether from the primary or from the secondary table). Later in our experiments, we will refer to these baseline methods as *add-1* and *add-2*, depending on how many additional features have been added. The values we used for these features in the baseline are given in Section 5.4; their weights in the log-linear model were set in the standard way using MERT.

Interpolation-based methods. A problem with the above method is that the scores in the merged phrase table that correspond to forward and backward phrase translation probabilities, and forward and backward lexicalized translation probabilities can no longer be interpreted as probabilities since they are not normalized any more. Theoretically, this is not necessarily a problem since the log-linear model used by the decoder does not assume that the scores for the feature functions come from a normalized probability distribution. While it is possible to re-normalize the scores to convert them into probabilities, this is rarely done; it also does not solve the problem with the dropped scores for the duplicated phrases. Instead, the conditional probabilities in the two phrase tables are often interpolated directly, e.g., using linear interpolation. Representative work adopting this approach is (Wu and Wang, 2007). We refer to this method as *interpolation*.

Our method. The above phrase merging approaches have been proposed for phrase tables derived from different sources. This is in contrast with our twin translation scenario, where the morpheme-token phrase tables are built from the same training dataset; the main difference being that word alignments and phrase extraction were performed at the word-token level for $PT_{w\rightarrow m}$ and at the morpheme-token level for PT_m. Thus, we propose different merging approaches for the phrase translation probabilities and for the lexicalized probabilities.

In phrase-based SMT, phrase translation probabilities are computed using maximum likelihood (ML) estimation $\phi(\bar{f}|\bar{e}) = \frac{\#(\bar{f},\bar{e})}{\sum_{\bar{f}} \#(\bar{f},\bar{e})}$, where $\#(\bar{f},\bar{e})$ is the number of times the pair $(\bar{f},\bar{e})$ is extracted from the training dataset (Koehn et al., 2003). In order to preserve the normalized ML estimations as much as possible, we refrain from interpolation. Instead, we use the raw counts for the two models $\#_m(\bar{f},\bar{e})$ and $\#_{w\rightarrow m}(\bar{f},\bar{e})$ directly as follows:

$$\phi(\bar{f},\bar{e}) = \frac{\#_m(\bar{f},\bar{e}) + \#_{w\rightarrow m}(\bar{f},\bar{e})}{\sum_{\bar{f}} \#_m(\bar{f},\bar{e}) + \sum_{\bar{f}} \#_{w\rightarrow m}(\bar{f},\bar{e})}$$

For lexicalized translation probabilities, we would like to use simple interpolation. However, we notice that when a phrase pair belongs to only one of the phrase tables, the corresponding lexicalized score for the other table would be zero. This might cause some good phrases to be penalized just because they were not extracted in both tables, which we want to prevent. We thus perform interpolation from PT_m and PT_w according to the following formula:

$$\begin{aligned} \text{lex}(\bar{f}|\bar{e}) &= \alpha \times \text{lex}_m(\bar{f}_m|\bar{e}_m) \\ &+ (1-\alpha) \times \text{lex}_w(\bar{f}_w|\bar{e}_w) \end{aligned}$$

where the concatenation of $\bar{f}_m$ and $\bar{e}_m$ into word-token sequences yields $\bar{f}_w$ and $\bar{e}_w$, respectively.

If both $(\bar{f}_m, \bar{e}_m)$ and $(\bar{f}_w, \bar{e}_w)$ are present in PT_m and PT_w, respectively, we have a simple interpolation of their corresponding lexicalized scores lex$_m$ and lex$_w$. However, if one of them is missing, we do not use a zero for its corresponding lexicalized score, but use an estimate as follows.

For example, if only the entry $(\bar{f}_m, \bar{e}_m)$ is present in PT_m, we first convert ($\bar{f}_m$,$\bar{e}_m$) into a word-token pair ($\bar{f}_{m\rightarrow w}$,$\bar{e}_{m\rightarrow w}$), and then induce a corresponding word alignment from the morpheme-token alignment of ($\bar{f}_m$,$\bar{e}_m$). We then estimate a lexicalized phrase score using the original formula given in (Koehn et al., 2003), where we plug this induced word alignment and word-token lexical translation probabilities estimated from the word-token dataset The case when $(\bar{f}_w, \bar{e}_w)$ is present in PT_w, but $(\bar{f}_m, \bar{e}_m)$ is not, is solved similarly.

5 Experiments and Evaluation

5.1 Datasets

In our experiments, we use the English-Finnish data from the 2005 shared task (Koehn and Monz, 2005), which is split into training, development, and test portions; see Table 1 for details. We further split the training dataset into four subsets T_1, T_2, T_3, and T_4 of sizes 40K, 80K, 160K, and 320K parallel sentence pairs, which we use for studying the impact of training data size on translation performance.

	Sent.	Avg. words		Avg. morph.	
		en	fi	en	fi
Train	714K	21.62	15.80	24.68	26.15
Dev	2K	29.33	20.99	33.40	34.94
Test	2K	28.98	20.72	33.10	34.47

Table 1: **Dataset statistics.** Shown are the number of parallel sentences, and the average number of words and *Morfessor* morphemes on the English and Finnish sides of the training, development and test datasets.

5.2 Baseline Systems

We build two phrase-based baseline SMT systems, both using Moses (Koehn et al., 2007):

w-system: works at the word-token level, extracts phrases of up to seven words, and uses a 4-gram word-token LM (as typical for phrase-based SMT);

m-system: works at the morpheme level, tokenized using *Morfessor*[4] and augmented with "+" as described in Section 3.1.

Following Oflazer and El-Kahlout (2007) and Virpioja et al. (2007), we use phrases of up to 10 morpheme-tokens and a 5-gram morpheme-token LM. None of the enhancements described previously is applied yet. After decoding, morphemes are concatenated back to words using the "+" markers.

To evaluate the translation quality, we compute BLEU (Papineni et al., 2001) at the word-token level. We further introduce a morpheme-token version of BLEU, which we call m-BLEU: it first segments the system output and the reference translation into morpheme-tokens and then calculates a BLEU score as usual. Table 2 shows the baseline results. We can see that the *m-system* achieves much higher m-BLEU scores, indicating that it may have better morpheme coverage[5]. However, the *m-system* is outperformed by the *w-system* on the classic word-token BLEU, which means that it either does not perform as well as the *w-system* or that word-token BLEU is not capable of measuring the morpheme-level improvements. We return to this question later.

	w-system		m-system	
	BLEU	m-BLEU	BLEU	m-BLEU
T_1	11.56	45.57	11.07	49.15
T_2	12.95	48.63	12.68	53.78
T_3	13.64	50.30	13.32	54.40
T_4	14.20	50.85	13.57	54.70
Full	14.58	53.05	14.08	55.26

Table 2: **Baseline system performance** (on the test dataset). Shown are word BLEU and morpheme m-BLEU scores for the *w-system* and *m-system*.

5.3 Adding Morphological Enhancements

We now add our three morphological enhancements from Section 3 to the baseline *m-system*:

phr (training) allow morpheme-token phrases to get potentially longer than seven morpheme-tokens as long as they cover no more than seven words;

tune (tuning) MERT for morpheme-token translations while optimizing word-token BLEU;

lm (decoding) scoring morpheme-token translation hypotheses with a 5-gram morpheme-token and a 4-gram word-token LM.

The results are shown in Table 3 (ii). As we can see, each of the three enhancements yields improvements in BLEU score over the *m-system*, both for small and for large training corpora. In terms of performance ranking, *tune* achieves the best absolute improvement of 0.66 BLEU points on T_1 and of 0.47 points on the full dataset, followed by *lm* and *phr*.

Table 3 (iii) further shows that using *phr* and *lm* together yields absolute improvements of 0.70 BLEU points on T_1 and 0.50 points on the full training dataset. Further incorporating *tune*, however, only helps when training on T_1.

Overall, the morphological enhancements are on par with the *w-system* baseline, and yield sizable im-

[4] We retrained *Morfessor* for Finnish/English on the Finnish/English side of the training dataset.

[5] Note that these morphemes were generated automatically and thus many of them are erroneous.

	System	T_1 (40K)	Full (714K)
(i)	*w-system* (*w*)	11.56	14.58
	m-system (*m*)	11.07	14.08
(ii)	*m+phr*	$11.44^{+0.37}$	$14.43^{+0.35}$
	m+tune	$11.73^{+0.66}$	$14.55^{+0.47}$
	m+lm	$11.58^{+0.51}$	$14.53^{+0.45}$
(iii)	*m+phr+lm*	$11.77^{+0.70}$	**14.58**$^{+0.50}$
	m+phr+lm+tune	**11.90**$^{+0.83}$	$14.39^{+0.31}$

Table 3: **Impact of the morphological enhancements** (on test dataset). Shown are BLEU scores (in %) for training on T_1 and on the full dataset for (i) baselines, (ii) enhancements individually, and (iii) combined. Superscripts indicate absolute improvements w.r.t *m-system*.

provements over the *m-system* baseline: 0.83 BLEU points on T_1 and 0.50 on the full training dataset.

5.4 Combining Translation Tables

Finally, we investigate the effect of combining phrase tables derived from a word-token and a morpheme-token input, as described in Section 4. We experiment with the following merging methods:

add-1: phrase table merging using one table as primary and adding *one* extra feature[6];

add-2: phrase table merging using one table as primary and adding *two* extra features[7];

interpolation: simple linear interpolation with one parameter α;

ourMethod: our interpolation-like merging method described in Section 4.2.

Parameter tuning. We tune the parameters of the above methods on the development dataset.

	T_1 (40K)	Full (714K)
PT_m is primary	11.99	13.45
$PT_{w\to m}$ is primary	12.26	14.19

Table 4: **Effect of selection of primary phrase table for *add-1*** (on dev dataset): $PT_{w\to m}$, derived from a word-token input, vs. PT_m, from a morpheme-token input. Shown is BLEU (in %) on T_1 and the full training dataset.

For *add-1* and *add-2*, we need to decide which ($PT_{w\to m}$ or PT_m) phrase table should be considered the primary table. Table 4 shows the results when trying both strategies on *add-1*. As we can see, using $PT_{w\to m}$ as primary performs better on T_1 and on the full training dataset; thus, we will use it as primary on the test dataset for *add-1* and *add-2*.

For interpolation-based methods, we need to choose a value for the interpolation parameters. Due to time constraints, we use the same value for the phrase translation probabilities and for the lexicalized probabilities, and we perform grid search for $\alpha \in \{0.3, 0.4, 0.5, 0.6, 0.7\}$ using *interpolate* on the full training dataset. As Table 5 shows, $\alpha = 0.6$ turns out to work best on the development dataset; we will use this value in our experiments on the test dataset both for *interpolate* and for *ourMethod*[8].

α	0.3	0.4	0.5	0.6	0.7
BLEU	14.17	14.49	14.6	14.73	14.52

Table 5: **Trying different values for *interpolate*** (on dev dataset). BLEU (in %) is for the full training dataset.

Evaluation on the test dataset. We integrate the morphologically enhanced system *m+phr+lm* and the word-token based *w-system* using the four merging methods above. The results for the full training dataset are shown in Table 6. As we can see, *add-1* and *add-2* make little difference compared to the *m-system* baseline. In contrast, *interpolation* and *ourMethod* yield sizable absolute improvements of 0.55 and 0.74 BLEU points, respectively, over the *m-system*; moreover, they outperform the *w-system*.

	Merging methods	Full (714K)
(i)	*m-system*	14.08
	w-system	14.58
(ii)	*add-1*	$14.25^{+0.17}$
	add-2	$13.89^{-0.19}$
(iii)	*interpolation*	$14.63^{+0.55}$
	ourMethod	**14.82**$^{+0.74}$

Table 6: **Merging *m+phr+lm* and *w-system*** (on test dataset). BLEU (in %) is for the full training dataset. Superscripts indicate performance gain/loss w.r.t *m-system*.

6 Discussion

Below we assess the significance of our results based on micro-analysis and human judgments.

[6] The feature values are e^1, $e^{2/3}$ or $e^{1/3}$ (e=2.71828...); when the phrase pair comes from both tables, from the primary table only, and from the secondary table only, respectively.

[7] The feature values are (e^1, e^1), (e^1, e^0) or (e^0, e^1) when the phrase pair comes from both tables, from the primary table only, and from the secondary table only, respectively.

[8] Note that this might put *ourMethod* at disadvantage.

6.1 Translation Model Comparison

We first compare the following three phrase tables: PT_m of *m-system*, maximum phrase length of 10 morpheme-tokens; $PT_{w \to m}$ of *w-system*, maximum phrase length of 7 word-tokens, re-segmented into morpheme-tokens; and PT_{m+phr} – morpheme-token input using word boundary-aware phrase extraction, maximum phrase length of 7 word-tokens.

		Full (714K)
(i)	PT_m	43.5M
	$PT_{w \to m}$	28.9M
	PT_{m+phr}	22.5M
(ii)	$PT_{m+phr} \bigcap PT_m$	21.4M
	$PT_{m+phr} \bigcap PT_{w \to m}$	10.7M

Table 7: **Phrase table statistics.** The number of phrase pairs in (i) individual PTs and (ii) PT overlap, is shown.

$\boldsymbol{PT_{m+phr}}$ **versus** $\boldsymbol{PT_m}$**.** Table 7 shows that PT_{m+phr} is about half the size of PT_m. Still, as Table 3 shows, *m+phr* outperforms the *m-system*. Moreover, 95.07% (21.4M/22.5M) of the phrase pairs in PT_{m+phr} are also in PT_m, which confirms that boundary-aware phrase extraction selects good phrase pairs from PT_m to be retained in PT_{m+phr}.

$\boldsymbol{PT_{m+phr}}$ **versus** $\boldsymbol{PT_{w \to m}}$**.** These two tables are comparable in size: 22.5M and 28.9M pairs, but their overlap is only 47.67% (10.7M/22.5M) of PT_{m+phr}. Thus, enriching the translation model with $PT_{w \to m}$ helps improve coverage.

6.2 Significance of the Results

Table 8 shows the performance of our system compared to the two baselines: *m-system* and *w-system*. We achieve an absolute improvement of 0.74 BLEU points over the *m-system*, from which our system evolved. This might look modest, but note that the baseline BLEU is only 14.08, and thus the relative improvement is 5.6%, which is not trivial. Furthermore, we outperform the *w-system* by 0.24 points (1.56% relative). Both improvements are statistically significant with $p < 0.01$, according to Collins' sign test (Collins et al., 2005).

In terms of m-BLEU, we achieve an improvement of 2.59 points over the *w-system*, which suggest our system might be performing better than what standard BLEU suggests. Below we test this hypothesis by means of micro-analysis and human evaluation.

	BLEU	**m-BLEU**
ourSystem	14.82	55.64
m-system	14.08	55.26
w-system	14.58	53.05

Table 8: **Our system vs. the two baselines** (on the test dataset): BLEU and m-BLEU scores (in %).

Translation Proximity Match. We performed automatic comparison based on corresponding phrases between the translation output (*out*) and the reference (*ref*), using the source (*src*) test dataset as a pivot. The decoding log gave us the phrases used to translate *src* to *out*, and we only needed to find correspondences between *src* and *ref*, which we accomplished by appending the test dataset to training and performing IBM Model 4 word alignments.

We then looked for phrase triples (*src*, *out*, *ref*), where there was a high character-level similarity between *out* and *ref*, measured using *longest common subsequence ratio* with a threshold of 0.7, set experimentally. We extracted 16,262 triples: for 6,758 of them, the translations matched the references exactly, while in the remaining triples, they were close wordforms[9]. These numbers support the hypothesis that our approach yields translations close to the reference wordforms but unjustly penalized by BLEU, which only gives credit for exact word matches[10].

Human Evaluation. We asked four native Finnish speakers to evaluate 50 random test sentences. Following (Callison-Burch et al., 2009), we provided them with the source sentence, its reference translation, and the outputs of three SMT systems (*m-system*, *w-system*, and *ourSystem*), which were shown in different order for each example and were named *sys1*, *sys2* and *sys3* (by order of appearance). We asked for three pairwise judgments: (i) *sys1* vs. *sys2*, (ii) *sys1* vs. *sys3*, and (iii) *sys2* vs. *sys3*. For each pair, a winner had to be designated; ties were allowed. The results are shown in Table 10. We can see that the judges consistently preferred

[9] Examples of such triples are (`constitutional structure`, perustuslaillinen rakenne, perustuslaillisempi rakenne) and (`economic and social`, taloudellisia ja sosiaalisia, taloudellisten ja sosiaalisten)

[10] As a reference, the *w-system* yielded 15,673 triples, and 6,392 of them were exact matches. Compared to our system, this means 589 triples and 366 exact matches less.

`src`: as a conservative , i am incredibly thrifty with taxpayers ’ money .
`ref`: maltillisen kokoomuspuolueen edustajana suhtaudun **erittain saastavaisesti veronmaksajien** rahoihin .
`our`: konservatiivinen , olen **erittain saastavaisesti veronmaksajien** rahoja .
`w`   : konservatiivinen , olen aarettoman tarkeaa kanssa *veronmaksajien* rahoja .
`m`   : *kuten* konservatiivinen , olen **erittain saastavaisesti veronmaksajien** rahoja .
Comment: **`our`** $\succ$ **`m`** $\succ$ **`w`**. **`our`** uses better paraphrases, from which the correct meaning could be inferred. The part “aarettoman tarkeaa kanssa” in **`w`** does not mention the “thriftiness” and replaces it with “important” (tarkeaa), which is wrong. **`m`** introduces “kuten”, which slightly alters the meaning towards “like a conservative, ...”.

`src`: we were very constructive and we negotiated until the last minute of these talks in the hague .
`ref`: olimme erittain **rakentavia** ja neuvottelimme haagissa **viime hetkeen saakka** .
`our`: olemme olleet hyvin **rakentavia** ja olemme neuvotelleet **viime hetkeen saakka** naiden neuvottelujen haagissa .
`w`   : olemme olleet hyvin **rakentavia** ja olemme neuvotelleet *viime tippaan niin* naiden neuvottelujen haagissa .
`m`   : olimme erittain *rakentavan* ja neuvottelimme **viime hetkeen saakka** naiden neuvotteluiden haagissa .
Comment: **`our`** $\succ$ **`m`** $\succeq$ **`w`**. In **`our`**, the meaning is very close to **`ref`** with only a minor difference in tense at the beginning. **`m`** only gets the case wrong in “rakentavan”, and the correct case is easily guessable. For **`w`**, the “viime tippaan” is in principle correct but somewhat colloquial, and the “niin” is extra and somewhat confusing.

`src`: it would be a very dangerous situation if the europeans were to become logistically reliant on russia .
`ref`: olisi **erittäin** vaarallinen tilanne , jos **eurooppalaiset** tulisivat **logistisesti** riippuvaisiksi venäjästä .
`our`: olisi **erittäin** vaarallinen tilanne , jos **eurooppalaiset** tulee **logistisesti** riippuvaisia venäjän .
`w`   : *se* olisi **erittäin** vaarallinen tilanne , jos *eurooppalaisten* tulisi *logistically* riippuvaisia venäjän .
`m`   : *se* olisi *hyvin* vaarallinen tilanne , jos **eurooppalaiset** *haluavat* tulla **logistisesti** riippuvaisia venäjän .
Comment: **`our`** $\succ$ **`w`** $\succeq$ **`m`**. **`our`** is almost correct except for the wrong inflections at the end. **`w`** is inferior since it failed to translate “logistically”. “haluavat tulla” in **`m`** suggests that the Europeans would “want to become logistically dependent”, which is not the case. The “se” (it), and “hyvin” (a synonym of “erittäin”) are minor mistakes/differences.

Table 9: **English-Finnish translation examples**. Shown are the source (`src`), the reference (`ref`), and the translations of three systems (`our`, `w`, `m`). Text in bold indicates matches with respect to the `ref`, while italics show where a system was judged inferior to the rest, as judged by native Finnish speakers.

(1) *ourSystem* to the *m-system*, (2) *ourSystem* to the *w-system*, (3) *w-system* to the *m-system*. These preferences are statistically significant, as found by the sign test. Comparing to Table 8, we can see that BLEU correlates with human judgments better than m-BLEU; we plan to investigate this in future work.

	our vs. m		**our vs. w**		**w vs. m**	
Judge 1	25	18	19	12	21	19
Judge 2	24	16	19	15	25	14
Judge 3	**27**†	**12**	17	11	**27**†	**15**
Judge 4	25	20	**26**†	**12**	22	22
Total	**101**‡	**66**	**81**‡	**50**	**95**†	**70**

Table 10: **Human judgments:** *ourSystem* (our) vs. *m-system* (m) vs. *w-system* (w). For each pair, we show the number of times each system was judged better than the other one, ignoring ties. Statistically significant differences are marked with † ($p < 0.05$) and ‡ ($p < 0.01$).

Finally, Table 9 shows some examples demonstrating how our system improves over the *w-system* and the *m-system*.

7 Conclusion and Future Work

In the quest towards a morphology-aware SMT that only uses unannotated data, there are two key challenges: (1) to bring the performance of morpheme-token systems to a level rivaling the standard word-token ones, and (2) to incorporate morphological analysis directly into the translation process.

This work satisfies the first challenge: we have achieved statistically significant improvements in BLEU for a large training dataset of 714K sentence pairs and this was confirmed by human evaluation.

We think we have built a solid framework for the second challenge, and we plan to extend it further.

Acknowledgements

“Poetic” Statistical Machine Translation: Rhyme and Meter

Abstract

As a prerequisite to translation of poetry, we implement the ability to produce translations with meter and rhyme for phrase-based MT, examine whether the hypothesis space of such a system is flexible enough to accomodate such constraints, and investigate the impact of such constraints on translation quality.

1 Introduction

Machine translation of poetry is probably one of the hardest possible tasks that can be considered in computational linguistics, MT, or even AI in general. It is a task that most humans are not truly capable of. Robert Frost is reported to have said that poetry is that which gets lost in translation. Not surprisingly, given the task’s difficulty, we are not aware of any work in the field that attempts to solve this problem, or even discuss it, except to mention its difficulty, and professional translators like to cite it as an example of an area where MT will never replace a human translator. This may well be true in the near or even long term. However, there are aspects of the problem that we can already tackle, namely the problem of the poetic form.

Vladimir Nabokov, in his famous translation of *Eugene Onegin* (Nabokov, 1965), a poem with a very strict meter and rhyming scheme, heavily disparages those translators that attempt to preserve the form, claiming that since it is impossible to perfectly preserve both the form and the meaning, the form must be entirely sacrificed. On the other hand, Douglas Hofstadter, who spends 600 pages describing how to translate a 60 word poem in 80 different ways in *Le Ton beau de Marot* (1998), makes a strong case that a poem’s form must be preserved in translation, if at all possible. Leaving the controversy to the professional translators, we investigate whether or not it is possible to produce translations that conform to certain metrical constraints common in poetry.

Statistical machine translation techniques, unlike their traditional rule-based counterparts, are in fact well-suited to the task. Because the number of potential translation hypotheses is very large, it is not unreasonable to expect that some of them should conform to an externally imposed standard. The goal of this paper is to investigate how these hypotheses can be efficiently identified, how often they are present, and what the quality penalty for imposing them is.

2 Related Work

There has been very little work related to the translation of poetry. There has been some work where MT techniques were used to produce poetry (Jiang and Zhou, 2008). In other computational poetry work, Ramakrishnan et al (2009) generate song lyrics from melody and various algorithms for poetry generation (Manurung et al., 2000; Díaz-Agudo et al., 2002). There are books (Hartman, 1996) and articles (Bootz, 1996) on the subject of computer poetry from a literary point of view. Finally, we must mention Donald Knuth’s seminal work on complexity of songs (Knuth, 1984).

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 158–166,
MIT, Massachusetts, USA, 9-11 October 2010.

3 Statistical MT and Poetry

We can treat any poetic form as a constraint on the potential outputs. A naive approach to ensure that an output of the MT system is, say, a *haiku*, is to create a *haiku* detector and to examine a (very large) n-best list of translations. This approach would not succeed very often, since the *haikus* that may be among the possible translations are a very small fraction of all translations, and the MT decoder is not actively looking for them, since it is not part of the cost it attempts to minimize. Instead, we would want to recast "Haikuness" as a feature function, such that a real *haiku* has 0 cost, and those outputs that are not, have large cost. This feature function must be local, rather than global, so as to guide the decoder search.

The concept of feature functions as used in statistical MT is described by Och and Ney (Och and Ney, 2002). For a phrase based system, a feature function is a function whose inputs are a partial hypothesis state s_{in}, and a phrase pair p, and whose outputs are the hypothesis state after p is appended to the hypothesis: s_{out}, and the cost incurred, c. For hierarchical, tree-to-string and some other types of MT systems which combine two partial hypotheses and are not generating translations left-to-right, one instead has two partial hypotheses states s_{left} and s_{right} as inputs, and the outputs are the same. Our first goal is to describe how these functions can be efficiently implemented.

The feature function costs are multiplied by fixed weights and added together to obtain the total hypothesis cost. Normally feature functions include the logarithm of probability of target phrase given source, source given target and other phrase-local features which require no state to be kept, as well as features like language model, which require non-trivial state. The weights are usually learned automatically, however we will set them manually for our feature functions to be effectively infinite, since we want them to override all other sources of information.

We will now examine some different kinds of poetry and consider the properties of such feature functions, especially with regard to keeping necessary state. We are concerned with minimizing the amount of information to be kept, both due to memory requirements, and especially to ensure that compatible hypotheses can be efficiently recombined by the decoder.

3.1 Line-length constrained poetry

Some poetic genres, like the above-mentioned *haiku*, require that a poem contain a certain number of lines (3 for *haiku*), each containing a certain number of syllables (5,7,5 for *haiku*). These genres include *lanternes*, *fibs*, *tankas*, and many others. These genres impose two constraints. The first constraint is on total length. This requires that each hypothesis state contain the current translation length (in syllables). In addition, whenever a hypothesis is expanded, we must keep track of whether or not it would be possible to achieve the desired final length with such an expansion. For example, if in the initial state, we have a choice between two phrases, and picking the longer of the two would make it impossible to have a 17-syllable translation later on, we must impose a high cost on it, so as to avoid going down a garden path.

The second constraint is on placing line breaks: they must come at word boundaries. Therefore the 5th and 12th (and obviously 17th) syllable must end words. This also requires knowing the current hypothesis' syllable length, but unlike the first constraint, it can be scored entirely locally, without considering possible future expansions. For either constraint, however, the sentence has to be assembled strictly left-to-right, which makes it impossible to build partial hypotheses that do not start the sentence, which hierarchical and tree-to-string decoders require.

3.2 Rhythmic poetry

Some famous Western poetry, notably Shakespeare, is written in rhythmic poetry, also known as *blank verse*. This poetry imposes a constraint on the pattern of stressed and unstressed syllables. For example, if we use 0 to indicate no stress, and 1 to indicate stress, *blank verse* with iambic foot obeys the regular expression $(01)*$, while one with a dactylic foot looks like $(100)*$. This genre is the easiest to handle, because it does not require current position, but only its value modulo foot length (e.g. for an iamb, whether the offset is even or odd). It is even possible, as described in Section 4, to track this form in a decoder that is not left-to-right.

3.3 Rhythmic and rhyming poetry

The majority of English poetry that was written until recently has both rhythm and rhyme. Generally speaking, a poetic genre of this form can be described by two properties. The first is a rhyming scheme. A rhyming scheme is a string of letters, each corresponding to a line of a poem, such that the same letter is used for the lines that rhyme. E.g. *aa* is a scheme for a couplet, a 2-line poem whose lines rhyme. A *sonnet* might have a complicated scheme like *abbaabbacdecde*. The second property concerns meter. Usually lines that rhyme have the same meter (i.e. the exact sequence of stressed and unstressed syllables). For example, an *iambic pentameter* is an *iamb* repeated 5 times, i.e. *0101010101*. We can describe a genre completely by its rhyming scheme and a meter for each letter used in the rhyming scheme. We will refer to this object as *genre description*. E.g. $\{abab, a : 010101, b : 10101010\}$ is a quatrain with trimeter iambic and tetrameter trochaic lines. Note that the other two kinds of poetry can also be fit by this structure, if one permits another symbol (we use *) to stand for the syllables whose stress is not important, e.g. a *haiku*: $\{abc, a : *****, b : *******, c : *****\}$. For this type of genre, we need to obey the same two constraints as in the line-based poetry, but also to ensure that rhyming constraints hold. This requires us to include in a state, for any outstanding rhyme letter, the word that occurred at the end of that line. It is not sufficient to include just the syllable that must rhyme, because we wish to avoid self-rhymes (word rhyming with an identical word).

4 Stress pattern feature function

We will first discuss an easier special case, namely a feature function for blank verse, which we will refer to as *stress pattern* feature function. This feature function can be used for both phrase-based and hierarchical systems.

In addition to a statistical MT system (Och and Ney, 2004; Koehn et al., 2007), it is necessary to have the means to count the syllables in a word and to find out which ones are stressed. This can be done with a pronunciation module of a text-to-speech system, or a freely available pronunciation dictionary, such as CMUDict (Rudnicky, 2010). Out-of-vocabulary words can be treated as always imposing a high cost.

4.1 Stress pattern for a phrase-based system

In a phrase based system, the feature function state consists of the current hypothesis length modulo foot length. For a 2-syllable foot, it is either 0 or 1, for a 3-syllable foot, 0, 1, or 2. The proposed target phrase is converted into a stress pattern using the pronunciation module, and the desired stress pattern is left shifted by the current offset. The cost is the number of mismatches of the target phrase vs. the pattern. For example, if the desired pattern is *010*, current offset is 1, and the proposed new phrase has pattern *10011*, we shift the desired pattern by 1, obtaining *100* and extend it to length 5, obtaining *10010*, matching it against the proposal. There is one mismatch, at the fifth position, and we report a cost of 1. The new state is simply the old state plus phrase length, modulo foot length, 0 in this example.

4.2 Stress pattern for a hierarchical system

In a hierarchical system, we in general do not know how a partial hypothesis might be combined on the left. A hypothesis that is a perfect fit for pattern *010* would be horrible if it is placed at an offset that is not divisible by 3, and vice versa, an apparently bad hypothesis might be perfectly good if placed at such an offset. To solve this problem, we create states that track how well a partial hypothesis fits not only the desired pattern, but all patterns obtained by placing this pattern at any offset, and also the hypothesis length (modulo foot length, as usual). For instance, if we observe a pattern *10101*, we record the following state: {*length: 1, 01 cost: 5, 10 cost: 0*}. If we now combine this state with another, such as {*length: 0, 01 cost: 1, 10 cost: 0*}, we simply add the lengths, and combine the costs either of the same kind (if left state's length is even), or the opposite (if it is odd). In this instance we get {*length: 1, 01 cost: 5, 10 cost: 1*}. If both costs are greater than 0, we can subtract the minimum cost and immediately output it as cost: this is the unavoidable cost of this combination. For this example we get cost of 1, and a new state: {*length: 1, 01 cost: 4, 10 cost: 0*}. For the final state, we output the remaining cost for the pattern we desire. The approach is very similar for feet of length 3.

4.3 Stress pattern: Whatever fits

With a trivial modification we can output translations that can fit any one of the patterns, as long as we do not care which. The approach is identical for both hierarchical and phrase-based systems. We simply track all foot patterns (length 2 and length 3 are the only ones used in poetry) as in the above algorithm, taking care to combine the right pattern scores based on length offset. The length offset now has to be tracked modulo 2*3.

This feature function can now be used to translate arbitrary text into blank verse, picking whatever meter fits best. If no meters can fit completely, it will produce translations with the fewest violations (assuming the weight for this feature function is set high).

5 General poetic form feature function

In this section we discuss a framework for tracking any poetic genre, specified as a genre description object (Section 3.3 above). As in the case of the stress pattern function, we use a statistical MT system, which is now required to be phrase-based only. We also use a pronunciation dictionary, but in addition to tracking the number and stress of syllables, we must now be able to provide a function that classifies a pair of words as rhyming or non-rhyming. This is in itself a non-trivial task (Byrd and Chodorow, 1985), due to lack of a clear definition of what constitutes a rhyme. In fact rhyming is a continuum, from very strong rhymes to weak ones. We use a very weak definition which is limited to a single syllable: if the final syllables of both words have the same nucleus and coda[1], we say that the words rhyme. We accept this weak definition because we prefer to err on the side of over-generation and accept even really bad poetry.

5.1 Tracking the target length

The hardest constraint to track efficiently is the range of lengths of the resulting sentence. Phrase-based decoders use a limited-width beam as they build up possible translations. Once a hypothesis drops out of the beam, it cannot be recovered, since no backtracking is done. Therefore we cannot afford to explore a part of the hypothesis space which has no possible solutions for our constraints, we must be able to prune a hypothesis as soon as it leads us to such a subspace, otherwise we will end up on an unrecoverable garden path. To avoid this problem, we need to have a set of possible sentence lengths available at any point in the search, and to impose a high cost if the desired length is not in that set.

Computing this set exactly involves a standard dynamic programming sweep over the phrase lattice, including only uncovered source spans. If the maximum source phrase size is k, source sentence length is n and maximum target/source length ratio for a phrase is l (and therefore target sentence is limited to at most ln words), this sweep requires going over $O(n^2)$ source ranges, each of which can be produced in k ways, and tracking ln potential lengths in each, resulting in $O(n^3kl)$ algorithm. This is unacceptably slow to be done for each hypothesis (even noting that hypotheses with the same set of already covered source position can share this computation).

We will therefore solve this task approximately. First, we can note that in most cases the set of possible target lengths is a range. This is due to phrase extraction constraints, which normally ensure that the lengths of target phrases form a complete range. This means that it is sufficient to track only a minimum and maximum value for each range, reducing time to $O(n^2k)$. Second, we can note that whenever a source range is interrupted by a covered phrase and split into two ranges, the minimal and maximal sentence length is simply the sum of the corresponding lengths over the two uncovered subranges, plus the current hypothesis length. Therefore, if we precompute the minimum and maximum lengths over all ranges, using the same dynamic programming algorithm in advance, it is only necessary to iterate over the uncovered ranges (at most $O(n)$, and $O(1)$ in practice, due to reordering constraints) at runtime and sum their minimum and maximum values. As a result, we only need to do $O(n^2k)$ work upfront, and on average $O(1)$ extra work for each hypothesis.

5.2 State space

A state for the feature function must contain the following elements:

- Current sentence length (in syllables)

[1] In phonology, nucleus and coda together are in fact called *rhyme* or *rime*

- Set of uncovered ranges (as needed for the computation above)

- Zero or more letters from the rhyming scheme with the associated word that has an outstanding rhyme

5.3 The combination algorithm

To combine the hypothesis state s_{in} with a phrase pair p, do the following

1. Initialize cost as 0, s_{out} as s_{in}

2. Update s_{out}: increment sentence length by target phrase length (in syllables), update coverage range

3. Compute minimum and maximum achievable sentence length; if desired length not in range, increment cost by a penalty

4. For each word in the target phrase

   (a) If the word's syllable pattern does not match against desired pattern, add number of mismatches to cost

   (b) If at the end of a line:

      i. If the line would end mid-word, increment cost by a penalty

      ii. Let x be this line's rhyme scheme letter

      iii. If x is present in the state s_{out}, check if the word associated with x rhymes with the current word, if not, increment cost by a penalty

      iv. Remove x with associated word from the state s_{out}

      v. If letter x occurs further in the rhyming scheme, add x with the current word to the state s_{out}

5.4 Tracking multiple patterns

The above algorithm will allow to efficiently search the hypothesis space for a single *genre description* object. In practice, however, there may be several desirable patterns, any one of which would be acceptable. A naive approach, to use multiple feature functions, one with each pattern, does not work, since the decoder is using a (log-)linear model, in which costs are additive. As a result, a pattern that matches one pattern, but not another, will still have high cost, perhaps as high as a pattern that partially matches both. We need to combine feature functions not linearly, but with a *min* operator. This is easily achieved by creating a combined state that encodes the union of each individual function's states (which can share most of the information), and in addition each feature function's current total cost. As long as at least one function has zero cost (i.e. can potentially match), no cost is reported to the decoder. As soon as all costs become positive, the minimum over all costs is reported to the decoder as unavoidable cost, and should be subtracted from each feature function cost, bringing the minimum stored in the output state back to 0.

It is also possible to prune the set of functions that are still viable, based on their cost, to avoid keeping track of patterns that cannot possibly match. Using this approach we can translate arbitrary text, provide a large number of poetic patterns and expect to get some sort of poem at the end. Given a wide variety of poetic genres, it is not unreasonable to expect that for most inputs, some pattern will apply. Of course, for translating actual poetry, we would likely have a specific form in mind, and a positive outcome would be less likely.

6 Results

We train a baseline phrase-based French-English system using WMT-09 corpora (Callison-Burch et al., 2009) for training and evaluation. We use a proprietary pronunciation module to provide phonetic representation of English words.

6.1 Stress Pattern Feature Function

We have no objective means of "poetic" quality evaluation. We are instead interested in two metrics: percentage of sentences that can be translated while obeying a stress pattern constraint, and the impact of this constraint on BLEU score (Papineni et al., 2002). Obviously, WMT test set is not itself in any way poetic, so we use it merely to see if arbitrary text can be forced into this constraint.

The BLEU score impact on WMT has been fairly consistent during our experimentation: the BLEU score is roughly halved. In particular, for the above system the baseline score is **35.33**, and stress

Table 1: Stress pattern distribution

Name	Pattern	% of matches
Iamb	01	9.6%
Trochee	10	7.2%
Anapest	001	27.1%
Amphibrach	010	32.1%
Dactyl	100	23.8%

pattern-constrained system only obtains **18.93**.

The proportion of sentences successfully matched is **85%**, and if we permit a single stress error, it is **93%**, which suggests that the constraint can be satisfied in the great majority of cases. The distribution of stress patterns among the perfect matches is given in Table 1.

Some of the more interesting example translations with stress pattern enforcement enabled are given in table 2.

6.2 Poetic Form Feature Function

For poetic form feature function, we perform the same evaluation as above, to estimate the impact of forcing prose into an arbitrary poetic form, but to get more relevant results we also translate a poetic work with a specific genre requirement.

Our poetic form feature function is given a list of some 210 genre descriptions which vary from Haikus to Shakespearean sonnets. Matching any one of them satisfies the constraint. We translate WMT blind set and obtain a BLEU score of **17.28** with the baseline of **35.33** as above. The proportion of sentences that satisfied one of the poetic constraints is **87%**. The distribution of matched genres is given in Table 3. Some of the more interesting example translations are given in table 2.

For a proper poetic evaluation, we use a French translation of Oscar Wilde's *Ballad of Reading Gaol* by Jean Guiloineau as input, and the original Wilde's text as reference. The poem consists of 109 stanzas of 6 lines each, with a genre description of {*abcbdb, a/c/d: 01010101, b: 010101*}. The French version obeys the same constraint. We treat each stanza as a sentence to be translated. The baseline BLEU score is **10.27**. This baseline score is quite low, as can be expected for matching a literal MT translation against a professional poetical translation. We evaluate our system with a poetic constraint given above.

Table 3: Genre distribution for WMT corpus.
(Descriptions of these genres can be found in Wikipedia, http://en.wikipedia.org)

Genre	Number	Percentage
No poem	809	13.1%
Blank verse	5107	82.7%
Couplet	81	1.3%
Haiku	42	0.7%
Cinquain	33	0.5%
Dodoitsu	24	0.4%
Quinzaine	23	0.4%
Choka	18	0.3%
Fib	15	0.2%
Tanka	14	0.2%
Lanterne	4	0.1%
Triplet	1	0.02%
Quatrain	1	0.02%
Total	6172	100%

The resulting score is **7.28**. Out of 109 stanzas, we found 12 translations that satisfy the genre constraint (If we allow any poetic form, 108 out of 109 stanzas match some form). Two sample stanzas that satisfied the constraints are given in Table 4.

7 Discussion and Future Work

In this work we demonstrate how modern-day statistical MT system can be constrained to search for translations obeying particular length, meter, and rhyming constraints, whether a single constraint, or any one of a set. We further demonstrate that the hypothesis space is often rich enough that these constraints can be satisfied. The impact on translation quality, however, is quite profound, as is to be expected. It seems that at the present state of machine translation, one does indeed have to choose between getting either the form or the meaning right. In the present form, however, we can already find good translations, as a sort of *found poetry* (Drury, 2006), by translating a large quantity of text, whether poetic or not.

This is the first attempt to deal with poetry translation, and the great majority of work to achieve reasonable quality in form and meaning still remains to be done. One major problem with the current feature function is that while it can avoid the areas of the search space where length constraints cannot be

Table 4: Sample translations from Oscar Wilde's *Ballad of Reading Gaol*.

Wilde's original	**Our translation**
He did not wring his hands, as do	Without hands twisted like these men,
Those witless men who dare	Poor men without hope, dare
To try to rear the changeling Hope	To nourish hope in our vault
In the cave of black Despair:	Of desperation there
He only looked upon the sun,	And looked toward the sun, drink cool
And drank the morning air.	Until the evening air.
With slouch and swing around the ring	We are in our circle we
We trod the Fool's Parade!	Dragged like the Fools' Parade!
We did not care: we knew we were	It mattered little, since we were
The Devil's Own Brigade:	The Devil's sad Brigade:
And shaven head and feet of lead	A shaved head and the feet of lead
Make a merry masquerade.	Regardless gay charade!

satisfied, it cannot avoid the areas where rhyming constraints are impossible to satisfy. As a result, we need to allow a very wide hypothesis beam (5000 per each source phrase coverage), to ensure that enough hypotheses are considered, so that there are some that lead to correct solutions later. We do not currently have a way to ensure that this happens, although we can attempt to constrain the words that end lines to have possible rhymes, or employ other heuristics. A more radical solution is to create an entirely different decoding algorithm which places words not left-to-right, or in a hierarchical fashion, but first placing words that must rhyme, and building hypotheses around them, like human translators of poetry do.

As a result, the system at present is too slow, and we cannot make it available online as a demo, although we may be able to do so in the future.

The current approach relies on having enough lexical variety in the phrase table to satisfy constraints. Since our goal is not to be literal, but to obtain a satisfactory compromise between form and meaning, it would clearly be beneficial to augment target phrases with synonyms and paraphrases, or to allow for words to be dropped or added.

Abstract

We describe a new scalable algorithm for semi-supervised training of conditional random fields (CRF) and its application to part-of-speech (POS) tagging. The algorithm uses a similarity graph to encourage similar n-grams to have similar POS tags. We demonstrate the efficacy of our approach on a domain adaptation task, where we assume that we have access to large amounts of unlabeled data from the target domain, but no additional labeled data. The similarity graph is used during training to smooth the state posteriors on the target domain. Standard inference can be used at test time. Our approach is able to scale to very large problems and yields significantly improved target domain accuracy.

1 Introduction

Semi-supervised learning (SSL) is the use of small amounts of labeled data with relatively large amounts of unlabeled data to train predictors. In some cases, the labeled data can be sufficient to provide reasonable accuracy on in-domain data, but performance on even closely related out-of-domain data may lag far behind. Annotating training data for all sub-domains of a varied domain such as all of Web text is impractical, giving impetus to the development of SSL techniques that can learn from unlabeled data to perform well across domains. The earliest SSL algorithm is self-training (Scudder, 1965), where one makes use of a previously trained model to annotate unlabeled data which is then used to re-train the model. While self-training is widely used and can yield good results in some applications (Yarowsky, 1995), it has no theoretical guarantees except under certain stringent conditions, which rarely hold in practice(Haffari and Sarkar, 2007).

Other SSL methods include co-training (Blum and Mitchell, 1998), transductive support vector machines (SVMs) (Joachims, 1999), and graph-based SSL (Zhu et al., 2003). Several surveys cover a broad range of methods (Seeger, 2000; Zhu, 2005; Chapelle et al., 2007; Blitzer and Zhu, 2008). A majority of SSL algorithms are computationally expensive; for example, solving a transductive SVM exactly is intractable. Thus we have a conflict between wanting to use SSL with large unlabeled data sets for best accuracy, but being unable to do so because of computational complexity. Some researchers attempted to resolve this conflict by resorting to approximations (Collobert et al., 2006), but those lead to suboptimal results (Chapelle et al., 2007).

Graph-based SSL algorithms (Zhu et al., 2003; Joachims, 2003; Corduneanu and Jaakkola, 2003; Belkin et al., 2005; Subramanya and Bilmes, 2009) are an important subclass of SSL techniques that have received much attention in the recent past, as they outperform other approaches and also scale easily to large problems. Here one assumes that the data (both labeled and unlabeled) is represented by vertices in a graph. Graph edges link vertices that are likely to have the same label. Edge weights govern how strongly the labels of the nodes linked by the edge should agree.

Most previous work in SSL has focused on unstructured classification problems, that is, problems with a relatively small set of atomic labels. There

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 167–176,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

has been much less work on SSL for structured prediction where labels are composites of many atomic labels with constraints between them. While the number of atomic labels might be small, there will generally be exponentially many ways to combine them into the final structured label. Structured prediction problems over sequences appear for example in speech recognition, named-entity recognition, and part-of-speech tagging; in machine translation and syntactic parsing, the output may be tree-structured.

Altun et al. (2005) proposed a max-margin objective for semi-supervised learning over structured spaces. Their objective is similar to that of manifold regularization (Belkin et al., 2005) and they make use of a graph as a smoothness regularizer. However their solution involves inverting a matrix whose size depends on problem size, making it impractical for very large problems. Brefeld and Scheffer (2006) present a modified version of the co-training algorithm for structured output spaces. In both of the above cases, the underlying model is based on structured SVM, which does not scale well to very large datasets. More recently Wang et al. (2009) proposed to train a conditional random field (CRF) (Lafferty et al., 2001) using an entropy-based regularizer. Their approach is similar to the entropy minimization algorithm (Grandvalet and Bengio, 2005). The problem here is that their objective is not convex and thus can pose issues for large problems. Further, graph-based SSL algorithms outperform algorithms based on entropy minimization (Chapelle et al., 2007).

In this work, we propose a graph-based SSL method for CRFs that is computationally practical for very large problems, unlike the methods in the studies cited above. Our method is scalable because it trains with efficient standard building blocks for CRF inference and learning and also standard graph label propagation machinery. Graph regularizer computations are only used for training, so at test time, standard CRF inference can be used, unlike in graph-based transductive methods. Briefly, our approach starts by training a CRF on the source domain labeled data, and then uses it to decode unlabeled data from the target domain. The state posteriors on the target domain are then smoothed using the graph regularizer. Best state sequences for the unlabeled target data are then created by Viterbi decoding with the smoothed state posteriors, and this automatic target domain annotation is combined with the labeled source domain data to retrain the CRF.

We demonstrate our new method in domain adaptation for a CRF part-of-speech (POS) tagger. While POS tagging accuracies have reached the level of inter-annotator agreement (>97%) on the standard PennTreebank test set (Toutanova et al., 2003; Shen et al., 2007), performance on out-of-domain data is often well below 90%, impairing language processing tasks that need syntactic information. For example, on the question domain used in this paper, the tagging accuracy of a supervised CRF is only 84%. Our domain adaptation algorithm improves performance to 87%, which is still far below in-domain performance, but a significant reduction in error.

2 Supervised CRF

We assume that we have a set of labeled source domain examples $\mathcal{D}_l = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{l}$, but only unlabeled target domain examples $\mathcal{D}_u = \{\mathbf{x}_i\}_{i=l+1}^{l+u}$. Here $\mathbf{x}_i = x_i^{(1)} x_i^{(2)} \cdots x_i^{(|\mathbf{x}_i|)}$ is the sequence of words in sentence i and $\mathbf{y}_i = y_i^{(1)} y_i^{(2)} \cdots y_i^{(|\mathbf{x}_i|)}$ is the corresponding POS tag sequence, with $y_i^{(j)} \in \mathcal{Y}$ where $\mathcal{Y}$ is the set of POS tags. Our goal is to learn a CRF of the form:

$$\mathrm{p}(\mathbf{y}_i|\mathbf{x}_i;\Lambda) \propto \exp\left(\sum_{j=1}^{N_i}\sum_{k=1}^{K}\lambda_k f_k(y_i^{(j-1)}, y_i^{(j)}, \mathbf{x}_i, j)\right)$$

for the target domain. In the above equation, $\Lambda = \{\lambda_1, \ldots, \lambda_K\} \in \mathbb{R}^K$, $f_k(y_i^{(j-1)}, y_i^{(j)}, \mathbf{x}_i, j)$ is the k-th feature function applied to two consecutive CRF states and some window of the input sequence, and λ_k is the weight of that feature. We discuss our features in detail in Section 6. Given only labeled data $\mathcal{D}_l$, the optimal feature weights are given by:

$$\Lambda^* = \underset{\Lambda \in \mathbb{R}^K}{\mathrm{argmin}} \left[-\sum_{i=1}^{l} \log \mathrm{p}(\mathbf{y}_i|\mathbf{x}_i;\Lambda) + \gamma\|\Lambda\|^2\right] \quad (1)$$

Here $\|\Lambda\|^2$ is the squared ℓ_2-norm and acts as the regularizer, and γ is a trade-off parameter whose setting we discuss in Section 6. In our case, we also have access to the unlabeled data $\mathcal{D}_u$ from the target domain which we would like to use for training the CRF. We first describe how we construct a similarity graph over the unlabeled which will be used in our algorithm as a graph regularizer.

3 Graph Construction

Graph construction is the most important step in graph-based SSL. The standard approach for unstructured problems is to construct a graph whose vertices are labeled and unlabeled examples, and whose weighted edges encode the degree to which the examples they link should have the same label (Zhu et al., 2003). Then the main graph construction choice is what similarity function to use for the weighted edges between examples. However, in structured problems the situation is more complicated. Consider the case of sequence tagging we are studying. While we might be able to choose some appropriate sequence similarity to construct the graph, such as edit distance or a string kernel, it is not clear how to use whole sequence similarity to constrain whole tag sequences assigned to linked examples in the learning algorithm. Altun et al. (2005) had the nice insight of doing the graph construction not for complete structured examples but instead for the *parts* of structured examples (also known as factors in graphical model terminology), which encode the local dependencies between input data and output labels in the structured problem. However, their approach is too demanding computationally (see Section 5), so instead we use local sequence contexts as graph vertices, exploting the empirical observation that the part of speech of a word occurrence is mostly determined by its local context.

Specifically, the set V of graph vertices consists of all the word n-grams[1] (*types*) that have occurrences (*tokens*) in training sentences (labeled and unlabeled). We partition $V = V_l \cup V_u$ where V_l corresponds to n-grams that occur at least once in the labeled data, and V_u corresponds to n-grams that occur only in the unlabeled data.

Given a symmetric similarity function between types to be defined below, we link types u and v with an edge of weight w_{uv}, defined as:

Description	Feature
Trigram + Context	$x_1\ x_2\ x_3\ x_4\ x_5$
Trigram	$x_2\ x_3\ x_4$
Left Context	$x_1\ x_2$
Right Context	$x_4\ x_5$
Center Word	x_2
Trigram – Center Word	$x_2\ x_4$
Left Word + Right Context	$x_2\ x_4\ x_5$
Left Context + Right Word	$x_1\ x_2\ x_4$
Suffix	HasSuffix(x_3)

Table 1: Features we extract given a sequence of words "$x_1\ x_2\ x_3\ x_4\ x_5$" where the trigram is "$x_2\ x_3\ x_4$".

$$w_{uv} = \begin{cases} \mathrm{sim}(u,v) & \text{if } v \in \mathcal{K}(u) \text{ or } u \in \mathcal{K}(v) \\ 0 & \text{otherwise} \end{cases}$$

where $\mathcal{K}(u)$ is the set of k-nearest neighbors of u according to the given similarity. For all experiments in this paper, $n = 3$ and $k = 5$.

To define the similarity function, for each token of a given type in the labeled and unlabeled data, we extract a set of context features. For example, for the token $x_2\ x_3\ x_4$ occurring in the sequence $x_1\ x_2\ x_3\ x_4\ x_5$, we use feature templates that capture the left ($x_1\ x_2$) and right contexts ($x_4\ x_5$). Additionally, we extract suffix features from the word in the middle. Table 1 gives an overview of the features that we used. For each n-gram type, we compute the vector of pointwise mutual information (PMI) values between the type and each of the features that occur with tokens of that type. Finally, we use the cosine distance between those PMI vectors as our similarity function.

We have thus circumvented the problem of defining similarities over sequences by defining the graph over types that represent local sequence contexts. Since our CRF tagger only uses local features of the input to score tag pairs, we believe that the graph we construct captures all significant context information. Figure 1 shows an excerpt from our graph. The figure shows the neighborhoods of a subset of the vertices with the center word 'book.' To reduce clutter, we included only closest neighbors and the edges that involve the nodes of interest.

[1] We pad the n-grams at the beginning and end of sentences with appropriate dummy symbols.

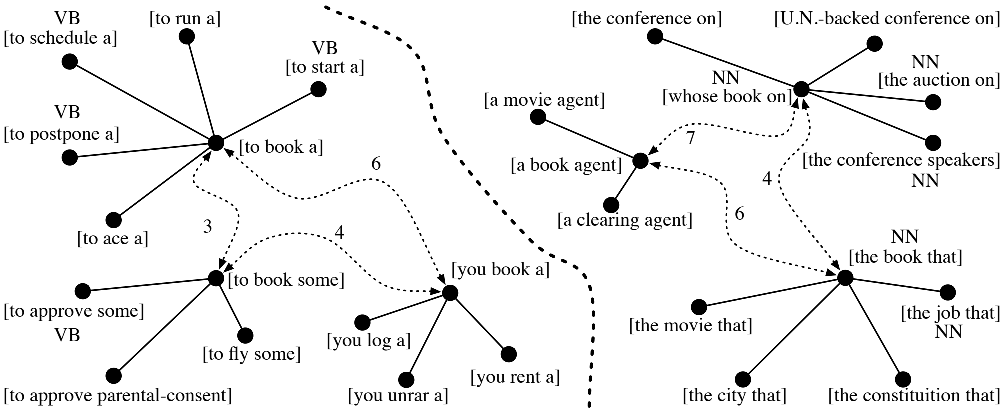

Figure 1: Vertices with center word 'book' and their local neighborhoods, as well as the shortest-path distance between them. Note that the noun (NN) and verb (VB) interpretations form two disjoint connected components.

It is remarkable that the neighborhoods are coherent, showing very similar syntactic configurations. Furthermore, different vertices that (should) have the same label are close to each other, forming connected components for each part-of-speech category (for nouns and verbs in the figure). We expect the similarity graph to provide information that cannot be expressed directly in a sequence model. In particular, it is not possible in a CRF to directly enforce the constraint that similar trigrams appearing in different sentences should have similar POS tags. This constraint however is important during (semi-supervised) learning, and is what makes our approach different and more effective than self-training.

In practice, we expect two main benefits from our graph-based approach. First, the graph allows new features to be discovered. Many words occur only in the unlabeled data and a purely supervised CRF would not be able to learn feature weights for those observations. We could use self-training to learn weights for those features, but self-training just tends to reinforce the knowledge that the supervised model already has. The similarity graph on the other hand can link events that occur only in the unlabeled data to similar events in the labeled data. Furthermore, because the graph is built over types rather than tokens, it will encourage the same interpretation to be chosen for similar trigrams occurring in different sentences. For example, the word 'unrar' will most likely not occur in the labeled training data. Seeing it in the neighborhood of words for which we know the POS tag will help us learn the correct POS tag for this otherwise unknown word (see Figure 1).

Second, the graph propagates adjustments to the weights of known features. Many words occur only a handful of times in our labeled data, resulting in poor estimates of their contributions. Even for frequently occurring events, their distribution in the target domain might be different from their distribution in the source domain. While self-training might be able to help adapt to such domain changes, its effectiveness will be limited because the model will always be inherently biased towards the source domain. In contrast, labeled vertices in the similarity graph can help disambiguate ambiguous contexts and correct (some of) the errors of the supervised model.

4 Semi-Supervised CRF

Given unlabeled data $\mathcal{D}_u$, we only have access to the prior $p(\mathbf{x})$. As the CRF is a discriminative model, the lack of label information renders the CRF weights independent of $p(\mathbf{x})$ and thus we cannot directly utilize the unlabeled data when training the CRF. Therefore, semi-supervised approaches to training discriminative models typically use the unlabeled data to construct a regularizer that is used to guide the learning process (Joachims, 1999; Lawrence and Jordan, 2005). Here we use the graph as a smoothness regularizer to train CRFs in a semi-supervised manner.

Our algorithm iterates between the following five

Algorithm 1 Semi-Supervised CRF Training

```
$\Lambda^s$ = crf-train($\mathcal{D}_l$, $\Lambda^0$)
Set $\Lambda_0^{(t)} = \Lambda^{(s)}$
while not converged do
    $\{\mathrm{p}\}$ = posterior_decode($\mathcal{D}_u$, $\Lambda_{old}$)
    $\{\mathrm{q}\}$ = token_to_type($\{\mathrm{p}\}$)
    $\{\hat{\mathrm{q}}\}$ = graph_propagate($\{\mathrm{q}\}$)
    $\mathcal{D}_u^{(1)}$ = viterbi_decode($\{\hat{\mathrm{q}}\}$, $\Lambda_{old}$)
    $\Lambda_{n+1}^{(t)}$ = crf-train($\mathcal{D}_l \cup \mathcal{D}_u^{(1)}$, $\Lambda_n^{(t)}$)
end while
Return last $\Lambda^{(t)}$
```

simple (and convex) steps: Given a set of CRF parameters, we first compute marginals over the unlabeled data (posterior_decode). The marginals over tokens are then aggregated to marginals over types (token_to_type), which are used to initialize the graph label distributions. After running label propagation (graph_propagate), the posteriors from the graph are used to smooth the state posteriors. Decoding the unlabeled data (viterbi_decode) produces a new set of automatic annotations that can be combined with the labeled data to retrain the CRF using the supervised CRF training objective (crf-train). These steps, summarized in Algorithm 1, are iterated until convergence.

4.1 Posterior Decoding

Let $\Lambda_n^{(t)}$ (t refers to target domain) represent the estimate of the CRF parameters for the target domain after the n-th iteration.[2] In this step, we use the current parameter estimates to compute the marginal probabilities

$$\mathrm{p}(y_i^{(j)}|\mathbf{x}_i;\Lambda_n^{(t)})\ 1 \le j \le |\mathbf{x}_i|, i \in \mathcal{D}_l$$

over POS tags for every word position j for i indexing over sentences in $\mathcal{D}_l \cup \mathcal{D}_u$.

4.2 Token-to-Type Mapping

Recall that our graph is defined over types while the posteriors computed above involve particular tokens. We accumulate token-based marginals to create type marginals as follows. For a sentence i and word position j in that sentence, let $T(i,j)$ be the trigram (graph node) centered at position j. Conversely, for a trigram type u, let $T^{-1}(u)$ be the set of actual occurrences (tokens) of that trigram u; that is, all pairs (i,j) where i is the index of a sentence where u occurs and j is the position of the center word of an occurrence of u in that sentence. We calculate type-level posteriors as follows:

$$\mathrm{q}_u(y) \triangleq \frac{1}{|T^{-1}(u)|} \sum_{(i,j)\in T^{-1}(u)} \mathrm{p}(y_i^{(j)}|\mathbf{x}_i;\Lambda_n^{(t)}) \quad .$$

This combination rule connects the token-centered CRF with the type-centered graph. Other ways of combining the token marginals, such as using weights derived from the entropies of marginals, might be worth investigating.

4.3 Graph Propagation

We now use our similarity graph (Section 3) to smooth the type-level marginals by minimizing the following convex objective:

$$\begin{aligned} \mathcal{C}(\mathrm{q}) &= \sum_{u\in V_l} \|\mathrm{r}_u - \mathrm{q}_u\|^2 \\ &+ \mu \sum_{u\in V, v\in\mathcal{N}(i)} w_{uv}\|\mathrm{q}_u - \mathrm{q}_v\|^2 + \nu \sum_{u\in V} \|\mathrm{q}_u - U\|^2 \\ \text{s.t.} & \sum_y \mathrm{q}_u(y) = 1\ \forall u\ \&\ \mathrm{q}_u(y) \ge 0\ \forall u, y \end{aligned} \qquad (2)$$

where $\mathrm{q} = \{\mathrm{q}_1, \mathrm{q}_2, \ldots \mathrm{q}_{|V|}\}$. The setting of the hyperparameters μ and ν will be discussed in Section 6, $\mathcal{N}(u)$ is the set of neighbors of node u, and r_u is the empirical marginal label distribution for trigram u in the labeled data. We use a squared loss to penalize neighboring nodes that have different label distributions: $\|\mathrm{q}_u - \mathrm{q}_v\|^2 = \sum_y(\mathrm{q}_u(y) - \mathrm{q}_v(y))^2$, additionally regularizing the label distributions towards the uniform distribution U over all possible labels $\mathcal{Y}$. It can be shown that the above objective is convex in q.

Our graph propagation objective can be seen as a multi-class generalization of the quadratic cost criterion (Bengio et al., 2007). The first term in the above objective requires that we respect the information in our labeled data. The second term is the graph smoothness regularizer which requires that the q_i's be smooth with respect to the graph. In other words, if w_{uv} is large, then q_u and q_v should be close in the

[2] In the first iteration, we initialize the target domain parameters to the source domain parameters: $\Lambda_0^{(t)} = \Lambda^{(s)}$.

squared-error sense. This implies that vertices u and v are likely to have similar marginals over POS tags. The last term is a regularizer and encourages all type marginals to be uniform to the extent that is allowed by the first two terms. If a unlabeled vertex does not have a path to any labeled vertex, this term ensures that the converged marginal for this vertex will be uniform over all tags, ensuring that our algorithm performs at least as well as a standard self-training based algorithm, as we will see later.

While the objective in Equation 2 admits a closed form solution, it involves inverting a matrix of order $|V|$ and thus we use instead the simple iterative update given by

$$\begin{aligned} q_u^{(m)}(y) &= \frac{\gamma_u(y)}{\kappa_u} \text{ where} \\ \gamma_u(y) &= r_u(y)\delta(u \in V_l) \\ &\quad + \sum_{v \in \mathcal{N}(u)} w_{uv} q_v^{(m-1)}(y) + \nu U(y), \\ \kappa_u &= \delta(u \in V_l) + \nu + \mu \sum_{v \in \mathcal{N}(u)} w_{uv} \end{aligned} \quad (3)$$

where m is the iteration index and δ is the indicator function that returns 1 if and only if the condition is true. The iterative procedure starts with $\mathrm{q}_u^{(0)}(y) = \mathrm{q}_u(y)$ as given in the previous section. In all our experiments we run 10 iterations of the above algorithm, and we denote the type marginals at completion by $\mathrm{q}_u^*(y)$.

4.4 Viterbi Decoding

Given the type marginals computed in the previous step, we interpolate them with the original CRF token marginals. This interpolation between type and token marginals encourages similar n-grams to have similar posteriors, while still allowing n-grams in different sentences to differ in their posteriors. For each unlabeled sentence i and word position j in it, we calculate the following interpolated tag marginal:

$$\begin{aligned} \hat{\mathrm{p}}(y_i^{(j)} = y|\mathbf{x}_i) = \alpha \mathrm{p}(y_i^{(j)} = y|\mathbf{x}_i; \Lambda_n^{(t)}) \\ + (1-\alpha)\mathrm{q}^*_{T(m,n)}(y) \end{aligned} \quad (4)$$

where α is a mixing coefficient which reflects the relative confidence between the original posteriors from the CRF and the smoothed posteriors from the graph. We discuss how we set α in Section 6.

The interpolated marginals summarize all the information obtained so far about the tag distribution at each position. However, if we were to use them on their own to select the most likely POS tag sequence, the first-order tag dependencies modeled by the CRF would be mostly ignored. This happens because the type marginals obtained from the graph after label propagation will have lost most of the sequence information. To enforce the first-order tag dependencies we therefore use Viterbi decoding over the combined interpolated marginals and the CRF transition potentials to compute the best POS tag sequence for each unlabeled sentence. We refer to these 1-best transcripts as $\mathbf{y}_i^*,\ i \in \mathcal{D}_u$.

4.5 Re-training the CRF

Now that we have successfully labeled the unlabeled target domain data, we can use it in conjunction with the source domain labeled data to re-train the CRF:

$$\begin{aligned} \Lambda_{n+1}^{(t)} = &\underset{\Lambda \in \mathbb{R}^K}{\text{argmin}} \Bigg[-\sum_{i=1}^{l} \log \mathrm{p}(\mathbf{y}_i|\mathbf{x}_i; \Lambda_n^{(t)}) \\ &- \eta \sum_{i=l+1}^{l+u} \log \mathrm{p}(\mathbf{y}_i^*|\mathbf{x}_i; \Lambda_n^{(t)}) + \gamma \|\Lambda\|^2 \Bigg] \end{aligned} \quad (5)$$

where η and γ are hyper-parameters whose setting we discuss in Section 6. Given the new CRF parameters Λ we loop back to step 1 (Section 4.1) and iterate until convergence. It is important to note that every step of our algorithm is convex, although their combination clearly is not.

5 Related Work

Our work differs from previous studies of SSL (Blitzer et al., 2006; III, 2007; Huang and Yates, 2009) for improving POS tagging in several ways. First, our algorithm can be generalized to other structured semi-supervised learning problems, although POS tagging is our motivating task and test application. Unlike III (2007), we do not require target domain labeled data. While the SCL algorithm (Blitzer et al., 2006) has been evaluated without target domain labeled data, that evaluation was to some extent transductive in that the target test data (unlabeled) was included in the unsupervised stage of SCL training that creates the structural correspondence between the two domains.

We mentioned already the algorithm of Altun et al. (2005), which is unlikely to scale up because its dual formulation requires the inversion of a matrix whose size depends on the graph size. Gupta et al. (2009) also constrain similar trigrams to have similar POS tags by forming cliques of similar trigrams and maximizing the agreement score over these cliques. Computing clique agreement potentials however is NP-hard and so they propose approximation algorithms that are still quite complex computationally. We achieve similar effects by using our simple, scalable convex graph regularization framework. Further, unlike other graph-propagation algorithms (Alexandrescu and Kirchhoff, 2009), our approach is inductive. While one might be able to make inductive extensions of transductive approaches (Sindhwani et al., 2005), these usually require extensive computational resources at test time.

6 Experiments and Results

We use the Wall Street Journal (WSJ) section of the Penn Treebank as our labeled source domain training set. We follow standard setup procedures for this task and train on sections 00-18, comprising of 38,219 POS-tagged sentences with a total of 912,344 words. To evaluate our domain-adaptation approach, we consider two different target domains: questions and biomedical data. Both target domains are relatively far from the source domain (newswire), making this a very challenging task.

The QuestionBank (Judge et al., 2006), provides an excellent corpus consisting of 4,000 questions that were manually annotated with POS tags and parse trees. We used the first half as our development set and the second half as our test set. Questions are difficult to tag with WSJ-trained taggers primarily because the word order is very different than that of the mostly declarative sentences in the training data. Additionally, the unknown word rate is more than twice as high as on the in-domain development set (7.29% vs. 3.39%). As our unlabeled data, we use a set of 10 million questions collected from anonymized Internet search queries. These queries were selected to be similar in style and length to the questions in the QuestionBank.[3] As running the CRF over 10 million sentences can be rather cumbersome and probably unnecessary, we randomly select 100,000 of these queries and treat this as $\mathcal{D}_u$. Because the graph nodes and the features used in the similarity function are based on n-grams, data sparsity can be a serious problem, and we therefore use the entire unlabeled data set for graph construction. We estimate the mutual information-based features for each trigram type over all the 10 million questions, and then construct the graph over only the set of trigram types that actually occurs in the 100,000 random subset and the WSJ training set.

For our second target domain, we use the Penn BioTreebank (PennBioIE, 2005). This corpus consists of 1,061 sentences that have been manually annotated with POS tags. We used the first 500 sentences as a development set and the remaining 561 sentences as our final test set. The high unknown word rate (23.27%) makes this corpus very difficult to tag. Furthermore, the POS tag set for this data is a super-set of the Penn Treebank's, including the two new tags HYPH (for hyphens) and AFX (for common post-modifiers of biomedical entities such as genes). These tags were introduced due to the importance of hyphenated entities in biomedical text, and are used for 1.8% of the words in the test set. Any tagger trained only on WSJ text will automatically predict wrong tags for those words. For unlabeled data we used 100,000 sentences that were chosen by searching MEDLINE for abstracts pertaining to cancer, in particular genomic variations and mutations (Blitzer et al., 2006). Since we did not have access to additional unlabeled data, we used the same set of sentences as target domain unlabeled data, $\mathcal{D}_u$. The graph here was constructed over the 100,000 unlabeled sentences and the WSJ training set. Finally, we remind the reader that we did not use label information for graph construction in either corpus.

6.1 Baselines

Our baseline supervised CRF is competitive with state-of-the-art discriminative POS taggers (Toutanova et al., 2003; Shen et al., 2007), achieving 97.17% on the WSJ development set (sections 19-21). We use a fairly standard set of features, including word identity, suffixes and prefixes and detectors

[3] In particular, we selected queries that start with an English function word that can be used to start a question (what, who, when, etc.), and have between 30 and 160 characters.

	Questions		Bio	
	Dev	Eval	Dev	Eval
Supervised CRF	84.8	83.8	86.5	86.2
Self-trained CRF	85.4	84.0	87.5	87.1
Semi-supervised CRF	**87.6**	**86.8**	**87.5**	**87.6**

Table 2: Domain adaptation experiments. POS tagging accuracies in %.

for special characters such as dashes and digits. We do not use of observation-dependent transition features. Both supervised and semi-supervised models are regularized with a squared ℓ_2-norm regularizer with weight set to 0.01.

In addition to the supervised baseline trained exclusively on the WSJ, we also consider a semi-supervised self-trained baseline ("Self-trained CRF" in Table 2). In this approach, we first train a supervised CRF on the labeled data and then do semi-supervised training without label propagation. This is different from plain self-training because it aggregates the posteriors over tokens into posteriors over types. This aggregation step allows instances of the same trigram in different sentences to share information and works better in practice than direct self-training on the output of the supervised CRF.

6.2 Domain Adaptation Results

The data set obtained concatenating the WSJ training set with the 10 million questions had about 20 million trigram types. Of those, only about 1.1 million trigram types occurred in the WSJ training set or in the 100,000 sentence sub-sample. For the biomedical domain, the graph had about 2.2 million trigrams. For all our experiments we set hyperparameters as follows: for graph propagation, $\mu = 0.5$, $\nu = 0.01$, for Viterbi decoding mixing, $\alpha = 0.6$, for CRF re-training, $\eta = 0.001$, $\gamma = 0.01$. These parameters were chosen based on development set performance. All CRF objectives were optimized using L-BFGS (Bertsekas, 2004).

Table 2 shows the results for both domains. For the question corpus, the supervised CRF performs at only 85% on the development set. While it is almost impossible to improve in-domain tagging accuracy and tagging is therefore considered a solved problem by many, these results clearly show that the problem is far from solved. Self-training improves over the baseline by about 0.6% on the development set. However the gains from self-training are more modest (0.2%) on the evaluation (test) set. Our approach is able to provide a more solid improvement of about 3% absolute over the supervised baseline and about 2% absolute over the self-trained system on the question development set. Unlike self-training, on the question evaluation set, our approach provides about 3% absolute improvement over the supervised baseline. For the biomedical data, while the performances of our approach and self-training are statistically indistinguishable on the development set, we see modest gains of about 0.5% absolute on the evaluation set. On the same data, we see that our approach provides about 1.4% absolute improvement over the supervised baseline.

7 Analysis & Conclusion

The results suggest that our proposed approach provides higher gains relative to self-training on the question data than on the biomedical corpus. We hypothesize that this caused by sparsity in the graph generated from the biomedical dataset. For the questions graph, the PMI statistics were estimated over 10 million sentences while in the case of the biomedical dataset, the same statistics were computed over just 100,000 sentences. We hypothesize that the lack of well-estimated features in the case of the biomedical dataset leads to a sparse graph.

To verify the above hypothesis, we measured the percentage of trigrams that occur in the target domain (unlabeled) data that do not have any path to a trigram in the source domain data, and the average minimum path length between a trigram in the target data and a trigram in the source data (when such a path exists). The results are shown in Table 3. For the biomedical data, close to 50% of the trigrams from the target data do not have a path to a trigram from the source data. Even when such a path exists, the average path length is about 22. On

	Questions	Bio
% of unlabeled trigrams not connected to any labeled trigrams	12.4	46.8
average path length between an unlabeled trigram and its nearest labeled trigram	9.4	22.4

Table 3: Analysis of the graphs constructed for the two datasets discussed in Section 6. Unlabeled trigrams occur in the target domain only. Labeled trigrams occur at least once in the WSJ training data.

the other hand, for the question corpus, only about 12% of the target domain trigrams are disconnected, and the average path length is about 9. These results clearly show the sparse nature of the biomedical graph. We believe that it is this sparsity that causes the graph propagation to *not* have a more noticeable effect on the final performance. It is noteworthy that making use of even such a sparse graph does not lead to any degradation in results, which we attribute to the choice of graph-propagation regularizer (Section 4.3).

We presented a simple, scalable algorithm for training structured prediction models in a semi-supervised manner. The approach is based on using as a regularizer a nearest-neighbor graph constructed over trigram types. Our results show that the approach not only scales to large datasets but also produces significantly improved tagging accuracies.

Better Punctuation Prediction with Dynamic Conditional Random Fields

Abstract

This paper focuses on the task of inserting punctuation symbols into transcribed conversational speech texts, without relying on prosodic cues. We investigate limitations associated with previous methods, and propose a novel approach based on dynamic conditional random fields. Different from previous work, our proposed approach is designed to jointly perform both sentence boundary and sentence type prediction, and punctuation prediction on speech utterances.

We performed evaluations on a transcribed conversational speech domain consisting of both English and Chinese texts. Empirical results show that our method outperforms an approach based on linear-chain conditional random fields and other previous approaches.

1 Introduction

Outputs of standard automatic speech recognition (ASR) systems typically consist of utterances where important linguistic and structural information (e.g., true case, sentence boundaries, punctuation symbols, etc) is not available. Such information is crucial in improving the readability of the transcribed speech texts, and plays an important role when further processing is required, such as in part-of-speech (POS) tagging, parsing, information extraction, and machine translation.

We focus on the punctuation prediction task in this work. Most previous punctuation prediction techniques, developed mostly by the speech processing community, exploit both lexical and prosodic cues. However, in order to fully exploit prosodic features such as pitch and pause duration, it is necessary to have access to the original raw speech waveforms. In some scenarios where further natural language processing (NLP) tasks on the transcribed speech texts become the main concern, speech prosody information may not be readily available. For example, in the recent evaluation campaign of the International Workshop on Spoken Language Translation (IWSLT) (Paul, 2009), only manually transcribed or automatically recognized speech texts are provided but the original raw speech waveforms are not available.

In this paper, we tackle the task of predicting punctuation symbols from a standard text processing perspective, where only the speech texts are available, without relying on additional prosodic features such as pitch and pause duration. Specifically, we perform the punctuation prediction task on transcribed conversational speech texts, using the IWSLT corpus (Paul, 2009) as the evaluation data.

Different from many other corpora such as broadcast news corpora, a conversational speech corpus consists of dialogs where informal and short sentences frequently appear. In addition, due to the nature of conversation, it also contains more question sentences compared to other corpora. An example English utterance randomly selected from the IWSLT corpus, along with its punctuated and cased version, are shown below:

you are quite welcome and by the way we may get other reservations so could you please call us as soon as you fix the date

You are quite welcome . And by the way , we may get other reservations , so could you please call us as soon as you fix the date ?

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 177–186,
MIT, Massachusetts, USA, 9-11 October 2010.

The rest of this paper is organized as follows. We start with surveying related work in Section 2. One class of widely-used previous techniques is then studied in detail in Section 3. Next, we investigate methods for improving existing methods in Section 4 and 5. Empirical evaluation results are presented and discussed in Section 6. We finally conclude in Section 7.

2 Related Work

Punctuation prediction has been extensively studied in the speech processing field. It is also sometimes studied together with a closely related task – sentence boundary detection.

Much previous work assumes that both lexical and prosodic cues are available for the task. Kim and Woodland (2001) performed punctuation insertion during speech recognition. Prosodic features together with language model probabilities were used within a decision tree framework. Christensen et al. (2001) focused on the broadcast news domain and investigated both finite state and multi-layer perceptron methods for the task, where prosodic and lexical information was incorporated. Huang and Zweig (2002) presented a maximum entropy-based tagging approach to punctuation insertion in spontaneous English conversational speech, where both lexical and prosodic features were exploited. Liu et al. (2005) focused on the sentence boundary detection task, by making use of conditional random fields (CRF) (Lafferty et al., 2001). Their method was shown to improve over a previous method based on hidden Markov model (HMM).

There is relatively less work that exploited lexical features only. Beeferman et al. (1998) focused on comma prediction with a trigram language model. A joint language model was learned from punctuated texts, and commas were inserted so as to maximize the joint probability score. Recent work by Gravano et al. (2009) presented a purely n-gram based approach that jointly predicted punctuation and case information of English.

Stolcke et al. (1998) presented a "hidden event language model" that treated boundary detection and punctuation insertion as an interword hidden event detection task. Their proposed method was implemented in the handy utility *hidden-ngram* as part of the SRILM toolkit (Stolcke, 2002). It was widely used in many recent spoken language translation tasks as either a preprocessing (Wang et al., 2008) or postprocessing (Kirchhoff and Yang, 2007) step. More details about this model will be given in the next section.

Recently, there are also several research efforts that try to optimize some downstream application after punctuation prediction, rather than the prediction task itself. Examples of such downstream applications include punctuation prediction for part-of-speech (POS) tagging and name tagging (Hillard et al., 2006), statistical machine translation (Matusov et al., 2006), and information extraction (Favre et al., 2008).

3 Hidden Event Language Model

Many previous research efforts consider the boundary detection and punctuation insertion task as a hidden event detection task. One such well-known approach was introduced by Stolcke et al. (1998). They adopted a HMM to describe a joint distribution over words and interword events, where the observations are the words, and the word/event pairs are encoded as hidden states. Specifically, in this task word boundaries and punctuation symbols are encoded as interword events. The training phase involves training an n-gram language model over all observed words and events with smoothing techniques. The learned n-gram probability scores are then used as the HMM state-transition scores. During testing, the posterior probability of an event at each word is computed with dynamic programming using the forward-backward algorithm. The sequence of most probable states thus forms the output which gives the punctuated sentence.

Such a HMM-based approach has several drawbacks. First, the n-gram language model is only able to capture surrounding contextual information. However, we argue that in many cases, modeling of longer range dependencies is required for punctuation insertion. For example, the method is unable to effectively capture the long range dependency between the initial phrase "*would you*" which strongly indicates a question sentence, and an ending question mark. This hurts the punctuation prediction performance for our task since we are particularly interested in conversational speech texts where question sentences appear frequently.

Thus, in practice, special techniques are usually required on top of using a hidden event language model in order to overcome long range dependencies. Examples include relocating or duplicating punctuation symbols to different positions of a sentence such that they appear closer to the indicative words (e.g., "*how much*" indicates a question sentence). One such technique was introduced by the organizers of the IWSLT evaluation campaign, who suggested duplicating the ending punctuation symbol to the beginning of each sentence before training the language model[1]. Empirically, the technique has demonstrated its effectiveness in predicting question marks in English, since most of the indicative words for English question sentences appear at the beginning of a question. However, such a technique is specially designed and may not be widely applicable in general or to languages other than English. Furthermore, a direct application of such a method may fail in the event of multiple sentences per utterance without clearly annotated sentence boundaries within an utterance.

Another drawback associated with such an approach is that the method encodes strong dependency assumptions between the punctuation symbol to be inserted and its surrounding words. Thus, it lacks the robustness to handle cases where noisy or out-of-vocabulary (OOV) words frequently appear, such as in texts automatically recognized by ASR systems. In this paper, we devise techniques based on conditional random fields to tackle the difficulties due to long range dependencies.

4 Linear-Chain Conditional Random Fields

One natural approach to relax the strong dependency assumptions encoded by the hidden event language model is to adopt an undirected graphical model, where arbitrary overlapping features can be exploited.

Conditional random fields (CRF) (Lafferty et al., 2001) have been widely used in various sequence labeling and segmentation tasks (Sha and Pereira, 2003; Tseng et al., 2005). Unlike a HMM which models the joint distribution of both the label sequence and the observation, a CRF is a discriminative model of the conditional distribution of the complete label sequence given the observation.

Specifically, a first-order linear-chain CRF which assumes first-order Markov property is defined by the following equation:

$$p_\lambda(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_t \sum_k \lambda_k f_k(\mathbf{x}, y_{t-1}, y_t, t)\right) \tag{1}$$

where $\mathbf{x}$ is the observation and $\mathbf{y}$ is the label sequence. Feature functions f_k with time step t are defined over the entire observation $\mathbf{x}$ and two adjacent hidden labels. $Z(\mathbf{x})$ is a normalization factor to ensure a well-formed probability distribution. Figure 1 gives a simplified graphical representation of the model, where only the dependencies between label and observation in the same time step are shown.

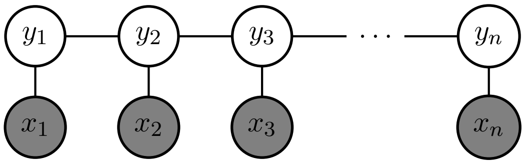

Figure 1: A simplified graphical representation for linear-chain CRF (observations are shaded)

proposed tags
NONE COMMA (,) PERIOD (.)
QMARK (?) EMARK (!)

Table 1: The set of all possible tags for linear-chain CRF

We can model the punctuation prediction task as the process of assigning a tag to each word, where the set of possible tags is given in Table 1. That is, we assume each word can be associated with an event, which tells us which punctuation symbol (possibly NONE) should be inserted after the word. The training data consists of a set of utterances where punctuation symbols are encoded as tags that are assigned to the individual words. The tag NONE means no punctuation symbol is inserted after the current word. Any other tag refers to inserting the corresponding punctuation symbol. In the testing phase, the most probable sequence of tags is

Figure 2: An example tagging of a training sentence for the linear-chain CRF

predicted and the punctuated text can then be constructed from such an output. An example tagging of an utterance is illustrated in Figure 2.

Following (Sutton et al., 2007), we factorize a feature of conditional random fields as a product of a binary function on assignment of the set of cliques at the current time step (in this case an edge), and a feature function solely defined on the observation sequence. n-gram occurrences surrounding the current word, together with position information, are used as binary feature functions, for $n = 1, 2, 3$. All words that appear within 5 words from the current word are considered when building the features. Special start and end symbols are used beyond the utterance boundaries. For example, for the word *do* shown in Figure 2, example features include unigram features *do@0*, *please@-1*, bigram feature *would+you@[2,3]*, and trigram feature *no+please+do@[-2,0]*.

Such a linear-chain CRF model is capable of modeling dependencies between words and punctuation symbols with arbitrary overlapping features, thus avoiding the strong dependency assumptions in the hidden event language model. However, the linear-chain CRF model still exhibits several problems for the punctuation task. In particular, the dependency between the punctuation symbols and the indicative words cannot be captured adequately, if they appear too far away from each other. For example, in the sample utterance shown in Figure 2, the long range dependency between the ending question mark and the indicative words *would you* which appear very far away cannot be directly captured. The problem arises because a linear-chain CRF only learns a sequence of tags at the individual word level but is not fully aware of sentence level information, such as the start and end of a complete sentence.

Hence, it would be more reasonable to hypothesize that the punctuation symbols are annotated at the sentence level, rather than relying on a limited window of surrounding words. A model that can jointly perform sentence segmentation and sentence type prediction, together with word level punctuation prediction would be more beneficial for our task. This motivates us to build a joint model for performing such a task, to be presented in the next section.

5 Factorial Conditional Random Fields

Extensions to the linear-chain CRF model have been proposed in previous research efforts to encode long range dependencies. One such well-known extension is the semi-Markov CRF (semi-CRF) (Sarawagi and Cohen, 2005). Motivated by the hidden semi-Markov model, the semi-CRF is particularly helpful in text chunking tasks as it allows a state to persist for a certain interval of time steps. This in practice often leads to better modeling capability of chunks, since state transitions within a chunk need not precisely follow the Markov property as in the case of linear-chain CRF. However, it is not clear how such a model can benefit our task, which requires word-level labeling in addition to sentence boundary detection and sentence type prediction.

The skip-chain CRF (Sutton and McCallum, 2004), another variant of linear-chain CRF, attaches additional edges on top of a linear-chain CRF for better modeling of long range dependencies between states with similar observations. However, such a model usually requires known long range dependencies in advance and may not be readily applicable to our task where such clues are not explicit.

As we have discussed above, since we would like to jointly model both the word-level labeling task and the sentence-level annotation task (sentence boundary detection and sentence type prediction), introducing an additional layer of tags to perform both tasks together would be desirable. In this section, we propose the use of factorial CRF (F-CRF) (Sutton et al., 2007), which has previously been shown to be effective for joint labeling of multiple sequences (McCallum et al., 2003).

The F-CRF as a specific case of dynamic conditional random fields was originally motivated from dynamic Bayesian networks, where an identical structure repeats over different time steps. Analogous to the linear-chain CRF, one can think of the F-CRF as a framework that provides the capability of simultaneously labeling multiple layers of tags for a given sequence. It learns a joint conditional distribution of the tags given the observation. Formally, dynamic conditional random fields define the conditional probability of a sequence of label vectors $\mathbf{y}$ given the observation $\mathbf{x}$ as:

$$p_\lambda(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_t \sum_{c \in \mathcal{C}} \sum_k \lambda_k f_k(\mathbf{x}, y_{(c,t)}, t)\right) \tag{2}$$

where cliques are indexed at each time step, $\mathcal{C}$ is a set of clique indices, and $y_{(c,t)}$ is the set of variables in the unrolled version of a clique with index c at time t (Sutton et al., 2007). Figure 3 gives a graphical representation of a two-layer factorial CRF, where the cliques include the two within-chain edges (e.g., $z_2 - z_3$ and $y_2 - y_3$) and one between-chain edge (e.g., $z_3 - y_3$) at each time step.

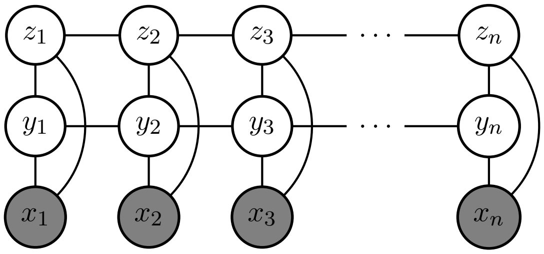

Figure 3: A two-layer factorial CRF

layer	proposed tags
word	NONE,COMMA,PERIOD, QMARK,EMARK
sentence	DEBEG,DEIN,QNBEG,QNIN, EXBEG,EXIN

Table 2: The set of all possible tags proposed for each layer

We build two layers of labels for this task, as listed in Table 2. The word layer tags are responsible for inserting a punctuation symbol (including NONE) after each word, while the sentence layer tags are used for annotating sentence boundaries and identifying the sentence type (declarative, question, or exclamatory). Tags from the word layer are the same as those of the linear-chain CRF. The sentence layer tags are designed for three types of sentences. DEBEG and DEIN indicate the start and the inner part of a declarative sentence respectively, likewise for QNBEG and QNIN (question sentences), as well as EXBEG and EXIN (exclamatory sentences). The same example utterance we looked at in the previous section is now tagged with these two layers of tags, as shown in Figure 4. Analogous feature factorization and the same n-gram feature functions used in linear-chain CRF are used in F-CRF.

When learning the sentence layer tags together with the word layer tags, the F-CRF model is capable of leveraging useful clues learned from the sentence layer about sentence type (e.g., a question sentence, annotated with QNBEG, QNIN, QNIN, ..., or a declarative sentence, annotated with DEBEG, DEIN, DEIN, ...), which can be used to guide the prediction of the punctuation symbol at each word, hence improving the performance at the word layer. For example, consider jointly labeling the utterance shown in Figure 4. Intuitively, when evidences show that the utterance consists of two sentences – a declarative sentence followed by a question sentence, the model tends to annotate the second half of the utterance with the sequence QNBEG QNIN .... This in turn helps to predict the word level tag at the end of the utterance as QMARK, given the dependencies between the two layers existing at each time step. In practice, during the learning process, the two layers of tags are jointly learned, thus providing evidences that influence each other's tagging process.

In this work, we use the GRMM package (Sutton, 2006) for building both the linear-chain CRF (L-CRF) and factorial CRF (F-CRF). The tree-based reparameterization (TRP) schedule for belief propagation (Wainwright et al., 2001) is used for approximate inference.

6 Experiments

We perform experiments on part of the corpus of the IWSLT09 evaluation campaign (Paul, 2009), where both Chinese and English conversational speech

texts are used. Two multilingual datasets are considered, the BTEC (Basic Travel Expression Corpus) dataset and the CT (Challenge Task) dataset. The former consists of tourism-related sentences, and the latter consists of human-mediated cross-lingual dialogs in travel domain. The official IWSLT09 BTEC training set consists of 19,972 Chinese-English utterance pairs, and the CT training set consists of 10,061 such pairs. We randomly split each of the two datasets into two portions, where 90% of the utterances are used for training the punctuation prediction models, and the remaining 10% for evaluating the prediction performance. For all the experiments, we use the default segmentation of Chinese as provided, and English texts are preprocessed with the Penn Treebank tokenizer[2]. We list the statistics of the two datasets after processing in Table 3. The proportions of sentence types in the two datasets are listed. The majority of the sentences are declarative sentences. However, question sentences are more frequent in the BTEC dataset compared to the CT dataset. Exclamatory sentences contribute less than 1% for all datasets and are not listed. We also count how often each utterance consists of multiple sentences. The utterances from the CT dataset are much longer (with more words per utterance), and therefore more CT utterances actually consist of multiple sentences.

	BTEC		CT	
	Cn	En	Cn	En

question sent.	36%	35%	22%	19%
multi.sent./uttr.	14%	17%	29%	39%
avg.words./uttr.	8.59	9.46	10.18	14.33

Table 3: Statistics of the BTEC and CT datasets

For the methods based on the hidden event language model, we design extensive experiments due to many possible setups. Specifically, these experiments can be divided into two categories: with or without duplicating the ending punctuation symbol to the start of a sentence before training. This setting can be used to assess the impact of the proximity between the punctuation symbol and the indicative words for the prediction task. Under each category, two possible approaches are tried. The single pass approach performs prediction in one single step, where all the punctuation symbols are predicted sequentially from left to right. In the cascaded approach, we format the training sentences by replacing all sentence-ending punctuation symbols with special sentence boundary symbols first. A model for sentence boundary prediction is learned based on such training data. This step is then followed by predicting the actual punctuation symbols. Both trigram and 5-gram language models are tried for all combinations of the above settings. This gives us a total of 8 possible combinations based on the hidden event language model. When training all the language models, modified Kneser-Ney smoothing (Chen and Goodman, 1996) for n-grams is used.

To assess the performance of the punctuation prediction task, we compute precision ($prec.$), recall ($rec.$), and F1-measure (F_1), as defined by the following equations:

$$\begin{aligned} prec. &= \frac{\text{\# Correctly predicted punctuation symbols}}{\text{\# predicted punctuation symbols}} \\ rec. &= \frac{\text{\# Correctly predicted punctuation symbols}}{\text{\# expected punctuation symbols}} \\ F_1 &= \frac{2}{1/prec. + 1/rec.} \end{aligned}$$

6.1 Performance on Correctly Recognized Texts

The performance of punctuation prediction on both Chinese (Cn) and English (En) texts in the correctly recognized output of the BTEC and CT datasets are presented in Table 4 and Table 5 respectively. The

performance of the hidden event language model heavily depends on whether the duplication method is used and on the actual language under consideration. Specifically, for English, duplicating the ending punctuation symbol to the start of a sentence before training is shown to be very helpful in improving the overall prediction performance. In contrast, applying the same technique to Chinese hurts the performance.

This observed difference is reasonable and expected. An English question sentence usually starts with indicative words such as *do you* or *where* that distinguish it from a declarative sentence. Thus, duplicating the ending punctuation symbol to the start of a sentence so that it is near these indicative words helps to improve the prediction accuracy. However, Chinese presents quite different syntactic structures for question sentences. First, we found that in many cases, Chinese tends to use semantically vague auxiliary words at the end of a sentence to indicate a question. Such auxiliary words include 吗 and 呢. Thus, retaining the position of the ending punctuation symbol before training yields better performance. Another interesting finding is that, different from English, other words that indicate a question sentence in Chinese can appear at almost any position in a Chinese sentence. Examples include 哪里有... (*where* ...), ...是什么 (*what* ...), or ...多少... (*how many/much* ...). These pose difficulties for the simple hidden event language model, which only encodes simple dependencies over surrounding words by means of n-gram language modeling.

By adopting a discriminative model which exploits non-independent, overlapping features, the L-Crf model generally outperforms the hidden event language model. By introducing an additional layer of tags for performing sentence segmentation and sentence type prediction, the F-Crf model further boosts the performance over the L-Crf model. We perform statistical significance tests using bootstrap resampling (Efron et al., 1993). The improvements of F-Crf over L-Crf are statistically significant ($p < 0.01$) on Chinese and English texts in the CT

dataset, and on English texts in the BTEC dataset. The improvements of F-CRF over L-CRF on Chinese texts are smaller, probably because L-CRF is already performing quite well on Chinese. F1 measures on the CT dataset are lower than those on BTEC, mainly because the CT dataset consists of longer utterances and fewer question sentences. Overall, our proposed F-CRF model is robust and consistently works well regardless of the language and dataset it is tested on. This indicates that the approach is general and relies on minimal linguistic assumptions, and thus can be readily used on other languages and datasets.

6.2 Performance on Automatically Recognized Texts

So far we only evaluated punctuation prediction performance on transcribed texts consisting of correctly recognized words. We now present the evaluation results on texts produced by ASR systems.

For evaluation, we use the 1-best ASR outputs of spontaneous speech of the official IWSLT08 BTEC evaluation dataset, which is released as part of the IWSLT09 corpus. The dataset consists of 504 utterances in Chinese, and 498 in English. Unlike the correctly recognized texts described in Section 6.1, the ASR outputs contain substantial recognition errors (recognition accuracy is 86% for Chinese, and 80% for English (Paul, 2008)). In the dataset released by the IWSLT organizers, the correct punctuation symbols are not annotated in the ASR outputs. To conduct our experimental evaluation, we manually annotated the correct punctuation symbols on the ASR outputs.

We used all the learned models in Section 6.1, and applied them to this dataset. The evaluation results are shown in Table 6. The results show that F-CRF still gives higher performance than L-CRF and the hidden event language model, and the improvements are statistically significant ($p < 0.01$).

6.3 Performance in Translation

The evaluation process as described in Section 6.2 requires substantial manual efforts to annotate the correct punctuation symbols. In this section, we instead adopt an indirect approach to automatically evaluate the performance of punctuation prediction on ASR output texts by feeding the punctuated ASR texts to a state-of-the-art machine translation system, and evaluate the resulting translation performance. The translation performance is in turn measured by an automatic evaluation metric which correlates well with human judgments. We believe that such a task-oriented approach for evaluating the quality of punctuation prediction for ASR output texts is useful, since it tells us how well the punctuated ASR output texts from each punctuation prediction system can be used for further processing, such as in statistical machine translation.

In this paper, we use Moses (Koehn et al., 2007), a state-of-the-art phrase-based statistical machine translation toolkit, as our translation engine. We use the entire IWSLT09 BTEC training set for training the translation system. The state-of-the-art unsupervised Berkeley aligner[3] (Liang et al., 2006) is used for aligning the training bitext. We use all the default settings of Moses, except with the lexicalized reordering model enabled. This is because

lexicalized reordering gives better performance than simple distance-based reordering (Koehn et al., 2005). Specifically, the default lexicalized reordering model (*msd-bidirectional-fe*) is used.

For tuning the parameters of Moses, we use the official IWSLT05 evaluation set where the correct punctuation symbols are present. Evaluations are performed on the ASR outputs of the IWSLT08 BTEC evaluation dataset, with punctuation symbols inserted by each punctuation prediction method. The tuning set and evaluation set include 7 reference translations. Following a common practice in statistical machine translation, we report Bleu-4 scores (Papineni et al., 2002), which were shown to have good correlation with human judgments, with the closest reference length as the effective reference length. The minimum error rate training (MERT) (Och, 2003) procedure is used for tuning the model parameters of the translation system. Due to the unstable nature of MERT, we perform 10 runs for each translation task, with a different random initialization of parameters in each run, and report the Bleu-4 scores averaged over 10 runs.

The results are reported in Table 7. The best translation performances for both translation directions are achieved by applying F-Crf as the punctuation prediction model to the ASR texts. Such improvements are observed to be consistent over different runs. The improvement of F-Crf over L-Crf in translation quality is statistically significant ($p < 0.05$) when translating from English to Chinese. In addition, we also assess the translation performance when the manually annotated punctuation symbols as mentioned in Section 6.2 are used for translation. The averaged Bleu scores for the two translation tasks are 31.58 (Chinese to English) and 24.16 (English to Chinese) respectively, which show that our punctuation prediction method gives competitive performance for spoken language translation.

It is important to note that in this work, we only focus on optimizing the punctuation prediction performance in the form of F1-measure, without regard to the subsequent NLP tasks. How to perform punctuation prediction so as to optimize translation performance is an important research topic that is beyond the scope of this paper and needs further investigation in future work.

7 Conclusion

In this paper, we have proposed a novel approach for predicting punctuation symbols for transcribed conversational speech texts. Our proposed approach is built on top of a dynamic conditional random fields framework, which jointly performs punctuation prediction together with sentence boundary and sentence type prediction on speech utterances. Unlike most previous work, it tackles the task from a purely text processing perspective and does not rely on prosodic cues.

Experimental results have shown that our proposed approach outperforms the widely used approach based on the hidden event language model, and also outperforms a method based on linear-chain conditional random fields. Our proposed approach has been shown to be general, working well on both Chinese and English, and on both correctly recognized and automatically recognized texts. Our proposed approach also results in better translation accuracy when the punctuated automatically recognized texts are used in subsequent translation.

Abstract

Many sequence labeling tasks in NLP require solving a cascade of segmentation and tagging subtasks, such as Chinese POS tagging, named entity recognition, and so on. Traditional pipeline approaches usually suffer from error propagation. Joint training/decoding in the cross-product state space could cause too many parameters and high inference complexity. In this paper, we present a novel method which integrates graph structures of two subtasks into one using virtual nodes, and performs joint training and decoding in the factorized state space. Experimental evaluations on CoNLL 2000 shallow parsing data set and Fourth SIGHAN Bakeoff CTB POS tagging data set demonstrate the superiority of our method over cross-product, pipeline and candidate reranking approaches.

1 Introduction

There is a typical class of sequence labeling tasks in many natural language processing (NLP) applications, which require solving a cascade of segmentation and tagging subtasks. For example, many Asian languages such as Japanese and Chinese which do not contain explicitly marked word boundaries, word segmentation is the preliminary step for solving part-of-speech (POS) tagging problem. Sentences are firstly segmented into words, then each word is assigned with a part-of-speech tag. Both syntactic parsing and dependency parsing usually start with a textual input that is tokenized, and POS tagged.

The most commonly approach solves cascaded subtasks in a pipeline, which is very simple to implement and allows for a modular approach. While, the key disadvantage of such method is that errors propagate between stages, significantly affecting the quality of the final results. To cope with this problem, Shi and Wang (2007) proposed a reranking framework in which N-best segment candidates generated in the first stage are passed to the tagging model, and the final output is the one with the highest overall segmentation and tagging probability score. The main drawback of this method is that the interaction between tagging and segmentation is restricted by the number of candidate segmentation outputs. Razvan C. Bunescu (2008) presented an improved pipeline model in which upstream subtask outputs are regarded as hidden variables, together with their probabilities are used as probabilistic features in the downstream subtasks. One shortcoming of this method is that calculation of marginal probabilities of features may be inefficient and some approximations are required for fast computation. Another disadvantage of these two methods is that they employ separate training and the segmentation model could not take advantages of tagging information in the training procedure.

On the other hand, joint learning and decoding using cross-product of segmentation states and tagging states does not suffer from error propagation problem and achieves higher accuracy on both subtasks (Ng and Low, 2004). However, two problems arises due to the large state space, one is that the amount of parameters increases rapidly, which is apt to overfit on the training corpus, the other is that the inference by dynamic programming could be inefficient. Sutton (2004) proposed Dynamic Conditional Random Fields (DCRFs) to perform joint training/decoding of subtasks using much fewer parameters than the cross-product approach. How-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 187–195,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

ever, DCRFs do not guarantee non-violation of hard-constraints that nodes within the same segment get a single consistent tagging label. Another drawback of DCRFs is that exact inference is generally time consuming, some approximations are required to make it tractable.

Recently, perceptron based learning framework has been well studied for incorporating node level and segment level features together (Kazama and Torisawa, 2007; Zhang and Clark, 2008). The main shortcoming is that exact inference is intractable for those dynamically generated segment level features, so candidate based searching algorithm is used for approximation. On the other hand, Jiang (2008) proposed a cascaded linear model which has a two layer structure, the inside-layer model uses node level features to generate candidates with their weights as inputs of the outside layer model which captures non-local features. As pipeline models, error propagation problem exists for such method.

In this paper, we present a novel graph structure that exploits joint training and decoding in the factorized state space. Our method does not suffer from error propagation, and guards against violations of those hard-constraints imposed by segmentation subtask. The motivation is to integrate two Markov chains for segmentation and tagging subtasks into a single chain, which contains two types of nodes, then standard dynamic programming based exact inference is employed on the hybrid structure. Experiments are conducted on two different tasks, CoNLL 2000 shallow parsing and SIGHAN 2008 Chinese word segmentation and POS tagging. Evaluation results of shallow parsing task show the superiority of our proposed method over traditional joint training/decoding approach using cross-product state space, and achieves the best reported results when no additional resources at hand. For Chinese word segmentation and POS tagging task, a strong baseline pipeline model is built, experimental results show that the proposed method yields a more substantial improvement over the baseline than candidate reranking approach.

The rest of this paper is organized as follows: In Section 2, we describe our novel graph structure. In Section 3, we analyze complexity of our proposed method. Experimental results are shown in Section 4. We conclude the work in Section 5.

2 Multi-chain integration using Virtual Nodes

2.1 Conditional Random Fields

We begin with a brief review of the Conditional Random Fields(CRFs). Let $\mathbf{x} = x_1 x_2 \ldots x_l$ denote the observed sequence, where x_i is the i^{th} node in the sequence, l is sequence length, $\mathbf{y} = y_1 y_2 \ldots y_l$ is a label sequence over $\mathbf{x}$ that we wish to predict. CRFs (Lafferty et al., 2001) are undirected graphic models that use Markov network distribution to learn the conditional probability. For sequence labeling task, linear chain CRFs are very popular, in which a first order Markov assumption is made on the labels:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_i \phi(\mathbf{x}, \mathbf{y}, i)$$

,where

$$\phi(\mathbf{x}, \mathbf{y}, i) = \exp\left(\mathbf{w}^T \mathbf{f}(\mathbf{x}, y_{i-1}, y_i, i)\right)$$
$$Z(\mathbf{x}) = \sum_{\mathbf{y}} \prod_i \phi(\mathbf{x}, \mathbf{y}, i)$$

$\mathbf{f}(\mathbf{x}, y_{i-1}, y_i, i) = [f_1(\mathbf{x}, y_{i-1}, y_i, i), \ldots, f_m(\mathbf{x}, y_{i-1}, y_i, i)]^T$, each element $f_j(\mathbf{x}, y_{i-1}, y_i, i)$ is a real valued feature function, here we simplify the notation of state feature by writing $f_j(\mathbf{x}, y_i, i) = f_j(\mathbf{x}, y_{i-1}, y_i, i)$, m is the cardinality of feature set $\{f_j\}$. $\mathbf{w} = [w_1, \ldots, w_m]^T$ is a weight vector to be learned from the training set. $Z(\mathbf{x})$ is the normalization factor over all label sequences for $\mathbf{x}$.

In the traditional joint training/decoding approach for cascaded segmentation and tagging task, each label y_i has the form s_i-t_i, which consists of segmentation label s_i and tagging label t_i. Let $\mathbf{s} = s_1 s_2 \ldots s_l$ be the segmentation label sequence over $\mathbf{x}$. There are several commonly used label sets such as BI, BIO, IOE, BIES, etc. To facilitate our discussion, in later sections we will use BIES label set, where B,I,E represents *Beginning, Inside* and *End* of a multi-node segment respectively, S denotes a single node segment. Let $\mathbf{t} = t_1 t_2 \ldots t_l$ be the tagging label sequence over $\mathbf{x}$. For example, in named entity recognition task, $t_i \in$ {PER, LOC, ORG, MISC, O} represents an entity type (person name, location name, organization name, miscellaneous entity

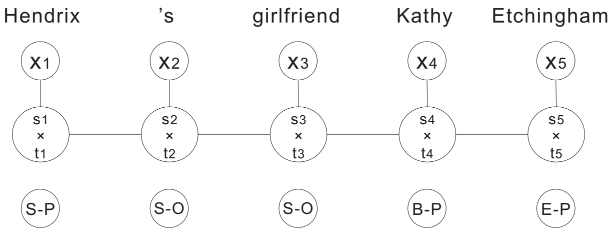

Figure 1: Graphical representation of linear chain CRFs for traditional joint learning/decoding

name and other). Graphical representation of linear chain CRFs is shown in Figure 1, where tagging label "P" is the simplification of "PER". For nodes that are labeled as other, we define s_i =S, t_i =O.

2.2 Hybrid structure for cascaded labeling tasks

Different from traditional joint approach, our method integrates two linear markov chains for segmentation and tagging subtasks into one that contains two types of nodes. Specifically, we first regard segmentation and tagging as two independent sequence labeling tasks, corresponding chain structures are built, as shown in the top and middle sub-figures of Figure 2. Then a chain of twice length of the observed sequence is built, where nodes $x_1, \dots, x_l$ on the even positions are original observed nodes, while nodes $v_1, \dots, v_l$ on the odd positions are virtual nodes that have no content information. For original nodes x_i, the state space is the tagging label set, while for virtual nodes, their states are segmentation labels. The label sequence of the hybrid chain is $\mathbf{y} = y_1 \dots y_{2l} = s_1 t_1 \dots s_l t_l$, where combination of consecutive labels $s_i t_i$ represents the full label for node x_i.

Then we let s_i be connected with s_{i-1} and s_{i+1} , so that first order Markov assumption is made on segmentation states. Similarly, t_i is connected with t_{i-1} and t_{i+1}. Then neighboring tagging and segmentation states are connected as shown in the bottom sub-figure of Figure 2. Non-violation of hard-constraints that nodes within the same segment get a single consistent tagging label is guaranteed by introducing second order transition features $f(t_{i-1}, s_i, t_i, i)$ that are true if $t_{i-1} \neq t_i$ and $s_i \in$ {I,E}. For example, $f_j(t_{i-1}, s_i, t_i, i)$ is defined as true if t_{i-1} =PER, s_i =I and t_i =LOC. In other words, it is true, if a segment is partially tagging as PER, and partially tagged as LOC. Since such features are always false in the training corpus, their corresponding weights will be very low so that inconsistent label assignments impossibly appear in decoding procedure. The hybrid graph structure can be regarded as a special case of second order Markov chain.

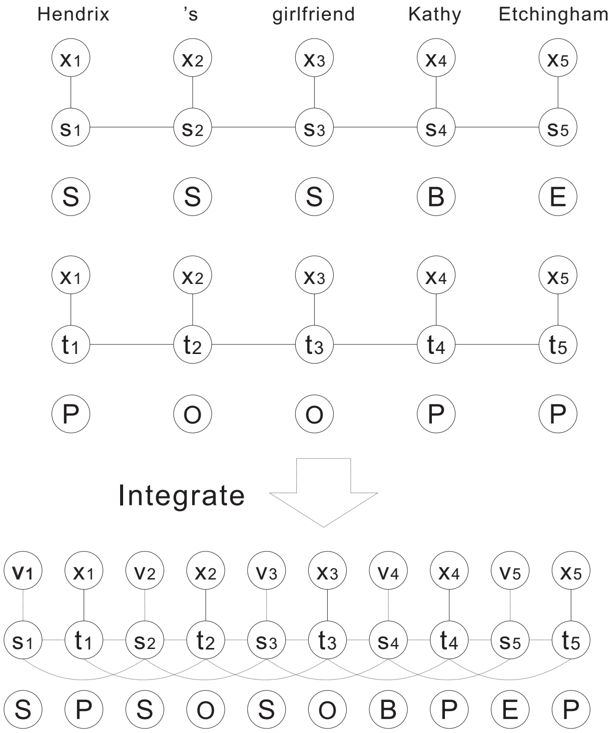

Figure 2: Multi-chain integration using Virtual Nodes

2.3 Factorized features

Compared with traditional joint model that exploits cross-product state space, our hybrid structure uses factorized states, hence could handle more flexible features. Any state feature $g(\mathbf{x}, y_i, i)$ defined in the cross-product state space can be replaced by a first order transition feature in the factorized space: $f(\mathbf{x}, s_i, t_i, i)$. As for the transition features, we use $f(s_{i-1}, t_{i-1}, s_i, i)$ and $f(t_{i-1}, s_i, t_i, i)$ instead of $g(y_{i-1}, y_i, i)$ in the conventional joint model.

Features in cross-product state space require that segmentation label and tagging label take on particular values simultaneously, however, sometimes we want to specify requirement on only segmentation or tagging label. For example, “Smith” may be an end of a person name, “Speaker: John Smith”; or a single word person name “Professor Smith will . . . ”. In such case, our observation is that “Smith” is likely a (part of) person name, we do not care about its segmentation label. So we could define state feature $f(\mathbf{x}, t_i, i) = true$, if x_i is “Smith” with tagging label t_i=PER.

Further more, we could define features like $f(\mathbf{x}, t_{i-1}, t_i, i)$, $f(\mathbf{x}, s_{i-1}, s_i, i)$, $f(\mathbf{x}, t_{i-1}, s_i, i)$, etc. The hybrid structure facilitates us to use varieties of features. In the remainder of the paper, we use notations $f(\mathbf{x}, t_{i-1}, s_i, t_i, i)$ and $f(\mathbf{x}, s_{i-1}, t_{i-1}, s_i, i)$ for simplicity.

2.4 Hybrid CRFs

A hybrid CRFs is a conditional distribution that factorizes according to the hybrid graphical model, and is defined as:

$$p(\mathbf{s}, \mathbf{t}|\mathbf{x}) \quad = \quad \frac{1}{Z(\mathbf{x})} \prod_i \phi(\mathbf{x}, \mathbf{s}, \mathbf{t}, i) \prod_i \psi(\mathbf{x}, \mathbf{s}, \mathbf{t}, i)$$

Where

$$\phi(\mathbf{x}, \mathbf{s}, \mathbf{t}, i) = \exp\left(\mathbf{w}_1^T \mathbf{f}(\mathbf{x}, s_{i-1}, t_{i-1}, s_i)\right)$$
$$\psi(\mathbf{x}, \mathbf{s}, \mathbf{t}, i) = \exp\left(\mathbf{w}_2^T \mathbf{f}(\mathbf{x}, t_{i-1}, s_i, t_i)\right)$$
$$Z(\mathbf{x}) = \sum_{\mathbf{s}, \mathbf{t}} \left(\prod_i \phi(\mathbf{x}, \mathbf{s}, \mathbf{t}, i) \prod_i \psi(\mathbf{x}, \mathbf{s}, \mathbf{t}, i) \right)$$

Where $\mathbf{w}_1$, $\mathbf{w}_2$ are weight vectors.

Luckily, unlike DCRFs, in which graph structure can be very complex, and the cross-product state space can be very large, in our cascaded labeling task, the segmentation label set is often small, so far as we known, the most complicated segmentation label set has only 6 labels (Huang and Zhao, 2007). So exact dynamic programming based algorithms can be efficiently performed.

In the training stage, we use second order forward backward algorithm to compute the marginal probabilities $p(\mathbf{x}, s_{i-1}, t_{i-1}, s_i)$ and $p(\mathbf{x}, t_{i-1}, s_i, t_i)$, and the normalization factor $Z(\mathbf{x})$. In decoding stage, we use second order Viterbi algorithm to find the best label sequence. The Viterbi decoding can be used to label a new sequence, and marginal computation is used for parameter estimation.

Table 1: Time Complexity

Method	Training	Decoding
Pipeline	$(\lvert S\rvert^2 c_s + \lvert T\rvert^2 c_t)L$	$(\lvert S\rvert^2 + \lvert T\rvert^2)U$
Cross-Product	$(\lvert S\rvert\lvert T\rvert)^2 cL$	$(\lvert S\rvert\lvert T\rvert)^2 U$
Reranking	$(\lvert S\rvert^2 c_s + \lvert T\rvert^2 c_t)L$	$(\lvert S\rvert^2 + \lvert T\rvert^2)NU$
Hybrid	$(\lvert S\rvert + \lvert T\rvert)\lvert S\rvert\lvert T\rvert cL$	$(\lvert S\rvert + \lvert T\rvert)\lvert S\rvert\lvert T\rvert U$

3 Complexity Analysis

The time complexity of the hybrid CRFs training and decoding procedures is higher than that of pipeline methods, but lower than traditional cross-product methods. Let

- $|S|$ = size of the segmentation label set.
- $|T|$ = size of the tagging label set.
- L = total number of nodes in the training data set.
- U = total number of nodes in the testing data set.
- c = number of joint training iterations.
- c_s = number of segmentation training iterations.
- c_t = number of tagging training iterations.
- N = number of candidates in candidate reranking approach.

Time requirements for pipeline, cross-product, candidate reranking and hybrid CRFs are summarized in Table 1. For Hybrid CRFs, original node x_i has features $\{f_j(t_{i-1}, s_i, t_i)\}$, accessing all label subsequences $t_{i-1}s_it_i$ takes $|S||T|^2$ time, while virtual node v_i has features $\{f_j(s_{i-1}, t_{i-1}, s_i)\}$, accessing all label subsequences $s_{i-1}t_{i-1}s_i$ takes $|S|^2|T|$ time, so the final complexity is $(|S| + |T|)|S||T|cL$.

In real applications, $|S|$ is small, $|T|$ could be very large, we assume that $|T| >> |S|$, so for each iteration, hybrid CRFs is about $|S|$ times slower than pipeline and $|S|$ times faster than cross-product

Table 2: Feature templates for shallow parsing task

Cross Product CRFs	Hybrid CRFs
$w_{i-2}y_i$, $w_{i-1}y_i$, w_iy_i	$w_{i-1}s_i$, w_is_i, $w_{i+1}s_i$

$p_{i-2}p_{i-1}p_iy_i$, $p_{i-1}p_ip_{i+1}y_i$, $p_ip_{i+1}p_{i+2}y_i$	$p_{i-2}p_{i-1}p_is_i$, $p_{i-1}p_ip_{i+1}s_i$, $p_ip_{i+1}p_{i+2}s_i$
	$w_ip_it_i$
	$w_is_{i-1}s_i$
	$w_{i-1}t_{i-1}t_i$, $w_it_{i-1}t_i$, $p_{i-1}t_{i-1}t_i$, $p_it_{i-1}t_i$
$y_{i-1}y_i$	$s_{i-1}t_{i-1}s_i$, $t_{i-1}s_it_i$

method. When decoding, candidate reranking approach requires more time if candidate number $N > |S|$.

Though the space complexity could not be compared directly among some of these methods, hybrid CRFs require less parameters than cross-product CRFs due to the factorized state space. This is similar with factorized CRFs (FCRFs) (Sutton et al., 2004).

4 Experiments

4.1 Shallow Parsing

Our first experiment is the shallow parsing task. We use corpus from CoNLL 2000 shared task, which contains 8936 sentences for training and 2012 sentences for testing. There are 11 tagging labels: noun phrase(NP), verb phrase(VP) , . . . and other (O), the segmentation state space we used is BIES label set, since we find that it yields a little improvement over BIO set.

We use the standard evaluation metrics, which are precision P (percentage of output phrases that exactly match the reference phrases), recall R (percentage of reference phrases returned by our system), and their harmonic mean, the F1 score $F1 = \frac{2PR}{P+R}$ (which we call F score in what follows).

We compare our approach with traditional cross-product method. To find good feature templates, development data are required. Since CoNLL2000 does not provide development data set, we divide the training data into 10 folds, of which 9 folds for training and 1 fold for developing. After selecting feature templates by cross validation, we extract features and learn their weights on the whole training data set. Feature templates are summarized in Table 2, where w_i denotes the i^{th} word, p_i denotes the i^{th} POS tag.

Notice that in the second row, feature templates of the hybrid CRFs does not contain $w_{i-2}s_i$, $w_{i+2}s_i$, since we find that these two templates degrade performance in cross validation. However, $w_{i-2}t_i$, $w_{i+2}t_i$ are useful, which implies that the proper context window size for segmentation is smaller than tagging. Similarly, for hybrid CRFs, the window size of POS bigram features for segmentation is 5 (from p_{i-2} to p_{i+2}, see the eighth row in the second column); while for tagging, the size is 7 (from p_{i-3} to p_{i+3}, see the ninth row in the second column). However for cross-product method, their window sizes must be consistent.

For traditional cross-product CRFs and our hybrid CRFs, we use fixed gaussian prior $\sigma = 1.0$ for both methods, we find that this parameter does not signifi-

Table 3: Results for shallow parsing task, Hybrid CRFs significantly outperform Cross-Product CRFs (McNemar's test; $p < 0.01$)

(Suzuki and Isozaki, 2008)	95.15	$1G$ words unlabeled data

cantly affect the results when it varies between 1 and 10. LBFGS(Nocedal and Wright, 1999) method is employed for numerical optimization. Experimental results are shown in Table 3. Our proposed CRFs achieve a performance gain of 0.43 points in F-score over cross-product CRFs that use state space while require less training time.

For comparison, we also listed the results of previous top systems, as shown in Table 4. Our proposed method outperforms other systems when no additional resources at hand. Though recently semi-supervised learning that incorporates large mounts of unlabeled data has been shown great improvement over traditional supervised methods, such as the last row in Table 4, supervised learning is fundamental. We believe that combination of our method and semi-supervised learning will achieve further improvement.

4.2 Chinese word segmentation and POS tagging

Our second experiment is the Chinese word segmentation and POS tagging task. To facilitate comparison, we focus only on the closed test, which means that the system is trained only with a designated training corpus, any extra knowledge is not allowed, including Chinese and Arabic numbers, letters and so on. We use the Chinese Treebank (CTB) POS corpus from the Fourth International SIGHAN Bakeoff data sets (Jin and Chen, 2008). The training data consist of 23444 sentences, 642246 Chinese words, 1.05M Chinese characters and testing data consist of 2079 sentences, 59955 Chinese words, 0.1M Chinese characters.

We compare our hybrid CRFs with pipeline and candidate reranking methods (Shi and Wang, 2007) using the same evaluation metrics as shallow parsing. We do not compare with cross-product CRFs due to large amounts of parameters.

For pipeline method, we built our word segmenter based on the work of Huang and Zhao (2007), which uses 6 label representation, 7 feature templates (listed in Table 5, where c_i denotes the i^{th} Chinese character in the sentence) and CRFs for parameter learning. We compare our segmentor with other top systems using SIGHAN CTB corpus and evaluation metrics. Comparison results are shown in Table 6, our segmenter achieved 95.12 F-score, which is ranked 4th of 26 official runs. Except for the first system which uses extra unlabeled data, differences between rest systems are not significant.

Our POS tagging system is based on linear chain CRFs. Since SIGHAN dose not provide development data, we use the 10 fold cross validation described in the previous experiment to turning feature templates and Gaussian prior. Feature templates are listed in Table 5, where w_i denotes the i^{th} word in

Table 5: Feature templates for Chinese word segmentation and POS tagging task

Table 6: Word segmentation results on Fourth SIGHAN Bakeoff CTB corpus

Rank	F1	Description
1/26	95.89*	official best, using extra unlabeled data (Zhao and Kit, 2008)
2/26	95.33	official second
3/26	95.17	official third
4/26	95.12	segmentor in pipeline system

Table 7: POS results on Fourth SIGHAN Bakeoff CTB corpus

Rank	Accuracy	Description
1/7	94.29	POS tagger in pipeline system
2/7	94.28	official best
3/7	94.01	official second
4/7	93.24	official third

the sentence, $c_j(w_i), j > 0$ denotes the j^{th} Chinese character of word w_i, $c_j(w_i), j < 0$ denotes the j^{th} last Chinese character, $l(w_i)$ denotes the word length of w_i. We compare our POS tagger with other top systems on Bakeoff CTB POS corpus where sentences are perfectly segmented into words, our POS tagger achieved 94.29 accuracy, which is the best of 7 official runs. Comparison results are shown in Table 7.

For reranking method, we varied candidate numbers n among $n \in \{10, 20, 50, 100\}$. For hybrid CRFs, we use the same segmentation label set as the segmentor in pipeline. Feature templates are listed in Table 5. Experimental results are shown in Figure 3. The gain of hybrid CRFs over the baseline pipeline model is 0.48 points in F-score, about 3 times higher than 100-best reranking approach which achieves 0.13 points improvement. Though larger candidate number can achieve higher performance, such improvement becomes trivial for $n > 20$.

Table 8 shows the comparison between our work and other relevant work. Notice that, such comparison is indirect due to different data sets and re-

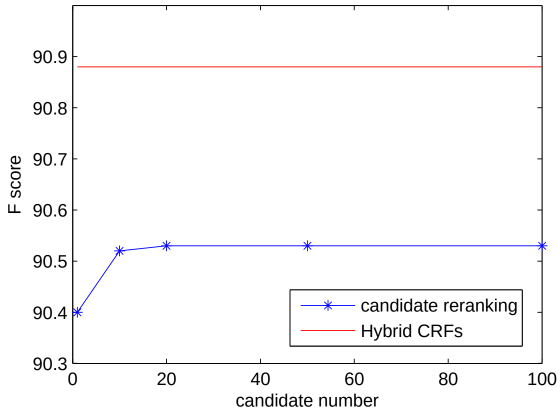

Figure 3: Results for Chinese word segmentation and POS tagging task, Hybrid CRFs significantly outperform 100-Best Reranking (McNemar's test; $p < 0.01$)

sources. One common conclusion is that joint models generally outperform pipeline models.

5 Conclusion

We introduced a framework to integrate graph structures for segmentation and tagging subtasks into one using virtual nodes, and performs joint training and decoding in the factorized state space. Our approach does not suffer from error propagation, and guards against violations of those hard-constraints imposed by segmentation subtask. Experiments on shallow parsing and Chinese word segmentation tasks demonstrate our technique.

Crouching Dirichlet, Hidden Markov Model: Unsupervised POS Tagging with Context Local Tag Generation

Abstract

We define the crouching Dirichlet, hidden Markov model (CDHMM), an HMM for part-of-speech tagging which draws state prior distributions for each local document context. This simple modification of the HMM takes advantage of the dichotomy in natural language between content and function words. In contrast, a standard HMM draws all prior distributions once over all states and it is known to perform poorly in unsupervised and semi-supervised POS tagging. This modification significantly improves unsupervised POS tagging performance across several measures on five data sets for four languages. We also show that simply using different hyperparameter values for content and function word states in a standard HMM (which we call HMM+) is surprisingly effective.

1 Introduction

Hidden Markov Models (HMMs) are simple, versatile, and widely-used generative sequence models. They have been applied to part-of-speech (POS) tagging in supervised (Brants, 2000), semi-supervised (Goldwater and Griffiths, 2007; Ravi and Knight, 2009) and unsupervised (Johnson, 2007) training scenarios. Though discriminative models achieve better performance in both semi-supervised (Smith and Eisner, 2005) and supervised (Toutanova et al., 2003) learning, there has been only limited work on unsupervised discriminative sequence models (e.g., on synthetic data and protein sequences (Xu et al., 2006)), and none to POS tagging.

The tagging accuracy of purely unsupervised HMMs is far below that of supervised and semi-supervised HMMs; this is unsurprising as it is still not well understood what kind of structure is being found by an unconstrained HMM (Headden III et al., 2008). However, HMMs are fairly simple directed graphical models, and it is straightforward to extend them to define alternative generative processes. This also applies to linguistically motivated HMMs for recovering states and sequences that correspond more closely to those implicitly defined by linguists when they label sentences with parts-of-speech.

One way in which a basic HMM's structure is a poor model for POS tagging is that there is no inherent distinction between (open-class) content words and (closed-class) function words. Here, we propose two extensions to the HMM. The first, HMM+, is a very simple modification where two different hyperparameters are posited for content states and function states, respectively. The other is the *crouching Dirichlet, hidden Markov model* (CDHMM), an extended HMM that captures this dichotomy based on the statistical evidence that comes from context. Content states display greater variance across local context (e.g. sentences, paragraphs, documents), and we capture this variance by adding a component to the model for content states that is based on latent Dirichlet allocation (Blei et al., 2003). This extension is in some ways similar to the LDAHMM of Griffiths et al. (2005). Both models are composite in that two distributions do not mix with each other. Unlike the LDAHMM, the generation of content states is folded into the CDHMM process.

We compare the HMM+ and CDHMM against a basic HMM and LDAHMM on POS tagging on a more extensive and diverse set of languages than previous work in monolingual unsupervised POS tagging: four languages from three families (*Germanic*: English and German; *Romance*: Portuguese;

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 196–206,
MIT, Massachusetts, USA, 9-11 October 2010.

and *Mayan*: Uspanteko). The CDHMM easily outperforms all other models, including HMM+, across three measures (accuracy, F-score, and variation of information) for unsupervised POS tagging on most data sets. However, the HMM+ is surprisingly competitive, outperforming the basic HMM and LDAHMM, and rivaling or even passing the CDHMM on some measures and data sets.

2 Background

The Bayesian formulation for a basic HMM (Goldwater and Griffiths, 2007) is:

$$\begin{array}{rcl} \psi_t|\xi & \sim & \mathrm{Dir}(\xi) \\ \delta_t|\gamma & \sim & \mathrm{Dir}(\gamma) \\ w_i|t_i = t & \sim & \mathrm{Mult}(\psi_t) \\ t_i|t_{i-1} = t & \sim & \mathrm{Mult}(\delta_t) \end{array}$$

Dir is the conjugate Dirichlet prior to Mult (a multinomial distribution). The state transitions are generated by Mult(δ_t) whose prior δ_t is generated by Dir(γ) with a symmetric (i.e. uniform) hyperparameter γ. Emissions are generated by Mult(ψ_t) with a prior ψ_t generated by Dir(ξ) with a symmetric hyperparameter ξ. Hyperparameter values smaller than one encourage posteriors that are peaked, with smaller values increasing this concentration. It is not necessary that the hyperparameters be symmetric, but this is a common approach when one wants to be naïve about the data. This is particularly appropriate in unsupervised POS tagging with regard to novel data since there won't be *a priori* grounds for favoring certain distributions over others.

There is considerable work on extensions to HMM-based unsupervised POS tagging (see §6), but here we concentrate on the LDAHMM (Griffiths et al., 2005), which models topics and state sequences jointly. The model is a composite of a probabilistic topic model and an HMM in which a single state is allocated for words generated from the topic model. A strength of this model is that it is able to use less supervision than previous topic models since it does not require a stopword list. While the topic model component still uses the bags-of-words assumption, the joint model infers which words are more likely to carry topical content and which words are more likely to contribute to the local sequence. This model is competitive with a standard topic model, and its output is also competitive when compared with a standard HMM. However, Griffiths et al. (2005) note that the topic model component inevitably loses some finer distinctions with respect to parts-of-speech. Though many content states such as adjectives, verbs, and nouns can vary a great deal across documents, the topic state groups these words together. This leads to assignment of word tokens to clusters that are a poorer fit for POS tagging. This paper shows that a model that conflates the LDAHMM topics with content states can significantly improve POS tagging.

3 Models

We aim to model the fact that in many languages words can generally be grouped into function words and content words and that these groups often have significantly different distributions. There are few function words and they appear frequently, while there are many content words appearing infrequently. Another difference in distribution is often implied in information retrieval by the use of stopword filters and *tf-idf* values to remove or reduce the influence of words which occur frequently but have low variance (i.e. their global probability is similar to their local probability in a document).

A difference in distribution is also revealed when the parts-of-speech are known. When no smoothing parameters are added, the joint probability of a word that is not 'the' or 'a' occurring with a `DT` tag (in the Penn Treebank) is almost always zero. Similarly peaked distributions are observed for other function categories such as `MD` and `CC`. On the other hand, the joint probability of any word occurring with `NN` is much less likely to be zero and the distribution is much less likely to be peaked.

We attempt to account for these two distributional properties—that certain words have higher variance across contexts (e.g. a document) and that certain tags have more peaked emission distributions—in a sequence model. To do this, we define the *crouching Dirichlet, hidden Markov model*[1] (CDHMM). This model, like LDAHMM, captures items of high variance across contexts, but it does so without losing

[1] We call our model a "crouching Dirichlet" model since it involves a Dirichlet prior that generates distributions for certain states as if it were "crouching" on the side.

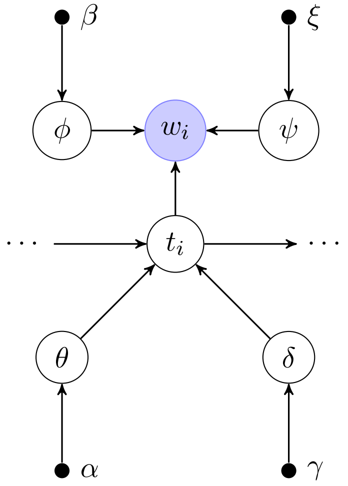

Figure 1: Graphical representation of relevant variables and dependencies at a given time step i. Observed word w_i is dependent on hidden state t_i. Edges to priors θ, ϕ, ψ may or may not be activated depending on the value of t_i. The edge to transition prior δ is always activated. Hyperparameters to priors are represented by dots. See §3.1 for details.

sequence distinctions, namely, a given word's local function via its part-of-speech. We also define the HMM+, a simple adaptation of a basic HMM which accounts for the latter property by using different priors for emissions from content and function states.

3.1 CDHMM

The CDHMM incorporates an LDA-like module to its graphical structure in order to capture words and tags which have high variance across contexts. Such tags correspond to content states. Like the LDAHMM, the model is composite in that distributions over a single random variable are composed of several different distribution functions which depend on the value of the underlying variable.

We posit the following model (see fig. 1 for a diagram of dependencies and all variables involved at a single time step). We observe a sequence of tokens $\mathbf{w}{=}(w_1, \ldots, w_N)$ that we assume is generated by an underlying state sequence $\mathbf{t}{=}(t_1, \ldots, t_N)$ over a state alphabet T with first order Markov dependencies. T is a union of disjoint content states C and function states F. In this composite model, the priors for the emission and transition for each step in the sequence depend on whether state t at step i is $t{\in}C$ or $t{\in}F$. If $t{\in}C$, the word emission is dependent on ϕ (the content word prior) and the state transition is dependent on θ (the "topic" prior) and δ (the transition prior). If $t{\in}F$, the word emission probability is dependent on ψ (the function word prior) and the state transition on δ (again, the transition prior). Therefore, if $t{\in}F$, the transition and emission structure is identical to the standard Bayesian HMM.

To elaborate, three prior distributions are defined globally for this model: (1) δ_t, the transition prior such that $p(\hat{t}|t, \delta_t) = \delta_{\hat{t}|t}$ (2) ψ_t, the function word prior such that $p(w|t, \psi_t) = \psi_{w|t}$ (3) ϕ_t, the content word prior such that $p(w|t, \phi_t) = \phi_{w|t}$. Locally for each context d (documents in our case), we define θ_d, the topic prior such that $p(t|\theta_d) = \theta_{t|d}$ for $t{\in}C$.

The generative story is as follows:

1. For each state $t{\in}T$
   (a) Draw a distribution over states $\delta_t \sim \text{Dir}(\gamma)$
   (b) If $t{\in}C$, draw a distribution over words $\phi_t \sim \text{Dir}(\beta)$
   (c) If $t{\in}F$, draw a distribution over words $\psi_t \sim \text{Dir}(\xi)$
2. For each context d
   (a) Draw a distribution $\theta_d \sim \text{Dir}(\alpha)$ over states $t{\in}C$
   (b) For each word w_i in d
      i. draw t_i from $\delta_{t_{i-1}} \circ \theta_d$
      ii. if $t_i{\in}C$, then draw w_i from ϕ_{t_i}, else draw w_i from ψ_{t_i}

For each context d, we draw a prior distribution θ_d—formally identical to the LDA topic prior—that is defined only for the states $t{\in}C$. This prior is then used to weight the draws for states at each word, from $\delta_{t_{i-1}} \circ \theta_d$, where we have defined the vector valued operation $\circ$ as follows:

$$(\delta_{t_{i-1}} \circ \theta_d)_{t_i} = \begin{cases} \frac{1}{Z}\delta_{t_i|t_{i-1}} \cdot \theta_{t_i|d} & t_i{\in}C \\ \frac{1}{Z}\delta_{t_i|t_{i-1}} & t_i{\in}F \end{cases}$$

where $(\delta_{t_{i-1}} \circ \theta_d)_{t_i}$ is the element corresponding to state t_i in the vector $\delta_{t_{i-1}} \circ \theta_d$. Z is a normalization constant such that the probability mass sums to one.

$$p(t_i|\mathbf{t}_{-i},\mathbf{w}) \propto \begin{cases} \frac{N_{w_i|t_i}+\beta}{N_{t_i}+W\beta}\ \frac{N_{t_i|d_i}+\alpha}{N_{d_i}+C\alpha}\ \frac{\left(N_{t_i|t_{i-1}}+\gamma\right)\left(N_{t_{i+1}|t_i}+\mathrm{I}[t_{i-1}=t_i=t_{i+1}]+\gamma\right)}{N_{t_i}+T\gamma+\mathrm{I}[t_i=t_{i-1}]} & t_i \in C \\ \frac{N_{w_i|t_i}+\xi}{N_{t_i}+W\xi}\ \frac{\left(N_{t_i|t_{i-1}}+\gamma\right)\left(N_{t_{i+1}|t_i}+\mathrm{I}[t_{i-1}=t_i=t_{i+1}]+\gamma\right)}{N_{t_i}+T\gamma+\mathrm{I}[t_i=t_{i-1}]} & t_i \in F \end{cases}$$

Figure 2: Conditional distribution for t_i in the CDHMM.

The important thing to note is that the draw for states at each word is proportional to a *composite* of (a) the product of the individual elements of the topic and transition priors when $t_i{\in}C$ and (b) the transition priors when $t_i{\in}F$. The draw is proportional to the product of topic and transition priors when $t_i{\in}C$ because we have made a product of experts (PoE) factorization assumption (Hinton, 2002) for tractability and to reduce the size of our model. Without such an assumption, the transition parameters would lie in a partitioned space of size $O(|C|^4)$ as opposed to $O(|T|^2)$ for the current model. Furthermore, this combination of a composite hidden state space with a product of experts assumption allows us to capture high variance for certain states.

To summarize, the CDHMM is a composite model where both the observed token and the hidden state variable are composite distributions. For the hidden state, this means that there is a "topical" element with high variance across contexts that is embedded in the state sequence for a subset of events. We embed this element through a PoE assumption where transitions into content states are modeled as a product of the transition probability and the local probability of the content state.

Inference. We use a Gibbs sampler (Gao and Johnson, 2008) to learn the parameters of this and all other models under consideration. In this inference regime, two distributions are of particular interest. One is the posterior density and the other is the conditional distribution, neither of which can be learned in closed form.

Letting $\Lambda = (\theta, \delta, \phi, \psi)$ and $h = (\alpha, \beta, \gamma, \xi)$, the posterior density is given as

$$p(\Lambda|\mathbf{w},\mathbf{t};h) \propto p(\mathbf{w},\mathbf{t}|\Lambda)p(\Lambda;h)$$

Note that $p(\mathbf{w},\mathbf{t}|\Lambda)$ is equal to

$$\prod_d^D \prod_i^{N_d} \left(\phi_{w_i|t_i}\theta_{t_i|d}\delta_{t_i|t_{i-1}}\right)^{\mathrm{I}[t_i \in C]} \left(\psi_{w_i|t_i}\delta_{t_i|t_{i-1}}\right)^{\mathrm{I}[t_i \in F]} \quad (1)$$

where I$[\cdot]$ is the indicator function, D is the number of documents in the corpus and N_d is the number of tokens in document d.

Another important measure is the conditional distribution which is conditioned on all the random variables except the hidden state variable of interest and which is derived by integrating out the priors:

$$p(t_i|\mathbf{t}_{-i},\mathbf{w};h) \propto p(t_i|\mathbf{t}_{-i};h)p(w_i|\mathbf{t},\mathbf{w}_{-i};h) \quad (2)$$

where $\mathbf{t}_{-i}$ is the joint random variable $\mathbf{t}$ without t_i and $\mathbf{w}_{-i}$ is $\mathbf{w}$ without w_i.

There are two well-known approaches to conducting Gibbs sampling for HMMs. The default method is to sample Λ based on the posterior, then sample each t_i based on the conditional distribution. Another approach is to sample directly from the conditional distribution without sampling from the posterior since the conditional distribution incorporates the posterior through integration. This is called a collapsed Gibbs sampler, which is the method employed for the models in this study.

The full conditional distribution for tag transitions for the Gibbs sampler is given in Figure 2. At each time step, we decrement all counts for the current value of t_i, sample a new value for t_i from a multinomial proportional to the conditional distribution and assign that value to t_i. β, ξ are the hyperparameters for the word emission priors of the content states and function states, respectively. γ is the hyperparameter for the state transition priors. α is the hyperparameter for the state prior given that it is in some context d. Note that we have overridden notation so that C and T here refer to the size of the alphabet. W is the size of the vocabulary. Notation such as $N_{t_i|t_{i-1}}$ refers to the counts of the events indicated by the subscript, minus the current token and tag under consideration. $N_{t_i|t_{i-1}}$ is the number of times t_i has occurred after t_{i-1} minus the tag for w_i. $N_{w_i|t_i}$ is the number of times w_i has occurred with t_i minus the current value. N_{t_i} and N_{d_i} are the counts for the given tag and document minus the current value.

In its broad outline, the CDHMM is not much more complicated than an HMM since the decomposition (eqn. 1) is nearly identical to that of an HMM with the exception that conditional probabilities for a subset of the states—the content states—are local. An inference algorithm can be derived that involves no more than adding a single term to the standard MCMC algorithm for HMMs (see Figure 2).

3.2 HMM+

The CDHMM explicitly posits two different types of states: function states and content states. Having made this distinction, there is a very simple way to capture the difference in emission distributions for function and content states within an otherwise standard HMM: posit different hyperparameters for the two types. One type has a small hyperparameter to model a sparse distribution for function words and the other has a relatively large hyperparameter to model a distribution with broader support. This extension, which we refer to as HMM+, provides an important benchmark to compare with the CDHMM to see how much is gained by its additional ability to model the fact that function words occur frequently but have low variance across contexts.

As with the CDHMM, we use Gibbs sampling to estimate the model parameters while holding the two different hyperparameters fixed. The conditional distribution for tag transitions for this model is identical to that in fig. 2 except that it does not have the second term $\frac{N_{t_i|d_i}+\alpha}{N_{d_i}+C\alpha}$ in the first case where $t_i \in C$.

We are not aware of a published instance of such an extension to the HMM—which our results show to be surprisingly effective. Goldwater and Griffiths (2007) posits different hyperparameters for individual states, but not for different groups of states.

corpus	tokens	docs	avg.	tags
WSJ	974254	1801	541	43
Brown	797328	343	2325	80
Tiger	447079	1090	410	58
Floresta	197422	1956	101	19
Uspanteko	70125	29	2418	83

Table 2: Number of tokens, documents, average tokens per document and total tag types for each corpus.

4 Data and Experiments

Data. We use five datasets from four languages (English, German, Portuguese, Uspanteko) for evaluating POS tagging performance.

- *English*: the Brown corpus (Francis et al., 1982) and the Wall Street Journal portion of the Penn Treebank (Marcus et al., 1994).
- *German*: the Tiger corpus (Brants et al., 2002).
- *Portuguese*: the full Bosque subset of the Floresta corpus (Afonso et al., 2002).
- *Uspanteko* (an endangered Mayan language of Guatemala): morpheme-segmented and POS-tagged texts collected and annotated by the OKMA language documentation project (Pixabaj et al., 2007); we use the cleaned-up version described in Palmer et al. (2009).

Table 2 provides the statistics for these corpora.

We lowercase all words, do not remove any punctuation or *hapax legomena*, and we do not replace numerals with a single identifier. Due to the nature of the models, document boundaries are retained.

Evaluation We report values for three evaluation metrics on all five corpora, using their full tagsets.

- *Accuracy*: We use a greedy search algorithm to map each unsupervised tag to a gold label such that accuracy is maximized. We evaluate on a **1-to-1** mapping between unsupervised tags and gold labels, as well as many-to-1 (**M-to-1**), corresponding to the evaluation mappings used in Johnson (2007). The 1-to-1 mapping provides a stricter evaluation. The many-to-one mapping, on the other hand, may be more adequate as unsupervised tags tend to be more fine-grained than

	Model	Accuracy		Pairwise P/R Scores			VI
		1-to-1	M-to-1	P	R	F

Table 1: Evaluation on WSJ, Brown, Tiger, Floresta and Uspanteko for models with 50 states. For VI, lower is better

gold part-of-speech tags. In particular, they tend to form semantically coherent sub-classes of gold parts of speech.

- *Pairwise Precision and Recall*: Viewing tagging as a clustering task over tokens, we evaluate pairwise precision (P) and recall (R) between the model tag sequence (M) and gold tag sequence (G) by counting the true positives (tp), false positives (fp) and false negatives (fn) between the two and setting $P = tp/(tp + fp)$ and $R = tp/(tp + fn)$. tp is the number of token pairs that share a tag in M as well as in G, fp is the number token pairs that share the same tag in M but have different tags in G, and fn is the number token pairs assigned a different tag in M but the same in G (Meila, 2007). We also provide the f-score which is the harmonic mean of P and R.
- *Variation of Information (VI)*: The variation of information is an information theoretic metric that measures the amount of information lost and gained in going from tag sequence M to G (Meila, 2007). It is defined as $VI(M, G) = H(M) + H(G) - 2I(M, G)$ where H denotes entropy and I mutual information. Goldwater and Griffiths (2007) noted that this measure can point out models that have more consistent errors in the form of lower VI, even when accuracy figures are the same.

We also report learning curves on **M-to-1** with geometrically increasing training set sizes of 8, 16, 32, 64, 128, 256, 512, 1024, and all documents, or as many as possible given the corpus.

5 Experiments

In this section we discuss our parameter settings and experimental results.

5.1 Models and Parameters

We compare four different models:

- HMM: a standard HMM
- HMM+: an HMM in which the hyperparameters for the word emissions are asymmetric, such that content states have different word emission priors compared to function states.
- LDAHMM: an HMM with a distinguished state that generates words from a topic model (Griffiths et al., 2005)

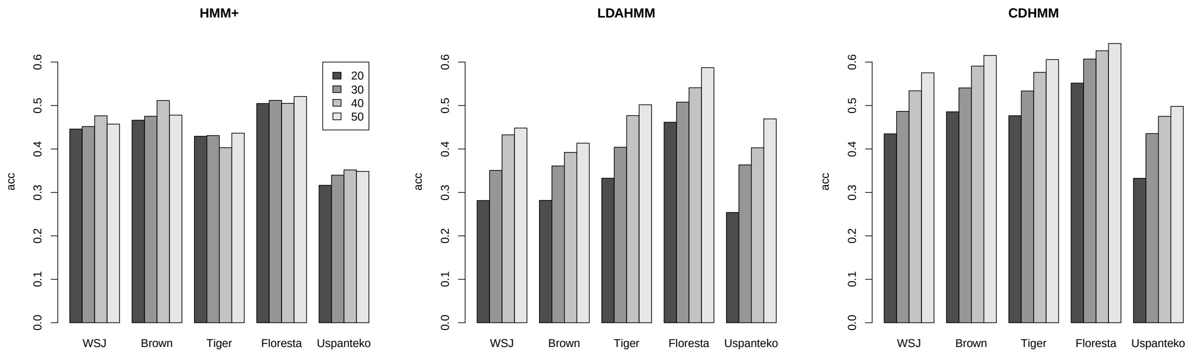

Figure 3: Averaged many-to-one accuracy on the full tagset for the models HMM+, LDAHMM, CDHMM when the number of states is set at 20, 30, 40 and 50 states.

- CDHMM: our HMM with context-based emissions, where the context used is the document

We implemented all of these models, ensuring performance differences are due to the models themselves rather than implementation details.

For all models, the transition hyperparameters γ are set to 0.1. For the LDAHMM and HMM all emission hyperparameters are set to 0.0001. These figures are the MCMC settings that provided the best results in Johnson (2007). For the models that distinguish content and function states (HMM+, CDHMM), we fixed the number of content states at 5 and set the function state emission hyperparameters $\xi = 0.0001$ and the content state emission hyperparameters $\beta = 0.1$. For the models with an LDA or LDA-like component (LDAHMM, CDHMM), we set the topic or content-state hyperparameter $\alpha = 1$.

For decoding, we use maximum posterior decoding to obtain a single sample after the required burn-in, as has been done in other unsupervised HMM experiments. We use this sample for evaluation.

5.2 Results

Results for all models on the full tagset are provided in table 1.[2] Each number is the mean accuracy of ten randomly initialized samples after a single chain burn-in of 1000 iterations. The model with a statistically significant ($p < 0.05$) best score for each measure and data set is given in plain bold. In cases where the differences for the best models are not significantly different from each other, but are significantly better from the others, the top model scores are given in bold italic.

CDHMM is extremely strong on the accuracy metric: it wins or ties for all datasets for both 1-to-1 and M-to-1 measures. For pairwise f-score, it obtains the best score for two datasets (WSJ and Tiger), and ties with HMM+ on Brown (we return to Uspanteko and Floresta below in an experiment that varies the number of states). For VI, HMM+ and CDHMM both easily outperform the other models, with CDHMM winning Brown and Uspanteko and HMM+ winning Floresta.

In the case of Uspanteko, the absolute difference in mean performance between models is smaller overall but still significant. This is due to the reduced variance between samples for all models. This is striking because the non-CDHMM models have much higher standard deviation on other corpora but have sharply reduced standard deviation only for Uspanteko. The most likely explanation is that the Uspanteko corpus is much smaller than the other corpora.[3] Nonetheless, CDHMM comes out strongest on most measures.

A simple baseline for accuracy is to choose the most frequent tag for all tokens; this gives accuracies of 0.14 (WSJ), 0.14 (Brown), 0.21 (Tiger), 0.20

[2] Similar results are obtained with reduced tagsets, as is commonly done in other work on unsupervised POS-tagging.

[3] which is interesting in itself since the weak law of large numbers implies that sample standard deviation decreases with sample size, which in our case is the number of tokens rather than the 10 samples under discussion

	Model	Accuracy		P/R Scores			VI
		1-to-1	M-to-1	P	R	F	
Usp. (100)	HMM	0.36 (0.01)	0.58 (0.01)	**0.56** (0.02)	0.16 (0.00)	0.25 (0.01)	3.53 (0.04)
	LDAHMM	0.35 (0.01)	0.58 (0.02)	0.45 (0.04)	0.17 (0.01)	0.24 (0.01)	3.46 (0.06)
	HMM+	0.35 (0.02)	0.41 (0.02)	0.18 (0.01)	**0.36** (0.03)	0.24 (0.01)	3.25 (0.08)
	CDHMM	**0.40** (0.01)	**0.59** (0.01)	0.25 (0.02)	0.27 (0.02)	**0.26** (0.01)	**3.05** (0.03)
Flor. (20)	HMM	0.31 (0.02)	0.48 (0.03)	**0.40** (0.03)	0.21 (0.01)	0.28 (0.02)	3.54 (0.10)
	LDAHMM	0.35 (0.06)	0.46 (0.06)	0.27 (0.07)	0.45 (0.08)	0.33 (0.05)	3.10 (0.10)
	HMM+	0.37 (0.04)	0.50 (0.03)	0.30 (0.02)	0.45 (0.06)	0.36 (0.03)	2.62 (0.06)
	CDHMM	**0.44** (0.02)	**0.55** (0.02)	0.30 (0.01)	**0.53** (0.03)	**0.39** (0.02)	**2.39** (0.07)

Table 3: Evaluation for Uspanteko and Floresta. Experiments in this table use state sizes that correspond more closely to the size of the tag sets in the respective corpora.

(Floresta), and 0.11 (Uspanteko). Clearly, all of the models easily outperform this baseline.

Number of states. Figure 3 shows the change in accuracy for the different models for different corpora when the overall number of states is varied between 20 and 50. The figure shows results for **M-to-1**. All models with the exception of HMM+ show improvements as the number of states is increased. This brings up the valid concern (Clark, 2003; Johnson, 2007) that a model could posit a very large number of states and obtain high M-to-1 scores. However, it is neither the case here nor in any of the studies we cite. Furthermore, as is strongly suggested with HMM+, it does not seem as if all models will benefit from assuming a large number of states.

Looking at the results by number of states on VI and f-score for CDHMM(Figure 5), it is clear that Floresta displays the reverse pattern of all other data sets where performance monotonically deteriorates as state sizes are increased. Though the exact reason is unknown, we believe it is partially due to the fact that Floresta has 19 tags. We therefore wondered whether positing a state size that more closely approximated the size of the gold tag set performs better. Since the discrepancy is greatest for Uspanteko and Floresta, we present tabulated results for experiments with state settings of 100 and 20 states respectively (table 3). With the exception of VI (where lower is better) for Uspanteko, the scores generally improve when the model state size is closer to the gold size. **M-to-1** goes down for Floresta when 20 states are posited, but this is to be expected since this score is defined, to a certain extent, to do better with larger models.

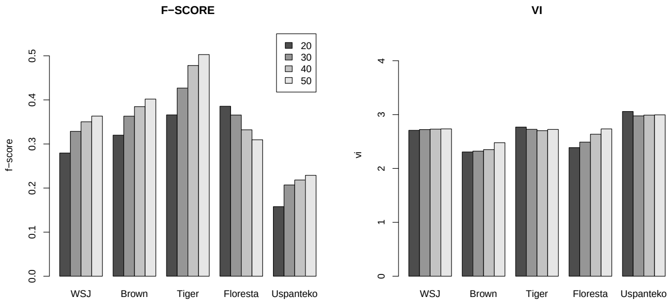

Figure 5: f-score and VI for CDHMM by number of states

Variance. As we average performance figures over ten runs for each model, it is also instructive to consider standard deviation across runs. Standard deviation is lowest for the CDHMM models and the vanilla HMM. Standard deviation is high for HMM+ and LDAHMM. This is not surprising for LDAHMM, since it has fifty topic parameters in addition to the number of states posited, and random initial conditions would have greater effect on the outcome than for the other models. It is unexpected, however, that HMM+ has high variance over different chains. The model shares the large content emission hyperparameter $\beta = 0.1$ with CDHMM. At this point, it can only be assumed that the additional LDA component acts as a regularization factor for CDHMM and reduced the volatility in having a large emission hyperparameter.

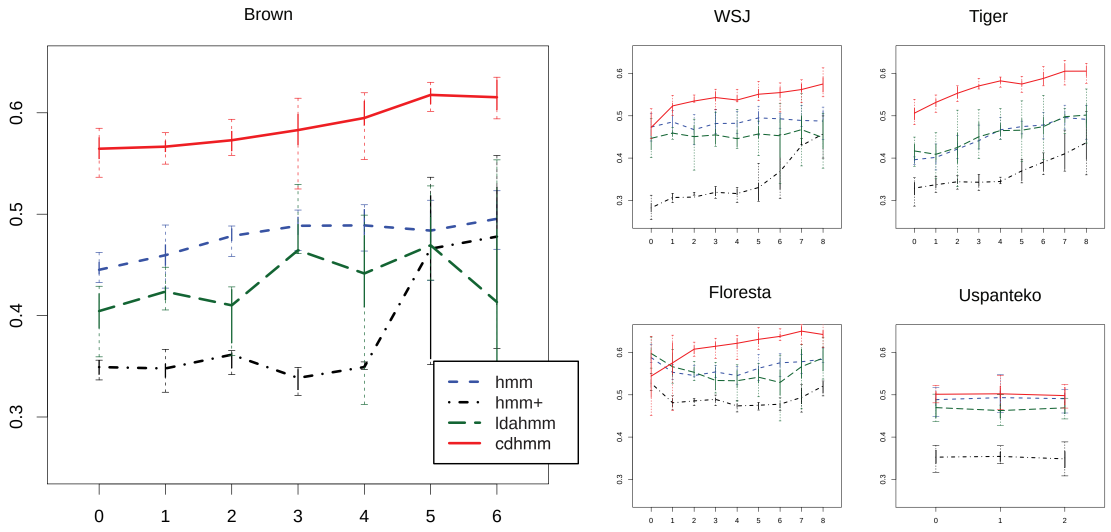

Figure 4: Learning curves on M-to-1 evaluation. The staples at each point represent two standard deviations.

Learning curves We present learning curves on different sizes of subcorpora in Figure 4. The graphs are box plots of the full M-1 accuracy figures on 10 randomly initialized training runs for seven subcorpora in Brown, nine in WSJ, Tiger, Floresta and three in Uspanteko.

Comparing the graphs, the performance of HMM+ shows the strongest improvement for English and German data as the amount of training data increases. Also, it is evident that CDHMM posts consistent performance gains across data sets as it trains on more data. This stands in opposition to HMM and LDAHMM which do not seem able to take advantage of more information for WSJ and Floresta. This suggests that performance for CDHMM and HMM+ could improve if the training corpora were augmented with out-of-corpus raw data. One exception to the consistent improvement over increased data is the performance of the models on Uspanteko, which uniformly flatline. One reason might be that the tags are labeled over segmented morphemes instead of words like the other corpora. Another could be that Uspanteko has a relatively large number of tags in a very small corpus.

6 Related work

Unsupervised POS tagging is an active area of research. Most recent work has involved HMMs. Given that an unconstrained HMM is not well understood in POS tagging, much work has been done on examining the mechanism and the properties of the HMM as applied to natural language data (Johnson, 2007; Gao and Johnson, 2008; Headden III et al., 2008). Conversely, there has also been work focused on improving the HMM as an inference procedure that looked at POS tagging as an example (Graca et al., 2009; Liang and Klein, 2009). Nonparametric HMMs for unsupervised POS tag induction (Snyder et al., 2008; Van Gael et al., 2009) have seen particular activity due to the fact that model size assumptions are unnecessary and it lets the data "speak for itself."

There is also work on alternative unsupervised models that are not HMMs (Schütze, 1993; Abend et al., 2010; Reichart et al., 2010b) as well as research on improving evaluation of unsupervised taggers (Frank et al., 2009; Reichart et al., 2010a).

Though they did not concentrate on unsupervised methods, Haghighi and Klein (2006) conducted an unsupervised experiment that utilized certain token features (e.g. character suffixes of 3 or less, has initial capital, etc.; the features themselves are from Smith and Eisner (2005)) to learn parameters in an undirected graphical model which was the equivalent of an HMM in directed models. It was also the first study to posit the one-to-one evaluation criterion which has been repeated extensively since (Johnson, 2007; Headden III et al., 2008; Graca et al., 2009).

Finkel et al. (2007) is an interesting variant of unsupervised POS tagging where a parse tree is assumed and POS tags are induced from this structure non-parametrically. It is the converse of unsupervised parsing which assumes access to a tagged corpus and induces a parsing model.

Other models more directly influenced or closely parallel our work. Griffiths et al. (2005) is the work that inspired the current approach where a set of states is designated to capture variance across contexts. The primary goal of that model was to induce a topic model given data that had not been filtered of noise in the form of function words. As such, distinguishing between topic states such that they model different syntactic states was not attempted, and we have seen in sec. 3 that such an extension is not entirely straightforward.[4] Boyd-Graber and Blei (2009) has some parallels to our model in that a hidden variable over topics is distributed according to a normalized product between a context prior and a syntactic prior. However, it assumes a much greater amount of information than we do in that a parse tree as well as (possibly) POS tags are taken as observed. The model has a very different goal from ours as well, which is to infer a syntactically informed topic model. Teichert and Daumé III (2010) is another study with close similarities to our own. This study models distinctions between closed class words and open class words within a modified HMM. It is unclear from their formulation how the distinction between open class and closed class words is learned.

There is also extensive literature on learning sequence structure from *unlabeled* text (Smith and Eisner, 2005; Goldberg et al., 2008; Ravi and Knight, 2009) which assume access to a tag dictionary. Goldwater and Griffiths (2007) deserves mention for examining a semi-supervised model that sampled emission hyperparameters for each state rather than a single symmetric hyperparameter. They showed that this outperformed a symmetric model. An interesting heuristic model is Zhao and Marcus (2009) that uses a seed set of closed class words to classify open class words.

7 Conclusion

We have shown that a hidden Markov model that allocates a subset of the states to have distributions conditioned on localized domains can significantly improve performance in unsupervised part-of-speech tagging. We have also demonstrated that significant performance gains are possible simply by setting a different emission hyperparameter for a subgroup of the states. It is encouraging that these results hold for both models not just on the WSJ but across a diverse set of languages and measures.

We believe our proposed extensions to the HMM are a significant contribution to the general HMM and unsupervised POS tagging literature in that both can be implemented with minimum modification of existing MCMC inferred HMMs, have (nearly) equivalent run times, produce output that is easy to interpret since they are based on a generative framework, and bring about considerable performance improvements at the same time.

Abstract

The problem of automatically classifying the gender of a blog author has important applications in many commercial domains. Existing systems mainly use features such as words, word classes, and POS (part-of-speech) n-grams, for classification learning. In this paper, we propose two new techniques to improve the current result. The first technique introduces a new class of features which are variable length POS sequence patterns mined from the training data using a sequence pattern mining algorithm. The second technique is a new feature selection method which is based on an ensemble of several feature selection criteria and approaches. Empirical evaluation using a real-life blog data set shows that these two techniques improve the classification accuracy of the current state-of-the-art methods significantly.

1 Introduction

Weblogs, commonly known as blogs, refer to online personal diaries which generally contain informal writings. With the rapid growth of blogs, their value as an important source of information is increasing. A large amount of research work has been devoted to blogs in the natural language processing (NLP) and other communities. There are also many commercial companies that exploit information in blogs to provide value-added services, e.g., blog search, blog topic tracking, and sentiment analysis of people's opinions on products and services. Gender classification of blog authors is one such study, which also has many commercial applications. For example, it can help the user find what topics or products are most talked about by males and females, and what products and services are liked or disliked by men and women. Knowing this information is crucial for market intelligence because the information can be exploited in targeted advertising and also product development.

In the past few years, several authors have studied the problem of gender classification in the natural language processing and linguistic communities. However, most existing works deal with formal writings, e.g., essays of people, the Reuters news corpus and the British National Corpus (BNC). Blog posts differ from such text in many ways. For instance, blog posts are typically short and unstructured, and consist of mostly informal sentences, which can contain spurious information and are full of grammar errors, abbreviations, slang words and phrases, and wrong spellings. Due to these reasons, gender classification of blog posts is a harder problem than gender classification of traditional formal text.

Recent work has also attempted gender classification of blog authors using features such as content words, dictionary based content analysis results, POS (part-of-speech) tags and feature selection along with a supervised learning algorithm (Schler et al., 2006; Argamon et al., 2007; Yan and Yan, 2006). This paper improves these existing methods by proposing two novel techniques. The first technique adds a new class of pattern based features to learning, which are not used in any existing work. The patterns are frequent sequences of POS tags which can capture complex stylistic characteristics of male and female authors. We note that these patterns are very different from the traditional n-grams because the

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 207–217,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

patterns are of variable lengths and need to satisfy some criteria in order for them to represent significant regularities. We will discuss them in detail in Section 3.5.

The second technique is a new feature selection algorithm which uses an ensemble of feature selection criteria and methods. It is well known that each individual feature selection criterion and method can be biased and tends to favor certain types of features. A combination of them should be able to capture the most useful or discriminative features.

Our experimental results based on a real life blog data set collected from a large number of blog hosting sites show that the two new techniques enable classification algorithms to significantly improve the accuracy of the current state-of-the-art techniques (Argamon et al., 2007; Schler et al., 2006; Yan and Yan, 2006). We also compare with two publicly available systems, *Gender Genie* (BookBlog, 2007) and *Gender Guesser* (Krawetz, 2006). Both systems implemented variations of the method given in (Argamon et al., 2003). Here, the improvement of our techniques is even greater.

2 Related Work

There have been several recent papers on gender classification of blogs (e.g., Schler et al., 2006, Argamon et al., 2007; Yan and Yan, 2006; Nowson et al., 2005). These systems use function/content words, POS tag features, word classes (Schler et al., 2006), content word classes (Argamon et al., 2007), results of dictionary based content analysis, POS unigram (Yan and Yan, 2006), and personality types (Nowson et al., 2005) to capture stylistic behavior of authors' writings for classifying gender. (Koppel et al. 2002) also used POS n-grams together with content words on the British National Corpus (BNC). (Houvardas and Stamatatos, 2006) even applied character (rather than word or tag) n-grams to capture stylistic features for authorship classification of news articles in Reuters.

However, these works use only one or a subset of the classes of features. None of them uses all features for classification learning. Given the complexity of blog posts, it makes sense to apply all classes of features jointly in order to classify genders. Moreover, having many feature classes is very useful as they provide features with varied granularities and diversities. However, this also results in a huge number of features and many of them are redundant and may obscure classification. Feature selection is thus needed. Following the idea, this paper proposes a new ensemble feature selection method which is capable of extracting good features from different feature classes using multiple criteria.

We also note some less relevant literature. For example, (Tannen, 1990) deals with gender differences in "conversational style" and in "formal written essays", and (Gefen and Straub, 1997) reports differences in perception of males and females in the use of emails.

Our new POS pattern features are related to POS n-grams used in (Koppel et al., 2002; Argamon et al., 2007), which considered POS 3-grams, 2-grams and unigrams as features. As shown in (Baayen et. al. 1996), POS n-grams are very effective in capturing the fine-grained stylistic and heavier syntactic information. In this work, we go further by finding POS sequence patterns. As discussed in the introduction, our patterns are entirely different from POS n-grams. First of all, they are of variable lengths depending on whatever lengths can catch the regularities. They also need to satisfy some constraints to ensure that they truly represent some significant regularity of male or female writings. Furthermore, our POS sequence patterns can take care of n-grams and capture additional sequence regularities. These automatically mined pattern features are thus more discriminating for classification.

3 Feature Engineering and Mining

There are different *classes* of features that have been experimented for gender classification, e.g., F-measure, stylistic features, gender preferential features, factor analysis and word classes (Nowson et al., 2005; Schler et al., 2006; Corney et al., 2002; Argamon et al., 2007). We use all these existing features and also propose a new class of features that are POS sequence patterns, which replace existing POS n-grams. Also, as mentioned before, using all feature classes gives us features with varied granularities. Upon extracting all these classes of features, a new *ensemble feature selection* (EFS) algorithm is proposed to select a subset of good or discriminative features.

Below, we first introduce the existing features, and then present the proposed class of new pattern based features and how to discover them.

3.1 F-measure

The F-measure feature was originally proposed in (Heylighen and Dewaele, 2002) and has been used in (Nowson et al., 2005) with good results. Note that F-measure here is not the F-score or F-measure used in text classification or information retrieval for measuring the classification or retrieval effectiveness (or accuracy).

F-measure explores the notion of implicitness of text and is a unitary measure of text's relative contextuality (implicitness), as opposed to its formality (explicitness). Contextuality and formality can be captured by certain parts of speech. A lower score of F-measure indicates contextuality, marked by greater relative use of pronouns, verbs, adverbs, and interjections; a higher score of F-measure indicates formality, represented by greater use of nouns, adjectives, prepositions, and articles. F-measure is defined based on the frequency of the POS usage in a text (*freq.x* below means the frequency of the part-of-speech *x*):

$$F = 0.5 * [(freq.noun + freq.adj + freq.prep + freq.art) - (freq.pron + freq.verb + freq.adv + freq.int) + 100]$$

(Heylighen and Dewaele, 2002) applied the F-measure to a corpus with known author genders and found a distinct difference between the sexes. Females scored lower preferring a more contextual style while males scored higher preferring a more formal style. F-measure values for male and female writings reported in (Nowson et al., 2005) also demonstrated a similar trend. In our work, we also use F-measure as one of the features.

3.2 Stylistic Features

These are features which capture people's writing styles. The style of writing is typically captured by three types of features: part of speech, words, and in the blog context, words such as *lol*, *hmm*, and *smiley* that appear with high frequency. In this work, we use words and blog words as stylistic features. Part of speech features are mined using our POS sequence pattern mining algorithm. POS n-grams can also be used as features. However, since we mine all POS sequence patterns and use them as features, most discriminative POS n-grams are already covered. In Section 5, we will also show that POS n-grams do not perform as well as our POS sequence patterns.

3.3 Gender Preferential Features

Gender preferential features consist of a set of signals that has been used in an email gender classification task (Corney et al., 2002). These features come from various studies that have been undertaken on the issue of gender and language use (Schiffman, 2002). It was suggested by these studies and also various other works that women's language makes more frequent use of emotionally intensive adverbs and adjectives like "so", "terribly", "awfully", "dreadfully" and women's language is more punctuated. On the other hand, men's conversational patterns express "independence" (Corney et al., 2002). In brief, the language expressed by males is more proactive at solving problems while the language used by females is more reactive to the contribution of others - agreeing, understanding and supporting. We used the gender preferential features listed in Table 1, which indicate adjectives and adverbs based on the presence of suffixes and apologies as used in (Corney et al., 2002). The feature value assignment will be discussed in Section 5.

3.4 Factor Analysis and Word Classes

Factor or word factor analysis refers to the process of finding groups of similar words that tend to occur in similar documents. This process is referred to as meaning extraction in (Chung and Pennebaker, 2007). Word lists for twenty factors, along with suggested labels/headings (for reference) were used as features in (Argamon et al., 2007). Here we list some of those features (word classes) in Table 2. For the detailed list of such word classes, the reader is referred to (Argamon et al., 2007). We also used these word classes as features in our work. In addition, we added three more new word classes implying positive, negative and emotional connotations and used them as features in our experiments. These are listed in Table 3.

Factor	*Words*
Conversation	*know, people, think, person, tell, feel, friends, talk, new, talking, mean, ask, understand, feelings, care, thinking, friend, relationship, realize, question, answer, saying*
Home	*woke, home, sleep, today, eat, tired, wake, watch, watched, dinner, ate, bed, day, house, tv, early, boring, yesterday, watching, sit*
Family	*years, family, mother, children, father, kids, parents, old, year, child, son, married, sister, dad, brother, moved, age, young, months, three, wife, living, college, four, high, five, died, six, baby, boy, spend, Christmas*
Food / Clothes	*food, eating, weight, lunch, water, hair, life, white, wearing, color, ice, red, fat, body, black, clothes, hot, drink, wear, blue, minutes, shirt, green, coffee, total, store, shopping*
Romance	*forget, forever, remember, gone, true, face, spent, times, love, cry, hurt, wish, loved*

Table 2: Words in factors

Positive	*absolutely, abundance, ace, active, admirable, adore, agree, amazing, appealing, attraction, bargain, beaming, beautiful, best, better, boost, breakthrough, breeze, brilliant, brimming, charming, clean, clear, colorful, compliment, confidence, cool, courteous, cuddly, dazzling, delicious, delightful, dynamic, easy, ecstatic, efficient, enhance, enjoy, enormous, excellent, exotic, expert, exquisite, flair, free, generous, genius, great, graceful, heavenly, ideal, immaculate, impressive, incredible, inspire, luxurious, outstanding, royal, speed, splendid, spectacular, superb, sweet, sure, supreme, terrific, treat, treasure, ultra, unbeatable, ultimate, unique, wow, zest*
Negative	*wrong, stupid, bad, evil, dumb, foolish, grotesque, harm, fear, horrible, idiot, lame, mean, poor, heinous, hideous, deficient, petty, awful, hopeless, fool, risk, immoral, risky, spoil, spoiled, malign, vicious, wicked, fright, ugly, atrocious, moron, hate, spiteful, meager, malicious, lacking*
Emotion	*aggressive, alienated, angry, annoyed, anxious, careful, cautious, confused, curious, depressed, determined, disappointed, discouraged, disgusted, ecstatic, embarrassed, enthusiastic, envious, excited, exhausted, frightened, frustrated, guilty, happy, helpless, hopeful, hostile, humiliated, hurt, hysterical, innocent, interested, jealous, lonely, mischievous, miserable, optimistic, paranoid, peaceful, proud, puzzled, regretful, relieved, sad, satisfied, shocked, shy, sorry, surprised, suspicious, thoughtful, undecided, withdrawn*

Table 3: Words implying positive, negative and emotional connotations

3.5 Proposed POS Sequence Pattern Features

We now present the proposed POS sequence pattern features and the mining algorithm. This results in a new feature class. A *POS sequence pattern* is a sequence of consecutive POS tags that satisfy some constraints (discussed below). We used (Tsuruoka and Tsujii, 2005) as our POS tagger.

As shown in (Baayen et. al., 1996), POS n-grams are good at capturing the heavy stylistic and syntactic information. Instead of using all such n-grams, we want to discover all those patterns that represent true regularities, and we also want to have flexible lengths (not fixed lengths as in n-grams). POS sequence patterns serve these purposes. Its mining algorithm mines all such patterns that satisfy the user-specified minimum support (*minsup*) and minimum adherence (*minadherence*) thresholds or constraints. These thresholds ensure that the mined patterns represent significant regularities.

The main idea of the algorithm is to perform a level-wise search for such patterns, which are POS sequences with minsup and minadherence. The *support* of a pattern is simply the proportion of documents that contain the pattern. If a pattern appears too few times, it is probably spurious. A sequence is called a *frequent sequence* if it satisfies minsup. The *adherence* of a pattern is measured using the *symmetrical conditional probability* (SCP) given in (Silva et al., 1999). The SCP of a sequence with two elements $|xy|$ is the product of the conditional probability of each given the other,

$$SCP(x,y) = P(x \mid y)P(y \mid x) = \frac{P(x,y)^2}{P(x)P(y)}$$

Given a consecutive sequence of POS tags $|x_1 \ldots x_n|$, called a *POS sequence* of length n, a dispersion point defines two subparts of the sequence. A sequence of length n contains n-1 possible dispersion points. The SCP of the sequence $|x_1 \ldots x_n|$ given the dispersion point (denoted by *) $|x_1 \ldots x_{n-1} * x_n|$ is:

$$SCP((x_1 \ldots x_{n-1}), x_n) = \frac{P(x_1 \ldots x_n)^2}{P(x_1 \ldots x_{n-1})P(x_n)}$$

The SCP measure can be extended so that all possible dispersion points are accounted for.

Hence the *fair*SCP of the sequence $|x_1...x_n|$ is given by:

$$fairSCP(x_1...x_n) = \frac{P(x_1...x_n)^2}{\frac{1}{n-1}\sum_{i=1}^{n-1} P(x_1...x_i)P(x_{i+1}...x_n)}$$

*fair*SCP measures the adherence strength of POS tags in a sequence. The higher the *fair*SCP value, the more dominant is the sequence. Our POS sequence pattern mining algorithm is given below.

Input: Corpus $D = \{d \mid d$ is a document containing a sequence of POS tags$\}$, Tagset $T = \{t \mid t$ is a POS tag$\}$, and the user specified minimum support (*minsup*) and minimum adherence (*minadherence*).

Output: All POS sequence patterns (stored in *SP*) mined from *D* that satisfy *minsup* and *minadherence*.

```
Algorithm mine-POS-pats(D, T, minsup, minadherence)
1.  $C_1 \leftarrow$ count each $t$ ($\in T$) in $D$;
2.  $F_1 \leftarrow \{f \mid f \in C_1, f.\text{count} / n \geq minsup\}$;   // $n = |D|$
3.  $SP_1 \leftarrow F_1$;
4.  for ($k = 2$; $k \leq$ MAX-length; $k$++)
5.      $C_k$ = candidate-gen($F_{k-1}$);
6.      for each document $d \in D$
7.          for each candidate POS sequence $c \in C_k$
8.              if ($c$ is contained in $d$)
9.                  $c$.count++;
10.         endfor
11.     endfor
12.     $F_k \leftarrow \{c \in C_k \mid c.\text{count} / n \geq minsup\}$;
13      $SP_k \leftarrow \{f \in F_k \mid fair\text{SCP}(f) \geq minadherence\}$
14. endfor
15. return $SP \leftarrow \bigcup_k SP_k$;
```

```
Function candidate-gen($F_{k-1}$)
1. $C_k \leftarrow \varnothing$;
2. for each POS n-gram $c \in F_{k-1}$
3.     for each $t \in T$
4.         $c' \leftarrow$ addsuffix($c$, $t$);   // adds tag $t$ to $c$ as suffix
5.         add $c'$ to $C_k$;
6.     endfor
7. endfor
```

We now briefly explain the mine-POS-pats algorithm. The algorithm is based on level-wise search. It generates all POS patterns by making multiple passes over data. In the first pass, it counts the support of individual POS tags and determines which of them have minsup (line 2). Multiple occurrences of a tag in a document are counted only once. Those in F_1 are called *length 1 frequent sequences*. All length 1 sequence patterns are stored in SP_1. Since adherence is not defined for a single element, we have $SP_1 = F_1$ (line 3). In each subsequent pass *k* until MAX-length (which is the maximum length limit of the mined patterns), there are three steps:

1. Using F_{k-1} (frequent sequences found in the (*k*-1) pass) as a set of seeds, the algorithm applies candidate-gen() to generate all possibly frequent POS *k*-sequences (sequences of length *k*) (line 5). Those infrequent sequences (which are not in F_{k-1}) are discarded as adding more POS tags will not make them frequent based on the downward closure property in (Agrawal and Srikant, 1994).
2. *D* is then scanned to compute the actual support count of each candidate in C_k (lines 6-11).
3. At the end of each scan, it determines which candidate sequences have minsup and minadherence (lines 12 - 13). We compute F_k and SP_k separately because adherence does not have the downward closure property as the support.

Finally, the algorithm returns the set of all sequence patterns (line 15) that meet the minsup and minadherence thresholds.

The candidate-gen() function generates all possibly frequent *k*-sequences by adding each POS tag *t* to *c* as suffix. *c* is a *k*-1-sequence in F_{k-1}.

In our experiments, we used MAX-length = 7, *minsup* = 30%, and *minadherence* = 20% to mine all POS sequence patterns. All the mined patterns are used as features.

Finally, it is worthwhile to note that mine-POS-pat is very similar to the well-known GSP algorithm (Srikant and Agrawal, 1996). Likewise, it has linear scale up with data size. If needed, one can use MapReduce (Dean and Ghemawat, 2004) with suitable modifications in mine-POS-pats to speed things up by distributing to multiple machines for large corpora. Moreover, mining is a part of preprocessing of the algorithm and its complexity does not affect the final prediction, as it will be later shown that for model building and prediction, standard machine learning methods are used.

4 Ensemble Feature Selection

Since all classes of features discussed in Section 3 are useful, we want to employ all of them. This results in a huge number of features. Many of them are redundant and even harmful. Feature selection thus becomes important. There are two common approaches to feature selection: the *filter* and the *wrapper* approaches (Blum and Langley, 1997; Kohavi and John, 1997). In the filter approach, features are first ranked based on a feature selection criterion such as information gain, chi-square (χ^2) test, and mutual information. A set of top ranked features are selected. On the contrary, the wrapper model chooses features and adds to the current feature pool based on whether the new features improve the classification accuracy.

Both these approaches have drawbacks. While the wrapper approach becomes very time consuming and impractical when the number of features is large as each feature is tested by building a new classifier. The filter approach often uses only one feature selection criterion (e.g., information gain, chi-square, or mutual information). Due to the bias of each criterion, using only a single one may result in missing out some good features which can rank high based on another criterion. In this work, we developed a novel feature selection method that uses multiple criteria, and combines both the wrapper and the filter approaches. Our method is called *ensemble feature selection* (EFS).

4.1 EFS Algorithm

EFS takes the best of both worlds. It first uses a number of feature selection criteria to rank the features following the filter model. Upon ranking, the algorithm generates some candidate feature subsets which are used to find the final feature set based on classification accuracy using the wrapper model. Since our framework generates much fewer candidate feature subsets than the total number of features, using wrapper model with candidate feature sets is scalable. Also, since the algorithm generates candidate feature sets using multiple criteria and all feature classes jointly, it is able to capture most of those features which are discriminating. We now detail our EFS algorithm.

The algorithm takes as input, a set of n features $F = \{f_1, \ldots, f_n\}$, a set of t feature selection criteria $\Theta = \{\theta_1, \ldots, \theta_t\}$, a set of t thresholds $T = \{\tau_1, \ldots, \tau_t\}$ corresponding to the criteria in Θ, and a window w. τ_i is the base number of features to be selected for criterion θ_i. w is used to vary τ_i (thus the number of features) to be used by the wrapper approach.

Algorithm: EFS (F, Θ, T, w)

```
1.  for each $\theta_i \in \Theta$
2.      Rank all features in $F$ based on criterion $\theta_i$ and
          let $\xi_i$ denotes the ranked features
3.  endfor
4.  for $i = 1$ to $t$
5.      $C_i \leftarrow \varnothing$
6.      for $\tau = \tau_i - w$ to $\tau = \tau_i + w$
7.          select first $\tau$ features $\zeta_i$ from $\xi_i$ and add $\zeta_i$ to $C_i$
              in order
8.      endfor
9.  endfor
10.     // $C_i = \{\zeta_1, \ldots, \zeta_{2w+1}\}$, where $\zeta_i$ is a set of fea-
        tures
11. OptCandFeatures $\leftarrow \varnothing$;
12. Repeat steps 13 – 18
13.     $\Lambda \leftarrow \varnothing$
14.     for $i = 1$ to $t$
15.         select and remove the *first* feature set $\zeta_i \in C_i$
              from $C_i$ in order
16.         $\Lambda \leftarrow \Lambda \cup \zeta_i$
17.     endfor
18.     add $\Lambda$ to OptCandFeatures
19.     // $\Lambda$ is a set of features comprising of features in
        // feature sets $\zeta_i \in C_i$ in the same position $\forall\ i$
20. until $C_i = \varnothing\ \forall\ i$
21. for each $\Lambda \in$ OptCandFeatures
22.     $\Lambda$.score $\leftarrow$ accuracy of 10-fold CV on training
          data on a chosen classifier (learning algo-
          rithm)
23. endfor
24. return $\underset{\Lambda.score}{\arg\max}\{\Lambda \mid \Lambda \in \text{OptCandFeatures}\}$
```

We now explain our EFS algorithm. Using a set of different feature selection measures, Θ, we rank all features in our feature pool, F, using the set of criteria (lines 1–3). This is similar to the filter approach. In lines 4–9, we generate feature sets C_i, $1 \leq i \leq t$ for each of the t criteria. Each set C_i contains feature subsets, and each subset ζ_i is the set of top τ features in ξ_i ranked based on criterion θ_i in lines 1–2. τ varies from $\tau_i - w$ to $\tau_i + w$ where τ_i is the threshold for criterion θ_i and w the window size. We vary τ and generate $2w + 1$ feature sets and add all such feature sets ζ_i to C_i (in lines 6–8) in order. We do so because it is difficult to know the optimal threshold τ_i for each criterion θ_i. It should be noted that "adding in order" ensures the ordering of feature sets ζ_i as shown in line 10, which will be later used to "select and remove in order" in line 15. In lines 11–20 we generate candidate feature sets using C_i and add each such candidate feature set Λ to OptCandFeatures. Each candidate feature set Λ is a collection of top ranked features based on multiple criteria. It is generated by unioning the features in the *first* feature subset ζ_i, which is then removed from C_i for each criterion θ_i (lines 14-17). Each candidate feature set is added to OptCandFeatures in line 18. Since each C_i has $2w$+1 feature subsets ζ_i, there are a total of $2w$+1 candidate feature sets Λ in OptCandFeatures. Lines 21–23 assign an accuracy to each candidate feature set Λ ϵ OptCandFeatures by running 10-fold cross validation on the training data using a chosen classifier with the features in Λ. Finally, the optimal feature set Λ ϵ OptCandFeatures is returned in line 24.

An interesting question arising in the EFS algorithm is: How does one select the threshold τ_i for each criterion θ_i and the window size w? Intuitively, suppose that for criterion θ_i, the optimal subset of features is S_{opt_i} based on some optimal threshold τ_i. Then the final feature set is a collection of all features $f \in S_{opt\_i}$ $\forall$ i. However, finding such optimal feature set S_{opt_i} or optimal threshold τ_i is a difficult problem. To counter this, we use the window w to select various feature subsets close to the top τ_i features in ξ_i. Thus, the threshold values τ_i and window size w should be approximated by experiments. In our experiments, we used τ_i = top 1/20th of the features ranked in ξ_i for $\forall$ i and window size $w = |F|/100$, and got good results. Fortunately, as we will see in Section 6.2, these parameters are not sensitive at all, and any reasonably large size feature set seems to work equally well.

Finally, we are aware that there are some existing ensemble feature selection methods in the machine learning literature (Garganté et al., 2007; Tuv et al., 2009). However, they are very different from our approach. They mainly use ensemble classification methods to help choose good features rather than combining different feature selection criteria and integrating different feature selection approaches as in our method.

4.2 Feature Selection Criteria

The set of feature selection criteria $\Theta = \{\theta_1 \ldots \theta_t\}$ used in our work are those commonly used individual selection criteria in the filter approach.

Let $C = \{c_1, c_2, \ldots, c_m\}$ denotes the set of classes, and $F = \{f_1, f_2, \ldots, f_n\}$ the set of features. We list the criteria in Θ used in our work below.

Information Gain (IG): This is perhaps the most commonly used criterion, which is based on entropy. The scoring function for information gain of a feature f is given by:

$$IG(f) = -\sum_{i=1}^{m} P(c_i)\log P(c_i) + \sum_{f,\bar{f}} P(f) \sum_{i=1}^{m} P(c_i \mid f)\log P(c_i \mid f)$$

Mutual Information (MI): This metric is commonly used in statistical language modeling. The mutual information MI(f, c) between a class c and a feature f is defined as:

$$MI(f,c) = \sum_{f,\bar{f}} \sum_{c,\bar{c}} P(f,c) \log \frac{P(f,c)}{P(f)P(c)}$$

The scoring function generally used as the criterion is the max among all classes. MI(f) = max$_i$ {MI (f, c_i)} (which we use). The weighted average over all classes can also be applied as the scoring function.

χ^2 Statistic: The χ^2 statistic measures the lack of independence between a feature f and class c, and can be compared to the χ^2 distribution with one degree of freedom. We use a 2x2 contingency table of a feature f and a class c to introduce χ^2 test.

	c	$\bar{c}$
f	W	X
$\bar{f}$	Y	Z

Table 4: Two-way contingency table of f and c

In the table, W denotes the number of documents in the corpus in which feature f and class c co-occur, X the number of documents in which f occurs without c, Y the number of documents in which c occurs without f, and Z the number of documents in which neither c nor f occurs. Thus, $N = W + X + Y + Z$ is the total number of documents in the corpus.

χ^2 test is defined as:

$$\chi^2(f,c) = \frac{N(WZ - YX)^2}{(W+Y)(X+Z)(W+X)(Y+Z)}$$

The scoring function using the χ^2 statistic is either the weighted average or max over all classes. In our experiments, we use the weighted average: $\chi^2(f) = \sum_{i=1}^{m} P(c_i)\chi^2(f,c_i)$

Cross Entropy (CE): This metric is similar to mutual information (Mladenic and Grobelnik, 1998):

$$CE(f) = P(f)\sum_{i=1}^{m} P(c_i \mid f)\log\frac{P(c_i \mid f)}{P(f)}$$

Weight of Evidence for Text (WET): This criterion is based on the average absolute weight of evidence (Mladenic and Grobelnik, 1998):

$$WET(f) = \sum_{i=1}^{m} P(c_i)P(f) \mid \log\frac{P(c_i \mid f)(1-P(c_i))}{P(c_i)(1-P(c_i \mid f))} \mid$$

5 Feature Value Assignments

After selecting features belonging to different classes, values are assigned differently to different classes of features. There are three common ways of feature value assignments: Boolean, TF (Term Frequency) and TF-IDF (product of term and inverted document frequency). For details of feature value assignments, interested readers are referred to (Joachims, 1997). While the Boolean scheme assigns a 1 to the feature value if the feature is present in the document and a 0 otherwise, the TF scheme assigns the relative frequency of the number of times that the feature occurs in the document. We did not use TF-IDF as it did not yield good results in our preliminary experiments.

The feature value assignment to different classes of features is done as follows: The value of F-measure was assigned based on its actual value. Stylistic features such words, and blog words were assigned values 1 or 0 in the Boolean scheme and the relative frequency in the TF scheme (we experimented with both schemes). Feature values for gender preferential features were also assigned in a similar way. Factor and word class features were assigned values according to the Boolean or TF scheme if any of the words belonging to the feature class exists (factor or word class appeared in that document). Each POS sequence pattern feature was assigned a value according to the Boolean (or TF) scheme based on the appearances of the pattern in the POS tagged document.

6 Experimental Results

This section evaluates the proposed techniques and sees how they affect the classification accuracy. We also compare with the existing state-of-the-art algorithms and systems. For algorithms, we compared with three representatives in (Argamon et al., 2007), (Schler et al., 2006) and (Yan and Yan, 2006). Since they do not have publicly available systems, we implemented them. Each of them just uses a subset of the features used in our system. Recall our system includes all their features and our own POS pattern based features. For systems, we compared with two public domain systems, *Gender Genie* (BookBlog, 2007) and *Gender Guesser* (Krawetz, 2006), which implemented variations of the algorithm in (Argamon et. al, 2003).

We used SVM classification, SVM regression, and Naïve Bayes (NB) as learning algorithms. Although SVM regression is not designed for classification, it can be applied based on the output of positive or negative values. It actually worked better than SVM classification for our data. For SVM classification and regression, we used SVMLight (Joachims, 1999), and for NB we used (Borgelt, 2003). In all our experiments, we used accuracy as the evaluation measure as the two classes (male and female) are roughly balanced (see the data description below), and both classes are equally important.

6.1 Blog Data Set

To keep the problem of gender classification of informal text as general as possible, we collected blog posts from many blog hosting sites and blog search engines, e.g., blogger.com, technorati.com, etc. The data set consists of 3100 blogs. Each blog is labeled with the gender of its author. The gender of the author was determined by visiting the profile of the author. Profile pictures or avatars associated with the profile were also helpful in confirming the gender especially when the gender information was not available explicitly. To ensure quality of the labels, one group of students collected the blogs and did the initial labeling, and the other group double-checked the labels by visiting the actual blog pages. Out of 3100 posts, 1588 (51.2%) were written by men and 1512 (48.8%) were written by women. The average post length is 250 words for men and 330 words for women.

6.2 Results

We used all features from different feature classes (Section 3) along with our POS patterns as our pool of features. We used τ and w values stated in Section 4.1 and criteria mentioned in Section 4.2 for our EFS algorithm. EFS was compared with three commonly used feature selection methods on SVM classification (denoted by SVM), SVM regression (denoted by SVM_R) and the NB classifier. The results are shown in Table 5. All results were obtained through 10-fold cross validation.

Also, the total number of features selected by IG, MI, χ^2, and EFS were roughly the same. Thus, the improvement in accuracy brought forth by EFS was chiefly due to the combination of features selected (based on multi-criteria).

To measure the accuracy improvement of using our POS patterns over common POS n-grams, we also compared our results with those from POS n-grams (Koppel et al., 2002). The comparison results are given in Table 6. Table 6 also includes results to show the overall improvement in accuracy with our two new techniques. We tested our system without any feature selection and without using the POS sequence patterns as features.

The comparison results with existing algorithms and public domain systems using our real-life blog data set are tabulated in Table 7.

Also, to see whether feature selection helps and how many features are optimal, we varied τ and w of the EFS algorithm and plotted the accuracy vs. no. of features. These results are shown in Figure 1.

Feature Selection	Value Assignment	NB	SVM	SVM_R
IG	Boolean	71.32	76.61	78.32
IG	TF	66.01	72.84	74.13
MI	Boolean	72.01	78.62	79.48
MI	TF	70.86	73.14	74.58
χ^2	Boolean	72.90	80.71	81.52
χ^2	TF	71.84	73.57	75.24
EFS	Boolean	73.57	86.24	88.56
EFS	TF	72.82	82.05	83.53

Table 5: Accuracies of SVM, SVM_R and NB with different feature selection methods

Settings	NB	SVM	SVM_R
All features	63.01	68.84	70.03
All features, no POS patterns	60.73	65.17	66.17
POS 1,2,3-grams + EFS	71.24	82.71	83.86
POS Patterns + EFS	73.57	86.24	88.56

Table 6: Accuracies of POS n-grams and POS patterns with or without EFS (Boolean value assignment)

System	Accuracy (%)
Gender Genie	61.69
Gender Guesser	63.78
(Argamon et al., 2007)	77.86
(Schler et al., 2006)	79.63
(Yan and Yan, 2006)	68.75
Our method	88.56

Table 7: Accuracy comparison with other systems

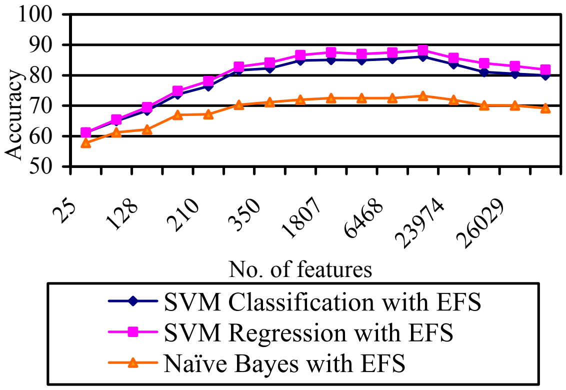

Figure 1: Accuracy vs. no. of features using EFS

6.3 Observations and Discussions

Based on the results given in the previous section, we make the following observations:

- SVM regression (SVM_R) performs the best (Table 5). SVM classification (SVM) also gives good accuracies. NB did not do so well.
- Table 5 also shows that our EFS feature selection method brings about 6-10% improvement in accuracy over the other feature selection methods based on SVM classification and SVM regression. The reason has been explained in the introduction section. Paired *t*-tests showed that all the improvements are statistically significant at the confidence level of 95%. For NB, the benefit is less (3%).
- Keeping all other parameters constant, Table 5 also shows that Boolean feature values yielded better results than the TF scheme across all classifiers and feature selection methods.
- Row 1 of Table 6 tells us that feature selection is very useful. Without feature selection (All features), SVM regression only achieves 70% accuracy, which is way inferior to the 88.56% accuracy obtained using EFS feature selection. Row 2 shows that without EFS and without POS sequence patterns, the results are even worse.

- Keeping all other parameters intact, Table 6 also demonstrated the effectiveness of our POS pattern features over POS n-grams. We have discussed the reason in Section 3.2 and 3.5.
- From Tables 5 and 6, we can infer that the overall accuracy improvement using EFS and all feature classes described in Section 3 is about 15% for SVM classification and regression and 10% for NB. Also, using POS sequence patterns with EFS brings about a 5% improvement over POS n-grams (Table 6). The improvement is more pronounced for SVM based methods than NB.
- Table 7 summarizes the accuracy improvement brought by our proposed techniques over the existing state-of-art systems. Our techniques have resulted in substantial (around 9%) accuracy improvement over the best of the existing systems. Note that (Argamon et al., 2007) used Logistic Regression with word classes and POS unigrams as features. (Schler et al., 2006) used Winnow classifier with function words, content word classes, and POS features. (Yan and Yan, 2006) used Naive Bayes with content words and blog-words as features. For all these systems, we used their features and ran their original classifiers and also the three classifiers in this paper and report the best results. For example, for (Argamon et al., 2007), we ran Logistic Regression and our three methods. SVM based methods always gave slightly better results. We could not run Winnow due to some technical issues. SVM and SVM_R gave comparable results to those given in their original papers. These results again show that our techniques are useful. All the gains are statistically significant at the confidence level of 95%.
- From Figure 1, we see that when the number of features selected is small (<100) the classification accuracy is lower than that obtained by using all features (no feature selection). However, the accuracy increases rapidly as the number of selected features increases. After obtaining the best case accuracy, it roughly maintains the accuracy over a long range. The accuracies then gradually decrease with the increase in the number of features. This trend is consistent with the prior findings in (Mladenic, 1998; Rogati and Yang, 2002; Forman 2003; Riloff et al., 2006; Houvardas and Stamatatos, 2006).

  It is important to note here that over a long range of 2000 to 20000 features, the accuracy is high and stable. This means that the thresholds of EFS are easy to set. As long as they are in the range, the accuracy will be good.

Finally, we would like to mention that (Herring and Paolillo, 06) has used genre relationships with gender classification. Their finding that subgenre “diary” contains more “female” and subgenre “filter” having more “male” stylistic features independent of the author gender, may obscure gender classification as there are many factors to be considered. Herring and Paolillo referred only words as features which are not as fine grained as our POS sequence patterns. We are also aware of other factors influencing gender classification like genre, age and ethnicity. However, much of such information is hard to obtain reliably in blogs. They definitely warren some future studies. Also, EFS being a useful method for feature selection in machine learning, it would be useful to perform further experiments to investigate how well it performs on a variety of classification datasets. This again will be an interesting future work.

7 Conclusions

This paper studied the problem of gender classification. Although there have been several existing papers studying the problem, the current accuracy is still far from ideal. In this work, we followed the supervised approach and proposed two novel techniques to improve the current state-of-the-art. In particular, we proposed a new class of features which are POS sequence patterns that are able to capture complex stylistic regularities of male and female authors. Since there are a large number features that have been considered, it is important to find a subset of features that have positive effects on the classification task. Here, we proposed an ensemble feature selection method which takes advantage of many different types of feature selection criteria in feature selection. Experimental results based on a real-life blog data set demonstrated the effectiveness of the proposed techniques. They help achieve significantly higher accuracy than the current state-of-the-art techniques and systems.

Abstract

This paper studies the effects of training data on binary text classification and postulates that negative training data is not needed and may even be harmful for the task. Traditional binary classification involves building a classifier using labeled positive and negative training examples. The classifier is then applied to classify test instances into positive and negative classes. A fundamental assumption is that the training and test data are identically distributed. However, this assumption may not hold in practice. In this paper, we study a particular problem where the positive data is identically distributed but the negative data may or may not be so. Many practical text classification and retrieval applications fit this model. We argue that in this setting negative training data should not be used, and that PU learning can be employed to solve the problem. Empirical evaluation has been conducted to support our claim. This result is important as it may fundamentally change the current binary classification paradigm.

1 Introduction

Text classification is a well-studied problem in machine learning, natural language processing, and information retrieval. To build a text classifier, a set of training documents is first labeled with predefined classes. Then, a supervised machine learning algorithm (e.g., Support Vector Machines (SVM), naïve Bayesian classifier (NB)) is applied to the training examples to build a classifier that is subsequently employed to assign class labels to the instances in the test set. In this paper, we focus on binary text classification with two classes (i.e. *positive* and *negative* classes).

Most learning methods assume that the training and test data have identical distributions. However, this assumption may not hold in practice, i.e., the training and the test distributions can be different. The problem is called *covariate shift* or *sample selection bias* (Heckman 1979; Shimodaira 2000; Zadrozny 2004; Huang et al. 2007; Sugiyama et al. 2008; Bickel et al. 2009). In general, this problem is not solvable because the two distributions can be arbitrarily far apart from each other. Various assumptions were made to solve special cases of the problem. One main assumption was that the conditional distribution of the class given an instance is the same over the training and test sets (Shimodaira 2000; Huang et al. 2007; Bickel et al. 2009).

In this paper, we study another special case of the problem in which the positive training and test samples have identical distributions, but the negative training and test samples may have different distributions. We believe this scenario is more applicable for binary text classification. As the focus in many applications is on identifying positive instances correctly, it is important that the positive training and the positive test data have the same distribution. The distributions of the negative training and negative test data can be different. We believe that this special case of the sample selection bias problem is also more applicable for machine learning. We will show that a partially supervised learning model, called *PU learning* (learning from *P*ositive and *U*nlabeled examples) fits this special case quite well (Liu et al. 2002).

Following the notations in (Bickel et al. 2009), our special case of the sample selection bias problem can be formulated as follows: We are given a training sample matrix $\mathbf{X}_L$ with row vectors $\mathbf{x}_1$, …, $\mathbf{x}_k$. The positive and negative training instances are governed by different unknown distributions $p(\mathbf{x}|\lambda)$

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 218–228,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

and $p(\mathbf{x}|\delta)$ respectively. The element y_i of vector $\mathbf{y} = (y_1, y_2, \ldots, y_k)$ is the class label for training instance x_i ($y_i \in \{+1, -1\}$, where +1 and -1 denote positive and negative classes respectively) and is drawn based on an unknown target concept $p(y|\mathbf{x})$. In addition, we are also given an unlabeled test set in matrix $\mathbf{X}_T$ with rows $\mathbf{x}_{k+1}, \ldots, \mathbf{x}_{k+m}$. The (hidden) positive test instances in $\mathbf{X}_T$ are also governed by the unknown distribution $p(\mathbf{x}|\lambda)$, but the (hidden) negative test instances in $\mathbf{X}_T$ are governed by an unknown distribution, $p(\mathbf{x}|\theta)$, where θ may or may not be the same as δ. $p(\mathbf{x}|\theta)$ and $p(\mathbf{x}|\delta)$ can differ arbitrarily, but there is only one unknown target conditional class distribution $p(y|\mathbf{x})$.

This problem setting is common in many applications, especially in those applications where the user is interested in identifying a particular type of documents (i.e. binary text classification). For example, we want to find sentiment analysis papers in the literature. For training a text classifier, we may label the papers in some EMNLP proceedings as sentiment analysis (positive) and non-sentiment analysis (negative) papers. A classifier can then be built to find sentiment analysis papers from ACL and other EMNLP proceedings. However, this labeled training set will not be appropriate for identifying sentiment analysis papers from the WWW, KDD and SIGIR conference proceedings. This is because although the sentiment analysis papers in these proceedings are similar to those in the training data, the non-sentiment analysis papers in these conferences can be quite different. Another example is email spam detection. A spam classification system built using the training data of spam and non-spam emails from a university may not perform well in a company. The reason is that although the spam emails (e.g., unsolicited commercial ads) are similar in both environments, the non-spam emails in them can be quite different.

One can consider labeling the negative data in each environment individually so that only the negative instances relevant to the testing environment are used to train the classifier. However, it is often impractical (if not impossible) to do so. For example, given a large blog hosting site, we want to classify its blogs into those that discuss stock markets (positive), and those that do not (negative). In this case, the negative data covers an arbitrary range of topics. It is clearly impractical to label all the negative data.

Most existing methods for addressing the sample selection bias problem work as follows. First, they estimate the bias of the training data based on the given test data using statistical methods. Then, a classifier is trained on a weighted version of the original training set based on the estimated bias. In this paper, we show that our special case of the sample selection bias problem can be solved in a much simpler and somewhat radical manner—by simply discarding the negative training data altogether. We can use the positive training data and the unlabeled test data to build the classifier using the PU learning model (Liu et al. 2002).

PU learning was originally proposed to solve the learning problem where no labeled negative training data exist. Several algorithms have been developed in the past few years that can learn from a set of labeled positive examples augmented with a set of unlabeled examples. That is, given a set P of positive examples of a particular class (called the *positive* class) and a set U of unlabeled examples (which contains both hidden positive and hidden negative examples), a classifier is built using P and U to classify the data in U as well as future test data into two classes, i.e., those belonging to P (positive) and those not belonging to P (negative). In this paper, we also propose a new PU learning method which gives more consistently accurate results than the current methods.

Our experimental evaluation shows that when the distributions of the negative training and test samples are different, PU learning is much more accurate than traditional supervised learning from the positive and negative training samples. This means that the negative training data actually harms classification in this case. In addition, when the distributions of the negative training and test samples are identical, PU learning is shown to perform equally well as supervised learning, which means that the negative training data is not needed.

This paper thus makes three contributions. First, it formulates a new special case of the sample selection bias problem, and proposes to solve the problem using PU learning by discarding the negative training data. Second, it proposes a new PU learning method which is more accurate than the existing methods. Third, it experimentally demonstrates the effectiveness of the proposed method and shows that negative training data is not needed and can even be harmful. This result is important as it may fundamentally change the way that many practical classification problems should be solved.

2 Related Work

A key assumption made by most machine learning algorithms is that the training and test samples must be drawn from the same distribution. As mentioned, this assumption can be violated in practice. Some researchers have addressed this problem under *covariate shift* or *sample selection bias*. Sample selection bias was first introduced in the econometrics by Heckman (1979). It came into the field of machine learning through the work of Zadrozny (2004). The main approach in machine learning is to first estimate the distribution bias of the training data based on the test data, and then learn using weighted training examples to compensate for the bias (Bickel et al. 2009).

Shimodaira (2000) and Sugiyama and Muller (2005) proposed to estimate the training and test data distributions using kernel density estimation. The estimated density ratio could then be used to generate weighted training examples. Dudik et al. (2005) and Bickel and Scheffer (2007) used maximum entropy density estimation, while Huang et al. (2007) proposed kernel mean matching. Sugiyama et al. (2008) and Tsuboi et al. (2008) estimated the weights for the training instances by minimizing the Kullback-Leibler divergence between the test and the weighted training distributions. Bickel et al. (2009) proposed an integrated model. In this paper, we adopt an entirely different approach by dropping the negative training data altogether in learning. Without the negative training data, we use PU learning to solve the problem (Liu et al. 2002; Yu et al. 2002; Denis et al. 2002; Li et al. 2003; Lee and Liu, 2003; Liu et al. 2003; Denis et al. 2003; Li et al. 2007; Elkan and Noto, 2008; Li et al. 2009; Li et al. 2010). We will discuss this learning model further in Section 3.

Another related work to ours is transfer learning or domain adaptation. Unlike our problem setting, transfer learning addresses the scenario where one has little or no training data for the target domain, but has ample training data in a related domain where the data could be in a different feature space and follow a different distribution. A survey of transfer learning can be found in (Pan and Yang 2009). Several NLP researchers have studied transfer learning for different applications (Wu et al. 2009a; Yang et al. 2009; Agirre & Lacalle 2009; Wu et al. 2009b; Sagae & Tsujii 2008; Goldwasser & Roth 2008; Li and Zong 2008; Andrew et al. 2008; Chan and Ng 2007; Jiang and Zhai 2007; Zhou et al. 2006), but none of them addresses the problem studied here.

3 PU Learning Techniques

In traditional supervised learning, ideally, there is a large number of labeled positive and negative examples for learning. In practice, the negative examples can often be limited or unavailable. This has motivated the development of the model of *learning from positive and unlabeled examples*, or PU learning, where *P* denotes a set of positive examples, and *U* a set of unlabeled examples (which contains both hidden positive and hidden negative instances). The PU learning problem is to build a classifier using *P* and *U* in the absence of negative examples to classify the data in *U* or a future test data *T*. In our setting, the test set *T* will also act as the unlabeled set *U*.

PU learning has been investigated by several researchers in the past decade. A study of PAC learning for the setting under the statistical query model was given in (Denis, 1998). Liu et al. reported the sample complexity result and showed how the problem may be solved (Liu et al., 2002). Subsequently, a number of practical algorithms (e.g., Liu et al., 2002; Yu et al., 2002; Li and Liu, 2003) were proposed. They generally follow a two-step strategy: (i) identifying a set of *reliable negative* documents *RN* from the unlabeled set; and then (ii) building a classifier using *P* (positive set), *RN* (reliable negative set) and *U-RN* (unlabelled set) by applying an existing learning algorithm (such as naive Bayesian classifier or SVM) iteratively. There are also some other approaches based on unbalanced errors (e.g., Liu et al. 2003; Lee and Liu, 2003; Elkan and Noto, 2008).

In this section, we first introduce a representative PU learning technique S-EM, and then present a new technique called CR-SVM.

3.1 S-EM Algorithm

S-EM (Liu et al. 2002) is based on naïve Bayesian classification (NB) (Lewis, 1995; Nigam et al., 2000) and the EM algorithm (Dempster et al. 1977). It has two steps. The first step uses a *spy* technique to identify some *reliable negatives* (*RN*) from the unlabeled set *U* and the second step uses the EM algorithm to learn a Bayesian classifier from *P*, *RN* and *U–RN*.

Step 1: Extracting reliable negatives *RN* from *U* using a spy technique

The *spy* technique in S-EM works as follows (Figure 1): First, a small set of positive examples (denoted by *SP*) called "spies" is randomly sampled from *P* (line 2). The default sampling ratio in S-EM is s = 15%. Then, an NB classifier is built using *P–SP* as the positive set and $U \cup SP$ as the negative set (lines 3-5). The NB classifier is applied to classify each $u \in U \cup SP$, i.e., to assign a probabilistic class label $p(+|u)$ (+ means positive) to u. The idea of the spy technique is as follows. Since the spy examples were from *P* and were put into *U* as negatives in building the NB classifier, they should behave similarly to the hidden positive instances in *U*. We thus can use them to find the reliable negative set *RN* from *U*. Using the probabilistic labels of spies in *SP* and an input parameter l (noise level), a probability threshold t is determined. Due to space constraints, we are unable to explain l. Details can be found in (Liu et al. 2002). t is then used to find *RN* from *U* (lines 8-10).

```
1.  $RN \leftarrow \varnothing$;                       // Reliable negative set
2.  $SP \leftarrow Sample(P, s\%)$;            // spy set
3.  Assign each example in $P - SP$ the class label +1;
4.  Assign each example in $U \cup SP$ the class label -1;
5.  $C \leftarrow$NB($P - SP$, $U \cup SP$);  // Produce a NB classifier
6.  Classify each $u \in U \cup SP$ using $C$;
7.  Decide a probability threshold $t$ using $SP$ and $l$;
8.  For each $u \in U$ do
9.      If its probability $p(+|u) < t$ then
10.         $RN \leftarrow RN \cup \{u\}$;
```

Figure 1. Spy technique for extracting *RN* from *U*

Step 2: Learning using the EM algorithm

Given the positive set *P*, the reliable negative set *RN,* and the remaining unlabeled set *U–RN*, we run EM using NB as the base learning algorithm.

The naive Bayesian (NB) method is an effective text classification algorithm. There are two different NB models, namely, the multinomial NB and the multi-variate Bernoulli NB. In this paper, we use the multinomial NB since it has been observed to perform consistently better than the multi-variate Bernoulli NB (Nigam et al., 2000).

```
Each document in $P$ is assigned the class label 1;
Each document in $RN$ is assigned the class label −1;
Learn an initial NB classifier $f$ from $P$ and $RN$, using Equations (1) and (2);
Repeat
    For each document $d_i$ in $U$-$RN$ do     // E-Step
        Using the current classifier $f$ compute
            $\Pr(c_j|d_i)$ using Equation (3);
    Learn a new NB classifier $f$ from $P$, $RN$ and $U$-$RN$ by computing $\Pr(c_j)$ and $\Pr(w_t|c_j)$, using
    Equations (1) and (2);                     // M-Step
Until the classifier parameters stabilize
The last iteration of EM gives the final classifier $f$;
For each document $d_i$ in $U$ do
    If its probability $\Pr(+|d_i) \geq 0.5$ then
        Output $d_i$ as a positive document;
    else Output $d_i$ as a negative document
```

Figure 2. EM algorithm with the NB classifier

Given a set of training documents D, each document $d_i \in D$ is an ordered list of words. We use $w_{d_i,k}$ to denote the word in position k of d_i, where each word is from the vocabulary $V = \{w_1, \ldots, w_{|v|}\}$, which is the set of all words considered in classification. We also have a set of classes $C = \{c_1, c_2\}$ representing positive and negative classes. For classification, we compute the posterior probability $\Pr(c_j|d_i)$. Based on the Bayes rule and multinomial model, we have

$$\Pr(c_j) = \frac{\sum_{i=1}^{|D|} \Pr(c_j \mid d_i)}{|D|} \quad (1)$$

and with Laplacian smoothing,

$$\Pr(w_t \mid c_j) = \frac{1 + \sum_{i=1}^{|D|} N(w_t, d_i) \Pr(c_j \mid d_i)}{|V| + \sum_{s=1}^{|V|} \sum_{i=1}^{|D|} N(w_s, d_i) \Pr(c_j \mid d_i)} \quad (2)$$

where $N(w_t,d_i)$ is the number of times that the word w_t occurs in document d_i, and $\Pr(c_j|d_i) \in \{0,1\}$ depending on the class label of the document. Assuming that probabilities of words are independent given the class, we have the NB classifier:

$$\Pr(c_j \mid d_i) = \frac{\Pr(c_j) \prod_{k=1}^{|d_i|} \Pr(w_{d_i,k} \mid c_j)}{\sum_{r=1}^{|C|} \Pr(c_r) \prod_{k=1}^{|d_i|} \Pr(w_{d_i,k} \mid c_r)} \quad (3)$$

EM (Dempster et al. 1977) is a popular class of iterative algorithms for maximum likelihood estimation in problems with incomplete data. It is often used to address missing values in the data by computing expected values using the existing values. The EM algorithm consists of two steps, the E-step and the M-step. The E-step fills in the missing data, and M-step re-estimated the parameters. This process is iterated till satisfaction (i.e. convergence). For NB, the steps used by EM are identical to those used to build the classifier (equations (3) for the E-step, and equations (1) and (2) for the

M-step). In EM, $\Pr(c_j|d_i)$ takes the value in [0, 1] instead of {0, 1} in all the three equations.

The algorithm for the second step of S-EM is given in Figure 2. Lines 1-3 build a NB classifier *f* using *P* and *RN*. Lines 4-8 run EM until convergence. Finally, the converged classifier is used to classify the unlabeled set *U* (lines 10-13).

3.2 Proposed CR-SVM

As we will see in the experiment section, the performance of S-EM can be weak in some cases. This is due to the mixture model assumption of its NB classifier (Nigam et al. 2000), which requires that the mixture components and classes be of one-to-one correspondence. Intuitively, this means that each class should come from a distinctive distribution rather than a mixture of multiple distributions. In our setting, however, the negative class often has documents of mixed topics, e.g., representing the broad class of everything else except the topic(s) represented by the positive class.

There are some existing PU learning methods based on SVM which can deal with this problem, e.g., Roc-SVM (Li and Liu, 2003). Like S-EM, Roc-SVM also has two steps. The first step uses Rocchio classification (Rocchio, 1971) to find a set of reliable negatives *RN* from *U*. In particular, this method treats the entire unlabeled set *U* as negative documents and then uses the positive set *P* and the unlabeled set *U* as the training data to build a Rocchio classifier. The classifier is subsequently applied to classify the unlabeled set *U*. Those documents that are classified as negative are then considered as reliable negative examples *RN*. The second step of Roc-SVM runs SVM iteratively (instead of EM). Unlike NB, SVM does not make any distributional assumption.

However, Roc-SVM does not do well due to the weakness of its first step in finding a good set of reliable negatives *RN*. This motivates us to propose a new SVM based method CR-SVM to detect a better quality *RN* set. The second step of CR-SVM is similar to that in Roc-SVM.

Step 1: Extracting reliable negatives *RN* from *U* using Cosine and Rocchio

The first step of the proposed CR-SVM algorithm for finding a *RN* set consists of two sub-steps:

Sub-step 1 (extracting the potential negative set *PN* using the *cosine similarity*): Given the positive set *P* and the unlabeled set *U*, we extract a set of potential negatives *PN* from *U* by computing the similarities of the unlabeled documents in *U* and the positive documents in *P*. The idea is that those documents in *U* that are very dissimilar to the documents in *P* are likely to be negative.

```
1.  $PN = \emptyset$;
2.  Represent each document in $P$ and $U$ as vectors using the TF-IDF representation;
3.  For each $\mathbf{d}_j \in P$ do
4.      $\mathbf{pr} = \frac{1}{|P|} * \sum_{j=1}^{|P|} \frac{\mathbf{d}_j}{\| \mathbf{d}_j \|_2}$
5.  $\mathbf{pr} = \mathbf{pr} / \| \mathbf{pr} \|_2$;
6.  For each $\mathbf{d}_j \in P$ do
7.      compute $cos(\mathbf{pr}, \mathbf{d}_j)$ using Equation (4);
8.  Sort all the documents $\mathbf{d}_j \in P$ according to $cos(\mathbf{pr}, \mathbf{d}_j)$ in decreasing order;
9.  $\omega = cos(\mathbf{pr}, \mathbf{d}_p)$ where $\mathbf{d}_p$ is ranked in the position of $(1- l)*|P|$;
10. For each $\mathbf{d}_i \in U$ do
11.     If $cos(\mathbf{pr}, \mathbf{d}_i) < \omega$ then
12.         $PN = PN \cup \{\mathbf{d}_i\}$
```

Figure 3. Extracting potential negatives *PN* from *U*

The detailed algorithm is given in Figure 3. Each document in *P* and *U* is first represented as a vector $\mathbf{d} = (q_1, q_2, \ldots, q_n)$ using the TF-IDF scheme (Salton 1986). Each element q_i (i=1, 2, …, n) in **d** represents a word feature w_i. A positive representative vector (**pr**) is built by summing up the documents in *P* and normalizing it (lines 3-5). Lines 6-7 compute the similarities of each document $\mathbf{d}_j$ in *P* with **pr** using the cosine similarity, $cos(\mathbf{pr}, \mathbf{d}_j)$.

Line 8 sorts the documents in *P* according to their $cos(\mathbf{pr}, \mathbf{d}_j)$ values. We want to filter away as many as possible hidden positive documents from *U* so that we can obtain a very pure negative set. Since the hidden positives in *U* should have the same behaviors as the positives in *P* in terms of their similarities to **pr**, we set their minimum similarity as the threshold value ω which is the minimum similarity before a document is considered as a potential negative document:

$$\omega = \min_{j=1}^{|P|} \cos(\mathbf{pr}, \mathbf{d}_j), \mathbf{d}_j \in P \qquad (4)$$

In a noiseless scenario, using the minimum similarity is acceptable. However, most real-life applications contain outliers and noisy artifacts. Using the absolute minimum similarity may be unreliable; the similarity $cos(\mathbf{pr}, \mathbf{d}_j)$ of an outlier docu-

```
1. $RN = \varnothing$;
2. Represent each document in $P$, $PN$ and $U$ as vectors
   using the TF-IDF representation;
3. $\mathbf{p} = \alpha \frac{1}{|P|} \sum_{\mathbf{d}_j \in P} \frac{\mathbf{d}_j}{\|\mathbf{d}_j\|} - \beta \frac{1}{|PN|} \sum_{\mathbf{d}_i \in PN} \frac{\mathbf{d}_i}{\|\mathbf{d}_i\|}$;
4. $\mathbf{n} = \alpha \frac{1}{|PN|} \sum_{\mathbf{d}_i \in PN} \frac{\mathbf{d}_i}{\|\mathbf{d}_i\|} - \beta \frac{1}{|P|} \sum_{\mathbf{d}_j \in P} \frac{\mathbf{d}_j}{\|\mathbf{d}_j\|}$;
5. For each $\mathbf{d}_i \in U$ do
6.     If $cos(\mathbf{d}_i, \mathbf{n}) > cos(\mathbf{d}_i, \mathbf{p})$ then
7.         $RN = RN \cup \{\mathbf{d}_i\}$
```

Figure 4. Identifying *RN* using the Rocchio classifier

ment $\mathbf{d}_j$ in *P* could be near 0 or smaller than most (or even all) negative documents. It would therefore be prudent to ignore a small percentage *l* of the documents in *P* most dissimilar to the representative positive (**pr**) and assume them as noise or outliers. Since we do not know the noise level of the data, to be safe, we use a noise level $l = 5\%$ as the default. The final classification result is not sensitive to *l* as long as it is not too big. In line 9, we use the noise level *l* to decide on a suitable ω. Then, for each document d_i in *U*, if its cosine similarity $cos(\mathbf{pr}, \mathbf{d}_i) < \omega$, we regard it as a potential negative and store it in *PN* (lines 10-12).

Our experiment results showed that *PN* is still not sufficient or big enough for accurate PU learning. Thus, we need to do a bit more work to find the final *RN*.

Sub-step 2 (extracting the final reliable negative set *RN* from *U* using Rocchio with *PN*): At this point, we have a positive set *P* and a potential negative set *PN* where *PN* is a purer negative set than *U*. To extract the final reliable negatives, we employ the Rocchio classification to build a classifier *RC* using *P* and *PN* (We do not use SVM here as it is very sensitive to the noise in *PN*). Those documents in *U* that are classified as negatives by *RC* will then be regarded as reliable negatives, and stored in set *RN*.

The algorithm for this sub-step is given in Figure 4. Following the Rocchio formula, a positive and a negative prototype vectors **p** and **n** are built (lines 3 and 4), which are used to classify the documents in *U* (lines 5-7). α and β are parameters for adjusting the relative impact of the positive and negative examples. In this work, we use $\alpha = 16$ and $\beta = 4$ as recommended in (Buckley et al. 1994).

Step 2: Learning by running SVM iteratively

This step is similar to that in Roc-SVM, building the final classifier by running SVM iteratively with the sets *P*, *RN* and the remaining unlabeled set *Q* ($Q = U - RN$).

The algorithm is given in Figure 5. We run SVM classifiers S_i (line 3) iteratively to extract more and more negative documents from *Q*. The iteration stops when no more negative documents can be extracted from *Q* (line 5). There is, however, a danger in running SVM iteratively, as SVM is quite sensitive to noise. It is possible that during some iteration, SVM is misled by noisy data to extract many positive documents from *Q* and put them in the negative set *RN*. If this happens, the final SVM classifier will be inferior. As such, we employ a test to decide whether to keep the first SVM classifier or the final one. To do so, we use the final SVM classifier obtained at convergence (called S_{last}, line 9) to classify the positive set *P* to see if many positive documents in *P* are classified as negatives. Roc-SVM chooses 5% as the threshold, so CR-SVM also uses this threshold. If there are 5% of positive documents (5%*|*P*|) in *P* that are classified as negative, it indicates that SVM has gone wrong and we should use the first SVM classifier (S_1). In our experience, the first classifier is always quite strong; good results can therefore be achieved even without catching the last (possibly better) classifier.

The main difference between Roc-SVM and CR-SVM is that Roc-SVM does not produce *PN*. It simply treats the unlabeled set *U* as negatives for extracting *RN*. Since *PN* is clearly a purer negative set than *U*, the use of *PN* by CR-SVM helps extract a better quality reliable negative set *RN* which subsequently allows the final classifier of CR-SVM to give better results than Roc-SVM.

Note that the methods (S-EM and CR-SVM) are all two-step algorithms in which the first step and the second step are independent of each other. The algorithm for the second step basically needs a good set of reliable negatives *RN* extracted from *U*. This means that one can pick any algorithm for the first step to work with any algorithm for the second step. For example, we can also have CR-EM which uses the algorithm (shown in Figures 3 and 4) of the first step of CR-SVM to combine with the algorithm of the second step of S-EM. CR-EM actually works quite well as it is also able to exploit the more accurate reliable negative set *RN* extracted using cosine and Rocchio.

4 Empirical Evaluation

We now present the experimental results to support our claim that negative training data is not needed and can even harm text classification. We also show the effectiveness of the proposed PU learning methods CR-SVM and CR-EM. The following methods are compared: (1) traditional supervised learning methods SVM and NB which use both positive and negative training data; (2) PU learning methods, including two existing methods S-EM and Roc-SVM and two new methods CR-SVM and CR-EM, and (3) one-class SVM (Schölkop et al., 1999) where only positive training data is used in learning (the unlabeled set is not used at all).

We used LIBSVM[1] for SVM and one-class SVM, and two publicly available[2] PU learning techniques S-EM and Roc-SVM. Note that we do not compare with some other PU learning methods such as those in (Liu et al. 2003, Lee and Liu, 2003 and Elkan and Noto, 2008) as the purpose of this paper is not to find the best PU learning method but to show that PU learning can address our special sample selection bias problem. Our current methods already do very well for this purpose.

4.1 Datasets and Experimental Settings

We used two well-known benchmark data collections for text classification, the Reuters-21578 collection[3] and the 20 Newsgroup collection[4]. Reuters-21578 contains 21578 documents. We used the most populous 10 out of the 135 categories following the common practice of other researchers. 20 Newsgroup has 11997 documents from 20 discussion groups. The 20 groups were also categorized into 4 main categories.

We have performed two sets of experiments, and just used bag-of-words as features since our objective in this paper is not feature engineering.

(1) **Test set has *other topic* documents.** This set of experiments simulates the scenario in which the negative training and test samples have different distributions. We select positive, negative and *other topic* documents for Reuters and 20 Newsgroup, and produce various data sets. Using these data sets, we want to show that PU learning can do better than traditional learning that uses both positive and negative training data.

```
1.  Every document in $P$ is assigned the class label +1;
2.  Every document in $RN$ is assigned the label –1;
3.  Use $P$ and $RN$ to train a SVM classifier $S_i$, with $i$ =
    1 initially and $i = i+1$ with each iteration (line 3-7);
4.  Classify $Q$ using $S_i$. Let the set of documents in $Q$
    that are classified as negative be $W$;
5.  If ($W = \emptyset$) then stop;
6.  else $Q = Q – W$;
7.          $RN = RN \cup W$
8.  goto (3);
9.  Use the last SVM classifier $S_{last}$ to classify $P$;
10. If more than 5% positives are classified as negative
11.     then use $S_1$ as the final classifier;
12. else use $S_{last}$ as the final classifier;
```

Figure 5. Constructing the final classifier using SVM

For the Reuters collection, each of the 10 categories is used as a positive class. We randomly select one or two of the remaining categories as the negative class (denoted by Neg 1 or Neg 2), and then we randomly choose some documents from the rest of the categories as *other topic* documents. These *other topic* documents are regarded as negatives and added to the test set but not to the negative training data. They thus introduce a different distribution to the negative test data. We generated 20 data sets (10*2) for our experiments this way.

The 20 Newsgroup collection has 4 main categories with sub-categories[5]; the sub-categories in the same main category are relatively similar to each other. We are able to simulate two scenarios: (1) the *other topic* documents are similar to the negative class documents (*similar case*), and (2) the *other topic* documents are quite different from the negative class documents (*different case*). This allows us to investigate whether the classification results will be affected when the *other topic* documents are somewhat similar or vastly different from the negative training set. To create the training and test data for our experiments, we randomly select one sub-category from a main category (*cat* 1) as the positive class, and one (or two) sub-category from another category (*cat* 2) as the negative class (again denoted by Neg 1 or Neg 2). For the *other topics*, we randomly choose some docu-

[1] http://www.csie.ntu.edu.tw/~cjlin/libsvm/

[2] http://www.cs.uic.edu/~liub/LPU/LPU-download.html

[3] http://www.research.att.com/~lewis/reuters21578.html

[4] http://people.csail.mit.edu/jrennie/20Newsgroups/

[5] The four main categories and their corresponding sub-categories are: *computer* (graphics, os, ibmpc.hardware, mac.hardware, windows.x), *recreation* (autos, motorcycles, baseball, hockey), *science* (crypt, electronics, med, space), and *talk* (politics.misc, politics.guns, politics.mideast, religion).

ments from the remaining sub-categories of *cat* 2 for the *similar case*, and some documents from a randomly chosen different category (*cat* 3) (as the *other topic* documents) for the *different case*. We generated 8 data sets (4*2) for the *similar case*, and 8 data sets (4*2) for the *different case*.

The training and test sets are then constructed as follows: we partition the positive (and similarly for the negative) class documents into two standard subsets: 70% for training and 30% for testing. In order to create different experimental settings, we vary the number of the *other topic* documents that are added to the test set as negatives, controlled by a parameter α, which is a percentage of $|TN|$, where $|TN|$ is the size of the negative test set without the *other topic* documents. That is, the number of *other topic* documents added is $\alpha \times |TN|$.

(2) **Test set has no *other topic* documents.** This set of experiments is the traditional classification in which the training and test data have the same distribution. We employ the same data sets as in (1) but without having any *other topic* documents in the test set. Here we want to show that PU learning can do equally well without using the negative training data even in the traditional setting.

4.2 Results with *Other Topic* Documents in Test Set

We show the results for experiment set (1), i.e. the distributions of the negative training and test data are different (caused by the inclusion of *other topic* documents in the test set, or the addition of *other topic* documents to complement existing negatives in the test set). The evaluation metric is the F-score on the positive class (Bollmann and Cherniavsky, 1981), which is commonly used for evaluating text classification.

4.2.1 Results on the Reuters data

Figure 6 shows the comparison results when the negative class contains only one category of documents (Neg 1), while Figure 7 shows the results when the negative class contains documents from two categories (Neg 2) in the Reuters collection. The data points in the figures are the averages of the results from the corresponding datasets.

Our proposed method CR-SVM is shown to perform consistently better than the other techniques. When the size of the *other topic* documents (*x*-axis) in the test set increases, the F-scores of the two traditional learning methods SVM and NB decreased much more dramatically as compared with the PU learning techniques. The traditional learning models were clearly unable to handle different distributions for training and test data. Among the PU learning techniques, the proposed CR-SVM gave the best results consistently. Roc-SVM did not do consistently well as it did not manage to find high quality reliable negatives *RN* sometimes. The EM based methods (CR-EM and S-EM) performed well in the case when we had only one negative class (Figure 6). However, it did not do well in the situation where there were two negative classes (Figure 7) due to the underlying mixture model assumption of the naïve Bayesian classifier. One-class SVM (OSVM) performed poorly because it did not exploit the useful information in the unlabeled set at all.

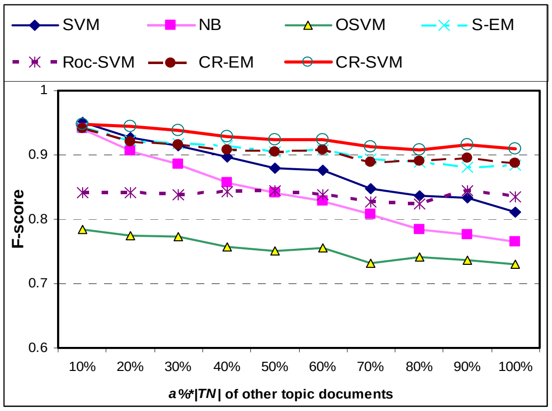

Figure 6. Results of Neg 1 using the Reuter data

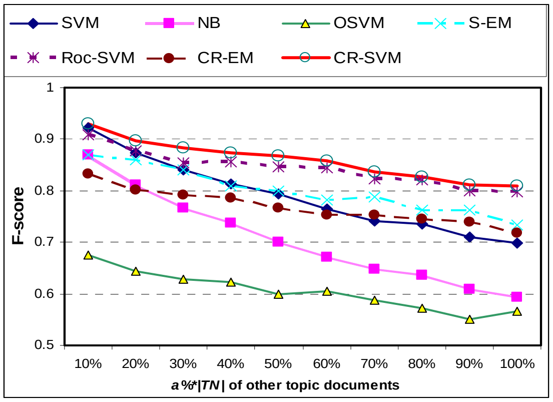

Figure 7. Results of Neg 2 using the Reuter data

4.2.2 Results on 20 Newsgroup data

Recall that for the 20 Newsgroup data, we have two settings: *similar case* and *different case*.

Similar case: Here, the *other topic* documents are similar to the *negative* class documents, as they belong to the same main category.

The comparison results are given in Figure 8 (Neg 1) and Figure 9 (Neg 2). We observe that CR-EM, S-EM and CR-SVM all performed well. EM based methods (CR-EM and S-EM) have a slight edge over CR-SVM. Again, the F-scores of the traditional supervised learning (SVM and NB) deteriorated when more *other topic* documents were added to the test set, while CR-EM, S-EM and CR-SVM were able to remain unaffected and maintained roughly constant F-scores. When the negative class contained documents from two categories (Neg 2), the F-scores of the traditional learning dropped even more rapidly. Both Roc-SVM and One-class SVM (OSVM) performed poorly, due to the same reasons given previously.

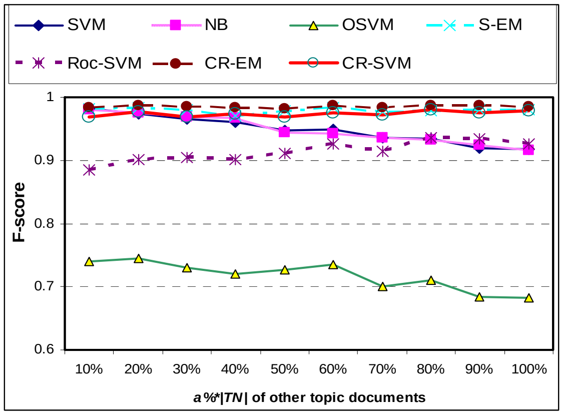

Figure 8. Results of Neg 1, *similar case* – using the 20 Newsgroup data

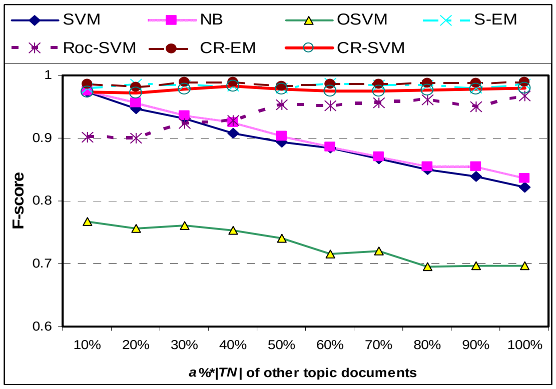

Figure 9. Results of Neg 2, *similar case* – using the 20 Newsgroup data

Different case: In this case, the *other topic* documents are quite different from the negative class documents, since they are originated from different main categories.

The results are shown in Figures 10 (Neg 1) and 11 (Neg 2). The trends are similar to those for the *similar case*, except that the performance of the traditional supervised learning methods (SVM and NB) dropped even more rapidly with more *other topic* documents. As the *other topic* documents have very different distributions from the negatives in the training set in this case, they really confused the traditional classifiers. In contrast, the three PU learning techniques were still able to perform consistently well, regardless of the number of *other topic* documents added to the test data.

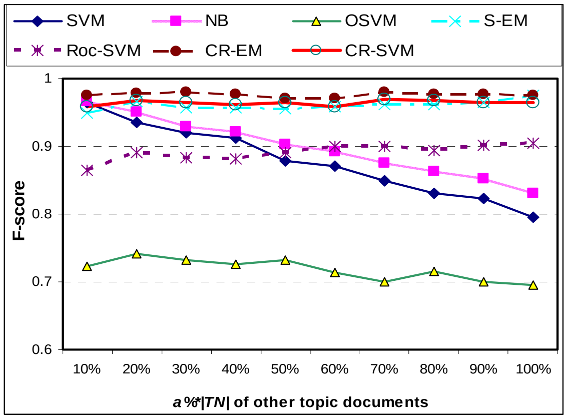

Figure 10. Results of Neg 1, *different case* – using the 20 Newsgroup data

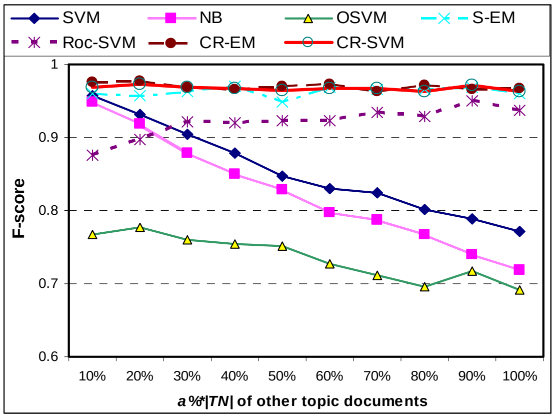

Figure 11. Results of Neg 2, *different case* – using the 20 Newsgroup data

In summary, the results showed that learning with negative training data based on the traditional paradigm actually harms classification when the identical distribution assumption does not hold.

4.3 Results without *Other Topic* Documents in Test Set

Given an application, one may not know whether the identical distribution assumption holds. The above results showed that PU learning is better when it does not hold. How about when the assumption does hold? To find out, we compared the results of SVM, NB, and three PU learning methods using the datasets without any *other topic* documents added to the test set. In this case, the training and test data distributions are the same.

Table 1 shows the results for this scenario. Note that for PU learning, the negative training data were not used. The traditional supervised learning techniques (SVM and NB), which made full use of the positive and negative training data, only performed just about 1-2% better than the PU learning method CR-SVM (which is not statistically significant based on paired *t*-test). This suggests that we can do away with negative training data, since PU learning can perform equally well without them. This has practical importance since the full coverage of negative training data is hard to find and to label in many applications.

From the results in Figures 6–11 and Table 1, we can conclude that PU learning can be used for binary text classification without the negative training data (which can be harmful for the task). CR-SVM is our recommended PU learning method based on its generally consistent performance.

Table 1. Comparison of methods without *other* documents in test set

Methods	Reuters (Neg 1)	Reuters (Neg 2)	20News (Neg 1)	20News (Neg 2)
SVM	0.971	0.964	0.988	0.990
NB	0.972	0.947	0.988	0.992
S-EM	0.952	0.921	0.974	0.975
CR-EM	0.955	0.897	0.983	0.986
CR-SVM	0.960	0.959	0.967	0.974

5 Conclusions

This paper studied a special case of the sample selection bias problem in which the positive training and test distributions are the same, but the negative training and test distributions may be different. We showed that in this case, the negative training data should not be used in learning, and PU learning can be applied to this setting. A new PU learning algorithm (called CR-SVM) was also proposed to overcome the weaknesses of the current two-step algorithms.

Our experiments showed that the traditional classification methods suffered greatly when the distributions are different for the negative training and test data, but PU learning does not. We also showed that PU learning performed equally well in the ideal case where the training and test data have identical distributions. As such, it can be advantageous to discard the potentially harmful negative training data and use PU learning for classification.

In our future work, we plan to do more comprehensive experiments to compare the classic supervised learning and PU learning techniques with different kinds of settings, for example, by varying the ratio between positive and negative examples, as well as their sizes. It is also important to explore how to catch the best iteration of the SVM/NB classifier in the iterative running process of the algorithms. Finally, we would like to point out that it is conceivable that negative training data could still be useful in many cases. An interesting direction to explore is to somehow combine the extracted reliable negative data from the unlabeled set and the existing negative training data to further enhance learning algorithms.

Abstract

Automated essay scoring is one of the most important educational applications of natural language processing. Recently, researchers have begun exploring methods of scoring essays with respect to particular dimensions of quality such as coherence, technical errors, and relevance to prompt, but there is relatively little work on modeling organization. We present a new annotated corpus and propose heuristic-based and learning-based approaches to scoring essays along the organization dimension, utilizing techniques that involve sequence alignment, alignment kernels, and string kernels.

1 Introduction

Automated essay scoring, the task of employing computer technology to evaluate and score written text, is one of the most important educational applications of natural language processing (NLP) (see Shermis and Burstein (2003) and Shermis et al. (2010) for an overview of the state of the art in this task). Recent years have seen a surge of interest in this and other educational applications in the NLP community, as evidenced by the panel discussion on "Emerging Application Areas in Computational Linguistics" at NAACL 2009, as well as increased participation in the series of workshops on "Innovative Use of NLP for Building Educational Applications". Besides its potential commercial value, automated essay scoring brings about a number of relatively less-studied but arguably rather challenging discourse-level problems that involve the computational modeling of different facets of text structure, such as content, coherence, and organization.

A major weakness of many existing essay scoring engines such as IntelliMetric (Elliot, 2001) and Intelligent Essay Assessor (Landauer et al., 2003) is that they adopt a holistic scoring scheme, which summarizes the quality of an essay with a single score and thus provides very limited feedback to the writer. In particular, it is not clear which dimension of an essay (e.g., coherence, relevance) a score should be attributed to. Recent work addresses this problem by scoring a particular dimension of essay quality such as coherence (Miltsakaki and Kukich, 2004), technical errors, and relevance to prompt (Higgins et al., 2004). Automated systems that provide instructional feedback along multiple dimensions of essay quality such as *Criterion* (Burstein et al., 2004) have also begun to emerge.

Nevertheless, there is an essay scoring dimension for which few computational models have been developed — *organization*. Organization refers to the structure of an essay. A high score on organization means that writers introduce a topic, state their position on that topic, support their position, and conclude, often by restating their position (Silva, 1993). A well-organized essay is structured in a way that logically develops an argument. Note that organization is a different facet of text structure than coherence, which is concerned with the transition of ideas at both the global (e.g., paragraph) and local (e.g., sentence) levels. While organization is an important dimension of essay quality, state-of-the-art essay scoring software such as e-rater V.2 (Attali and Burstein, 2006) employs rather simple heuristic-based methods for computing the score of an essay along this particular dimension.

Our goal in this paper is to develop a computational model for the organization of student es-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 229–239,

says. While many models of text coherence have been developed in recent years (e.g., Barzilay and Lee (2004), Barzilay and Lapata (2005), Soricut and Marcu (2006), Elsner et al. (2007)), the same is not true for text organization. One reason is the availability of training and test data for coherence modeling. Coherence models are typically evaluated on the sentence ordering task, and hence training and test data can be generated simply by scrambling the order of the sentences in a text. On the other hand, it is not particularly easy to find poorly organized texts for training and evaluating organization models. We believe that student essays are an ideal source of well- and poorly-organized texts. We evaluate our organization model on a data set of 1003 essays annotated with organization scores.

In sum, our contributions in this paper are two-fold. First, we address a less-studied discourse-level task — predicting the organization score of an essay — by developing a computational model of organization, thus establishing a baseline against which future work on this task can be compared. Second, we annotate a subset of our student essay corpus with organization scores and make this data set publicly available. Since progress in organization modeling is hindered in part by the lack of a publicly annotated corpus, we believe that our data set will be a valuable resource to the NLP community.

2 Corpus Information

We use as our corpus the 4.5 million word International Corpus of Learner English (ICLE) (Granger et al., 2009), which consists of more than 6000 essays written by university undergraduates from 16 countries and 16 native languages who are learners of English as a Foreign Language. 91% of the ICLE texts are argumentative. The essays we used vary greatly in length, containing an average of 31.1 sentences in 7.5 paragraphs, averaging 4.1 sentences per paragraph. About one quarter of the essays had five or fewer paragraphs, and another quarter contained nine or more paragraphs. Similarly, about one quarter of essays contained 24 or fewer sentences and the longest quarter contained 36 or more sentences

We selected a subset consisting of 1003 essays from the ICLE to annotate and use for training and testing of our model of essay organization. While narrative writing asks students to compose descriptive stories, *argumentative* (also known as *persuasive*) writing requires students to state their opinion on a topic and to validate that opinion with convincing arguments. For this reason, we selected only argumentative essays rather than narrative pieces, because they contain the discourse structures and kind of organization we are interested in modeling.

Topic	Languages	Essays
Most university degrees are theoretical and do not prepare students for the real world. They are therefore of very little value.	13	147
The prison system is outdated. No civilized society should punish its criminals: it should rehabilitate them.	11	103
In his novel *Animal Farm*, George Orwell wrote “All men are equal but some are more equal than others.” How true is this today?	10	82

Table 1: Some examples of writing topics.

To ensure representation across native languages of the authors, we selected mostly essays written in response to topics which are well-represented in multiple languages. This avoids many issues that may arise when certain vocabulary is used in response to a particular topic for which essays written by authors from only a few languages are available. Table 1 shows three of the twelve topics selected for annotation. Fifteen native languages are represented in the set of essays selected for annotation.

3 Corpus Annotation

To develop our essay organization model, human annotators scored 1003 essays using guidelines in an essay annotation rubric. Annotators evaluated the organization of each essay using a numerical score from 1 to 4 at half-point increments. This contrasts with previous work on essay scoring, where the corpus is annotated with a binary decision (i.e., *good* or *bad*) for a given scoring dimension (e.g., Higgins et al. (2004)). Hence, our annotation scheme not only provides a finer-grained distinction of organization quality (which can be important in practice), but also makes the prediction task more challenging.

The meaning of each integer score was described and discussed in detail. Table 2 shows the description of each score for the organization dimension.

Score	Description of Essay Organization
4	essay is **well structured** and is organized in a way that logically develops an argument
3	essay is **fairly well structured** but could somewhat benefit from reorganization
2	essay is **poorly structured** and would greatly benefit from reorganization
1	essay is **completely unstructured** and requires major reorganization

Table 2: Descriptions of the meaning of each score.

Our annotators were selected from over 30 applicants who were familiarized with the scoring rubric and given sample essays to score. The six who were most consistent with the expected scores were given additional essays to annotate. To ensure consistency in scoring, we randomly selected a large subset of our corpus (846 essays) to have graded by two different annotators. Analysis of these doubly annotated essays reveals that, though annotators only exactly agree on the organization score of an essay 29% of the time, the scores they apply are within 0.5 points in 71% of essays and within 1.0 point in 93% of essays. Additionally, if we treat one annotator's scores as a gold standard and the other annotator's scores as predictions, the predicted scores have a mean error of 0.54 and a mean squared error of 0.50. Table 3 shows the number of essays that received each of the seven scores for organization.

score	1.0	1.5	2.0	2.5	3.0	3.5	4.0
essays	24	14	35	146	416	289	79

Table 3: Distribution of organization scores.

4 Function Labeling

As mentioned before, a high score on organization means that writers introduce a topic, support their position, and conclude. If one or more of these elements are missing or if they appear out of order (e.g., the conclusion appears before the introduction), the resulting essay will typically be considered poorly organized. Hence, knowing the *discourse function label* of each paragraph in an essay would be helpful for predicting its organization score.

Two questions naturally arise. First, how can we obtain the discourse function label of each paragraph? One way is to automatically acquire such labels from a corpus of student essays where each paragraph is annotated with its discourse function label. To our knowledge, however, there is no publicly available corpus that is annotated with such information. As a result, we will resort to labeling a paragraph with its function label heuristically.

Second, which paragraph function labels would be most useful for scoring the organization of an essay? Based on our linguistic intuition, we identify four potentially useful paragraph function labels: Introduction, Body, Rebuttal, and Conclusion. Table 4 gives the descriptions of these labels.

Label	Name	Paragraph Type
I	Introduction	introduces essay topic and states author's position and main ideas
B	Body	provides reasons, evidence, and examples to support main ideas
C	Conclusion	summarizes and concludes arguments made in body paragraphs
R	Rebuttal	considers counter-arguments to thesis or main ideas

Table 4: Descriptions of paragraph function labels.

Setting aside for the moment the problem of exactly how to predict an essay's organization score given its paragraph sequence, the problem of obtaining paragraph labels to use for this task still remains. As mentioned above, we adopt a heuristic approach to paragraph function labeling. The question, then, is: what kind of knowledge sources should our heuristics be based on? We have identified two types of knowledge sources that are potentially useful for paragraph labeling. The first of these are positional, dealing with where in the essay a paragraph appears. So for example, the first paragraph in an essay is likely to be an Introduction, while the last is likely to be a Conclusion. A paragraph in any other position, on the other hand, is more likely to be a Body or Rebuttal paragraph.

Label	Name	Sentence Function
P	Prompt	restates the prompt given to the author and contains no new material or opinions
T	Transition	shifts the focus to new topics but contains no meaningful information
H	Thesis	states the author's position on the topic for which he/she is arguing
M	Main Idea	asserts reasons and foundational arguments that support the thesis
E	Elaboration	further explains reasons and ideas but contains no evidence or examples
S	Support	provides evidence and examples to support the claims made in other statements
C	Conclusion	summarizes and concludes the entire argument or one of the main ideas
R	Rebuttal	considers counter-arguments that contrast with the thesis or main ideas
O	Solution	puts to rest the questions and problems brought up by counter-arguments
U	Suggestion	proposes solutions the problems brought up by the argument

Table 5: Descriptions of sentence function labels.

A second potentially useful knowledge source involves the types of sentences appearing in a paragraph. This idea presupposes that, like paragraphs, sentences too can have discourse function labels indicating the logical role they play in an argument. The sentence label schema we propose, which is described in Table 5, is based on work in discourse structure by Burstein et al. (2003), but features additional sentence labels.

To illustrate why these sentence function labels may be useful for paragraph labeling, consider a paragraph containing a Thesis sentence. The presence of a Thesis sentence is a strong indicator that the paragraph containing it is either an Introduction or Conclusion. Similarly, a paragraph containing Rebuttal or Solution sentences is more likely to be a Body or Rebuttal paragraph.

Hence, to obtain a paragraph's function label, we need to first label its sentences. However, we are faced with the same problem: how can we obtain the sentence function labels? One way is to learn them from a corpus where each sentence is manually annotated with its sentence function label, which is the approach adopted by Burstein et al. (2003). However, this annotated corpus is not publicly available. In fact, to our knowledge, there is no publicly-available corpus that is annotated with sentence function labels. Consequently, we adopt a heuristic approach to sentence function labeling.

Overall, we created a knowledge-lean set of heuristic rules labeling paragraphs and sentences. Because many of the paragraph labeling heuristics depend on the availability of sentence labels, we will describe the sentence labeling heuristics first. For each sentence function label x, we identify several features whose presence increases our confidence that a given sentence is an example of x. So for example, the presence of any of the words "agree", "think", or "opinion" increases our confidence that the sentence they occur in is a Thesis. If the sentence instead contains words such as "however", "but", or "argue", these increase our confidence that the sentence is a Rebuttal. The features we examine for sentence labeling are not limited to words, however. Each content word the sentence shares with the essay prompt gives us evidence that the sentence is a restatement of the prompt. Having searched a sentence for all these clues, we finally assign the sentence the function label having the most support among the clues found.

The heuristic rules for paragraph labeling are similar in nature, though they depend heavily on the labels of a paragraph's component sentences. If a paragraph contains Thesis, Prompt, or Background sentences, the paragraph is likely to be an Introduction. However, if a paragraph contains Main Idea, Support, or Conclusion sentences, it is likely to be a Body paragraph. Finally, as mentioned previously, some positional information is used in labeling paragraphs. For example, a paragraph that is the first paragraph in an essay is likely to be an Introduction, but a paragraph that is neither the first nor the last is likely to be either a Rebuttal or Body paragraph. After searching a paragraph for all these features, we gather the pieces of evidence in support of each paragraph label and assign the paragraph the label having the most support.[1]

[1] Space limitations preclude a complete listing of these para-

graph and sentence labeling heuristics. See our website at `http://www.hlt.utdallas.edu/~alan/ICLE/` for the complete list of heuristics.

5 Heuristic-Based Organization Scoring

Having applied labels to each paragraph in an essay, how can we use these labels to predict the essay's score? Recall that the importance of each paragraph label stems not from the label itself, but from the sequence of labels it appears in. Motivated by this observation, we exploit a technique that is commonly used in bioinformatics — *sequence alignment*. While sequence alignment has also been used in text and paraphrase generation (e.g., Barzilay and Lee (2002; 2003)), it has not been extensively applied to other areas of language processing, including essay scoring. In this section, we will present two heuristic approaches to organization scoring, one based on aligning *paragraph sequences* and the other on aligning *sentence sequences*.

5.1 Aligning Paragraph Sequences

As mentioned above, our first approach to heuristic organization scoring involves aligning paragraph sequences. Specifically, this approach operates in two steps. Given an essay e in the test set, we (1) find the k essays in the training set that are most similar to e via paragraph sequence alignment, and then (2) predict the organization score of e by aggregating the scores of its k nearest neighbors obtained in the first step. Below we describe these two steps in detail.

First, to obtain the k nearest neighbors of e, we employ the Needleman-Wunsch alignment algorithm (Needleman and Wunsch, 1970), which computes a similarity score for any pair of essays by finding an optimal alignment between their paragraph sequences. To illustrate why we believe sequence alignment can help us determine which essays are most similar, consider two example essays. One essay, which we will call IBBBC, begins with an Introductory paragraph, follows it with three Body paragraphs, and finally ends with a Concluding paragraph. Another essay CRRRI begins with a paragraph stating its Conclusion, follows it with three Rebuttal paragraphs, and ends with a paragraph Introducing the essay's topic. We can tell by a casual glance at the sequences that any reasonable similarity function should tell us that they are not very similar. The Needleman-Wunsch alignment algorithm has this effect since the score of the alignment it produces would be hurt by the facts that (1) there is not much overlap in the sets of paragraph labels each contains, and (2) the paragraph labels they do share (I and C) do not occur in the same order. The resulting alignment would therefore contain many mismatches or indels.[2]

If we now consider a third essay whose paragraph sequence could be represented as IBRBC, a good similarity function should tell us that IBBBC and IBRBC are very similar. The Needleman-Wunsch alignment score between the two paragraph sequences has this property, as the alignment algorithm would discover that the two sequences are identical except for the third paragraph label, which could be mismatched for a small penalty. We would therefore conclude that the IBBBC and IBRBC essays should receive similar organization scores.

To fully specify how to find the k nearest neighbors of an essay, we need to define a similarity function between paragraph labels. In sequence alignment, similarity function $S(i, j)$ tells us how likely it is that symbol i (in our case, a paragraph label) will be substituted with another symbol j. While we expect that in an alignment between high-scoring essays, an Introduction paragraph is most likely to be aligned with another Introduction paragraph, how much worse should the alignment score be if an Introduction paragraph needs to be mismatched with a Rebuttal paragraph or replaced with an indel? We solve this problem by heuristically defining the similarity function as follows: $S(i, j) = 1$ when $i = j$, $S(i, j) = -1$ when $i \neq j$, and also $S(i, -) = S(-, i) = -1$, where '$-$' is an indel. In other words, the similarity function encourages the alignment between two identical function labels and discourages the alignment between two different function labels, regardless of the type of function labels.

After obtaining the k nearest neighbors of e, the next step is to predict the organization score of e by aggregating the scores of its k nearest neighbors into one number. (Note that we know the organiza-

[2] In pairwise sequence alignment, a mismatch occurs when one symbol has to be substituted for another to make two sequences match. An indel indicates that in order to transform one sequence to match another, we must either **in**sert a symbol into one sequence or **del**ete a symbol from the other sequence.

tion score of each nearest neighbor, since they are all taken from the training set.) One natural way to do this would be to take the mean, median, or mode of its k nearest neighboring essays from the training set. Hence, our first heuristic method H_p for scoring organization has three variants.

5.2 Aligning Sentence Sequences

An essay's paragraph sequence captures information about its organization at a high level, but ignores much of its lower level structure. Since we have also heuristically labeled sentences, it now makes sense to examine the sequences of sentence function labels within an essay's paragraphs. The intuition is that at least some portion of an essay's organization score can be attributed to the organization of the sentence sequences of its component paragraphs.

To address this concern, we propose a second heuristic approach to organization scoring. Given a test essay e, we first find for each *paragraph* in e the k *paragraphs* in the training set that are most similar to it. Specifically, each paragraph is represented by its sequence of *sentence* function labels. Given this paragraph representation, we can find the k nearest neighbors of a paragraph by applying the Needleman-Wunsch algorithm described in the previous subsection to align *sentence* sequences, using the same similarity function we defined above.

Next, we score each paragraph p_i by aggregating the scores of its k nearest neighbors obtained in the first step, assuming the score of a nearest neighbor paragraph is the same as the organization score of the training set essay containing it. As before, we can employ the mean, median, or mode to aggregate the scores of the nearest neighbors of p_i.

Finally, we predict the organization score of e by aggregating the scores of its paragraphs obtained in the second step. Again, we can employ mean, median, or mode to aggregate the scores. Since we have three ways of aggregating the scores of a paragraph's nearest neighbors and three ways of aggregating the resulting paragraph scores, this second method H_s for scoring organization has nine variants.

6 Learning-Based Organization Scoring

In the previous section, we proposed two heuristic approaches to organization scoring, one based on aligning paragraph label sequences and the other based on aligning sentence label sequences. In the process of constructing these two systems, however, we created a lot of information about the essays which might also be useful for organization scoring, but which the heuristic systems are unable to exploit. To remedy the problem, we introduce three learning-based systems which abstract the additional information we produced in three different ways. In each system, we use the SVM^{light} (Joachims, 1999) implementation of regression support vector machines (SVMs) (Cortes and Vapnik, 1995) to train a regressor because SVMs have been frequently and successfully applied to a variety of NLP problems.

6.1 Linear Kernel

Owing to the different ways we presented of combining the scores of an essay's nearest neighbors, the paragraph label sequence alignment approach has three variants, and its sentence label sequence alignment counterpart has nine. Unfortunately, these heuristic approaches suffer from two major weaknesses. First, it is not intuitively clear which of these 12 ways for predicting an essay's organization score is clearly better than the others. Second, it is not clear that the k nearest neighbors of an essay will always be similar to it with respect to organization score. While we do expect the alignment scores between good essays with reasonable paragraph sequences to be high, poorly organized essays by their nature have more random paragraph sequences. Hence, we have no intuition about the k nearest neighbors of a poor essay, as it may have as high an alignment score with another poorly organized essay as with a good essay.

Our solution to these problems is to use the organization scores obtained by the 12 heuristic variants as features in a linear kernel SVM learner. We believe that using the estimates given by all the 12 variants of the two heuristic approaches rather than only one of them addresses the first weakness mentioned above. The second weakness, on the other hand, is addressed by treating the organization score predictions obtained by the nearest neighbor methods as features for an SVM learner rather than as estimates of an essay's organization score.

The approach we have just described, however, does not exploit the full power of linear kernel

SVMs. One strength of linear kernels is that they make it easy to incorporate a wide variety of different types of features. In an attempt to further enhance the prediction capability of the SVM regressor, we will provide it with not only the 12 features derived from the heuristic-based approaches, but also with two additional types of features.

First, to give our learner more direct access to the information we used to heuristically predict essay scores, we can extract *paragraph label subsequences*[3] from each essay and use them as features. To illustrate the intuition behind these features, consider two paragraph subsequences: Introduction–Body and Rebuttal–Introduction. It is fairly typical to see the first subsequence, I–B, at the beginning of a good essay, so its occurrence should give us a small amount of evidence that the essay it occurs in is well-organized. The presence of the second subsequence, R–I, however, should indicate that its essay's organization is poor because, in general, a good essay should not give a Rebuttal before an Introduction. Because we can envision subsequences of various lengths being useful, we create a binary presence or absence feature in the linear kernel for each paragraph subsequence of length 1, 2, 3, 4, or 5 appearing in the training set.

Second, we employ *sentence label subsequences* as features in the linear kernel. Recall that when describing our alignment-based nearest neighbor organization score prediction methods, we noted that an essay's organization score may be partially attributable to how well the sentences within its paragraphs are organized. For example, if one of an essay's paragraphs contains the sentence label subsequence Main Idea–Elaboration–Support–Conclusion this gives us some evidence that the essay is overall well-organized since one of its component paragraphs contains this reasonably-organized subsequence. An essay with a paragraph containing the subsequence Conclusion–Support–Thesis–Rebuttal, however, is likely to be poorly organized because this is a poorly-organized subsequence. Since sentence label subsequences of differing lengths may be useful for score prediction, we create a binary presence or absence feature for each sentence label subsequence of length 1, 2, 3, 4, or 5 in the training set.

While the number of nearest neighbor features is manageable, the presence of a large number of features can sometimes confuse a learner. For that reason, we do feature selection on the two types of subsequence features, selecting only 100 features for each type that has the highest information gain (see Yang and Pedersen (1997) for details). We call the system resulting from the use of these three types of features Rl_{nps} because it uses **R**egression with **l**inear kernel to predict essay scores, and it uses **n**earest neighbor, **p**aragraph subsequence, and **s**entence subsequence features.

6.2 String Kernel

In a traditional learning setting, the feature set employed by an off-the-shelf learning algorithm typically consists of *flat* features (i.e., features whose values are discrete- or real-valued, as the ones described in the Linear Kernel subsection). Advanced machine learning algorithms such as SVMs, on the other hand, have enabled the use of *structured* features (i.e., features whose values are structures such as parse trees and sequences), owing to their ability to employ *kernels* to efficiently compute the similarity between two potentially complex structures.

Perhaps the most obvious advantage of employing structured features is *simplicity*. To understand this advantage, consider learning in a traditional setting. Recall that we can only employ flat features in this setting, as we did with the linear kernel. Hence, if we want to use information from a parse tree as features, we will need to design heuristics to extract the desired parse-based features from parse trees. For certain tasks, designing a good set of heuristics can be time-consuming and sometimes difficult. On the other hand, SVMs enable a parse tree to be employed directly as a structured feature, obviating the need to design heuristics to extract information from potentially complex structures. However, structured features have only been applied to a handful of NLP tasks such as semantic role labeling (Moschitti, 2004), syntactic parsing and named entity identification (Collins and Duffy, 2002), relation extraction (Bunescu and Mooney, 2005), and coreference resolution (Versley et al., 2008). Our goal here is to explore this rarely-exploited capability of SVMs for the task of essay scoring.

[3] Note that a subsequence is not necessarily contiguous.

While the vast majority of previous NLP work on using structured features have involved tree kernels, we employ a kernel that is rarely investigated in NLP: *string kernels* (Lodhi et al., 2002). Informally, a string kernel aims to efficiently compute the similarity between two strings (or sequences) of symbols based on the similarity of their subsequences. We apply string kernels to essay scoring as follows: we represent each essay using its paragraph function label sequence, and employ a string kernel to compute the similarity between two essays based on this representation. Typically, a string kernel takes as input two parameters: K (which specifies the length of the subsequences in the two strings to compare) and λ (which is a value between 0 and 1 that specifies whether matches between non-contiguous subsequences in the two strings should be considered as important as matches between contiguous subsequences). In our experiments, we select values for these parameters in a somewhat arbitrary manner. In particular, since λ ranges between 0 and 1, we simply set it to 0.5. For K, since in the flat features we considered all paragraph label sequences of lengths from 1 to 5, we again take the middle value, setting it to 3. We call the system using this kernel Rs because it uses a **R**egression SVM with a **s**tring kernel to predict essay scores.

6.3 Alignment Kernel

In general, the purpose of a kernel function is to measure the similarity between two examples. The string kernel we described in the previous subsection is just one way of measuring the similarity of two essays given their paragraph sequences. While this may be the most obvious way to use paragraph sequence information from a machine learning perspective, our earlier use of the Needleman-Wunsch algorithm suggests a more direct way of extracting structured information from paragraph sequences.

More specifically, recall that the Needleman-Wunsch algorithm finds an optimal alignment between two paragraph sequences, where an optimal alignment is defined as an alignment having the highest possible alignment score. The optimal alignment score can be viewed as another similarity measure between two essays. As such, with some slight modifications, the alignment score between two paragraph sequences can be used as the kernel value for an Alignment Kernel.[4] We call the system using this kernel Ra because it uses a **R**egression SVM with an **a**lignment kernel to predict essay scores.

6.4 Combining Kernels

Recall that the flat features are computed using a linear kernel, while the two types of structured features are computed using string and alignment kernels. If we want our learner to make use of more than one of these types of features, we need to employ a *composite* kernel to combine them. Specifically, we define and employ the following composite kernel:

$$K_c(F_1, F_2) = \frac{1}{n}\sum_{i=1}^{n} K_i(F_1, F_2),$$

where F_1 and F_2 are the full set of features (containing both flat and structured features) that represent the two essays under consideration, K_i is the ith kernel we are combining, and n is the number of kernels we are combining. To ensure that each kernel under consideration contributes equally to the composite kernel, each kernel value $K_i(F_1, F_2)$ is normalized so that its value falls between 0 and 1.

7 Evaluation

7.1 Evaluation Metrics

We designed three evaluation metrics to measure the error of our organization scoring system. The simplest metric, $S1$, is perhaps the most intuitive. It measures the frequency at which a system predicts the wrong score out of the seven possible scores. Hence, a system that predicts the right score only 25% of the time would receive an $S1$ score of 0.75.

The $S2$ metric is slightly less intuitive than $S1$, but no less reasonable. It measures the average distance between the system's score and the actual score. This metric reflects the idea that a system that estimates scores close to the annotator-assigned scores should be preferred over a system whose estimations are further off, even if both systems estimate the correct score at the same frequency.

Finally, the $S3$ evaluation metric measures the average square of the distance between a system's

[4] In particular, we note that for theoretical reasons, a kernel function must always return a non-negative value. The alignment score function does not have this property, so we increase all alignment scores until their theoretical minimum value is 0.

organization score estimations and the annotator-assigned scores. The intuition behind this system is that not only should we prefer a system whose estimations are close to the annotator scores, but we should also prefer one whose estimations are not too frequently very far away from the annotator scores. These three scores are given by:

$$\frac{1}{N}\sum_{A_i \neq E_i} 1, \quad \frac{1}{N}\sum_{i=1}^{N} |A_i - E_i|, \quad \frac{1}{N}\sum_{i=1}^{N} (A_i - E_i)^2,$$

where A_i and E_i are the annotator assigned and system estimated scores respectively for essay i, and N is the number of essays. Since many of the systems we have described assign test essays real-valued organization scores, to obtain E_i for system $S1$ we round the outputs of each system to the nearest of the seven scores the human annotators were permitted to assign (1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0).

To test our system, we performed 5-fold cross validation on our 1003 essay set, micro-averaging our results into three scores corresponding to the three scoring metrics described above.

7.2 Results and Discussion

The average baseline. As mentioned before, there is no standard baseline for organization modeling against which we can compare our systems. To start with, we employ a simple "average" baseline. Avg computes the average organization score of essays in the training set and assigns this score to each test set essay. Results of this baseline are shown in row 1 of Table 6. Though simple, this baseline is by no means easy-to-beat, since 41% of the essays have a score of 3, and 96% of the essays have a score that is within one point of 3.

Heuristic baselines. Recall that we have 12 versions of the two heuristic approaches to organization prediction. Space limitations preclude a discussion of the results of all these versions, so instead, to obtain the strongest baseline results, we show only the best results achieved by the three versions based on aligning paragraph label sequences in row 2 (H_p) and the best results achieved by the nine versions based on aligning sentence label sequences in row 3 (H_s) of Table 6. It is clear from the results that the H_p systems yielded the best baseline predictions under all three scoring metrics, performing significantly better than both the Avg and H_s systems ($p < 0.01$) with respect to the $S2$ and $S3$ metrics, but its $S1$ performance is less significant with respect to Avg ($p < 0.1$) and is indistinguishable at even the $p < 0.1$ level from H_s.[5] In general, however, it appears to be the case that systems based on aligning paragraph label sequences achieve better results than systems that attempt to align sentence label sequences.

	System	$S1$	$S2$	$S3$
1	Avg	.585	.412	.348
2	H_p	.548	.339	.198
3	H_s	.575	.397	.329
4	Rl_{nps}	.520	.331	.186
5	Rs	.577	.369	.222
6	Ra	.686	.519	.429
7	Rls_{nps}	.534	.332	.187
8	Rla_{nps}	.541	.332	.178
9	Rsa	.517	.325	.177
10	$Rlsa_{nps}$	.517	.323	.175

Table 6: System Performance

Learning-based approaches. Rows 4–6 of Table 6 show the results we obtained using each of the three single-kernel systems. When compared to the best baseline, these results suggest that H_p is a pretty good heuristic approach to organization scoring. In fact, only one of these three learning-based systems (Rl_{nps}) performs better than H_p under the three scoring metrics, and in each case, the difference between the two is not significant even at $p < 0.1$. This suggests that, even though Rl_{nps} performs slightly better than H_p, the only major benefit we have obtained by using the linear kernel is that it has made it unnecessary for us to choose between the 12 proposed heuristic systems.

Considering that the second best one-kernel system, Rs, does not have access to any of the nearest neighbor features, which have already proven useful, its performance seems reasonably good in that its performance is at least better than the Avg system. This suggests that, even though Rs does not perform exceptionally, it is extracting some useful information for organization scoring from the heuristically assigned paragraph label sequences. The best one-kernel system, Rl_{nps}, however, is sig-

[5] All significance tests are two-tailed paired t-tests.

nificantly better than Rs with respect to all three scoring metrics, with $p < 0.1$ for $S1$ and $p < 0.05$ for $S2$ and $S3$. By contrast, it initially appears that the alignment kernel is not extracting any useful information from these paragraph sequences at all, since its $S1$, $S2$, and $S3$ scores are all much worse than all of the baseline systems. The second best one-kernel system Rs performs significantly better than Ra at $p < 0.01$ for all three scoring metrics.

Next, we explore the impact of composite kernels, which allow our learners to make use of multiple types of flat and structured features. Specifically, the results shown in rows 7–9 are obtained by combining two kernels at a time. These experiments reveal the surprising result that the two worst performing single-kernel systems, Rs and Ra, when combined into Rsa, yield the best two-kernel system results, which are significant with respect to the best one-kernel system results under $S3$ at $p < 0.1$. This result suggests that these two different methods of extracting information from paragraph sequences provide us with different kinds of evidence useful for organization scoring, although neither method by itself was exceptionally useful. Though Rsa does not have any access to nearest neighbor information, it still performs significantly better than H_p at $p < 0.05$ under $S1$ and $S3$.

While we have already pointed out that Rsa is the best composite two-kernel system, it is not clear which of Rls_{nps} and Rla_{nps} is second-best. Neither system consistently performs better than the other under all three scoring metrics, and the differences between them are not significant even at $p < 0.1$. It is clear only that Rsa is better than both, as its scores are statistically significantly better at $p < 0.01$ with respect to Rls_{nps} and Rla_{nps} under at least one of the three scoring metrics in each case.

Finally, in the last row of Table 6, we combine all three kernels into one SVM learner. The most important lesson we learn from this experiment is that each of the three kernels provides the learner with a different kind of useful information, so that a composite kernel using all three sources of information performs better than any system using fewer kernels. Although the improvements over the best two-kernel system (Rsa) and one-kernel system (Rl_{nps}) are small, they are still statistically significant at $p < 0.1$ under one of the scoring metrics, $S3$. When we compare this combined system to the best baseline (H_p), we discover the improvements derived from the three-kernel system are significant improvements over it at $p < 0.05$ and $p < 0.01$ with respect to $S1$ and $S3$ respectively.

Feature analysis. To better understand which of the three flat features (nearest neighbors, paragraph label sequences, or sentence label sequences) contributes the most to the linear kernel portion of the systems' performances, we analyze the three feature types on Rl_{nps} using the backward elimination feature selection algorithm. First, we remove each of the three feature groups independently from the Rl_{nps}'s feature set and determine which of the three removals yields the best performance according to each scoring metric. Next, among the remaining two feature groups, we repeat the same step, removing each of the two groups independently from the feature set to determine which of the two removals yields the best performance.

While space limitations preclude showing the actual numbers, the trend is consistent among all three scoring metrics: the first feature type to remove is paragraph sequences (meaning that they are the least important) and the last to remove is the nearest neighbor features. Nevertheless, performance always drops when a feature type is removed, indicating that all three feature types contribute positively to overall performance. The fact that flat paragraph sequence features proved to be least useful highlights the importance of the structured methods we presented for using paragraph sequence information.

8 Conclusions

We have investigated the relatively less-studied problem of modeling the organization in student essays. The contributions of our work include the novel application of two techniques from bioinformatics and machine learning — sequence alignment and string kernels, as well as the introduction of alignment kernels — to essay scoring. We showed that each technique makes a significant contribution to a scoring system, and we hope that this work will increase awareness of these powerful techniques among NLP researchers. Finally, to stimulate work on this problem, we make our corpus of annotated essays available to other researchers.

Acknowledgments

We thank the three reviewers for their comments. Our six annotators, Andrew Hubbs, Karin Khoo, Jayne Koath, Christopher Maier, Andrew Mallon, and Cory Thornton, all deserve numerous thanks, because without the countless hours they each spent annotating hundreds of essays, none of the research described in this paper would have been possible.

Evaluating Models of Latent Document Semantics in the Presence of OCR Errors

Daniel D. Walker, William B. Lund, and Eric K. Ringger
Brigham Young University
Provo, Utah, USA
danl4@cs.byu.edu, bill_lund@byu.edu, ringger@cs.byu.edu

Abstract

Models of latent document semantics such as the mixture of multinomials model and Latent Dirichlet Allocation have received substantial attention for their ability to discover topical semantics in large collections of text. In an effort to apply such models to noisy optical character recognition (OCR) text output, we endeavor to understand the effect that character-level noise can have on unsupervised topic modeling. We show the effects both with document-level topic analysis (document clustering) and with word-level topic analysis (LDA) on both synthetic and real-world OCR data. As expected, experimental results show that performance declines as word error rates increase. Common techniques for alleviating these problems, such as filtering low-frequency words, are successful in enhancing model quality, but exhibit failure trends similar to models trained on unprocessed OCR output in the case of LDA. To our knowledge, this study is the first of its kind.

1 Introduction

As text data becomes available in massive quantities, it becomes increasingly difficult for human curators to manually catalog and index modern document collections. To aid in the automation of such tasks, algorithms can be used to create models of the latent semantics present in a given corpus. One example of this type of analysis is document clustering, in which documents are grouped into clusters by topic. Another type of topic analysis attempts to discover finer-grained topics—labeling individual words in a document as belonging to a particular topic. This type of analysis has grown in popularity recently as inference on models containing large numbers of latent variables has become feasible.

The modern explosion of data includes vast amounts of historical documents, made available by means of Optical Character Recognition (OCR), which can introduce significant numbers of errors. Undertakings to produce such data include the Google Books, Internet Archive, and HathiTrust projects. In addition, researchers are having increasing levels of success in digitizing hand-written manuscripts (Bunke, 2003), though error rates remain much higher than for OCR. Due to their nature, these collections often lack helpful meta-data or labels. In the absence of such labels, unsupervised machine learning methods can reveal patterns in the data.

Finding good estimates for the parameters of models such as the mixture of multinomials document model (Walker and Ringger, 2008) and the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003) requires accurate counts of the occurrences and co-occurrences of words. Depending on the age of a document and the way in which it was created, the OCR process results in text containing many types of noise, including character-level errors, which distort these counts. It is obvious, therefore, that model quality must suffer, especially since unsupervised methods are typically much more sensitive to noise than supervised methods. Good supervised learning algorithms are substantially more immune to spurious patterns in the data created by noise for the following reason: under the mostly reasonable assumption that the process contributing the noise operates independently from the class labels, the noise in the features will not correlate well with the class labels, and the algorithm will learn

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 240–250,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

to ignore those features arising from noise. Unsupervised models, in contrast, have no grounding in labels to prevent them from confusing patterns that emerge by chance in the noise with the "true" patterns of potential interest. For example, even on clean data, LDA will often do poorly if the very simple feature selection step of removing stop-words is not performed first. Though we expect model quality to decrease, it is not well understood how sensitive these models are to OCR errors, or how quality deteriorates as the level of OCR noise increases.

In this work we show how the performance of unsupervised topic modeling algorithms degrades as character-level noise is introduced. We demonstrate the effect using both artificially corrupted data and an existing real-world OCR corpus. The results are promising, especially in the case of relatively low word error rates (e.g. less than 20%). Though model quality declines as errors increase, simple feature selection techniques enable the learning of relatively high quality models even as word error rates approach 50%. This result is particularly interesting in that even humans find it difficult to make sense of documents with error rates of that magnitude (Munteanu et al., 2006).

Because of the difficulties in evaluating topic models, even on clean data, these results should not be interpreted as definitive answers, but they do offer insight into prominent trends. For example, properties of the OCR data suggest measures that can be taken to improve performance in future work. It is our hope that this work will lead to an increase in the usefulness of collections of OCRed texts, as document clustering and topic modeling expose useful patterns to historians and other interested parties.

The remainder of the paper is outlined as follows. After an overview of related work in Section 2, Section 3 introduces the data used in our experiments, including an explanation of how the synthetic data were created and of some of their properties. Section 4 describes how the experiments were designed and carried out, and gives an analysis of the results both empirically and qualitatively. Finally, conclusions and future work are presented in Section 5.

2 Related Work

Topic models have been used previously to process documents digitized by OCR, including eighteenth-century American newspapers (Newmann and Block, 2006), OCRed editions of *Science* (Blei and Lafferty, 2006), OCRed NIPS papers (Wang and McCallum, 2006), and books digitized by the Open Content Alliance (Mimno and Mccallum, 2007). Most of this previous work ignores the presence of OCR errors or attempts to remove corrupted tokens with special pre-processing such as stop-word removal and frequency cutoffs. Also, there are at least two instances of using topic modeling to improve the results of an OCR algorithm (Wick et al., 2007; Farooq et al., 2009).

Similar evaluations to ours have been conducted to assess the effect of OCR errors on supervised document classification (Taghva et al., 2001; Agarwal et al., 2007), information retrieval (Taghva et al., 1994; Beitzel et al., 2003), and a more general set of natural language processing tasks (Lopresti, 2008). Results suggest that in these supervised tasks OCR errors have a minimal impact on the performance of the methods employed, though it has remained unclear how well these results transfer to unsupervised methods.

3 Data

We conducted experiments on synthetic and real OCR data. As a real-world dataset, we used a corpus consisting of 604 of the Eisenhower World War II communiqués (Jordan, 1945; Lund and Ringger, 2009). These documents relate the daily progress of the Allied campaign from D-Day until the German surrender. They were originally produced as telegrams and were distributed as mimeographed copies. The quality of the originals is often quite poor, making them a challenging case for OCR engines. The communiqués have been OCRed using three popular OCR engines: ABBYY FineReader (ABBYY, 2010), OmniPage Pro (Nuance Communications, Inc., 2010), and Tesseract (Google, Inc., 2010). In addition, the curator of the collection has created a "gold standard" transcription, from which it is possible to obtain accurate measures of average document word error rates (WER) for each engine, which are: 19.9%, 30.4%, and 50.1% respectively.

While the real-world data is attractive as an example of just the sort of data that the questions addressed here apply to, it is limited in size and scope. All of the documents in the Eisenhower corpus discuss the fairly narrow topic of troop movements and battle developments taking place at the end of World War II. Neither the subject matter nor the means of conveyance allowed for a large or diverse vocabulary of discourse.

In an attempt to generalize our results to larger and more diverse data, we also ran experiments using synthetic OCR data. This synthetic data was created by corrupting "clean" datasets, adding character-level noise. The synthetic data was created by building a noise model based on mistakes made by the worst performing OCR engine on the Eisenhower dataset, Tesseract.

To construct the noise model, a character-level alignment between the human transcribed Eisenhower documents and the OCR output was first computed. From this alignment, the contingency table $\mathbf{M}^d$ was generated such that $\mathbf{M}^d_{x,y}$ was the count of the instances in which a character x in the transcript was aligned with a y in the OCR output. The rows in this matrix were then normalized so that each represented the parameters of a categorical distribution, conditioned on x. To parameterize the amount of noise being generated, the $\mathbf{M}^d$ matrix was interpolated with an identity matrix $\mathbf{I}$ using a parameter γ so that the final interpolated parameters $\mathbf{M}^i$ were calculated with the formula $\mathbf{M}^i = \gamma\mathbf{M}^d + (1-\gamma)\mathbf{I}$. So that at $\gamma = 0$, $\mathbf{M}^i = \mathbf{I}$ and no errors were introduced. At $\gamma = 1.0$, $\mathbf{M}^i = \mathbf{M}^d$, and we would expect to see characters corrupted at the same rate as in the output of the OCR engine.

We then iterated over each document, choosing a new (possibly the same) character y_l for each original character x_l according to the probability distribution $p(y_l = w'|x_l = w) = M^i_{w,w'}$. Our process was a one-substitution algorithm, as we did not include instances of insertions or deletions, consequently words were changed but not split or deleted. This allowed for a more straightforward calculation of word error rate. Segmentation errors can still occur in the learning stage, however, as the noise model sometimes replaced alphabet characters with punctuation characters, which were treated as delimiters by our tokenizer.

Dataset	**|D|**	K	**# Types**	**# Tokens**
20 News	19997	20	107211	2261805
Reuters	11367	81	29034	747458
Enron	4935	32	60495	2063667
Eisenhower	604	N/A	8039	76674

Table 1: Summary of test dataset characteristics. $|D|$ is the number of documents in the dataset. K is the number of human-labeled classes provided with the dataset.

We chose three datasets to corrupt: 20 Newsgroups (Lang, 1995), Reuters 21578 (Lewis, 1997), and the LDC-annotated portion of the Enron e-mail archive (Berry et al., 2007). Each of these datasets were corrupted at values $\gamma = i * 0.01$ for $i \in (0, 13)$. At this point, the word error rate of the corrupted data was near 50% and, since this was approximately the WER observed for the worst OCR engine on the real-world data, we chose to stop there. The word error rate was calculated during the corruption process. Here is an example sentence corrupted at two γ values:

$\gamma = 0.000$ I am also attaching the RFP itself.
$\gamma = 0.02$ I am also attachEng the RFP itself.
$\gamma = 0.10$ I Jm alAo attaching the RFP itself.

Table 3 shows some basic statistics for the datasets. The values shown are for the "clean" versions of the data. For an example of how noise and pre-processing techniques affect these counts see Section 4.1.

It is interesting to note that the word error rates produced by the noise model appear to be significantly higher than first expected. One might assume that the WER should increase fairly steadily from 0% at $\gamma = 0$ to about 50% (the error rate achieved by the Tesseract OCR engine on the Eisenhower dataset) at $\gamma = 1$. There are at least two sources for the discrepancy. First, the vocabulary of the Eisenhower dataset does not match well with that of any of the source datasets from which the synthetic data were generated. This means that the word and character distributions are different and so the error rates will be as well. Secondly, whereas our technique gives the same probability of corruption to all instances of a given character, errors in true OCR output are bursty and more likely to be concentrated in specific tokens, or regions, of a document. This is because most sources of noise do not affect document images uniformly. Also, modern OCR engines do not operate at just the character level. They incorporate dictionaries and language models to prevent them from positing words that are highly unlikely. As a consequence, an OCR engine is much more likely to either get a whole word correct, or to miss it completely, concentrating multiple errors in a single word. This is the difference between 10 errors in a single word, which only contributes 1 to the numerator of the WER formula and 10 errors spread across 10 different words, which contributes 10 to the numerator. Furthermore, because content bearing words tend to be relatively rare, language models are poorer for them than for frequent function words, meaning that the words most correlated with semantics are also the most likely to be corrupted by an OCR engine.

An example of this phenomenon is easy to find. In the Enron corpus, there are 165,871 instances of the word "the" and 102 instances of the string "thc". Since "c" has a high rate of confusion with "e", we would expect at least some instances of "the" to be corrupted to "thc" by the error model. At $\gamma = 0.03$, there are 156,663 instances of the word "the" and 513 instances of "thc". So, the noise model converts "the" to "thc" roughly 0.3% of the time. In contrast, there are no instances of "thc" in the Tesseract OCR output even though there are 5186 instances of "the" in the transcription text, and so we would expect approximately 16 occurrences of "thc" if the errors introduced by the noise model were truly representative of the errors in the actual OCR output.

Another interesting property of the noise introduced by actual OCR engines and our synthetic noise model is the way in which this noise affects words distributions. This is very important, since word occurrence and co-occurrence counts are the basis for model inference in both clustering and topic modeling. As mentioned previously, one common way of lessening the impact of OCR noise when training topic models over OCRed data is to apply a frequency cutoff filter to cull words that occur fewer than a certain number of times. Figures 1 and 2 show the number of word types that are culled from the synthetic 20 Newsgroups OCR data and the Eisenhower OCR data, respectively, at various levels of noise. Note that the cutoff filters use a strict "less than", so a frequency cutoff of 2 eliminates only words that occur once in the entire dataset. Also, these series are additive, as the words culled with a frequency cutoff of 2 are a subset of those culled with a frequency cutoff of $j > 2$.

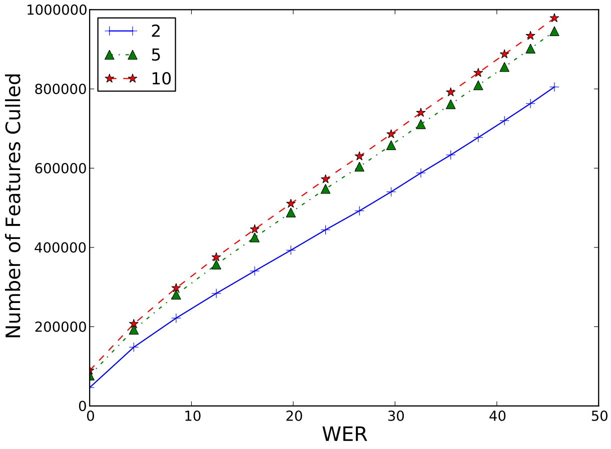

Figure 1: The number of word types culled with frequency cutoff filters applied to the 20 Newsgroups data with various levels of errors introduced.

In both cases, it is apparent that by far the largest impact that noise has is in the creation of singletons. It seems that the most common corruptions in these scenarios is the creation of one-off word types through a unique corruption of a (most likely rare) word. This means that it is unlikely that enough evidence will be available to associate, through similar contexts, the original word and its corrupted forms.

Due to the fact that most clustering and topic models ignore the forms of word tokens (the characters that make them up), and only take into account word identities, we believe that the similarity in the way in which real OCR engines and our synthetic OCR noise model distort word distributions is sufficient evidence to support the use of the synthetic data until larger and better real-world OCR datasets can be made available. Though the actual errors will take a different form, the character-level details of the errors are less relevant than the word distribution alterations for the models in question.

4 Experimental Results

We ran experiments on both the real and synthetic OCR data. In this section we explain our experi-

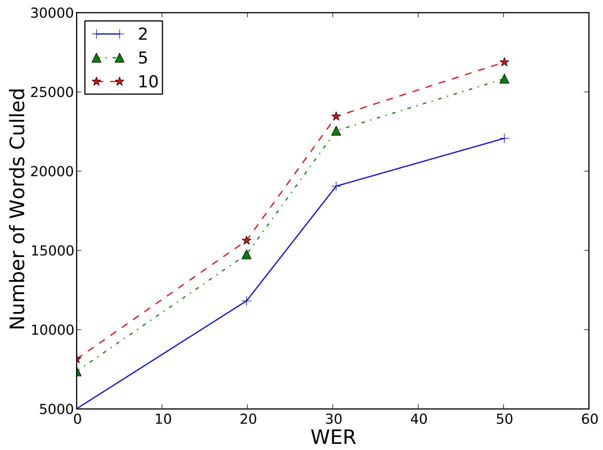

Figure 2: The number of word types culled with frequency cutoff filters applied to the transcript and three OCR engine outputs for the Eisenhower data.

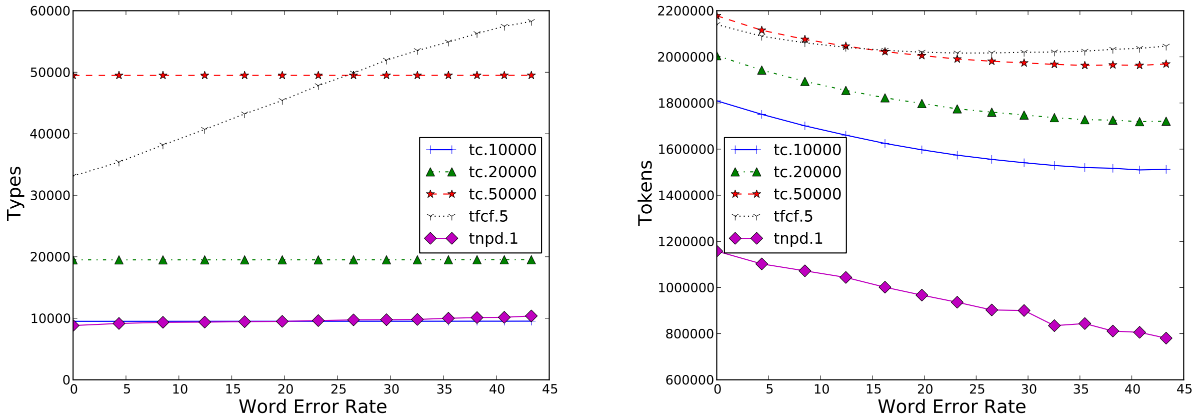
mental methodology and present both empirical and qualitative analyses of the results.

4.1 Methodology

For the synthetic OCR datasets, we ran clustering experiments using EM on a mixture of multinomials (c.f. (Walker and Ringger, 2008)). We specified the number of clusters to be the same as the number of classes provided with the data. Clusters were evaluated using several external cluster quality metrics which compare "gold standard" labels to those created through clustering. The metrics used were Variation of Information (VI) (Meilă, 2007), and the Adjusted Rand Index (ARI) (Hubert and Arabie, 1985). Other metrics were also calculated (e.g. the V-Measure (Rosenberg and Hirschberg, 2007), and Average Entropy (Liu et al., 2003)), but these results were excluded due to space constraints and the fact that their plots are similar to those shown. We did not cluster the Eisenhower data because of the absence of the class labels necessary for evaluation.

For both the synthetic and non-synthetic data we also trained LDA topic models (Blei et al., 2003) using Gibbs sampling. We used the implementation found in the MALLET software package (McCallum, 2002) with the option enabled to learn the priors during sampling as discussed by Wallach et al. (2009a). Each LDA model was trained on 90% of the documents in each dataset. The trained model was used to calculate an estimate of the marginal log-likelihood of the remaining 10% of the documents using the left-to-right algorithm (Wallach et al., 2009b). The number of topics used for each dataset was adjusted *a priori* according to the number of documents it contained. We used 100 topics for Enron and Eisenhower, 150 for Reuters, and 200 for 20 Newsgroups.

In addition to running experiments on the "raw" synthetic data, we also applied simple unsupervised feature selectors before training in order to evaluate the effectiveness of such measures in mitigating problems caused by OCR errors. For the topic modeling (LDA) experiments three feature selectors were used. The first method employed was a simple term frequency cutoff filter (TFCF), with a cutoff of 5 as in (Wang and McCallum, 2006). The next method employed was Term Contribution (TC), a feature selection algorithm developed for document clustering (Liu et al., 2003). Term contribution is parameterized by the number of word types that are to remain after selection. We attempted three values for this parameter, 10,000, 20,000, and 50,000. The final method we employed was a method called Top-N per Document (TNPD) (Walker and Ringger, 2010), which is a simple feature selection algorithm that first assigns each type in every document a document-specific score (e.g. its TF-IDF weight), and then selects words to include in the final vocabulary by choosing the N words with the highest score from each document in the corpus. We found that $N = 1$ gave the best results at the greatest reduction in word types. After the vocabulary is built, all words not in the vocabulary are culled from the documents. This does not mean that all documents contain only one word after feature selection, as the top word in one document may occur in many other documents, even if it is not the top word in those documents. Likewise, if two documents would both contribute the same word, then the second document makes no contribution to the vocabulary. This process can result in vocabularies with thousands of words, leaving sufficient words in each document for analysis. For the clustering experiments, initial tests showed little difference in the performance of the feature selectors, so only the TNPD selector was used. Figures 3(a) and 3(b) show how the various pre-processing methods affect word type and token



(a) The number of word types remaining after pre-processing.

(b) The number of word tokens remaining after pre-processing.

Figure 3: The effect of pre-processing on token and type counts for the 20 Newsgroups dataset at various error rates.

counts, respectively, for the 20 Newsgroups dataset. In contrast, without pre-processing the number of types scales from 107,211 to 892,983 and the number of tokens from 2,261,805 to 3,073,208.

Because all of these procedures alter the number of words and tokens in the final data, log-likelihood measured on a held-out set cannot be used to accurately compare the quality of topic models trained on pre-processed data, as the held-out data will contain many unknown words. If the held-out data is also pre-processed to only include known words, then the likelihood will be greater for those procedures that remove the most tokens, as the product that dominates the calculation will have fewer terms. If unknown words are allowed to remain, even a smoothed model will assign them very little probability and so models will be heavily penalized.

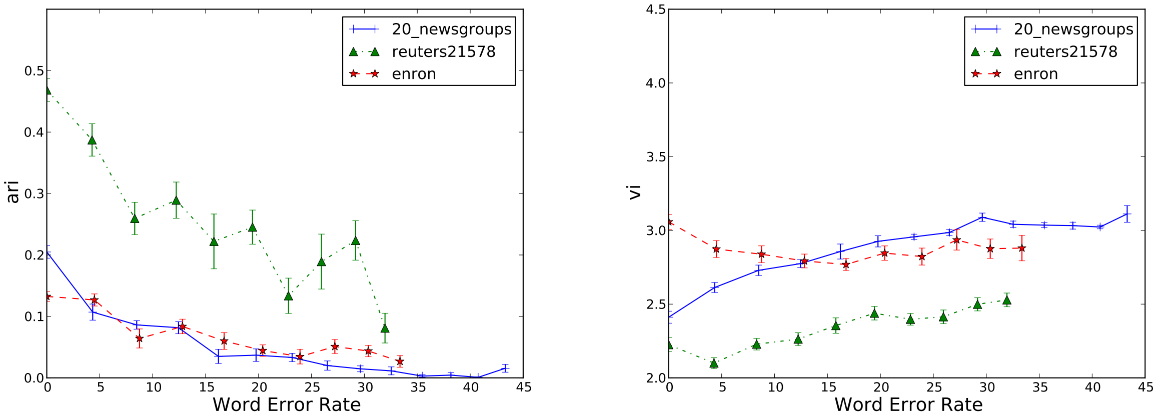
We use an alternative method for evaluating the topic models, discussed in (Griffiths et al., 2005), to avoid the aforementioned problems with an evaluation based on log-likelihood. Since the synthetic data is derived from datasets that have topical document labels, we are able to use the output from LDA in a classification problem with the word vectors for each document being replaced by the assigned topic vectors. This is equivalent to using LDA as a dimensionality reduction pre-process for document classification. A naive Bayes learner is trained on a portion of the topic vectors, labeled with the original document label, and then the classification accuracy on a held-out portion of the data is computed. Ten-fold cross-validation is used to control for sampling issues. The rationale behind this evaluation is that, even though the topics discovered by LDA will not correspond directly to the labels, there should at least be a high degree of correlation. Models that discover topical semantics that correlate well with the labels applied by humans will yield higher classification accuracies and be considered better models according to this metric.

To compensate for the randomness inherent in the algorithms, each experiment was replicated ten times. The results of these runs were averaged to produce the values reported here.

4.2 Empirical Analysis

Both the mixture of multinomials document model and LDA appear to be fairly resilient to character-level noise. Figures 4 and 5 show the results of the document clustering experiments with and without feature selection, respectively. Memory issues prevented the collection of results for the highest error rates on the Enron and Reuters data without feature selection.

With no pre-processing, the results are somewhat mixed. The Enron dataset experiences almost no quality degradation as the WER increases, yielding remarkably constant results according to the metrics. However, this may be an artifact of the relatively poor starting performance for this dataset, a result of the fact that the gold standard labels do not align



(a) Adjusted Rand Index results

(b) Variation of Information results (lower is better)

Figure 4: Results for the clustering experiments on the three synthetic datasets *without* feature selection.

well with automatically discovered patterns because they correspond to external events. In contrast, the Reuters data appears to experience drastic degradation in performance. Once feature selection occurs, however, performance remains much more stable as error rates increase.

Figure 6(a) shows the results of running LDA on the transcript and digitized versions of the Eisenhower dataset. Log-likelihoods of the held-out set are plotted with respect to the WER observed for each OCR engine. The results support the finding that the WER of the OCR engine that produced the data has a significant negative correlation with model quality. Unfortunately, it was not possible to compare the performance of the pre-processing methods on this dataset, due to a lack of document topic labels and the deficiencies of log-likelihood mentioned previously.

Figure 6(b) shows the results of the LDA topic-modeling experiments on the three "raw" synthetic datasets. Similar trends are observed in this graph. LDA experiences a marked degree of performance degradation, with all of the trend lines indicating a linear decrease in log-likelihood.

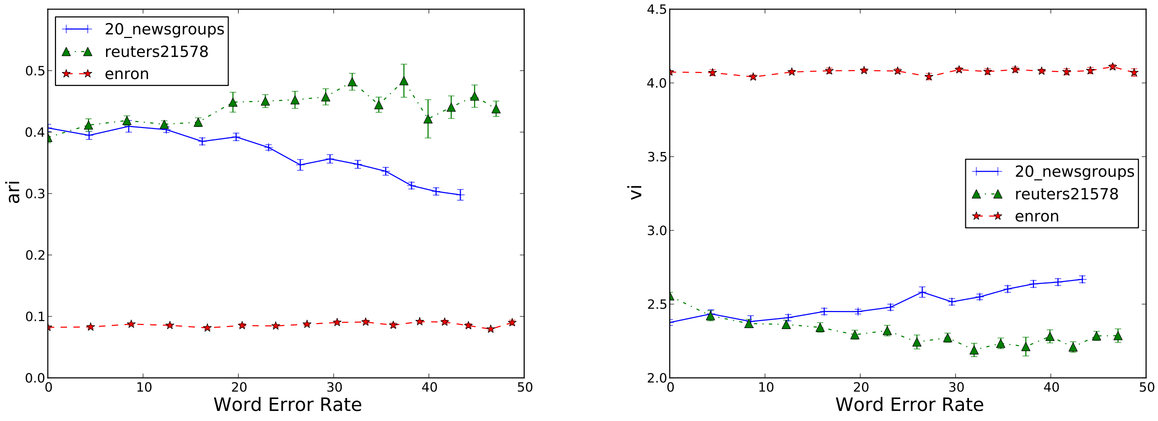
Figures 7(a) through 7(c) show the results of evaluating the various proposed pre-processing procedures in the context of topic modeling. In the graph "noop.0" represents no pre-processing, "tc.N" are the Term Contribution method parameterized to select N word types, "tfcf.5" is the term frequency cutoff filter with a cutoff of 5 and "tnpd.1" is the Top N per Document method with $N = 1$. The y-axis is the average of the results for 10 distinct trials, where the output for each trial is the average of the ten accuracies achieved using ten-fold cross-validation as described in Section 4.1.

Here, the cross-validation accuracy metric reveals a slightly different story. These results show that topic quality on both the raw and pre-processed noisy data degrades at a rate relative to the amount of errors in the data. That is, the difference in performance between two relatively low word error rates (e.g. 5% and 7% on the Reuters data) is small, whereas the differences between two high error rates (e.g. 30% and 32% on the Reuters data) can be relatively quite large.

While pre-processing does improve model quality, in the case of LDA this improvement amounts to a nearly constant boost; at high error rates quality is improved the same amount as at low error rates. Degradations in model quality, therefore, follow the same trends, occurring at mostly the same rate in pre-processed data as in the raw noisy data. This is in contrast to the clustering experiments where pre-processing virtually eliminates failure trends.

4.3 Qualitative Analysis

Higher values measured with automated metrics such as log-likelihood on a held-out set and the cross-validation classification metric discussed here



(a) Adjusted Rand Index results

(b) Variation of Information results (lower is better)

Figure 5: Results for the clustering experiments on the three synthetic OCR datasets *with* TNPD feature selection.

do not necessarily indicate superior topics according to human judgement (Chang et al., 2009). In order to provide a more thorough discussion of the relative quality of the topic models induced on the OCR data versus those induced on clean data, we sampled the results of several of the runs of the LDA algorithm. In Tables 2 and 3 we show the top words for the five topics with the highest learned topic prior (α in the LDA literature) learned during Gibbs sampling. This information is shown for the Reuters data first with no corruption and then at the highest error rate for which we have results for that data of 45% WER.

In general, there appears to be a surprisingly good correlation between the topics learned on the clean data and those learned on the corrupted data, given the high level of noise involved. The topics are generally cohesive, containing mostly terms relating to financial market news. However, the topics trained on the clean data, though all related to financial markets, are fairly distinctive. Topic 3, for example seems to be about fluctuations in stock prices, and Topics 106 and 34 about business acquisitions and mergers. The topics trained on the noisy data are fairly homogeneous and the differences between them are more difficult to identify.

In addition, it appears as though the first topic (topic 93) is not very coherent at all. This topic is significantly larger, in terms of the number of tokens assigned to it than the other topics shown in either table. In addition, the most probable words listed for the topic seem less cohesive than for the other topics. It contains many two-letter words that are likely a mixture of valid terms (e.g., stock exchange and ticker symbols, and parts of place names like “Rio de Janeiro”) and corruptions of real words. For example, even though there are no instances of “ts” as a distinct token in the clean Reuters data, it is in the list of the top 19 words for topic 93. This is perhaps due to the fact that “is” can easily be converted to “ts” by mistaking t for i.

It is also the case that, for most topics learned on the corrupted data, the most probable words for those topics tend to be shorter, on average, than for topics learned on clean data. We believe this is due to the fact that the processes used to add noise to the data (both real OCR engines and our synthetic noise model) are more likely to corrupt long words, especially in the case of the synthetic data which was created using a character-level noise model.

Examination of the data tends to corroborate this hypothesis, though even long words usually contain only a few errors. For example, in the 20 Newsgroups data there are 379 instances of the word “yesterday”, a long word that is not close to other English words in edit distance. When the data has been corrupted to a WER of 47.9%, however, there are only 109 instances of “yesterday” and 132 tokens that are within an edit distance of 1 from “yesterday”.

To some extent, we would expect to observe similar trends in real-world data. However, most OCR

engines employ language models and dictionaries to attempt to mitigate OCR errors. As a result, given that a word recognition error has occurred in true OCR output, it is more likely to be an error that lies at an edit distance greater than one from the true word, or else it would have been corrected internally. For example, there are 349 instances of the word “yesterday” in the Eisenhower transcripts, and 284 instances in the Tesserect OCR output and only 5 tokens within an edit distance of one, meaning that 60 corruptions of this word contained more than one error, making up 90% of the errors for that word. However, many of these errors still contain most of the letters from the original word (e.g. “yesterdj.”, and “yestjkday”). In all cases, the corrupted versions of a given word are very rare, occurring usually only once or twice in the noisy output, making them useless features for informing a model.

5 Conclusions and Future Work

The primary outcome of these experiments is an understanding regarding when clustering and LDA topic models can be expected to function well on noisy OCR data. Our results imply that clustering methods should perform almost as well on OCR data as they do on clean data, provided that a reasonable feature selection algorithm is employed. The LDA topic model degraded less gracefully in performance with the addition of character level errors to its input, with higher error rates impacting model quality in a way that was apparent empirically in the log-likelihood and ten-fold cross-validation metrics as well as through human inspection of the produced topics. Pre-processing the data also helps model quality for LDA, yet still yields failure trends similar to those observed on unprocessed data.

We found it to be the case that even in data with high word error rates, corrupted words often share many characters in common with their uncorrupted form. This suggests an approach in which word similarities are used to cluster the unique corrupted versions of a word in order to increase the evidence available to the topic model during training time and improve model quality. As the quality of models increases on these noisy datasets, we anticipate a consequent rise in their usefulness to researchers and historians as browsing the data and mining it for useful patterns becomes more efficient and profitable.

Translingual Document Representations from Discriminative Projections

Abstract

Representing documents by vectors that are independent of language enhances machine translation and multilingual text categorization. We use discriminative training to create a projection of documents from multiple languages into a single translingual vector space. We explore two variants to create these projections: Oriented Principal Component Analysis (OPCA) and Coupled Probabilistic Latent Semantic Analysis (CPLSA). Both of these variants start with a basic model of documents (PCA and PLSA). Each model is then made discriminative by encouraging comparable document pairs to have similar vector representations. We evaluate these algorithms on two tasks: parallel document retrieval for Wikipedia and Europarl documents, and cross-lingual text classification on Reuters. The two discriminative variants, OPCA and CPLSA, significantly outperform their corresponding baselines. The largest differences in performance are observed on the task of retrieval when the documents are only comparable and not parallel. The OPCA method is shown to perform best.

1 Introduction

Given the growth of multiple languages on the Internet, Natural Language Processing must operate on dozens of languages. It is becoming critical that computers reach high performance on the following two tasks:

- **Comparable and parallel document retrieval** — Cross-language information retrieval and text categorization have become important with the growth of the Web (Oard and Diekema, 1998). In addition, machine translation (MT) systems can be improved by training on sentences extracted from parallel or comparable documents mined from the Web (Munteanu and Marcu, 2005). Comparable documents can also be used for learning word-level translation lexicons (Fung and Yee, 1998; Rapp, 1999).
- **Cross-language text categorization** — Applications of text categorization, such as sentiment classification (Pang et al., 2002), are now required to run on multiple languages. Categorization is usually trained on the language of the developer: it needs to be easily extended to other languages.

There are two broad approaches to comparable document retrieval and cross-language text categorization. One approach is to translate queries or a training set from different languages into a single target language. Standard monolingual retrieval and classification algorithms can then be applied in the target language.

Alternatively, a cross-language system can project a bag-of-words vector into a translingual lower-dimensional vector space. Ideally, vectors in this space represent the semantics of a document, independent of the language.

The advantage of pre-translation is that MT systems tend to preserve the meaning of documents. However, MT can be very slow (more than 1 second per document), preventing its use on large training sets. When full MT is not practical, a fast word-by-word translation model can be used instead, (Ballesteros and Croft, 1996) but may be less accurate.

Conversely, applying a projection into a low-dimensional space is quick. Linear projection algorithms use matrix-sparse vector multiplication, which can be easily parallelized. However, as seen in section 3, the accuracies of previous projection

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 251–261,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

techniques are not as high as machine translation.

This paper presents two techniques: Oriented PCA and Coupled PLSA. These techniques retain the high speed of projection, while approaching or exceeding the quality level of word glossing. We improve the quality of the projections by the use of discriminative training: we minimize the difference between comparable documents in the projected vector space. Oriented PCA minimizes the difference by modifying the eigensystem of PCA (Diamantaras and Kung, 1996), while Coupled PLSA uses posterior regularization (Graca et al., 2008; Ganchev et al., 2009) on the topic assignments of the comparable documents.

1.1 Previous work

There has been extensive work in projecting monolingual documents into a vector space. The initial algorithm for projecting documents was Latent Semantic Analysis (LSA), which modeled bag-of-word vectors as low-rank Gaussians (Deerwester et al., 1990). Subsequent projection algorithms were based on generative models of individual terms in the documents, including Probabilistic Latent Semantic Analysis (PLSA) (Hofmann, 1999) and Latent Dirichlet Allocation (LDA) (Blei et al., 2003).

Work on cross-lingual projections followed a similar pattern of moving from Gaussian models to term-wise generative models. Cross-language Latent Semantic Indexing (CL-LSI) (Dumais et al., 1997) applied LSA to concatenated comparable documents from multiple languages. Similarly, Polylingual Topic Models (PLTM) (Mimno et al., 2009) generalized LDA to tuples of documents from multiple languages. The experiments in section 3 use CL-LSI and an algorithm similar to PLTM as benchmarks.

The closest previous work to this paper is the use of Canonical Correlation Analysis (CCA) to find projections for multiple languages whose results are maximally correlated with each other (Vinokourov et al., 2003).

PLSA-, LDA-, and CCA-based cross-lingual models have also been trained without the use of parallel or comparable documents, using only knowledge from a translation dictionary to achieve sharing of topics across languages (Haghighi et al., 2008; Jagarlamudi and Daumé, 2010; Zhang et al., 2010). Such work is complementary to ours and can be used to extend the models to domains lacking parallel documents.

Outside of NLP, researchers have designed algorithms to find discriminative projections. We build on the Oriented Principal Component Analysis (OPCA) algorithm (Diamantaras and Kung, 1996), which finds projections that maximize a signal-to-noise ratio (as defined by the user). OPCA has been used to create discriminative features for audio fingerprinting (Burges et al., 2003).

1.2 Structure of paper

This paper now presents two algorithms for translingual document projection (in section 2): OPCA and Coupled PLSA (CPLSA). To explain OPCA, we first review CL-LSI in section 2.1, then discuss the details of OPCA (section 2.2), and compare it to CCA (section 2.3). To explain CPLSA, we first introduce Joint PLSA (JPLSA), analogous to CL-LSI, in section 2.4, and then describe the details of CPLSA (section 2.5).

We have evaluated these algorithms on two different tasks: comparable document retrieval (section 3.2) and cross-language text categorization (section 3.3). We discuss the findings of the evaluations and extensions to the algorithms in section 4.

2 Algorithms for translingual document projection

2.1 Cross-language Latent Semantic Indexing

Cross-language Latent Semantic Indexing (CL-LSI) is Latent Semantic Analysis (LSA) applied to multiple languages. First, we review the mathematics of LSA.

LSA models an $n \times k$ document-term matrix $\mathbf{D}$, where n is the number of documents and k is the number of terms. The model of the document-term matrix is a low-rank Gaussian. Originally, LSA was presented as performing a Singular Value Decomposition (Deerwester et al., 1990), but here we present it as eigendecomposition, to clarify its relationship with OPCA.

LSA first computes the correlation matrix between terms:

$$\mathbf{C} = \mathbf{D}^T\mathbf{D}. \tag{1}$$

The Rayleigh quotient for a vector $\vec{v}$ with the matrix $\mathbf{C}$ is

$$\frac{\vec{v}^T \mathbf{C} \vec{v}}{\vec{v}^T \vec{v}}, \tag{2}$$

and is equal to the variance of the data projected using the vector $\vec{v}$, normalized by the length of $\vec{v}$, if $\mathbf{D}$ has columns that are zero mean. Good projections retain a large amount of variance. LSA maximizes the Rayleigh ratio by taking its derivative against $\vec{v}$ and setting it to zero. This yields a set of projections that are eigenvectors of $\mathbf{C}$,

$$\mathbf{C}\vec{v}_j = \lambda_j \vec{v}_j, \tag{3}$$

where λ_j is the jth-largest eigenvalue. Each eigenvalue is also the variance of the data when projected by the corresponding eigenvector $\vec{v}_j$. LSA simply uses top d eigenvectors as projections.

LSA is very similar to Principal Components Analysis (PCA). The only difference is that the correlation matrix $\mathbf{C}$ is used, instead of the covariance matrix. In practice, the document-term matrix $\mathbf{D}$ is sparse, so the column means are close to zero, and the correlation matrix is close to the covariance matrix.

There are a number of methods to form the document-term matrix $\mathbf{D}$. One method that works well in practice is to compute the log(tf)-idf weighting: (Dumais, 1990; Wild et al., 2005)

$$D_{ij} = \log_2(f_{ij} + 1) \log_2(n/d_j), \tag{4}$$

where f_{ij} is the number of times term j occurs in document i, n is the total number of documents, and d_j is the total number of documents that contain term j. Applying a logarthm to the term counts makes the distribution of matrix entries approach Gaussian, which makes the LSA model more valid.

Cross-language LSI is an application of LSA where each row of $\mathbf{D}$ is formed by concatenating comparable or parallel documents in multiple languages. If a single term occurs in multiple languages, the term only has one slot in the concatenation, and the term count accumulates for all languages. Such terms could be proper nouns, such as "Smith" or "Merkel".

In general, the elements of $\mathbf{D}$ are computed via

$$D_{ij} = \log_2\left(\sum_m f_{ij}^m + 1\right) \log_2(n/d_j), \tag{5}$$

where f_{ij}^m is the number of times term j occurs in document i in language m. Here, d_j is the number of documents term j appears in, and n is the total number of documents across all languages.

Because CL-LSI is simply LSA applied to concatenated documents, it models terms in document vectors jointly across languages as a single low-rank Gaussian.

2.2 Oriented Principal Component Analysis

The limitations of CL-LSI can be illustrated by considering Oriented Principal Components Analysis (OPCA), a generalization of PCA. A user of OPCA computes a signal covariance matrix $\mathbf{S}$ and a noise covariance matrix $\mathbf{N}$. OPCA projections $\vec{v}_j$ maximize the ratio of the variance of the signal projected by $\vec{v}_j$ to the variance of the noise projected by $\vec{v}_j$. This signal-to-noise ratio is the generalized Rayleigh quotient: (Diamantaras and Kung, 1996)

$$\frac{\vec{v}^T \mathbf{S} \vec{v}}{\vec{v}^T \mathbf{N} \vec{v}}. \tag{6}$$

Taking the derivative of the Rayleigh quotient with respect to the projections $\vec{v}$ and setting it to zero yields the generalized eigenproblem

$$\mathbf{S}\vec{v}_j = \lambda_j \mathbf{N} \vec{v}_j. \tag{7}$$

This eigenproblem has no local minima, and can be solved with commonly available parallel code.

PCA is a specialization of OPCA, where the noise covariance matrix is assumed to be the identity (i.e., uncorrelated noise). PCA projections maximize the signal-to-noise ratio where the signal is the empirical covariance of the data, and the noise is spherical white noise. PCA projections are not truly appropriate for forming multilingual document projections.

Instead, we want multilingual document projections to maximize the projected covariance of document vectors across all languages, while simultaneously minimizing the projected distance between comparable documents (see Figure 1). OPCA gives us a framework for finding such discriminative projections. The covariance matrix for all documents is the signal covariance in OPCA, and captures the meaning of documents across all languages. The projection of this covariance matrix should be maximized. The covariance matrix formed from differences between comparable documents is the noise covariance in OPCA: we wish to minimize the latter covariance, to make the projection language-independent.

Specifically, we create the weighted document-term matrix $\mathbf{D}_m$ for each language:

$$D_{ij,m} = \log_2(f_{ij}^m + 1)log_2(n/d_j). \tag{8}$$

We then derive a signal covariance matrix over all languages:

$$\mathbf{S} = \sum_m \mathbf{D}_m^T \mathbf{D}_m / n - \vec{\mu}_m^T \vec{\mu}_m, \tag{9}$$

where $\vec{\mu}_m$ is the mean of each $\mathbf{D}_m$ over its columns, and a noise covariance matrix,

$$\mathbf{N} = \sum_m (\mathbf{D}_m - \mathbf{D})^T (\mathbf{D}_m - \mathbf{D})/n + \gamma \mathbf{I}, \tag{10}$$

where $\mathbf{D}$ is the mean across all languages of the document-term matrix,

$$\mathbf{D} = \frac{1}{M} \sum_m \mathbf{D}_m, \tag{11}$$

and M is the number of languages. Applying equation (7) to these matrices and taking the top generalized eigenvectors yields the projection matrix for OPCA.

Note the regularization term of $\gamma \mathbf{I}$ in equation (10). The empirical sample of comparable documents may not cover the entire space of translation noise the system will encounter in the test set. For safety, we add a regularizer that prevents the variance of a term from getting too small. We tuned γ on the development sets in section 3.2: for log(tf)-idf weighted vectors, $C = 0.1$ works well for the data sets and dimensionalities that we tried. We use $C = 0.1$ for all final tests.

2.3 Canonical Correlation Analysis

Canonical Correlation Analysis (CCA) is a technique that is related to OPCA. CCA was kernelized and applied to creating cross-language document models by (Vinokourov et al., 2003). In CCA, a linear projection is found for each language, such that the projections of the corpus from each language are maximally correlated with each other. Similar to OPCA, this linear projection can be found by finding the top generalized eigenvectors of the system (7), where $\mathbf{S}$ is now a matrix of cross-correlations that the projection maximizes,

$$\mathbf{S} = \begin{bmatrix} 0 & \mathbf{C}_{12} \\ \mathbf{C}_{21} & 0 \end{bmatrix}, \tag{12}$$

and $\mathbf{N}$ is a matrix of autocorrelations that the projection minimizes,

$$\mathbf{N} = \begin{bmatrix} \mathbf{C}_{11} + \gamma I & 0 \\ 0 & \mathbf{C}_{22} + \gamma I \end{bmatrix}. \tag{13}$$

Here, C_{ij} is the (cross-)covariance matrix, with dimension equal to the vocabulary size, that is computed between the document vectors for languages i and j. Analogous to OPCA, γ is a regularization term, set by optimizing performance on a validation set. Like OPCA, these matrices can be generalized to more than two languages. Unlike OPCA, CCA finds projections that maximize the cross-covariance between the projected vectors, instead of minimizing Euclidean distance.[1]

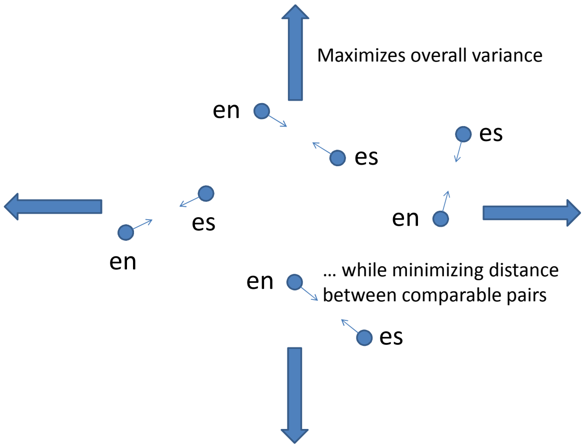

Figure 1: OPCA finds a projection that maximizes the variance of all documents, while minimizing distance between comparable documents

By definition, CCA cannot take advantage of the information that same term occurs simultaneously in comparable documents. As shown in section 3, this

[1] Note that the eigenvectors have length equal to the sum of the length of the vocabularies of each language. The projections for each language are created by splitting the eigenvectors into sections, each with length equal to the vocabulary size for each language.

information is useful and helps OPCA perform better then CCA. In addition, CCA encourages comparable documents to be projected to vectors that are mutually linearly predictable. This is not the same OPCA's projected vectors that have low Euclidean distance: the latter may be preferred by algorithms that consume the projections.

2.4 Cross-language Topic Models

We now turn to a baseline generative model that is analogous to CL-LSI. Our baseline joint PLSA model (JPLSA) is closely related to the poly-lingual LDA model of (Mimno et al., 2009). The graphical model for JPLSA is shown at the top in Figure 2. We describe the model for two languages, but it is straightforward to generalize to more than two languages, as in (Mimno et al., 2009).

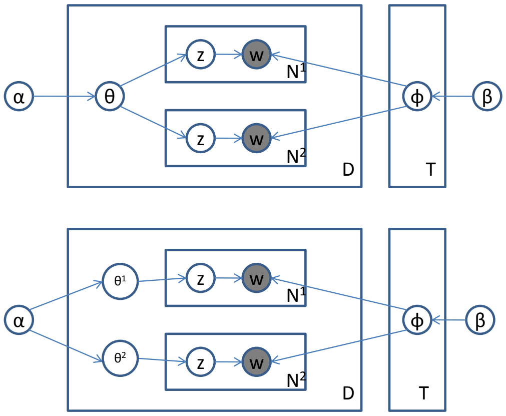

Figure 2: Graphical models for JPLSA (top) and CPLSA (bottom)

The model sees documents d_i as sequences of words $w_1, w_2, \ldots, w_{n_i}$ from a vocabulary V. There are T cross-language topics, each of which has a distribution ϕ_t over words in V. In the case of models for two languages, we define the vocabulary V to contain word types from both languages. In this way, each topic is shared across languages.

Each topic-specific distribution ϕ_t, for $t = 1 \ldots T$, is drawn from a symmetric Dirichlet prior with concentration parameter β. Given the topic-specific word distributions, the generative process for a corpus of paired documents $[d_i^1, d_i^2]$ in two languages L_1 and L_2 is described in the next paragraph.

For each pair of documents, pick a distribution over topics θ_i, from a symmetric Dirichlet prior with concentration parameter α. Then generate the documents d_i^1 and d_i^2 in turn. Each word token in each document is generated independently by first picking a topic z from a multinomial distribution with parameter θ_i ($\textsc{Multi}(\theta_i)$), and then generating the word token from the topic-specific word distribution for the chosen topic $\textsc{Multi}(\phi_z)$.

The probability of a document pair $[d^1, d^2]$ with words $[w_1^1, w_2^1, \ldots, w_{n_1}^1]$, $[w_1^2, w_2^2, \ldots, w_{n_2}^2]$, topic assignments $[z_1^1, \ldots, z_{n_1}^1]$, $[z_1^2, \ldots, z_{n_2}^2]$, and a common topic vector θ is given by:

$$P(\theta|\alpha) \prod_{j=1}^{n_1} P(z_j^1|\theta) P(w_j^1|\phi_{z_j^1}) \prod_{j=1}^{n_2} P(z_j^2|\theta) P(w_j^2|\phi_{z_j^2})$$

The difference between the JPLSA model and the poly-lingual topic model of (Mimno et al., 2009) is that we merge the vocabularies in the two languages and learn topic-specific word distributions over these merged vocabularies, instead of having pairs of topic-specific word distributions, one for each language, like in (Mimno et al., 2009). Thus our model is more similar to the CL-LSI model, because it can be seen as viewing a pair of documents in two languages as one bigger document containing the words in both documents.

Another difference between our model and the poly-lingual LDA model of (Mimno et al., 2009) is that we use maximum aposteriori (MAP) instead of Bayesian inference. Recently, MAP inference was shown to perform comparably to the best inference method for LDA (Asuncion et al., 2009), if the hyper-parameters are chosen optimally for the inference method. Our initial experiments with Bayesian versus MAP inference for parallel document retrieval using JPLSA confirmed this result. In practice our baseline model outperforms poly-lingual LDA as mentioned in our experiments.

2.5 Coupled Probabilistic Latent Semantic Analysis

The JPLSA model assumes that a pair of translated or comparable documents have a common topic distribution θ. JPLSA fits its parameters to optimize the probability of the data, given this assumption.

For the task of comparable document retrieval, we want our topic model to assign similar topic distributions θ to a pair of corresponding documents. But this is not exactly what the JPLSA model is doing. Instead, it derives a common topic vector θ which explains the union of all tokens in the English and foreign documents, instead of making sure that the best topic assignment for the English document is close to the best topic assignment of the foreign document. This difference becomes especially apparent when corresponding documents have different lengths. In this case, the model will tend to derive a topic vector θ which explains the longer document best, making the sum of the two documents' log-likelihoods higher. Modeling the shorter document's best topic carries little weight.

Modeling both documents equally is what Coupled PLSA (CPLSA) is designed to do. The graphical model for CPLSA is shown at the bottom of Figure 2. In this figure, the topic vectors of a pair of documents in two languages are shown completely independent. We use the log-likelihood according to this model, but also add a regularization term, which tries to make the topic assignments of corresponding documents close. In particular, we use posterior regularization (Graca et al., 2008; Ganchev et al., 2009) to place linear constraints on the expectations of topic assignments to two corresponding documents.

For two linked documents d_1 and d_2, we would like our model to be such that the expected fraction of tokens in d_1 that get assigned topic t is approximately the same as the expected fraction of tokens in d_2 that get assigned the same topic t, for each topic $t = 1 \dots T$. This is exactly what we need to make each pair of corresponding documents close.

Let $\mathbf{z^1}$ and $\mathbf{z^2}$ denote vectors of topic assignments to the tokens in document d^1 and d^2, respectively. Their dimensionality is equal to the lengths of the two documents, n_1 and n_2. We define a space of posterior distributions Q over hidden topic assignments to the tokens in d^1 and d^2, that has the desired property: the expected fraction of each topic is approximately equal in d^1 and d^2. We can formulate this constrained space Q as follows:

$$Q = \{q_1(\mathbf{z^1}), q_2(\mathbf{z^2})\}$$

such that

$$\mathbf{E}_{q_1}[\frac{\sum_{j=1}^{n_1} \mathbf{1}(z_j^1 = t)}{n_1}] - \mathbf{E}_{q_2}[\frac{\sum_{j=1}^{n_2} \mathbf{1}(z_j^2 = t)}{n_2}] \le \epsilon_t$$

$$\mathbf{E}_{q_2}[\frac{\sum_{j=1}^{n_2} \mathbf{1}(z_j^2 = t)}{n_2}] - \mathbf{E}_{q_1}[\frac{\sum_{j=1}^{n_1} \mathbf{1}(z_j^1 = t)}{n_1}] \le \epsilon_t$$

We then formulate an objective function that maximizes the log-likelihood of the data while simultaneously minimizing the KL-divergence between the desired distribution set Q and the posterior distribution according to the model: $P(\mathbf{z_1}|d_1, \theta_1, \phi)$ and $P(\mathbf{z_2}|d_2, \theta_2, \phi)$.

The objective function for a single document pair is as follows:

$$\begin{aligned}&\log P(d_1|\theta_1, \phi) + \log P(d_2|\theta_2, \phi)\\ &\qquad -\mathbf{KL}(Q||P(\mathbf{z_1}|d_1, \theta_1, \phi), P(\mathbf{z_2}|d_2, \theta_2, \phi))\\ &\qquad -||\epsilon||\end{aligned}$$

The final corpus-wide objective is summed over document-pairs, and also contains terms for the probabilities of the parameters θ and ϕ given the Dirichlet priors. The norm of ϵ is minimized, which makes the expected proportions of topics in two documents as close as possible.

Following (Ganchev et al., 2009), we fit the parameters by an EM-like algorithm, where for each document pair, after finding the posterior distribution of the hidden variables, we find the KL-projection of this posterior onto the constraint set, and take expected counts with respect to this projection; these expected counts are used in the M-step. The projection is found using a simple projected gradient algorithm.[2]

For both the baseline JPLSA and the CPLSA models, we performed learning through MAP inference using EM (with a projection step for CPLSA). We did up to 500 iterations for each model, and did early stopping based on task performance on the development set. The JPLSA model required more iterations before reaching its peak accuracy, tending to require around 300 to 450 iterations for convergence. CPLSA required fewer iterations, but each iteration was slower due to the projection step.

[2] We initialized the models deterministically by assigning each word to exactly one topic to begin with, such that all topics have roughly the same number of words. Words were sorted by frequency and thus words of similar frequency are more likely to be assigned to the same topic.This initialization method outperformed random initialization and we use it for all models.

All models use $\alpha = 1.1$ and $\beta = 1.01$ for the values of the concentration parameters. We found that the performance of the models was not very sensitive to these values, in the region that we tested ($\alpha, \beta \in [1.001, 1.1]$). Higher hyper-parameter values resulted in faster convergence, but the final performance was similar across these different values.

3 Experimental validation

We test the proposed discriminative projections versus more established cross-language models on the two tasks described in the introduction: retrieving comparable documents from a corpus, and training a classifier in one language and using it in another. We measure accuracy on a test set, and also examine the sensitivity to dimensionality of the projection on development sets.

3.1 Speed of training and evaluation

We first test the speed of the various algorithms discussed in this paper, compared to a full machine translation system. When finding document projections, CL-LSI, OPCA, CCA, JPLSA, and CPLSA are equally fast: they perform a matrix multiplication and require $O(nk)$ operations, where n is the number of distinct words in the documents and k is the dimensionality of the projection.[3] A single CPU core can read the indexed documents into memory and take logarithms at 216K words per second. Projecting into a 2000-dimensional space operates at 41K words per second. Translating word-by-word operates at 274K words per second. In contrast, machine translation processes 50 words per second, approximately 3 orders of magnitude slower.

Total training time for OPCA on 43,380 pairs of comparable documents was 90 minutes, running on an 8-core CPU for 2000 dimensions. On the same corpus, JPLSA requires 31 minutes per iteration and CPLSA requires 377 minutes per iteration. CPLSA requires a factor of five times fewer iterations: overall, it is twice as slow as JPLSA.

3.2 Retrieval of comparable documents

In comparable document retrieval, a query is a document in one language, which is compared to a corpus of documents in another language. By mapping all documents into the same vector space, the comparison is a vector comparison. For our experiments with CL-LSI, OPCA, and CCA, we use cosine similarity between vectors to rank the documents.

For the JPLSA and CPLSA models, we map the documents to corresponding topic vectors θ, and compute distance between these probability vectors. The mapping to topic vectors requires EM iterations, or folding-in (Hofmann, 1999). We found that performing a single EM iteration resulted in best performance so we used this for all models. For computing distance we used the L1-norm of the difference, which worked a bit better than the Jensen-Shannon divergence between the topic vectors used in (Mimno et al., 2009).

We test all algorithms on the Europarl data set of documents in English and Spanish, and a set of Wikipedia articles in English and Spanish that contain interlanguage links between them (i.e., articles that the Wikipedia community have identified as comparable across languages).

For the Europarl data set, we use 52,685 documents as training, 11,933 documents as a development set, and 18,415 documents as a final test set. Documents are defined as speeches by a single speaker, as in (Mimno et al., 2009).[4] For the Wikipedia set, we use 43,380 training documents, 8,675 development documents, and 8,675 final test set documents.

For both corpora, the terms are extracted by word-breaking all documents, removing the top 50 most frequent terms and keeping the next 20,000 most frequent terms. No stemming or folding is applied.

We assess performance by testing each document in English against all possible documents in Spanish, and *vice versa*. We measure the Top-1 accuracy (i.e., whether the true comparable is the closest in the test set), and the Mean Reciprocal Rank of the true comparable, and report the average performance over the two retrieval directions. Ties are counted as errors.

We tuned the dimensionality of the projections on the development set, as shown in Figures 3 and 4.

[3] For JPLSA and CPLSA this is the case only when performing a single EM iteration at test time, which we found to perform best.

[4] The training section contains documents from the years 96 through 99 and the year 02; the dev section contains documents from 01, and the test section contains documents from 00 plus the first 9 months of 03.

We chose the best dimension on the development set for each algorithm, and used it on the final test set. The regularization γ was tuned for CCA: $\gamma = 10$ for Europarl, and $\gamma = 3$ for Wikipedia.

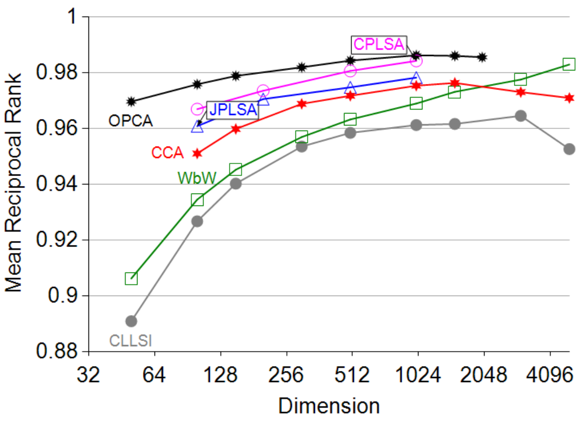

Figure 3: Mean reciprocal rank versus dimension for Europarl

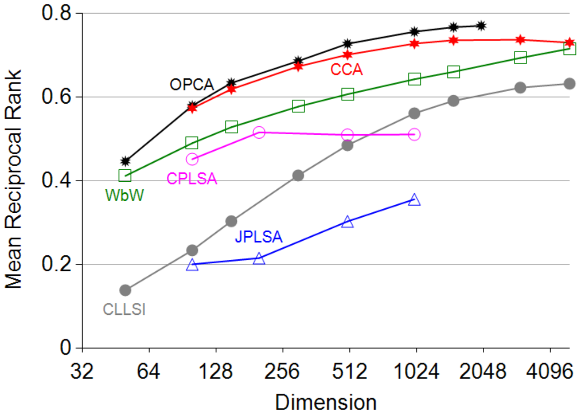

Figure 4: Mean reciprocal rank versus dimension for Wikipedia

In the two figures, we evaluate the five projection methods, as well as a word-by-word translation method (denoted by WbW in the graphs). Here "word-by-word" refers to using cosine distance after applying a word-by-word translation model to the Spanish documents.

The word-by-word translation model was trained on the Europarl training set, using the WDHMM model (He, 2007), which performs similarly to IBM Model 4. The probability matrix of generating English words from Spanish words was multiplied by each document's log(tf)-idf vector to produce a translated document vector. We found that multiplying the probability matrix to the log(tf)-idf vector was more accurate on the development set than multiplying the tf vector directly. This vector was either tested as-is, or mapped through LSA learned from the English training set of the corpus. In the figures, the dimensionality of WbW translation refers to the dimensionality of monolingual LSA.

The overall ordering of the six models is different for the Europarl and Wikipedia development datasets. The discriminative models outperform the corresponding generative ones (OPCA vs CL-LSI) and (CPLSA vs JPLSA) for both datasets, and OPCA performs best overall, dominating the best fast-translation based model, as well as the other projection methods, including CCA.

On Europarl, JPLSA and CPLSA outperform CL-LSI, with the best dimension or JPLSA also slightly outperforming the best setting for the word-by-word translation model, whereas on Wikipedia the PLSA-based models are significantly worse than the other models.

The results on the final test set, evaluating each model using its best dimensionality setting, confirm the trends observed on the development set. The final results are shown in Tables 1 and 2. For these experiments, we use the unpaired t-test with Bonferroni correction to determine the smallest set of algorithms that have statistically significantly better accuracy than the rest. The p-value threshold for significance is chosen to be 0.05. The accuracies for these significantly superior algorithms are shown in boldface.

For Wikipedia and Europarl, we include an additional baseline model,"Untranslated": this refers to applying cosine distance to both the Spanish and English documents directly (since they share some vocabulary terms). For Wikipedia, comparable documents seem to share many common terms, so cosine distance between untranslated documents is a reasonable benchmark.

From the final Europarl results we can see that the best models can learn to retrieve parallel documents from the narrow Europarl domain very well. All dimensionality reduction methods can learn from cleanly parallel data, but discriminative training can bring additional error reduction.

In previously reported work, (Mimno et al., 2009) evaluate parallel document retrieval using PLTM on Europarl speeches in English and Spanish, using training and test sets of size similar to ours. They report an accuracy of 81.2% when restricting to test documents of length at least 100 and using 50 topics. JPLSA with 50 topics obtains accuracy of 98.9% for documents of that length.

The final Wikipedia results are also similar to the the development set results. The problem setting for Wikipedia is different, because corresponding documents linked in Wikipedia may have widely varying degrees of parallelism. While most linked documents share some main topics, they could cover different numbers of sub-topics at varying depths. Thus the training data of linked documents is noisy, which makes it hard for projection methods to learn. The word-by-word translation model in this setting is trained on clean, but out-of-domain parallel data (Europarl), so it has the disadvantage that it may not have a good coverage of the vocabulary; however, it is not able to make use of the Wikipedia training data since it requires sentence-aligned translations. We find it encouraging that the best projection method OPCA outperformed word-by-word translation. This means that OPCA is able to uncover topic correspondence given only comparable document pairs, and to learn well in this noisy setting.

The PLSA-based models fare worse on Wikipedia document retrieval. CPLSA outperforms JPLSA more strongly, but both are worse than CL-LSI and even the Untranslated baseline. We think this is partly explained by the diverse vocabulary in the heterogenous Wikipedia collection. All other models use log(tf)-idf weighting, which automatically assigns importance weights to terms, whereas the topic models use word counts. This weighting is very useful for Wikipedia. For example, if we apply the untranslated matching using raw word counts, the MRR is 0.1024 on the test set, compared to 0.5383 for log(tf)-idf. We hypothesize that using a hierarchical topic model that automatically learns about more general and more topic-specific words would be helpful in this case. It is also possible that PLSA-based models require cleaner data to learn well.

The overall conclusion is that OPCA outperformed all other document retrieval methods we tested, including fast machine translation of documents. Additionally, both discriminative projection methods outperformed their generative counterparts.

Algorithm	Dimension	Accuracy	MRR

3.3 Cross-language text classification

The second task is to train a text categorization system in one language, and test it with documents in another. To evaluate on this task, we use the Multilingual Reuters Collection, defined and provided by (Amini et al., 2009). We test the English/Spanish language pair. The collection has news articles in English and Spanish, each of which has been translated to the other by the Portage translation system (Ueffing et al., 2007).

From the English news corpus, we take 13,131 documents as training, 1,875 documents as development, and 1,875 documents as test. We take the English training documents translated into Spanish as our comparable training data. For testing, we use the entire Spanish news corpus of 12,342 documents, either mapped with cross-lingual projection, or translated by Portage.

The data set was provided by (Amini et al., 2009) as already-processed document vectors, using BM25 weighting. Thus, we only test OPCA, CL-LSI, and related methods: JPLSA and CPLSA require modeling the term counts directly.

The performance on the task is measured by classification accuracy on the six disjoint category labels defined by (Amini et al., 2009). To introduce minimal bias due to the classifier model, we use 1-nearest neighbor on top of the cosine distance between vectors as a classifier. For all of the techniques, we treated the vocabulary in each language as completely separate, using the top 10,000 terms from each language.

Note that no Spanish labeled data is provided for training any of these algorithms: only English and translated English news is labeled. The optimal dimension (and γ for CCA) on the development set was chosen to maximize the accuracy of English classification and translated English-to-Spanish classification.

Algorithm	Dim.	English Accuracy	Spanish Accuracy
Full MT	50	**0.8483**	**0.6484**
OPCA	100	**0.8412**	0.5954
Word-by-word	50	**0.8483**	0.5780
CCA	150	**0.8388**	0.5384
Full MT	N/A	0.8046	0.5323
CL-LSI	150	**0.8401**	0.5105
Word-by-word	N/A	0.8046	0.4481

Table 3: Test results for cross-language text categorization

The test classification accuracy is shown in Table 3. As above, the smallest set of superior algorithms as determined by Bonferroni-corrected t-tests are shown in boldface. The results for MT and word-by-word translation use the log(tf)-idf vector directly for documents that were written in English, and use a Spanish-to-English translated vector if the document was written in Spanish. As in section 3.2, word-by-word translation multiplied each log(tf)-idf vector by the translation probability matrix trained on Europarl.

The tests show that OPCA is better than CCA, CL-LSI, plain word-by-word translation, and even full translation for Spanish documents. However, if we post-process full translation by an LSI model trained on the English training set, full translation is the most accurate. If full translation is time-prohibitive, then OPCA is the best method: it is significantly better than word-by-word translation followed by LSI.

4 Discussion and Extensions

OPCA extends naturally to multiple languages. However, it requires memory and computation time that scales quadratically with the size of the vocabulary. As the number of languages goes up, it may become impractical to perform OPCA directly on a large vocabulary.

Researchers have solved the problem of scaling OPCA by using Distortion Discriminant Analysis (DDA) (Burges et al., 2003). DDA performs OPCA in two stages which avoids the need for solving a very large generalized eigensystem. As future work, DDA could be applied to mapping documents in many languages simultaneously.

Spherical Admixture Models (Reisinger et al., 2010) have recently been proposed that combine an LDA-like hierarchical generative model with the use of tf-idf representations. A similar model could be used for CPLSA: future work will show whether such a model can outperform OPCA.

5 Conclusions

This paper presents two different methods for creating discriminative projections: OPCA and CPLSA. Both of these methods avoid the use of artificial concatenated documents. Instead, they model documents in multiple languages, with the constraint that comparable documents should map to similar locations in the projected space.

When compared to other techniques, OPCA had the highest accuracy while still having a run-time that allowed scaling to large data sets. We therefore recommend the use of OPCA as a pre-processing step for large-scale comparable document retrieval or cross-language text categorization.

Abstract

We present three novel methods of compactly storing very large n-gram language models. These methods use substantially less space than all known approaches and allow n-gram probabilities or counts to be retrieved in constant time, at speeds comparable to modern language modeling toolkits. Our basic approach generates an *explicit* minimal perfect hash function, that maps all n-grams in a model to distinct integers to enable storage of associated values. Extensions of this approach exploit distributional characteristics of n-gram data to reduce storage costs, including variable length coding of values and the use of *tiered* structures that partition the data for more efficient storage. We apply our approach to storing the full Google Web1T n-gram set and all 1-to-5 grams of the Gigaword newswire corpus. For the 1.5 billion n-grams of Gigaword, for example, we can store full count information at a cost of 1.66 bytes per n-gram (around 30% of the cost when using the current state-of-the-art approach), or quantized counts for 1.41 bytes per n-gram. For applications that are tolerant of a certain class of relatively innocuous errors (where unseen n-grams may be accepted as rare n-grams), we can reduce the latter cost to below 1 byte per n-gram.

1 Introduction

The availability of very large text collections, such as the Gigaword corpus of newswire (Graff, 2003), and the Google Web1T 1-5gram corpus (Brants and Franz, 2006), have made it possible to build models incorporating counts of billions of n-grams. The storage of these language models, however, presents serious problems, given both their size and the need to provide rapid access. A prevalent approach for language model storage is the use of compact trie structures, but these structures do not scale well and require space proportional to both to the number of n-grams and the vocabulary size. Recent advances (Talbot and Brants, 2008; Talbot and Osborne, 2007b) involve the development of Bloom filter based models, which allow a considerable reduction in the space required to store a model, at the cost of allowing some limited extent of false positives when the model is queried with previously unseen n-grams. The aim is to achieve sufficiently compact representation that even very large language models can be stored totally within memory, avoiding the latencies of disk access. These Bloom filter based models exploit the idea that it is not actually necessary to *store* the n-grams of the model, as long as, when queried with an n-gram, the model returns the correct count or probability for it. These techniques allow the storage of language models that no longer depend on the size of the vocabulary, but only on the number of n-grams.

In this paper we give three different models for the efficient storage of language models. The first structure makes use of an explicit perfect hash function that is *minimal* in that it maps n keys to integers in the range 1 to n. We show that by using a minimal perfect hash function and exploiting the distributional characteristics of the data we produce n-gram models that use less space than all know approaches with no reduction in speed. Our two further models achieve even more compact storage while maintaining constant time access by using variable length coding to compress the n-grams values and by using tiered hash structures to parti-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 262–272,

tion the data into subsets requiring different amounts of storage. This combination of techniques allows us, for example, to represent the *full* count information of the Google Web1T corpus (Brants and Franz, 2006) (where count values range up to 95 billion) at a cost of just 2.47 bytes per n-gram (assuming 8-bit fingerprints, to exclude false positives) and just 1.41 bytes per n-gram if we use 8-bit quantization of counts. These costs are 36% and 57% respectively of the space required by the Bloomier Filter approach of Talbot and Brants (2008). For the Gigaword dataset, we can store full count information at a cost of only 1.66 bytes per n-gram. We report empirical results showing that our approach allows a look-up rate which is comparable to existing modern language modeling toolkits, and much faster than a competitor approach for space-efficient storage. Finally, we propose the use of *variable length fingerprinting* for use in contexts which can tolerate a higher rate of 'less damaging' errors. This move allows, for example, the cost of storing a quantized model to be reduced to 1 byte per n-gram or less.

2 Related Work

A range of *lossy* methods have been proposed, to reduce the storage requirements of LMs by discarding information. Methods include the use of entropy pruning techniques (Stolcke, 1998) or clustering (Jelinek et al., 1990; Goodman and Gao, 2000) to reduce the number of n-grams that must be stored. A key method is *quantization* (Whittaker and Raj, 2001), which reduces the value information stored with n-grams to a limited set of *discrete* alternatives. It works by grouping together the values (probabilities or counts) associated with n-grams into clusters, and replacing the value to be stored for each n-gram with a code identifying its value's cluster. For a scheme with n clusters, codes require $\log_2 n$ bits. A common case is 8-bit quantization, allowing up to 256 distinct 'quantum' values. Different methods of dividing the range of values into clusters have been used, e.g. Whittaker and Raj (2001) used the Lloyd-Max algorithm, whilst Federico and Bertoldi (2006) use the simpler Binning method to quantize probabilities, and show that the LMs so produced out-perform those produced using the Lloyd-Max method on a phrase-based machine translation task. Binning partitions the range of values into regions that are uniformly populated, i.e. producing clusters that contain the same number of unique values. Functionality to perform uniform quantization of this kind is provided as part of various LM toolkits, such as IRSTLM. Some of the empirical storage results reported later in the paper relate to LMs recording n-gram *count* values which have been quantized using this uniform binning approach. In the rest of this section, we turn to look at some of the approaches used for *storing* language models, irrespective of whether lossy methods are first applied to reduce the size of the model.

2.1 Language model storage using Trie structures

A widely used approach for storing language models employs the *trie* data structure (Fredkin, 1960), which compactly represents sequences in the form of a *prefix tree*, where each step down from the root of the tree adds a new element to the sequence represented by the nodes seen so far. Where two sequences share a prefix, that common prefix is jointly represented by a single node within the trie. For language modeling purposes, the steps through the trie correspond to *words* of the vocabulary, although these are in practice usually represented by 24 or 32 bit integers (that have been uniquely assigned to each word). Nodes in the trie corresponding to *complete* n-grams can store other information, e.g. a probability or count value. Most modern language modeling toolkits employ some version of a trie structure for storage, including SRILM (Stolcke, 2002), CMU toolkit (Clarkson and Rosenfeld, 1997), MITLM (Hsu and Glass, 2008), and IRSTLM (Federico and Cettolo, 2007) and implementations exist which are very compact (Germann et al., 2009). An advantage of this structure is that it allows the stored n-grams to be enumerated. However, although this approach achieves a compact of representation of sequences, its memory costs are still such that very large language models require very large storage space, far more than the Bloom filter based methods described shortly, and far more than might be held in memory as a basis for more rapid access. The memory costs of such models have been addressed using compression methods, see Harb et al. (2009), but such extensions of the approach present further obstacles to rapid access.

2.2 Bloom Filter Based Language Models

Recent randomized language models (Talbot and Osborne, 2007b; Talbot and Osborne, 2007a; Talbot and Brants, 2008; Talbot and Talbot, 2008; Talbot, 2009) make use of Bloom filter like structures to map n-grams to their associated probabilities or counts. These methods store language models in relatively little space by not actually keeping the n-gram key in the structure and by allowing a small probability of returning a false positive, i.e. so that for an n-gram that is not in the model, there is a small risk that the model will return some random probability instead of correctly reporting that the n-gram was not found. These structures do not allow enumeration over the n-grams in the model, but for many applications this is not a requirement and their space advantages make them extremely attractive. Two major approaches have been used for storing language models: Bloom Filters and Bloomier Filters. We give an overview of both in what follows.

2.2.1 Bloom Filters

A Bloom filter (Bloom, 1970) is a compact data structure for membership queries, i.e. queries of the form "Is this key in the Set?". This is a weaker structure than a dictionary or hash table which also associates a value with a key. Bloom filters use well below the information theoretic lower bound of space required to actually store the keys and can answer queries in O(1) time. Bloom filters achieve this feat by allowing a small probability of returning a false positive. A Bloom filter stores a set S of n elements in a bit array B of size m. Initially B is set to contain all zeros. To store an item x from S in B we compute k random independent hash functions on x that each return a value in the range $[0 \,..\, m-1]$. These values serve as indices to the bit array B and the bits at those positions are set to 1. We do this for all elements in S, storing to the same bit array. Elements may hash to an index in B that has already been set to 1 and in this case we can think of these elements as "sharing" this bit. To test whether set S contains a key w, we run our k hash functions on w and check if all those locations in B are set to 1. If $w \in S$ then the bloom filter will always declare that w belongs to S, but if $x \notin S$ then the filter can only say with high probability that w is not in S. This error rate depends on the number of k hash functions and the ratio of m/n. For instance with $k = 3$ hash functions and a bit array of size $m = 20n$, we can expect to get a false positive rate of 0.0027.

Talbot and Osborne (2007b) and Talbot and Osborne (2007a) adapt Bloom filters to the requirement of storing values for n-grams by concatenating the key (n-gram) and value to form a single item that is inserted into the filter. Given a quantization scheme allowing values in the range $[1 \,..\, V]$, a quantized value v is stored by inserting into the filter all pairings of the n-gram with values from 1 up to v. To retrieve the value for a given key, we serially probe the filter for pairings of the key with each value from 1 upwards, until the filter returns false. The last value found paired with the key in the filter is the value returned. Talbot and Osborne use a simple logarithmic quantization of counts that produce limited quantized value ranges, where most items will have values that are low in the range, so that the serial look-up process will require quite a low number of steps *on average*. For alternative quantization schemes that involve greater value ranges (e.g. the 256 values of a uniform 8-bit scheme) and/or distribute n-grams more evenly across the quantized values, the average number of look-up steps required will be higher and hence the speed of access per n-gram accordingly lower. In that case also, the requirement of inserting n-grams more than once in the filter (i.e. with values from 1 up to the actual value v being stored) could substantially reduce the space efficiency of the method, especially if low false positive rates are required, e.g. the case $k = 3, m = 20n$ produces a false positive rate of 0.0027, as noted above, but in a situation where 3 key-value items were being stored per n-gram on average, this error rate would in fact require a storage cost of 60 bits per original n-gram.

2.2.2 Bloomier Filters

More recently, Talbot and Brants (2008) have proposed an approach to storing large language models which is based on the *Bloomier Filter* technique of Chazelle et al. (2004). Bloomier Filters generalize the Bloom Filter to allow values for keys to be stored in the filter. To test whether a given key is present in a populated Bloomier filter, we apply k hash functions to the key and use the results as indices for retrieving the data stored at k locations within the filter, similarly to look-up in a Bloom filter. In this case, however, the data retrieved from the filter consists of k *bit vectors*, which are combined with a fingerprint of the key, using *bitwise XOR*, to return the stored value. The risk of false positives is managed by making incorporating a fingerprint of the n-gram, and by making bit vectors longer than the minimum length required to store values. These additional *error bits* have a fairly predictable impact on error rates, i.e. with e error bits, we anticipate the probability of falsely construing an unseen n-gram as being stored in the filter to be 2^{-e}. The algorithm required to correctly populate the Bloomier filter with stored data is complicated, and we shall not consider its details here. Nevertheless, when using v bits to represent values and e bits for error detection, this approach allows a language model to be stored at a cost of is $1.23 \cdot (v + e)$ bits per n-gram.

3 Single Minimal Perfect Hash Ranking Approach

We first describe our basic structure we call Single Minimal Perfect Hash Rank (S-MPHR) that is more compact than that of Talbot and Brants (2008) while still keeping a constant look up time. In the next two sections we describe variations on this model to further reduce the space required while maintaining a constant look up time. The S-MPHR structure can be divided into 3 parts as shown in Figure 1: Stage 1 is a minimal perfect hash function; Stage 2 is a fingerprint and rank array; and Stage 3 is a unique value array. We discuss each stage in turn.

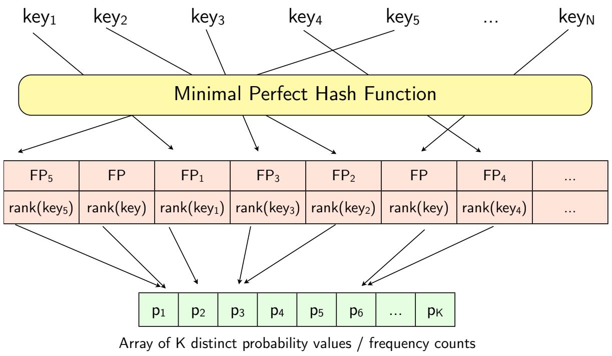

Figure 1: The Single MPHR structure

3.1 Minimal Perfect Hash Function

The first part of the structure is a *minimal* perfect hash function that maps every n-gram in the training data to a distinct integer in the range 0 to $N - 1$, where N is the total number of n-grams to store. We use these integers as indices into the array of Stage 2 of our structure.

We use the *Hash, displace, and compress (CHD)* (Belazzougui et al., 2009) algorithm to generate a minimal perfect hash function that requires 2.07 bits per key and has $O(1)$ access. The algorithm works as follows. Given a set S that contains $N = |S|$ keys (in our case n-grams) that we wish to map to integers in the range 0 to $N - 1$, so that every key maps to a distinct integer (no collisions).

The first step is to use a hash function $g(x)$, to map every key to a bucket B in the range 0 to r. (For this step we use a simple hash function like the one used for generating fingerprints in the pervious section.)

$$B_i = \{x \in S | g(x) = i\} \; 0 \leq i \leq r$$

The function $g(x)$ is not perfect so several keys can map to the same bucket. Here we choose $r \leq N$, so that the number of buckets is less than or equal to the number of keys (to achieve 2.07 bits per key we use $r = \frac{N}{5}$, so that the average bucket size is 5). The buckets are then sorted into descending order according to the number of keys in each bucket $|B_i|$.

For the next step, a bit array, T, of size N is initialized to contain all zeros $T[0 \ldots N - 1]$. This bit array is used during construction to keep track of which integers in the range 0 to $N - 1$ the minimal perfect hash has already mapped keys to. Next we must assume we have access to a family of random and independent hash functions $h_1, h_2, h_3, \ldots$ that can be accessed using an integer index. In practice it sufficient to use functions that behave similarly to fully random independent hash functions and Belazzougui et al. (2009) demonstrate how such functions can be generated easily by combining two simple hash functions.

Next is the “displacement” step. For each bucket, in the sorted order from largest to smallest, they search for a random hash function that maps all elements of the bucket to values in T that are currently set to 0. Once this function has been found those positions in T are set to 1. So, for each bucket B_i, it is necessary to iteratively try hash functions, h_ℓ for $\ell = 1, 2, 3, \ldots$ to hash every element of B_i to a distinct index j in T that contains a zero.

$$\{h_\ell(x)|x \in B_i\} \cap \{j|T[j] = 1\} = \emptyset$$

where the size of $\{h_\ell(x)|x \in B_i\}$ is equal to the size of B_i. When such a hash function is found we need only to store the index, ℓ, of the successful function in an array σ and set $T[j] = 1$ for all positions j that h_ℓ hashed to. Notice that the reason the largest buckets are handled first is because they have the most elements to displace and this is easier when the array T contains more empty positions (zeros).

The final step in the algorithm is to compress the σ array (which has length equal to the number of buckets $|B|$), retaining $O(1)$ access. This compression is achieved using simple variable length encoding with an index array (Fredriksson and Nikitin, 2007).

3.2 Fingerprint and Rank Array

The hash function used in Stage 1 is perfect, so it is guaranteed to return unique integers for seen n-grams, but our hash function will also return integer values in the range 0 to $N - 1$ for n-grams that have not been seen before (were not used to build the hash function). To reduce the probability of these unseen n-grams giving false positives results from our model we store a fingerprint of each n-gram in Stage 2 of our structure that can be compared against the fingerprints of unseen n-grams when queried. If these fingerprints of the queried n-gram and the stored n-gram do not match then the model will correctly report that the n-gram has not been seen before. The size of this fingerprint determines the rate of false positives. Assuming that the fingerprint is generated by a random hash function, and that the returned integer of an *unseen* key from the MPH function is also random, expected false positive rate for the model is the same as the probability of two keys randomly hashing to the same value, $\frac{1}{2^m}$, where m is the number of bits of the fingerprint. The fingerprint can be generated using any suitably random hashing algorithm. We use Austin Appleby's Murmurhash2[1] implementation to fingerprint each n-gram and then store the m highest order bits. Stage 2 of the MPHR structure also stores a *rank* for every n-gram along with the fingerprint. This rank is an index into the array of Stage 3 of our structure that holds the unique values associated with any n-gram.

3.3 Unique Value Array

We describe our storage of the values associated with n-grams in our model assuming we are storing frequency "counts" of n-grams, but it applies also to storing quantized probabilities. For every n-gram, we store the 'rank' of the frequency count $r(key)$, ($r(key) \in [0...R - 1]$) and use a separate array in Stage 3 to store the frequency count value. This is similar to quantization in that it reduces the number of bits required for storage, but unlike quantization it does not require a loss of any information. This was motivated by the sparsity of n-gram frequency counts in corpora in the sense that if we take the lowest n-gram frequency count and the highest n-gram frequency count then most of the integers in that range do not occur as a frequency count of any n-grams in the corpus. For example in the Google Web1T data, there are 3.8 billion unique n-grams with frequency counts ranging from 40 to 95 Billion yet these n-grams only have 770 thousand distinct frequency counts (see Table 2). Because we only store the frequency rank, to keep the precise frequency information we need only $\lceil \log_2 K \rceil$ bits per n-gram, where K is the number of distinct frequency counts. To keep all information in the Google Web1T data we need only $\lceil \log_2 771058 \rceil = 20$ bits per n-gram. Rather than the bits needed to store the maximum frequency count associated with an n-gram, $\lceil \log_2 \text{maxcount} \rceil$, which for Google Web1T would be $\lceil \log_2 95119665584 \rceil = 37$ bits per n-gram.

	unique n-grams	maximum n-gram frequency count	unique counts

3.4 Storage Requirements

We now consider the storage requirements of our S-MPHR approach, and how it compares against the Bloomier filter method of Talbot and Brants (2008). To start with, we put aside the gains that can come from using the ranking method, and instead consider just the costs of using the CHD approach for storing any language model. We saw that the storage requirements of the Talbot and Brants (2008) Bloomier filter method are a function of the number of n-grams n, the bits of data d to be stored per n-gram (with $d = v + e$: v bits for value storage, and e bits for error detection), and a multiplying factor of 1.23, giving an overall cost of $1.23d$ bits per n-gram. The cost for our basic approach is also easily computed. The explicit minimal PHF computed using the CHD algorithm brings a cost of 2.07 bits per n-gram for the PHF itself, and so the comparable overall cost to store a S-MPHR model is $2.07 + d$ bits per n-gram. For small values of d, the Bloomier filter approach has the smaller cost, but the 'break-even' point occurs when $d = 9$. When d is greater than 9 bits (as it usually will be), our approach wins out, being up to 18% more efficient.

The benefits that come from using the ranking method (Stage 3), for compactly storing count values, can only be evaluated in relation to the distributional characteristics specific corpora, for which we show results in Section 6.

4 Compressed MPHR Approach

Our second approach, called Compressed MPHR, further reduces the size of the model whilst maintaining O(1) time to query the model. Most compression techniques work by exploiting the redundancy in data. Our fingerprints are unfortunately random sequences of bits, so trying to compress these is fruitless, but the ranks associated with n-grams contain much redundancy and so are likely to compress well. We therefore modify our original architecture to put the ranks and fingerprints into separate arrays, of which the ranks array will be compressed, as shown in Figure 2.

Much like the final stage of the CHD minimal perfect hash algorithm we employ a random access compression algorithm of Fredriksson and Nikitin (2007) to reduce the size required by the array of ranks. This method allows compression while retaining O(1) access to query the model.

The first step in the compression is to encode the ranks array using a dense variable length coding. This coding works by assigning binary codes with different lengths to each number in the rank array, based on how frequent that number occurs. Let $s_1, s_2, s_3, \ldots, s_K$ be the ranks that occur in the rank array sorted by there frequency. Starting with most frequent number in the rank array (clearly 1 is the most common frequency count in the data unless it has been pruned) s_1 we assign it the bit code 0 and then assign s_2 the bit code 1, we then proceed by assigning bit codes of two bits, so s_3 is assigned 00, $s4$ is assigned 01, etc. until all two bit codes are used up. We then proceed to assign 3 bit codes and so on. All of the values from the rank array are coded in this form and concatenated to form a large bit vector retaining their original ordering. The length in bits for the ith number is thus $\lfloor \log_2 (i + 2) \rfloor$ and so the number of bits required for the whole variable length coded rank array is: $b = \sum_{i=0}^{K} f(s_i) \lfloor \log_2 (i + 2) \rfloor$. Where $f()$ gives the frequency that the rank occurs and K is the total number of distinct ranks. The code for the ith number is the binary representation with length $\lfloor \log_2{(i+2)} \rfloor$ of the number obtained using the formula:

$$\text{code} = i + 2 - 2^{\lfloor \log_2{(i+2)} \rfloor}$$

This variable length coded array is not useful by itself because we do not know where each number begins and ends, so we also store an index array hold this information. We create an additional bit array D of the same size b as the variable length coded array that simply contains ones in all positions that a code begins in the rank array and zeros in all other positions. That is the ith rank in the variable length coded array occurs at position $\text{select}_1(D, i)$, where select_1 gives the position of the ith one in the array. We do not actually store the D array, but instead we build a more space efficient structure to answer select_1 queries. Due the distribution of n-gram frequencies, the D array is typically dense in containing a large proportion of ones, so we build a *rank9sel* dictionary structure (Vigna, 2008) to answer these queries in constant time. We can use this structure to identify the ith code in our variable length encoded rank array by querying for its starting position, $\text{select}_1(D, i)$, and compute its length using its ending position, $\text{select}_1(D, i+1) - 1$. The code and its length can then be decoded to obtain the original rank:

$$\text{rank} = \text{code} + 2^{(\text{length in bits})} - 2$$

5 Tiered MPHR

In this section we describe an alternative route to extending our basic S-MPHR model to achieve better space efficiency, by using multiple hash stores. The method exploits distributional characteristics of the data, i.e. that lower rank values (those assigned to values shared by very many n-grams) are sufficient for representing the value information of a disproportionately large subset of the data. For the Google Web 1T data, for example, we find that the first 256 ranks account for nearly 85% of distinct n-grams, so if we could store ranks for these n-grams using only the 8 bits they require, whilst allowing perhaps 20 bits per n-gram for the remaining 15%, we would achieve an average of just under 10 bits per n-gram to store all the rank values.

To achieve this gain, we might *partition* the n-gram data into subsets requiring different amounts of space for value storage, and put these subsets in separate MPHRs, e.g. for the example just mentioned, with two MPHRs having 8 and 20 bit value storage respectively. Partitioning to a larger number h of MPHRs might further reduce this average cost. This simple approach has several problems. Firstly, it potentially requires a *series* of look up steps (i.e. up to h) to retrieve the value for any n-gram, with *all* hashes needing to be addressed to determine the unseen status of an unseen n-gram. Secondly, multiple look ups will produce a *compounding* of error rates, since we have up to h opportunities to falsely construe an unseen n-gram as seen, or to construe a seen n-gram as being stored in the wrong MPHR and so return an incorrect count for it.

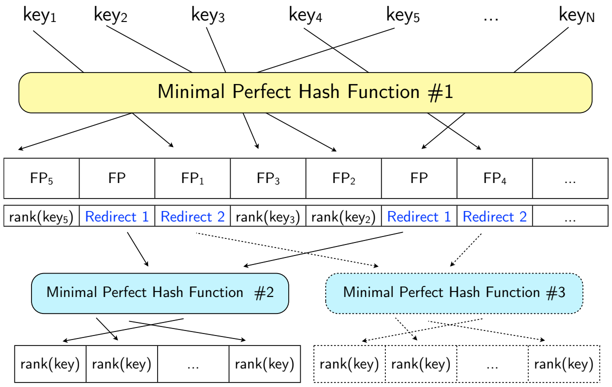

Figure 3: Tiered minimal perfect hash data structure

We will here explore an alternative approach that we call *Tiered* MPHR, which avoids this compounding of errors, and which limits the number of looks ups to a maximum of 2, irrespective of how many hashes are used. This approach employs a single *top-level* MPHR which has the full set of n-grams for its key-set, and stores a fingerprint for each. In addition, space is allocated to store rank values, but with some possible values being reserved to indicate *redirection* to other *secondary* hashes where values can be found. Each secondary hash has a minimal perfect hash function that is computed only for the n-grams whose values it stores. Secondary hashes do *not* need to record fingerprints, as fingerprint testing is done in the top-level hash.

For example, we might have a configuration of three hashes, with the top-level MPHR having 8-bit storage, and with secondary hashes having 10 and 20 bit storage respectively. Two values of the 8-bit store (e.g. 0 and 1) are reserved to indicate redirection to the specific secondary hashes, with the remaining values ($2\,..\,255$) representing ranks 1 to 254. The 10-bit secondary hash can store 1024 different values, which would then represent ranks 255 to 1278, with all ranks above this being represented in the 20-bit hash. To look up the count for an n-gram, we begin with the top-level hash, where fingerprint testing can immediately reject unseen n-grams. For some seen n-grams, the required rank value is provided directly by the top-level hash, but for others a redirection value is returned, indicating precisely the secondary hash in which the rank value will be found by simple look up (with no additional fingerprint testing). Figure 3 gives a generalized presentation of the structure of tiered MPHRs. Let us represent a configuration for a tiered MPHR as a sequence of bit values for their value stores, e.g. `(8,10,20)` for the example above, or $H = (b_1, \ldots .b_h)$ more generally (with b_1 being the top-level MPHR).

The overall memory cost of a particular configuration depends on distributional characteristics of the data stored. The top-level MPHR of configuration $(b_1, \ldots .b_h)$ stores all n-grams in its keyset, so its memory cost is calculated as before as $N \times (2.07 + m + b_1)$ (m the fingerprint size). The top-level MPHR must reserve $h - 1$ values for redirection, and so covers ranks $[1\,..\,(2^{b_1} - h + 1)]$. The second MPHR then covers the next 2^{b_2} ranks, starting at $(2^{b_1} - h + 2)$, and so on for further secondary MPHRs. This range of ranks determines the proportion μ_i of the overall n-gram set that each secondary MPHR b_i stores, and so the memory cost of each secondary MPHR is $N \times \mu_i \times (2.07 + b_i)$. The optimal T-MPHR configuration for a given data set is easily determined from distributional information (of the coverage of each rank), by a simple search.

6 Results

In this section, we present some results comparing the performance of our new storage methods to some of the existing methods, regarding the costs of storing LMs, and regarding the data access speeds that alternative systems allow.

Method	Gigaword		Web1T	
	full	quantized	full	quantized
Bloomier	6.00	3.08	7.53	3.08
S-MPHR	3.76	2.76	4.26	2.76
C-MPHR	2.19	2.09	3.40	2.09
T-MPHR	2.16	1.91	2.97	1.91

Table 3: Space usage in bytes/ngram using **12-bit** fingerprints and storing all 1 to 5 grams

Method	Gigaword		Web1T	
	full	quantized	full	quantized
Bloomier	5.38	2.46	6.91	2.46
S-MPHR	3.26	2.26	3.76	2.26
C-MPHR	1.69	1.59	2.90	1.59
T-MPHR	1.66	1.41	2.47	1.41

Table 4: Space usage in bytes/n-gram using **8-bit** fingerprints and storing all 1 to 5 grams

6.1 Comparison of memory costs

To test the effectiveness of our models we built models storing n-grams and full frequency counts for both the Gigaword and Google Web1T corpus storing all 1,2,3,4 and 5 grams. These corpora are very large, e.g. the Google Web1T corpus is 24.6GB when gzip compressed and contains over 3.7 billion n-grams, with frequency counts as large as 95 billion, requiring at least 37 bits to be stored. Using the Bloomier algorithm of Talbot and Brants (2008) with 37 bit values and 12 bit fingerprints would require 7.53 bytes/n-gram, so we would need 26.63GB to store a model for the entire corpus.

In comparison, our S-MPHR method requires only 4.26 bytes per n-gram to store full frequency count information and stores the entire Web1T corpus in just **15.05GB** or **57%** of the space required by the Bloomier method. This saving is mostly due to the ranking method allowing values to be stored at a cost of only 20 bits per n-gram. Applying the same rank array optimization to the Bloomier method significantly reduces its memory requirement, but S-MPHR still uses only 86% of the space that the Bloomier approach requires. Using T-MPHR instead, again with 12-bit fingerprints, we can store full counts for the Web 1T corpus in 10.50GB, which is small enough to be held in memory on many modern machines. Using 8-bit fingerprints, T-

Method	bytes/ ngram
SRILM Full, Compact	33.6
IRSTLM, 8-bit Quantized	9.1
Bloomier 12bit fp, 8bit Quantized	3.08
S-MPHR 12bit fp, 8bit Quantized	2.76
C-MPHR 12bit fp, 8bit Quantized	2.09
T-MPHR 12bit fp, 8bit Quantized	**1.91**

Table 5: Comparison between approaches for storing all 1 to 5 grams of the Gigaword Corpus

MPHR can store this data in just 8.74GB.

Tables 3, 4 and 5 show results for all methods[2] on both corpora, for storing full counts, and for when 8-bit binning quantization of counts is used.

6.2 Access speed comparisons

The three models we present in this paper perform queries in O(1) time and are thus asymptotically optimal, but this does not guarantee they perform well in practice, therefore in this section we measure query speed on a large set of n-grams and compare it to that of modern language modeling toolkits. We build a model of all unigrams and bigrams in the Gigaword corpus (see Table 1) using the C-MPHR method, SRILM (Stolcke, 2002), IRSTLM (Federico and Cettolo, 2007), and randLM[3] (Talbot and Osborne, 2007a) toolkits. RandLM is a modern language modeling toolkit that uses Bloom filter based structures to store large language models and has been integrated so that it can be used as the language model storage for the Moses statistical machine translation system (Koehn et al., 2007). We use randLM with the *BloomMap* (Talbot and Talbot, 2008) storage structure option with 8 bit quantized values and an error rate equivalent to using 8 bit fingerprints (as recommended in the Moses documentation). All methods are implemented in C++ and are run on a machine with 2.80GHz Intel Xeon E5462 processor and 64 GB of RAM. In addition we show a comparison to using a modern database, MySQL 5.0, to store the same data. We measure the speed of querying all models for the 55 million distinct bigrams that occur in the Gigaword, these results are shown in Table 6. Unsurprisingly all methods perform significantly faster than using a database as they build models that reside completely in memory. The C-MPHR method tested here is slower than both S-MPHR and T-MPHR models due to the extra operations required for access to the variable length encoded array yet still performs similarly to SRILM and IRSTLM and is 14.99 times faster than using randLM.

Test	Time (hr :min:sec)	Speed queries/sec
C-MPHR	00 : 01 : 50	507362
IRSTLM	00 : 02 : 12	422802
SRILM	00 : 01 : 29	627077
randLM	00 : 27 : 28	33865
MySQL 5	29 : 25 : 01	527

Table 6: Look-up speed performance comparison for C-MPHR and several other LM storage methods

7 Variable Length Fingerprints

To conclude our presentation of new methods for space-efficient language model storage, we suggest an additional possibility for reducing storage costs, which involves using different sizes of fingerprint for different n-grams. Recall that the only errors allowed by our approach are false-positives, i.e. where an unseen n-gram is falsely construed as being part of the model and a value returned for it. The idea behind using different sizes of fingerprint is that, intuitively, some possible errors seem worse than others, and in particular, it seems likely to be less damaging if we falsely construe an unseen n-gram as being a seen n-gram that has a low count or probability than as being one with a high count or probability.

False positives arise when our perfect hashing method maps an unseen n-gram to position where the stored n-gram fingerprint happens to coincide with that computed for the unseen n-gram. The risk of this occurring is a simple function of the size of fingerprints. To achieve a scheme that admits a higher risk of less damaging errors, but enforces a lower risk of more damaging errors, we need only store shorter fingerprints for n-grams in our model that have low counts or probabilities, and longer fingerprints for n-grams with higher values. This

[2] All T-MPHR results are for optimal configurations: Gigaword full: `(2,3,16)`, Gigaword quant: `(1,8)`, Web1T full: `(8,6,7,8,9,10,13,20)`, Web1T quant: `(1,8)`.

[3] `http://sourceforge.net/projects/randlm/`

idea could be implemented in different ways, e.g. by storing fingerprints of different lengths contiguously within a bit array, and constructing a 'selection structure' of the kind described in Section 4 to allow us to locate a given fingerprint within the bit array.

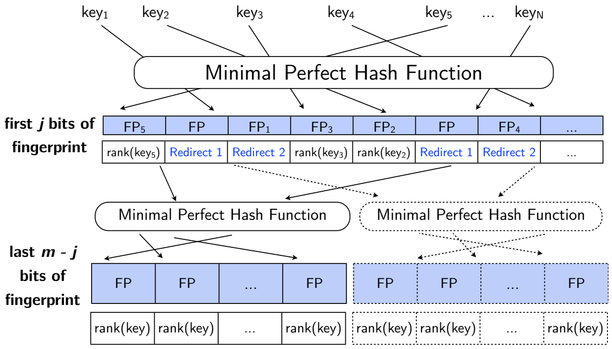

Figure 4: Variable length fingerprint T-MPHR structure using j bit fingerprints for the n-grams which are most rare and m bit fingerprints for all others.

We here instead consider an alternative implementation, based on the use of tiered structures. Recall that for T-MPHR, the top-level MPHR has all n-grams of the model as keys, and stores a fingerprint for each, plus a value that may represent an n-gram's count or probability, or that may redirect to a second-level hash where that information can be found. Redirection is done for items with higher counts or probabilities, so we can achieve lower error rates for precisely these items by storing *additional* fingerprint information for them in the second-level hash (see Figure 4). For example, we might have a top-level hash with only 4-bit fingerprints, but have an additional 8-bits of fingerprint for items also stored in a second-level hash, so there is quite a high risk (close to $\frac{1}{16}$) of returning a low count for an unseen n-gram, but a much lower risk of returning any higher count. Table 7 applies this idea to storing full and quantized counts of the Gigaword and Web 1T models, when fingerprints in the top-level MPHR have sizes in the range 1 to 6 bits, with the fingerprint information for items stored in secondary hashes being 'topped up' to 12 bits. This approach achieves storage costs of around 1 byte per n-gram or less for the quantized models.

Bits in lowest fingerprint	Gigaword Quantized	Web1T Quantized	Gigaword All	Web1T All
1	0.55	0.55	1.00	1.81
2	0.68	0.68	1.10	1.92
3	0.80	0.80	1.21	2.02
4	0.92	0.92	1.31	2.13
5	1.05	1.04	1.42	2.23
6	1.17	1.17	1.52	2.34

Table 7: Bytes per fingerprint for T-MPHR model using 1 to 6 bit fingerprints for rarest n-grams and 12 bit (in total) fingerprints for all other n-grams. (All configurations are as in Footnote 2.)

8 Conclusion

We have presented novel methods of storing large language models, consisting of billions of n-grams, that allow for quantized values or frequency counts to be accessed quickly and which require far less space than all known approaches. We show that it is possible to store all 1 to 5 grams in the Gigaword corpus, with full count information at a cost of just 1.66 bytes per n-gram, or with quantized counts for just 1.41 bytes per n-gram. We have shown that our models allow n-gram look-up at speeds comparable to modern language modeling toolkits (which have much greater storage costs), and at a rate approximately 15 times faster than a competitor approach for space-efficient storage.

Abstract

Syntax-based translation models should *in principle* be efficient with polynomially-sized search space, but in practice they are often embarassingly slow, partly due to the cost of language model integration. In this paper we borrow from phrase-based decoding the idea to generate a translation *incrementally* left-to-right, and show that for tree-to-string models, with a clever encoding of derivation history, this method runs in average-case polynomial-time in theory, and linear-time with beam search in practice (whereas phrase-based decoding is exponential-time in theory and quadratic-time in practice). Experiments show that, with comparable translation quality, our tree-to-string system (in Python) can run more than 30 times faster than the phrase-based system Moses (in C++).

1 Introduction

Most efforts in statistical machine translation so far are variants of either phrase-based or syntax-based models. From a theoretical point of view, phrase-based models are neither expressive nor efficient: they typically allow arbitrary permutations and resort to language models to decide the best order. In theory, this process can be reduced to the Traveling Salesman Problem and thus requires an exponential-time algorithm (Knight, 1999). In practice, the decoder has to employ beam search to make it tractable (Koehn, 2004). However, even beam search runs in quadratic-time in general (see Sec. 2), unless a small *distortion limit* (say, d=5) further restricts the possible set of reorderings to those local ones by ruling out any long-distance reorderings that have a "jump" longer than d. This has been the standard practice with phrase-based models (Koehn et al., 2007), which fails to capture important long-distance reorderings like SVO-to-SOV.

	in theory	*in practice*
phrase-based	exponential	quadratic
tree-to-string	polynomial	linear

Table 1: [main result] Time complexity of our incremental tree-to-string decoding compared with phrase-based. In practice means "approximate search with beams."

Syntax-based models, on the other hand, use syntactic information to restrict reorderings to a computationally-tractable and linguistically-motivated subset, for example those generated by synchronous context-free grammars (Wu, 1997; Chiang, 2007). In theory the advantage seems quite obvious: we can now express global reorderings (like SVO-to-VSO) in polynomial-time (as opposed to exponential in phrase-based). But unfortunately, this polynomial complexity is super-linear (being generally cubic-time or worse), which is slow in practice. Furthermore, language model integration becomes more expensive here since the decoder now has to maintain target-language boundary words at *both* ends of a subtranslation (Huang and Chiang, 2007), whereas a phrase-based decoder only needs to do this at one end since the translation is always growing left-to-right. As a result, syntax-based models are often embarassingly slower than their phrase-based counterparts, preventing them from becoming widely useful.

Can we combine the merits of both approaches? While other authors have explored the possibilities

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 273–283,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

of enhancing phrase-based decoding with syntax-aware reordering (Galley and Manning, 2008), we are more interested in the other direction, i.e., can syntax-based models learn from phrase-based decoding, so that they still model global reordering, but in an efficient (preferably linear-time) fashion?

Watanabe et al. (2006) is an early attempt in this direction: they design a phrase-based-style decoder for the hierarchical phrase-based model (Chiang, 2007). However, this algorithm even with the beam search still runs in quadratic-time in practice. Furthermore, their approach requires grammar transformation that converts the original grammar into an equivalent binary-branching Greibach Normal Form, which is not always feasible in practice.

We take a fresh look on this problem and turn our focus to one particular syntax-based paradigm, tree-to-string translation (Liu et al., 2006; Huang et al., 2006), since this is the simplest and fastest among syntax-based approaches. We develop an incremental dynamic programming algorithm and make the following contributions:

- we show that, unlike previous work, our incremental decoding algorithm runs in average-case **polynomial-time** in theory for tree-to-string models, and the beam search version runs in **linear-time** in practice (see Table 1);
- large-scale experiments on a tree-to-string system confirm that, with comparable translation quality, our incremental decoder (in Python) can run more than 30 times faster than the phrase-based system Moses (in C++) (Koehn et al., 2007);
- furthermore, on the same tree-to-string system, incremental decoding is slightly faster than the standard cube pruning method at the same level of translation quality;
- this is also the first linear-time incremental decoder that performs global reordering.

We will first briefly review phrase-based decoding in this section, which inspires our incremental algorithm in the next section.

2 Background: Phrase-based Decoding

We will use the following running example from Chinese to English to explain both phrase-based and syntax-based decoding throughout this paper:

$_0$ *Bùshí* $_1$	*yǔ* $_2$ *Shālóng* $_3$	*jǔxíng* $_4$	*le* $_5$	*huìtán* $_6$
Bush	with Sharon	hold	-ed	meeting

'Bush held talks with Sharon'

2.1 Basic Dynamic Programming Algorithm

Phrase-based decoders generate partial target-language outputs in left-to-right order in the form of *hypotheses* (Koehn, 2004). Each hypothesis has a *coverage vector* capturing the source-language words translated so far, and can be extended into a longer hypothesis by a phrase-pair translating an uncovered segment. This process can be formalized as a deductive system. For example, the following deduction step grows a hypothesis by the phrase-pair ⟨*yǔ Shālóng*, with Sharon⟩ covering Chinese span [1-3]:

$$\frac{(\bullet\_\_\bullet\bullet\bullet_6) : (w, \text{“Bush held talks”})}{(\bullet\bullet\bullet_3\bullet\bullet\bullet) : (w', \text{“Bush held talks with Sharon”})} \quad (1)$$

where a $\bullet$ in the coverage vector indicates the source word at this position is "covered" and where w and $w' = w+c+d$ are the weights of the two hypotheses, respectively, with c being the cost of the phrase-pair, and d being the *distortion cost*. To compute d we also need to maintain the ending position of the last phrase (the $_3$ and $_6$ in the coverage vector).

To add a bigram model, we split each $-$LM item above into a series of $+$LM items; each $+$LM item has the form $(v,^{a}\ )$ where a is the last word of the hypothesis. Thus a $+$LM version of (1) might be:

$$\frac{(\bullet\_\_\bullet\bullet\bullet_6,^{\text{talks}}\ ) : (w, \text{“Bush held talks”})}{(\bullet\bullet\bullet_3\bullet\bullet\bullet,^{\text{Sharon}}\ ) : (w', \text{“Bush held talks with Sharon”})}$$

where the score of the resulting $+$LM item

$$w' = w + c + d - \log P_{lm}(\text{with} \mid \text{talk})$$

now includes a *combination cost* due to the bigrams formed when applying the phrase-pair. The complexity of this dynamic programming algorithm for g-gram decoding is $O(2^n n^2 |V|^{g-1})$ where n is the sentence length and $|V|$ is the English vocabulary size (Huang and Chiang, 2007).

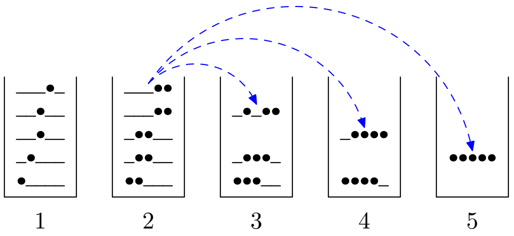

Figure 1: Beam search in phrase-based decoding expands the hypotheses in the current bin (#2) into longer ones.

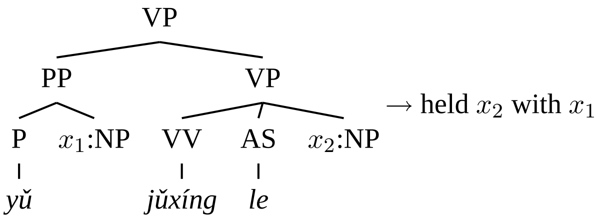

Figure 2: Tree-to-string rule r_3 for reordering.

2.2 Beam Search in Practice

To make the exponential algorithm practical, beam search is the standard approximate search method (Koehn, 2004). Here we group +LM items into n bins, with each bin B_i hosting at most b items that cover exactly i Chinese words (see Figure 1). The complexity becomes $O(n^2b)$ because there are a total of $O(nb)$ items in all bins, and to expand each item we need to scan the whole coverage vector, which costs $O(n)$. This quadratic complexity is still too slow in practice and we often set a small *distortion limit* of $d_{\max}$ (say, 5) so that no jumps longer than $d_{\max}$ are allowed. This method reduces the complexity to $O(nbd_{\max})$ but fails to capture long-distance reorderings (Galley and Manning, 2008).

3 Incremental Decoding for Tree-to-String Translation

We will first briefly review tree-to-string translation paradigm and then develop an incremental decoding algorithm for it inspired by phrase-based decoding.

3.1 Tree-to-string Translation

A typical tree-to-string system (Liu et al., 2006; Huang et al., 2006) performs translation in two steps: parsing and decoding. A parser first parses the source language input into a 1-best tree T, and the decoder then searches for the best *derivation* (a sequence of translation steps) d^* that converts source tree T into a target-language string.

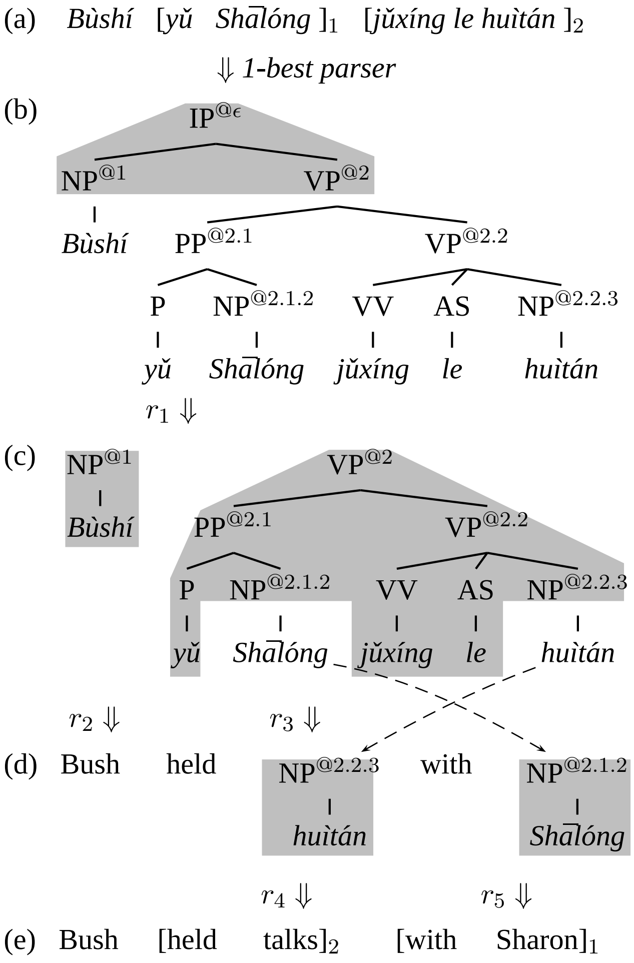

Figure 3: An example derivation of tree-to-string translation (much simplified from Mi et al. (2008)). Shaded regions denote parts of the tree that matches the rule.

Figure 3 shows how this process works. The Chinese sentence (a) is first parsed into tree (b), which will be converted into an English string in 5 steps. First, at the root node, we apply rule r_1 preserving the top-level word-order

(r_1) IP (x_1:NP x_2:VP) → x_1 x_2

which results in two unfinished subtrees, NP$^{@1}$ and VP$^{@2}$ in (c). Here $X^{@\eta}$ denotes a tree node of label X at tree address η (Shieber et al., 1995). (The root node has address ϵ, and the first child of node η has address η.1, etc.) Then rule r_2 grabs the *Bùshí* subtree and transliterate it into the English word

	in theory	in practice
phrase*	$O(2^n n^2 \cdot \|V\|^{g-1})$	$O(n^2 b)$
tree-to-str	$O(nc \cdot \|V\|^{4(g-1)})$	$O(ncb^2)$
*this work**	$O(n^{k \log^2(cr)} \cdot \|V\|^{g-1})$	$O(ncb)$

Table 2: Summary of time complexities of various algorithms. b is the beam width, V is the English vocabulary, and c is the number of translation rules per node. As a special case, phrase-based decoding with distortion limit $d_{\max}$ is $O(nbd_{\max})$. *: incremental decoding algorithms.

"Bush". Similarly, rule r_3 shown in Figure 2 is applied to the VP subtree, which swaps the two NPs, yielding the situation in (d). Finally two phrasal rules r_4 and r_5 translate the two remaining NPs and finish the translation.

In this framework, decoding without language model ($-$LM decoding) is simply a linear-time depth-first search with memoization (Huang et al., 2006), since a tree of n words is also of size $O(n)$ and we visit every node only once. Adding a language model, however, slows it down significantly because we now have to keep track of target-language boundary words, but unlike the phrase-based case in Section 2, here we have to remember both sides the leftmost and the rightmost boundary words: each node is now split into $+$LM items like $(\eta\ ^{a \star b})$ where η is a tree node, and a and b are left and right English boundary words. For example, a bigram $+$LM item for node VP$^{@2}$ might be

$$(\text{VP}^{@2\ \text{held} \star \text{Sharon}}).$$

This is also the case with other syntax-based models like Hiero or GHKM: language model integration overhead is the most significant factor that causes syntax-based decoding to be slow (Chiang, 2007). In theory $+$LM decoding is $O(nc|V|^{4(g-1)})$, where V denotes English vocabulary (Huang, 2007). In practice we have to resort to beam search again: at each node we would only allow top-b $+$LM items. With beam search, tree-to-string decoding with an integrated language model runs in time $O(ncb^2)$, where b is the size of the beam at each node, and c is (maximum) number of translation rules matched at each node (Huang, 2007). See Table 2 for a summary.

3.2 Incremental Decoding

Can we borrow the idea of phrase-based decoding, so that we also grow the hypothesis strictly left-to-right, and only need to maintain the rightmost boundary words?

The key intuition is to adapt the coverage-vector idea from phrase-based decoding to tree-to-string decoding. Basically, a coverage-vector keeps track of which Chinese spans have already been translated and which have not. Similarly, here we might need a "tree coverage-vector" that indicates which subtrees have already been translated and which have not. But unlike in phrase-based decoding, we can not simply choose any arbitrary uncovered subtree for the next step, since rules already dictate which subtree to visit next. In other words what we need here is not really a tree coverage vector, but more of a derivation history.

We develop this intuition into an agenda represented as a stack. Since tree-to-string decoding is a top-down depth-first search, we can simulate this recursion with a stack of active rules, i.e., rules that are not completed yet. For example we can simulate the derivation in Figure 3 as follows. At the root node IP$^{@\epsilon}$, we choose rule r_1, and push its English-side to the stack, with variables replaced by matched tree nodes, here x_1 for NP$^{@1}$ and x_2 for VP$^{@2}$. So we have the following stack

$$s = [\centerdot\ \text{NP}^{@1}\ \text{VP}^{@2}],$$

where the dot $\centerdot$ indicates the next symbol to process in the English word-order. Since node NP$^{@1}$ is the first in the English word-order, we expand it first, and push rule r_2 rooted at NP to the stack:

$$[\centerdot\ \text{NP}^{@1}\ \text{VP}^{@2}\ ]\ [\centerdot\ \text{Bush}].$$

Since the symbol right after the dot in the top rule is a word, we immediately grab it, and append it to the current hypothesis, which results in the new stack

$$[\centerdot\ \text{NP}^{@1}\ \text{VP}^{@2}\ ]\ [\text{Bush}\ \centerdot\ ].$$

Now the top rule on the stack has finished (dot is at the end), so we trigger a "pop" operation which pops the top rule and advances the dot in the second-to-top rule, denoting that NP$^{@1}$ is now completed:

$$[\text{NP}^{@1}\ \centerdot\ \text{VP}^{@2}].$$

Figure 4: Simulation of tree-to-string derivation in Figure 3 in the incremental decoding algorithm. Actions: p, predict; s, scan; c, complete (see Figure 5).

Item $\quad \ell : \langle s,\ \rho\rangle :\ w; \quad \ell$: step, s: stack, ρ: hypothesis, w: weight

Equivalence $\quad \ell : \langle s,\ \rho\rangle \sim \ell : \langle s',\ \rho'\rangle$ iff. $s = s'$ and $last_{g-1}(\rho) = last_{g-1}(\rho')$

Axiom
$$0 : \langle [\texttt{<s>}^{g-1} \bullet \epsilon\ \texttt{</s>}],\ \texttt{<s>}^{g-1}\rangle :\ 0$$

Predict
$$\frac{\ell : \langle ...\ [\alpha \bullet \eta\ \beta],\ \rho\rangle :\ w}{\ell + |C(r)| : \langle ...\ [\alpha \bullet \eta\ \beta]\ [\bullet\ f(\eta, E(r))],\ \rho\rangle :\ w + c(r)} \qquad match(\eta, C(r))$$

Scan
$$\frac{\ell : \langle ...\ [\alpha \bullet e\ \beta],\ \rho\rangle :\ w}{\ell : \langle ...\ [\alpha\ e \bullet \beta],\ \rho e\rangle :\ w - \log \Pr(e \mid last_{g-1}(\rho))}$$

Complete
$$\frac{\ell : \langle ...\ [\alpha \bullet \eta\ \beta]\ [\gamma \bullet],\ \rho\rangle :\ w}{\ell : \langle ...\ [\alpha\ \eta \bullet \beta],\ \rho\rangle :\ w}$$

Goal
$$|T| : \langle [\texttt{<s>}^{g-1}\ \epsilon\ \texttt{</s>}\bullet],\ \rho\texttt{</s>}\rangle :\ w$$

Figure 5: Deductive system for the incremental tree-to-string decoding algorithm. Function $last_{g-1}(\cdot)$ returns the rightmost $g - 1$ words (for g-gram LM), and $match(\eta, C(r))$ tests matching of rule r against the subtree rooted at node η. $C(r)$ and $E(r)$ are the Chinese and English sides of rule r, and function $f(\eta, E(r)) = [x_i \mapsto \eta.var(i)]E(r)$ replaces each variable x_i on the English side of the rule with the descendant node $\eta.var(i)$ under η that matches x_i.

The next step is to expand VP$^{@2}$, and we use rule r_3 and push its English-side "VP → held x_2 with x_1" onto the stack, again with variables replaced by matched nodes:

$$[\text{NP}^{@1} \bullet \text{VP}^{@2}]\ [\bullet\ \text{held NP}^{@2.2.3} \text{ with NP}^{@2.1.2}]$$

Note that this is a reordering rule, and the stack always follows the English word order because we generate hypothesis incrementally left-to-right. Figure 4 works out the full example.

We formalize this algorithm in Figure 5. Each item $\langle s,\ \rho\rangle$ consists of a stack s and a hypothesis ρ. Similar to phrase-based dynamic programming, only the last $g-1$ words of ρ are part of the signature for decoding with g-gram LM. Each stack is a list of *dotted rules*, i.e., rules with dot positions indicting progress, in the style of Earley (1970). We call the last (rightmost) rule on the stack the *top rule*, which is the rule being processed currently. The symbol after the dot in the top rule is called the *next symbol*, since it is the symbol to expand or process next. Depending on the next symbol a, we can perform one of the three actions:

- if a is a node η, we perform a Predict action which expands η using a rule r that can pattern-match the subtree rooted at η; we push r is to the stack, with the dot at the beginning;
- if a is an English word, we perform a Scan action which immediately adds it to the current hypothesis, advancing the dot by one position;
- if the dot is at the end of the top rule, we perform a Complete action which simply pops stack and advance the dot in the new top rule.

3.3 Polynomial Time Complexity

Unlike phrase-based models, we show here that incremental decoding runs in average-case polynomial-time for tree-to-string systems.

Lemma 1. *For an input sentence of n words and its parse tree of depth d, the worst-case complexity of our algorithm is $f(n,d) = c(cr)^d|V|^{g-1} = O((cr)^d n^{g-1})$, assuming relevant English vocabulary $|V| = O(n)$, and where constants c, r and g are the maximum number of rules matching each tree node, the maximum arity of a rule, and the language-model order, respectively.*

Proof. The time complexity depends (in part) on the number of all possible stacks for a tree of depth d. A stack is a list of rules covering a path from the root node to one of the leaf nodes in the following form:

$$\overbrace{[\dots \bullet\eta_1 \dots]}^{R_1}\ \overbrace{[\dots \bullet\eta_2 \dots]}^{R_2}\ \dots\ \overbrace{[\dots \bullet\eta_s \dots]}^{R_s},$$

where $\eta_1 = \epsilon$ is the root node and η_s is a leaf node, with stack depth $s \le d$. Each rule $R_i (i > 1)$ expands node η_{i-1}, and thus has c choices by the definition of grammar constant c. Furthermore, each rule in the stack is actually a dotted-rule, i.e., it is associated with a dot position ranging from 0 to r, where r is the arity of the rule (length of English side of the rule). So the total number of stacks is $O((cr)^d)$.

Besides the stack, each state also maintains $(g-1)$ rightmost words of the hypothesis as the language model signature, which amounts to $O(|V|^{g-1})$. So the total number of states is $O((cr)^d|V|^{g-1})$. Following previous work (Chiang, 2007), we assume a constant number of English translations for each foreign word in the input sentence, so $|V| = O(n)$. And as mentioned above, for each state, there are c possible expansions, so the overall time complexity is $f(n,d) = c(cr)^d|V|^{g-1} = O((cr)^d n^{g-1})$. □

We do average-case analysis below because the tree depth (height) for a sentence of n words is a random variable: in the worst-case it can be linear in n (degenerated into a linear-chain), but we assume this adversarial situation does not happen frequently, and the average tree depth is $O(\log n)$.

Theorem 1. *Assume for each n, the depth of a parse tree of n words, notated d_n, distributes normally with logarithmic mean and variance, i.e., $d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)$, where $\mu_n = O(\log n)$ and $\sigma_n^2 = O(\log n)$, then the average-case complexity of the algorithm is $h(n) = O(n^{k\log^2(cr)+g-1})$ for constant k, thus polynomial in n.*

Proof. From Lemma 1 and the definition of average-case complexity, we have

$$h(n) = \mathbb{E}_{d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)}[f(n, d_n)],$$

where $\mathbb{E}_{x\sim D}[\cdot]$ denotes the expectation with respect to the random variable x in distribution D.

$$\begin{aligned} h(n) &= \mathbb{E}_{d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)}[f(n, d_n)] \\ &= \mathbb{E}_{d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)}[O((cr)^{d_n} n^{g-1})], \\ &= O(n^{g-1} \mathbb{E}_{d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)}[(cr)^{d_n}]), \\ &= O(n^{g-1} \mathbb{E}_{d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)}[\exp(d_n \log(cr))]) \quad (2) \end{aligned}$$

Since $d_n \sim \mathcal{N}(\mu_n, \sigma_n^2)$ is a normal distribution, $d_n \log(cr) \sim \mathcal{N}(\mu', \sigma'^2)$ is also a normal distribution, where $\mu' = \mu_n \log(cr)$ and $\sigma' = \sigma_n \log(cr)$. Therefore $\exp(d_n \log(cr))$ is a log-normal distribution, and by the property of log-normal distribution, its expectation is $\exp(\mu' + \sigma'^2/2)$. So we have

$$\begin{aligned} & \mathbb{E}_{d_n \sim \mathcal{N}(\mu_n, \sigma^2/2)}[\exp(d_n \log(cr))] \\ = \; & \exp(\mu' + \sigma'^2/2) \\ = \; & \exp(\mu_n \log(cr) + \sigma_n^2 \log^2(cr)/2) \\ = \; & \exp(O(\log n) \log(cr) + O(\log n) \log^2(cr)/2) \\ = \; & \exp(O(\log n) \log^2(cr)) \\ \leq \; & \exp(k(\log n) \log^2(cr)), \qquad \text{for some constant } k \\ = \; & \exp(\log n^{k \log^2(cr)}) \\ = \; & n^{k \log^2(cr)}. \qquad (3) \end{aligned}$$

Plug it back to Equation (2), and we have the average-case complexity

$$\begin{aligned} \mathbb{E}_{d_n}[f(n, d_n)] &\leq O(n^{g-1} n^{k \log^2(cr)}) \\ &= O(n^{k \log^2(cr) + g - 1}). \qquad (4) \end{aligned}$$

Since k, c, r and g are constants, the average-case complexity is polynomial in sentence length n. □

The assumption $d_n \sim \mathcal{N}(O(\log n), O(\log n))$ will be empirically verified in Section 5.

3.4 Linear-time Beam Search

Though polynomial complexity is a desirable property in theory, the degree of the polynomial, $O(\log cr)$ might still be too high in practice, depending on the translation grammar. To make it linear-time, we apply the beam search idea from phrase-based again. And once again, the only question to decide is the choice of "binning": how to assign each item to a particular bin, depending on their progress?

While the number of Chinese words covered is a natural progress indicator for phrase-based, it does not work for tree-to-string because, among the three actions, only scanning grows the hypothesis. The prediction and completion actions do not make real progress in terms of *words*, though they do make progress on the *tree*. So we devise a novel progress indicator natural for tree-to-string translation: the number of tree nodes covered so far. Initially that number is zero, and in a prediction step which expands node η using rule r, the number increments by $|C(r)|$, the size of the Chinese-side treelet of r. For example, a prediction step using rule r_3 in Figure 2 to expand VP$^{@2}$ will increase the tree-node count by $|C(r_3)| = 6$, since there are six tree nodes in that rule (not counting leaf nodes or variables).

Scanning and completion do not make progress in this definition since there is no new tree node covered. In fact, since both of them are deterministic operations, they are treated as "closure" operators in the real implementation, which means that after a prediction, we always do as many scanning/completion steps as possible until the symbol after the dot is another node, where we have to wait for the next prediction step.

This method has $|T| = O(n)$ bins where $|T|$ is the size of the parse tree, and each bin holds b items. Each item can expand to c new items, so the overall complexity of this beam search is $O(ncb)$, which is linear in sentence length.

4 Related Work

The work of Watanabe et al. (2006) is closest in spirit to ours: they also design an incremental decoding algorithm, but for the hierarchical phrase-based system (Chiang, 2007) instead. While we leave detailed comparison and theoretical analysis to a future work, here we point out some obvious differences:

1. due to the difference in the underlying translation models, their algorithm runs in $O(n^2 b)$ time with beam search in practice while ours is linear. This is because each prediction step now has $O(n)$ choices, since they need to expand nodes like VP[1, 6] as:

   $$\text{VP[1,6]} \rightarrow \text{PP[1, } i \text{]} \;\; \text{VP[} i \text{, 6]},$$

   where the midpoint i in general has $O(n)$ choices (just like in CKY). In other words, their grammar constant c becomes $O(n)$.

2. different binning criteria: we use the number of tree nodes covered, while they stick to the orig-

inal phrase-based idea of number of Chinese words translated;

3. as a result, their framework requires grammar transformation into the binary-branching Greibach Normal Form (which is not always possible) so that the resulting grammar always contain at least one Chinese word in each rule in order for a prediction step to always make progress. Our framework, by contrast, works with any grammar.

Besides, there are some other efforts less closely related to ours. As mentioned in Section 1, while we focus on enhancing syntax-based decoding with phrase-based ideas, other authors have explored the reverse, but also interesting, direction of enhancing phrase-based decoding with syntax-aware reordering. For example Galley and Manning (2008) propose a shift-reduce style method to allow hieararchical non-local reorderings in a phrase-based decoder. While this approach is certainly better than pure phrase-based reordering, it remains quadratic in run-time with beam search.

Within syntax-based paradigms, cube pruning (Chiang, 2007; Huang and Chiang, 2007) has become the standard method to speed up $+$LM decoding, which has been shown by many authors to be highly effective; we will be comparing our incremental decoder with a baseline decoder using cube pruning in Section 5. It is also important to note that cube pruning and incremental decoding are not mutually exclusive, rather, they could potentially be combined to further speed up decoding. We leave this point to future work.

Multipass coarse-to-fine decoding is another popular idea (Venugopal et al., 2007; Zhang and Gildea, 2008; Dyer and Resnik, 2010). In particular, Dyer and Resnik (2010) uses a two-pass approach, where their first-pass, $-$LM decoding is also incremental and polynomial-time (in the style of Earley (1970) algorithm), but their second-pass, $+$LM decoding is still bottom-up CKY with cube pruning.

5 Experiments

To test the merits of our incremental decoder we conduct large-scale experiments on a state-of-the-art tree-to-string system, and compare it with the standard phrase-based system of Moses. Furturemore we also compare our incremental decoder with the standard cube pruning approach on the same tree-to-string decoder.

5.1 Data and System Preparation

Our training corpus consists of 1.5M sentence pairs with about 38M/32M words in Chinese/English, respectively. We first word-align them by GIZA++ and then parse the Chinese sentences using the Berkeley parser (Petrov and Klein, 2007), then apply the GHKM algorithm (Galley et al., 2004) to extract tree-to-string translation rules. We use SRILM Toolkit (Stolcke, 2002) to train a trigram language model with modified Kneser-Ney smoothing on the target side of training corpus. At decoding time, we again parse the input sentences into trees, and convert them into translation forest by rule pattern-matching (Mi et al., 2008).

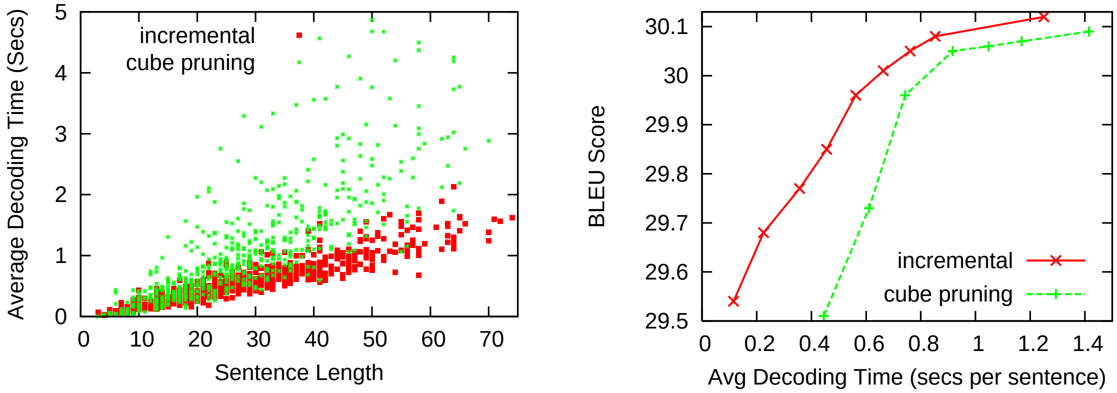
We use the newswire portion of 2006 NIST MT Evaluation test set (616 sentences) as our development set and the newswire portion of 2008 NIST MT Evaluation test set (691 sentences) as our test set. We evaluate the translation quality using the BLEU-4 metric, which is calculated by the script mteval-v13a.pl with its default setting which is case-insensitive matching of n-grams. We use the standard minimum error-rate training (Och, 2003) to tune the feature weights to maximize the system's BLEU score on development set.

We first verify the assumptions we made in Section 3.3 in order to prove the theorem that tree depth (as a random variable) is normally-distributed with $O(\log n)$ mean and variance. Qualitatively, we verified that for most n, tree depth $d(n)$ does look like a normal distribution. Quantitatively, Figure 6 shows that average tree height correlates extremely well with $3.5 \log n$, while tree height variance is bounded by $5.5 \log n$.

5.2 Comparison with Cube pruning

We implemented our incremental decoding algorithm in Python, and test its performance on the development set. We first compare it with the standard cube pruning approach (also implemented in Python) on the same tree-to-string system.[1] Fig-

[1] Our implementation of cube pruning follows (Chiang, 2007; Huang and Chiang, 2007) where besides a beam size b of unique $+$LM items, there is also a hard limit (of 1000) on the



(a) decoding time against sentence length

(b) BLEU score against decoding time

Figure 7: Comparison with cube pruning. The scatter plot in (a) confirms that our incremental decoding scales linearly with sentence length, while cube pruning super-linearly ($b = 50$ for both). The comparison in (b) shows that at the same level of translation quality, incremental decoding is slightly faster than cube pruning, especially at smaller beams.

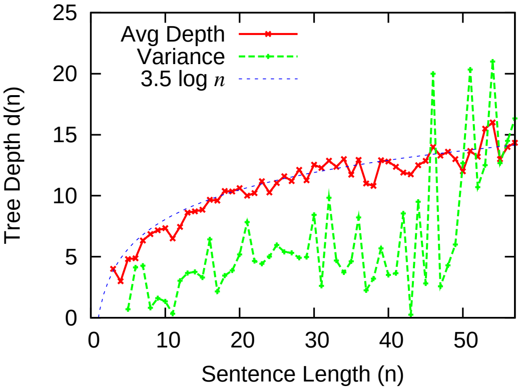


Figure 6: Mean and variance of tree depth vs. sentence length. The mean depth clearly scales with $3.5 \log n$, and the variance is bounded by $5.5 \log n$.

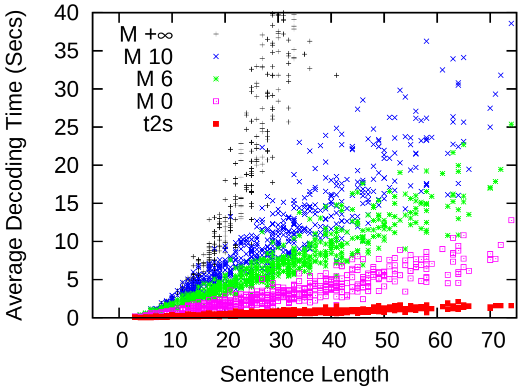

Figure 8: Comparison of our incremental tree-to-string decoder with Moses in terms of speed. Moses is shown with various distortion limits (0, 6, 10, $+\infty$; optimal: 10).

ure 7(a) is a scatter plot of decoding times versus sentence length (using beam $b = 50$ for both systems), where we confirm that our incremental decoder scales linearly, while cube pruning has a slight tendency of superlinearity. Figure 7(b) is a side-by-side comparison of decoding speed versus translation quality (in BLEU scores), using various beam sizes for both systems (b=10–70 for cube pruning, and b=10–110 for incremental). We can see that incremental decoding is slightly faster than cube pruning at the same levels of translation quality, and the difference is more pronounced at smaller beams: for example, at the lowest levels of translation quality (BLEU scores around 29.5), incremental decoding takes only 0.12 seconds, which is about 4 times as fast as cube pruning. We stress again that cube pruning and incremental decoding are not mutually exclusive, and rather they could potentially be combined to further speed up decoding.

5.3 Comparison with Moses

We also compare with the standard phrase-based system of Moses (Koehn et al., 2007), with standard settings except for the ttable limit, which we set to 100. Figure 8 compares our incremental decoder

number of (non-unique) pops from priority queues.

system/decoder	BLEU	time
Moses (optimal $d_{\max}$=10)	29.41	10.8
tree-to-str: cube pruning (b=10)	29.51	0.65
tree-to-str: cube pruning (b=20)	29.96	0.96
tree-to-str: incremental (b=10)	29.54	0.32
tree-to-str: incremental (b=50)	29.96	0.77

Table 3: Final BLEU score and speed results on the test data (691 sentences), compared with Moses and cube pruning. Time is in seconds per sentence, including parsing time (0.21s) for the two tree-to-string decoders.

with Moses at various distortion limits ($d_{\max}$=0, 6, 10, and $+\infty$). Consistent with the theoretical analysis in Section 2, Moses with no distortion limit ($d_{\max} = +\infty$) scale *quadratically*, and monotone decoding ($d_{\max} = 0$) scale linearly. We use MERT to tune the best weights for each distortion limit, and $d_{\max} = 10$ performs the best on our dev set.

Table 3 reports the final results in terms of BLEU score and speed on the test set. Our linear-time incremental decoder with the small beam of size $b = 10$ achieves a BLEU score of 29.54, comparable to Moses with the optimal distortion limit of 10 (BLEU score 29.41). But our decoding (including source-language parsing) only takes 0.32 seconds a sentences, which is more than 30 times faster than Moses. With a larger beam of $b = 50$ our BLEU score increases to 29.96, which is a half BLEU point better than Moses, but still about 15 times faster.

6 Conclusion

We have presented an incremental dynamic programming algorithm for tree-to-string translation which resembles phrase-based based decoding. This algorithm is the first incremental algorithm that runs in polynomial-time in theory, and linear-time in practice with beam search. Large-scale experiments on a state-of-the-art tree-to-string decoder confirmed that, with a comparable (or better) translation quality, it can run more than 30 times faster than the phrase-based system of Moses, even though ours is in Python while Moses in C++. We also showed that it is slightly faster (and scale better) than the popular cube pruning technique. For future work we would like to apply this algorithm to forest-based translation and hierarchical system by pruning the first-pass $-$LM forest. We would also combine cube pruning with our incremental algorithm, and study its performance with higher-order language models.

Abstract

Strong indications of perspective can often come from collocations of arbitrary length; for example, someone writing *get the government out of my X* is typically expressing a conservative rather than progressive viewpoint. However, going beyond unigram or bigram features in perspective classification gives rise to problems of data sparsity. We address this problem using nonparametric Bayesian modeling, specifically adaptor grammars (Johnson et al., 2006). We demonstrate that an *adaptive naïve Bayes* model captures multiword lexical usages associated with perspective, and establishes a new state-of-the-art for perspective classification results using the Bitter Lemons corpus, a collection of essays about mid-east issues from Israeli and Palestinian points of view.

1 Introduction

Most work on the computational analysis of sentiment and perspective relies on lexical features. This makes sense, since an author's choice of words is often used to express overt opinions (e.g. describing healthcare reform as *idiotic* or *wonderful*) or to frame a discussion in order to convey a perspective more implicitly (e.g. using the term *death tax* instead of *estate tax*). Moreover, it is easy and efficient to represent texts as collections of the words they contain, in order to apply a well known arsenal of supervised techniques (Laver et al., 2003; Mullen and Malouf, 2006; Yu et al., 2008).

At the same time, standard lexical features have their limitations for this kind of analysis. Such features are usually created by selecting some small n-gram size in advance. Indeed, it is not uncommon to see the feature space for sentiment analysis limited to unigrams. However, important indicators of perspective can also be longer (*get the government out of my*). Trying to capture these using standard machine learning approaches creates a problem, since allowing n-grams as features for larger n gives rise to problems of data sparsity.

In this paper, we employ nonparametric Bayesian models (Orbanz and Teh, 2010) in order to address this limitation. In contrast to parametric models, for which a fixed number of parameters are specified in advance, nonparametric models can "grow" to the size best suited to the observed data. In text analysis, models of this type have been employed primarily for unsupervised discovery of latent structure — for example, in topic modeling, when the true number of topics is not known (Teh et al., 2006); in grammatical inference, when the appropriate number of nonterminal symbols is not known (Liang et al., 2007); and in coreference resolution, when the number of entities in a given document is not specified in advance (Haghighi and Klein, 2007). Here we use them for supervised text classification.

Specifically, we use *adaptor grammars* (Johnson et al., 2006), a formalism for nonparametric Bayesian modeling that has recently proven useful in unsupervised modeling of phonemes (Johnson, 2008), grammar induction (Cohen et al., 2010), and named entity structure learning (Johnson, 2010), to make supervised naïve Bayes classification nonparametric in order to improve perspective modeling. Intuitively, naïve Bayes associates each class or label with a probability distribution over a fixed vocabulary. We introduce *adaptive naïve Bayes* (ANB), for which in principle the vocabulary can grow as needed to include collocations of arbitrary length, as determined

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 284–292,

by the properties of the dataset. We show that using adaptive naïve Bayes improves on state of the art classification using the Bitter Lemons corpus (Lin et al., 2006), a document collection that has been used by a variety of authors to evaluate perspective classification.

In Section 2, we review adaptor grammars, show how naïve Bayes can be expressed within the formalism, and describe how — and how easily — an adaptive naïve Bayes model can be created. Section 3 validates the approach via experimentation on the Bitter Lemons corpus. In Section 4, we summarize the contributions of the paper and discuss directions for future work.

2 Adapting Naïve Bayes to be Less Naïve

In this work we apply the *adaptor grammar* formalism introduced by Johnson, Griffiths, and Goldwater (Johnson et al., 2006). Adaptor grammars are a generalization of probabilistic context free grammars (PCFGs) that make it particularly easy to express nonparametric Bayesian models of language simply and readably using context free rules. Moreover, Johnson *et al.* provide an inference procedure based on Markov Chain Monte Carlo techniques that makes parameter estimation straightforward for all models that can be expressed using adaptor grammars.[1] Variational inference for adaptor grammars has also been recently introduced (Cohen et al., 2010).

Briefly, adaptor grammars allow nonterminals to be rewritten to entire subtrees. In contrast, a nonterminal in a PCFG rewrites only to a collection of grammar symbols; their subsequent productions are independent of each other. For instance, a traditional PCFG might learn probabilities for the rewrite rule PP $\mapsto$ P NP. In contrast, an adaptor grammar can learn (or "cache") the production PP $\mapsto$ (P up)(NP(DET a)(N tree)). It does this by positing that the distribution over children for an adapted non-terminal comes from a Pitman-Yor distribution.

A Pitman-Yor distribution (Pitman and Yor, 1997) is a distribution over distributions. It has three parameters: the discount, a, such that $0 \leq a < 1$, the strength, b, a real number such that $-a < b$, and a probability distribution G_0 known as the base distribution. Adaptor grammars allow distributions over subtrees to come from a Pitman-Yor distribution with the PCFG's original distribution over trees as the base distribution. The generative process for obtaining draws from a distribution drawn from a Pitman-Yor distribution can be described by the "Chinese restaurant process" (CRP). We will use the CRP to describe how to obtain a distribution over observations composed of sequences of n-grams, the key to our model's ability to capture perspective-bearing n-grams.

Suppose that we have a base distribution Ω that is some distribution over all sequences of words (the exact structure of such a distribution is unimportant; such a distribution will be defined later in Table 1). Suppose further we have a distribution ϕ drawn from $PY(a, b, \Omega)$, and we wish to draw a series of observations $\boldsymbol{w}$ from ϕ. The CRP gives us a generative process for doing those draws from ϕ, marginalizing out ϕ. Following the restaurant metaphor, we imagine the i^{th} customer in the series entering the restaurant to take a seat at a table. The customer sits by making a choice that determines the value of the n-gram w_i for that customer: she can either sit at an existing table or start a new table of her own.[2]

If she sits at a new table j, that table is assigned a draw y_j from the base distribution, Ω; note that, since Ω is a distribution over n-grams, y_j is an n-gram. The value of w_i is therefore assigned to be y_j, and y_j becomes the sequence of words assigned to that new table. On the other hand, if she sits at an existing table, then w_i simply takes the sequence of words already associated with that table (assigned as above when it was first occupied).

The probability of joining an existing table j, with c_j patrons already seated at table j, is $\frac{c_j - a}{c. + b}$, where $c.$ is the number of patrons seated at all tables: $c. = \sum_{j'} c_{j'}$. The probability of starting a new table is $\frac{b + t * a}{c. + b}$, where t is the number of tables presently occupied.

Notice that ϕ is a distribution over the same space as Ω, but it can drastically shift the mass of the distribution, compared with Ω, as more and more pa-

[1] And, better still, they provide code that implements the inference algorithm; see http://www.cog.brown.edu/ mj/Software.htm.

[2] Note that we are abusing notation by allowing w_i to correspond to a word sequence of length ≥ 1 rather than a single word.

trons are seated at tables. However, there is always a chance of drawing from the base distribution, and therefore every word sequence can also always be drawn from ϕ.

In the next section we will write a naïve Bayes-like generative process using PCFGs. We will then use the PCFG distribution as the base distribution for a Pitman-Yor distribution, adapting the naïve Bayes process to give us a distribution over n-grams, thus learning new language substructures that are useful for modeling the differences in perspective.

2.1 Classification Models as PCFGs

Naïve Bayes is a venerable and popular mechanism for text classification (Lewis, 1998). It posits that there are K distinct categories of text — each with a distinct distribution over words — and that every document, represented as an exchangeable bag of words, is drawn from one (and only one) of these distributions. Learning the per-category word distributions and global prevalence of the classes is a problem of posterior inference which can be approached using a variety of inference techniques (Lowd and Domingos, 2005).

More formally, naïve Bayes models can be expressed via the following generative process:[3]

1. Draw a global distribution over classes $\theta \sim \text{Dir}(\alpha)$
2. For each class $i \in \{1, \dots, K\}$, draw a word distribution $\phi_i \sim \text{Dir}(\lambda)$
3. For each document $d \in \{1, \dots, M\}$:
   (a) Draw a class assignment $z_d \sim \text{Mult}(\theta)$
   (b) For each word position $n \in \{1, \dots, N_d$, draw $w_{d,n} \sim \text{Mult}(\phi_{z_d})$

A variant of the naïve Bayes generative process can be expressed using the adaptor grammar formalism (Table 1). The left hand side of each rule represents a nonterminal which can be expanded, and the right hand side represents the rewrite rule. The rightmost indices show replication; for instance, there are $|V|$ rules that allow Word$_i$ to rewrite to each word in the vocabulary. One can assume a symmetric Dirichlet prior of $\text{Dir}(\bar{1})$ over the production choices unless otherwise specified — as with the Doc$_d$ production rule above, where a sparse prior is used.

Sent	$\mapsto$	Doc$_d$	$d = 1, \dots, m$
Doc$_d{}^{0.001}$	$\mapsto$	ID$_d$ Words$_i$	$d = 1, \dots, m;$ $i \in \{1, K\}$
Words$_i$	$\mapsto$	Words$_i$ Word$_i$	$i \in \{1, K\}$
Words$_i$	$\mapsto$	Word$_i$	$i \in \{1, K\}$
Word$_i$	$\mapsto$	v	$v \in V; i \in \{1, K\}$

Table 1: A naïve Bayes-inspired model expressed as a PCFG.

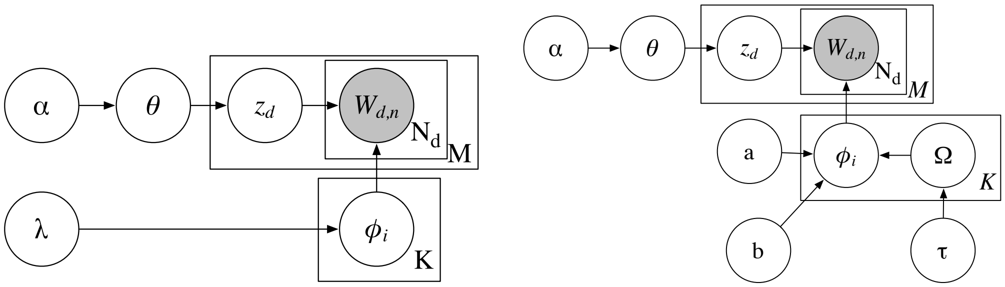
Notice that the distribution over expansions for Word$_i$ corresponds directly to ϕ_i in Figure 1(a). There are, however, some differences between the model that we have described above and the standard naïve Bayes model depicted in Figure 1(a). In particular, there is no longer a single choice of class per document; each *sentence* is assigned a class. If the distribution over per-sentence labels is sparse (as it is above for Doc$_d$), this will closely approximate naïve Bayes, since it will be very unlikely for the sentences in a document to have different labels. A non-sparse prior leads to behavior more like models that allow parts of a document to express sentiment or perspective differently.

2.2 Moving Beyond the Bag of Words

The naïve Bayes generative distribution posits that when writing a document, the author selects a distribution of categories z_d for the document from θ. The author then generates words one at a time: each word is selected independently from a flat multinomial distribution ϕ_{z_d} over the vocabulary.

However, this is a very limited picture of how text is related to underlying perspectives. Clearly words are often connected with each other as collocations, and, just as clearly, extending a flat vocabulary to include bigram collocations does not suffice, since sometimes relevant perspective-bearing phrases are longer than two words. Consider phrases like *health care for all* or *government takeover of health care*, connected with progressive and conservative positions, respectively, during the national debate on healthcare reform. Simply applying naïve Bayes, or any other model, to a bag of n-grams for high n is

[3] Here α and λ are hyperparameters used to specify priors for the class distribution and classes' word distributions, respectively; α is a symmetric K-dimensional vector where each element is π. N_d is the length of document d. Resnik and Hardisty (2010) provide a tutorial introduction to the naïve Bayes generative process and underlying concepts.



(a) Naïve Bayes

(b) Adaptive Naïve Bayes

Figure 1: A plate diagram for naïve Bayes and adaptive naïve Bayes. Nodes represent random variables and parameters; shaded nodes represent observations; lines represent probabilistic dependencies; and the rectangular plates denote replication.

going to lead to unworkable levels of data sparsity; a model should be flexible enough to support both unigrams and longer phrases as needed.

Following Johnson (2010), however, we can use adaptor grammars to extend naïve Bayes *flexibly* to include richer structure like collocations when they improve the model, and not including them when they do not. This can be accomplished by introducing *adapted* nonterminal rules: in a revised generative process, the author can draw from Pitman-Yor distribution whose base distribution is over word *sequences* of arbitrary length.[4] Thus in a setting where, say, $K = 2$, and our two classes are PROGRESSIVE and CONSERVATIVE, the sequence *health care for all* might be generated as a single unit for the progressive perspective, but in the conservative perspective the same sequence might be generated as three separate draws: *health care*, *for*, *all*. Such a model is presented in Figure 1(b). Note the following differences between Figures 1(a) and 1(b):

- z_d selects which Pitman-Yor distribution to draw from for document d.
- ϕ_i is the distribution over n-grams that comes from the Pitman-Yor distribution.
- $W_{d,n}$ represents an n-gram draw from ϕ_i
- a, b are the Pitman-Yor strength and discount parameters.
- Ω is the Pitman-Yor base distribution with τ as its uniform hyperparameter.

Returning to the CRP metaphor discussed when we introduced the Pitman-Yor distribution, there are two restaurants, one for the PROGRESSIVE distribution and one for the CONSERVATIVE distribution. *Health care for all* has its own table in the PROGRESSIVE restaurant, and enough people are sitting at it to make it popular. There is no such table in the CONSERVATIVE restaurant, so in order to generate those words, the phrase *health care for all* would need to come from a new table; however, it is more easily explained by three customers sitting at three existing, popular tables: *health care*, *for*, and *all*.

We follow the convention of Johnson (2010) by writing adapted nonterminals as underlined. The grammar for adaptive naïve Bayes is shown in Table 2. The adapted $\underline{\text{COLLOC}_i}$ rule means that every time we need to generate that nonterminal, we are actually drawing from a distribution drawn from a Pitman-Yor distribution. The distribution over the possible yields of the WORDS$_i$ rule serves as the base distribution.

Given this generative process for documents, we can now use statistical inference to uncover the posterior distribution over the latent variables, thus discovering the tables and seating assignments of our metaphorical restaurants that each cater to a specific perspective filled with tables populated by words and n-grams.

The model presented in Table 2 is the most straightforward way of extending naïve Bayes to collocations. For completeness, we also consider the alternative of using a shared base distribution rather than distinguishing the base distributions of the two classes.

[4] As defined above, the base distribution is that of the PCFG production rule WORDS$_i$. Although it has non-zero probability of producing any sequence of words, it is biased toward shorter word sequences.

SENT	$\mapsto$	DOC$_d$	$d = 1, \ldots, m$
DOC$_d^{0.001}$	$\mapsto$	ID$_d$ SPAN$_i$	$d = 1, \ldots, m;$ $i \in \{1, K\}$
SPAN$_i$	$\mapsto$	SPAN$_i$ COLLOC$_i$	$i \in \{1, K\}$
SPAN$_i$	$\mapsto$	COLLOC$_i$	$i \in \{1, K\}$
$\underline{\text{COLLOC}_i}$	$\mapsto$	WORDS$_i$	$i \in \{1, K\}$
WORDS$_i$	$\mapsto$	WORDS$_i$ WORD$_i$	$i \in \{1, K\}$
WORDS$_i$	$\mapsto$	WORD$_i$	$i \in \{1, K\}$
WORD$_i$	$\mapsto$	v	$v \in V; i \in \{1, K\}$

Table 2: An adaptive naïve Bayes grammar. The $\underline{\text{COLLOC}_i}$ nonterminal's distribution over yields is drawn from a Pitman-Yor distribution rather than a Dirichlet over production rules.

SENT	$\mapsto$	DOC$_d$	$d = 1, \ldots, m$
DOC$_d^{0.001}$	$\mapsto$	ID$_d$ SPAN$_i$	$d = 1, \ldots, m;$ $i \in \{1, K\}$
SPAN$_i$	$\mapsto$	SPAN$_i$ COLLOC$_i$	$i \in \{1, K\}$
SPAN$_i$	$\mapsto$	COLLOC$_i$	$i \in \{1, K\}$
$\underline{\text{COLLOC}_i}$	$\mapsto$	WORDS	$i \in \{1, K\}$
WORDS	$\mapsto$	WORDS WORD	
WORDS	$\mapsto$	WORD	
WORD	$\mapsto$	v	$v \in V$

Table 3: An adaptive naïve Bayes grammar with a common base distribution for collocations. Note that, in contrast to Table 2, there are no subscripts on WORDS or WORD.

Briefly, using a shared base distribution posits that the two classes use similar word distributions, but generate collocations unique to each class, whereas using separate base distributions assumes that the distribution of words is unique to each class.

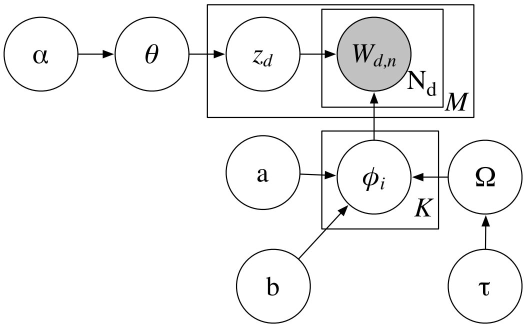


Figure 2: An alternative adaptive naïve Bayes with a common base distribution for both classes.

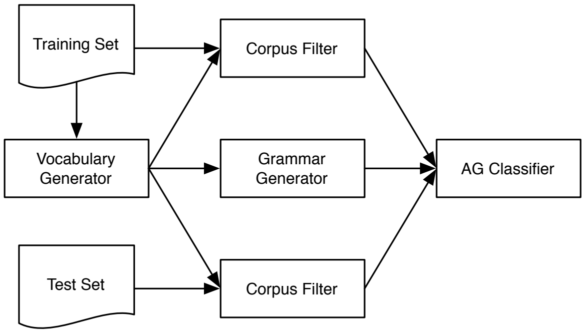

Figure 3: Corpus preparation and experimental setup.

3 Experiments

3.1 Corpus Description

We conducted our classification experiments on the Bitter Lemons (BL) corpus, which is a collection of 297 essays averaging 700-800 words in length, on various Middle East issues, written from both the Israeli and Palestinian perspectives. The BL corpus was compiled by Lin *et al.* (2006) and is derived from a website that invites weekly discussions on a topic and publishes essays from two sets of authors each week.[5] Two of the authors are guests, one from each perspective, and two essays are from the site's regular contributors, also one from each perspective, for a total of four essays on each topic per week. We chose this corpus to allow us to directly compare our results with Greene and Resnik's (2009) Observable Proxies for Underlying Semantics (OPUS) features and Lin *et al.*'s Latent Sentence Perspective Model (LSPM). The classification goal for this corpus is to label each document with the perspective of its author, either Israeli or Palestinian.

Consistent with prior work, we prepared the corpus by dividing it into two groups, one group containing all of the essays written by the regular site contributors, which we call the Editor set, and one group comprised of all the essays written by the guest contributors, which we call the Guest set. Similar to the above mentioned prior work, we perform classification using one group as training data and the other as test data and perform two folds of classification. The overall experimental setup and corpus preparation process is presented in Figure 3.

[5] `http://www.bitterlemons.org`

3.2 Experimental Setup

The vocabulary generator determines the vocabulary used by a given experiment by converting the training set to lower case, stemming with the Porter stemmer, and filtering punctuation. We remove from the vocabulary any words that appeared in only one document regardless of frequency within that document, words with frequencies lower than a threshold, and stop words.[6] The vocabulary is then passed to a grammar generator and a corpus filter.

The grammar generator uses the vocabulary to generate the terminating rules of the grammar from the ANB grammar presented in Tables 2 and 3. The corpus filter takes in a set of documents and replaces all words not in the vocabulary with "out of vocabulary" markers. This process ensures that in all experiments the vocabulary is composed entirely of words from the training set. After the groups have been filtered, the group used as the test set has its labels removed. The test and training set are then sent, along with the grammar, into the adaptor grammar inference engine.

Each experiment ran for 3000 iterations. For the runs where adaptation was used we set the initial Pitman-Yor a and b parameters to 0.01 and 10 respectively, then slice sample (Johnson and Goldwater, 2009).

We use the resulting sentence parses for classification. By design of the grammar, each sentence's words will belong to one and only one distribution. We identify that distribution from each of the test set sentence parses and use it as the sentence level classification for that particular sentence. We then use majority rule on the individual sentence classifications in a document to obtain the document classification. (In most cases the sentence-level assignments are overwhelmingly dominated by one class.)

3.3 Results and Analysis

Table 4 gives the results and compares to prior work. The support vector machine (SVM), NB-B and LSPM results are taken directly from Lin *et al.* (2006). NB-B indicates naïve Bayes with full Bayesian inference. LSPM is the Latent Sentence Perspective Model, also from Lin *et al.* (2006). OPUS results are taken from Greene and Resnik (2009). Briefly, OPUS features are generated from observable grammatical relations that come from dependency parses of the corpus. Use of these features provided the best classification accuracy for this task prior to this work. ANB* refers to the grammar from Table 2, but with adaptation disabled. The reported accuracy values for ANB*, ANB with a common base distribution (see Table 3), and ANB with separate base distributions (see Table 2) are the mean values from five separate sampling chains. Bold face indicates statistical signficance ($p < 0.05$) by unpaired t-test between the reported value and ANB*.

Training Set	Test Set	Classifier	Accuracy
Guests	Editors	SVM	88.22
Guests	Editors	NB-B	93.46
Guests	Editors	LSPM	94.93
Guests	Editors	OPUS	97.64
Guests	Editors	ANB*	99.32
Guests	Editors	ANB Com	**99.93**
Guests	Editors	ANB Sep	**99.87**
Editors	Guests	SVM	81.48
Editors	Guests	NB-B	85.85
Editors	Guests	LSPM	86.99
Editors	Guests	OPUS	85.86
Editors	Guests	ANB*	84.98
Editors	Guests	ANB Com	82.76
Editors	Guests	ANB Sep	**88.28**

Table 4: Classification results. ANB* indicates the same grammar as Adapted Naïve Bayes, but with adaptation disabled. Com and Sep refer to whether the base distribution was common to both classes or separate.

Consistent with all prior work on this corpus we found that the classification accuracy for training on editors and testing on guests was lower than the other direction since the larger number of editors in the guest set allows for greater generalization. The difference between ANB* and ANB with a common base distribution is not statistically significant. Also of note is that the classification accuracy improves for testing on Guests when the ANB grammar is allowed to adapt and a separate base distribution is used for the two classes (88.28% versus 84.98% without adaptation).

Table 5 presents some data on adapted rules

[6] In these experiments, a frequency threshold of 4 was selected prior to testing.

Class	Group	Unique Unigrams Cached	Unique n-grams Cached	Percent of Group Vocabulary Cached
Israeli	Editors	2,292	19,614	77.62
Palestinian	Editors	2,180	17,314	86.54
Israeli	Guests	2,262	19,398	79.91
Palestinian	Guests	2,005	16,946	74.94

Table 5: Counts of cached unigrams and n-grams for the two classes compared to the vocabulary sizes.

Israeli	Palestinian
zionist dream	american jew
zionist state	achieve freedom
zionist movement	palestinian freedom
american leadership	support palestinian
american victory	palestinian suffer
abandon violence	palestinian territory
freedom (of the) press	palestinian statehood
palestinian violence	palestinian refugee

Table 6: Charged bigrams captured by the framework.

learned once inference is complete. The column labeled *unique unigrams cached* indicates the number of unique unigrams that appear on the right hand side of the adapted rules. Similarly, *unique n-grams cached* indicates the number of unique n-grams that appear on the right hand side of the adapted rules. The rightmost column indicates the percentage of terms from the group vocabulary that appear on the right hand side of adapted rules as unigrams. Values less than 100% indicate that the remaining vocabulary terms are cached in n-grams. As the table shows, a significant number of the rules learned during inference are n-grams of various sizes.

Inspection of the captured bigrams showed that it captured sequences that a human might associate with one perspective over the other. Table 6 lists just a few of the more charged bigrams that were captured in the adapted rules.

More specific caching information on the individual groups and classes is provided in Table 7. This data clearly demonstrates that raw n-gram frequency alone is not indicative of how many times an n-gram is used as a cached rule. For example, consider the bigram *people go*, which is used as a cached bigram only three times, yet appears in the corpus 407 times. Compare that with *isra palestinian*, which is cached the same number of times but appears only 18 times in the corpus. In other words, the sequence *people go* is more easily explained by two sequential unigrams, not a bigram. The ratio of cache use counts to raw bigrams gives a measure of strength of collocation between the terms of the n-gram. We conjecture that the rareness of caching for $n > 2$ is a function of the small corpus size. Also of note is the improvement in performance of ANB* over NB-B when training on guests, which we suspect is due to our use of sampled versus fixed hyperparameters.

4 Conclusions

In this paper, we have applied adaptor grammars in a supervised setting to model lexical properties of text and improve document classification according to perspective, by allowing nonparametric discovery of collocations that aid in perspective classification. The adaptive naïve Bayes model improves on state of the art supervised classification performance in head-to-head comparisons with previous approaches.

Although there have been many investigations on the efficacy of using multiword collocations in text classification (Bekkerman and Allan, 2004), usually such approaches depend on a preprocessing step such as computing *tf-idf* or other measures of frequency based on either word bigrams (Tan et al., 2002) or character n-grams (Raskutti et al., 2001). In contrast, our approach combines phrase discovery with the probabilistic model of the text. This allows for the collocation selection and classification to be expressed in a single model, which can then be extended later; it also is truly generative, as compared with feature induction and selection algorithms that either under- or over-generate data.

There are a number of interesting directions in which to take this research. As Johnson *et al.* (2006) argue, and as we have confirmed here, the adaptor

grammar formalism makes it quite easy to work with latent variable models, in order to automatically discover structures in the data that have predictive value. For example, it is easy to imagine a model where in addition to a word distribution for each class, there is also an additional shared "neutral" distribution: for each sentence, the words in that sentence can either come from the class-specific content distribution or the shared neutral distribution. This turns out to be the Latent Sentence Perspective Model of Lin *et al.* (2006), which is straightforward to encode using the adaptor grammar formalism simply by introducing two new nonterminals to represent the neutral distribution:

$$\begin{array}{llll}
\textsc{Sent} & \mapsto & \textsc{Doc}_d & d = 1, \ldots, m \\
\textsc{Doc}_d & \mapsto & \textsc{ID}_d\ \textsc{Words}_i & d = 1, \ldots, m; \\
 & & & i \in \{1, K\} \\
\textsc{Doc}_d & \mapsto & \textsc{ID}_d\ \textsc{Neuts} & d = 1, \ldots, m; \\
\textsc{Words}_i & \mapsto & \textsc{Words}_i\ \textsc{Word}_i & i \in \{1, K\} \\
\textsc{Words}_i & \mapsto & \textsc{Word}_i & i \in \{1, K\} \\
\textsc{Word}_i & \mapsto & \text{v} & v \in V; i \in \{1, K\} \\
\textsc{Neut} & \mapsto & \textsc{Neuts}_i\ \textsc{Neut}_i & \\
\textsc{Neut} & \mapsto & \textsc{Neut} & \\
\textsc{Neut} & \mapsto & \text{v} & v \in V
\end{array}$$

Running this grammar did not produce improvements consistent with those reported by Lin *et al.* We plan to investigate this further, and a natural follow-on would be to experiment with adaptation for this variety of latent structure, to produce an adapted LSPM-like model analogous to adaptive naïve Bayes.

Viewed in a larger context, computational classification of perspective is closely connected to social scientists' study of *framing*, which Entman (1993) characterizes as follows: "To frame is to select some aspects of a perceived reality and make them more salient in a communicating text, in such a way as to promote a particular problem definition, causal interpretation, moral evaluation, and/or treatment recommendation for the item described." Here and in other work (e.g. (Laver et al., 2003; Mullen and Malouf, 2006; Yu et al., 2008; Monroe et al., 2008)), it is clear that lexical evidence is one key to understanding how language is used to frame discussion from one perspective or another; Resnik and Greene (2009) have shown that syntactic choices can provide important evidence, as well. Another promising direction for this work is the application of adaptor grammar models as a way to capture both lexical and grammatical aspects of framing in a unified model.

Predicting the Semantic Compositionality of Prefix Verbs

Shane Bergsma, Aditya Bhargava, Hua He, Grzegorz Kondrak

Abstract

In many applications, replacing a complex word form by its stem can reduce sparsity, revealing connections in the data that would not otherwise be apparent. In this paper, we focus on prefix verbs: verbs formed by adding a prefix to an existing verb stem. A prefix verb is considered compositional if it can be decomposed into a semantically equivalent expression involving its stem. We develop a classifier to predict compositionality via a range of lexical and distributional features, including novel features derived from web-scale N-gram data. Results on a new annotated corpus show that prefix verb compositionality can be predicted with high accuracy. Our system also performs well when trained and tested on conventional morphological segmentations of prefix verbs.

1 Introduction

Many verbs are formed by adding prefixes to existing verbs. For example, *remarry* is composed of a prefix, *re*-, and a stem, *marry*. We present an approach to predicting the compositionality of prefix verbs. The verb *remarry* is compositional; it means to *marry again*. On the other hand, *retire* is generally non-compositional; it rarely means *to tire again*. There is a continuum of compositionality in prefix verbs, as in other complex word forms and multiword expressions (Bannard et al., 2003; Creutz and Lagus, 2005; Fazly et al., 2009; Xu et al., 2009).

We adopt a definition of compositionality specifically designed to support downstream applications that might benefit from knowledge of verb stems. For example, suppose our corpus contains the following sentence: “Pope Clement VII denied Henry VIII permission to marry again before a decision was given in Rome.” A user might submit the question, “Which pope refused Henry VIII permission to remarry?” If we can determine that the meaning of *remarry* could also be provided via the stem *marry*, we could add *marry* to our search terms. This is known as *morphological query expansion* (Bilotti et al., 2004). Here, such an expansion leads to a better match between question and answer.

Previous work has shown that “full morphological analysis provides at most very modest benefits for retrieval” (Manning et al., 2008). Stemming, lemmatization, and compound-splitting often increase recall at the expense of precision, but the results depend on the morphological complexity of the text’s language (Hollink et al., 2004).

The lack of success in applying morphological analysis in IR is unsurprising given that most previous systems are not designed with applications in mind. For example, the objective of the influential *Linguistica* program is “to produce an output that matches as closely as possible the analysis that would be given by a human morphologist” (Goldsmith, 2001). Unsupervised systems achieve this aim by exploiting learning biases such as minimum description length for lexicons (Goldsmith, 2001; Creutz and Lagus, 2007) and high entropy across morpheme boundaries (Keshava and Pitler, 2006). Supervised approaches learn directly from words annotated by morphologists (Van den Bosch and Daelemans, 1999; Toutanova and Cherry, 2009), often using CELEX, a lexical database that includes

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 293–303,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

morphological information (Baayen et al., 1996).

The conventional approach in morphology is to segment words into separate morphemes even when the words are not entirely compositional combinations of their parts (Creutz and Lagus, 2005). For example, while *co-* is considered a separate morpheme in the verb *cooperate*, the meaning of *cooperate* is not simply *to operate jointly*. These forms are sometimes viewed as *perturbations* of composition (de Marken, 1996). In practice, a user may query, "Which nations do not cooperate with the International Criminal Court?" An expansion of the query to include *operate* may have undesirable consequences.

Rather than relying on conventional standards, we present an algorithm whose objective is to find only those prefix verbs that exhibit semantic compositionality; i.e., prefix verbs that are fully meaning-preserving, sums-of-their-parts. We produce a new corpus, annotated according to this definition. We use these annotated examples to learn a discriminative model of semantic compositionality.

Our classifier relies on a variety of features that exploit the distributional patterns of verbs and stems. We build on previous work that applies semantics to morphology (Yarowsky and Wicentowski, 2000; Schone and Jurafsky, 2001; Baroni et al., 2002), and also on work that exploits web-scale data for semantic analysis (Turney, 2001; Nakov, 2007; Kummerfeld and Curran, 2008). For example, we measure how often a prefix verb appears with a hyphen between the prefix and stem. We also look at the distribution of the stem as a separate word: we calculate the probability of the prefix verb and the separated stem's co-occurrence in a segment of discourse; we also calculate the distributional similarity between the verb and the separated stem. High scores for these measures indicate compositionality. We extract counts from a web-scale N-gram corpus, allowing us to efficiently leverage huge volumes of unlabeled text.

Our system achieves 93.6% accuracy on held-out data, well above several baselines and comparison systems. We also train and test our system on conventional morphological segmentations. Our classifier remains reliable in this setting, making half as many errors as the state-of-the-art unsupervised Morfessor system (Creutz and Lagus, 2007).

2 Problem Definition and Setting

A prefix verb is a derived word with a bound morpheme as prefix. While derivation can change both the meaning and part-of-speech of a word (as opposed to inflection, which does not change "referential or cognitive meaning" (Katamba, 1993)), here the derived form remains a verb.

We define prefix-verb compositionality as a semantic equivalence between a verb and a paraphrase involving the verb's stem. The stem must be used as a verb in the paraphrase. Words can be introduced, if needed, to account for the meaning contributed by the prefix, e.g., *outbuild⇒build more/better/faster than*. A bidirectional entailment between the prefix verb and the paraphrase is required.

Words can have different meanings in different contexts. For example, a nation might "*resort* to force," (non-compositional) while a computer program can "*resort* a linked list" (compositional). We therefore define prefix-verb compositionality as a context-specific property of verb tokens rather than a global property of verb types. However, it is worth noting that we ultimately found the compositionality of types to be very consistent across contexts (Section 5.1.2), and we were unable to leverage contextual information to improve classification accuracy; our final system is essentially type-based. Other recent morphological analyzers have also been type-based (Keshava and Pitler, 2006; Poon et al., 2009).

Our system takes as input a verb token in uninflected form along with its sentence as context. The verb must be divisible into an initial string and a following remainder such that the initial string is on our list of prefixes and the remainder is on our list of stems. Hyphenation is allowed, e.g., both *re-enter* and *reenter* are acceptable inputs. The system determines whether the prefix/stem combination is compositional in the current context. For example, the verb *unionize* in, "The workers must unionize," can be divided into a prefix *un-* and a stem *ionize*. The system should determine that here *unionize* is not a compositional combination of these parts.

The algorithm requires a list of prefixes and stems in a given language. For our experiments, we use both dictionary and corpus-based methods to construct these lists (Section 4).

3 Supervised Compositionality Detection

We use a variety of lexical and statistical information when deciding whether a prefix verb is compositional. We adopt a discriminative approach. We assume some labeled examples are available to train a classifier. Relevant information is encoded in a feature vector, and a learning algorithm determines a set of weights for the features using the training data. As compositionality is a binary decision, we can adopt any standard package for binary classification. In our experiments we use support vector machines.

Our features include both local information that depends only on the verb string (sometimes referred to as lexical features) and also global information that depends on the verb and the stem's distribution in text. Our approach can therefore be regarded as a simple form of semi-supervised learning; we leverage both a small number of labeled examples and a large volume of unlabeled text.

If a frequency or similarity is undefined in our corpus, we indicate this with a separate feature; weights on these features act as a kind of smoothing.

3.1 Features based on Web-Scale N-gram Data

We use web-scale N-gram data to extract distributional features. The most widely-used N-gram corpus is the Google 5-gram Corpus (Brants and Franz, 2006). We use *Google V2*: a new N-gram corpus (also with N-grams of length one-to-five) created from the same one-trillion-word snapshot of the web as the Google 5-gram Corpus, but with enhanced filtering and processing of the source text (Lin et al., 2010). For Google V2, the source text was also part-of-speech tagged, and the resulting part-of-speech tag distribution is included for each N-gram. There are 4.1 billion N-grams in the corpus.

The part-of-speech tag distributions are particularly useful, as they allow us to collect verb-specific counts. For example, while a string like *reuse* occurs 1.1 million times in the web corpus, it is only tagged as a verb 270 thousand times. Conflating the noun/verb senses can lead to misleading scores for certain features. E.g., the hyphenation frequency of *re-use* would appear relatively low, even though *reuse* is semantically compositional.

Lin et al. (2010) also provide a high-coverage, 10-million-phrase set of clusters extracted from the N-grams; we use these for our similarity features (Section 3.1.3). There are 1000 clusters in total. The data does not provide the context vectors for each phrase; rather, each phrase is listed with its 20 most similar clusters, measured by cosine similarity with the cluster centroid. We use these centroid similarities as values in a 1000-dimensional cluster-membership feature space. To calculate the similarity between two verbs, we calculate the cosine similarity between their cluster-membership vectors.

The feature classes in the following four subsections each make use of web-scale N-gram data.

3.1.1 HYPH features

Hyphenated verbs are usually compositional (e.g., *re-elect*). Of course, a particular instance of a compositional verb may or may not occur in hyphenated form. However, across a large corpus, compositional prefix verbs tend to occur in a hyphenated form more often than do non-compositional prefix verbs. We therefore provide real-valued features for how often the verb was hyphenated and unhyphenated on the web. For example, we collect counts for the frequencies of *re-elect* (33K) and *reelect* (9K) in our web corpus, and we convert the frequencies to log-counts. We also give real-valued features for the hyphenated/unhyphenated log-counts using only those occurrences of the verb that were *tagged* as a verb, exploiting the tag distributions in our web corpus as described above.

Nakov and Hearst (2005) previously used hyphenation counts as an indication of a syntactic relationship between nouns. In contrast, we leverage hyphenation counts as an indication of a semantic property of verbs.

3.1.2 COOC features

COOC features, and also the SIM (Section 3.1.3) and YAH (Section 3.2.2) features, concern the association in text between the prefix verb and its stem, where the stem occurs as a separate word. We call this the separated stem.

If a prefix verb is compositional, it is more likely to occur near its separated stem in text. We often see *agree* and *disagree*, *read* and *reread*, etc. occurring in the same segment of discourse. We create features for the association of the prefix verb and its separated stem in a discourse. We include the log-count of how often the verb and stem occur in the same N-gram (of length 2-to-5) in our N-gram corpus. Note that the 2-to-4-gram counts are not strictly a subset of the 5-gram counts, since fewer 5-grams pass the data's minimum frequency threshold.

We also include a real-valued pointwise mutual information (PMI) feature for the verb and separated stem's co-occurrence in an N-gram. For the PMI, we regard occurrence in an N-gram as an event, and calculate the probability that a verb and separated stem jointly occur in an N-gram, divided by the probability of their occurring in an N-gram independently.

3.1.3 SIM features

If a prefix verb is compositional, it should occur in similar contexts to its stem. The idea that a stem and stem+affix should be semantically similar has been exploited previously for morphological analysis (Schone and Jurafsky, 2000). We include a real-valued feature for the distributional similarity of the verb and stem using Lin's thesaurus (Lin, 1998). The coverage of this measure was low: it was non-zero for only 93 of the 1000 prefix verbs in our training set. We therefore also include distributional similarity calculated using the web-scale 10-million-phrase clustering as described above. Using this data, similarity is defined for 615 of the 1000 training verbs. We also explored a variety of WordNet-based similarity measures, but these ultimately did not prove helpful on development data.

3.1.4 FRQ features

We include real-valued features for the raw frequencies of the verb and the stem on the web. If these frequencies are widely different, it may indicate a non-compositional usage. Yarowsky and Wicentowski (2000) use similar statistics to identify words related by inflection, but they gather their counts from a much smaller corpus. In addition, higher-frequency prefix verbs may be *a priori* more likely to be non-compositional. A certain frequency is required for an irregular usage to become familiar to language speakers. The potential correlation between frequency and non-compositionality could thus also be exploited by the classifier via the FRQ features.

3.2 Other Features

3.2.1 LEX features

We provide lexical features for various aspects of a prefix verb. Binary features indicate the occurrence of particular verbs, prefixes, and stems, and whether the prefix verb is hyphenated. While hyphenated prefix verbs are usually compositional, even non-compositional prefix verbs may be hyphenated if the prefix and stem terminate and begin with a vowel, respectively. For example, non-compositional uses of *co-operate* are often hyphenated, whereas the compositional *remarry* is rarely hyphenated. We therefore have indicator features for the conjunction of the prefix and the first letter of the stem (e.g., *co-o*), and also for the prefix conjoined with a flag indicating whether the stem begins with a vowel (e.g., *co+vowel*).

3.2.2 YAH features

While the COOC features capture many cases where the verb and separated stem occur in close proximity (especially, but not limited to, conjunctions), there are many other cases where a longer distance might separate a compositional verb and its separated stem. For example, consider the sentence, "Brush the varnish on, but do not overbrush." Here, the verb and separated stem do not co-occur within a 5-gram window, and their co-occurrence will therefore not be recorded in our N-gram corpus. As an approximation for co-occurrence counts within a longer segment of discourse, we count the number of *pages* on the web where the verb and separated stem co-occur. We use hit-counts returned by the Yahoo search engine API.[1] Similar to our COOC features, we include a real-valued feature for the pointwise mutual information of the prefix verb and separated stem's co-occurrence on a web page, i.e., we use Turney's PMI-IR (Turney, 2001).

Baroni et al. (2002) use similar statistics to help discover morphologically-related words. In contrast to our features, however, their counts are derived from source text that is several orders of magnitude smaller in size.

[1] http://developer.yahoo.com/search/boss/

3.2.3 DIC features

One potentially useful resource, when available, is a dictionary of the conventional morphological segmentations of words in the language. Although these segmentations have been created for a different objective than that of our annotations, we hypothesize that knowledge of morphology can help inform our system's predictions. For each prefix verb, we include features for whether or not the prefix and stem are conventionally segmented into separate morphemes, according to a morphological dictionary. Similar to the count-based features, we include a DIC-undefined feature for the verbs that are not in the dictionary; any precompiled dictionary will have imperfect coverage of actual test examples.

Interestingly, DIC features are found to be among our least useful features in the final evaluation.

4 Experiments

4.1 Resources

We use CELEX (Baayen et al., 1996) as our dictionary for the DIC features. We also use CELEX to help extract our lists of prefixes and stems. We take every prefix that is marked in CELEX as forming a new verb by attaching to an existing verb. For stems, we use every verb that occurs in CELEX, but we also extend this list by automatically collecting a large number of words that were automatically tagged as verbs in the NYT section of Gigaword (Graff, 2003). To be included in the extra-verb list, a verb must occur more than ten times and be tagged as a verb more than 70% of the time by a part-of-speech tagger. We thereby obtain 43 prefixes and 6613 stems.[2] We aimed for an automatic, high-precision list for our initial experiments. This procedure is also amenable to human intervention; one could alternatively cast a wider net for possible stems and then manually filter false positives.

4.2 Annotated Data

We carried out a medium-scale annotation to provide training and evaluation data for our experiments.[3] The data for our annotations also comes from the NYT section of Gigaword. We first build a list of possible prefix verbs. We include any verb that a) is composed of a valid prefix and stem; and b) occurs at least twice in the corpus.[4] If the verb occurs less than 50 times in the corpus, we also require that it was tagged as a verb in at least 70% of cases. This results in 2077 possible prefix verbs for annotation.

For each verb type in our list of possible prefix verbs, we randomly select for annotation sentences from Gigaword containing the verb. We take at most three sentences for each verb type so that a few very common types (such as *become*, *understand*, and *improve*) do not comprise the majority of annotated examples. The resulting set of sentences includes a small number of sentences with incorrectly-tagged non-verbs; these are simply marked as non-verbs by our annotators and excluded from our final data sets. A graphical program was created for the annotation; the program automatically links to the online Merriam-Webster dictionary entries for the prefix verb and separated stem. When in doubt about a verb's meaning, our annotators adhere to the dictionary definitions. A single annotator labeled 1718 examples, indicating for each sentence whether the prefix verb was compositional. A second annotator then labeled a random subset of 150 of these examples, and agreement was calculated. The annotators agreed on 137 of the 150 examples. The *Kappa* statistic (Jurafsky and Martin, 2000, page 315), with P(E) computed from the confusion matrices, is 0.82, above the 0.80 level considered to indicate good reliability.

For our experiments, the 1718 annotated examples are randomly divided into 1000 training, 359 development, and 359 held-out test examples.

4.3 Classifier Settings

We train a linear support vector machine classifier using the efficient LIBLINEAR package (Fan et al., 2008). We use L2-loss and L2-regularization. We

[3] Our annotated data is publicly available at: http://www.cs.ualberta.ca/~ab31/verbcomp/

[4] We found that the majority of single-occurrence verbs in the Gigaword data were typos. We would expect true hapax legomena to be largely compositional, and we could potentially derive better statistics if we include them (Baayen and Sproat, 1996). One possible option, employed in previous work, is to ensure words of interest are "manually corrected for typing errors before further analysis" (Baayen and Renouf, 1996).

optimize the choice of features and regularization hyperparameter on development data, attaining a maximum when $C = 0.1$.

4.4 Evaluation

We compare the following systems:

1. **Base1**: always choose compositional (the majority class).
2. **Base2**: for each prefix, choose the majority class over the verbs having that prefix in training data.
3. **Morf**: the unsupervised Morfessor system (Creutz and Lagus, 2007) (Categories-ML, from 110K-word corpus). If Morfessor splits the prefix and stem into separate morphemes, we take the prediction as compositional. If it does anything else, we take it as non-compositional.
4. **SCD**: **S**upervised **C**ompositionality **D**etection: the system proposed in this paper.

We evaluate using *accuracy*: the percentage of examples classified correctly in held-out test data.

5 Results

We first analyze our annotations, gaining insight into the relation between our definition and conventional segmentations. We also note the consistency of our annotations across contexts. We then provide the main results of our system. Finally, we provide the results of our system when trained and tested on conventional morphological segmentations.

5.1 Analysis of Annotations

5.1.1 Annotation consistency with dictionaries

The majority of our examples are not present in a morphological dictionary, even in one as comprehensive as CELEX. The prefix verbs are in CELEX for only 670 of the 1718 total annotated instances.

For those that are in CELEX, Table 1 provides the confusion matrix that relates the CELEX segmentations to our annotations. The table shows that the major difference between our annotations and CELEX is that our definition of compositionality is more strict than conventional morphological segmentations. When CELEX does not segment the prefix from the stem (case 0), our annotations agree in 183 of 193 cases. When CELEX does split the prefix from the stem (case 1), the meaning is semantically compositional in less than half the cases. This is a key difference between conventional morphology and our semantic definition.

		CELEX segmentation	
		1	0
Compositionality	1	227	10
annotation	0	250	183

Table 1: Confusion matrix on the subset of prefix verb annotations that are also in CELEX. **1** indicates that the prefix and stem are segmented into separate morphemes, **0** indicates otherwise.

It is also instructive to analyze the 10 cases that are semantically compositional but which CELEX did not segment. Most of these are verbs that are conventionally viewed as single morphemes because they entered English as complete words. For example, *await* comes from the Old North French *awaitier*, itself from *waitier*. In practice, it is useful to know that *await* is compositional, i.e. that it can be rephrased as *wait for*. Downstream applications can exploit the compositionality of *await*, but miss the opportunity if using the conventional lack of segmentation.

5.1.2 Annotation consistency across contexts

We next analyze our annotated data to determine the consistency of compositionality across different occurrences of the same prefix-verb type. There are 1248 unique prefix verbs in our 1718 labeled examples: 45 verbs occur three times, 380 occur twice and 823 occur only once. Of the 425 verbs that occur multiple times, only 6 had different annotations in different examples (i.e., six verbs occur in both compositional and non-compositional usages in our dataset). These six instances are subtle, debatable, and largely uninteresting, depending on distinctions like whether the *proclaim* sense of *blazon* can substitute for the *celebrate* sense of *emblazon*, etc.

It is easy to find clearer ambiguities online, such as compositional examples of typically non-compositional verbs (how to *recover* a couch, when to *redress* a wound, etc.). However, in our data verbs like *recover* and *redress* always occur in their more dominant non-compositional sense. People may

Set	#	Base1	Base2	Morf	SCD
Test	359	65.7	87.2	73.8	93.6
∈ CELEX	128	30.5	73.4	50.8	89.8
∉ CELEX	231	85.3	94.8	86.6	95.7
∈ train	107	69.2	93.5	74.8	97.2
∉ train	252	64.3	84.5	73.4	92.1

Table 2: Number of examples (#) and accuracy (%) on test data, and on in-CELEX vs. not-in-CELEX, and in-training-data vs. not-in-training splits.

consciously or unconsciously recognize the possibility for confusion and systematically hyphenate prefixes from the stem if a less-common compositional usage is employed. For example, our data has "*repress* your feelings" for the non-compositional case but the hyphenated "*re-press* the center" for the compositional usage.[5]

Due to the consistency of compositionality across contexts, context-based *features* may simply not be very useful for classification. All the features we describe in Section 3 depend only on the prefix verb itself and not the verb context. Various context-dependent features did not improve accuracy on our development data and were thus excluded from the final system.

5.2 Main Results

The first row of Table 2 gives the results of all systems on test data. SCD achieves 93.6% accuracy, making one fifth as many errors as the majority-class baseline (Base1) and half as many errors as the more competitive prefix-based predictor (Base2). The substantial difference between SCD and Base2 shows that SCD is exploiting much information beyond the trivial memorization of a decision for each prefix. Morfessor performs better than Base1 but significantly worse than Base2. This indicates that state-of-the-art *unsupervised* morphological segmentation is not yet practical for semantic preprocessing. Of course, Morfessor was also designed with a different objective; in Section 5.3 we compare Morfessor and SCD on conventional morphological segmentations.

co-	7	6	100.0
en-	5	2	60.0

Table 3: Total number of examples (# Tot), number of examples that are compositional (# Comp), and accuracy (%) of SCD on test data, by prefix.

We further analyzed the systems by splitting the test data two ways.

First, we separate verbs that occur in our morphological dictionary (∈ CELEX) from those that do not (∉ CELEX). Despite using the dictionary segmentation itself as a feature, the performance of SCD is worse on the ∈ CELEX verbs (89.8%). The comparison systems drop even more dramatically on this subset. The ∈ CELEX verbs comprise the more frequent, irregular verbs in English. Non-compositionality is the majority class on the examples that are in the dictionary.

On the other hand, one would expect verbs that are *not* in a comprehensive dictionary to be largely *compositional*, and indeed most of the ∉ CELEX verbs are compositional. However, there is still much to be gained from applying SCD, which makes a third as many errors as the system which always assigns compositional (95.7% for SCD vs. 85.3% for Base1).

Our second way of splitting the data is to divide our test set into prefix verbs that also occurred in training sentences (∈ train) and those that did not (∉ train). Over 70% did not occur in training. SCD scores 97.2% accuracy on those that did. The classifier is thus able to exploit the consistency of annotations across different contexts (Section 5.1.2). The 92.1% accuracy on the ∉-train portion also shows the features allow the system to generalize well to new, previously-unseen verbs.

Table 3 gives the results of our system on sets of

[5] Note that many examples like *recover*, *repress* and *redress* are only ambiguous in text, not in speech. Pronunciation reduces ambiguity in the same way that hyphens do in text. Conversely, observe that knowledge of compositionality could potentially help speech synthesis.

84.1	90.3	93.3	93.6			
87.5	90.5	93.0				
85.5	89.4					

Table 4: Accuracy (%) of SCD as different feature classes are removed. Performance with all features is 93.6%.

verbs divided according to their prefix. The table includes those prefixes that occurred at least 5 times in the test set. Note that the prefixes have a long tail: these ten prefixes cover only 303 of the 359 test examples. Accuracy is fairly high across all the different prefixes. Note also that the three prefixes *de*-, *un*-, and *dis*- almost always correspond to non-compositional verbs. Each of these prefixes corresponds to a subtle form of negation, and it is usually difficult to paraphrase the negation using the stem. For example, *to demilitarize* does not mean *to not militarize* (or any other simple re-phrasing using the stem as a verb), and so our annotation marks it as non-compositional. Whether such a strict strategy is ultimately best may depend on the target application.

Feature Analysis

We perform experiments to evaluate which features are most useful for this task. Table 4 gives the accuracy of our system as different feature classes are *removed*. A similar table was previously used for feature analysis in Daumé III and Marcu (2005). Each row corresponds to performance with a group of features; each entry is performance with a particular feature class individually removed the group. We remove the least helpful feature class from each group in succession moving group-to-group down the rows.

We first remove the DIC features. These do not impact performance on test data. The last row gives the performance with only HYPH features (85.5, removing LEX), and only LEX features (89.4, removing HYPH). These are found to be the two most effective features for this task, followed by the COOC statistics. The other features, while marginally helpful on development data, are relatively ineffective on the test set. In all cases, removing LEX features hurts the most. Removing LEX not only removes useful stem, prefix, and hyphen information, but it also impairs the ability of the classifier to use the other features to separate the examples.

Base1	Base2	Morf	SCD
76.0	79.6	72.4	86.4

Table 5: Accuracy (%) on CELEX.

5.3 CELEX Experiments and Results

Finally, we train and test our system on prefix verbs where the segmentation decisions are provided by a morphological dictionary. We are interested in whether the strong results of our system could transfer to conventional morphological segmentations. We extract all verbs in CELEX that are valid verbs for our system (divisible into a prefix and verb stem), and take the CELEX segmentation as the label; i.e., whether the prefix and stem are separated into distinct morphemes. We extract 1006 total verbs.

We take 506 verbs for training, 250 verbs as a development set (to tune our classifier's regularization parameter) and 250 verbs as a final held-out test set. We use the same features and classifier as in our main results, except we remove the DIC features which are now the instance labels.

Table 5 shows the performance of our two baseline systems along with Morfessor and SCD. While the majority-class baseline is much higher, the prefix-based baseline is 7% *lower*, indicating that knowledge of prefixes, and lexical features in general, are less helpful for conventional segmentations. In fact, performance only drops 2% when we remove the LEX features, showing that web-scale information alone can enable solid performance on this task. Surprisingly, Morfessor performs worse here, below both baselines and substantially below the supervised system. We confirmed our Morfessor program was generating the same segmentations as the online demo. We also experimented with Linguistica (Goldsmith, 2001), training on a large corpus, but results were worse than with Morfessor.

Accurate segmentation of prefix verbs is clearly part of the mandate of these systems; prefix verb segmentation is simply a very challenging task. Unlike other, less-ambiguous tasks in morphology, a prefix/stem segmentation is plausible for all of our input verbs, since the putative morphemes are by definition valid morphemes in the language.

Overall, the results confirm and extend previous studies that show semantic information is helpful in morphology (Schone and Jurafsky, 2000; Yarowsky and Wicentowski, 2000). However, we reiterate that optimizing systems according to conventional morphology may not be optimal for downstream applications. Furthermore, accuracy is substantially lower in this setting than in our main results. Targeting conventional segmentations may be both more challenging and less useful than focusing on semantic compositionality.

6 Related Work

There is a large body of work on morphological analysis of English, but most of this work does not handle prefixes. Porter's stemmer is a well-known *suffix*-stripping algorithm (Porter, 1980), while publicly-available lemmatizers like *morpha* (Minnen et al., 2001) and PC-KIMMO (Karp et al., 1992) only process inflectional morphology. FreeLing (Atserias et al., 2006) comes with a few simple rules for deterministically stripping prefixes in some languages, but not English (e.g., only *semi*- and *re*- can be stripped when analyzing OOV Spanish verbs).

A number of modern morphological analyzers use supervised machine learning. These systems could all potentially benefit from the novel distributional features used in our model. Van den Bosch and Daelemans (1999) use memory-based learning to analyze Dutch. Wicentowski (2004)'s supervised WordFrame model includes a prefixation component. Results are presented on over 30 languages. Erjavec and Džeroski (2004) present a supervised lemmatizer for Slovene. Dreyer et al. (2008) perform supervised lemmatization on Basque, English, Irish and Tagalog; like us they include results when the set of lemmas is given. Toutanova and Cherry (2009) present a discriminative lemmatizer for English, Bulgarian, Czech and Slovene, but only handle suffix morphology. Poon et al. (2009) present an unsupervised segmenter, but one that is based on a log-linear model that can include arbitrary and interdependent features of the type proposed in our work. We see potential in combining the best elements of both approaches to obtain a system that does not need annotated training data, but can make use of powerful web-scale features.

Our approach follows previous systems for morphological analysis that leverage semantic as well as orthographic information (Yarowsky and Wicentowski, 2000; Schone and Jurafsky, 2001; Baroni et al., 2002). Similar problems also arise in core semantics, such as how to detect the compositionality of multi-word expressions (Lin, 1999; Baldwin et al., 2003; Fazly et al., 2009). Our problem is similar to the analysis of verb-particle constructions or VPCs (e.g., *round up, sell off*, etc.) (Bannard et al., 2003). Web-scale data can be used for a variety of problems in semantics (Lin et al., 2010), including classifying VPCs (Kummerfeld and Curran, 2008).

We motivated our work by describing applications in information retrieval, and here Google is clearly the elephant in the room. It is widely reported that Google has been using stemming since 2003; for example, a search today for *Porter stemming* returns pages describing the *Porter stemmer*, and the returned snippets have words like **stemming**, **stemmer**, and **stem** in bold text. Google can of course develop high-quality lists of morphological variants by paying attention to how users reformulate their queries. User query sessions have previously been used to expand queries using similar terms, such as substituting *feline* for *cat* (Jones et al., 2006). We show that high-quality, IR-friendly stemming is possible even without query data. Furthermore, query data could be combined with our other features for highly discriminative word stemming in context.

Beyond information retrieval, suffix-based stemming and lemmatization have been used in a range of NLP applications, including text categorization, textual entailment, and statistical machine translation. We believe accurate prefix-stripping can also have an impact in these areas.

7 Conclusions and Future Work

We presented a system for predicting the semantic compositionality of prefix verbs. We proposed a new, well-defined and practical definition of compositionality, and we annotated a corpus of sentences according to this definition. We trained a discriminative model to predict compositionality using a range of lexical and web-scale statistical features. Novel features include measures of the frequency of prefix-stem hyphenation, and statistics for the likelihood of the verb and stem co-occurring as separate words in an N-gram. The classifier is highly accurate across a range of prefixes, correctly predicting compositionality for 93.6% of examples.

Our preliminary results provide strong motivation for investigating and applying new distributional features in the prediction of both conventional morphology and in task-directed semantic compositionality. Our techniques could be used on a variety of other complex word forms. In particular, many of our features extend naturally to identifying stem-stem compounds (like *panfry* or *healthcare*). Also, it would be possible for our system to handle inflected forms by first converting them to their lemmas using a morphological analyzer. We could also jointly learn the compositionality of words across their inflections, along the lines of Yarowsky and Wicentowski (2000).

There are also other N-gram-derived features that warrant further investigation. One source of information that has not previously been exploited is the "lexical fixedness" (Fazly et al., 2009) of non-compositional prefix verbs. If prefix verbs are rarely rephrased in another form, they are likely to be non-compositional. For example, in our N-gram data, the count of *quest again* is relatively low compared to the count of *request*, indicating *request* is non-compositional. On the other hand, *marry again* is relatively frequent, indicating that *remarry* is compositional. Incorporation of these and other N-gram counts could further improve classification accuracy.

Joint Inference for Bilingual Semantic Role Labeling

Tao Zhuang and **Chengqing Zong**
National Laboratory of Pattern Recognition
Institute of Automation, Chinese Academy of Sciences
{tzhuang, cqzong}@nlpr.ia.ac.cn

Abstract

We show that jointly performing semantic role labeling (SRL) on bitext can improve SRL results on both sides. In our approach, we use monolingual SRL systems to produce argument candidates for predicates in bitext at first. Then, we simultaneously generate SRL results for two sides of bitext using our joint inference model. Our model prefers the bilingual SRL result that is not only reasonable on each side of bitext, but also has more consistent argument structures between two sides. To evaluate the consistency between two argument structures, we also formulate a log-linear model to compute the probability of aligning two arguments. We have experimented with our model on Chinese-English parallel PropBank data. Using our joint inference model, F1 scores of SRL results on Chinese and English text achieve 79.53% and 77.87% respectively, which are 1.52 and 1.74 points higher than the results of baseline monolingual SRL combination systems respectively.

1 Introduction

In recent years, there has been an increasing interest in SRL on several languages. However, little research has been done on how to effectively perform SRL on bitext, which has important applications including machine translation (Wu and Fung, 2009). A conventional way to perform SRL on bitext is performing SRL on each side of bitext separately, as has been done by Fung et al. (2007) on Chinese-English bitext. However, it is very difficult to obtain good SRL results on both sides of bitext in this way. The reason is that even the state-of-the-art SRL systems do not have very high accuracy on both English text (Màrquez et al., 2008; Pradhan et al., 2008; Punyakanok et al., 2008; Toutanova et al., 2008), and Chinese text (Che et al., 2008; Xue, 2008; Li et al., 2009; Sun et al., 2009).

On the other hand, the semantic equivalence between two sides of bitext means that they should have consistent predicate-argument structures. This bilingual argument structure consistency can guide us to find better SRL results. For example, in Figure 1(a), the argument structure consistency can guide us to choose a correct SRL result on Chinese side. Consistency between two argument structures is reflected by sound argument alignments between them, as shown in Figure 1(b). Previous research has shown that bilingual constraints can be very helpful for parsing (Burkett and Klein, 2008; Huang et al., 2008). In this paper, we show that the bilingual argument structure consistency can be leveraged to substantially improve SRL results on both sides of bitext.

Formally, we present a joint inference model to preform bilingual SRL. Using automatic word alignment on bitext, we first identify a pair of predicates that align with each other. And we use monolingual SRL systems to produce argument candidates for each predicate. Then, our model jointly generate SRL results for both predicates from their argument candidates, using integer linear programming (ILP) technique. An overview of our approach is shown in Figure 2.

Our joint inference model consists of three components: the source side, the target side, and the ar-

(a) Word alignment and SRL results for a Chinese-English predicate pair.

(b) Argument alignments for a Chinese-English predicate pair.

Figure 1: An example from Chinese-English parallel PropBank. In (a), the SRL results are generated by the state-of-the-art monolingual SRL systems. The English SRL result is correct. But it is to more difficult to get correct SRL result on Chinese side, because the AM-TMP argument embeds into a discontinuous A1 argument. The Chinese SRL result in the row marked by 'R1' is correct and consistent with the result on English side. Whereas the result in the row marked by 'R2' is incorrect and inconsistent with the result on English side, with the circles showing their inconsistency. The argument structure consistency can guide us to choose the correct Chinese SRL result.

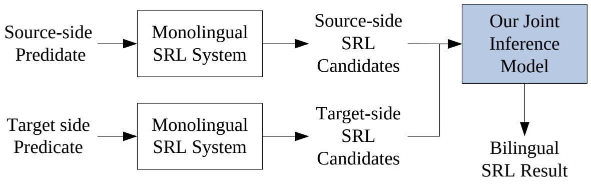

Figure 2: Overview of our approach.

gument alignment between two sides. These three components correspond to three interrelated factors: the quality of the SRL result on source side, the quality of the SRL result on target side, and the argument structure consistency between the SRL results on both sides. To evaluate the consistency between the two argument structures in our joint inference model, we formulate a log-linear model to compute the probability of aligning two arguments. Experiments on Chinese-English parallel PropBank shows that our model significantly outperforms monolingual SRL combination systems on both Chinese and English sides.

The rest of this paper is organized as follows: Section 2 introduces related work. Section 3 describes how we generate SRL candidates on each side of bitext. Section 4 presents our joint inference model. Section 5 presents our experiments. And Section 6 concludes our work.

2 Related Work

Some existing work on monolingual SRL combination is related to our work. Punyakanok et al. (2004; 2008) formulated an ILP model for SRL. Koomen et al. (2005) combined several SRL outputs using ILP method. Màrquez et al. (2005) and Pradhan et al. (2005) proposed combination strategies that are not based on ILP method. Surdeanu et al. (2007) did a complete research on a variety of combination strategies. Zhuang and Zong (2010) proposed a minimum error weighting combination strategy for Chinese SRL combination.

Research on SRL utilizing parallel corpus is also related to our work. Padó and Lapata (2009) did research on cross-lingual annotation projection on English-German parallel corpus. They performed SRL only on the English side, and then mapped the English SRL result to German side. Fung et al. (2007) did pioneering work on studying argument alignment on Chinese-English parallel PropBank. They performed SRL on Chinese and English sides separately. Then, given the SRL result on both sides, they automatically induced the argument alignment between two sides.

The major difference between our work and all existing research is that our model performs SRL inference on two sides of bitext simultaneously. In our model, we jointly consider three interrelated factors: SRL result on the source side, SRL result on the target side, and the argument alignment between them.

3 Generating Candidates for Inference

3.1 Monolingual SRL System

As shown in Figure 2, we need to use a monolingual SRL system to generate candidates for our joint inference model. We have implemented a monolingual SRL system which utilize full phrase-structure parse trees to perform SRL. In this system, the whole SRL process is comprised of three stages: pruning, argument identification, and argument classification. In the pruning stage, the heuristic pruning method in (Xue, 2008) is employed. In the argument identification stage, a number of argument locations are identified in a sentence. In the argument classification stage, each location identified in the previous stage is assigned a semantic role label. Maximum entropy classifier is employed for both the argument identification and classification tasks. And Zhang Le's MaxEnt toolkit[1] is used for implementation.

We use the monolingual SRL system described above for both Chinese and English SRL tasks. For the Chinese SRL task, the features used in this paper are the same with those used in (Xue, 2008). For the English SRL task, the features used are the same with those used in (Pradhan et al., 2008).

3.2 Output of the Monolingual SRL System

The maximum entropy classifier in our monolingual SRL system can output classification probabilities. We use the classification probability of the argument classification stage as an argument's probability. As illustrated in Figure 3, in an individual system's output, each argument has three attributes: its location in sentence loc, represented by the number of its first word and last word; its semantic role label l; and its probability p.

So each argument outputted by a system is a triple (loc, l, p). For example, the `A0` argument in Figure 3 is $((0, 2), \texttt{A0}, 0.94)$. Because these outputs are to be combined, we call such triple a **candidate**.

Sent:	外商 投资 企业	成为	中国 外贸 重要 增长点
Args:	[A0]	[Pred]	[A1]
loc:	(0, 2)		(4, 7)
l:	A0		A1
p:	0.94		0.92

Figure 3: Three attributes of an output argument: location loc, label l, and probability p.

3.3 Generating and Merging Candidates

To generate candidates for joint inference, we need to have multiple SRL results on each side of bitext. Therefore, for both Chinese and English SRL systems, we use the 3-best parse trees of Berkeley parser (Petrov and Klein, 2007) and 1-best parse trees of Bikel parser (Bikel, 2004) and Stanford parser (Klein and Manning, 2003) as inputs. All the three parsers are multilingual parsers. The second and third best parse trees of Berkeley parser are used for their good quality. Therefore, each monolingual SRL system produces 5 different outputs.

Candidates from different outputs may have the same loc and l but different p. So we merge all candidates with the same loc and l into one by averaging their probabilities. For a merged candidate (loc, l, p), we say that p is **the probability of assigning l to loc.**

4 Joint Inference Model

Our model can be conceptually decomposed to three components: the source side, the target side, and the argument alignment. The objective function of our joint inference model is the weighted sum of three sub-objectives:

$$\max\ O_s + \lambda_1 O_t + \lambda_2 O_a \tag{1}$$

where O_s and O_t represent the quality of the SRL results on source and target sides, and O_a represents the soundness of the argument alignment between the SRL results on two sides, λ_1, λ_2 are positive weights corresponding to the importance of O_t and O_a respectively.

4.1 Components of Source and Target Sides

4.1.1 Source Side Component

The source side component aims to improve the SRL result on source side. This is equivalent to a

[1] http://homepages.inf.ed.ac.uk/lzhang10/maxent_toolkit .html

monolingual SRL combination problem.

For convenience, we denote the whole semantic role label set for source language as $\{l_1^s, l_2^s, \ldots, l_{L_s}^s\}$, in which $l_1^s \sim l_6^s$ stand for the key argument labels `A0` $\sim$ `A5` respectively. Suppose there are N_s different locations, denoted as $loc_1^s, \ldots, loc_{N_s}^s$, among all candidates on the source side. The probability of assigning l_j^s to loc_i^s is p_{ij}^s. An indicator variable x_{ij} is defined as:

$$x_{ij} = [loc_i^s \text{ is assigned label } l_j^s].$$

Then the source side sub-objective O_s in equation (1) is the sum of arguments' probabilities on source side:

$$O_s = \sum_{i=1}^{N_s} \sum_{j=1}^{L_s} (p_{ij}^s - T_s) x_{ij} \tag{2}$$

where T_s is a bias to prevent including too many candidates in solution (Surdeanu et al., 2007).

We consider the following two linguistically motivated constraints:

1. *No duplication*: There is no duplication for key arguments: `A0` $\sim$ `A5`.

2. *No overlapping*: Arguments cannot overlap with each other.

In (Punyakanok et al., 2004), several more constraints are considered. According to (Surdeanu et al., 2007), however, no significant performance improvement can be obtained by considering more constraints than the two above. So we do not consider other constraints.

The inequalities in (3) make sure that each loc_i^s is assigned at most one label.

$$\forall 1 \le i \le N_s : \sum_{j=1}^{L_s} x_{ij} \le 1 \tag{3}$$

The inequalities in (4) satisfy the *No duplication* constraint.

$$\forall 1 \le j \le 6 : \sum_{i=1}^{N_s} x_{ij} \le 1 \tag{4}$$

For any source side location loc_i^s, let C_i denote the index set of the locations that overlap with it. Then the *No overlapping* constraint means that if loc_i^s is assigned a label, i.e., $\sum_{j=1}^{N_s} x_{ij} = 1$, then for any $u \in C_i$, loc_u^s cannot be assigned any label, i.e., $\sum_{j=1}^{N_s} x_{uj} = 0$. A common technique in ILP modeling to form such a constraint is to use a sufficiently large auxiliary constant M. And the constraint is formulated as:

$$\forall 1 \le i \le N_s : \sum_{u \in C_i} \sum_{j=1}^{L_s} x_{uj} \le (1 - \sum_{j=1}^{L_s} x_{ij}) M \tag{5}$$

In this case, M only needs to be larger than the number of candidates to be combined. In this paper, $M = 500$ is large enough.

4.1.2 Target Side Component

In principle, the target side component of our joint inference model is the same with the source side component.

The whole semantic role label set for target language is denoted by $\{l_1^t, l_2^t, \ldots, l_{L_t}^t\}$. There are N_t different locations, denoted as $loc_1^t, \ldots, loc_{N_t}^t$, among all candidates in the target side. And $l_1^t \sim l_6^t$ stand for the key argument labels `A0` $\sim$ `A5` respectively. The probability of assigning l_j^t to loc_k^t is p_{kj}^t. An indicator variable y_{kj} is defined as:

$$y_{kj} = [loc_k^t \text{ is assigned label } l_j^t].$$

Then the target side sub-objective O_t in equation (1) is:

$$O_t = \sum_{k=1}^{N_t} \sum_{j=1}^{L_t} (p_{kj}^t - T_t) y_{kj} \tag{6}$$

The constraints on target side are as follows:

Each loc_k^t is assigned at most one label:

$$\forall 1 \le k \le N_t : \sum_{j=1}^{L_t} y_{kj} \le 1 \tag{7}$$

The *No duplication* constraint:

$$\forall 1 \le j \le 6 : \sum_{k=1}^{N_t} y_{kj} \le 1 \tag{8}$$

The *No overlapping* constraint:

$$\forall 1 \le k \le N_t : \sum_{v \in C_k} \sum_{j=1}^{L_t} y_{vj} \le (1 - \sum_{j=1}^{L_t} y_{kj}) M \tag{9}$$

In (9), C_k denotes the index set of the locations that overlap with loc_k^t, and the constant M is set to 500 in this paper.

4.2 Argument Alignment

The argument alignment component is the core of our joint inference model. It gives preference to the bilingual SRL results that have more consistent argument structures.

For a source side argument $arg_i^s = (loc_i^s, l^s)$ and a target side argument $arg_k^t = (loc_k^t, l^t)$, let z_{ik} be the following indicator variable:

$$z_{ik} = [arg_i^s \text{ aligns with } arg_k^t].$$

We use p_{ik}^a to represent the probability that arg_i^s and arg_k^t align with each other, i.e., $p_{ik}^a = P(z_{ik} = 1)$. We call p_{ik}^a the **argument alignment probability between** arg_i^s **and** arg_k^t.

4.2.1 Argument Alignment Probability Model

We use a log-linear model to compute the argument alignment probability p_{ik}^a between arg_i^s and arg_k^t. Let (s, t) denote a bilingual sentence pair and wa denote the word alignment on (s, t). Our log-linear model defines a distribution on z_{ik} given the tuple $tup = (arg_i^s, arg_k^t, wa, s, t)$:

$$P(z_{ik}|tup) \propto \exp(w^T \phi(tup))$$

where $\phi(tup)$ is the feature vector. With this model, p_{ik}^a can be computed as $p_{ik}^a = P(z_{ik} = 1|tup)$.

In order to study the argument alignment in corpus and to provide training data for our log-linear model, we have manually aligned the arguments in 60 files (chtb_0121.fid to chtb_0180.fid) of Chinese-English parallel PropBank. On this data set, we get the argument alignment matrix in Table 1.

Ch\En	A0	A1	A2	A3	A4	AM⋆	NUL
A0	492	30	4	0	0	0	46
A1	98	853	43	2	0	0	8
A2	9	57	51	1	0	47	0
A3	1	0	2	6	0	0	0
A4	0	0	2	0	3	0	0
AM⋆	0	2	39	0	0	895	221
NUL	53	14	27	0	0	45	0

Table 1: The argument alignment matrix on manually aligned corpus.

Each entry in Table 1 is the number of times for which one type of Chinese argument aligns with one type of English argument. AM⋆ stands for all adjuncts types like AM-TMP, AM-LOC, etc., and NUL means that the argument on the other side cannot be aligned with any argument on this side. For example, the number 46 in the A0 row and NUL column means that Chinese A0 argument cannot be aligned with any argument on English side for 46 times in our manually aligned corpus.

We use the following features in our model.

Word alignment feature: If there are many word-to-word alignments between arg_i^s and arg_k^t, then it is very probable that arg_i^s and arg_k^t would align with each other. We adopt the method used in (Padó and Lapata, 2009) to measure the word-to-word alignments between arg_i^s and arg_k^t. And the word alignment feature is defined as same as the *word alignment-based word overlap* in (Padó and Lapata, 2009). Note that this is a real-valued feature.

Head word alignment feature: The head word of an argument is usually more representative than other words. So we use whether the head words of arg_i^s and arg_k^t align with each other as a binary feature. The use of this feature is inspired by the work in (Burkett and Klein, 2008).

Semantic role labels of two arguments: From Table 1, we can see that semantic role labels of two arguments are a good indicator of whether they should align with each other. For example, a Chinese A0 argument aligns with an English A0 argument most of the times, and never aligns with an English AM⋆ argument in Table 1. Therefore, the semantic role labels of arg_i^s and arg_k^t are used as a feature.

Predicate verb pair: Different predicate pairs have different argument alignment patterns. Let's take the Chinese predicate *增长/zengzhang* and the English predicate *grow* as an example. The argument alignment matrix for all instances of the Chinese-English predicate pair (*zengzhang*, *grow*) in our manually aligned corpus is shown in Table 2.

CH \EN	A0	A1	A2	AM⋆	NUL
A0	0	16	0	0	0
A1	0	0	12	0	0
AM⋆	0	0	4	7	10
NUL	0	0	0	2	0

Table 2: The argument alignment matrix for the predicate pair (*zengzhang*, *grow*).

From Table 2 we can see that all A0 arguments of *zengzhang* align with A1 arguments of *grow*. This is very different from the results in Table 1, where a Chinese A0 argument tends to align with an English A0 argument. This phenomenon shows that a predicate pair can determine which types of arguments should align with each other. Therefore, we use the predicate pair as a feature.

4.2.2 Argument Alignment Component

The argument alignment sub-objective O_a in equation (1) is the sum of argument alignment probabilities:

$$O_a = \sum_{i=1}^{N_s} \sum_{k=1}^{N_t} (p_{ik}^a - T_a) z_{ik} \qquad (10)$$

where T_a is a bias to prevent including too many alignments in final solution, and p_{ik}^a is computed using the log-linear model described in subsection 4.2.1.

O_a reflects the consistency between argument structures on two sides of bitext. Larger O_a means better argument alignment between two sides, thus indicates more consistency between argument structures on two sides.

The following constraints are considered:

1. *Conformity with bilingual SRL result.* For all candidates on both source and target sides, only those that are chosen to be arguments on each side can be aligned.

2. *One-to-many alignment limit.* Each argument can not be aligned with more than 3 arguments.

3. *Complete argument alignment.* Each argument on source side must be aligned with at least one argument on target side, and vice versa.

The *Conformity with bilingual SRL result* constraint is necessary to validly integrate the bilingual SRL result with the argument alignment. This constraint means that if arg_i^s and arg_k^t align with each other, i.e., $z_{ik} = 1$, then loc_i^s must be assigned a label on source side, i.e., $\sum_{j=1}^{L_s} x_{ij} = 1$, and loc_k^t must be assigned a label on target side, i.e., $\sum_{j=1}^{L_t} y_{kj} = 1$. So this constraint can be represented as:

$$\forall 1 \leq i \leq N_s, 1 \leq k \leq N_t : \sum_{j=1}^{L_s} x_{ij} \geq z_{ik} \qquad (11)$$

$$\forall 1 \leq k \leq N_t, 1 \leq i \leq N_s : \sum_{j=1}^{L_t} y_{kj} \geq z_{ik} \qquad (12)$$

The *One-to-many alignment limit* constraint comes from our observation on manually aligned corpus. We have found that no argument aligns with more than 3 arguments in our manually aligned corpus. This constraint can be represented as:

$$\forall 1 \leq i \leq N_s : \sum_{k=1}^{N_t} z_{ik} \leq 3 \qquad (13)$$

$$\forall 1 \leq k \leq N_t : \sum_{i=1}^{N_s} z_{ik} \leq 3 \qquad (14)$$

The *Complete argument alignment* constraint comes from the semantic equivalence between two sides of bitext. For each source side location loc_i^s, if it is assigned a label, i.e., $\sum_{j=1}^{L_s} x_{ij} = 1$, then it must be aligned with some arguments on target side, i.e., $\sum_{k=1}^{N_t} z_{ik} \geq 1$. This can be represented as:

$$\forall 1 \leq i \leq N_s : \sum_{k=1}^{N_t} z_{ik} \geq \sum_{j=1}^{L_s} x_{ij} \qquad (15)$$

Similarly, each target side argument must be aligned to at least one source side argument. This can be represented as:

$$\forall 1 \leq k \leq N_t : \sum_{i=1}^{N_s} z_{ik} \geq \sum_{j=1}^{L_t} y_{kj} \qquad (16)$$

4.3 Complete Argument Alignment as a Soft Constraint

Although the hard *Complement argument alignment* constraint is ideally reasonable, in real situations this constraint does not always hold. The manual argument alignment result shown in Table 1 indicates that in some cases an argument cannot be aligned with any argument on the other side (see the NUL row and column in Table 1). Therefore, it would be reasonable to change the hard *Complement argument alignment* constraint to a soft one. To do so, we need to remove the hard *Complement argument alignment* constraint and add penalty for violation of this constraint.

If an argument does not align with any argument on the other side, we say it aligns with NUL. And we define the following indicator variables:

$z_{i,NUL} = [arg_i^s \text{ aligns with NUL}], 1 \leq i \leq N_s$.

$z_{NUL,k} = [arg_k^t$ aligns with $\mathtt{NUL}], 1 \leq k \leq N_t$. Then $\sum_{i=1}^{N_s} z_{i,NUL}$ is the number of source side arguments that align with NUL. And $\sum_{k=1}^{N_t} z_{NUL,k}$ is the number of target side arguments that align with NUL. For each argument that aligns with NUL, we add a penalty λ_3 to the argument alignment sub-objective O_a. Therefore, the sub-objective O_a in equation (10) is changed to:

$$O_a = \sum_{i=1}^{N_s} \sum_{k=1}^{N_t} (p_{ik}^a - T_a) z_{ik} \\ -\lambda_3 (\sum_{i=1}^{N_s} z_{i,NUL} + \sum_{k=1}^{N_t} z_{NUL,k}) \quad (17)$$

From the definition of $z_{i,NUL}$, it is obvious that, for any $1 \leq i \leq N_s$, $z_{i,NUL}$ and $z_{ik}(1 \leq k \leq N_t)$ have the following relationship: If $\sum_{k=1}^{N_t} z_{ik} \geq 1$, i.e., arg_i^s aligns with some arguments on target side, then $z_{i,NUL} = 0$; Otherwise, $z_{i,NUL} = 1$. These relationships can be captured by the following constraints:

$$\forall 1 \leq i \leq N_s, 1 \leq k \leq N_t : z_{i,NUL} \leq 1 - z_{ik} \quad (18)$$

$$\forall 1 \leq i \leq N_s : \sum_{k=1}^{N_t} z_{ik} + z_{i,NUL} \geq 1 \quad (19)$$

Similarly, for any $1 \leq k \leq N_t$, $z_{NUL,k}$ and $z_{ik}(1 \leq i \leq N_s)$ observe the following constraints:

$$\forall 1 \leq k \leq N_t, 1 \leq i \leq N_s : z_{NUL,k} \leq 1 - z_{ik} \quad (20)$$

$$\forall 1 \leq k \leq N_t : \sum_{i=1}^{N_s} z_{ik} + z_{NUL,k} \geq 1 \quad (21)$$

4.4 Models Summary

So far, we have presented two versions of our joint inference model. The first version treats *Complement argument alignment* as a hard constraint. We will refer to this version as *Joint1*. The objective function of *Joint1* is defined by equations (1, 2, 6, 10). And the constraints of *Joint1* are defined by equations (3-5, 7-9, 11-16).

The sencond version treats *Complement argument alignment* as a soft constraint. We will refer to this version as *Joint2*. The objective function of *Joint2* is defined by equations (1, 2, 6, 17). And the constraints of *Joint2* are defined by equations (3-5, 7-9, 11-14, 18-21).

Our baseline models are monolingual SRL combination models. We will refer to the source side combination model as *SrcCmb*. The objective of *SrcCmb* is to maximize O_s, which is defined in equation (2). And the constraints of *SrcCmb* are defined by equations (3-5). Similarly, we will refer to the target side combination model as *TrgCmb*. The objective of *TrgCmb* is to maximize O_t defined in equation (6). And the constraints of *TrgCmb* are defined by equations (7-9). In this paper, we employ lpsolve[2] to solve all ILP models.

5 Experiments

5.1 Experimental Setup

In our experiments, we use the Xinhua News portion of Chinese and English data in LDC OntoNotes Release 3.0. This data is a Chinese-English parallel proposition bank described in (Palmer et al., 2005). It contains parallel proposition annotations for 325 files (chtb_0001.fid to chtb_0325.fid) from Chinese-English parallel Treebank. The English part of this data contains proposition annotations only for verbal predicates. Therefore, we only consider verbal predicates in this paper.

We employ the GIZA++ toolkit (Och and Ney, 2003) to perform automatic word alignment. Besides the parallel PropBank data, we use additional 4,500K Chinese-English sentence pairs[3] to induce word alignments for both directions, with the default GIZA++ settings. The alignments are symmetrized using the intersection heuristic (Och and Ney, 2003), which is known to produce high-precision alignments.

We use 80 files (chtb_0001.fid to chtb_0080.fid) as test data, and 40 files (chtb_0081.fid to chtb_0120.fid) as development data. Although our joint inference model needs no training, we still need to train a log-linear argument alignment probability model, which is used in the joint inference model. As specified in subsection 4.2.1, the train-

[2] http://lpsolve.sourceforge.net/

[3] These data includes the following LDC corpus: LDC2002E18, LDC2003E07, LDC2003E14, LDC2005T06, LDC2004T07, LDC2000T50.

ing set for the argument alignment probability model consists of 60 files (chtb_0121.fid to chtb_0180.fid) with manual argument alignment. Unfortunately, the quality of automatic word alignment on one-to-many Chinese-English sentence pairs is usually very poor. So we only include one-to-one Chinese-English sentence pairs in all data. And not all predicates in a sentence pair can be included. Only bilingual predicate pairs are included. A bilingual predicate pair is defined to be a pair of predicates in bitext which align with each other in automatic word alignment. Table 3 shows how many sentences and predicates are included in each data set.

	Test	Dev	Train
Articles	1-80	81-120	121-180
Chinese Sentences	1067	578	778
English Sentences	1182	620	828
Bilingual pairs	821	448	614
Chinese Predicates	3792	2042	2572
English Predicates	2864	1647	1860
Bilingual pairs	1476	790	982

Table 3: Sentence and predicate counts.

Our monolingual SRL systems are trained separately. Our Chinese SRL system is trained on 640 files (chtb_0121.fid to chtb_0931.fid) in Chinese Propbank 1.0. Because Xinhua News is a quite different domain from WSJ, the training set for our English SRL system includes not only Sections 02∼21 of WSJ data in English Propbank, but also 205 files (chtb_0121.fid to chtb_0325.fid) in the English part of parallel PropBank. For Chinese, the syntactic parsers are trained on 640 files (chtb_0121.fid to chtb_0931.fid) plus the broadcast news portion of Chinese Treebank 6.0. For English, the syntactic parsers are trained on the following data: Sections 02∼21 of WSJ data in English Treebank, 205 files (chtb_0121.fid to chtb_0325.fid) of Xinhua News data in OntoNotes 3.0, and the Sinorama data in OntoNotes 3.0. We treat discontinuous and coreferential arguments in accordance to the CoNLL-2005 shared task (Carreras and Màrquez, 2005). The first part of a discontinuous argument is labeled as it is, and the second part is labeled with a prefix "C-". All coreferential arguments are labeled with a prefix "R-".

5.2 Tuning Parameters in Models

The models *Joint1*, *Joint2*, *SrcCmb*, and *TrgCmb* have different parameters. For each model, we have automatically tuned its parameters on development set using Powell's Mothod (Brent, 1973). Powell's Method is a heuristic optimization algorithm that does not require the objective function to have an explicit analytical formula. For a monolingual model like *SrcCmb* or *TrgCmb*, our objective is to maximize the F_1 score of the model's result on development set. But a joint model, like *Joint1* or *Joint2*, generates SRL results on both sides of bitext. So our objective is to maximize the sum of the two F_1 scores of the model's results for both Chinese and English on development set. For all models, we regard the parameters to be tuned as variables. Then we optimize our objective using Powell's Method. The solution of this optimization is the values of parameters. To avoid finding poor local optimum, we perform the optimization 30 times with different initial parameter values, and choose the best solution found. The final parameter values are listed in Table 4.

Model	T_s	T_t	T_a	λ_1	λ_2	λ_3
SrcCmb	0.21	-	-	-	-	-
TrgCmb	-	0.32	-	-	-	-
Joint1	0.17	0.22	0.36	0.96	1.04	-
Joint2	0.15	0.26	0.42	1.02	1.21	0.15

Table 4: Parameter values in models.

5.3 Individual SRL Outputs' Performance

As specified in subsection 3.3, the monoligual SRL system uses different parse trees to generate multiple SRL outputs. The performance of these outputs on test set is shown in Table 5. In Table 5, O1∼O3 are the outputs using 3-best parse trees of Berkeley parser respectively, O4 and O5 are the outputs using the best parse trees of Stanford parser and Bikel parser respectively.

As specified in subsection 5.1, only a small part of English SRL training data is in the same domain with test data. Therefore, the English SRL result in Table 5 is not very impressive. But the Chinese SRL result is pretty good.

Side	Outputs	P(%)	R(%)	F_1
Chinese	O1	**79.84**	**71.95**	**75.69**
	O2	78.53	70.32	74.20
	O3	78.41	69.99	73.96
	O4	73.21	67.13	70.04
	O5	75.32	63.78	69.07
English	O1	**77.13**	**70.42**	**73.62**
	O2	75.88	69.06	72.31
	O3	75.74	68.65	72.02
	O4	71.57	66.11	68.73
	O5	73.12	68.04	70.49

Table 5: The results of individual monolingual SRL outputs on test set.

5.4 Effects of Different Constraints

The *One-to-many limit* and *Complete argument alignment* constraints in subsection 4.2.2 comes from our empirical knowledge. To investigate the effect of these two constraits, we remove them from our joint inference models one by one, and observe the performance variations on test set. The results are shown in Table 6. In Table 6, 'c2' refers to the *One-to-many limit* constraint, 'c3' refers to the *Complete argument alignment* constraint, and '-' means removing. For example, '*Joint1* - c2' means removing the constraint 'c2' from the model *Joint1*. Recall that the only difference between *Joint1* and *Joint2* is that 'c3' is a hard constraint in *Joint1*, but a soft constraint in *Joint2*. Therefore, '*Joint2* - c3' and '*Joint2* - c2 - c3' do not appear in Table 6, because they are the same with '*Joint1* - c3' and '*Joint1* - c2 - c3' respectively.

Model	Side	P(%)	R(%)	F_1
Joint1	Chinese	82.95	75.21	78.89
Joint1 - c2		81.46	75.97	78.62
Joint1 - c3		82.36	74.68	78.33
Joint1 - c2 - c3		82.04	74.67	78.18
Joint2		**83.35**	**76.04**	**79.53**
Joint2 - c2		82.41	76.03	79.09
Joint1	English	79.38	75.16	77.21
Joint1 - c2		78.51	75.22	76.83
Joint1 - c3		78.66	74.55	76.55
Joint1 - c2 - c3		78.37	74.37	76.32
Joint2		**79.64**	**76.18**	**77.87**
Joint2 - c2		78.41	75.89	77.13

Table 6: Results of different joint models on test set.

From Table 6, we can see that the constraints 'c2' and 'c3' both have positive effect in our joint inference model, because removing any one of them causes performance degradation. And removing 'c3' from *Joint1* causes more performance degradation than removing 'c2'. This means that 'c3' plays a more important role than 'c2' in our joint inference model. Indeed, by treating 'c3' as a soft constraint, the model *Joint2* has the best performance on both sides of bitext.

5.5 Final Results

We use *Joint2* as our final joint inference model. And as specified in subsection 4.4, our baselines are monolingual SRL combination models: *SrcCmb* for Chinese, and *TrgCmb* for English. Note that *SrcCmb* and *TrgCmb* are basically the same as the state-of-the-art combination model in (Surdeanu et al., 2007) with *No overlapping* and *No duplication* constraints. The final results on test set are shown in Table 7.

Side	Model	P(%)	R(%)	F_1
Chinese	*SrcCmb*	82.58	73.92	78.01
	Joint2	**83.35**	**76.04**	**79.53**
English	*TrgCmb*	79.02	73.44	76.13
	Joint2	**79.64**	**76.18**	**77.87**

Table 7: Comparison between monolingual combination model and our joint inference model on test set.

From Table 5 and Table 7, we can see that *SrcCmb* and *TrgCmb* improve F_1 scores over the best individual SRL outputs by 2.32 points and 2.51 points on Chinese and English seperately. Thus they form strong baselines for our joint inference model. Even so, our joint inference model still improves F_1 score over *SrcCmb* by 1.52 points, and over *TrgCmb* by 1.74 points.

From Table 7, we can see that, despite only part of training data for English SRL system is in-domain, our joint inference model still produces good English SRL result. And the F_1 score of Chinese SRL result reaches 79.53%, which represents the state-of-the-art Chinese SRL performance to date.

6 Conclusions

In this paper, we propose a joint inference model to perform bilingual SRL. Our joint inference model incorporates not only linguistic constraints on source and target sides of bitext, but also the bilingual argument structure consistency requirement on bitext. Experiments on Chinese-English parallel PropBank show that our joint inference model is very effective for bilingual SRL. Compared to state-of-the-art monolingual SRL combination baselines, our joint inference model substantially improves SRL results on both sides of bitext. In fact, the solution of our joint inference model contains not only the SRL results on bitext, but also the optimal argument alignment between two sides of bitext. This makes our model especially suitable for application in machine translation, which needs to obtain the argument alignment.

Abstract

This paper presents a method for the automatic discovery of MANNER relations from text. An extended definition of MANNER is proposed, including restrictions on the sorts of concepts that can be part of its domain and range. The connections with other relations and the lexico-syntactic patterns that encode MANNER are analyzed. A new feature set specialized on MANNER detection is depicted and justified. Experimental results show improvement over previous attempts to extract MANNER. Combinations of MANNER with other semantic relations are also discussed.

1 Introduction

Extracting semantic relations from text is an important step towards understanding the meaning of text. Many applications that use no semantics, or only shallow semantics, could benefit by having available more text semantics. Recently, there is a growing interest in text semantics (Màrquez et al., 2008; Davidov and Rappoport, 2008).

An important semantic relation for many applications is the MANNER relation. Broadly speaking, MANNER encodes the mode, style, way or fashion in which something is done or happened. For example, *quick delivery* encodes a MANNER relation, since *quick* is the manner in which the *delivery* happened.

An application of MANNER detection is Question Answering, where many *how* questions refer to this particular relation. Consider for example the question *How did the President communicate his message?*, and the text *Through his spokesman, Obama sent a strong message [. . .]*. To answer such questions, it is useful to identify first the MANNER relations in text.

MANNER occurs frequently in text and it is expressed by a wide variety of lexico-syntactic patterns. For example, PropBank annotates 8,037 ARGM-MNR relations (10.7%) out of 74,980 adjunct-like arguments (ARGMs). There are verbs that state a particular way of doing something, e.g., *to limp* implicitly states a particular way of *walking*. Adverbial phrases and prepositional phrases are the most productive patterns, e.g., *The nation's industrial sector is now growing very slowly if at all* and *He started the company on his own*. Consider the following example: *The company said Mr. Stronach will personally direct the restructuring assisted by Manfred Gingl, [. . .]*[1]. There are two MANNER relations in this sentence: the underlined chunks of text encode the way in which *Mr. Stronach will direct the restructuring*.

2 Previous Work

The extraction of semantic relations in general has caught the attention of several researchers. Approaches to detect semantic relations usually focus on particular lexical and syntactic patterns. There are both unsupervised (Davidov et al., 2007; Turney, 2006) and supervised approaches. The SemEval-2007 Task 04 (Girju et al., 2007) aimed at relations between nominals. Work has been done on detecting relations within noun phrases (Nulty, 2007),

named entities (Hirano et al., 2007), clauses (Szpakowicz et al., 1995) and syntax-based comma resolution (Srikumar et al., 2008). There have been proposals to detect a particular relation, e.g., CAUSE (Chang and Choi, 2006), INTENT (Tatu, 2005), PART-WHOLE (Girju et al., 2006) and IS-A (Hearst, 1992).

MANNER is a frequent relation, but besides theoretical studies there is not much work on detecting it. Girju et al. (2003) propose a set of features to extract MANNER exclusively from adverbial phrases and report a precision of 64.44% and recall of 68.67%. MANNER is a semantic role, and all the works on the extraction of roles (Gildea and Jurafsky, 2002; Giuglea and Moschitti, 2006) extracts MANNER as well. However, these approaches treat MANNER as any other role and do not use any specific features for its detection. As we show in this paper, MANNER has its own unique characteristics and identifying them improves the extraction accuracy. The two most used semantic role annotation resources, FrameNet (Baker et al., 1998) and PropBank (Palmer et al., 2005), include MANNER.

The main contributions of this paper are: (1) empirical study of MANNER and its semantics; (2) analysis of the differences with other relations; (3) lexico-syntactic patterns expressing MANNER; (4) a set of features specialized on the detection of MANNER; and (5) the way MANNER combines with other semantic relations.

3 The Semantics of MANNER Relation

Traditionally, a semantic relation is defined by stating the kind of connection linking two concepts. For example, MANNER is loosely defined by the PropBank annotation guidelines[2] as *manner adverbs specify how an action is performed [...] manner should be used when an adverb be an answer to a question starting with 'how?'*. We find this kind of definition weak and prone to confusion (Section 3.2). Nonetheless, to the best of our knowledge, semantic relations have been mostly defined stating only a vague definition.

Following (Helbig, 2005), we propose an extended definition for semantic relations, including semantic restrictions for its domain and range. These restrictions help deciding which relation holds between a given pair of concepts. A relation shall not hold between two concepts unless they belong to its domain and range. These restrictions are based on theoretical and empirical grounds.

3.1 MANNER Definition

Formally, MANNER is represented as MNR(x, y), and it should be read x *is the manner in which* y *happened*. In addition, DOMAIN(MNR) and RANGE(MNR) are the sets of sorts of concepts that can be part of the first and second argument.

RANGE(MNR), namely y, is restricted to situations, which are defined as *anything that happens at a time and place*. Situations include events and states and can be expressed by verbs or nouns, e.g., *conference*, *race*, *mix* and *grow*. DOMAIN(MNR), namely x, is restricted to qualities (ql), non temporal abstract objects (ntao) and states (st). Qualities represent characteristics that can be assigned to other concepts, such as *slowly* and *abruptly*. Non temporal abstract objects are intangible entities. They are somehow product of human reasoning and are not palpable. They do not encode periods or points of time, such as *week*, or *yesterday*. For example, *odor*, *disease*, and *mile* are ntao; *book* and *car* are not because they are tangible. Unlike events, states are situations that do not imply a change in the concepts involved. For example, *standing there* or *holding hands* are states; whereas *walking to the park* and *pinching him* are events. For more details about these semantic classes, refer to (Helbig, 2005).

These semantic restrictions on MANNER come after studying previous definitions and manual examination of hundreds of examples. Their use and benefits are described in Section 4.

3.2 MANNER and Other Semantic Relations

MANNER is close in meaning with several other relations, specifically INSTRUMENT, AT-LOCATION and AT-TIME.

Asking *how* does not identify MANNER in many cases. For example, given *John broke the window [with a hammer]*, the question *how did John break the window?* can be answered by *with the hammer*, and yet *the hammer* is not the MANNER but the INSTRUMENT of the *broke* event. Other relations that

[2] http://verbs.colorado.edu/˜mpalmer/projects/ace/PBguidelines.pdf, page 26.

may be confused as MANNER include AT-LOCATION and AT-TIME, like in *[The dog jumped]$_x$ [over the fence]$_y$* and *[John used to go]$_x$ [regularly]$_y$*.

A way of solving this ambiguity is by prioritizing the semantic relations among the possible candidates for a given pair of concepts. For example, if both INSTRUMENT and MANNER are possible, the former is extracted. In a similar fashion, AT-LOCATION and AT-TIME could have higher priority than MANNER. This idea has one big disadvantage: the correct detection of MANNER relies on the detection of several other relations, a problem which has proven difficult and thus would unnecessarily introduce errors.

Using the proposed extended definition one may discard the false MANNER relations above. *Hammer* is not a quality, non temporal abstract object or state (*hammers* are palpable objects), so by definition a relation of the form MNR(*the hammer*, *y*) shall not hold. Similarly, *fence* and *week* do not fulfill the domain restriction, so MNR(*over the fence*, *y*) and MNR(*every other week*, *y*) are not valid either.

MANNER also relates to CAUSE. Again, asking *how?* does not resolve the ambiguity. Given *The legislation itself noted that it [was introduced]$_x$ "by request," [...]* (wsj_0041, 47), we believe the underlined PP indicates the CAUSE and not the MANNER of *x* because the *introduction of the legislation* is the effect of the *request*. Using the extended definition, since *request* is an event (it implies a change), MNR(*by request*, *y*) is discarded based on the domain and range restrictions.

4 Argument Extraction

In order to implement domain and range restrictions, one needs to map words to the four proposed semantic classes: situations (si), states (st), qualities (ql) and non temporal abstract objects (ntao). These classes are the ones involved in MNR; work has been done to define in a similar way more relations, but we do not report on that in this paper.

First, the head word of a potential argument is identified. Then, the head is mapped into a semantic class using three sources of information: POS tags, WordNet hypernyms and named entity (NE) types. Table 1 presents the rules that define the mapping. We obtained them following a data-driven approach using a subset of MANNER annotation from PropBank and FrameNet. Intermediate classes are defined to facilitate legibility; intermediate classes ending in -NE only involve named entity types.

Words are automatically POS tagged using a modified Brill tagger. We do not perform word sense disambiguation because in our experiments it did not bring any improvement; all senses are considered for each word. isHypo(x) for a given word *w* indicates if any of the senses of *w* is a hyponym of *x* in WordNet 2.0. An in-house NE recognizer is used to assign NE types. It detects 90 types organized in a hierarchy with an accuracy of 92% and it has been used in a state-of-the-art Question Answering system (Moldovan et al., 2007). As far as the mapping is concerned, only the following NE types are used: *human*, *organization*, *country*, *town*, *province*, *other-loc*, *money*, *date* and *time*. The mapping also uses an automatically built list of verbs and nouns that encode events (verb_events and noun_events).

The procedure to map words into semantic classes has been evaluated on a subset of PropBank which was not used to define the mapping. First, we selected 1,091 sentences which contained a total of 171 MANNER relations. We syntactically parsed the sentences using Charniak's parser and then performed argument detection by matching the trees to the syntactic patterns depicted in Section 5. 52,612 arguments pairs were detected as potential MANNER. Because of parsing errors, 146 (85.4%) of the 171 MANNER relations are in this set.

After mapping and enforcing domain and range constraints, the argument pairs were reduced to 11,724 (22.3%). The filtered subset includes 140 (81.8%) of the 171 MANNER relations. The filtering does make mistakes, but the massive pruning mainly filters out potential relations that do not hold: it filters 77.7% of argument pairs and it only misclassifies 6 pairs.

5 Lexico-Syntactic Patterns Expressing MANNER

MANNER is expressed by a wide variety of lexico-syntactic patterns, implicitly or explicitly.

Table 2 shows the syntactic distribution of MANNER relation in PropBank. We only consider relations between a single node in the syntactic tree and

Class	Rule
situation	`state || event`
state	`POStag=verb || isHypo(state.n.4)`
event	`(POStag=verb && in(verb_events)) || (POStag=noun && !animate_object && (isHypo(phenomenon.n.1) || isHypo(event.n.1) || in(noun_events)))`
animate_object	`livingNE || (POStag=noun && ((isHypo(entity.n.1) && !isHypo(thing.n.9) && !isHypo(anticipation.n.4)) || isHypo(social_group.n.1)))`
livingNE	`neType=(human | organization | country | town | province | other-loc)`
quality	`POStag=(adverb | gerund) || headPP=(with | without)`
non_temporal_abstract_object	`abstract_object && !temporal`
abstract_object	`neType=money || isHypo(thing.n.9) || (!isHypo(social_group.n.1) && (isHypo(abstraction.n.6 | psychological_feature.n.1 | possession.n.2 | event.n.1 | state.n.4 | group.n.1 | act.n.2)))`
temporal	`TemporalNE || isHypo(time_period.n.1) || isHypo(time.n.5)`
temporalNE	`ne-type=(date | time)`

Table 2: Syntactic patterns encoding MANNER in PropBank, number of occurrences, and examples. A total of 7,852 MANNER relations are encoded in PropBank between a single node in the syntactic tree and a verb. In all examples, MNR(x, y) holds, where x is the text underlined. Syntactic annotation comes straight from the Penn TreeBank.

a verb; MANNER relations expressed by trace chains identifying coreference and split arguments are ignored. This way, we consider 7,852 MANNER out of the total of the 8,037 PropBank annotates. Because ADVPs and PPs represent 90% of MANNER relations, in this paper we focus exclusively on these two phrases.

For both ADVP and PP the most common direct ancestor is either a VP or S, although examples are found that do not follow this rule. Table 3 shows the number of occurrences for several parent nodes and examples. Only taking into account phrases whose ancestor is either a VP or S yields a coverage of 98% and thus those are the focus of this work.

5.1 Ambiguities of MANNER

Both ADVPs and PPs are highly ambiguous when the task is to identify their semantics. The PropBank authors (Palmer et al., 2005) report discrepancies between annotators mainly with AT-LOCATION and simply no relation, i.e., when a phrase does not encode a role at all. In their annotation, 22.2% of ADVPs encode MANNER (30.3% AT-TIME), whereas only 4.6% of PPs starting with *in* and 6.1% start-

Parent	#Occ.	Example

Table 3: Examples of ADVPs and PPs encoding MANNER with different nodes as parents. In all examples, MNR(x, y) holds, where x is the underlined phrase. Syntactic annotation comes straight from the Penn TreeBank.

ing with *at* encode MANNER. The vast majority of PPs encode either a AT-TIME or AT-LOCATION.

MANNER relations expressed by ADVPs are easier to detect since the adverb is a clear signal. Adverbs ending in *-ly* are more likely to encode a MANNER. Not surprisingly, the verb they attach to also plays an important role. Section 6.2 depicts the features used.

PPs are more complicated since the preposition per se is not a signal of whether or not the phrase encodes a MANNER. Even prepositions such as *under* and *over* can introduce a MANNER. For example, *A majority of an NIH-appointed panel recommended late last year that the research continue under carefully controlled conditions, [...]* (wsj_0047, 9) and *[...] bars where Japanese revelers sing over recorded music, [...]* (wsj_0300, 3). Note that in both cases, the head of the NP contained in the PP encoding MANNER (*conditions* and *music*) belongs to ntao (Section 4). Other prepositions, like *with* and *like* are more likely to encode a MANNER, but again it is not guaranteed.

6 Approach

We propose a supervised learning approach, where instances are positive and negative MANNER examples. Due to their intrinsic difference, we build different models for ADVPs and PPs.

6.1 Building the Corpus

The corpus building procedure is as follows. First, all ADVPs and PPs whose parent node is a VP or S and encode a MANNER according to PropBank are extracted, yielding 3559 and 3499 positive instances respectively. Then, 10,000 examples of ADVPs and another 10,000 of PPs from the Penn TreeBank not encoding a MANNER according to PropBank are added. These negative instances must have as their parent node either VP or S as well and are selected randomly.

The total number of instances, 13,559 for ADVPs and 13,499 for PPs, are then divided into training (60%), held-out (20%) and test (20%). The held-out portion is used to tune the feature set and the final results provided are the ones obtained with the test portion, i.e., instances that have not been used in any way to learn the models. Because PropBank adds semantic role annotation on top of the Penn TreeBank, we have gold syntactic annotation for all instances.

6.2 Selecting features

Selected features are derived from previous works on detecting semantic roles, namely (Gildea and Jurafsky, 2002) and the participating systems in

No.	Feature	Values	Explanation
1	parent-node	{S, VP}	syntactic node of ADVP's parent
2	num-leaves	ℕ	number of words in ADVP
3	**adverb**	{often, strongly, . . . }	main adverb of ADVP
4	**dictionary**	{yes, no}	is adverb is in dictionary?
5	**ends-with-ly**	{yes, no}	does adverb end in *-ly*?
6	POS-tag-bef	POStags	POS tag word before adverb
7	POS-tag-aft	POStags	POS tag word after adverb
8	verb	{assigned, go, . . . }	main verb the ADVP attaches to
9	distance	ℕ	number of words between adverb and verb

Table 4: Features used for extracting MANNER from ADVPs, their values and explanation. Features 4 and 5 are specialized on MANNER detection.

No.	Feature	Values	Explanation
1	parent-node	{S, VP}	syntactic node of PP's parent
2	next-node	{NP, SBAR, , . . . }	syntactic node of sibling to the right of PP
3	**num-pp-bef**	ℕ	number of sibling before PP which are PP
4	**num-pp-aft**	ℕ	number of sibling after PP which are PP
5	first-word	{with, after, . . . }	first word in PP
6	first-POS-tag	POStags	first POS tag in PP
7	**first-prep**	{by, on, . . . }	first preposition in PP
8	POS-tag-bef	POStags	POS tag before first-word
9	POS-tag-aft	POStags	POs tag after first-word
10	word-aft	{one, their, . . . }	word after first-word
11	**has-rb**	{yes, no}	does the PP contain an adverb?
12	**has-quotes**	{yes, no}	does the PP have any quotes?
13	**head-np-lemma**	{amount, year, . . . }	head of the NP whose parent is the PP
14	**head-is-last**	{yes, no}	is head-np the last word of the sentence?
15	**head-has-cap**	{yes, no}	does the PP have a capitalized word?
16	verb	{approved, fly, . . . }	verb the PP attaches to
17	verb-lemma	{approve, be, . . . }	verb lemma the PP attaches to
18	**verb-pas**	{yes, no}	is verb in passive voice?

Table 5: Features used for extracting MANNER from PPs, their values and explanation. Features in bold letters are new and specialized on detecting MANNER from PPs.

CoNLL-2005 Shared Task (Carreras and Màrquez, 2005), combined with new, manner-specific features that we introduce. These new features bring a significant improvement and are dependent on the phrase potentially encoding a MANNER. Experimentation has shown that MANNER relations expressed by an ADVP are easier to detect than the ones expressed by a PP.

Adverbial Phrases The feature set used is depicted in Table 4. Some features are typical of semantic role labeling, but features adverb, dictionary and ends-with-ly are specialized to MANNER extraction from ADVPs. These three additional features bring a significant improvement (Section 7). We only provide details for the non-obvious features.

The main adverb and verb are retrieved by selecting the last adverb or verb of a sequence. For example, in *more strongly*, the main adverb is *strongly*, and in *had been rescued* the main verb is *rescued*.

Dictionary tests the presence of the adverb in a custom built dictionary which contains all lemmas for adverbs in WordNet whose gloss matches the regular expression *in a .* (manner|way|fashion|style)*. For example, *more.adv.1: used to form the comparative of some adjectives and adverbs* does not belong to the dictionary, and *strongly.adv.1: with strength or in a* *strong manner* does. This feature is an extension of the dictionary presented in (Girju et al., 2003).

Given the sentence *[...] We [work [damn hard]$_{ADVP}$ at what we do for damn little pay]$_{VP}$, and [...]* (wsj_1144, 128), the features are: {parent-node:VP, num-leaves:2, adverb:hard, dictionary:no, ends-with-ly:no, POS-tag-bef:RB, POS-tag-aft:IN, verb:work, distance:1}, and it is a positive instance.

Prepositional Phrases PPs are known to be highly ambiguous and more features need to be added. The complete set is depicted in Table 5.

Some features are typical of semantic role detection; we only provide a justification for the new features added. `Num-pp-bef` and `num-pp-aft` captures the number of PP siblings before and after the PP. The relative order of PPs is typically MANNER, AT-LOCATION and AT-TIME (Hawkins, 1999), and this feature captures this idea without requiring temporal or local annotation.

PPs having quotes are more likely to encode a MANNER, the chunk of text between quotes being the manner. For example, *use in "very modest amounts"* (wsj_0003, 10) and *reward with "page bonuses"* (wsj_0012, 8).

`head-np` indicates the head noun of the NP that attaches to the preposition to form the PP. It is retrieved by selecting the last noun in the NP. Certain nouns are more likely to indicate a MANNER than others. This feature captures the domain restriction. For nouns, only non temporal abstract objects and states can encode a MANNER. Some examples of positive instances are *haul in the guests' [honor]*, *lift in two [stages]*, *win at any [cost]*, *plunge against the [mark]* and *ease with little [fanfare]*. However, counterexamples can be found as well: *say through his [spokesman]* and *do over the [counter]*.

`Verb-pas` indicates if a verb is in passive voice. In that case, a PP starting with *by* is much more likely to encode an AGENT than a MANNER. For example, compare (1) *"When the fruit is ripe, it [falls]$_y$ from the tree [by itself]$_{PP}$," he says.* (wsj_0300, 23); and (2) *Four of the planes [were purchased]$_y$ [by International Lease]$_{PP}$ from Singapore Airlines in a [...] transaction* (wsj_0243, 3). In the first example a MANNER holds; in the second an AGENT.

Given the sentence *Kalipharma is a New Jersey-based pharmaceuticals concern that [sells products [under the Purepac label]$_{PP}$]$_{VP}$.* (wsj_0023, 1), the features are: {parent-node:VP, next-node:-, num-pp-bef:0, num-pp-aft:0, first-word:under, first-POS-tag:IN, first-prep:under, POS-tag-bef:NNS, POS-tag-aft:DT, word-aft:the, has-rb:no, has-quotes:no, head-np-lemma:label, head-is-last:yes, head-has-cap:yes, verb:sells, verb-lemma:sell, verb-pas:no}, and it is a positive instance.

7 Learning Algorithm and Results

7.1 Experimental Results

As a learning algorithm we use a Naive Bayes classifier, well known for its simplicity and yet good performance. We trained our models with the training corpus using 10-fold cross validation, and used the held-out portion to tune the feature set and adjust parameters. More features than the ones depicted were tried, but we only report the final set. For example, named entity recognition and flags indicating the presence of AT-LOCATION and AT-TIME relations for the verb were tried, but they did not bring any significant improvement.

Table 6 summarizes the results obtained. We report results only on the test corpus, which corresponds to instances not seen before and therefore they are a honest estimation of the performance. The improvement brought by subsets of features and statistical significance tests are also reported. We test the significance of the difference in performance between two feature sets i and j on a set of ins instances with the Z-score test, where $z = \frac{abs(err_i, err_j)}{\sigma_d}$, err_k is the error made using set k, and $\sigma_d = \sqrt{\frac{err_i(1-err_i)}{ins} + \frac{err_j(1-err_j)}{ins}}$.

ADVPs The full set of features yields a F-measure of 0.815. The three specialized features (3, 4 and 5) are responsible for an improvement of .168 in the F-measure. This difference in performance yields a Z-score of 7.1, which indicates that it is statistically significant.

PPs All the features proposed yield a F-measure of 0.693. The novel features specialized in MANNER detection from PPs (in bold letters in Table 5) bring an improvement of 0.059, which again is significant.

Phrase	#MNR	Feat. Set	#MNR retrieved	#MNR correct	P	R	F
ADVP	678	1,2,6-9	908	513	.565	.757	.647
		all	757	585	.773	.863	**.815**
PP	705	1,2,5,6,8-10,16,17	690	442	.641	.627	.634
		all	713	491	.689	.696	**.693**

Table 6: Results obtained during testing for different sets of features.

The Z-score is 2.35, i.e., the difference in performance is statistically significant with a confidence greater than 97.5%. Thus, adding the specialized features is justified.

7.2 Error Analysis

The mapping of words to semantic classes is data-driven and decisions were taken so that the overall accuracy is high. However, mistakes are made. Given *We want to [see]*$_y$ *the market from the inside*, the underlined PP encodes a MANNER and the mapping proposed (Table 1) does not map *inside* to ntao. Similarly, given *Like their cohorts in political consulting, the litigation advisers [encourage]*$_y$ *their clients [. . .]*, the underlined text encodes a MANNER and yet *cohorts* is subsumed by *social_group.n.1* and therefore is not mapped to ntao.

The model proposed for MANNER detection makes mistakes as well. For ADVPs, if the main adverb has not been seen during training, chances of detecting MANNER are low. For example, the classifier fails to detect the following MANNER relations: *[. . .] which together own about [. . .]* (wsj_0671, 1); and *who has ardently supported [. . .]* (wsj_1017, 26) even though *ardently* is present in the dictionary and ends in *-ly*;

For PPs, some errors are due to the PropBank annotation. For example, in *Shearson Lehman Hutton began its coverage of the company with favorable ratings.* (wsj_2061, 57), the underlined text is annotated as ARG2, even though it does encode a MANNER. Our model correctly detects a MANNER but it is counted as a mistake. Manners encoded by *under* and *at* are rarely detected, as in *that have been consolidated in federal court under U.S. District Judge Milton Pollack* (wsj_1022.mrg, 10).

8 Comparison with Previous Work

To the best of our knowledge, there have not been much efforts to detect MANNER alone. Girju et al. (2003), present a supervised approach for ADVP similar to the one reported in this paper, yielding a F-measure of .665. Our augmented feature set obtains a F-measure of .815, clearly outperforming their method (Z-test, confidence $>$ 97.5%). Moreover, ADVPs only represent 45.3% of MANNER as a semantic role in PropBank. We also have presented a model to detect MANNER encoded by a PP, the other big chunk of MANNER (44.6%) in PropBank.

Complete systems for Semantic Role Labeling perform poorly when detecting MANNER; the Top-10 systems in CoNLL-2005 shared task[3] obtained F-measures ranging from .527 to .592. We have trained our models using the training data provided by the task organizers (using the Charniak parser syntactic information), and tested with the provided test set (test.wsj). Our models yield a Precision of .759 and Recall of .626 (F-measure .686), bringing a significant improvement over those systems (Z-test, confidence $>$ 97.5%). When calculating recall, we take into account all MANNER in the test set, not only ADVPs and PPs whose fathers are S or VP (i.e. not only the ones our models are able to detect). This evaluation is done with exactly the same data provided from the task organizers for both training and test.

Unlike typical semantic role labelers, our features do not include rich syntactic information (e.g. syntactic path from verb to the argument). Instead, we only require the value of the parent and in the case of PPs, the sibling node. When repeating the CoNLL-2005 Shared Task training and test using gold syntactic information, the F-measure obtained is .714, very close to the .686 obtained with Charniak syntactic trees (not significant, confidence $>$ 97.5%).

[3] http://www.lsi.upc.es/˜srlconll/st05/st05.html

Even though syntactic parsers achieve a good performance, they make mistakes and the less our models rely on them, the better.

9 Composing MANNER with PURPOSE

MANNER can combine with other semantic relations in order to reveal implicit relations that otherwise would be missed. The basic idea is to compose MANNER with other relations in order to infer another MANNER. A necessary condition for combining MANNER with another relation R is the compatibility of RANGE(MNR) with DOMAIN(R) or RANGE(R) with DOMAIN(MNR). The extended definition (Section 3) allows to quickly determine if two relations are compatible (Blanco et al., 2010).

The new MANNER is automatically inferred by humans when reading, but computers need an explicit representation. Consider the following example: *[. . .] the traders [place]*$_{y}$ *orders [via computers]*$_{MNR}$ *[to buy the basket of stocks . . .]*$_{PRP}$ (wsj_0118, 48). PropBank states the basic annotation between brackets: *via computers* is the MANNER and *to buy the basket [. . .]* the PURPOSE of the *place orders* event. We propose to combine these two relations in order to come up with the new relation MNR(*via computers*, *buy the basket [. . .]*). This relation is obvious when reading the sentence, so it is omitted by the writer. However, any semantic representation of text needs as much semantics as possible explicitly stated.

This claim is supported by several PropBank examples: (1) *The classics have [zoomed]*$_{y}$ *[in price]*$_{MNR}$ *[to meet the competition]*$_{PRP}$*, and . . .* (wsj_0071, 9) and (2) *. . . the government [curtailed]*$_{y}$ *production [with land-idling programs]*$_{MNR}$ *[to reduce price-depressing surpluses]*$_{PRP}$ (wsj_0113, 12). In both examples, PropBank encodes the MANNER and PURPOSE for event y indicated with brackets. After combining both relations, two new MANNER arise: MNR(*in price*, *meet the competition*) and MNR(*with land-idling programs*, *reduce price-depressing surpluses*).

Out of 237 verbs having in PropBank both PURPOSE and MANNER annotation, the above inference method yields 189 new valid MANNER not present in PropBank (Accuracy .797).

MANNER and other relations. MANNER does not combine with relations such as CAUSE, AT-LOCATION or AT-TIME. For example, given *And they continue [anonymously]*$_{x,MNR}$ *[attacking]*$_{y}$ *CIA Director William Webster [for being too accommodating to the committee]*$_{z,CAU}$ (wsj_0590, 27), there is no relation between x and z. Similarly, given *[In the tower]*$_{x,LOC}$*, five men and women [pull]*$_{y}$ *[rhythmically]*$_{z,MNR}$ *on ropes attached to [. . .]* (wsj_0089, 5) and *[In May]*$_{x,TMP}$*, the two companies, [through their jointly owned holding company]*$_{z,MNR}$*, Temple, [offered]*$_{y}$ *[. . .]* (wsj_0063, 3), no connection exists between x and z.

10 Conclusions

We have presented a supervised method for the automatic discovery of MANNER. Our approach is simple and outperforms previous work. Our models specialize in detecting the most common pattern encoding MANNER. By doing so we are able to specialize our feature sets and outperform previous approaches that followed the idea of using dozens of features, most of them potentially useless, and letting a complicated machine learning algorithm decide the actual useful features.

We believe that each relation or role has its own unique characteristics and capturing them improves performance. We have shown this fact for MANNER by examining examples, considering the kind of arguments that can be part of the domain and range, and considering theoretical works (Hawkins, 1999).

We have shown performance using both gold syntactic trees and the output from the Charniak parser, and there is not a big performance drop. This is mainly due to the fact that we do not use deep syntactic information in our feature sets.

The combination of MANNER and PURPOSE opens up a novel paradigm to perform semantic inference. We envision a layer of semantics using a small set of basic semantic relations and inference mechanisms on top of them to obtain more semantics on demand. Combining semantic relations in order to obtain more relation is only one of the possible inference methods.

Tense Sense Disambiguation: a New Syntactic Polysemy Task

Abstract

Polysemy is a major characteristic of natural languages. Like words, syntactic forms can have several meanings. Understanding the correct meaning of a syntactic form is of great importance to many NLP applications. In this paper we address an important type of syntactic polysemy – the multiple possible senses of tense syntactic forms. We make our discussion concrete by introducing the task of *Tense Sense Disambiguation* (TSD): given a concrete tense syntactic form present in a sentence, select its appropriate sense among a set of possible senses. Using English grammar textbooks, we compiled a syntactic sense dictionary comprising common tense syntactic forms and semantic senses for each. We annotated thousands of BNC sentences using the defined senses. We describe a supervised TSD algorithm trained on these annotations, which outperforms a strong baseline for the task.

1 Introduction

The function of syntax is to combine words to express meanings, using syntactic devices such as word order, auxiliary words, and morphology (Goldberg, 1995). Virtually all natural language devices used for expressing meanings (e.g., words) exhibit polysemy. Like words, concrete syntactic forms (the sentence words generated by specific syntactic devices) can have several meanings. Consider the following sentences:

(a) They **are playing** chess in the park.

(b) They **are playing** chess next Tuesday.

Both contain the concrete syntactic form 'are playing', generated by the abstract syntactic form usually known as 'present progressive' (am/is/are + V-ing). In (a), the meaning is 'something happening now', while in (b) it is 'a plan to do something in the future'. Note that the polysemy is of the syntactic form as a unit, not of individual words. In particular, the verb 'play' is used in the same sense in both cases.

In this paper we address a prominent type of syntactic form polysemy: the multiple possible senses that tense syntactic forms can have. Disambiguating the polysemy of tense forms is of theoretical and practical importance (Section 2). To make our discussion concrete, we introduce the task of *Tense Sense Disambiguation* (TSD): given a concrete tense syntactic form in a sentence, select its correct sense among a given set of possible senses (Section 3).

The disambiguation of polysemy is a fundamental problem in NLP. For example, Word Sense Disambiguation (WSD) continues to attract a large number of researchers (Agirre and Edmonds, 2006). TSD has the same structure as WSD, with different disambiguated entities.

For experimenting with the TSD task, we compiled an English syntactic sense dictionary based on a thorough study of three major English grammar projects (Section 4). We selected 3000 sentences from the British National Corpus containing 4702 concrete syntactic forms, and annotated each of these by its sense (Section 5).We developed a supervised learning TSD algorithm that uses various feature types and takes advantage of the task structure (Section 6). Our algorithm substantially outper-

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 325–334,
MIT, Massachusetts, USA, 9-11 October 2010.

forms the ‘most frequent sense’ baseline (Section 7).

TSD is fundamental to sentence understanding and thus to NLP applications such as textual inference, question answering and information retrieval. To the best of our knowledge, this is the first paper to address this task. In Section 8 we discuss research directions relevant to TSD placing the new task in the context of the previous research of syntactic ambiguity resolution.

2 TSD Motivation

In this work we follow linguistics theories that posit that tense does not directly reflect conceptual time as one might think. Dinsmore (1991) and Cutrer (1994) explain that the same tense may end up indicating very different objective time relations relative to the sentence production time.

Fauconnier (2007) exemplifies such phenomena. In the following sentences, the present tense corresponds to the *future* time: (1) The boat leaves next week. (2) When he comes tomorrow, I will tell him about the party. (3) If I see him next week, I will ask him to call you.

In contrast, the following present tense sentences talk about events that happened in the *past*: (1) I am walking down the street one day when suddenly this guy walks up to me. (2) He catches the ball. He runs. He makes a touchdown. (morning-after sports report).

Another set of examples is related to the past tense. In the following sentences it corresponds to a *present* time: (1) Do you have a minute? I wanted to ask you a question. (2) I wish I lived closer to my family now. In contrast, in the following two sentences, it corresponds to a future time: (1) If I had the time next week, I would go to your party. (2) I cannot go to the concert tonight. You will have to tell me how it was.

Fauconnier explains these phenomena by a model for the grammar of tense. According to this model, the grammar specifies partial constraints on time and fact/prediction status that hold locally between mental spaces within a discourse configuration. We may obtain actual information about time by combining this with other available pragmatic information. Accordingly, the same tense may end up indicating very different objective time relations relative to the speech event.

TSD fits well with modern linguistics theories. For example, in the construction grammar framework (Goldberg, 1995), the ‘construction’ is the basic unit, comprised of a form and a meaning. Words, multiword expressions, and syntactic forms are all valid constructions. It is thus very natural to address the sense disambiguation problem for all of these. In this paper we focus on tense constructions.

For many NLP applications, it is very important to disambiguate the tense forms of the sentence. Among these applications are: (1) machine translation, as the actual time described by one tense form in the source language may be described by a different tense form in the target language; (2) understanding the order of events in a text; (3) textual entailment, when the optional entailed sentences refer to the time and/or order of events of the source sentence. Many more examples also exist.

3 The TSD Task

In this section we formally define the TSD task, discuss its nature vs. WSD, and describe various concrete task variants.

Task definition. First, some essential terminology. The function of syntax is to combine lexical items (words, multiword expressions) to express meanings. This function is achieved through syntactic *devices*. The most common devices in English are word order, morphology, and the usage of auxiliary words. An *Abstract Syntactic Form (ASF)* is a particular set of devices that can be used to express a set of meanings. A *Concrete Syntactic Form (CSF)* is a concrete set of words generated by an ASF for expressing a certain meaning in an utterance[1]. A CSF is *ambiguous* if its generating ASF has more than one meaning, which is the usual case. In this case we also say that the ASF is ambiguous.

Here are a few examples. The ‘present progressive’ ASF has the form ‘am/is/are V-ing’[2], which employs all three main devices. It is ambiguous,

[1] In some linguistic theories, the central notion is the *construction*, which combines an ASF (referred to as the form of the construction) with a single meaning (Goldberg, 1995).

[2] Note that strictly speaking, these are three different ASFs. We refer to this ASF family by a single name because they have the same set of meanings and because it is standard to treat them as a single ASF.

as shown in Section 1. The 'present simple' ASF has the form 'V(+s)'[3], and is ambiguous as well: in the sentence 'My Brother arrives this evening', the CSF 'arrives' conveys the meaning of 'a future event arranged for a definite time', while in the sentence 'The sun rises in the East' the meaning is that of a repeated event.

TSD vs. WSD. The TSD task is to disambiguate the semantic sense of a tense syntactic form. TSD is clearly different from WSD. This is obvious when the CSF comprises two words that are not a multiword expression, and is usually also the case when it comprises a single word. Consider the 'My Brother arrives this evening' example above. While the verb 'arrive' has two main senses: 'reach a place', and 'begin', as in 'Summer has arrived', in that example we focused on the disambiguation of the tense sense of the 'arrives' construction.

Concrete task variants. Unlike with words, the presence of a particular CSF in a sentence is not trivially recognizable. Consequently, there are three versions of the TSD task: (1) we are given the sentence, a marked subset of its words comprising a CSF, and the ASF that has generated these words; (2) we are given the sentence and a marked subset of its words comprising a CSF, without knowing the generating ASF; (3) we are given only the sentence and we need to find the contained CSFs and their ASFs. In all cases, we need to disambiguate the sense of the ASFs. We feel that the natural granularity of the task is captured by version (2). However, since the ASF can usually be identified using relatively simple features, we also report results for version (1). The main difficulty in all versions is identifying the appropriate sense, as is the case with WSD.

4 The Syntactic Sense Dictionary

A prerequisite to any concrete experimentation with the TSD task is a syntactic sense dictionary. Based on a thorough examination of three major English grammar projects, we compiled a set of 18 common English tense ASFs and their possible senses. The projects are (1) the Cambridge University Press English Grammar In Use series, comprising three books (essential, intermediate and advanced) (Murphy, 2007; Murphy, 1994; Hewings, 2005); (2) the English grammar texts resulting from the seminal corpus-based Cobuild project (elementary, advanced) (Willis and Wright, 2003; Willis, 2004); (3) the Longman Grammar of Spoken and Written English (Biber et al., 1999).

As in any sense dictionary, in many cases it is hard to draw the line between senses. In order to be able to explore the computational limits of the task, we have adopted a policy of fine sense granularity. For example, senses 1 and 3 of the 'present simple' ASF in Table 1 can be argued to be quite similar to each other, having a very fine semantic distinction. A specific application may choose to collapse some senses into one.

We used the conventional ASF names, which should not be confused with their meanings (e.g., the 'present simple' ASF can be used to refer to *future*, not present, events, as in Table 1, sense 4).

The ASF set thus obtained is: real conditionals, hypothetical conditionals, wishes, reported speech, present simple, present progressive, present perfect, present perfect progressive, past simple, past progressive, past perfect, past perfect progressive, 'be + going + to + infinitive', future progressive, future perfect, future perfect progressive, 'would' tense forms, and 'be + to + infinitive'. Note that the first four ASFs are not direct tense forms; we include them because they involve tensed sub-sentences whose disambiguation is necessary for disambiguation of the whole ASF. The total number of possible senses for these 18 ASFs is 103.

Table 1 shows the complete senses set for the 'present simple' and 'be + to + infinitive' ASFs, plus an example sentence for each sense. Space limitations prevent us from listing all form senses here; we will make the listing available online.

5 Corpus Creation and Annotation

We selected 3000 sentences from the British National Corpus (BNC) (Burnard, 2000), containing 4702 CSFs (1.56 per sentence). These sentences with their CSFs were sense annotated. To select the 3000 sentences, we randomly sampled sentences from the various written and spoken sections of the

[3] Again, these are two ASFs, one adding an 's' and one using the verb as is.

	Present Simple
1	*Things that are always true* It gets cold in the winter.
2	*Regular and repeated actions and habits* My parents often eat meat.
3	*General facts* Mr. Brown is a teacher.
4	*A future event arranged for a definite time* The next train arrives at 11:30.
5	*Plans, expectations and hopes* We hope to see you soon.
6	*Ordering someone to do something* Take your hands out of your pockets!
7	*Something happening now, with verbs that are not used in the present progressive in this sense* I do not deny the allegation.
8	*Events happening now (informal; common in books, scripts, radio etc.)* She goes up to this man and looks into his eyes.
9	*Past actions* I was sitting in the park reading a newspaper when all of a sudden this dog jumps at me.
10	*Newspaper headlines, for recent events* Quake hits central Iran.
11	*When describing the content of a book* Thompson gives an exhaustive list in chapter six.
	'be + to + infinitive'
1	*Events that are likely to happen in the near future* Police officers are to visit every home in the area.
2	*Official arrangements, formal instructions & orders* You are not to leave without my permission.
3	*In an if-clause to say that something must happen before something else can happen* If the human race is to survive, we must look at environmental problems now.

Table 1: The full set of senses of the 'present simple' and 'be + to + infinitive' abstract syntactic forms (ASFs), with an example for each.

corpus, giving each section an equal weight. To guarantee ample representation of ASFs, we manually defined auxiliary words typical of each ASF (e.g., 'does', 'been' etc), and sampled hundreds of sentences for each set of these auxiliary words. To make sure that our definition of auxiliary words does not skew the sampling process, and to obtain ASFs that do not have clear auxiliary words, we have also added 1000 random sentences. The number of CSF instances obtained for each ASF ranges from 100 (future perfect) to over 850 (present simple). All senses are represented; the number of senses represented by at least 15 CSFs is 77 (out of 103, average number of CSFs per sense is 45.65).

We implemented an interactive application that displays a sentence and asks an annotator to (1) mark words that participate in the CSFs contained in the sentence; (2) specify the ASF(s) of these CSFs; and (3) select the appropriate ASF sense from the set of possible senses. Annotators could also indicate 'none of these senses', which they did for 2.6% (122 out of 4702) of the CSFs.

Annotation was done by two annotators (university students). To evaluate inter-annotator agreement, a set of 210 sentences (7% of the corpus), containing at least 10 examples of each ASF, was tagged by both annotators. The CSF+ASF identification inter-annotator agreement was 98.7%, and the inter-annotator agreement for the senses was 84.2%. We will make the annotated corpus and annotation guidelines available online.

6 Learning Algorithm

In this section we describe our learning model for the TSD task. First, note that the syntactic sense is not easy to deduce from readily computable annotations such as the sentence's POS tagging, dependency structure, or parse tree (see Section 8). Hence, a learning algorithm is definitely needed.

As common in supervised learning, we encode the CSFs into feature vectors and then apply a learning algorithm to induce a classifier. We first discuss the feature set and then the algorithm.

Features. We utilize three sets of features: basic features, lexical features, and a set of features based on part-of-speech (POS) tags (Table 2). The 'auxiliary words' referred to in the table are the manually specified words for each ASF that have assisted us in sampling the corpus (see Section 5). 'Content words' are the non-auxiliary words appearing in the CSF[4]. Content words are usually verbs, since we focus here on tense-related ASFs. The position and distance of a form are based on its leftmost word (auxiliary or content).

The personal pronouns used in the position features are: I, you, he, she, it, they, and we. For

[4] Usually, there is a single content word. However, there may be more than one, e.g. for phrasal verbs.

simplicity, we considered every word starting with a capital letter that is not the first word in the sentence to be a name.

Each ‘Conditional’ CSF contains two tense CSFs. The one that is not the CSF currently encoded by the features is referred to as its ‘mate’.

For the time lexical features we used 16 words (e.g., recently, often, now). For the reported speech lexical features we used 14 words (e.g., said, replied, wrote[5]). The words were obtained from the grammar texts and our corpus development set.

The POS tagset used by the POS-based features is that of the WSJ PennTreebank (see Section 7). The possible verb tags in this tagset are: VB for the base form, VBD for past tense, VBN for past participle, VBG for a present participle or gerund (-ing), VBP for present tense that is not 3rd person singular, and VBZ for present simple 3rd person singular.

Conjunctions and prepositions are addressed through the POS tags CC and IN. Using the PRP tag to detect pronouns or lexical lists for conjunctions and prepositions yielded no significant change in the results.

In Section 7 we explore the impact each of the feature sets has on the performance of the algorithm. Our results indicate that the basic features have the strongest impact, the POS-based features enhance the performance in specific cases and the lexical features only marginally affect the final results.

Algorithm. Denote by x_i the feature vector of a CSF instance i, by C_i the set of possible labels for x_i, and by $c_i \in C_i$ the correct label. The training set is $\{(x_j, C_j, c_j)\}_{j=1}^{n}$. Let (x_{n+1}, C_{n+1}) be a test CSF. As noted in Section 3, there are two versions of the task, one in which C_i includes the totality of sense labels, and one in which it includes only the labels associated with a particular ASF. In both cases, the task is to select which of the labels in C_{n+1} is its correct label c_{n+1}.

Owing to the task structure, it is preferable to use an algorithm that allows us to restrict the possible labels of each CSF. For both task versions, this would help in computing better probabilities during the training stage, since we know the ASF type of training CSFs. For the task version in which the ASF type is known at test time, this would also help during the test stage.

Basic Features
Form words. Auxiliary and content words of the CSF.
Form type. The type, if it is known during test time.
Other forms. The auxiliary and content words (and type, if known) of the other CSFs present in the sentence.
Position. The position of the CSF in the sentence, its distance from the end of the sentence, whether it is in the first (last) three words in the sentence, its distance from the closest personal pronoun or name.
Wish. Is there a CSF of type ‘wish’ before the encoded form, the number of CSFs between that ‘wish’ form and the encoded CSF (if there are several such ‘wish’ forms, we take the closest one to the encoded form).
Conditional. Does the word ‘if’ appear before the encoded form, is the ‘if’ the first word in the sentence, the number of CSFs between the ‘if’ and the encoded form, the auxiliary and content words (and type, if known) of the mate form, is there a comma between the encoded form and its mate form, does the word ‘then’ appear between the encoded form and its mate form.
Punctuation. The type of end of sentence marker, distance of the encoded form from the closest predecessor (successor) comma.
Lexical Features
Time. Time words appearing in the sentence, if any.
Reported speech. Reported speech words appearing in the sentence, if any.
Be. Does the encoded form contain the verb ‘be’.
Features Based on POS Tags
*Form.*The POS of the verb in the encoded form.
Other forms. The POS of the verb in the other CSFs in the sentence.
POS tags. The POS tags of the two words to the left (right) of the encoded form.
Conjunction POS. Is there a Conjunction (CC) between the encoded form and its closest predecessor (successor) form, the distance from that conjunction.
Preposition POS. Is there a Preposition (IN) between the encoded form and its closest predecessor (successor) form, the distance from that preposition.

Table 2: Basic features (top), lexical features (middle) and POS tags-based features (bottom) used by the TSD classifier.

For the version in which ASF type is known at test time, we experimented in two scenarios. In the first,

[5] These are all in a past form due to the semantics of the reported speech form.

we take the ASF type at test time from the manual annotation and provide it to the algorithm. In the second, instead of the manual annotation, we implemented a simple rule-based classifier for selecting ASF types. The classifier decides what is the type of an ASF according to the POS tag of its verb and to its auxiliary words (given in the annotation). For example, if we see the auxiliary phrase 'had been' and the verb POS is not VBG, then the ASF is 'past perfect simple'. This classifier's accuracy on our development (test) data is 94.1 (91.6)%. In this scenario, when given a test CSF, X_{n+1}, its set of possible labels C_{n+1} is defined by the classifier output. In the features in which ASF type is used (see table 2), it is taken from the classifier output in this case.

The sequential model algorithm presented by Even-Zohar and Roth (2001) directly supports this label restriction requirement [6]. We use the SNOW learning architecture for multi-class classification (Roth, 1998), which contains an implementation of that algorithm. The SNOW system allows us not to define restrictions if so desired. It also lets us choose the learning algorithm used when it builds its classifier network. The algorithm can be Perceptron (MacKay, 2002), Winnow (Littlestone, 1988) or Naive Bayes (MacKay, 2002)[7]. In Section 7 we analyze the effect that these decisions have on our results.

Classifier Selection. Investigating the best configuration of the SNOW system with development data, we found that Naive Bayes gave the best or close to best result in all experimental conditions. We therefore report our results when this algorithm is used. Naive Bayes is particularly useful when relatively small amounts of training CSF instances are available (Zhang, 2004), and achieves good results when compared to other classifiers for the WSD task (Mooney, 1996), which might explain our results. Fine tuning of Winnow parameters also leads to high performance (sometimes the best), but most other parameter configurations lead to disappointing results. For the Perceptron, most parameter configurations lead to good results (much better than the baseline), but these were a few percent worse than the best Winnow or Naive Bayes results.

7 Experimental Results

Experimental setup. We divided the 3000 annotated sentences (containing 4702 CSFs) to three datasets: training data (2100 sentences, 3183 forms), development data (300 sentences, 498 forms) and test data (600 sentences, 1021 forms). We used the development data to design the features for our learning model and to tune the parameters of the SNOW sequential model. In addition we used this data to design the rules of the ASF type classifier (which is not statistical and does not have a training phase).

For the POS features, we induced POS tags using the MXPOST POS tagger (Ratnaparkhi, 1996). The tagger was trained on sections 2-21 of the WSJ PennTreebank (Marcus et al., 1993) annotated with gold standard POS tags. We used a publicly available implementation of the sequential SNOW model[8].

We experimented in three conditions. In the first (TypeUnknown), the ASF type is not known at test time. In the last two, it is known at test time. These two conditions differ in whether the type is taken from the gold standard annotation of the test sentences (TypeKnown), or from the output of the simple rule-based classifier (TypeClassifier, see Section 6). For both conditions, the results reported below are when both ASF type features and possible labels sets are provided during training by the manual annotation. This is true also for the training of the MFS baseline (see below)[9].

We report an algorithm's quality using accuracy, that is, the number of test CSFs that were correctly resolved by the algorithm divided by the total number of test CSFs.

Baseline. We compared the performance of our algorithm to the 'most frequent sense' (MFS) base-

[6] Note that the name of the learning algorithm is derived from the fact that it utilizes classifiers to sequentially restrict the number of competing classes while maintaining with high probability the presence of the true outcome. The classification task it performs is not sequential in nature.

[7] Or a combination of these algorithms, which we did not explore in this paper.

[8] http://l2r.cs.uiuc.edu/∼cogcomp/asoftware.php?skey=SNOW

[9] For the TypeClassifier condition, we also experimented using an ML technique that sometimes reduces noise, where training is done using the classifier types. We obtained very similar results to those reported.

	TypeUnknown	TypeClassifier	TypeKnown
Our algorithm	**49.7%**	**58.8%**	**62%**
MFS baseline	13.5%	42.9%	46.7%

Table 3: Performance of our algorithm and of the MFS baseline where at test time ASF type is known (right), unknown (left) or given by a simple rule-based classifier (middle). Our algorithm is superior in all three conditions.

	Constrained Model		Unconstrained Classifier	
	All features	Base+Lexical features	All features	Base+Lexical features
Type features	57.9%	57.7%	53%	50.1%
No type features	57.2%	55.4%	48%	42.6%

Table 4: Impact of POS features. When the constrained model is used (left section), POS features have no effect on the results when ASF type information is encoded. When an unconstrained classifier is used, POS features affect the results both when ASF type features are used and when they are not (see discussion in the text).

line. This baseline is common in semantic disambiguation tasks and is known to be quite strong. In the condition where the ASF type is not known at test time, MFS gives each form in the test set the sense that was the overall most frequent in the training set. That is, in this case the baseline gives all test set CSFs the same sense. When the ASF type is known at test time, MFS gives each test CSF the most frequent sense *of that ASF type* in the training set. That is, in this case all CSFs having the same ASF type get the same sense, and forms of different types are guaranteed to get different senses.

Recall that the condition where ASF type is known at test time is further divided to two conditions. In the TypeKnown condition, MFS selects the most frequent sense of the manually created ASF type, while in the TypeClassifier condition it selects the most frequent sense of the type decided by the rule-based classifier. In this condition, if the classifier makes a mistake, MFS will necessarily make a mistake as well.

Note that a random baseline which selects a sense for every test CSF from a uniform distribution over the possible senses (103 in our case) would score very poorly.

Results. Table 3 shows our results. Results are shown where ASF type is not known at test time (left), when it is decided at test time by a rule-based classifier (middle) and when it is known at test time (right). Our algorithm outperforms the MFS baseline in all three conditions. As expected, both our algorithm and the MFS baseline perform better when ASF type information is available at test time (TypeClassifier and TypeKnown conditions), and improve as this data becomes more accurate (the TypeKnown condition)[10].

Analyzing the per-type performance of our algorithm reveals that it outperforms the MFS baseline for each and every ASF type. For example, in the TypeKnown condition, the accuracy gain of our algorithm over the baseline[11] varies from 4% for the ‘present perfect’ to 30.6% and 29.1% for the ‘past perfect’ and ‘present simple’ ASFs.

Below we analyze the roles of the different components of our learning algorithm in performing the TSD task. Since this is the first exploration of the task, it is important to understand what properties are essential for achieving good performance. The analysis is done by experimenting with development data, and focuses on the TypeKnown and TypeUnknown conditions. Patterns for the TypeClassifier condition are very similar to the patterns for the TypeKnown condition.

The Possible Senses Constraint. We use the learning model of Even-Zohar and Roth (2001), which allows us to constrain the possible senses an input vector can get to the senses of its ASF type. We ran our model without this constraint during both training and test time (recall that for the above results, this constraint was always active during training). In this case, the only difference between the TypeKnown and the TypeUnknown conditions is whether ASF type features are encoded at test time. In the TypeKnown condition, the accuracy of the algorithm drops from 57.9% (when using training and test time constraints and ASF type features) to 53% (when using only ASF type features but no constraints). In the TypeUnknown condition, accuracy drops from 57.24% (when using training time constraints) to 48.03% (when neither constraints nor ASF type features are used). Note

[10] Recall that the performance of the rule-based ASF type classifier on test data is not 100% but 91.6% (Section 6).

[11] $accuracy(algorithm) - accuracy(MFS)$.

that the difference between the constrained model and the unconstrained model is quite large.

The MFS baseline achieves on development data 42.9% and 13.2% in the TypeKnown and TypeUnknown conditions respectively[12]. Thus, the algorithm outperforms the baseline both when the constrained model is used and when an unconstrained multi-class classifier is used.

Note also that when constraints on the possible labels are available at training time, test time constraints and ASF type features (whose inclusion is the difference between the TypeKnown and TypeUnknown) have a minor effect on the results (57.9% for TypeKnown compared to 57.24% for TypeUnknown). However, when training time constraints on the possible labels are not available at training time, ASF type features alone do have a significant effect on the result (53% for TypeKnown compared to 48.03% for TypeUnknown).

POS Features. We next explore the impact of the POS features on the results. These features encode the inflection of the verbs in the CSF, as well as the POS tags of the two words to the left and right of the CSF.

Verb forms provide some partial information corresponding to the ASF type features encoded at the TypeKnown scenario. Table 4 shows that when both label constraints and ASF type features are used, POS features have almost no impact on the final results. When the constrained model is used but ASF type features are not encoded, POS features have an effect on the results. We conclude that when using the constrained model, POS features are important mainly for ASF type information. When the unconstrained classifier is used, POS features have an effect on performance whether ASF type features are encoded or not. In the last case the impact of POS features is larger. In other words, when using an unconstrained classifier, POS features give more than ASF type information to to the model.

Lexical Features. To explore the impact of the lexical features, we removed the following features: time words, reported speech words and 'be' indication features. We saw no impact on model performance when using the constrained model, and a 0.5% decrease when using the unconstrained classifier. That is, our model does not require these lexical features, which is somewhat counter-intuitive. Lexical statistics may turn out to be helpful when using a much larger training set.

Conditional and Wish Features. The conditionals and 'wish' features have a more substantial impact on the results, as they have a role in defining the overall syntactic structure of the sentence. Discarding these features leads to 4% and 1.4% degradation in model accuracy when using the constrained and unconstrained models respectively.

8 Relevant Previous Work

As far as we know, this is the first paper to address the TSD task. In this section we describe related research directions and compare them with TSD.

A relevant task to TSD is WSD (Section 1 and Section 3). Many algorithmic approaches and techniques have been applied to supervised WSD (for reviews see (Agirre and Edmonds, 2006; Mihalcea and Pedersen, 2005; Navigli, 2009)). Among these are various classifiers, ensemble methods combining several supervised classifiers, bootstrapping and semi-supervised learning methods, using the Web as a corpus and knowledge-based methods relying mainly on machine readable dictionaries. Specifically related to this paper are works that exploit syntax (Martinez et al., 2002; Tanaka et al., 2007) and ensemble methods (e.g. (Brody et al., 2006)) to WSD. The references above also describe some unsupervised word sense induction algorithms.

Our TSD algorithm uses the SNOW algorithm, which is a sparse network of classifiers (Section 6). Thus, it most resembles the ensemble approach to WSD. That approach has achieved very good results in several WSD shared tasks (Pedersen, 2000; Florian and Yarowsky, 2002).

Since temporal reasoning is a direct application of TSD, research on this direction is relevant. Such research goes back to (Passonneau, 1988), which introduced the PUNDIT temporal reasoning system. For each tensed clause, PUNDIT first decides whether it refers to an actual time (as in 'We flew TWA to Boston') or not (as in 'Tourists flew TWA to Boston', or 'John always flew his own plane to Boston'). The temporal structure of actual time

[12] Note that these numbers are for development data only.

clauses is then further analyzed. PUNDIT's classification is much simpler than in the TSD task, addressing only actual vs. non-actual time. PUNDIT's algorithmic approach is that of a Prolog rule based system, compared to our statistical learning corpus-based approach. We are not aware of further research that followed their sense disambiguation direction.

Current temporal reasoning research focuses on temporal ordering of events (e.g., (Lapata, 2006; Chambers and Jurafsky, 2008)), for which an accepted atomic task is the identification of the temporal relation between two expressions (see e.g., the TempEval task in SemEval '07 (Verhagen et al., 2007)). This direction is very different from TSD, which deals with the semantics of *individual* concrete tense syntactic forms. In this sense, TSD is an even more atomic task for temporal reasoning.

A potential application of TSD is machine translation where it can assist in translating tense and aspect. Indeed several papers have explored tense and aspect in the MT context. Dorr (1992) explored the integration of tense and aspect information with lexical semantics for machine translation. Schiehlen (2000) analyzed the effect tense understanding has on MT. Ye and Zhang (2005) explored tense tagging in a cross-lingual context. Ye et al., (2006) extracted features for tense translation between Chinese and English. Murata et al., (2007) compared the performance of several MT systems in translating tense and aspect and found that various ML techniques perform better on the task.

Another related field is 'deep' parsing, where a sentence is annotated with a structure containing information that might be relevant for semantic interpretation (e.g. (Hajic, 1998; Baldwin et al., 2007)). TSD senses, however, are not explicitly represented in these grammatical structures, and we are not aware of any work that utilized them to do something close to TSD. This is a good subject for future research.

9 Conclusion and Future Work

In this paper we introduced the Tense Sense Disambiguation (TSD) task, defined as selecting the correct sense of a concrete tense syntactic form in a sentence among the senses of abstract syntactic forms in a syntactic sense dictionary. Unlike in other semantic disambiguation tasks, the sense to be disambiguated is not lexical but of a *syntactic* structure. We prepared a syntactic sense dictionary, annotated a corpus by it, and developed a supervised classifier for sense disambiguation that outperformed a strong baseline.

An obvious direction for future work is to expand the annotated corpus and improve the algorithm by experimenting with additional features. For example, we saw that seeing the full paragraph containing a sentence helps human annotators decide on the appropriate sense which implies that using larger contexts may improve the algorithm.

TSD can be a very useful operation for various high-level applications, for example textual inference, question answering, and information retrieval, in the same way that textual entailment (Dagan et al., 2006) was designed to be. In fact, TSD can assist textual entailment as well, since the sense of a tense form may provide substantial information about the relations entailed from the sentence. Using TSD in such applications is a major direction for future work.

{raduf,pitrelli,roukos,izitouni}us.ibm.com

Abstract

Information-extraction (IE) research typically focuses on clean-text inputs. However, an IE engine serving real applications yields many false alarms due to less-well-formed input. For example, IE in a multilingual broadcast processing system has to deal with inaccurate automatic transcription and translation. The resulting presence of non-target-language text in this case, and non-language material interspersed in data from other applications, raise the research problem of making IE robust to such noisy input text. We address one such IE task: entity-mention detection. We describe augmenting a statistical mention-detection system in order to reduce false alarms from spurious passages. The diverse nature of input noise leads us to pursue a multi-faceted approach to robustness. For our English-language system, at various miss rates we eliminate 97% of false alarms on inputs from other Latin-alphabet languages. In another experiment, representing scenarios in which genre-specific training is infeasible, we process real financial-transactions text containing mixed languages and data-set codes. On these data, because we do not train on data like it, we achieve a smaller but significant improvement. These gains come with virtually no loss in accuracy on clean English text.

1 Introduction

Information-extraction (IE) research is typically performed on clean text in a predetermined language. Lately, IE has improved to the point of being usable for some real-world tasks whose accuracy requirements are reachable with current technology. These uses include media monitoring, topic alerts, summarization, population of databases for advanced search, etc. These uses often combine IE with technologies such as speech recognition, machine translation, topic clustering, and information retrieval.

The propagation of IE technology from isolated use to aggregates with such other technologies, from NLP experts to other types of computer scientists, and from researchers to users, feeds back to the IE research community the need for additional investigation which we loosely refer to as "information-extraction robustness" research. For example:

1. Broadcast monitoring demands that IE handle as input not only clean text, but also the transcripts output by speech recognizers.

2. Multilingual applications, and the imperfection of translation technology, require IE to contend with non-target-language text input (Pitrelli et al., 2008).

3. Naive users at times input to IE other material which deviates from clean text, such as a PDF file that "looks" like plain text.

4. Search applications require IE to deal with databases which not only possess clean text but at times exhibit other complications like markup codes particular to narrow, application-specific data-format standards, for example, the excerpt from a financial-transactions data set shown in Figure 1.

   Legacy industry-specific standards, such as illustrated in this example, are part of long-established processes which are cumbersome to convert to a more-modern database format. Transaction data sets typically build up over a period of years, and as seen here, can exhibit

Figure 1: Example application-specific text, in this case from financial transactions.

peculiar mark-up interspersed with meaningful text. They also suffer complications arising from limited-size entry fields and a diversity of data-entry personnel, leading to effects like haphazard abbreviation and improper spacing, as shown. These issues greatly complicate the IE problem, particularly considering that adapting IE to such formats is hampered by the existence of a multitude of such “standards” and by lack of sufficient annotated data in each one.

A typical state-of-the-art statistical IE engine will happily process such “noisy” inputs, and will typically provide garbage-in/garbage-out performance, embarrassingly reporting spurious “information” no human would ever mistake. Yet it is also inappropriate to discard such documents wholesale: even poor-quality inputs may have relevant information interspersed. This information can include accurate speech-recognition output, names which are recognizable even in wrong-language material, and clean target-language passages interleaved with the mark-up. Thus, here we address methods to make IE robust to such varied-quality inputs. Specifically, our overall goals are

- to skip processing non-language material such as standard or database-specific mark-up,
- to process all non-target-language text cautiously, catching interspersed target-language text as well as text which is compatible with the target language, *e.g.* person names which are the same in the target- and non-target language, and
- to degrade gracefully when processing anomalous target-language material,

while minimizing any disruption of the processing of clean, target-language text, and avoiding any necessity for explicit pre-classification of the genre of material being input to the system. Such explicit classification would be impractical in the presence of the interleaving and the unconstrained data formats from unpredetermined sources.

We begin our robustness work by addressing an important and basic IE task: mention detection (MD). MD is the task of identifying and classifying textual references to entities in open-domain texts. Mentions may be of type “named” (*e.g.* `John`, `Las Vegas`), “nominal” (*e.g.* `engineer`, `dentist`) or “pronominal” (*e.g.* `they`, `he`). A mention also has a specific class which describes the type of entity it refers to. For instance, consider the following sentence:

```
Julia Gillard, prime
minister of Australia,
declared she will enhance
the country's economy.
```

Here we see three mentions of one person entity: `Julia Gillard`, `prime minister`, and `she`; these mentions are of type named, nominal, and pronominal, respectively. `Australia` and `country` are mentions of type named and nominal, respectively, of a single geopolitical entity. Thus, the MD task is a more general and complex task than named-entity recognition, which aims at identifying and classifying only named mentions.

Our approach to IE has been to use language-independent algorithms, in order to facilitate reuse across languages, but we train them with language-specific data, for the sake of accuracy. Therefore, input is expected to be predominantly in a target language. However, real-world data genres inevitably include some mixed-language/non-linguistic input. Genre-specific training is typically infeasible due to such application-specific data sets being unannotated, motivating this line of research. Therefore, the goal of this study is to investigate schemes to make a language-specific MD engine robust to the types of interspersed non-target material described above. In these initial experiments, we work with English as the target language, though we aim to make our approach to robustness as target-language-independent as possible.

While our ultimate goal is a language-independent approach to robustness, in these initial experiments, English is the target language. However, we process mixed-language material including real-world data with its own peculiar mark-up, text conventions including abbreviations, and mix of languages, with the goal of English MD.

We approach robust MD using a multi-stage strategy. First, non-target-character-set passages (here, non-Latin-alphabet) are identified and marked for non-processing. Then, following word-tokenization, we apply a language classifier to a sliding variable-length set of windows in order to generate features for each word indicative of how much the text around that word resembles good English, primarily in comparison to other Latin-alphabet languages. These features are used in a separate maximum-entropy classifier whose output is a single feature to add to the MD classifier. Additional features, primarily to distinguish English from non-language input, are added to MD as well. An example is the minimum of the number of letters and the number of digits in the "word", which when greater than zero often indicates database detritus. Then we run the MD classifier enhanced with these new robustness-oriented features. We evaluate using a detection-error-trade-off (DET) (Martin et al., 1997) analysis, in addition to traditional precision/recall/F-measure.

This paper is organized as follows. Section 2 discusses previous work. Section 3 describes the baseline maximum-entropy-based MD system. Section 4 introduces enhancements to the system to achieve robustness. Section 5 describes databases used for experiments, which are discussed in Section 6, and Section 7 draws conclusions and plots future work.

2 Previous work on mention detection

The MD task has close ties to named-entity recognition, which has been the focus of much recent research (Bikel et al., 1997; Borthwick et al., 1998; Tjong Kim Sang, 2002; Florian et al., 2003; Benajiba et al., 2009), and has been at the center of several evaluations: MUC-6, MUC-7, CoNLL'02 and CoNLL'03 shared tasks. Usually, in computational-linguistics literature, a named entity represents an instance of either a location, a person, an organization, and the named-entity-recognition task consists of identifying each individual occurrence of names of such an entity appearing in the text. As stated earlier, in this paper we are interested in identification and classification of textual references to object/abstraction *mentions*, which can be either named, nominal or pronominal. This task has been a focus of interest in ACE since 2003. The recent ACE evaluation campaign was in 2008.

Effort to handle noisy data is still limited, especially for scenarios in which the system at decoding time does not have prior knowledge of the input data source. Previous work dealing with unstructured data assumes the knowledge of the input data source. As an example, E. Minkov *et al.* (Minkov et al., 2005) assume that the input data is text from e-mails, and define special features to enhance the detection of named entities. Miller *et al.* (Miller et al., 2000) assume that the input data is the output of a speech or optical character recognition system, and hence extract new features for better named-entity recognition. In a different research problem, L. Yi *et al.* eliminate the noisy text from the document before performing data mining (Yi et al., 2003). Hence, they do not try to process noisy data; instead, they remove it. The approach we propose in this paper does not assume prior knowledge of the data source. Also we do not want to eliminate the noisy data, but rather attempt to detect the appropriate mentions, if any, that appear in that portion of the data.

3 Mention-detection algorithm

Similarly to classical NLP tasks such as base phrase chunking (Ramshaw and Marcus, 1999) and named-entity recognition (Tjong Kim Sang, 2002), we formulate the MD task as a sequence-classification problem, by assigning to each word token in the text a label indicating whether it starts a specific mention, is inside a specific mention, or is outside any mentions. We also assign to every non-outside label a class to specify entity type *e.g.* person, organization, location, etc. We are interested in a statistical approach that can easily be adapted for several languages and that has the ability to integrate easily and make effective use of diverse sources of information to achieve high system performance. This is because, similar to many NLP tasks, good performance has been shown to depend heavily on integrating many sources of information (Florian et al., 2004). We choose a Maximum Entropy Markov Model (MEMM) as described previously (Florian et al., 2004; Zitouni and Florian, 2009). The maximum-entropy model is trained using the *sequential conditional generalized iterative scaling* (SCGIS) technique (Goodman, 2002), and it uses a *Gaussian prior* for regularization (Chen and Rosenfeld, 2000)[1].

3.1 Mention detection: standard features

The featues used by our mention detection systems can be divided into the following categories:

1. **Lexical Features** Lexical features are implemented as token n-grams spanning the current token, both preceding and following it. For a token x_i, token n-gram features will contain the previous $n-1$ tokens ($x_{i-n+1}, \dots x_{i-1}$) and the following $n-1$ tokens ($x_{i+1}, \dots x_{i+n-1}$). Setting n equal to 3 turned out to be a good choice.

2. **Gazetteer-based Features** The gazetteer-based features we use are computed on tokens. The gazetteers consist of several class of dictionaries: including person names, country names, company names, etc. Dictionaries contain single names such as `John` or `Boston`, and also phrases such as `Barack Obama`, `New York City`, or `The United States`. During both training and decoding, when we encounter in the text a token or a sequence of tokens that completely matches an entry in a dictionary, we fire its corresponding class.

The use of this framework to build MD systems for clean English text has given very competitive results at ACE evaluations (Florian et al., 2006). Trying other classifiers is always a good experiment, which we didn't pursue here for two reasons: first, the MEMM system used here is state-of-the-art, as proven in evaluations and competitions – while it is entirely possible that another system might get better results, we don't think the difference would be large. Second, we are interested in ways of improving performance on noisy data, and we expect any system to observe similar degradation in performance when presented with unexpected input – showing results for multiple classifier types might very well dilute the message, so we stuck to one classifier type.

4 Enhancements for robustness

As stated above, our goal is to skip spans of characters which do not lend themselves to target-language MD, while minimizing impact on MD for target-language text, with English as the initial target language for our experiments. More specifically, our task is to process data automatically in any unpredetermined format from any source, during which we strive to avoid outputting spurious mentions on:

- non-language material, such as mark-up tags and other data-set detritus, as well as non-text data such as code or binaries likely mistakenly submitted to the MD system,
- non-target-character-set material, here, non-Latin-alphabet material, such as Arabic and Chinese in their native character sets, and
- target-character-set material not in the target language, here, Latin-alphabet languages other than English.

It is important to note that this is not merely a document-classification problem; this non-target data is often interspersed with valid input text.

[1] Note that the resulting model cannot really be called a maximum-entropy model, as it does not yield the model which has the maximum entropy (the second term in the product), but rather is a maximum-*a-posteriori* model.

Mark-up is the obvious example of interspersing; however, other categories of non-target data can also interleave tightly with valid input. A few examples:

- English text is sometimes infixed right in a Chinese sentence, such as 其他BBC网站
- some translation algorithms will leave unchanged an untranslatable word, or will transliterate it into the target language using a character convention which may not be a standard known to the MD engine, and
- some target-alphabet-but-non-target-language material will be compatible with the target language, particularly people's names. An example with English as the target language is `Barack Obama` in the Spanish text `...presidente de Estados Unidos, Barack Obama, dijo el da 24 que ....`

Therefore, to minimize needless loss of processable material, a robustness algorithm ideally does a sliding analysis, in which, character-by-character or word-by-word, material may be deemed to be suitable to process. Furthermore, a variety of strategies will be needed to contend with the diverse nature of non-target material and the patterns in which it will appear among valid input.

Accordingly, the following is a summary of algorithmic enhancements to MD:

1. detection of standard file formats, such as SGML, and associated detagging,
2. segmentation of the file into target- vs. non-target-character-set passages, such that the latter not be processed further,
3. tokenization to determine word and sentence units, and
4. MD, augmented as follows:
   - Sentence-level categorization of likelihood of good English.
   - If "clean" English was detected, run the same clean baseline model as described in Section 3.
   - If the text is determined to be a bad fit to English, run an alternate maximum-entropy model that is heavily based on gazetteers, using only context-independent (*e.g.* primarily gazetteer-based) features, to catch isolated obvious English/English-compatible names embedded in otherwise-foreign text.
   - If in between "clean" and "bad", use a "mixed" maximum-entropy MD model whose training data and feature set are augmented to handle interleaving of English with mark-up and other languages.

These MD-algorithm enhancements will be described in the following subsections.

4.1 Detection and detagging for standard file formats

Some types of mark-up are well-known standards, such as SGML (Warmer and van Egmond, 1989). Clearly the optimal way of dealing with them is to apply detectors of these specific formats, and associated detaggers, as done previously (Yi et al., 2003). For this reason, standard mark-up is not a subject of the current study; rather, our concern is with mark-up peculiar to specific data sets, as described above, and so while this step is part of our overall strategy, it is not employed in the present experiments.

4.2 Character-set segmentation

Some entity mentions may be recognizable in a non-target language which shares the target-language's character set, for example, a person's name recognizable by English speakers in an otherwise-not-understandable Spanish sentence. However, non-target character sets, such as Arabic and Chinese when processing English, represent pure noise for an IE system. Therefore, deterministic character-set segmentation is applied, to mark non-target-character-set passages for non-processing by the remainder of the system, or, in a multilingual system, to be diverted to a subsystem suited to process that character set. Characters which can be ambiguous with regard to character set, such as some punctuation marks, are attached to target-character-set passages when possible, but are not considered to break non-target-character-set passages surrounding them on both sides.

4.3 Tokenization

Subsequent processing is based on determination of the language of target-alphabet text. The fundamental unit of such processing is target-alphabet word, necessitating tokenization at this point into word-level units. This step includes punctuation separation as well as the detction of sentence boundary (Zimmerman et al., 2006).

4.4 Robust mention detection

After preprocessing steps presented earlier, we detect mentions using a cascaded approach that combines several MD classifiers. Our goal is to select among maximum-entropy MD classifiers trained separately to represent different degrees of "noisiness" occurring in many genres of data, including machine-translation output, informal communications, mixed-language material, varied forms of non-standard database mark-up, etc. We somewhat-arbitrarily choose to employ three classifiers as described below. We select a classifier based on a sentence-level determination of the material's fit to the target language. First, we build an n-gram language model on clean target-language training text. This language model is used to compute the perplexity (PP) of each sentence during decoding. The PP indicates the quality of the text in the target-language (*i.e.* English) (Brown et al., 1992); the lower the PP, the cleaner the text. A sentence with a PP lower than a threshold θ_1 is considered "clean" and hence the "clean" baseline MD model described in Section 3 is used to detect mentions of this sentence. The clean MD model has access to standard features described in Section 3.1. In the case where a sentence looks particularly badly matched to the target language, defined as $PP > \theta_2$, we use a "*gazetteer-based*" model based on a dictionary look-up to detect mentions; we retreat to seeking known mentions in a context-independent manner reflecting that most of the context consists of out-of-vocabulary words. The gazetteer-based MD model has access only to gazetteer information and does not look to lexical context during decoding, reflecting the likelihood that in this poor material, words surrounding any recognizable mention are foreign and therefore unusable. In the case of an in-between determination, that is, a sentence with $\theta_1 < PP < \theta_2$, we use a "*mixed*" MD model, based on augmenting the training data set and the feature set as described in the next section. The values of θ_1 and θ_2 are estimated empirically on a separate development data set that is also used to tune the Gaussian prior (Chen and Rosenfeld, 2000). This set contains a mix of clean English and Latin-alphabet-but-non-English text that is not used for traning and evaluation.

The advantage of this combination strategy is that we do not need pre-defined knowledge of the text source in order to apply an appropriate model. The selection of the appropriate model to use for decoding is done automatically based on PP value of the sentence. We will show in the experiments section how this combination strategy is effective not only in maintaining good performance on a clean English text but also in improving performance on non-English data when compared to other source-specific MD models.

4.5 Mixed mention detection model

The mixed MD model is designed to process "sentences" mixing English with non-English, whether foreign-language or non-language material. Our approach is to augment model training compared to the clean baseline by adding non-English, mixed-language, and non-language material, and to augment the model's feature set with language-identification features more localized than the sentence-level perplexity described above, as well as other features designed primarily to distinguish non-language material such as mark-up codes.

4.5.1 Language-identification features

We apply an n-gram-based language classifier (Prager, 1999) to variable-length sliding windows as follows. For each word, we run 1- through 6-preceding-word windows through the classifier, and 1- through 6-word windows beginning with the word, for a total of 12 windows, yielding for each window a result like:

```
0.235 Swedish
0.148 English
0.134 French
...
```

For each of the 12 results, we extract three features: the identity of the top-scoring language, here, Swedish; the confidence score in the top-scoring language, here, 0.235; and the score difference between the target language (English for these experiments) and the top-scoring non-target language, here, $0.148 - 0.235 = -0.087$. Thus we have a 36-feature vector for each word. We bin these and use them as input to a maximum-entropy classifier (separate from the MD classifier) which outputs "English" or "Non-English", and a confidence score. These scores in turn are binned into six categories to serve as a "how-English-is-it" feature in the augmented MD model. The language-identification classifier and the maximum-entropy "how-English" classifier are each trained on text data separate from each other and from the training and test sets for MD.

4.5.2 Additional features

The following features are designed to capture evidence of whether a "word" is in fact linguistic material or not: number of alphabetic characters, number of characters, maximum consecutive repetitions of a character, numbers of non-alphabetic and non-alphanumeric characters, fraction of characters which are alphabetic, fraction alphanumeric, and number of vowels. These features are part of the augmentation of the mixed MD model relative to the clean MD model.

5 Data sets

Four data sets are used for our initial experiments. One, "English", consists of 367 documents totaling 170,000 words, drawn from web news stories from various sources and detagged to be plain text. This set is divided into 340 documents as a training set and 27 for testing, annotated as described in more detail elsewhere (Han, 2010). These data average approximately 21 annotated mentions per 100 words.

The second set, "Latin", consists of 23 detagged web news articles from 11 non-English Latin-alphabet languages totaling 31,000 words. Of these articles, 12 articles containing 19,000 words are used as a training set, with the remaining used for testing, and each set containing all 11 languages. They are annotated using the same annotation conventions as "English", and from the perspective of English; that is, only mentions which would be clear to an English speaker are labeled, such as `Barack Obama` in the Spanish example in Section 4. For this reason, these data average only approximately 5 mentions per 100 words.

The third, "Transactions", consists of approximately 60,000 words drawn from a text data set logging real financial transactions. Figure 1 shows example passages from this database, anonymized while preserving the character of the content.

This data set logs transactions by a staff of customer-service representatives. English is the primary language, but owing to international clientele, occasionally representatives communicate in other languages, such as the German here, or in English but mentioning institutions in other countries, here, a Czech bank. Interspersed among text are codes specific to this application which delineate and identify various information fields and punctuate long passages. The application also places constraints on legal characters, leading to the unusual representation of underline and the "at" sign as shown, making for an e-mail address which is human-readable but likely not obvious to a machine. Abbreviations represent terms particularly common in this application area, though they may not be obvious without adapting to the application; these include standards like `HUF`, a currency code which stands for Hungarian forint, and financial-transaction peculiarities like `BNF` for "beneficiary" as seen in Figure 1. In short, good English is interspersed with non-language content, foreign-language text, and rough English like data-entry errors and haphazard abbreviations. These data average 4 mentions per 100 words.

Data sets with peculiarities analogous to those in this Transactions set are commonplace in a variety of settings. Training specific to data sets like this is often infeasible due to lack of labeled data, insufficient data for training, and the multitude of such data formats. For this reason, we do not train on Transactions, letting our testing on this data set serve as an example of testing on such data formats unseen.

6 Experiments

MD systems were trained to recognize the 116 entity-mention types shown in Table 1, annotated as described previously (Han, 2010). The clean-data classifier was trained on the English training data using the feature set described in Section 3.1. The classifier for "mixed"-quality data and the "gazetteer" model were each trained on that set plus the "Latin" training set and the supplemental set. In addition, "mixed" training included the additional features described in Section 4.5. The framework used to build the baseline MD system is similar to the one we used in the ACE evaluation[2]. This system has achieved competitive results with an F-measure of 82.7 when trained on the seven main types of ACE data with access to wordnet and part-of-speech-tag information as well as output of other MD and named-entity recognizers (Zitouni and Florian, 2008).

It is instructive to evaluate on the individual component systems as well as the combination, despite the fact that the individual components are not well-suited to all the data sets, for example, the mixed and gazetteer systems being a poorer fit to the English task than the baseline, and vice versa for the

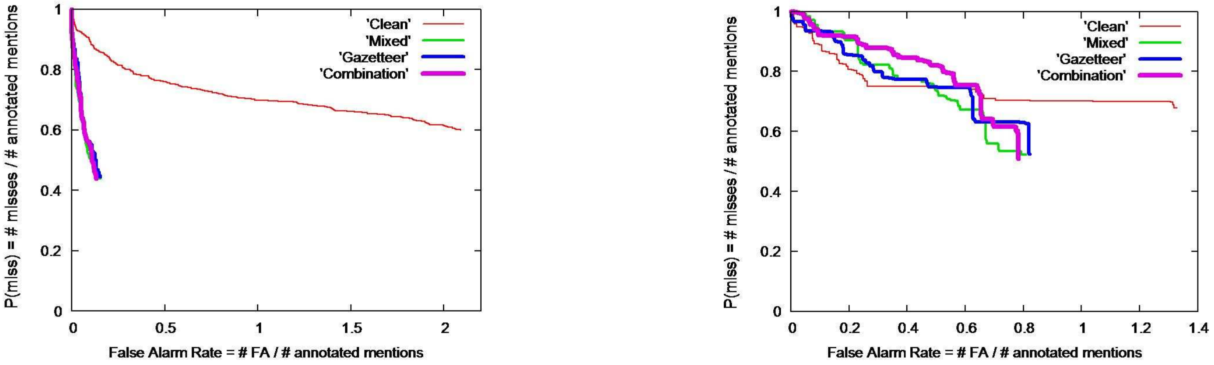
Table 2: Performance of clean, mixed, and gazetteer-based mention detection systems as well as their combination. Performance is presented in terms of Precision (P), Recall (R), and F-measure (F).

non-target data sets. Precision/recall/F-measure results are shown in Table 2. Not surprisingly, the baseline system, intended for clean data, performs poorly on noisy data. The mixed and gazetteer systems, having a variety of noisy data in their training set, perform much better on the noisy conditions, particularly on Latin-alphabet-non-English data because that is one of the conditions included in its training, while Transactions remains a condition not covered in the training set and so shows less improvement. However, because the mixed classifier, and moreso the gazetteer classifier, are oriented to noisy data, on clean data they suffer in performance by 2.5 and 5 F-measure points, respectively. But system combination serves us well: it recovers all but 0.5 F-measure point of this loss, while also actually performing better on the noisy data sets than the two classifiers specifically targeted toward them, as can be seen in Table 2. It is important to note that the major advantage of using the combination model is the fact that we do not have to know the data source in order to select the appropriate MD model to use. We assume that the data source is unknown, which is our claim in this work, and we show that we obtain better performance than using source-specific MD models. This reflects the fact that a noisy data set will in fact have portions with varying degrees of “noise”, so the combination outperforms any single model targeted to a single particular level of noise, enabling the system to contend with such variability without the need for pre-segregating sub-types of data for noise level. The obtained improvement from the system combination over all other models is statistically significant based on the stratified bootstrap re-sampling significance test (Noreen, 1989). We consider results statistically significant when $p < 0.05$, which is the case in this paper. This approach was used in the named-entity-recognition shared task of CoNNL-2002[3].

It should be noted that some completely-non-target types of data, such as non-target-character set data, have been omitted from analysis here. Including them would make our system look comparatively stronger, as they would have only spurious mentions and so generate false alarms but no correct mentions in the baseline system, while our system deterministically removes them.

As mentioned above, we view MD robustness primarily as an effort to eliminate, relative to a baseline system, large volumes of spurious “mentions” detected in non-target input content, while minimiz-

[3] http://www.cnts.ua.ac.be/conll2002/ner/



(a) DET plot for clean (baseline), mixed, gazetteer, and combination MD systems on the Latin-alphabet-non-English text. The clean system (upper curve) performs far worse than the other three systems designed to provide robustness; these systems in turn perform nearly indistinguishably.

(b) DET plot for clean (baseline), mixed, gazetteer, and combination MD systems on the Transactions data set. The clean system (upper/longer curve) reaches far higher false-alarm rates, while never approaching the lower miss rates achievable by any of the other three systems, which in turn perform comparably to each other.

Figure 2: DET plots for Latin-alphabet-non-English and Transactions data sets

ing disruption of detection in target input. A secondary goal is recall in the event of occasional valid mentions in such non-target material. Thus, as input material degrades, precision increases in importance relative to recall. As such, we view precision and recall asymmetrically on this task, and so rather than evaluating purely in terms of F-measure, we perform a detection-error-trade-off (DET) (Martin et al., 1997) analysis, in which we plot a curve of miss rate on valid mentions vs. false-alarm rate, with the curve traced by varying a confidence threshold across its range. We measure false-alarm and miss rates relative to the number of actual mentions annotated in the data set:

$$\text{FA rate} = \frac{\#\text{ false alarms}}{\#\text{ annotated mentions}} \qquad (1)$$

$$\text{Miss rate} = \frac{\#\text{ misses}}{\#\text{ annotated mentions}} \qquad (2)$$

where false alarms are "mentions" output by the system but not appearing in annotation, while misses are mentions which are annotated but do not appear in the system output. Each mention is treated equally in this analysis, so frequently-recurring entity/mention types weigh on the results accordingly.

Figure 2a shows a DET plot for the clean, mixed, gazetteer, and combination systems on the "Latin" data set, while Figure 2b shows the analogous plot for the "Transactions" data set. The drastic gains made over the baseline system by the three experimental systems are evident in the plots. For example, on Latin, choosing an operating point of a miss rate of 0.6 (nearly the best achievable by the clean system), we find that the robustness-oriented systems eliminate 97% of the false alarms of the clean baseline system, as the plot shows false-alarm rates near 0.07 compared to the baseline's of 2.08. Gains on Transaction data are more modest, owing to this case representing a data genre not included in training. It should be noted that the jaggedness of the Transaction curves traces to the repetitive nature of some of the terms in this data set.

In making a system more oriented toward robustness in the face of non-target inputs, it is important to quantify the effect of these systems being less-oriented toward clean, target-language text. Figure 3 shows the analogous DET plot for the English test set, showing that achieving robustness through the combination system comes at a small cost to accuracy on the text the original system is trained to process.

7 Conclusions

For information-extraction systems to be useful, their performance must degrade gracefully when confronted with inputs which deviate from ideal and/or derive from unknown sources in unknown formats. Imperfectly-translated, mixed-language, marked-up text and non-language material must not

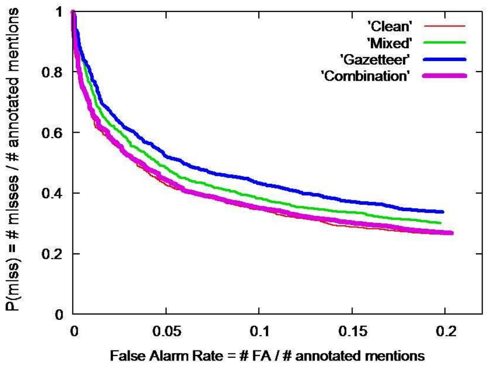


Figure 3: DET plot for clean (baseline), mixed, gazetteer, and combination MD systems on clean English text, verifying that performance by the clean system (lowest curve) is very closely approximated by the combination system (second-lowest curve), while the mixed system performs somewhat worse and the gazetteer system (top curve), worse still, reflecting that these systems are increasingly oriented toward noisy inputs.

be processed in a garbage-in-garbage-out fashion merely because the system was designed only to handle clean text in one language. Thus we have embarked on information-extraction-robustness work, to improve performance on imperfect inputs while minimizing disruption of processing of clean text. We have demonstrated that for one IE task, mention detection, a multi-faceted approach, motivated by the diversity of input data imperfections, can eliminate a large proportion of the spurious outputs compared to a system trained on the target input, at a relatively small cost of accuracy on that target input. This outcome is achieved by a system-combination approach in which a perplexity-based measure of how well the input matches the target language is used to select among models designed to deal with such varying levels of noise. Rather than relying on explicit recognition of genre of source data, the experimental system merely does its own assessment of how much each sentence-sized chunk matches the target language, an important feature in the case of unknown text sources.

Chief among directions for further work is to continue to improve performance on noisy data, and to strengthen our findings via larger data sets. Additionally, we look forward to expanding analysis to different types of imperfect input, such as machine-translation output, different types of mark-up, and different genres of real data. Further work should also explore the degree to which the approach to achieving robustness must vary according to the target language. Finally, robustness work should be expanded to other information-extraction tasks.

Abstract

Seed sampling is critical in semi-supervised learning. This paper proposes a clustering-based stratified seed sampling approach to semi-supervised learning. First, various clustering algorithms are explored to partition the unlabeled instances into different strata with each stratum represented by a center. Then, diversity-motivated intra-stratum sampling is adopted to choose the center and additional instances from each stratum to form the unlabeled seed set for an oracle to annotate. Finally, the labeled seed set is fed into a bootstrapping procedure as the initial labeled data. We systematically evaluate our stratified bootstrapping approach in the semantic relation classification subtask of the ACE RDC (Relation Detection and Classification) task. In particular, we compare various clustering algorithms on the stratified bootstrapping performance. Experimental results on the ACE RDC 2004 corpus show that our clustering-based stratified bootstrapping approach achieves the best F1-score of 75.9 on the subtask of semantic relation classification, approaching the one with golden clustering.

1 Introduction

Semantic relation extraction aims to detect and classify semantic relationships between a pair of named entities occurring in a natural language text. Many machine learning approaches have been proposed to attack this problem, including supervised (Miller et al., 2000; Zelenko et al., 2003; Culotta and Soresen, 2004; Kambhatla, 2004; Zhao and Grishman, 2005; Zhou et al., 2005; Zhang et al., 2006; Zhou and Zhang, 2007; Zhou et al., 2007; Qian et al., 2008; Zhou et al., 2010), semi-supervised (Brin, 1998; Agichtein and Gravano, 2000; Zhang, 2004; Chen et al., 2006; Qian et al., 2009; Zhou et al., 2009), and unsupervised methods (Hasegawa et al., 2004; Zhang et al., 2005; Chen et al., 2005).

Current work on relation extraction mainly adopts supervised learning methods, since they achieve much better performance. However, they normally require a large number of manually labeled relation instances, whose acquisition is both time consuming and labor intensive. In contrast, unsupervised methods do not need any manually labeled instances. Nevertheless, it is difficult to assess their performance due to the lack of evaluation criteria. As something between them, semi-supervised learning has received more and more attention recently. With the plenitude of unlabeled natural language text at hand, semi-supervised learning can significantly reduce the need for labeled data with only limited sacrifice in performance. For example, Abney (2002) proposes a bootstrapping algorithm which chooses the unlabeled instances with the highest probability of being correctly labeled and add them in turn into the labeled training data iteratively.

This paper focuses on bootstrapping-based semi-supervised learning in relation extraction. Since the performance of bootstrapping depends much on the quality and quantity of the seed set and researchers tend to employ as few seeds as possible (e.g. 100 instances) to save time and labor, the quality of the seed set plays a critical role in bootstrapping. Furthermore, the imbalance of different classes and

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 346–355,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

the inherent structural complexity of instances will severely weaken the strength of bootstrapping and semi-supervised learning as well. Therefore, it is critical for a bootstrapping procedure to select an appropriate seed set, which should be representative and diverse. However, most of current semi-supervised relation extraction systems (Zhang, 2004; Chen et al., 2006) use a random seed sampling strategy, which fails to fully exploit the affinity nature in the training data to derive the seed set. Alternatively, Zhou et al. (2009) bootstrap a set of weighted support vectors from both labeled and unlabeled data using SVM and feed these instances into semi-supervised relation extraction. However, their seed set is sequentially generated only to ensure that there are at least 5 instances for each relation class. Our previous work (Qian et al., 2009) attempts to solve this problem via a simple stratified sampling strategy for selecting the seed set. Experimentation on the ACE RDC 2004 corpus shows that the stratified sampling strategy achieves promising results for semi-supervised learning. Nevertheless, the success of the strategy relies on the assumption that the true distribution of all relation types is already known, which is impractical for real NLP applications.

This paper presents a clustering-based stratified seed sampling approach for semi-supervised relation extraction, without the assumption on the true distribution of different relation types. The motivations behind our approach are that the unlabeled data can be partitioned into a number of strata using a clustering algorithm and that representative and diverse seeds can be derived from such strata in the framework of stratified sampling (Neyman, 1934) for an oracle to annotate. Particularly, we employ a diversity-motivated intra-stratum sampling scheme to pick a center and additional instances as seeds from each stratum. Experimental results show the effectiveness of the clustering-based stratified seed sampling for semi-supervised relation classification.

The rest of this paper is organized as follows. First an overview of the related work is given in Section 2. Then, Section 3 introduces the stratified bootstrapping framework including an intra-stratum sampling scheme while Section 4 describes various clustering algorithms. The experimental results on the ACE RDC 2004 corpus are reported in Section 5. Finally we conclude our work and indicate some future directions in Section 6.

2 Related Work

In semi-supervised learning for relation extraction, most of previous work construct the seed set either randomly (Zhang, 2004; Chen et al., 2006) or sequentially (Zhou et al., 2009). Qian et al. (2009) adopt a stratified sampling strategy to select the seed set. However, their method needs a stratification variable such as the known distribution of the relation types, while our method uses clustering to divide relation instances into different strata.

In the literature, clustering techniques have been employed in active learning to sample representative seeds in a certain extent (Nguyen and Smeulders, 2004; Tang et al., 2002; Shen et al., 2004). Our work is similar to the formal framework, as proposed in Nguyen and Smeulders (2004), in which K-medoids clustering is incorporated into active learning. The cluster centers are used to construct a classifier and which in turn propagates classification decision to other examples via a local noise model. Unlike their probabilistic models, we apply various clustering algorithms together with intra-stratum sampling to select a seed set in discriminative models like SVMs. In active learning for syntactic parsing, Tang et al. (2002) employ a sampling strategy of “most uncertain per cluster” to select representative examples and weight them using their cluster density, while we pick a few seeds (the number of the sampled seeds is proportional to the cluster density) from a cluster in addition to its center. Shen et al. (2004) combine multiple criteria to measure the informativeness, representativeness, and diversity of examples in active learning for named entity recognition. Unlike our sampling strategy of clustering for representativeness and stratified sampling for diversity, they either select cluster centroids or diverse examples from a prechosen set in terms of some combined metrics. To the best of our knowledge, this is the first work to address the issue of seed selection using clustering techniques for semi-supervised learning with discriminative models.

3 Stratified Bootstrapping Framework

The stratified bootstrapping framework consists of three major components: an underlying supervised learner and a bootstrapping algorithm on top of it as usual, plus a clustering-based stratified seed sampler.

3.1 Underlying Supervised Learner

Due to recent success in tree kernel-based relation extraction, this paper adopts a tree kernel-based method in the underlying supervised learner. Following the previous work in relation extraction (Zhang et al., 2006; Zhou et al., 2007; Qian et al., 2008), we use the standard convolution tree kernel (Collins and Duffy, 2001) to count the number of common sub-trees as the structural similarity between two parse trees. Besides, to properly represent a relation instance, this paper adopts the Unified Parse and Semantic Tree (UPST), as proposed in Qian et al. (2008). To our knowledge, the USPT has achieved the best performance in relation extraction so far on the ACE RDC 2004 corpus.

In particular, we use the SVM^{light}-TK[1] package as our classifier. Since the package is a binary classifier, we adapt it to the multi-class tasks of relation extraction by applying the *one vs. others* strategy, which builds *K* binary classifiers so as to separate one class from all others. The final classification decision of an instance is determined by the class that has the maximal SVM output margin.

3.2 Bootstrapping Algorithm

Following Zhang (2004), we have developed a baseline self-bootstrapping procedure, which keeps augmenting the labeled data by employing the models trained from previously available labeled data, as shown in Figure 1.

Since the SVM^{light}-TK package doesn't output any probability that it assigns to the class label on an instance, we devise a metric to measure the confidence with regard to the classifier's prediction. Given a sequence of output margins of all *K* binary classifiers at some iteration, denoted as $\{m_1, m_2, \ldots m_K\}$ with m_i the margin for the *i*-th classifier, we compute the margin gap between the largest and the mean of the others, i.e.

$$H = \max_{i=1}^{K} m_i - (\sum_{i=1}^{K} m_i - \max_{i=1}^{K} m_i)/(K-1) \qquad (1)$$

Where *K* denotes the total number of relation classes, and m_i denotes the output margin of the *i*-th classifier. Intuitively, the bigger the *H*, the greater the difference between the maximal margin and all others, and thus the more reliably the classifier makes the prediction on the instance.

```
**Algorithm** self-bootstrapping
Require: labeled seed set L
Require: unlabeled data set U
Require: batch size S
Repeat
    Train a single classifier on L
    Run the classifier on U
    Find at most S instances in U that the classifier has the highest prediction confidence
    Add them into L
Until: no data points available or the stoppage condition is reached
```

Figure 1: Self-bootstrapping algorithm

3.3 Clustering-based Stratified Seed Sampler

Stratified sampling is a method of sampling in statistics, in which the members of a population are grouped into relatively homogeneous subgroups (i.e. strata) according to one certain property, and then a sample is selected from each stratum. This process of grouping is called stratification, and the property on which the stratification is performed is called the stratification variable. Previous work justifies theoretically and practically that stratified sampling is more appropriate than random sampling for general use (Neyman, 1934) as well as for relation extraction (Qian et al., 2009). However, the difficulty lies in how to find the appropriate stratification variable for complicated tasks, such as relation extraction.

The idea of clustering-based stratification circumvents this problem by clustering the unlabeled data into a number of strata without the need to explicitly specify a stratification variable. Figure 2 illustrates the clustering-based stratified seed sampling strategy employed in the bootstrapping procedure, where *RSET* denotes the whole unlabeled data, *SeedSET* the seed set to be labeled and $|RSET_i|$ the number of instances in the *i*-th cluster[2] $RSET_i$. Here, a relation instance is represented using USPT and the similarity between two instances is computed using the standard convolution tree

[1] http://ai-nlp.info.uniroma2.it/moschitti/

[2] Hereafter, when we refer to clusters from the viewpoint of stratified sampling, they are often called "strata".

kernel, as described in Section 3.1 (i.e., both the clustering and the classification adopt the same structural representation, since we want the representative seeds in the clustering space to be also representative in the classification space). After clustering, a certain number of instances from every stratum are sampled using an intra-stratum scheme (c.f. Subsection 3.4). Normally, this number is proportional to the size of that stratum in the whole data set. However, in case this number is 0 due to the rounding of real numbers, it is set to 1 to ensure the existence of at least one seed from that stratum. Furthermore, to ensure that the total number of instances being sampled equals the prescribed N_S, the number of seeds from dominant strata may be slightly adjusted accordingly. Finally, these instances form the unlabeled seed set for an oracle to annotate as the input to the underlying supervised learner in the bootstrapping procedure.

3.4 Intra-stratum sampling

Given the distribution of clusters, a simple way to select the most representative instances is to choose the center of each cluster with the cluster prior as the weight of the center (Tang et al., 2002; Nguyen and Smeulders, 2004). Nevertheless, for the complicated task of relation extraction on the ACE RDC corpora, which is highly skewed across different relation classes, only considering the center of each cluster would severely under-represent the high-density data. To overcome this problem, we adopt a sampling approach, in particular stratified sampling, which takes the size of each stratum into consideration.

Given the size of the seed set N_S and the number of strata K, a natural question will arise as how to select the remaining (N_S-K) seeds after we have extracted the K centers from the K strata. We view this problem as intra-stratum sampling, which is required to choose the remaining number of seeds from inside individual stratum (excluding the centers themselves).

At the first glance, sampling a certain number of seeds from one particular stratum (e.g., $RSET_i$), seems to be the same sampling problem as we have encountered before, which aims to select the most representative and diverse seeds. This will naturally lead to another application of a clustering algorithm to the stratification of the stratum $RSET_i$.

```
Require: $RSET = \{R_1, R_2, \ldots, R_N\}$, the set of unlabeled relation instances and $K$, the number of strata being clustered
Output: $SeedSET$ with the size of $N_S$ (100)
Procedure
    Initialize $SeedSET = NULL$
    Cluster $RSET$ into $K$ strata using a clustering
        algorithm and perform stratum pruning if necessary.
    Calculate the number of instances being sampled
        for each stratum $i=\{1,2,\ldots,K\}$
            $N_i = \frac{|RSET_i|}{N} * N_S$        (2)
            and adjust this number if necessary.
    Perform intra-strata sampling to form $SeedSET_i$
        from each stratum $RSET_i$, by selecting the center
        $C_i$ and ($N_i$-1) additional instances
    Generate $SeedSET$ by summating $RSET_i$ from each
        stratum
```

Figure 2: Clustering-based stratified seed sampling

Nevertheless, remember the fact that, this time for the stratum $RSET_i$, the center C_i has been chosen, so it may not be reasonable to extract additional centers in this way. Therefore, in order to avoid recursion and over-complexity, we employ a diversity-motivated intra-stratum sampling scheme (Shen et al., 2004), called KDN (K-diverse neighbors), which aims to maximize the training utility of all seeds from a stratum. The motivation is that we prefer the seeds with high variance to each other, thus avoiding repetitious seeds from a single stratum. The basic idea is to add a candidate instance to the seed set only if it is sufficiently different from any previously selected seeds, i.e., the similarity between the candidate instance and any of the current seeds is less than a threshold β. In this paper, the threshold β is set to the average pair-wise similarity between any two instances in a stratum.

4 Clustering Algorithms

This section describes several typical clustering algorithms in the literature, such as K-means, HAC, spectral clustering and affinity propagation, as well as their application in this paper.

4.1 K-medoids (KM)

As a simple yet effective clustering method, the K-means algorithm assigns each instance to the cluster whose center (also called centroid) is nearest. In particular, the center is the average of all the instances in the cluster, i.e., with its coordinates the arithmetic means for each dimension separately over all the instances in the cluster.

One problem with K-means is that it does not yield the same result with each run while the other problem is the requirement for the concept of a mean to be definable, which is unfortunately not available in our setting (we employ a parse tree representation for a relation instance). Hence, we adopt a variant of K-means, namely, K-medoids, where a medoid, rather than a centroid, is defined as a representative of a cluster. Besides, K-medoids has proved to be more robust to noise and outliers in comparison with K-means.

4.2 Hierarchical Agglomerative Clustering (HAC)

Different from K-medoids, hierarchical clustering creates a hierarchy of clusters which can be represented in a tree structure called a dendrogram. The root of the tree consists of a single cluster containing all objects, and the leaves correspond to individual object.

Typically, hierarchical agglomerative clustering (HAC) starts at the leaves and successively merges two clusters together as long as they have the shortest distance among all the pair-wise distances between any two clusters.

Given a specified number of clusters, the key problem is to determine where to cut the hierarchical tree into clusters. In this paper, we generate the final flat cluster structures greedily by maximizing the equal distribution of instances among different clusters.

4.3 Spectral Clustering (SC)

Spectral clustering has become more and more popular recently. Taking as input a similarity matrix between any two instances, spectral clustering makes use of the spectrum of the similarity matrix of the data to perform dimensionality reduction for clustering in fewer dimensions.

Compared to the “traditional algorithms” such as K-means or HAC, spectral clustering has many fundamental advantages. Results obtained by spectral clustering often outperform the traditional approaches. Furthermore, spectral clustering is very simple to implement and can be solved efficiently using standard linear algebra methods (von Luxburg, 2006).

4.4 Affinity Propagation (AP)

As a new emerging clustering algorithm, affinity propagation (AP) (Frey and Dueck, 2007) is basically an iterative message-passing procedure in which the instances being clustered compete to serve as cluster exemplars by exchanging two types of messages, namely, “responsibility” and “availability”. After the procedure converges or has repeated a finite number of iterations, each cluster is represented by an exemplar. AP was reported to find clusters with much lower error than those found by other methods.

For our application, affinity propagation takes as input a similarity matrix, whose elements represent either the similarity between two different instances or the preference (a real number *p*) for an instance when two instances are the same. One problem with AP is that the number of clusters cannot be pre-defined, which is indirectly determined by the preference as well as the convergence procedure itself.

5 Experimentation

This section systematically evaluates the bootstrapping approach using clustering-based stratified seed sampling, in the relation classification (i.e., given the relationship already detected) subtask of relation extraction on the ACE RDC 2004 corpus.

5.1 Experimental Setting

The ACE RDC 2004 corpus[3] is gathered from various newspapers, newswire and broadcasts. It contains 451 documents and 5702 positive relation instances of 7 relation types and 23 subtypes between 7 entity types. For easy reference with related work in the literature, evaluation is done on 347 documents (from *nwire* and *bnews* domains), which include 4305 relation instances. Table 1 lists the major relation types and subtypes, including their corresponding instance numbers and ratios in our evaluation set. One obvious observation from the table is that the numbers of different relation types is highly imbalanced. These 347 documents are then divided into 3 disjoint sets randomly, with

Total		4305	100.0

Table 1: Relation types and their corresponding instance numbers and ratios in the ACE RDC 2004 corpus

10% of them (35 files, around 400 instances) held out as the test data set, 10% of them (35 files, around 400 instances) used as the development data set to fine-tune various settings and parameters, while the remaining 277 files (over 3400 instances) used as the training data set, from which the seed set will be sampled.

The corpus is parsed using Charniak's parser (Charniak, 2001) and relation instances are generated by extracting all pairs of entity mentions occurring in the same sentence with positive relationships. For easy comparison with related work, we only evaluate the relation classification task on the 7 major relation types of the ACE RDC 2004 corpus. For the SVM^{light}-TK classifier, the training parameters C (SVM) and λ (tree kernel) are fine-tuned to 2.4 and 0.4 respectively.

The performance is measured using the standard P/R/F1 (Precision/Recall/F1-measure). For each relation type, P is the ratio of the true relation instances in all the relation instances being identified, R is the ratio of the true relation instances being identified in all the true relation instances in the corpus, and F1 is the harmonic mean of P and R. The overall performance P/R/F1 is then calculated using the micro-average measure over all major class types.

5.2 Experimental Results

Comparison of various seed sampling strategies without intra-stratum sampling on the development data

Table 2 compares the performance of bootstrapping-based relation classification using various seed sampling strategies without intra-stratum sampling on the development data. Here, the size of the seed set *L* is set to 100, and the top 100 instances with the highest confidence (c.f. Formula 1) are augmented at each iteration. For sampling strategies marked with an asterisk, we performed 10 trials and calculated their averages. Since for these strategies the seed sets sampled from different trials may be quite different, their performance scores vary in a great degree accordingly. This experimental setting and notation are also used in all the subsequent experiments unless specified. Besides, two additional baseline sampling strategies are included for comparison: sequential sampling (SEQ), which selects a sequentially-occurring *L* instances as the seed set, and random sampling (RAND), which randomly selects *L* instances as the seed set.

Table 2 shows that

1) RAND outperforms SEQ by 1.2 units in F1-score. This is due to the fact that the seed set via RAND may better reflect the distribution of the whole training data than that via SEQ, nevertheless at the expense of collecting the whole training data in advance.
2) While HAC performs moderately better than RAND, it is surprising that both KM and AP perform even worse than SEQ, and that SC performs worse than RAND. Furthermore, all the four clustering-based seed sampling strategies achieve much smaller performance improvement in F1-score than RAND, among which KM performs worst with performance improvement of only 0.1 in F1-score.

Sampling strategies	P(ΔP)	R(ΔR)	F1(ΔF1)
RAND*	69.1(3.1)	66.4(0.2)	67.8(2.0)
SEQ*	65.8(2.6)	68.0(0.1)	66.6(1.3)
KM*	62.0(0.9)	61.0(-0.5)	61.3(0.1)
HAC	**69.9(1.3)**	**70.4(0.4)**	**70.1(0.8)**
SC*	67.1(1.5)	68.1(0.0)	67.5(0.8)
AP	66.6(2.0)	66.2(0.1)	66.4(1.1)

Table 2: Comparison of various seed sampling strategies without intra-stratum sampling on the development data

3) All the performance improvements from bootstrapping largely come from the improvements in precision. While the bootstrapping procedure makes the SVM classifier more accurate, it lacks enough generalization ability.

To explain above special phenomena, we have a look at the clustering results. Our inspection reveals that most of them are severely imbalanced, i.e., some clusters are highly dense while others are extremely sparse. This indicates that merely selecting the centers from each cluster cannot properly represent the overall distribution. Moreover, the centers with high density lack the generalization ability due to its solitude in the cluster, leading to less performance enhancement than expected.

The only exception is HAC, which much outperforms RAND by 2.3 in F1-score, although HAC is usually not considered as an effective clustering algorithm. The reason may be that HAC creates a hierarchy of clusters in the top-down manner by cutting a cluster into two. Therefore, the centers in the two sibling clusters will be closer to each other than they are to the centers in other clusters. Besides, the final flat cluster structures given a special number of clusters are generated greedily from the cluster hierarchy by maximizing the equal distribution of instances among different clusters. In other words, when the cluster number reaches a certain threshold, the dense area will get more seeds represented in the seed set. As a consequence, the distribution of all the seeds sampled by HAC will approximate the distribution of the whole training data in some degree, while the seeds sampled by other clustering algorithm are kept as far as possible due to the objective of clustering and the lack of intra-stratum sampling.

These observations also justify the application of the stratified seed sampling to the bootstrapping procedure, which enforces the number of seeds sampled from a cluster to be proportional to its density, presumably approximated by its size in this paper.

Comparison of different cluster numbers with intra-stratum sampling on the development data

In order to fine-tune the optimal cluster numbers for seed sampling, we compare the performance of different numbers of clusters for each clustering algorithm on the development data set and report their F-scores in Table 3. For reference, we also list the F-score for golden clustering (GOLD), in which all instances are grouped in terms of their annotated ground relation major types (7), major types considering relation direction (13), subtypes (23), and subtypes considering direction (38). Besides, the performance of clustering-based semi-supervised relation classification is also measured over other typical cluster numbers (i.e., 1, 50, 60, 80, 100). Particularly, when the cluster number equals 1, it means that only diversity other than representativeness is considered in the seed sampling. Among these clustering algorithms, one of the distinct characteristics with the AP algorithm is that the number of clusters cannot be specified in advance, rather, it is determined by the pre-defined preference parameter (c.f. Subsection 4.4). Therefore, we should tune the preference parameter so as to get the pre-defined cluster number. However, sometimes we still couldn't get the exact number of clusters as we expected. In these cases, we use the approximate cluster numbers for AP instead.

Table 3 shows that

1) The performance for all the clustering algorithms varies in some degree with the number of clusters being grouped. Interestingly, the performance with only one cluster is better than those of clustering-based strategies with 100 clusters, at most cases. This implies that the diversity of the seeds is at least as important as their representativeness. And this could be further explained by our observation that, with the increase of cluster numbers, the clusters get smaller and denser while their centers also come closer to each other. Therefore, the representativeness and diversity as well as the distribution of the seeds sampled from them may vary accordingly, leading to different performance.

# of Clusters	GOLD	KM*	HAC	SC*	AP
1	-	68.7	68.7	-	-
7	**73.9**	70.3	**73.3**	**72.1**	-
13	70.2	68.9	70.3	67.3	-
23	64.9	**72.3**	72.9	68.9	71.1
38	60.8	69.9	71.6	68.0	**71.6**
50	-	68.5	69.9	68.5	70.4
60	-	66.3	68.5	68.6	69.7
80	-	64.2	65.9	68.0	68.1
100	-	61.3	70.1	67.5	66.4

Table 3: Performance in F1-score over different cluster numbers with intra-stratum sampling on the development data

2) Golden clustering achieves the best performance of 73.9 in F1-score when the cluster number is set to 7, significantly higher than the performance using other cluster numbers. Interestingly, this number coincides with the number of major relation types needed to be classified in our task. This is reasonable since the instances with the same relation type should be much more similar than those with different relation types and it is easy to discriminate the seed set of one relation type from that of other relation types.

3) Among the four clustering algorithms, HAC achieves best performance over most of cluster numbers. This further verifies the aforementioned analysis. That is, as a hierarchical clustering algorithm, HAC can sample seeds that better capture the distribution of the training data.

4) For KM, the best performance is achieved around the number of 23 while for both HAC and SC, the optimal cluster number is consistent with GOLD clustering, namely, 7. For AP, the optimal cluster number for AP is 38. This is largely due to that we fail to cluster the training data into about 7 and 13 groups no matter how we vary the preference parameter.

Final comparison of different clustering algorithms on the held-out test data

After the optimal cluster numbers are determined for each clustering algorithm, we apply these numbers on the held-out test data and report the performance results (P/R/F1 and their respective improvements) in Table 4. For easy reference, we also include the performance for GOLD, RAND, and SEQ sampling strategies.

Sampling strategies	P(ΔP)	R(ΔR)	F1(ΔF1)
GOLD	**79.5(7.8)**	72.7(2.1)	**76.0**(4.8)
RAND*	71.9(3.7)	69.7(0.1)	70.8(1.8)
SEQ*	71.9(2.6)	65.2(0.1)	69.3(1.3)
KM*	73.6(2.1)	72.3(0.3)	72.9(1.2)
HAC	79.0(10.2)	**73.0(1.1)**	**75.9(5.6)**
SC*	72.3(2.1)	72.1(0.4)	72.2(1.2)
AP	75.7(2.5)	72.0(0.4)	73.7(1.4)

Table 4: Performance of various clustering-based seed sampling strategies on the held-out test data with the optimal cluster number for each clustering algorithm

Table 4 shows that

1) Among all the clustering algorithms, HAC achieves the best F1-score of 75.9, significantly higher than RAND and SEQ by 5.1 and 6.6 respectively. The improvement comes not only from significant precision boost, but also from moderate recall increase. This further justifies the merits of HAC as a clustering algorithm for stratified seed sampling in semi-supervised relation classification.

2) HAC approaches the best F1-score of 76.0 for golden clustering. Obviously, this doesn't mean HAC performs as well as golden clustering in terms of clustering quality measures, rather it does imply that HAC achieves the performance improvement by making the seed set better represent the overall distribution over inherent structure of relation instances, while golden clustering accomplishes this using the distribution over relation types. Since the distribution over relation types doesn't always conform to that over instance structures, and for a statistical discriminative classifier, often the latter is more important than the former, it will be no surprise if HAC outperforms golden clustering in some real applications, e.g. clustering-based stratified sampling.

6 Conclusion and Future Work

This paper presents a stratified seed sampling strategy based on clustering algorithms for semi-supervised learning. Our strategy does not rely on any stratification variable to divide the training instances into a number of strata. Instead, the strata are formed via clustering, given a metric measuring the similarity between any two instances. Further, diversity-motivated intra-strata sampling is employed to sample additional instances from within each stratum besides its center. We compare the effect of various clustering algorithms on the performance of semi-supervised learning and find that HAC achieves the best performance since the distribution of its seed set better approximates that of the whole training data. Extensive evaluation on the ACE RDC 2004 benchmark corpus shows that our clustering-based stratified seed sampling strategy significantly improves the performance of semi-supervised relation classification.

We believe that our clustering-based stratified seed sampling strategy can not only be applied to other semi-supervised learning tasks, but also can be incorporated into active learning, where the instances to be labeled at each iteration as well as the seed set could be selected using clustering techniques, thus further reducing the amount of instances needed to be annotated.

For the future work, it is possible to adapt our one-level clustering-based sampling to the multi-level one, where for every stratum it is still possible to divide it into lower sub-strata for further stratified sampling in order to make the seeds better represent the true distribution of the data.

Unsupervised discovery of negative categories in lexicon bootstrapping

Tara McIntosh

Abstract

Multi-category bootstrapping algorithms were developed to reduce semantic drift. By extracting multiple semantic lexicons simultaneously, a category's search space may be restricted. The best results have been achieved through reliance on manually crafted negative categories. Unfortunately, identifying these categories is non-trivial, and their use shifts the unsupervised bootstrapping paradigm towards a supervised framework.

We present NEG-FINDER, the first approach for discovering negative categories automatically. NEG-FINDER exploits unsupervised term clustering to generate multiple negative categories during bootstrapping. Our algorithm effectively removes the necessity of manual intervention and formulation of negative categories, with performance closely approaching that obtained using negative categories defined by a domain expert.

1 Introduction

Automatically acquiring semantic lexicons from text is essential for overcoming the knowledge bottleneck in many NLP tasks, e.g. question answering (Ravichandran and Hovy, 2002). Many of the successful methods follow the unsupervised iterative bootstrapping framework (Riloff and Shepherd, 1997). Bootstrapping has since been effectively applied to extracting general semantic lexicons (Riloff and Jones, 1999), biomedical entities (Yu and Agichtein, 2003) and facts (Carlson et al., 2010).

Bootstrapping is often considered to be minimally supervised, as it is initialised with a small set of seed terms of the target category to extract. These seeds are used to identify patterns that can match the target category, which in turn can extract new lexicon terms (Riloff and Jones, 1999). Unfortunately, *semantic drift* often occurs when ambiguous or erroneous terms and/or patterns are introduced into the iterative process (Curran et al., 2007).

In multi-category bootstrapping, semantic drift is often reduced when the target categories compete with each other for terms and/or patterns (Yangarber et al., 2002). This process is most effective when the categories bound each other's search space. To ensure this, manually crafted negative categories are introduced (Lin et al., 2003; Curran et al., 2007). Unfortunately, this makes these algorithms substantially more supervised.

The design of negative categories is a very time consuming task. It typically requires a domain expert to identify the semantic drift and its cause, followed by a significant amount of trial and error in order to select the most suitable combination of negative categories. This introduces a substantial amount of supervised information into what was an unsupervised framework, and in turn negates one of the main advantages of bootstrapping — the quick construction of accurate semantic lexicons.

We show that although excellent performance is achieved using negative categories, it varies greatly depending on the negative categories selected. This highlights the difficulty of crafting negative categories and thus the necessity for tools that can automatically identify them.

Our second contribution is the first fully unsupervised approach, NEG-FINDER, for discovering

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 356–365,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

negative categories automatically. During bootstrapping, efficient clustering techniques are applied to sets of drifted candidate terms to generate new negative categories. Once a negative category is identified it is incorporated into the subsequent iterations whereby it provides the necessary semantic boundaries for the target categories.

We demonstrate the effectiveness of our approach for extracting biomedical semantic lexicons by incorporating NEG-FINDER within the WMEB-DRIFT bootstrapping algorithm (McIntosh and Curran, 2009). NEG-FINDER significantly outperforms bootstrapping prior to the domain expert's negative categories. We show that by using our discovered categories we can reach near expert-guided performance. Our methods effectively remove the necessity of manual intervention and formulation of negative categories in semantic lexicon bootstrapping.

2 Background

Various automated pattern-based bootstrapping algorithms have been proposed to iteratively build semantic lexicons. In multi-level bootstrapping, a lexicon is iteratively expanded from a small sample of seed terms (Riloff and Jones, 1999). The seed terms are used to identify contextual patterns they appear in, which in turn may be used to extract new lexicon entries. This process is repeated with the new expanded lexicon identifying new patterns.

When bootstrapping semantic lexicons, polysemous or erroneous terms and/or patterns that weakly constrain the semantic class are eventually extracted. This often causes *semantic drift* — when a lexicon's intended meaning shifts into another category during bootstrapping (Curran et al., 2007). For example, *female names* may drift into *gemstones* when the terms *Ruby* and *Pearl* are extracted.

Multi-category bootstrapping algorithms, such as BASILISK (Thelen and Riloff, 2002), NOMEN (Yangarber et al., 2002), and WMEB (McIntosh and Curran, 2008), aim to reduce semantic drift by extracting multiple semantic categories simultaneously. These algorithms utilise information about other semantic categories in order to reduce the categories from drifting towards each other. This framework has recently been extended to extract different relations from text (Carlson et al., 2010).

2.1 Weighted MEB

In Weighted Mutual Exclusion Bootstrapping (WMEB, McIntosh and Curran, 2008), multiple semantic categories iterate simultaneously between the term and pattern extraction phases, competing with each other for terms and patterns. Semantic drift is reduced by forcing the categories to be mutually exclusive. That is, candidate terms can only be extracted by a single category and patterns can only extract terms for a single category.

In WMEB, multiple bootstrapping instances are initiated for each competing target category. Each category's seed set forms its initial lexicon. For each term in the category lexicon, WMEB identifies all candidate contextual patterns that can match the term in the text. To ensure mutual exclusion between the categories, candidate patterns that are identified by multiple categories in an iteration are excluded. The remaining patterns are then ranked according to the *reliability measure* and *relevance weight*.

The reliability of a pattern for a given category is the number of extracted terms in the category's lexicon that match the pattern. A pattern's relevance weight is defined as the sum of the χ-squared values between the pattern (p) and each of the lexicon terms (t): $\mathrm{weight}(p) = \sum_{t \in T} \chi^2(p, t)$. These metrics are symmetrical for both candidate terms and patterns.

The top-m patterns are then added to the pool of extracting patterns. If each of the top-m patterns already exists in the pool, the next unseen pattern is added to the pool. This ensures at least one new pattern is added to the pool in each iteration.

In the term selection phase, all patterns within the pattern pool are used to identify candidate terms. Like the candidate patterns, terms that are extracted by multiple categories in the same iteration are also excluded. The remaining candidate terms are ranked with respect to their reliability and relevance weight, and the top-n terms are added to the lexicon.

2.2 Detecting semantic drift in WMEB

In McIntosh and Curran (2009), we showed that multi-category bootstrappers are still prone to semantic drift in the later iterations. We proposed a drift detection metric based on our hypothesis that semantic drift occurs when a candidate term is more similar to the recently added terms than to the seed and high precision terms extracted in the earlier iterations. Our metric is based on distributional similarity measurements and can be directly incorporated into WMEB's term selection phase to prevent drifting terms from being extracted (WMEB-DRIFT).

The drift metric is defined as the ratio of the average distributional similarity of the candidate term to the first n terms extracted into the lexicon L, and to the last m terms extracted in the previous iterations:

$$\mathrm{drift}(term, n, m) = \frac{\mathrm{avgsim}(L_{1...n}, term)}{\mathrm{avgsim}(L_{(N-m+1)...N}, term)} \quad (1)$$

2.3 Negative categories

In multi-category bootstrapping, improvements in precision arise when semantic boundaries between multiple target categories are established. Thus, it is beneficial to bootstrap categories that share similar semantic spaces, such as *female names* and *flowers*.

Unfortunately, it is difficult to predict if a target category will suffer from semantic drift and/or whether it will naturally compete with the other target categories. Once a domain expert establishes semantic drift and its possible cause, a set of *negative/stop* categories that may be of no direct interest are manually crafted to prevent semantic drift. These additional categories are then exploited during another round of bootstrapping to provide further competition for the target categories (Lin et al., 2003; Curran et al., 2007).

Lin et al. (2003) improved NOMEN's performance for extracting *diseases* and *locations* from the ProMED corpus by incorporating negative categories into the bootstrapping process. They first used one general negative category, seeded with the 10 most frequent nouns in the corpus that were unrelated to the target categories. This single negative category resulted in substantial improvements in precision. In their final experiment, six negative categories that were notable sources of semantic drift were identified, and the inclusion of these lead to further performance improvements (∼20%).

In similar experiments, both Curran et al. (2007) and McIntosh (2010) manually crafted negative categories that were necessary to prevent semantic drift. In particular, in McIntosh (2010), a biomedical expert spent considerable time (∼15 days) and effort identifying potential negative categories and subsequently optimising their associated seeds in trial and error bootstrapping runs.

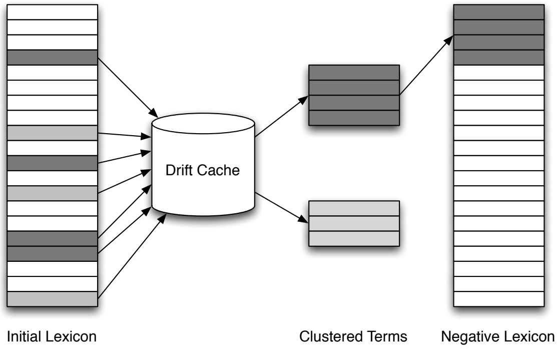

Figure 1: NEG-FINDER: Local negative discovery

By introducing manually crafted negative categories, a significant amount of expert domain knowledge is introduced. The use of this expert knowledge undermines the principle advantages of unsupervised bootstrapping, by making it difficult to bootstrap lexicons for a large number of categories across diverse domains or languages. In this paper, we aim to push multi-category bootstrapping back into its original minimally-supervised framework, with as little performance loss as possible.

3 NEG-FINDER

Our approach, *Negative Category Finder for Bootstrapping* (NEG-FINDER), can be easily incorporated into bootstrapping algorithms that exclude candidate terms or facts based on a selection criteria, including WMEB-DRIFT and Paşca et al.'s (2006) large-scale fact extraction system. For simplicity, we describe our approach within the WMEB-DRIFT bootstrapping algorithm. Figure 1 shows the framework of our approach.

To discover negative categories during bootstrapping, NEG-FINDER must identify a representative cluster of the drifted terms. In this section, we present the two types of clustering used (*maximum* and *outlier*), and our three different levels of negative discovery (*local*, *global* and *mixture*).

3.1 Discovering negative categories

We have observed that semantic drift begins to dominate when clusters of incorrect terms with similar meanings are extracted. In the term selection phase of WMEB-DRIFT, the top-n candidate terms that satisfy the drift detection threshold are added to the expanding lexicon. Those terms which are considered but do not meet the threshold are excluded.

In NEG-FINDER, these drifted terms are cached as they may provide adequate seed terms for new negative categories. However, the drifted terms can also include scattered polysemous or correct terms that share little similarity with the other drifted terms. Therefore, simply using the first set of drifted terms to establish a negative category is likely to introduce noise rather than a cohesive competing category.

To discover negative categories, we exploit hierarchical clustering to group similar terms within the cache of drifted terms. In agglomerative hierarchical clustering, a single term is assigned to an individual cluster, and these clusters are iteratively merged until a final cluster is formed containing all terms (Kaufmann and Rousseeuw, 1990). In our approach, the similarity between two clusters is computed as the average distributional similarity between all pairs of terms across the clusters (average-link clustering).

For calculating the similarity between two terms we use the distributional similarity approach described in Curran (2004). We extracted window-based features from the set of candidate patterns to form context vectors for each term. We use the standard t-test weight and weighted Jaccard measure functions (Curran, 2004).

To ensure adequate coverage of the possible drifting topics, negative discovery and hence clustering is only performed when the drift cache consists of at least 20 terms.

3.2 Maximum and outlier clustering

Although hierarchical clustering is quadratic, we can efficiently exploit the agglomerative process as the most similar terms will merge into clusters first. Therefore, to identify the k most similar terms, we can exit the clustering process as soon as a cluster of size k is established. We refer to this approach as *maximum clustering*.

In our next clustering method, we aim to form a negative category with as little similarity to the target seeds. We use an *outlier clustering* strategy, in which the drifted term t with the least average distributional similarity to the first n terms in the lexicon must be contained in the cluster of seeds. We use average similarity to the first n terms, as it is already pre-computed for the drift detection metric. As with *maximum clustering*, once a cluster of size k containing the term t is formed, the clustering process can be terminated.

3.3 Incorporating the negative category

After a cluster of negative seed terms is established, the drift cache is cleared, and a new negative category is created and introduced into the iterative bootstrapping process in the next iteration. This means that the negative category can only influence the subsequent iterations of bootstrapping. The negative categories can compete with all other categories, including any previously introduced negative categories, however the negative categories do not contribute to the drift caches.

Before the new category is introduced, its first set of extracting patterns must be identified. For this, the complete set of extracting patterns matching any of the negative seeds are considered and ranked with respect to the seeds. The top scoring patterns are considered sequentially until m patterns are assigned to the new negative category. To ensure mutual exclusion between the new category and the target categories, a candidate pattern that has previously been selected by a target category cannot be used to extract terms for either category in the subsequent iterations.

3.4 Levels of negative discovery

Negative category discovery can be performed at a *local* or *global* level, or as a *mixture* of both. In *local discovery*, each target category has its own drifted term cache and can generate negative categories irrespective of the other target categories. This is shown in Figure 1. The drifted terms (shaded) are extracted away from the lexicon into the local drift cache, which is then clustered. A cluster is then used to initiate a negative category's lexicon. Target categories can also generate multiple negative categories across different iterations.

In *global discovery*, all drifted terms are pooled into a global cache, from which a single negative category can be identified in an iteration. This is based on our intuition that multiple target categories

TYPE	MEDLINE
No. Terms	1 347 002
No. Patterns	4 090 412

No. Unfiltered tokens	6 642 802 776

Table 1: Filtered 5-gram dataset statistics.

may be drifting into similar semantic categories, and enables these otherwise missed negative categories to be established.

In the *mixture discovery* method, both global and local negative categories can be formed. A category's drifted terms are collected into its local cache as well as the global cache. Negative discovery is then performed on each cache when they contain at least 20 terms. Once a local negative category is formed, the terms within the local cache are cleared and also removed from the global cache. This prevents multiple negative categories being instantiated with overlapping seed terms.

4 Experimental setup

To compare the effectiveness of our negative discovery approaches we consider the task of extracting biomedical semantic lexicons from raw text.

4.1 Data

The algorithms take as input a set of candidate terms to be extracted into semantic lexicons. The source text collection consists of 5-grams (t_1, t_2, t_3, t_4, t_5) from approximately 16 million MEDLINE abstracts.[1] The set of possible candidate terms correspond to the middle tokens (t_3), and the possible patterns are formed from the surrounding tokens (t_1, t_2, t_4, t_5). We do not use syntactic knowledge, as we did not wish to rely on any tools that require supervised training, to ensure our technique is as domain and language independent as possible.

Limited preprocessing was required to extract the 5-grams from MEDLINE. The XML markup was removed, and the collection was tokenised and split into sentences using bio-specific NLP tools (Grover et al., 2006). Filtering was applied to remove infrequent patterns and terms – patterns appearing with less than 7 different terms, and terms only appearing with those patterns were removed. The statistics of the resulting dataset are shown in Table 1.

CAT	DESCRIPTION
ANTI	Antibodies: *MAb IgG IgM rituximab infliximab* (κ_1:0.89, κ_2:1.0)
CELL	Cells: *RBC HUVEC BAEC VSMC SMC* (κ_1:0.91, κ_2:1.0)

Table 2: The MEDLINE semantic categories

4.2 Semantic categories

The semantic categories we extract from MEDLINE were inspired by the TREC Genomics entities (Hersh et al., 2007) and are described in detail in McIntosh (2010). The hand-picked seeds selected by a domain expert for each category are shown in italics in Table 2. These were carefully chosen to be as unambiguous as possible with respect to the other categories.

4.3 Negative categories

In our experiments, we use two different sets of negative categories. These are shown in Table 3. The first set corresponds to those used in McIntosh and Curran (2008), and were identified by a domain expert as common sources of semantic drift in preliminary experiments with MEB and WMEB. The AMINO ACID category was created in order to filter common MUTN errors. The ANIMAL and BODY PART categories were formed with the intention of preventing drift in the CELL, DISE and SIGN categories. The ORGANISM category was then created to reduce the new drift forming in the DISE category after the first set of negative categories were introduced.

The second set of negative categories was identified by an independent domain expert with limited

[1] The set contains all MEDLINE titles and abstracts available up to Oct 2007.

CATEGORY	SEED TERMS
1 AMINO ACID	arginine cysteine glycine glutamate histamine
ANIMAL	insect mammal mice mouse rats
BODY PART	breast eye liver muscle spleen
ORGANISM	Bartonella Borrelia Cryptosporidium Salmonella toxoplasma
2 AMINO ACID	Asn Gly His Leu Valine
ANIMAL	animals dogs larvae rabbits rodents
ORGANISM	Canidia Shigella Scedosporium Salmonella Yersinia
GENERIC	decrease effects events increase response
MODIFIERS	acute deep intrauterine postoperative secondary
PEOPLE	children females men subjects women
SAMPLE	biopsies CFU sample specimens tissues

Table 3: Manually crafted negative categories

knowledge of NLP and bootstrapping. This expert identified three similar categories to the first expert, however their seeds are very different. They also identified three more categories than the first.

4.4 Lexicon evaluation

Our evaluation process follows that of McIntosh and Curran (2009) and involved manually inspecting each extracted term and judging whether it was a member of the semantic class. This manual evaluation was performed by two domain experts and is necessary due to the limited coverage of biomedical resources. Inter-annotator agreement scores are provided in Table 2.[2] To make later evaluations more efficient, all evaluators' decisions for each category are cached.

Unfamiliar terms were checked using online resources including MEDLINE, MeSH, and Wikipedia. Each ambiguous term was counted as correct if it was classified into one of its correct categories, such as *lymphoma*, which is a TUMR and DISE. If a term was unambiguously part of a multi-word term we considered it correct. Abbreviations, acronyms, and obvious misspelled words were included.

For comparing the performance of the algorithms, the average precision for the top-1000 terms over the 10 target categories is measured. To identify when semantic drift has a significant impact, we report the precision of specific sections of the lexicon, e.g. the 801-1000 sample corresponds to the last 200 terms.

	1-500	1-1000
WMEB-DRIFT	74.3	68.6
+negative 1	87.7	82.8
+negative 2	83.8	77.8

Table 4: Influence of negative categories

4.5 System settings

All experiments were performed using the 10 target categories as input. Unless otherwise stated, no hand-picked negative categories are used.

Each target category is initialised with the 5 hand-picked seed terms (Table 2). In each iteration a maximum of 5 lexicon terms and 5 new patterns can be extracted by a category. The bootstrapping algorithms are run for 200 iterations.

The drift detection metric is calculated over the first 100 terms and previous 5 terms extracted into the lexicon, and the filter threshold is set to 0.2, as in McIntosh and Curran (2009). To ensure infrequent terms are not used to seed negative categories, drifted terms must occur at least 50 times to be retained in the drift cache. Negative category discovery is only initiated when the drifted cache contains at least 20 terms, and a minimum of 5 terms are used to seed a negative category.

4.6 Random seed experiments

Both McIntosh and Curran (2009) and Pantel et al. (2009) have shown that a bootstrapper's performance can vary greatly depending on the input seeds. To ensure our methods are compared reliably, we also report the average precision of randomised seed experiments. Each algorithm is instantiated 10 times with different random gold seeds for each target category. These gold seeds are randomly sampled from the evaluation cache formed in McIntosh and Curran (2009).

5 Results

5.1 Influence of negative categories

In our first experiments, we investigate the performance variations and improvements gained using negative categories selected by two independent domain experts. Table 4 shows WMEB-DRIFT's average precision over the 10 target categories with and without the two negative category sets. Both

[2] All disagreements were discussed, and the kappa scores κ_1 and κ_2 are those before and after the discussions, respectively.

	1-200	201-400	401-600	601-800	801-1000	1-1000
WMEB-DRIFT	79.5	74.8	64.7	61.9	62.1	68.6
NEG-FINDER						
First discovered	79.5	74.3	64.8	67.8	66.6	70.7
Local discovery						
+maximum	79.5	74.8	67.3	69.3	70.5	72.2
+outlier	79.5	73.9	64.8	67.8	71.0	71.5
Global discovery						
+maximum	79.5	73.9	65.7	73.2	72.7	73.4
+outlier	79.5	74.7	65.6	71.4	68.2	72.1
Mixture discovery						
+maximum	79.5	74.7	69.3	73.3	72.8	74.0
+outlier	79.5	75.2	69.7	72.0	69.4	73.2

Table 5: Performance comparison of WMEB-DRIFT and NEG-FINDER

sets significantly improve WMEB-DRIFT, however there is a significant performance difference between them. This demonstrates the difficulty of selecting appropriate negative categories and seeds for the task, and in turn the necessity for tools to discover them automatically.

5.2 Negative category discovery

Table 5 compares the performance of NEG-FINDER incorporated with WMEB-DRIFT. Each method has equal average precision over the first 200 terms, as semantic drift does not typically occur in the early iterations. Each discovery method significantly outperforms WMEB-DRIFT in the later stages, and over the top 1000 terms.[3]

The *first discovery* approach corresponds to the naïve NEG-FINDER system that generates *local* negative categories from the first five drifted terms. Although it outperforms WMEB-DRIFT, its advantage is smaller than the clustering methods.

The *outlier clustering* approach, which we predicted to be the most effective, was surprisingly less accurate than the *maximum* approach for selecting negative seeds. This is because the seed cluster formed around the outlier term is not guaranteed to have high pair-wise similarity and thus it may represent multiple semantic categories.

Local discovery was the least effective discovery approach. Compared to local discovery, *global discovery* is capable of detecting new negative categories earlier, and the categories it detects are more likely to compete with multiple target categories.

CATEGORY	NEGATIVE SEEDS
CELL-NEG	animals *After* Lambs Pigs Rabbits
TUMR-NEG	inoperable multinodular nonresectable operated unruptured
GLOBAL	days Hz mM post Torr
GLOBAL	aortas eyes legs mucosa retinas
GLOBAL	men offspring parents persons relatives
GLOBAL	Australian Belgian Dutch European Italian
GLOBAL	Amblyospora Branhamella Phormodium Pseudanabaena Rhodotorula

Table 6: Negative categories from mixture discovery

The NEG-FINDER *mixture* approach, which benefits from both *local* and *global discovery*, identifies the most useful negative categories. Table 6 shows the seven discovered categories — two local negative categories from CELL and TUMOUR, and five global categories were formed. Many of these categories are similar to those identified by the domain experts. For example, clear categories for ANIMAL, BODY PART, PEOPLE and ORGANISM are created. By identifying and then including these negative categories, NEG-FINDER significantly outperforms WMEB-DRIFT by 5.4% over the top-1000 terms and by 10.7% over the last 200 terms, where semantic drift is prominent. These results demonstrate that suitable negative categories can be identified and exploited during bootstrapping.

5.3 Boosting hand-picked negative categories

In our next set of experiments, we investigate whether NEG-FINDER can improve state-of-the-art performance by identifying new negative categories in addition to the manually selected negative

[3] Statistical significance was tested using computationally-intensive randomisation tests (Cohen, 1995).

+negative 1	74.6	79.8	82.8
NEG-FINDER			
+negative 1 +local	76.4	80.1	83.2
+negative 1 +global	77.5	76.0	82.7
+negative 1 +mixture	76.7	79.9	83.2

Table 8: Performance of NEG-FINDER with manually crafted negative categories

categories. Both NEG-FINDER and WMEB-DRIFT are initialised with the 10 target categories and the first set of negative categories.

Table 8 compares our best performing systems (NEG-FINDER *maximum clustering*) with standard WMEB-DRIFT, over the last 400 terms where semantic drift dominates. NEG-FINDER effectively discovers additional categories and significantly outperforms WMEB-DRIFT. This further demonstrates the utility of our approach.

5.4 Restarting with new negative categories

The performance improvements so far using NEG-FINDER have been limited by the time at which new negative categories are discovered and incorporated into the bootstrapping process. That is, system improvements can only be gained from the negative categories after they are generated. For example, in *Local* NEG-FINDER, five negative categories are discovered in iterations 83, 85, 126, 130 and 150. On the other hand, in the WMEB-DRIFT +negative experiments (Table 8 row 2), the hand-picked negative categories can start competing with the target categories in the very first iteration of bootstrapping.

To test the full utility of NEG-FINDER, we use the set of discovered categories as competing input for WMEB-DRIFT. Table 7 shows the average precision of WMEB-DRIFT over the 10 target categories when it is restarted with the new negative categories discovered from our three approaches (using *maximum clustering*). Over the first 200 terms, significant improvements are gained using the new negative categories (+6%). However, the manually selected categories are far superior in preventing drift (+11%). This may be attributed by the target categories not strongly drifting into the new negative categories until the later stages, whereas the hand-picked categories were selected on the basis of observed drift in the early stages (over the first 500 terms).

Each NEG-FINDER approach significantly outperforms WMEB-DRIFT with no negative categories. For example, using the NEG-FINDER *mixture* categories increases precision by 12.8%. These approaches also outperform their corresponding inline discovery methods (e.g. +7.4% with *mixture discovery* – Table 5).

Table 7 shows that each of the discovered negative sets can significantly outperform the negative categories selected by a domain expert (negative set 2) (+0.6 – 3.9%). Our best system's performance (*mixture*: 81.4%) closely approaches that of the superior negative set, trailing by only 1.4%.

5.5 Individual categories

In this section, we analyse the effect of NEG-FINDER on the individual target categories. Table 9 shows the average precision of the lexicons for some target categories. All categories, except TUMOUR, improve significantly with the inclusion of the discovered negative categories. In particular, the CELL and SIGN categories, which are affected severely by semantic drift, increase by up to 33.3% and 45.2%, respectively. The discovered negative categories are more effective than the manually crafted sets in reducing semantic drift in the ANTIBODY, CELL and DISEASE lexicons.

	ANTI	CELL	DISE	SIGN	TUMR
WMEB-DRIFT	92.9	47.8	49.3	27.9	39.5
+negative 1	91.6	73.1	87.8	76.5	48.7
+negative 2	85.8	68.0	84.2	71.3	16.3
NEG-FINDER					
+mixture	94.9	73.9	56.0	41.0	42.2
+mixture +negative 1	90.8	77.2	87.8	78.2	48.2
WMEB-DRIFT					
+restart +local	89.9	78.8	71.6	73.1	32.2
+restart +global	94.6	79.0	81.9	62.6	35.2
+restart +mixture	92.6	81.1	91.1	63.6	47.5

Table 9: Individual category results (1-1000 terms)

5.6 Random seed experiments

In Table 10, we report the results of our randomised experiments. Over the last 200 terms, WMEB-DRIFT with the first set of negative categories (row 2) is outperformed by NEG-FINDER (row 4). NEG-FINDER also significantly boosts the performance of the original negative categories by identifying additional negative categories (row 5). Our final experiment, where WMEB-DRIFT is re-initialised with the negative categories discovered by NEG-FINDER, further demonstrates the utility of our method. On average, the discovered negative categories significantly outperform the manually crafted negative categories.

6 Conclusion

In this paper, we have proposed the first completely unsupervised approach to identifying the negative categories that are necessary for bootstrapping large yet precise semantic lexicons. Prior to this work, negative categories were manually crafted by a domain expert, undermining the advantages of an unsupervised bootstrapping paradigm.

There are numerous avenues for further examination. We intend to use sophisticated clustering methods, such as CBC (Pantel, 2003), to identify multiple negative categories across the target categories in a single iteration. We would also like to explore the suitability of NEG-FINDER for relation extraction.

Our initial analysis demonstrated that although excellent performance is achieved using negative categories, large performance variations occur when using categories crafted by different domain experts.

In NEG-FINDER, unsupervised clustering approaches are exploited to automatically discover negative categories during bootstrapping. NEG-FINDER identifies cohesive negative categories and many of these are semantically similar to those identified by domain experts.

	401-600	801-1000
WMEB-DRIFT	66.9	58.5
+negative 1	73.1	61.7
NEG-FINDER		
+mixture	71.9	64.2
+mixture +negative 1	76.1	66.7
WMEB-DRIFT		
+restart +mixture	78.0	70.8

Table 10: Random seed results

NEG-FINDER significantly outperforms the state-of-the-art algorithm WMEB-DRIFT, before negative categories are crafted, by up to 5.4% over the top-1000 terms; and by 10.7% over the last 200 terms extracted, where semantic drift is extensive. The new discovered categories can also be fully exploited in bootstrapping, where they successfully outperform a domain expert's negative categories and approach that of another expert.

The result is an effective approach that can be incorporated within any bootstrapper. NEG-FINDER successfully removes the necessity of including manually crafted supervised knowledge to boost a bootstrapper's performance. In doing so, we revert the multi-category bootstrapping framework back to its originally intended minimally supervised framework, with little performance trade-off.

Abstract

Existing graph-based ranking methods for keyphrase extraction compute a *single* importance score for each word via a *single* random walk. Motivated by the fact that both documents and words can be represented by a mixture of semantic topics, we propose to decompose traditional random walk into multiple random walks specific to various topics. We thus build a Topical PageRank (TPR) on word graph to measure word importance with respect to different topics. After that, given the topic distribution of the document, we further calculate the ranking scores of words and extract the top ranked ones as keyphrases. Experimental results show that TPR outperforms state-of-the-art keyphrase extraction methods on two datasets under various evaluation metrics.

1 Introduction

Keyphrases are defined as a set of terms in a document that give a brief summary of its content for readers. Automatic keyphrase extraction is widely used in information retrieval and digital library (Turney, 2000; Nguyen and Kan, 2007). Keyphrase extraction is also an essential step in various tasks of natural language processing such as document categorization, clustering and summarization (Manning and Schutze, 2000).

There are two principled approaches to extracting keyphrases: supervised and unsupervised. The supervised approach (Turney, 1999) regards keyphrase extraction as a classification task, in which a model is trained to determine whether a candidate phrase is a keyphrase. Supervised methods require a document set with human-assigned keyphrases as training set. In Web era, articles increase exponentially and change dynamically, which demands keyphrase extraction to be efficient and adaptable. However, since human labeling is time consuming, it is impractical to label training set from time to time. We thus focus on the unsupervised approach in this study.

In the unsupervised approach, graph-based ranking methods are state-of-the-art (Mihalcea and Tarau, 2004). These methods first build a word graph according to word co-occurrences within the document, and then use random walk techniques (e.g., PageRank) to measure word importance. After that, top ranked words are selected as keyphrases.

Existing graph-based methods maintain a *single* importance score for each word. However, a document (e.g., news article or research article) is usually composed of multiple semantic topics. Taking this paper for example, it refers to two major topics, “keyphrase extraction” and “random walk”. As words are used to express various meanings corresponding to different semantic topics, a word will play different importance roles in different topics of the document. For example, the words “phrase” and “extraction” will be ranked to be more important in topic “keyphrase extraction”, while the words “graph” and “PageRank” will be more important in topic “random walk”. Since they do not take topics into account, graph-based methods may suffer from the following two problems:

1. Good keyphrases should be relevant to the major topics of the given document. In graph-based methods, the words that are strongly connected with other words tend to be ranked high,

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 366–376,
MIT, Massachusetts, USA, 9-11 October 2010.

which do not necessarily guarantee they are relevant to major topics of the document.

2. An appropriate set of keyphrases should also have a good coverage of the document's major topics. In graph-based methods, the extracted keyphrases may fall into a single topic of the document and fail to cover other substantial topics of the document.

To address the problem, it is intuitive to consider the topics of words and document in random walk for keyphrase extraction. In this paper, we propose to decompose traditional PageRank into multiple PageRanks specific to various topics and obtain the importance scores of words under different topics. After that, with the help of the document topics, we can further extract keyphrases that are relevant to the document and at the same time have a good coverage of the document's major topics. We call the topic-decomposed PageRank as Topical PageRank (TPR).

In experiments we find that TPR can extract keyphrases with high relevance and good coverage, which outperforms other baseline methods under various evaluation metrics on two datasets. We also investigate the performance of TPR with different parameter values and demonstrate its robustness. Moreover, TPR is unsupervised and language-independent, which is applicable in Web era with enormous information.

TPR for keyphrase extraction is a two-stage process:

1. Build a topic interpreter to acquire the topics of words and documents.

2. Perform TPR to extract keyphrases for documents.

We will introduce the two stages in Section 2 and Section 3.

2 Building Topic Interpreters

To run TPR on a word graph, we have to acquire topic distributions of words. There are roughly two approaches that can provide topics of words: (1) Use manually annotated knowledge bases, e.g., WordNet (Miller et al., 1990); (2) Use unsupervised machine learning techniques to obtain word topics from a large-scale document collection. Since the vocabulary in WordNet cannot cover many words in modern news and research articles, we employ the second approach to build topic interpreters for TPR.

In machine learning, various methods have been proposed to infer latent topics of words and documents. These methods, known as latent topic models, derive latent topics from a large-scale document collection according to word occurrence information. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is a representative of topic models. Compared to Latent Semantic Analysis (LSA) (Landauer et al., 1998) and probabilistic LSA (pLSA) (Hofmann, 1999), LDA has more feasibility for inference and can reduce the risk of over-fitting.

In LDA, each word w of a document d is regarded to be generated by first sampling a topic z from d's topic distribution $\theta^{(d)}$, and then sampling a word from the distribution over words $\phi^{(z)}$ that characterizes topic z. In LDA, $\theta^{(d)}$ and $\phi^{(z)}$ are drawn from conjugate Dirichlet priors α and β, separately. Therefore, θ and ϕ are integrated out and the probability of word w given document d and priors is represented as follows:

$$pr(w|d,\alpha,\beta) = \sum_{z=1}^{K} pr(w|z,\beta) pr(z|d,\alpha), \quad (1)$$

where K is the number of topics.

Using LDA, we can obtain the topic distribution of each word w, namely $pr(z|w)$ for topic $z \in K$. The word topic distributions will be used in TPR. Moreover, using the obtained word topic distributions, we can infer the topic distribution of a new document (Blei et al., 2003), namely $pr(z|d)$ for each topic $z \in K$, which will be used for ranking keyphrases.

3 Topical PageRank for Keyphrase Extraction

After building a topic interpreter to acquire the topics of words and documents, we can perform keyphrase extraction for documents via TPR. Given a document d, the process of keyphrase extraction using TPR consists of the following four steps which is also illustrated in Fig. 1:

1. Construct a word graph for d according to word co-occurrences within d.

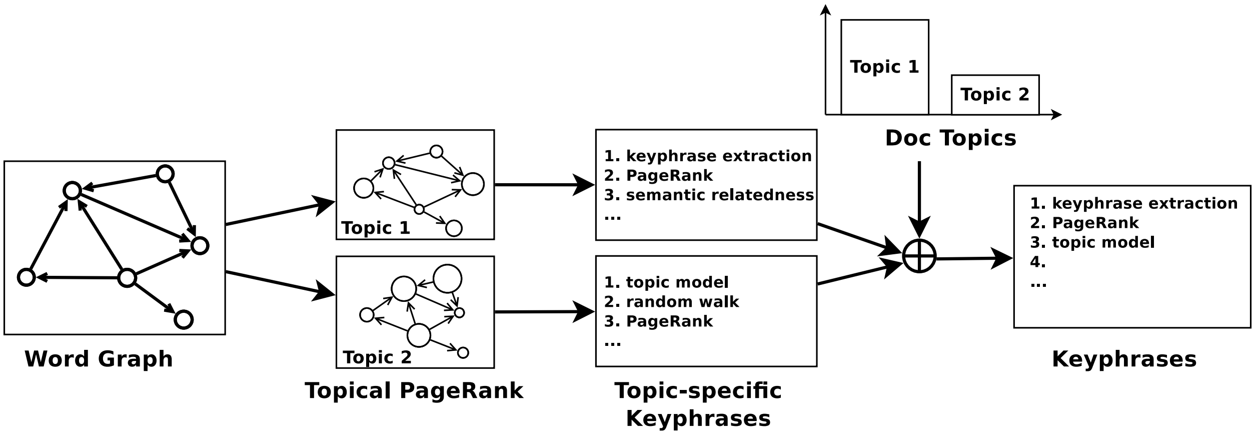

Figure 1: Topical PageRank for Keyphrase Extraction.

2. Perform TPR to calculate the importance scores for each word with respect to different topics.

3. Using the topic-specific importance scores of words, rank candidate keyphrases respect to each topic separately.

4. Given the topics of document d, integrate the topic-specific rankings of candidate keyphrases into a final ranking, and the top ranked ones are selected as keyphrases.

3.1 Constructing Word Graph

We construct a word graph according to word co-occurrences within the given document, which expresses the cohesion relationship between words in the context of document. The document is regarded as a word sequence, and the link weights between words is simply set to the co-occurrence count within a sliding window with maximum W words in the word sequence.

It was reported in (Mihalcea and Tarau, 2004) the graph direction does not influence the performance of keyphrase extraction very much. In this paper we simply construct word graphs with directions. The link directions are determined as follows. When sliding a W-width window, at each position, we add links from the first word pointing to other words within the window. Since keyphrases are usually noun phrases, we only add adjectives and nouns in word graph.

3.2 Topical PageRank

Before introducing TPR, we first give some formal notations. We denote $G = (V, E)$ as the graph of a document, with vertex set $V = \{w_1, w_2, \cdots, w_N\}$ and link set $(w_i, w_j) \in E$ if there is a link from w_i to w_j. In a word graph, each vertex represents a word, and each link indicates the relatedness between words. We denote the weight of link (w_i, w_j) as $e(w_i, w_j)$, and the out-degree of vertex w_i as $O(w_i) = \sum_{j:w_i \rightarrow w_j} e(w_i, w_j)$.

Topical PageRank is based on PageRank (Page et al., 1998). PageRank is a well known ranking algorithm that uses link information to assign global importance scores to web pages. The basic idea of PageRank is that a vertex is important if there are other important vertices pointing to it. This can be regarded as voting or recommendation among vertices. In PageRank, the score $R(w_i)$ of word w_i is defined as

$$R(w_i) = \lambda \sum_{j:w_j \rightarrow w_i} \frac{e(w_j, w_i)}{O(w_j)} R(w_j) + (1 - \lambda) \frac{1}{|V|}, \tag{2}$$

where λ is a *damping factor* range from 0 to 1, and $|V|$ is the number of vertices. The damping factor indicates that each vertex has a probability of $(1 - \lambda)$ to perform random jump to another vertex within this graph. PageRank scores are obtained by running Eq. (2) iteratively until convergence. The second term in Eq. (2) can be regarded as a smoothing factor to make the graph fulfill the property of being aperiodic and irreducible, so as to guarantee that PageRank converges to a unique stationary distribution. In PageRank, the second term is set to be the same value $\frac{1}{|V|}$ for all vertices within the graph, which indicates there are equal probabilities of random jump to all vertices.

In fact, the second term of PageRank in Eq. (2) can be set to be non-uniformed. Suppose we assign larger probabilities to some vertices, the final PageRank scores will prefer these vertices. We call this *Biased PageRank*.

The idea of Topical PageRank (TPR) is to run Biased PageRank for each topic separately. Each topic-specific PageRank prefers those words with high relevance to the corresponding topic. And the preferences are represented using random jump probabilities of words.

Formally, in the PageRank of a specific topic z, we will assign a topic-specific preference value $p_z(w)$ to each word w as its random jump probability with $\sum_{w \in V} p_z(w) = 1$. The words that are more relevant to topic z will be assigned larger probabilities when performing the PageRank. For topic z, the topic-specific PageRank scores are defined as follows:

$$R_z(w_i) = \lambda \sum_{j:w_j \to w_i} \frac{e(w_j, w_i)}{O(w_j)} R_z(w_j) + (1-\lambda) p_z(w_i). \tag{3}$$

In Fig. 1, we show an example with two topics. In this figure, we use the size of circles to indicate how relevant the word is to the topic. In the PageRanks of the two topics, high preference values will be assigned to different words with respect to the topic. Finally, the words will get different PageRank values in the two PageRanks.

The setting of preference values $p_z(w)$ will have a great influence to TPR. In this paper we use three measures to set preference values for TPR:

- $p_z(w) = pr(w|z)$, is the probability that word w occurs given topic z. This indicates how much that topic z focuses on word w.
- $p_z(w) = pr(z|w)$, is the probability of topic z given word w. This indicates how much that word w focuses on topic z.
- $p_z(w) = pr(w|z) \times pr(z|w)$, is the product of hub and authority values. This measure is inspired by the work in (Cohn and Chang, 2000).

Both PageRank and TPR are all iterative algorithms. We terminate the algorithms when the number of iterations reaches 100 or the difference of each vertex between two neighbor iterations is less than 0.001.

3.3 Extract Keyphrases Using Ranking Scores

After obtaining word ranking scores using TPR, we begin to rank candidate keyphrases. As reported in (Hulth, 2003), most manually assigned keyphrases turn out to be noun phrases. We thus select noun phrases from a document as candidate keyphrases for ranking.

The candidate keyphrases of a document is obtained as follows. The document is first tokenized. After that, we annotate the document with part-of-speech (POS) tags [1]. Third, we extract noun phrases with pattern `(adjective)*(noun)+`, which represents zero or more adjectives followed by one or more nouns. We regard these noun phrases as candidate keyphrases.

After identifying candidate keyphrases, we rank them using the ranking scores obtained by TPR. In PageRank for keyphrase extraction, the ranking score of a candidate keyphrase p is computed by summing up the ranking scores of all words within the phrase: $R(p) = \sum_{w_i \in p} R(w_i)$ (Mihalcea and Tarau, 2004; Wan and Xiao, 2008a; Wan and Xiao, 2008b). Then candidate keyphrases are ranked in descending order of ranking scores. The top M candidates are selected as keyphrases.

In TPR for keyphrase extraction, we first compute the ranking scores of candidate keyphrases separately for each topic. That is for each topic z we compute

$$R_z(p) = \sum_{w_i \in p} R_z(w_i). \tag{4}$$

By considering the topic distribution of document, We further integrate topic-specific rankings of candidate keyphrases into a final ranking and extract top-ranked ones as the keyphrases of the document. Denote the topic distribution of the document d as $pr(z|d)$ for each topic z. For each candidate keyphrase p, we compute its final ranking score as

[1] In experiments we use Stanford POS Tagger from `http://nlp.stanford.edu/software/tagger.shtml` with English tagging model `left3words-distsim-wsj`.

follows:

$$R(p) = \sum_{z=1}^{K} R_z(p) \times pr(z|d). \qquad (5)$$

After ranking candidate phrases in descending order of their integrated ranking scores, we select the top M as the keyphrases of document d.

4 Experiments

4.1 Datasets

To evaluate the performance of TPR for keyphrase extraction, we carry out experiments on two datasets.

One dataset was built by Wan and Xiao [2] which was used in (Wan and Xiao, 2008b). This dataset contains 308 news articles in DUC2001 (Over et al., 2001) with $2,488$ manually annotated keyphrases. There are at most 10 keyphrases for each document. In experiments we refer to this dataset as NEWS.

The other dataset was built by Hulth [3] which was used in (Hulth, 2003). This dataset contains $2,000$ abstracts of research articles and $19,254$ manually annotated keyphrases. In experiments we refer to this dataset as RESEARCH.

Since neither NEWS nor RESEARCH itself is large enough to learn efficient topics, we use the Wikipedia snapshot at March 2008 [4] to build topic interpreters with LDA. After removing non-article pages and the articles shorter than 100 words, we collected $2,122,618$ articles. After tokenization, stop word removal and word stemming, we build the vocabulary by selecting $20,000$ words according to their document frequency. We learn LDA models by taking each Wikipedia article as a document. In experiments we learned several models with different numbers of topics, from 50 to $1,500$ respectively. For the words absent in topic models, we simply set the topic distribution of the word as uniform distribution.

4.2 Evaluation Metrics

For evaluation, the words in both standard and extracted keyphrases are reduced to base forms using Porter Stemmer [5] for comparison. In experiments we select three evaluation metrics.

The first metric is precision/recall/F-measure represented as follows,

$$p = \frac{c_{correct}}{c_{extract}}, \quad r = \frac{c_{correct}}{c_{standard}}, \quad f = \frac{2pr}{p+r}, \qquad (6)$$

where $c_{correct}$ is the total number of correct keyphrases extracted by a method, $c_{extract}$ the total number of automatic extracted keyphrases, and $c_{standard}$ the total number of human-labeled standard keyphrases.

We note that the ranking order of extracted keyphrases also indicates the method performance. An extraction method will be better than another one if it can rank correct keyphrases higher. However, precision/recall/F-measure does not take the order of extracted keyphrases into account. To address the problem, we select the following two additional metrics.

One metric is *binary preference measure* (Bpref) (Buckley and Voorhees, 2004). Bpref is desirable to evaluate the performance considering the order in which the extracted keyphrases are ranked. For a document, if there are R correct keyphrases within M extracted keyphrases by a method, in which r is a correct keyphrase and n is an incorrect keyphrase, Bpref is defined as follows,

$$\text{Bpref} = \frac{1}{R} \sum_{r \in R} 1 - \frac{|n \text{ ranked higher than } r|}{M}. \qquad (7)$$

The other metric is *mean reciprocal rank* (MRR) (Voorhees, 2000) which is used to evaluate how the first correct keyphrase for each document is ranked. For a document d, $rank_d$ is denoted as the rank of the first correct keyphrase with all extracted keyphrases, MRR is defined as follows,

$$\text{MRR} = \frac{1}{|D|} \sum_{d \in D} \frac{1}{rank_d}, \qquad (8)$$

where D is the document set for keyphrase extraction.

Note that although the evaluation scores of most keyphrase extractors are still lower compared to

[2] http://wanxiaojun1979.googlepages.com.

[3] It was obtained from the author.

[4] http://en.wikipedia.org/wiki/Wikipedia_database.

[5] http://tartarus.org/~martin/PorterStemmer.

other NLP-tasks, it does not indicate the performance is poor because even different annotators may assign different keyphrases to the same document.

4.3 Influences of Parameters to TPR

There are four parameters in TPR that may influence the performance of keyphrase extraction including: (1) window size W for constructing word graph, (2) the number of topics K learned by LDA, (3) different settings of preference values $p_z(w)$, and (4) damping factor λ of TPR.

In this section, we look into the influences of these parameters to TPR for keyphrase extraction. Except the parameter under investigation, we set parameters to the following values: $W = 10$, $K = 1,000$, $\lambda = 0.3$ and $p_z(w) = pr(z|w)$, which are the settings when TPR achieves the best (or near best) performance on both `NEWS` and `RESEARCH`. In the following tables, we use "Pre.", "Rec." and "F." as the abbreviations of precision, recall and F-measure.

4.3.1 Window Size W

In experiments on `NEWS`, we find that the performance of TPR is stable when W ranges from 5 to 20 as shown in Table 1. This observation is consistent with the findings reported in (Wan and Xiao, 2008b).

Size	Pre.	Rec.	F.	Bpref	MRR
5	0.280	0.345	0.309	0.213	0.636
10	0.282	0.348	0.312	0.214	0.638
15	0.282	0.347	0.311	0.214	0.646
20	0.284	0.350	0.313	0.215	0.644

Table 1: Influence of window size W when the number of keyphrases $M = 10$ on `NEWS`.

Similarly, when W ranges from 2 to 10, the performance on `RESEARCH` does not change much. However, the performance on `NEWS` will become poor when $W = 20$. This is because the abstracts in `RESEARCH` (there are 121 words per abstract on average) are much shorter than the news articles in `NEWS` (there are 704 words per article on average). If the window size W is set too large on `RESEARCH`, the graph will become full-connected and the weights of links will tend to be equal, which cannot capture the local structure information of abstracts for keyphrase extraction.

4.3.2 The Number of Topics K

We demonstrate the influence of the number of topics K of LDA models in Table 2. Table 2 shows the results when K ranges from 50 to $1,500$ and $M = 10$ on `NEWS`. We observe that the performance does not change much as the number of topics varies until the number is much smaller ($K = 50$). The influence is similar on `RESEARCH` which indicates that LDA is appropriate for obtaining topics of words and documents for TPR to extract keyphrases.

K	Pre.	Rec.	F.	Bpref	MRR
50	0.268	0.330	0.296	0.204	0.632
100	0.276	0.340	0.304	0.208	0.632
500	0.284	0.350	0.313	0.215	0.648
1000	0.282	0.348	0.312	0.214	0.638
1500	0.282	0.348	0.311	0.214	0.631

Table 2: Influence of the number of topics K when the number of keyphrases $M = 10$ on `NEWS`.

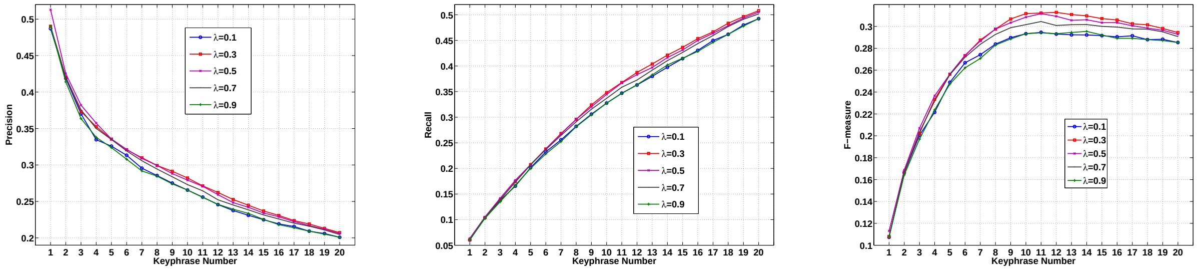
4.3.3 Damping Factor λ

Damping factor λ of TPR reconciles the influences of graph walks (the first term in Eq.(3)) and preference values (the second term in Eq.(3)) to the topic-specific PageRank scores. We demonstrate the influence of λ on `NEWS` in Fig. 2. This figure shows the precision/recall/F-measure when $\lambda = 0.1, 0.3, 0.5, 0.7, 0.9$ and M ranges from 1 to 20. From this figure we find that, when λ is set from 0.2 to 0.7, the performance is consistently good. The values of Bpref and MRR also keep stable with the variations of λ.

4.3.4 Preference Values

Finally, we explore the influences of different settings of preference values for TPR in Eq.(3). In Table 3 we show the influence when the number of keyphrases $M = 10$ on `NEWS`. From the table, we observe that $pr(z|w)$ performs the best. The similar observation is also got on `RESEARCH`.

In keyphrase extraction task, it is required to find the keyphrases that can appropriately represent the topics of the document. It thus does not want to extract those phrases that may appear in multiple topics like common words. The measure $pr(w|z)$ assigns preference values according to how frequently that words appear in the given topic. Therefore, the



(a) Precision

(b) Recall

(c) F-measure

Figure 2: Precision, recall and F-measure of TPR with $\lambda = 0.1, 0.3, 0.5, 0.7$ and 0.9 when M ranges from 1 to 20 on NEWS.

common words will always be assigned to a relatively large value in each topic-specific PageRank and finally obtain a high rank. $pr(w|z)$ is thus not a good setting of preference values in TPR. In the contrast, $pr(z|w)$ prefers those words that are focused on the given topic. Using $pr(z|w)$ to set preference values for TPR, we will tend to extract topic-focused phrases as keyphrases.

Pref	Pre.	Rec.	F.	Bpref	MRR
$pr(w\|z)$	0.256	0.316	0.283	0.192	0.584
$pr(z\|w)$	0.282	0.348	0.312	0.214	0.638
prod	0.259	0.320	0.286	0.193	0.587

Table 3: Influence of three preference value settings when the number of keyphrases $M = 10$ on NEWS.

4.4 Comparing with Baseline Methods

After we explore the influences of parameters to TPR, we obtain the best results on both NEWS and RESEARCH. We further select three baseline methods, i.e., TFIDF, PageRank and LDA, to compare with TPR.

The TFIDF computes the ranking scores of words based on words' $tfidf$ values in the document, namely $R(w) = tf_w \times \log(idf_w)$. While in PageRank (i.e., TextRank), the ranking scores of words are obtained using Eq.(2). The two baselines do not use topic information of either words or documents. The LDA computes the ranking score for each word using the topical similarity between the word and the document. Given the topics of the document d and a word w, We have used various methods to compute similarity including cosine similarity, predictive likelihood and KL-divergence (Heinrich, 2005), among which cosine similarity performs the best on both datasets. Therefore, we only show the results of the LDA baseline calculated using cosine similarity.

In Tables 4 and 5 we show the comparing results of the four methods on both NEWS and RESEARCH. Since the average number of manual-labeled keyphrases on NEWS is larger than RESEARCH, we set $M = 10$ for NEWS and $M = 5$ for RESEARCH. The parameter settings on both NEWS and RESEARCH have been stated in Section 4.3.

Method	Pre.	Rec.	F.	Bpref	MRR
TFIDF	0.239	0.295	0.264	0.179	0.576
PageRank	0.242	0.299	0.267	0.184	0.564
LDA	0.259	0.320	0.286	0.194	0.518
TPR	**0.282**	**0.348**	**0.312**	**0.214**	**0.638**

Table 4: Comparing results on NEWS when the number of keyphrases $M = 10$.

Method	Pre.	Rec.	F.	Bpref	MRR
TFIDF	0.333	0.173	0.227	0.255	0.565
PageRank	0.330	0.171	0.225	0.263	0.575
LDA	0.332	0.172	0.227	0.254	0.548
TPR	**0.354**	**0.183**	**0.242**	**0.274**	**0.583**

Table 5: Comparing results on RESEARCH when the number of keyphrases $M = 5$.

From the two tables, we have the following observations.

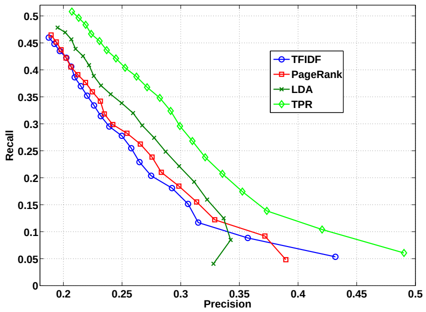


Figure 3: Precision-recall results on NEWS when M ranges from 1 to 20.

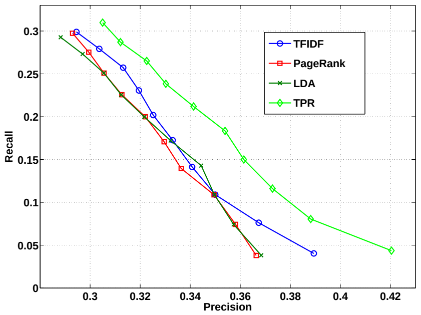

Figure 4: Precision-recall results on RESEARCH when M ranges from 1 to 10.

First, TPR outperform all baselines on both datasets. The improvements are all statistically significant tested with bootstrap re-sampling with 95% confidence. This indicates the robustness and effectiveness of TPR.

Second, LDA performs equal or better than TFIDF and PageRank under precision/recall/F-measure. However, the performance of LDA under MRR is much worse than TFIDF and PageRank, which indicates LDA fails to correctly extract the first keyphrase earlier than other methods. The reason is: (1) LDA does not consider the local structure information of document as PageRank, and (2) LDA also does not consider the frequency information of words within the document. In the contrast, TPR enjoys the advantages of both LDA and TFIDF/PageRank, by using the external topic information like LDA and internal document structure like TFIDF/PageRank.

Moreover, in Figures 3 and 4 we show the precision-recall relations of four methods on NEWS and RESEARCH. Each point on the precision-recall curve is evaluated on different numbers of extracted keyphrases M. The closer the curve to the upper right, the better the overall performance. The results again illustrate the superiority of TPR.

4.5 Extracting Example

At the end, in Table 6 we show an example of extracted keyphrases using TPR from a news article with title "Arafat Says U.S. Threatening to Kill PLO Officials" (The article number in DUC2001 is AP880510-0178). Here we only show the top 10 keyphrases, and the correctly extracted ones are marked with "(+)". We also mark the number of correctly extracted keyphrases after method name like "(+7)" after TPR. We also illustrate the top 3 topics of the document with their topic-specific keyphrases. It is obvious that the top topics, on "Palestine", "Israel" and "terrorism" separately, have a good coverage on the discussion objects of this article, which also demonstrate a good diversity with each other. By integrating these topic-specific keyphrases considering the proportions of these topics, we obtain the best performance of keyphrase extraction using TPR.

In Table 7 we also show the extracted keyphrases of baselines from the same news article. For TFIDF, it only considered the frequency properties of words, and thus highly ranked the phrases with "PLO" which appeared about 16 times in this article, and failed to extract the keyphrases on topic "Israel". LDA only measured the importance of words using document topics without considering the frequency information of words and thus missed keyphrases with high-frequency words. For example, LDA failed to extract keyphrase "political assassination", in which the word "assassination" occurred 8 times in this article.

5 Related Work

In this paper we proposed TPR for keyphrase extraction. A pioneering achievement in keyphrase extraction was carried out in (Turney, 1999) which regarded keyphrase extraction as a classification task. Generally, the supervised methods need manually annotated training set which is time-consuming and in this paper we focus on unsupervised method.

Table 7: Extracted keyphrases by baselines.

Starting with TextRank (Mihalcea and Tarau, 2004), graph-based ranking methods are becoming the most widely used unsupervised approach for keyphrase extraction. Litvak and Last (2008) applied HITS algorithm on the word graph of a document for keyphrase extraction. Although HITS itself worked the similar performance to PageRank, we plan to explore the integration of topics and HITS in future work. Wan (2008b; 2008a) used a small number of nearest neighbor documents to provide more knowledge for keyphrase extraction. Some methods used clustering techniques on word graphs for keyphrase extraction (Grineva et al., 2009; Liu et al., 2009). The clustering-based method performed well on short abstracts (with F-measure 0.382 on `RESEARCH`) but poorly on long articles (`NEWS` with F-measure score 0.216) due to two non-trivial issues: (1) how to determine the number of clusters, and (2) how to weight each cluster and select keyphrases from the clusters. In this paper we focus on improving graph-based methods via topic decomposition, we thus only compare with PageRank as well as TFIDF and LDA and do not compare with clustering-based methods in details.

In recent years, two algorithms were proposed to rank web pages by incorporating topic information of web pages within PageRank (Haveliwala, 2002; Nie et al., 2006). The method in (Haveliwala, 2002), is similar to TPR which also decompose PageRank into various topics. However, the method in (Haveliwala, 2002) only considered to set the preference values using $pr(w|z)$ (In the context of (Haveliwala, 2002), w indicates Web pages). In Section 4.3.4 we have shown that the setting of using $pr(z|w)$ is much better than $pr(w|z)$.

Nie et al. (2006) proposed a more complicated ranking method. In this method, topical PageRanks are performed together. The basic idea of (Nie et al., 2006) is, when surfing following a graph link from vertex w_i to w_j, the ranking score on topic z of w_i will have a higher probability to pass to the same topic of w_j and have a lower probability to pass to a different topic of w_j. When the inter-topic jump probability is 0, this method is identical to (Haveliwala, 2002). We implemented the method and found that the random jumps between topics did not help improve the performance for keyphrase extraction, and did not demonstrate the results of this method.

6 Conclusion and Future Work

In this paper we propose a new graph-based framework, Topical PageRank, which incorporates topic information within random walk for keyphrase extraction. Experiments on two datasets show that TPR achieves better performance than other baseline methods. We also investigate the influence of various parameters on TPR, which indicates the effectiveness and robustness of the new method.

We consider the following research directions as future work.

1. In this paper we obtained latent topics using LDA learned from Wikipedia. We design to obtain topics using other machine learning methods and from other knowledge bases, and investigate the influence to performance of keyphrase extraction.

2. In this paper we integrated topic information in PageRank. We plan to consider topic information in other graph-based ranking algorithms such as HITS (Kleinberg, 1999).

3. In this paper we used Wikipedia to train LDA by assuming Wikipedia is an extensive snapshot of human knowledge which can cover most topics talked about in NEWS and RESEARCH. In fact, the learned topics are highly dependent on the learning corpus. We will investigate the influence of corpus selection in training LDA for keyphrase extraction using TPR.

Incorporating Content Structure into Text Analysis Applications

Abstract

In this paper, we investigate how modeling content structure can benefit text analysis applications such as extractive summarization and sentiment analysis. This follows the linguistic intuition that rich contextual information should be useful in these tasks. We present a framework which combines a supervised text analysis application with the induction of latent content structure. Both of these elements are learned jointly using the EM algorithm. The induced content structure is learned from a large unannotated corpus and biased by the underlying text analysis task. We demonstrate that exploiting content structure yields significant improvements over approaches that rely only on local context.[1]

1 Introduction

In this paper, we demonstrate that leveraging document structure significantly benefits text analysis applications. As a motivating example, consider the excerpt from a DVD review shown in Table 1. This review discusses multiple aspects of a product, such as audio and video properties. While the word "pleased" is a strong indicator of positive sentiment, the sentence in which it appears does not specify the aspect to which it relates. Resolving this ambiguity requires information about global document structure.

A central challenge in utilizing such information lies in finding a relevant representation of content structure for a specific text analysis task. For instance, when performing single-aspect sentiment analysis, the most relevant aspect of content structure is whether a given sentence is objective or subjective (Pang and Lee, 2004). In a multi-aspect setting, however, information about the sentence topic is required to determine the aspect to which a sentiment-bearing word relates (Snyder and Barzilay, 2007). As we can see from even these closely related applications, the content structure representation should be intimately tied to a specific text analysis task.

> **Audio** Audio choices are English, Spanish and French Dolby Digital 5.1 ... Bass is still robust and powerful, giving weight to just about any scene – most notably the film's exciting final fight. Fans should be **pleased** with the presentation.
>
> **Extras** This single-disc DVD comes packed in a black amaray case with a glossy slipcover. Cover art has clearly been designed to appeal the Twilight crowd ... Finally, we've got a deleted scenes reel. Most of the excised scenes are actually pretty interesting.

Table 1: An excerpt from a DVD review.

In this work, we present an approach in which a content model is learned jointly with a text analysis task. We assume complete annotations for the task itself, but we learn the content model from raw, unannotated text. Our approach is implemented in a discriminative framework using latent variables to represent facets of content structure. In this framework, the original task features (e.g., lexical ones) are conjoined with latent variables to enrich the features with global contextual information. For example, in Table 1, the feature associated with the

[1] Code and processed data presented here are available at http://groups.csail.mit.edu/rbg/code/content_structure.html

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 377–387,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

word “pleased” should contribute most strongly to the sentiment of the *audio* aspect when it is augmented with a relevant topic indicator.

The coupling of the content model and the task-specific model allows the two components to mutually influence each other during learning. The content model leverages unannotated data to improve the performance of the task-specific model, while the task-specific model provides feedback to improve the relevance of the content model. The combined model can be learned effectively using a novel EM-based method for joint training.

We evaluate our approach on two complementary text analysis tasks. Our first task is a multi-aspect sentiment analysis task, where a system predicts the aspect-specific sentiment ratings (Snyder and Barzilay, 2007). Second, we consider a multi-aspect extractive summarization task in which a system extracts key properties for a pre-specified set of aspects. On both tasks, our method for incorporating content structure consistently outperforms structure-agnostic counterparts. Moreover, jointly learning content and task parameters yields additional gains over independently learned models.

2 Related Work

Prior research has demonstrated the usefulness of content models for discourse-level tasks. Examples of such tasks include sentence ordering (Barzilay and Lee, 2004; Elsner et al., 2007), extraction-based summarization (Haghighi and Vanderwende, 2009) and text segmentation (Chen et al., 2009). Since these tasks are inherently tied to document structure, a content model is essential to performing them successfully. In contrast, the applications considered in this paper are typically developed without any discourse information, focusing on capturing sentence-level relations. Our goal is to augment these models with document-level content information.

Several applications in information extraction and sentiment analysis are close in spirit to our work (Pang and Lee, 2004; Patwardhan and Riloff, 2007; McDonald et al., 2007). These approaches consider global contextual information when determining whether a given sentence is relevant to the underlying analysis task. All assume that relevant sentences have been annotated. For instance, Pang and Lee (2004) refine the accuracy of sentiment analysis by considering only the subjective sentences of a review as determined by an independent classifier. Patwardhan and Riloff (2007) take a similar approach in the context of information extraction. Rather than applying their extractor to all the sentences in a document, they limit it to event-relevant sentences. Since these sentences are more likely to contain information of interest, the extraction performance increases.

Another approach, taken by Choi and Cardie (2008) and Somasundaran et al. (2009) uses linguistic resources to create a latent model in a task-specific fashion to improve performance, rather than assuming sentence-level task relevancy. Choi and Cardie (2008) address a sentiment analysis task by using a heuristic decision process based on word-level intermediate variables to represent polarity. Somasundaran et al. (2009) similarly uses a bootstrapped local polarity classifier to identify sentence polarity.

McDonald et al. (2007) propose a model which jointly identifies global polarity as well as paragraph- and sentence-level polarity, all of which are observed in training data. While our approach uses a similar hierarchy, McDonald et al. (2007) is concerned with recovering the labels at all levels, whereas in this work we are interested in using latent document content structure as a means to benefit task predictions.

While our method also incorporates contextual information into existing text analysis applications, our approach is markedly different from the above approaches. First, our representation of context encodes more than the relevance-based binary distinction considered in the past work. Our algorithm adjusts the content model dynamically for a given task rather than pre-specifying it. Second, while previous work is fully supervised, in our case relevance annotations are readily available for only a few applications and are prohibitively expensive to obtain for many others. To overcome this drawback, our method induces a content model in an unsupervised fashion and connects it via latent variables to the target model. This design not only eliminates the need for additional annotations, but also allows the algorithm to leverage large quantities of raw data for training the content model. The tight coupling of relevance learning with the target analysis task leads to further performance gains.

Finally, our work relates to supervised topic models in Blei and McAullife (2007). In this work, latent topic variables are used to generate text as well as a supervised sentiment rating for the document. However, this architecture does not permit the usage of standard discriminative models which condition freely on textual features.

3 Model

3.1 Problem Formulation

In this section, we describe a model which incorporates content information into a multi-aspect summarization task.[2] Our approach assumes that at training time we have a collection of labeled documents $\mathcal{D}_L$, each consisting of the document text $\boldsymbol{s}$ and true task-specific labeling $\boldsymbol{y}^*$. For the multi-aspect summarization task, $\boldsymbol{y}^*$ consists of sequence labels (e.g., *value* or *service*) for the tokens of a document. Specifically, the document text $\boldsymbol{s}$ is composed of sentences $s_1, \ldots, s_n$ and the labelings $\boldsymbol{y}^*$ consists of corresponding label sequences $y_1, \ldots, y_n$.[3]

As is common in related work, we model each y_i using a CRF which conditions on the observed document text. In this work, we also assume a content model, which we fix to be the document-level HMM as used in Barzilay and Lee (2004). In this content model, each sentence s_i is associated with a hidden topic variable T_i which generates the words of the sentence. We will use $\boldsymbol{T} = (T_1, \ldots, T_n)$ to refer to the hidden topic sequence for a document. We fix the number of topics to a pre-specified constant K.

3.2 Model Overview

Our model, depicted in Figure 1, proceeds as follows: First the document-level HMM generates a hidden content topic sequence $\boldsymbol{T}$ for the sentences of a document. This content component is parametrized by θ and decomposes in the standard HMM fashion:[4]

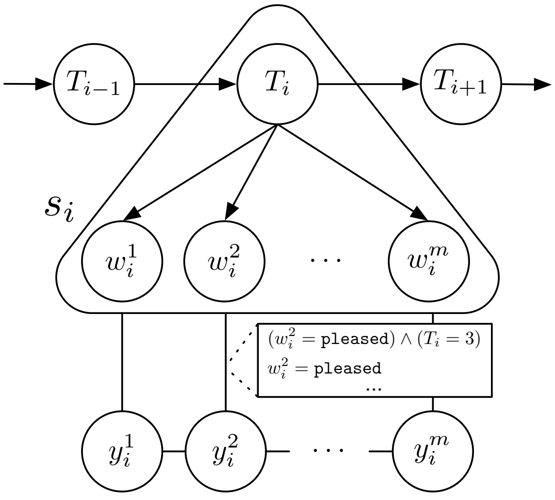

Figure 1: A graphical depiction of our model for sequence labeling tasks. The T_i variable represents the content model topic for the ith sentence s_i. The words of s_i, $(w_i^1, \ldots, w_i^m)$, each have a task label $(y_i^1, \ldots, y_i^m)$. Note that each token label has an undirected edge to a factor containing the words of the current sentence, s_i as well as the topic of the current sentence T_i.

$$P_\theta(\boldsymbol{s}, \boldsymbol{T}) = \prod_{i=1}^{n} P_\theta(T_i | T_{i-1}) \prod_{w \in s_i} P_\theta(w | T_i) \qquad (1)$$

Then the label sequences for each sentence in the document are independently modeled as CRFs which condition on both the sentence features and the sentence topic:

$$P_\phi(\boldsymbol{y} | \boldsymbol{s}, \boldsymbol{T}) = \prod_{i=1}^{n} P_\phi(y_i | s_i, T_i) \qquad (2)$$

Each sentence CRF is parametrized by ϕ and takes the standard form:

$$P_\phi(y|s, T) \propto \exp \left\{ \sum_j \phi^T \left[f_N(y^j, s, T) + f_E(y^j, y^{j+1}) \right] \right\}$$

[2] In Section 3.6, we discuss how this framework can be used for other text analysis applications.

[3] Note that each y_i is a label sequence across the words in s_i, rather than an individual label.

[4] We also utilize a hierarchical emission model so that each topic distribution interpolates between a topic-specific distribution as well as a shared background model; this is intended to capture domain-specific stop words.

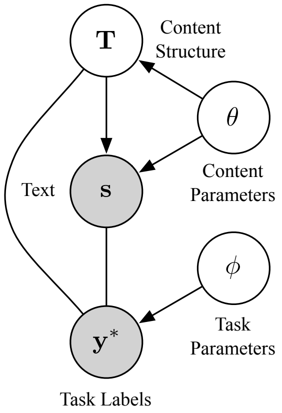

Figure 2: A graphical depiction of the generative process for a labeled document at training time (See Section 3); shaded nodes indicate variables which are observed at training time. First the latent underlying content structure $\boldsymbol{T}$ is drawn. Then, the document text $\boldsymbol{s}$ is drawn conditioned on the content structure utilizing content parameters θ. Finally, the observed task labels for the document are modeled given $\boldsymbol{s}$ and $\boldsymbol{T}$ using the task parameters ϕ. Note that the arrows for the task labels are undirected since they are modeled discriminatively.

where $f_N(\cdot)$ and $f_E(\cdot)$ are feature functions associated with CRF nodes and transitions respectively.

Allowing the CRF to condition on the sentence topic T_i permits predictions to be more sensitive to content. For instance, using the example from Table 1, we could have a feature that indicates the word "pleased" conjoined with the segment topic (see Figure 1). These topic-specific features serve to disambiguate word usage.

This joint process, depicted graphically in Figure 2, is summarized as:

$$P(\boldsymbol{T}, \boldsymbol{s}, \boldsymbol{y}^*) = P_\theta(\boldsymbol{T}, \boldsymbol{s}) P_\phi(\boldsymbol{y}^* | \boldsymbol{s}, \boldsymbol{T}) \qquad (3)$$

Note that this probability decomposes into a document-level HMM term (the content component) as well as a product of CRF terms (the task component).

3.3 Learning

During learning, we would like to find the document-level HMM parameters θ and the summarization task CRF parameters ϕ which maximize the likelihood of the labeled documents. The only observed elements of a labeled document are the document text $\boldsymbol{s}$ and the aspect labels $\boldsymbol{y}^*$. This objective is given by:

$$\begin{aligned}\mathcal{L}_L(\phi, \theta) &= \sum_{(\boldsymbol{s}, \boldsymbol{y}^*) \in \mathcal{D}_L} \log P(\boldsymbol{s}, \boldsymbol{y}^*) \\ &= \sum_{(\boldsymbol{s}, \boldsymbol{y}^*) \in \mathcal{D}_L} \log \sum_{\boldsymbol{T}} P(\boldsymbol{T}, \boldsymbol{s}, \boldsymbol{y}^*)\end{aligned}$$

We use the EM algorithm to optimize this objective.

E-Step The E-Step in EM requires computing the posterior distribution over latent variables. In this model, the only latent variables are the sentence topics $\boldsymbol{T}$. To compute this term, we utilize the decomposition in Equation (3) and rearrange HMM and CRF terms to obtain:

$$\begin{aligned}P(\boldsymbol{T}, \boldsymbol{s}, \boldsymbol{y}^*) &= P_\theta(\boldsymbol{T}, \boldsymbol{s}) P_\phi(\boldsymbol{y}^* | \boldsymbol{T}, \boldsymbol{s}) \\ &= \left(\prod_{i=1}^{n} P_\theta(T_i | T_{i-1}) \prod_{w \in s_i} P_\theta(w | T_i) \right) \cdot \\ &\quad \left(\prod_{i=1}^{n} P_\phi(y_i^* | s_i, T_i) \right) \\ &= \prod_{i=1}^{n} P_\theta(T_i | T_{i-1}) \cdot \\ &\quad \left(\prod_{w \in s_i} P_\theta(w | T_i) P_\phi(y_i^* | s_i, T_i) \right)\end{aligned}$$

We note that this expression takes the same form as the document-level HMM, except that in addition to emitting the words of a sentence, we also have an observation associated with the sentence sequence labeling. We treat each $P_\phi(y_i^* | s_i, T_i)$ as part of the node potential associated with the document-level HMM. We utilize the Forward-Backward algorithm as one would with the document-level HMM in isolation, except that each node potential incorporates this CRF term.

M-Step We perform separate M-Steps for content and task parameters. The M-Step for the content parameters is identical to the document-level HMM content model: topic emission and transition distributions are updated with expected counts derived from E-Step topic posteriors.

The M-Step for the task parameters does not have a closed-form solution. Recall that in the M-Step, we maximize the log probability of all random variables given expectations of latent variables. Using the decomposition in Equation (3), it is clear that the only component of the joint labeled document probability which relies upon the task parameters is $\log P_\phi(\boldsymbol{y}^*|\boldsymbol{s}, \boldsymbol{T})$. Thus for the M-Step, it is sufficient to optimize the following with respect to ϕ:

$$\begin{aligned}
&\mathbb{E}_{\boldsymbol{T}|\boldsymbol{s},\boldsymbol{y}^*} \log P_\phi(\boldsymbol{y}^*|\boldsymbol{s}, \boldsymbol{T}) \\
&= \sum_{i=1}^{n} \mathbb{E}_{T_i|s_i, y_i^*} \log P_\phi(y_i^*|s_i, T_i) \\
&= \sum_{i=1}^{n} \sum_{k=1}^{K} P(T_i = k|s_i, y_i^*) \log P_\phi(y_i^*|s_i, T_i)
\end{aligned}$$

The first equality follows from the decomposition of the task component into independent CRFs (see Equation (2)). Optimizing this objective is equivalent to a weighted version of the conditional likelihood objective used to train the CRF in isolation. An intuitive explanation of this process is that there are multiple CRF instances, one for each possible hidden topic T. Each utilizes different content features to explain the sentence sequence labeling. These instances are weighted according to the posterior over T obtained during the E-Step. While this objective is non-convex due to the summation over T, we can still optimize it using any gradient-based optimization solver; in our experiments, we used the LBFGS algorithm (Liu et al., 1989).

3.4 Inference

We must predict a label sequence y for each sentence s of the document. We assume a loss function over a sequence labeling y and a proposed labeling $\hat{y}$, which decomposes as:

$$L(y, \hat{y}) = \sum_j L(y^j, \hat{y}^j)$$

where each position loss is sensitive to the kind of error which is made. Failing to extract a token is penalized to a greater extent than extracting it with an incorrect label:

$$L(y^j, \hat{y}^j) = \begin{cases} 0 & \text{if } \hat{y}^j = y^j \\ c & \text{if } y^j \neq \text{NONE and } \hat{y}^j = \text{NONE} \\ 1 & \text{otherwise} \end{cases}$$

In this definition, NONE represents the background label which is reserved for tokens which do not correspond to labels of interest. The constant c represents a user-defined trade-off between precision and recall errors. For our multi-aspect summarization task, we select $c = 4$ for Yelp and $c = 5$ for Amazon to combat the high-precision bias typical of conditional likelihood models.

At inference time, we select the single labeling which minimizes the expected loss with respect to model posterior over label sequences:

$$\begin{aligned}
\hat{y} &= \min_{\hat{y}} \mathbb{E}_{y|\boldsymbol{s}} L(y, \hat{y}) \\
&= \min_{\hat{y}} \sum_{j=1} \mathbb{E}_{y^j|\boldsymbol{s}} L(y^j, \hat{y}^j)
\end{aligned}$$

In our case, we must marginalize out the sentence topic T:

$$\begin{aligned}
P(y^j|s) &= \sum_T P(y^j, T|s) \\
&= \sum_T P_\theta(T|s) P_\phi(y^j|s, T)
\end{aligned}$$

This minimum risk criterion has been widely used in NLP applications such as parsing (Goodman, 1999) and machine translation (DeNero et al., 2009). Note that the above formulation differs from the standard CRF due to the latent topic variables. Otherwise the inference task could be accomplished by directly obtaining posteriors over each y^j state using the Forward-Backwards algorithm on the sentence CRF.

Finding $\hat{y}$ can be done efficiently. First, we obtain marginal token posteriors as above. Then, the expected loss of a token prediction is computed as follows:

$$\sum_{\hat{y}^j} P(y^j|s) L(y^j, \hat{y}^j)$$

Once we obtain expected losses of each token prediction, we compute the minimum risk sequence labeling by running the Viterbi algorithm. The potential for each position and prediction is given by the negative expected loss. The maximal scoring sequence according to these potentials minimizes the expected risk.

3.5 Leveraging unannotated data

Our model allows us to incorporate unlabeled documents, denoted $\mathcal{D}_U$, to improve the learning of the content model. For an unlabeled document we only observe the document text s and assume it is drawn from the same content model as our labeled documents. The objective presented in Section 3.3 assumed that all documents were labeled; here we supplement this objective by capturing the likelihood of unlabeled documents according to the content model:

$$\begin{aligned}\mathcal{L}_U(\theta) &= \sum_{\boldsymbol{s}\in\mathcal{D}_U} \log P_\theta(\boldsymbol{s}) \\ &= \sum_{\boldsymbol{s}\in\mathcal{D}_U} \log \sum_{\boldsymbol{T}} P_\theta(\boldsymbol{s}, \boldsymbol{T})\end{aligned}$$

Our overall objective function is to maximize the likelihood of both our labeled and unlabeled data. This objective corresponds to:

$$\mathcal{L}(\phi, \theta) = \mathcal{L}_U(\theta) + \mathcal{L}_L(\phi, \theta)$$

This objective can also be optimized using the EM algorithm, where the E-Step for labeled and unlabeled documents is outlined above.

3.6 Generalization

The approach outlined can be applied to a wider range of task components. For instance, in Section 4.1 we apply this approach to multi-aspect sentiment analysis. In this task, the target y consists of numeric sentiment ratings $(y_1, \ldots, y_K)$ for each of K aspects. The task component consists of independent linear regression models for each aspect sentiment rating. For the content model, we associate a topic with each paragraph; $\boldsymbol{T}$ consists of assignments of topics to each document paragraph.

The model structure still decomposes as in Figure 2, but the details of learning are slightly different. For instance, because the task label (aspect sentiment ratings) is not localized to any region of the document, all content model variables influence the target response. Conditioned on the target label, all topic variables become correlated. Thus when learning, the E-Step requires computing a posterior over paragraph topic tuples $\boldsymbol{T}$:

$$P(\boldsymbol{T}|\boldsymbol{y}, \boldsymbol{s}) \propto P(\boldsymbol{s}, \boldsymbol{T})P(\boldsymbol{y}|\boldsymbol{T}, \boldsymbol{s})$$

For the case of our multi-aspect sentiment task, this computation can be done exactly by enumerating $\boldsymbol{T}$ tuples, since the number of sentences and possible topics is relatively small. If summation is intractable, the posterior may be approximated using variational techniques (Bishop, 2006), which is applicable to a broad range of potential applications.

4 Experimental Set-Up

We apply our approach to two text analysis tasks that stand to benefit from modeling content structure: multi-aspect sentiment analysis and multi-aspect review summarization.

4.1 Tasks

In the following section, we define each task in detail, explain the task-specific adaptation of the model and describe the data sets used in the experiments. Table 2 summarizes statistics for all the data sets.

For all tasks, when using a content model with a task model, we utilize a new set of features which include all the original features as well as a copy of each feature conjoined with the content topic assignment (see Figure 1). We also include a feature which indicates whether a given word was most likely emitted from the underlying topic or from a background distribution.

Multi-Aspect Sentiment Ranking The goal of multi-aspect sentiment classification is to predict a set of numeric ranks that reflects the user satisfaction for each aspect (Snyder and Barzilay, 2007). One of the challenges in this task is to attribute sentiment-bearing words to the aspects they describe. Information about document structure has the potential to greatly reduce this ambiguity.

Following standard sentiment ranking approaches (Wilson et al., 2004; Pang and Lee, 2005; Goldberg and Zhu, 2006; Snyder and Barzilay, 2007), we employ ordinary linear regression to independently map bag-of-words representations into predicted aspect ranks. In addition to commonly used lexical features, this set is augmented

Task	Labeled		Unlabeled	Avg. Size	
	Train	Test		Words	Sents
Multi-aspect sentiment	600	65	—	1,027	20.5
Multi-aspect summarization					
Amazon	35	24	12,684	214	11.7
Yelp	48	48	33,015	178	11.2

Table 2: This table summarizes the size of each corpus. In each case, the unlabeled texts of both labeled and unlabeled documents are used for training the content model, while only the labeled training corpus is used to train the task model. Note that the entire data set for the multi-aspect sentiment analysis task is labeled.

with content features as described above. For this application, we fix the number of HMM states to be equal to the predefined number of aspects.

We test our sentiment ranker on a set of DVD reviews from the website IGN.com.[5] Each review is accompanied by 1-10 scale ratings in four categories that assess the quality of a movie's content, video, audio, and DVD extras. In this data set, segments corresponding to each of the aspects are clearly delineated in each document. Therefore, we can compare the performance of the algorithm using automatically induced content models against the gold standard structural information.

Multi-Aspect Review Summarization The goal of this task is to extract informative phrases that identify information relevant to several predefined aspects of interest. In other words, we would like our system to both extract important phrases (e.g., *cheap food*) and label it with one of the given aspects (e.g., *value*). For concrete examples and lists of aspects for each data set, see Figures 3b and 3c. Variants of this task have been considered in review summarization in previous work (Kim and Hovy, 2006; Branavan et al., 2009).

This task has elements of both information extraction and phrase-based summarization — the phrases we wish to extract are broader in scope than in standard template-driven IE, but at the same time, the type of selected information is restricted to the defined aspects, similar to query-based summarization. The difficulty here is that phrase selection is highly context-dependent. For instance, in TV reviews such as in Figure 3b, the highlighted phrase "easy to read" might refer to either the menu or the remote; broader context is required for correct labeling.

We evaluated our approach for this task on two data sets: Amazon TV reviews (Figure 3b) and Yelp restaurant reviews (Figure 3c). To eliminate noisy reviews, we only retain documents that have been rated "helpful" by the users of the site; we also remove reviews which are abnormally short or long.

Each data set was manually annotated with aspect labels using Mechanical Turk, which has been used in previous work to annotate NLP data (Snow et al., 2008). Since we cannot select high-quality annotators directly, we included a control document which had been previously annotated by a native speaker among the documents assigned to each annotator. The work of any annotator who exhibited low agreement on the control document annotation was excluded from the corpus. To test task annotation agreement, we use Cohen's Kappa (Cohen, 1960). On the Amazon data set, two native speakers annotated a set of four documents. The agreement between the judges was 0.54. On the Yelp data set, we simply computed the agreement between all pairs of reviewers who received the same control documents; the agreement was 0.49.

4.2 Baseline Comparison and Evaluation

Baselines For all the models, we obtain a baseline system by eliminating content features and only using a task model with the set of features described above. We also compare against a simplified variant of our method wherein a content model is induced in isolation rather than learned jointly in the context of the underlying task. In our experiments, we refer to the two methods as the No Content Model (NoCM) and Independent Content Model (IndepCM) settings, respectively. The Joint Content

(c) Sample labeled text from the Yelp multi-aspect summarization corpus

Figure 3: Excerpts from the three corpora with the corresponding labels. Note that sentences from the multi-aspect summarization corpora generally focus on only one or two aspects. The multi-aspect sentiment corpus has labels per paragraph rather than per sentence.

Model (JointCM) setting refers to our full model described in Section 3, where content and task components are learned jointly.

Evaluation Metrics For multi-aspect sentiment ranking, we report the average L_2 (squared difference) and L_1 (absolute difference) between system prediction and true 1-10 sentiment rating across test documents and aspects.

For the multi-aspect summarization task, we measure average token precision and recall of the label assignments (Multi-label). For the Amazon corpus, we also report a coarser metric which measures extraction precision and recall while ignoring labels (Binary labels) as well as ROUGE (Lin, 2004). To compute ROUGE, we control for length by limiting each system to predict the same number of tokens as the original labeled document.

	L_1	L_2
NoCM	1.37	3.15
IndepCM	1.28†*	2.80†*
JointCM	**1.25**†	**2.65**†*
Gold	1.18†*	2.48†*

Table 3: The error rate on the multi-aspect sentiment ranking. We report mean L_1 and L_2 between system prediction and true values over all aspects. Marked results are statistically significant with $p < 0.05$: * over the previous model and † over NoCM.

	F_1	F_2	Prec.	Recall
NoCM	28.8%	34.8%	22.4%	40.3%
IndepCM	37.9%	43.7%	31.1%†*	**48.6%**†*
JointCM	**39.2%**	**44.4%**	**32.9%**†*	**48.6%**†

Table 4: Results for multi-aspect summarization on the Yelp corpus. Marked precision and recall are statistically significant with $p < 0.05$: * over the previous model and † over NoCM.

Our metrics of statistical significance vary by task. For the sentiment task, we use Student's t-test. For the multi-aspect summarization task, we perform chi-square analysis on the ROUGE scores as well as on precision and recall separately, as is commonly done in information extraction (Freitag, 2004; Weeds et al., 2004; Finkel and Manning, 2009).

5 Results

In this section, we present the results of the methods on the tasks described above (see Tables 3, 4, and 5).

Baseline Comparisons Adding a content model significantly outperforms the NoCM baseline on both tasks. The highest F_1 error reduction – 14.7% – is achieved on multi-aspect summarization on the Yelp corpus, followed by the reduction of 11.5% and 8.75%, on multi-aspect summarization on the Amazon corpus and multi-aspect sentiment ranking, respectively.

We also observe a consistent performance boost when comparing against the IndepCM baseline. This result confirms our hypothesis about the ad-

	Multi-label				Binary labels

vantages of jointly learning the content model in the context of the underlying task.

Comparison with additional context features One alternative to an explicit content model is to simply incorporate additional features into NoCM as a proxy for contextual information. In the multi-aspect summarization case, this can be accomplished by adding unigram features from the sentences before and after the current one.[6]

When testing this approach, however, the performance of NoCM actually decreases on both Amazon (to 15.0% F_1) and Yelp (to 24.5% F_1) corpora. This result is not surprising for this particular task – by adding these features, we substantially increase the feature space without increasing the amount of training data. An advantage of our approach is that our learned representation of context is coarse, and we can leverage large quantities of unannotated training data.

Impact of content model quality on task performance In the multi-aspect sentiment ranking task, we have access to gold standard document-level content structure annotation. This affords us the ability to compare the ideal content structure, provided by the document authors, with one that is learned automatically. As Table 3 shows, the manually created document structure segmentation yields the best results. However, the performance of our JointCM model is not far behind the gold standard content structure.

The quality of the induced content model is determined by the amount of training data. As Figure 4 shows, the multi-aspect summarizer improves with the increase in the size of raw data available for learning content model.

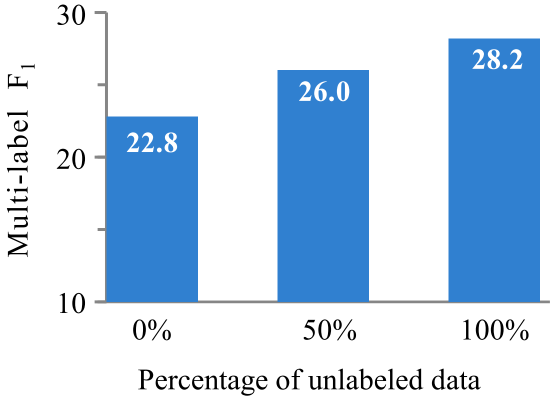

Figure 4: Results on the Amazon corpus using the complete annotated set with varying amounts of additional unlabeled data.[7]

Compensating for annotation sparsity We hypothesize that by incorporating rich contextual information, we can reduce the need for manual task annotation. We test this by reducing the amount of annotated data available to the model and measuring performance at several quantities of unannotated data. As Figure 5 shows, the performance increase achieved by doubling the amount of annotated data can also be achieved by adding only 12.5% of the unlabeled data.

6 Conclusion

In this paper, we demonstrate the benefits of incorporating content models in text analysis tasks. We also introduce a framework to allow the joint learning of an unsupervised latent content model with a supervised task-specific model. On multiple tasks and datasets, our results empirically connect model quality and task performance, suggesting that fur-

[6] This type of feature is not applicable to our multi-aspect sentiment ranking task, as we already use unigram features from the entire document.

[7] Because we append the unlabeled versions of the labeled data to the unlabeled set, even with 0% additional unlabeled data, there is a small data set to train the content model.

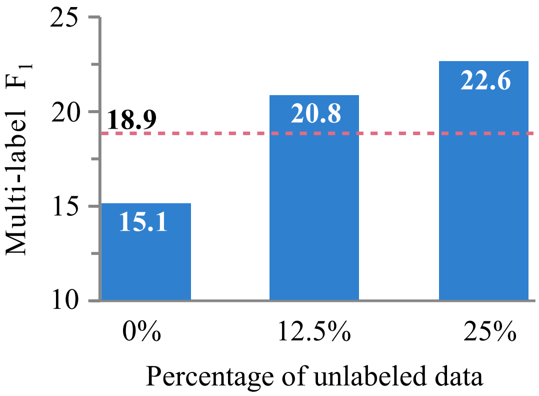

Figure 5: Results on the Amazon corpus using half of the annotated training documents. The content model is trained with 0%, 12.5%, and 25% of additional unlabeled data.[7] The dashed horizontal line represents NoCM with the complete annotated set.

ther improvements in content modeling may yield even further gains.

Abstract

This work concerns automatic topic segmentation of email conversations. We present a corpus of email threads manually annotated with topics, and evaluate annotator reliability. To our knowledge, this is the first such email corpus. We show how the existing topic segmentation models (i.e., Lexical Chain Segmenter (LCSeg) and Latent Dirichlet Allocation (LDA)) which are solely based on lexical information, can be applied to emails. By pointing out where these methods fail and what any desired model should consider, we propose two novel extensions of the models that not only use lexical information but also exploit finer level conversation structure in a principled way. Empirical evaluation shows that LCSeg is a better model than LDA for segmenting an email thread into topical clusters and incorporating conversation structure into these models improves the performance significantly.

1 Introduction

With the ever increasing popularity of emails and web technologies, it is very common for people to discuss issues, events, agendas or tasks by email. Effective processing of the email contents can be of great strategic value. In this paper, we study the problem of *topic segmentation for emails*, i.e., grouping the sentences of an email thread into a set of coherent topical clusters. Adapting the standard definition of topic (Galley et al., 2003) to conversations/emails, we consider a topic is something about which the participant(s) discuss or argue or express their opinions. For example, in the email thread shown in Figure 1, according to the majority of our annotators, participants discuss three topics (e.g., 'telecon cancellation', 'TAG document', and 'responding to I18N'). Multiple topics seem to occur naturally in social interactions, whether synchronous (e.g., chats, meetings) or asynchronous (e.g., emails, blogs) conversations. In multi-party chat (Elsner and Charniak, 2008) report an average of 2.75 discussions active at a time. In our email corpus, we found an average of 2.5 topics per thread.

Topic segmentation is often considered a prerequisite for other higher-level conversation analysis and applications of the extracted structure are broad, encompassing: summarization (Harabagiu and Lacatusu, 2005), information extraction and ordering (Allan, 2002), information retrieval (Dias et al., 2007), and intelligent user interfaces (Dredze et al., 2008). While extensive research has been conducted in topic segmentation for monologues (e.g., (Malioutov and Barzilay, 2006), (Choi et al., 2001)) and synchronous dialogs (e.g., (Galley et al., 2003), (Hsueh et al., 2006)), none has studied the problem of segmenting asynchronous multi-party conversations (e.g., email). Therefore, there is no reliable annotation scheme, no standard corpus, and no agreed-upon metrics available. Also, it is our key hypothesis that, because of its asynchronous nature, and the use of quotation (Crystal, 2001), topics in an email thread often do not change in a sequential way. As a result, we do not expect models which have proved successful in monologue or dialog to be as effective when they are applied to email conversations.

Our contributions in this paper aim to remedy

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 388–398,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

these problems. First, we present an email corpus annotated with topics and evaluate annotator agreement. Second, we adopt a set of metrics to measure the local and global structural similarity between two annotations from the work on multi-party chat disentanglement (Elsner and Charniak, 2008). Third, we show how the two state-of-the-art topic segmentation methods (i.e., LCSeg and LDA) which are solely based on lexical information and make strong assumptions on the resulting topic models, can be effectively applied to emails, by having them to consider, in a principled way, a finer level structure of the underlying conversations. Experimental results show that both LCSeg and LDA benefit when they are extended to consider the conversational structure. When comparing the two methods, we found that LCSeg is better than LDA and this advantage is preserved when they are extended to incorporate conversational structure.

2 Related Work

Three research areas are directly related to our study: a) text segmentation models, b) probabilistic topic models, and c) extracting and representing the conversation structure of emails.

Topic segmentation has been extensively studied both for monologues and dialogs. (Malioutov and Barzilay, 2006) uses the minimum cut model to segment spoken lectures (i.e., monologue). They form a weighted undirected graph where the vertices represent sentences and the weighted links represent the similarity between sentences. Then the segmentation problem can be solved as a graph partitioning problem, where the assumption is that the sentences in a segment should be similar, while sentences in different segments should be dissimilar. They optimize the 'normalized cut' criterion to extract the segments. In general, the minimization of the normalized cut criterion is NP-complete. However, the linearity constraint on text segmentation for monologue allows them to find an exact solution in polynomial time. In our extension of LCSeg, we use a similar method to consolidate different segments; however, in our case the linearity constraint is absent. Therefore, we approximate the optimal solution by spectral clustering (Shi and Malik, 2000). Moving to the task of segmenting dialogs, (Galley et al., 2003) first proposed the lexical chain based unsupervised segmenter (LCSeg) and a supervised segmenter for segmenting meeting transcripts. Their supervised approach uses C4.5 and C4.5 rules binary classifiers with lexical and conversational features (e.g., cue phrase, overlap, speaker, silence, and lexical cohesion function). Their supervised approach performs significantly better than LCSeg. (Hsueh et al., 2006) follow the same approaches as (Galley et al., 2003) on both manual transcripts and ASR output of meetings. They perform segmentation at both coarse (topic) and fine (subtopic) levels. For the topic level, they achieve similar results as (Galley et al., 2003), with the supervised approach outperforming LCSeg. However, for the subtopic level, LCSeg performs significantly better than the supervised one. In our work, we show how LCSeg performs when applied to the temporal ordering of the emails in a thread. We also propose its extension to leverage the finer conversation structure of emails.

The probabilistic generative topic models, such as LDA and its variants (e.g., (Blei et al., 2003), (Steyvers and Griffiths, 2007)), have proven to be successful for topic segmentation in both monologue (e.g., (Chen et al., 2009)) and dialog (e.g., (Georgescul et al., 2008)). (Purver et al., 2006) uses a variant of LDA for the tasks of segmenting meeting transcripts and extracting the associated topic labels. However, their approach for segmentation does not perform better than LCSeg. In our work, we show how the general LDA performs when applied to email conversations and describe how it can be extended to exploit the conversation structure of emails.

Several approaches have been proposed to capture an email conversation . Email programs (e.g., Gmail, Yahoomail) group emails into threads using headers. However, our annotations show that topics change at a finer level of granularity than emails. (Carenini et al., 2007) present a method to capture an email conversation at the finer level by analyzing the embedded quotations in emails. A fragment quotation graph (FQG) is generated, which is shown to be beneficial for email summarization. In this paper, we show that topic segmentation models can also benefit significantly from this fine conversation structure of email threads.

3 Corpus and Evaluation Metrics

There are no publicly available email corpora annotated with topics. Therefore, the first step was to develop our own corpus. We have annotated the BC3 email corpus (Ulrich et al., 2008) with topics[1]. The BC3 corpus, previously annotated with sentence level speech acts, meta sentence, subjectivity, extractive and abstractive summaries, is one of a growing number of corpora being used for email research. The corpus contains 40 email threads from the W3C corpus[2]. It has 3222 sentences and an average of 5 emails per thread.

3.1 Topic Annotation

Topic segmentation in general is a nontrivial and subjective task (Hsueh et al., 2006). The conversation phenomenon called 'Schism' makes it even more challenging for conversations. In schism a new conversation takes birth from an existing one, not necessarily because of a topic shift but because some participants refocus their attention onto each other, and away from whoever held the floor in the parent conversation and the annotators can disagree on the birth of a new topic (Aoki et al., 2006). In the example email thread shown in Figure 1, a schism takes place when people discuss about 'responding to I18N'. All the annotators do not agree on the fact that the topic about 'responding to I18N' swerves from the one about 'TAG document'. The annotators can disagree on the number of topics (i.e., some are specific and some are general), and on the topic assignment of the sentences[3]. To properly design an effective annotation manual and procedure we performed a two-phase pilot study before carrying out the actual annotation. For the pilot study we picked five email threads randomly from the corpus. In the first phase of the pilot study we selected five university graduate students to do the annotation. We then revised our instruction manual based on their feedback and the source of disagreement found. In the second phase we tested with a university postdoc doing the annotation.

For the actual annotation we selected three computer science graduates who are also native speakers of English. They annotated 39 threads of the BC3 corpus[4]. On an average they took seven hours to annotate the whole dataset.

BC3 contains three human written abstract summaries for each email thread. With each email thread the annotators were also given an associated human written summary to give a brief overview of the corresponding conversation. The task of finding topics was carried out in two phases. In the first phase, the annotators read the conversation and the associated summary and list the topics discussed. They specify the topics by a short description (e.g., "meeting agenda", "location and schedule") which provides a high-level overview of the topic. The target number of topics and the topic labels were not given in advance and they were instructed to find as many topics as needed to convey the overall content structure of the conversation.

In the second phase the annotators identify the most appropriate topic for each sentence. However, if a sentence covers more than one topic, they were asked to label it with all the relevant topics according to their order of relevance. If they find any sentence that does not fit into any topic, they are told to label those as the predefined topic 'OFF-TOPIC'. Wherever appropriate they were also asked to make use of two other predefined topics: 'INTRO' and 'END'. INTRO (e.g., 'hi', 'hello') signifies the section (usually at the beginning) of an email that people use to begin their email. Likewise, END (e.g., 'Cheers', 'Best') signifies the section (usually at the end) that people use to end their email. The annotators carried out the task on paper. We created the hierarchical thread view ('reply to' relation) using 'TAB's (indentation) and each participant's name is printed in a different color as in Gmail.

Table 1 shows some basic statistics computed on the three annotations of the 39 email threads[5]. On

[1] The BC3 corpus had already been annotated for email summarization, speech act recognition and subjectivity detection. This new annotation with topics will be also made publicly available at http://www.cs.ubc.ca/labs/lci/bc3.html

[2] http://research.microsoft.com/en-us/um/people/nickcr/w3c-summary.html

[3] The annotators also disagree on the topic labels, however in this work we are not interested in finding the topic labels.

[4] The annotators in the pilot and in the actual study were different so we could reuse the threads used in pilot study. However, one thread on which the pilot annotators agree fully, was used as an example in the instruction manual. This gives 39 threads left for the actual study.

[5] We got 100% agreement on the two predefined topics 'IN-

average we have 26.3 sentences and 2.5 topics per thread. A topic contains an average of 12.6 sentences. The average number of topics active at a time is 1.4. The average entropy is 0.94 and corresponds (as described in detail in the next section) to the granularity of the annotation. These statistics (number of topics and topic density) indicate that the dataset is suitable for topic segmentation.

	Mean	Max	Min
Number of sentences	26.3	55	13
Number of topics	2.5	7	1
Avg. topic length	12.6	35	3
Avg. topic density	1.4	3.1	1
Entropy	0.94	2.7	0

Table 1: Corpus statistics of human annotations

Metrics	Mean	Max	Min
1-to-1	0.804	1	0.31
loc_k	0.831	1	0.43
m-to-1	0.949	1	0.61

Table 2: Annotator agreement in the scale of 0 to 1

3.2 Evaluation Metrics

In this section we describe the metrics used to compare different human annotations and system's output. As different annotations (or system's output) can group sentences in different number of clusters, metrics widely used in classification, such as the κ statistic, are not applicable. Again, our problem of topic segmentation for emails is not sequential in nature. Therefore, the standard metrics widely used in sequential topic segmentation for monologues and dialogs, such as P_k and $WindowDiff(WD)$, are also not applicable. We adopt the more appropriate metrics 1-to-1, loc_k and m-to-1, introduced recently by (Elsner and Charniak, 2008). The 1-to-1 metric measures the global similarity between two annotations. It pairs up the clusters from the two annotations in a way that maximizes (globally) the total overlap and then reports the percentage of overlap. loc_k measures the local agreement within a context of k sentences. To compute the loc_3 metric for the m-th sentence in the two annotations, we consider the previous 3 sentences: m-1, m-2 and m-3, and mark them as either 'same' or 'different' depending on their topic assignment. The loc_3 score between two annotations is the mean agreement on these 'same' or 'different' judgments, averaged over all sentences. We report the agreement found in 1-to-1 and loc_k in Table 2. In both of the metrics we get high agreement, though the local agreement (average of 83%) is little higher than the global agreement (average of 80%).

If we consider the topic of a randomly picked sentence as a random variable then its entropy measures the level of detail in an annotation. If the topics are evenly distributed then the uncertainty (i.e., entropy) is higher. It also increases with the increase of the number of topics. Therefore, it is a measure of how specific an annotator is and in our dataset it varies from 0 [6] to 2.7. To measure how much the annotators agree on the general structure we use the m-to-1 metric. It maps each of the source clusters to the single target cluster with which it gets the highest overlap, then computes the total percentage of overlap. This metric is asymmetrical and not a measure to be optimized[7], but it gives us some intuition about specificity (Elsner and Charniak, 2008). If one annotator divides a cluster into two clusters then, the m-to-1 metric from fine to coarse is 1. In our corpus by mapping from fine to coarse we get an m-to-1 average of 0.949.

4 Topic Segmentation Models

Developing automatic tools for segmenting an email thread is challenging. The example email thread in Figure 1 demonstrates why. We use different colors and fonts to represent sentences of different topics[8]. One can notice that email conversations are different from written monologues (e.g., newspaper) and dialogs (e.g., meeting, chat) in various ways. As a communication media Email is distributed (unlike face to face meeting) and asynchronous (unlike

TRO' and 'END'. In all our computation (i.e., statistics, agreement, system's input) we excluded the sentences marked as either 'INTRO' or 'END'

[6] 0 uncertainty happens when there is only one topic found

[7] hence we do not use it to compare our models.

[8] 2 of the 3 annotators agree on this segmentation. Green represents topic 1 ('telecon cancellation'), orange indicates topic 2 ('TAG document') and magenta represents topic 3 ('responding to I18N')

chat), meaning that different people from different locations can collaborate at different times. Therefore, topics in an email thread may not change in sequential way. In the example, we see that topic 1 (i.e., 'telecon cancellation') is revisited after some gaps.

The headers (i.e., subjects) do not convey much information and are often misleading. In the example thread, participants use the same subject (i.e., 20030220 telecon) but they talk about 'responding to I18N' and 'TAG document' instead of 'telecon cancellation'. Writing style varies among participants, and many people tend to use informal, short and ungrammatical sentences. These properties of email limit the application of techniques that have been successful in monologues and dialogues.

LDA and *LCSeg* are the two state-of-the-art models for topic segmentation of multi-party conversation (e.g., (Galley et al., 2003), (Hsueh et al., 2006), (Georgescul et al., 2008)). In this section, at first we describe how the existing models of topic segmentation can be applied to emails. We then point out where these methods fail and propose extensions of these basic models for email conversations.

4.1 Latent Dirichlet Allocation (LDA)

Our first model is the probabilistic LDA model (Steyvers and Griffiths, 2007). This model relies on the fundamental idea that documents are mixtures of topics, and a topic is a multinomial distribution over words. The generative topic model specifies the following distribution over words within a document:

$$P(w_i) = \sum_{j=1}^{T} P(w_i|z_i = j)P(z_i = j)$$

Where T is the number of topics. $P(w_i|z_i = j)$ is the probability of word w_i under topic j and $P(z_i = j)$ is the probability that j^{th} topic was sampled for the i^{th} word token. We refer the multinomial distributions $\phi^{(j)} = P(w|z_i = j)$ and $\theta^{(d)} = P(z)$ as topic-word distribution and document-topic distribution respectively. (Blei et al., 2003) refined this basic model by placing a Dirichlet (α) prior on θ. (Griffiths and Steyvers, 2003) further refined it by placing a Dirichlet (β) prior on ϕ. The inference problem is to find ϕ and θ given a document set. Variational EM has been applied to estimate these two parameters directly. Instead of estimating ϕ and θ, one can also directly estimate the posterior distribution over $z = P(z_i = j|w_i)$ (topic assignments for words). One efficient estimation technique uses Gibbs sampling to estimate this distribution.

This framework can be directly applied to an email thread by considering each email as a document. Using LDA we get $z = P(z_i = j|w_i)$ (i.e., topic assignments for words). By assuming the words in a sentence occur independently we can estimate the topic assignments for sentences as follows:

$$P(z_i = j|s_k) = \prod_{w_i \in s_k} P(z_i = j|w_i)$$

where, s_k is the k^{th} sentence for which we can assign the topic by: $j^* = argmax_j P(z_i = j|s_k)$.

4.2 Lexical Chain Segmenter (LCSeg)

Our second model is the lexical chain based segmenter LCSeg, (Galley et al., 2003). LCSeg assumes that topic shifts are likely to occur where strong term repetitions start and end[9]. LCSeg at first computes 'lexical chains' for each non-stop word based on word repetitions. It then ranks the chains according to two measures: 'number of words in the chain' and 'compactness of the chain'. The more compact (in terms of number of sentences) and the more populated chains get higher scores.

The algorithm then works with two adjacent analysis windows, each of a fixed size k which is empirically determined. For each sentence boundary, LCSeg computes the cosine similarity (or lexical cohesion function) at the transition between the two windows. Low similarity indicates low lexical cohesion, and a sharp change signals a high probability of an actual topic boundary. This method is similar to TextTiling (Hearst, 1997) except that the similarity is computed based on the scores of the 'lexical chains' instead of 'term counts'. In order to apply LCSeg on email threads we arrange the emails based on their temporal relation (i.e., arrival time) and apply the LCSeg algorithm to get the topic boundaries.

[9] One can also consider other lexical semantic relations (e.g., synonym, hypernym, hyponym) in lexical chaining. However, Galley et al., (Galley et al., 2003) uses only repetition relation as previous research results (e.g., (Choi, 2000)) account only for repetition.

I think that means we will not formally respond to I18N on the charmod comments, shall I tell them that we do not intend to, but that the e-mail discussion has not shown any disagreement. [d]
e.g. I have informed the RDF Core WG of your decisions, and no one has indicated unhappiness - however we have not formally discussed these issues; and are not likely to. [e]

Ah. Is this a problem. Have I understood correctly they are going through last call again anyway. [f]
> e.g. I have informed the RDF Core WG of your decisions, and no one has indicated unhappiness
> - however we have not formally discussed these issues; and are not likely to.
When is the deadline? I'm prepared to decide by email so we can formally respond by email. [g]

> I propose to cancel this weeks telecon and schedule another for 12 Mar 2004, if needed.
Im assuming that they are all cancelled unless I hear otherwise. Maybe that should be our default? [h]
> I would like to get moving on comments on the TAG architecture document.
I still plan to write a rather long diatribe on this if I can find the time. I doubt if the rest of the WG will endorse all of it but I will send it along asap, hopefully some time next week. [i]

> Ah. Is this a problem.
> Have I understood correctly they are going through last call again anyway.
Yes - I could change my draft informal response to indicate that if we have any other formal response it will be included in our LC review comments on their new documents. [j]
> When is the deadline?
> I'm prepared to decide by email so we can formally respond by email.
Two weeks from when I received the message ....i.e. during Cannes [k]
-I suspect that is also the real deadline, in that I imagine they want to make their final decisions at Cannes.
I am happy to draft a formal response that is pretty vacuous, for e-mail vote. [l]

>Likewise, whether or not anyone else in the WG agrees with any of my own personal comments, ...[m]
That is a reasonable working assumption. I've been announcing telecon's in advance and cancelling If not needed to keep within w3c process. [n]

Please do. [o]

Figure 1: Sample thread from the BC3 corpus. Each different color/font indicates a different topic. Right most column specifies the fragments (sec 4.4).

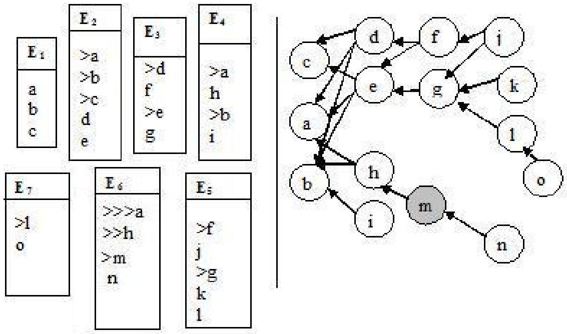

Figure 2: Fragment Quotation Graph for emails

4.3 Limitation of Existing Approaches

The main limitation of the two models discussed above is that they take the bag-of-words (BOW) assumption without considering the fact that an email thread is a multi-party, asynchronous conversation[10]. The only information relevant to LDA is term frequency. LCSeg considers both term frequency and how closely the terms occur in a document. These models do not consider the word order, syntax and semantics. However, several improvements of LDA over the BOW approach have been proposed. (Wallach, 2006) extends the model beyond BOW by considering n-gram sequences. (Griffiths et al., 2005) presents an extension of the topic model that is sensitive to word-order and automatically learns the syntactic as well as semantic factors that guide word choice. (Boyd-Graber and Blei, 2010) describes another extension to consider syntax of the text. As described earlier, one can also incorporate lexical semantics (i.e., synonym, hypernym, hyponym) into the LCSeg model. However, we argue that these models are still inadequate for finding topics in emails especially when topics are closely related (e.g., ‘extending the meeting’ and ‘scheduling the meeting’) and distributional variations are subtle. To better identify the topics in an email thread we need to consider the email specific conversation features (e.g., reply-to relation, usage of quotations). As can be seen in the example (Figure 1), people often use quotations to talk about the same topic. In fact in our corpus we found an average quotation usage of 6.44 per thread. Therefore,

[10] though in LCSeg we provide minimal conversation structure in the form of temporal relation between emails.

we need to leverage this useful information in a principled way to get the best out of our models. Specifically, we need to capture the conversation structure at the fragment (quotation) level and to incorporate this structure into our models.

In the next section, we describe how one can capture the conversation structure at the fragment level in the form of Fragment Quotation Graph (henceforth, FQG). In Section 4.5 and 4.6 respectively, we show how the LDA and LCSeg models can be extended so that they take this conversation structure into account for topic segmentation.

4.4 Extracting Conversation Structure

We demonstrate how to build a FQG through the example email thread involving 7 emails shown in Figure 1. For convenience we do not show the real content but abbreviate them as a sequence of fragments.

In the first pass by processing the whole thread we identify the new (i.e., quotation depth 0) and quoted (i.e., quotation depth $>$ 0) fragments based on the usage of quotation ($>$) marks. For instance, email E_3 contains two new fragments (f, g), and two quoted fragments (d, e) of depth 1. E_2 contains abc and de. Then in the second step, we compare the fragments with each other and based on the overlap we find the distinct fragments. If necessary we split the fragments in this step. For example, de in E_2 is divided into d and e distinct fragments when compared with the fragments of E_3. This process gives 15 distinct fragments which constitute the vertices of the FQG. In the third step, we compute the edges, which represent referential relations between fragments. For simplicity we assume that any new fragment is a potential reply to its neighboring quoted fragments. For example, for the fragments of E_4 we create two edges from h ((h,a),(h,b)) and one edge from i ((i,b)). We then remove the redundant edges. In E_6 we found the edges (n,h), (n,a) and (n,m). As (h,a) is already there we exclude (n,a). The FQG with all the redundant edges removed is shown at the right in Figure 2. If an email does not contain quotes then the fragments of that email are connected to the fragments of the source email to which it replies.

The advantage of the FQG is that it captures the conversation at finer granularity level in contrast to the structure found by the 'reply-to' relation at the email level, which would be merely a sequence from E_1 to E_7 in this example. Another advantage of this structure is that it allows us to find the 'hidden fragments'. Hidden fragments are quoted fragments (shaded fragment m in fig 2 which corresponds to the fragment made bold in fig 1), whose original email is missing in the user's inbox. (Carenini et al., 2007) study this phenomenon and its impact on email summarization in detail.

4.5 Regularizing LDA with FQG

The main advantage of the probabilistic (Bayesian) models is that they allow us to incorporate multiple knowledge sources in a coherent way in the form of priors (or regularizer). We want to regularize LDA in a way that will force two sentences in the same or adjacent fragments to fall in the same topical cluster. The first step forwards this aim is to regularize the topic-word distribution with a word network such that two connected words get similar topic distributions. Then we can easily extend it to fragments. In this section, at first we describe how one can regularize the LDA model with a word network, then we extend this by regularizing LDA with FQG.

Assume we are given a word network as an undirected graph with nodes (V) representing the words and the edges (E) representing the links between words. We want to regularize the LDA model such that two connected words u, v have similar topic-word distributions (i.e., $\phi_j^{(u)} \approx \phi_j^{(v)}$ for $j = 1 \dots T$). Note that the standard conjugate Dirichlet prior on ϕ is limited in that all words share a common variance parameter, and are mutually independent except normalization constraint (Minka, 1999). Therefore it does not allow us to encode this knowledge. Very recently, (Andrzejewski et al., 2009) shows how to encode 'must-link' and 'cannot-link' (between words) into the LDA model by using a Dirichlet Forest prior. We reimplemented this model; however, we only use its capability of encoding 'must-links'. Therefore, we just illustrate how to encode 'must-links' here. Interested readers can see (Andrzejewski et al., 2009) for the method of encoding 'cannot-links'.

Must links such as $(a, b), (b, c)$, or (x, y) in Figure 3(A) can be encoded into the LDA model by using a Dirichlet Tree (henceforth, DT) prior. Like the traditional Dirichlet, DT is also a conjugate to the multinomial but under a different parameterization.

Instead of representing a multinomial sample as the outcome of a K-sided die, in this representation we represent a sample as the outcome of a finite stochastic process. The probability of a leaf is the product of branch probabilities leading to that leaf. The words constitute the leaves of the tree.

DT distribution is the distribution over leaf probabilities. Let ω^n be the DT edge weight leading into node n, $C(n)$ be the children of node n, L be the leaves of the tree, I the internal nodes, and $L(n)$ be the leaves in the subtree under n. We generate a sample ϕ^k from Dirichlet_Tree(Ω) by drawing a multinomial at each internal node $i \in I$ from Dirichlet($\omega^{C(i)}$) (i.e., the edge weights from i to its children). The probability density function of DT($\phi^k|\Omega$) is given by:

$$DT(\phi^k|\Omega) \approx \left(\prod_{l\in L} \phi_l^{k^{\omega^l-1}}\right)\left(\prod_{i\in I}\left(\sum_{j\in L(i)} \phi_j^k\right)^{\Delta(i)}\right)$$

Here $\Delta(i) = \omega^i - \sum_{j\in C(i)} \omega^j$ (i.e., the difference between the in-degree and out-degree of internal node i. Note that if $\Delta(i) = 0$ for all $i \in I$, then the DT reduces to the typical Dirichlet distribution.

Suppose we have the following (Figure 3(A)) word network. The network can be decomposed into a collection of chains (e.g., (a,b,c), (p), and (x,y)). For each chain having number of elements more than one (e.g., (a,b,c), (x,y)), we have a subtree (see Figure 3(B)) in the DT with one internal node (blank in figure) and the words as leaves. We assign $\lambda\beta$ as the weights of these edges where λ is the regularization strength and β is the hyperparameter of the symmetric Dirichlet prior on ϕ. The root node of the Dirichlet tree then connects to the internal node i with weight $|L(i)|\beta$. The other nodes (words) which form single element chains (e.g, (p)) are connected to the root directly with weight β. Notice that when $\lambda = 1$ (i.e., no regularization), $\Delta(i) = 0$ and our model reduces to the original LDA. By tuning λ we control the strength of regularization.

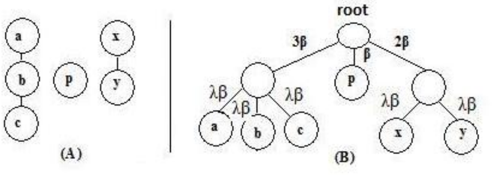

Figure 3: Incorporating word network into DT

To regularize LDA with FQG, we form the word network where a word is connected to the words in the same or adjacent fragments. Specifically, if word $w_i \in frag_x$ and word $w_j \in frag_y$ ($w_i \neq w_j$), we create a link (w_i, w_j) if $x = y$ or $(x, y) \in E$, where E is the set of edges of the FQG. Implicitly by doing this we want two sentences in the same or adjacent fragments to have similar topic distributions, and fall in the same topical cluster.

4.6 LCSeg with FQG

If we examine the FQG carefully, different paths (considering the fragments of the first email as root nodes) can be interpreted as subconversations. As we walk down a path topic shifts may occur along the pathway. We incorporate FQG into the LCSeg model in three steps. First, we extract the paths of a FQG. We then apply LCSeg algorithm on each of the extracted paths separately. This process gives the segmentation decisions along the paths of the FQG. Note that a fragment can be in multiple paths (e.g., f, g, in Figure 2) which will cause its sentences to be in multiple segments found by LCSeg. Therefore, as a final step we need a consolidation method. Our intuition is that sentences in a consolidated segment should fall in same segments more often when we apply LCSeg in step 2. To consolidate the segments found, we form a weighted undirected graph where the vertices V represent the sentences and the edge weights $w(u, v)$ represent the number of times sentence u and v fall in the same segment. The consolidation problem can be formulated as a *N-mincut* graph partitioning problem where we try to optimize the *Normalized Cut* criterion:

$$Ncut(A, B) = \frac{cut(A, B)}{assoc(A, V)} + \frac{cut(B, A)}{assoc(B, V)}$$

where $cut(A, B) = \Sigma_{u\in A, v\in B} w(u, v)$ and $assoc(A, V) = \Sigma_{u\in A, t\in V} w(u, t)$ is the total connection from nodes in partition A to all nodes in the graph and $assoc(B, V)$ is similarly defined. However, solving this problem turns out to be NP-hard. Hence, we approximate the solution following (Shi and Malik, 2000) which has been successfully applied to image segmentation in computer vision.

This approach makes a difference only if FGQ contains more than one path. In fact in our corpus we found an average paths of 7.12 per thread.

Avg. Topic	LDA	LDA +FQG	LCSeg	LCSeg +FQG	Speaker	Block 5
Number	2.10	1.90	2.2	2.41	4.87	5.69
Length	13.3	15.50	13.12	12.41	5.79	4.60
Density	1.83	1.60	1.01	1.39	1.37	1.00
Entropy	0.98	0.75	0.81	0.93	1.88	2.39

Table 3: Corpus statistics of different system's annotation

5 Experiments

We ran our four systems *LDA, LDA+FQG, LCSeg, and LCSeg+FQG* on the dataset[11]. The statistics of these four annotations and two best performing baselines (i.e., 'Speaker' and 'Block 5' as described below) are shown in Table 3. For brevity we just mention the average measures. Comparing with Table 1, we see that these fall within the bounds of the human annotations.

We compare our results in Table 4, where we also provide the results of some simple baseline systems. We evaluated the following baselines and report the best two in Table 4.

All different: Each sentence is a separate topic.

All same: The whole thread is a single topic.

Speaker: The sentences from each participant constitute a separate topic.

Blocks of $k (= 5, 10, 15)$**:** Each consecutive group of k sentences is a topic.

Most of these baselines perform rather poorly. **All different** is the worst baseline with mean 1-to-1 score of 0.10 (max: 0.33, min: 0.03) and mean loc_3 score of 0.245 (max: 0.67, min: 0). **Block 10** has mean 1-to-1 score of 0.35 (max: 0.71, min: 0.13) and mean loc_3 score of 0.584 (max: 0.76, min: 0.31). **Block 15** has mean 1-to-1 score of 0.32 (max: 0.77, min: 0.16) and mean loc_3 score of 0.56 (max: 0.82, min: 0.38). **All same** is optimal for threads containing only one topic, but its performance rapidly degrades as the number of topics in a thread increases. It has mean 1-to-1 score of 0.28 (max: 1[12], min: 0.11) and mean loc_3 score of 0.54 (max: 1, min: 0.34).

As shown in Table 4, **Speaker** and **Blocks of** 5 are two strong baselines especially for the loc_3. In general, our systems perform better than the baselines, but worse than the gold standard. Of all the systems, the basic LDA model performs very disappointingly. In the local agreement it even fails to beat the baselines. A likely explanation is that the independence assumption made by LDA when computing the distribution over topics for a sentence from the distribution over topics for the words causes sentences in a local context to be excessively distributed over topics. Another possible explanation for LDA's disappointing performance is the limited amount of data available for training. In our corpus, the average number of sentences per thread is 26.3 (see table 1) which might not be sufficient for the LDA models.

If we compare the performance of the regularized LDA (in the table LDA+FQG) with the basic LDA we get a significant (p=0.0002 (1-to-1), p=9.8e-07 (loc_3)) improvement in both of the measures [13]. This supports our claim that sentences connected by referential relations in the FQG usually refer to the same topic. The regularization also prevents the local context from being overly distributed over topics.

A comparison of the basic LCSeg with the basic LDA reveals that LCSeg is a better model for email topic segmentation (p=0.00017 (1-to-1), p<2.2e-16 (loc_3)). One possible reason is that LCSeg extracts the topics keeping the local context intact. Another reason could be the term weighting scheme employed by LCSeg. Unlike LDA, which considers only 'repetition', LCSeg also considers how tightly the 'repetition' happens. When we incorporate the conversation structure (i.e., FQG) into LCSeg (in the table LCSeg+FQG), we get a significant improvement in the 1-to-1 measure over the basic LCSeg (p=0.0014). Though the local context (i.e., loc_3) suf-

[11] For a fair comparison of the systems we set the same topic number per thread for all of them. If at least two of the annotators agree on the topic number we set that number, otherwise we set the floor value of the average topic number. λ is set to 20 in LDA+FQG.

[12] The maximum value of 1 is due to the fact that for some threads some annotators found only one topic

[13] Tests of significance were done by paired t-test with df=116

	Baselines		Systems				Human
Scores	Speaker	Block 5	LDA	**LDA+FQG**	LCSeg	**LCSeg+FQG**	
Mean 1-to-1	0.52	0.38	0.57	**0.62**	0.62	**0.68**	0.80
Max 1-to-1	0.94	0.77	1.00	1.00	1.00	1.00	1.00
Min 1-to-1	0.23	0.14	0.24	0.24	0.33	0.33	0.31
Mean loc_3	0.64	0.57	0.54	**0.61**	**0.72**	**0.71**	0.83
Max loc_3	0.97	0.73	1.00	1.00	1.00	1.00	1.00
Min loc_3	0.27	0.42	0.38	0.38	0.40	0.40	0.43

Table 4: Comparison of Human, System and best Baseline annotations

fers a bit, the decrease in performance is minimal and it is not significant. The fact that LCSeg is a better model than LDA is also preserved when we incorporate FQG into them (p=2.140e-05 (1-to-1), p=1.3e-09 (loc_3)). Overall, LCSeg+FQG is the best model for this data.

6 Future Work

There are some other important features that our models do not consider. The 'Speaker' feature is a key source of information. A participant usually contributes to the same topic. The best baseline 'Speaker' in Table 4 also favours this claim. Another possibly critical feature is the 'mention of names'. In multi-party discussion people usually mention each other's name for the purpose of disentanglement (Elsner and Charniak, 2008). In our corpus we found 175 instances where a participant mentions other participant's name. In addition to these, 'Subject of the email', 'topic-shift cue words' can also be beneficial for a model. As a next step for this research, we will investigate how to exploit these features in our methods.

We are also interested in the near future to transfer our approach to other similar domains by hierarchical Bayesian multi-task learning and other domain adaptation methods. We plan to work on both synchronous (e.g., chats, meetings) and asynchronous (e.g., blogs) domains.

7 Conclusion

In this paper we presented an email corpus annotated for topic segmentation. We extended LDA and LCSeg models by incorporating the fragment quotation graph, a fine-grain model of the conversation, which is based on the analysis of quotations. Empirical evaluation shows that the fragment quotation graph helps both these models to perform significantly better than their basic versions, with LCSeg+FQG being the best performer.

Acknowledgments

We are grateful to the 6 pilot annotators, 3 test annotators and to the 3 anonymous reviewers for their helpful comments. This work was supported in part by NSERC PGS award, NSERC BIN project, NSERC discovery grant and Institute for Computing, Information and Cognitive Systems (ICICS) at UBC.

Abstract

Several recent discourse parsers have employed fully-supervised machine learning approaches. These methods require human annotators to beforehand create an extensive training corpus, which is a time-consuming and costly process. On the other hand, unlabeled data is abundant and cheap to collect. In this paper, we propose a novel semi-supervised method for discourse relation classification based on the analysis of co-occurring features in unlabeled data, which is then taken into account for extending the feature vectors given to a classifier. Our experimental results on the RST Discourse Treebank corpus and Penn Discourse Treebank indicate that the proposed method brings a significant improvement in classification accuracy and macro-average F-score when small training datasets are used. For instance, with training sets of c.a. 1000 labeled instances, the proposed method brings improvements in accuracy and macro-average F-score up to 50% compared to a baseline classifier. We believe that the proposed method is a first step towards detecting low-occurrence relations, which is useful for domains with a lack of annotated data.

1 Introduction

Automatic detection of discourse relations in natural language text is important for numerous tasks in NLP, such as sentiment analysis (Somasundaran et al., 2009), text summarization (Marcu, 2000) and dialogue generation (Piwek et al., 2007). However, most of the recent work employing discourse relation classifiers are based on fully-supervised machine learning approaches (duVerle and Prendinger, 2009; Pitler et al., 2009; Lin et al., 2009). Two of the main corpora with discourse annotations are the RST Discourse Treebank (RSTDT) (Carlson et al., 2001) and the Penn Discourse Treebank (PDTB) (Prasad et al., 2008a), which are both based on the Wall Street Journal (WSJ) corpus.

In the RSTDT, annotation is done using 78 fine-grained discourse relations, which are usually grouped into 18 coarser-grained relations. Each of these relations has furthermore several possible configurations for its arguments—its 'nuclearity' (Mann and Thompson, 1988). In practice, a classifier trained on these coarse-grained relations must solve a 41-class classification problem. Some of the relations corresponding to these classes are relatively more frequent in the corpus, such as the ELABORATION[N][S] relation (4441 instances), or the ATTRIBUTION[S][N] relation (1612 instances).[1] However, other relation types occur very rarely, such as TOPIC-COMMENT[S][N] (2 instances), or EVALUATION[N][N] (3 instances). A similar phenomenon can be observed in PDTB, in which 15 level-two relations are employed: Some, such as EXPANSION.CONJUNCTION, occur as often as 8759 times throughout the corpus, whereas the remainder of the relations, such as EXPANSION.EXCEPTION and COMPARISON.PRAGMATIC CONCESSION, can appear as rarely as 17 and 12 times respectively. Although supervised approaches to discourse relation learning achieve good results on frequent relations, performance is poor on rare relation types (duVerle and Prendinger, 2009).

Nonetheless, certain infrequent relation types might be important for specific tasks. For instance,

[1] We use the notation [N] and [S] respectively to denote the nucleus and satellite in a RST discourse relation.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 399–409,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

capturing the RST TOPIC-COMMENT[S][N] and EVALUATION[N][N] relations can be useful for sentiment analysis (Pang and Lee, 2008).

Another situation where detection of low-occurring relations is desirable is the case where we have only a small training set at our disposal, for instance when there is not enough annotated data for all the relation types described in a discourse theory. In this case, all the dataset's relations can be considered rare, and being able to build an efficient classifier depends on the capacity to deal with this lack of annotated data.

Our contributions in this paper are summarized as follows.

- We propose a semi-supervised method that exploits the abundant, freely-available unlabeled data, which is harvested for feature co-occurrence information, and used as a basis to extend feature vectors to help classification for cases where unknown features are found in test vectors.

- The proposed method is evaluated on the RSTDT and PDTB corpus, where it significantly improves accuracy and macro-average F-score when small training sets are used. For instance, when trained on moderately small datasets with ca. 1000 instances, the proposed method increases the macro-average F-score and accuracy up to 50%, compared to a baseline classifier.

2 Related Work

Since the release in 2001 of the RSTDT corpus, several fully-supervised discourse parsers have been built in the RST framework. In the recent work of duVerle and Prendinger (2009), a discourse parser based on Support Vector Machines (SVM) (Vapnik, 1995) is proposed. SVMs are employed to train two classifiers: One, binary, for determining the presence of a relation, and another, multi-class, for determining the relation label between related text spans. For the discourse relation classifier, shallow lexical, syntactic and structural features, including 'dominance sets' (Soricut and Marcu, 2003) are used. For relation classification, they report an accuracy of 0.668, and an F-score of 0.509 for the creation of the full discourse tree.

The unsupervised method of Marcu and Echihabi (2002) was the first that tried to detect implicit relations (i.e. relations not accompanied by a cue phrase, such as *'however'*, *'but'*), using word pairs extracted from two spans of text. Their method attempts to capture the difference of polarity in words. For example, the word pair *(sell, hold)* indicates a CONTRAST relation.

Discourse relation classifiers have also been trained using PDTB. Pitler et al. (2008) performed a corpus study of the PDTB, and found that 'explicit' relations can be most of the times distinguished by their discourse connectives. Their discourse relation classifier reported an accuracy of 0.93 for explicit relations and in overall an accuracy of 0.744 for all relations in PDTB.

Lin et al. (2009) studied the problem of detecting implicit relations in PDTB. Their relational classifier is trained using features extracted from dependency paths, contextual information, word pairs and production rules in parse trees. They reported for their classifier an accuracy of 0.402, which is an improvement of 14.1% over the previous state-of-the-art for implicit relation classification in PDTB. For the same task, Pitler et al. (2009) also used word pairs, as well as several other types of features such as verb classes, modality, context, and lexical features.

In text classification, similarity measures have been employed in kernel methods, where they have been shown to improve accuracy over 'bag-of-words' approaches. In Siolas and d'Alché-Buc (2000), a semantic proximity measure based on WordNet (Fellbaum, 1998) is defined, as a basis to create a proximity matrix for all terms of the problem. This matrix is then used to smooth the vectorial data, and the resulting 'semantic' metric is incorporated into a SVM kernel, resulting in a significant increase of accuracy and F-score over a baseline.

Cristianini et al. (2002) have used a lexical similarity measure derived from Latent Semantic Indexing (Deerwester et al., 1990), where the semantic similarity between two terms is inferred from the analysis of their co-occurrence patterns: Terms that co-occur often in the same documents are considered as related. In this work, the statistical co-occurrence information is extracted by the means of singular value decomposition. The authors observe substantial improvements in performance for some datasets, while little effect is obtained for others.

Semantic kernels have also been shown to be efficient for text classification tasks, in the case in of unbalanced and sparse datasets. In Basili et al. (2006), a ‘conceptual density’ metric based on WordNet is introduced, and employed in a SVM kernel. Using this metric results in improved accuracy of 10% for text classification in poor training conditions. However, the authors observe that when the number of training documents is increased, the improvement produced by the semantic kernel is lower.

Bloehdorn et al. (2006) compare the performance of different semantic kernels, based on several measures of semantic relatedness in WordNet. For each measure, the authors note a performance increase when little training data is available, or when the feature representations are very sparse. However, for our task, classification of discourse relations, we employ not only words but also other types of features such as parse tree production rules, and thus cannot compute semantic kernels using WordNet.

In this paper, we are not aiming at defining novel features for improving performance in RST or PDTB relation classification. Instead we incorporate numerous features that have been shown to be useful for discourse relation learning and explore the possibilities of using unlabeled data for this task. One of our goals is to improve classification accuracy for rare discourse relations.

3 Method

Given a set of unlabeled instances U and labeled instances L, our objective is to learn an n-class relation classifier H such that for a given test instance $\mathbf{x}$ return its correct relation type $H(\mathbf{x})$. In the case of discourse relation learning we are interested in the situation where $|U| >> |L|$. Here, we use the notation $|A|$ to denote the number of elements in a set A. A fundamental problem that one encounters when trying to learn a classifier for a large number of relations with small training dataset is that most of the features that appear in the test instances either never occur in training instances or appear a small number of times. Therefore, the classification algorithm does not have sufficient information to correctly predict the relation type of the given test instance. We propose a method that first computes the co-occurrence between features using unlabeled data and use that information to *extend* the feature vectors during training and testing, thereby reducing the sparseness in test feature vectors. In Section 3.1, we introduce the concept of *feature co-occurrence matrix* and describe how it is computed using unlabeled data. A method to extend feature vectors during training and testing is presented in Section 3.2. We defer the details on exact features used in the method to Section 3.3. It is noteworthy that the proposed method does not depend or assume a particular multi-class classification algorithm. Consequently, it can be used with any multi-class classification algorithm to learn a discourse relation classifier.

3.1 Feature Co-occurrence Matrix

We represent an instance using a d dimensional feature vector $\mathbf{f} = [f_1, \ldots, f_d]^{\mathrm{T}}$, where $f_i \in \mathbb{R}$. We define a *feature co-occurrence matrix*, C such that the (i, j)-th element of C, $C_{(i,j)} \in [0, 1]$ denotes the degree of co-occurrence between the two features f_i and f_j. If both f_i and f_j appear in a feature vector then we define them to be co-occurring. The number of different feature vectors in which f_i and f_j co-occur is denoted by the function $h(f_i, f_j)$. From our definition of co-occurrence it follows that $h(f_i, f_j) = h(f_j, f_i)$. Importantly, feature co-occurrences can be calculated only using unlabeled data.

Feature co-occurrence matrices can be computed using any co-occurrence measure. For the current task we use the χ^2-measure (Plackett, 1983) as the preferred co-occurrence measure because of its simplicity. χ^2-measure between two features f_i and f_j is defined as follows,

$$\chi^2_{i,j} = \sum_{k=1}^{2}\sum_{l=1}^{2} \frac{(O^{i,j}_{k,l} - E^{i,j}_{k,l})^2}{E^{i,j}_{k,l}}. \qquad (1)$$

Therein, $O^{i,j}$ and $E^{i,j}$ are the 2×2 matrices containing respectively observed frequencies and expected frequencies, which are respectively computed using C as,

$$O^{i,j} = \begin{pmatrix} h(f_i, f_j) & Z_i - h(f_i, f_j) \\ Z_j - h(f_i, f_j) & Z_s - Z_i - Z_j \end{pmatrix}, \qquad (2)$$

and

$$E^{i,j} = \begin{pmatrix} \frac{Z_i \cdot Z_j}{Z_s} & \frac{Z_i \cdot (Z_s - Z_j)}{Z_s} \\ \frac{Z_j \cdot (Z_s - Z_i)}{Z_s} & \frac{(Z_s - Z_i) \cdot (Z_s - Z_j)}{Z_s} \end{pmatrix}. \quad (3)$$

Here, $Z_i = \sum_{k \neq i} h(f_i, f_k)$, and $Z_s = \sum_{i=1}^{n} Z_i$.

Finally, we create the feature co-occurrence matrix C, such that, for all pairs of features (f_i, f_j),

$$C_{(i,j)} = \begin{cases} \hat{\chi}^2_{i,j} \text{ if } \chi^2_{i,j} > c \\ 0 \text{ otherwise} \end{cases}. \quad (4)$$

Here $\hat{\chi}^2_{i,j} = \frac{\chi^2_{i,j} - \chi^2_{min}}{\chi^2_{max} - \chi^2_{min}} \in [0, 1]$, and c is the critical value, which, for a confidence level of 0.05 and one degree of freedom, can be set to 3.84. Keeping $C_{(i,j)}$ in the range $[0, 1]$ makes it convenient to filter out low-relevance co-occurrences at the feature vector extension step of Section 3.2.

In discourse relation learning, the feature space can be extremely large. For example, with word pair features (discussed later in Section 3.3), any two words that appear in two adjoining discourse units can form a feature. Because the number of elements in the feature co-occurrence matrix is proportional to the square of the feature space's dimension, computing co-occurrences for all pairs of features can be computationally costly. Moreover, storing a large matrix in memory for further computations can be problematic. To reduce the dimensionality and improve the sparseness in the feature co-occurrence matrix, we use entropy-based feature selection (Manning and Schütze, 1999). The negative entropy, $E(f_i)$, of a feature f_i is defined as follows,

$$\mathrm{E}(f_i) = -\sum_{j \neq i} p(i,j) \cdot \log\left(p\left(i,j\right)\right). \quad (5)$$

Here, $p(i,j)$ is the probability that feature f_i co-occurs with feature f_j, and is given by $p(i,j) = h(f_i, f_j)/Z_i$.

If a particular feature f_i co-occurs with many other features, then its negative entropy $E(f_i)$ decreases. Because we are interested in identifying salient co-occurrences between features, we can ignore the features that tend to co-occur with many other features. Consequently, we sort the features in the descending order of their entropy, and select the top ranked N number of features to build the feature co-occurrence matrix. This feature selection procedure can efficiently reduce the dimensions of the feature co-occurrence matrix to $N \times N$. Because the feature co-occurrence matrix is symmetric, we must only store the elements for the upper (or lower) triangular portion of it.

3.2 Feature Vector Extension

Once the feature co-occurrence matrix is computed using unlabeled data as described in Section 3.1, we can use it to extend a feature vector during training and testing. The proposed feature vector extension method is inspired by query expansion in the field of Information Retrieval (Salton and Buckley, 1983; Fang, 2008). One of the reasons that a classifier might perform poorly on a test instance is that there are features in the test instance that were not observed during training. We call $F_U = \{f_i\}$ the set of features that were not observed by the classifier during training (i.e. occurring in test data but not in training data). For each of those features, we use the feature co-occurrence matrix to find the set of co-occurring features, $F_c(f_i)$.

Let us denote the feature vector corresponding to a training or test instance x by $\mathbf{f}_x$. We use the superscript notation, f_x^i to denote the i-th feature in $\mathbf{f}_x$. Moreover, the total number of features of $\mathbf{f}_x$ is indicated by $d(x)$. For a feature f_x^i in $\mathbf{f}_x$, we define $n(i)$ number of *expansion features*, $f_x^{(i,1)}, \ldots, f_x^{(i,n(i))}$ as follows. First, we require that each expansion feature $f_x^{(i,j)}$ belongs to $F_c(f_i)$. Second, the value of $f_x^{(i,j)}$ is set to $f_x^i \cdot C_{(i,j)}$. The expansion features for each feature f_x^i are then appended to the original feature vector $\mathbf{f}_x$ to create an extended feature vector, $\mathbf{f}'_x$, where,

$$\begin{aligned} \mathbf{f}'_x \quad = \quad & (f_x^1, \ldots, f_x^{d(x)}, \\ & f_x^{(i,1)}, \ldots, f_x^{(i,n(i))}, \ldots, \\ & f_x^{(d(x),1)}, \ldots, f_x^{(d(x),n(d(x)))}). \end{aligned} \quad (6)$$

In total, doing so augments the original vector's size by $\sum_{f_i \in U} |F_c(f_i)|$. All training and test instances are extended in this fashion.

Note that because this process can potentially increase the dimension too much, it is possible to retain only candidate co-occurring features of $F_c(f_i)$ possessing a co-occurrence value $C_{(i,j)}$ above a certain threshold. In the experiments of Section 4 however, we experienced dimension increase of 10000 at most, which did not require us to use thresholding.

3.3 Features

We use three types of features: Word pairs, production rules from the parse tree, as well as features encoding the lexico-syntactic context at the border between two units of text (Soricut and Marcu, 2003). Our word pairs are lemmatized using the Wordnet-based lemmatizer of NLTK (Loper and Bird, 2002).

Figure 1 shows the parse tree for a sentence composed of two discourse units, which serve as arguments of a discourse relation we want to generate a feature vector from. Lexical heads have been calculated using the projection rules of Magerman (1995), and annotated between brackets. Surrounded by dots is, for each argument, the minimal set of sub-parse trees containing strictly all the words of the argument.

We first extract all possible lemmatized word-pairs from the two arguments, such as *(Mr., when)*, *(decline, ask)* or *(comment, sale)*. Next, we extract from left and right argument separately, all production rules from the sub-parse trees, such as NP $\mapsto$ NNP NNP, NNP $\mapsto$ "Sherry" or TO $\mapsto$ "to".

Finally, we encode in our features three nodes of the parse tree, which capture the local context at the connection point between the two arguments: The first node, which we call N_w, is the highest ancestor of the first argument's last word w, and is such that N_w's right-sibling is the ancestor of the second argument's first word. N_w's right-sibling node is called N_r. Finally, we call N_p the parent of N_w and N_r. For each node, we encode in the feature vector its part-of-speech (POS) and lexical head. For instance, in Figure 1, we have N_w = S(comment), N_r = SBAR(when), and N_p = VP(declined). In the PDTB, certain discourse relations have disjoint arguments. In this case, as well as in the case where the two arguments belong to different sentences, the nodes N_w, N_r, N_p cannot be defined, and their corresponding features are given the value zero.

4 Experiments

The proposed method is independent of any particular classification algorithm. Because our goal is strictly to evaluate the relative benefit of employing the proposed method, and not the absolute performance when used with a specific classification algorithm, we select a logistic regression classifier, for its simplicity. We use the multi-class logistic regression (maximum entropy model) implemented in the Classias toolkit (Okazaki, 2009). Regularization parameters are set to their default value of one and are fixed throughout the experiments described in the paper.

To create our unlabeled dataset, we use sentences extracted from the English Wikipedia[2], as they are freely available and relatively easy to collect. For further extraction of syntactic features, these sentences are automatically parsed using the Stanford parser (Klein and Manning, 2003). Then, they are segmented into elementary discourse units (EDUs) using our sequential discourse segmenter (Hernault et al., 2010). The relatively high performance of this RST segmenter, which has an F-score of 0.95 compared to that of 0.98 between human annotators (Soricut and Marcu, 2003), is acceptable for this task. We collect and parse 100000 sentences from random Wikipedia articles. As there is no segmentation tool for the PDTB framework, we assume that co-occurrence information taken from EDUs created using a RST segmenter is also useful for extending feature vectors of PDTB relations. Unless otherwise noted, the experiments presented in the rest of this paper are done using those 100000 unlabeled instances.

In the unlabeled data, any two consecutive discourse units might not always be connected by a discourse relation. Therefore, we introduce an artificial NONE relation in the training set, in order to facilitate this. Instances of the NONE relation are generated randomly by pairing consecutive discourse units which are not connected by a discourse relation in the training data. NONE is also learnt as a separate discourse relation class by the multi-class classification algorithm. This enables us to detect discourse units between which there exist no discourse relation, thereby improving the classification accuracy for other relation types.

We follow the common practice in discourse research for partitioning the discourse corpora into training and test set. For the RST classifier, the dedicated training and test sets of the RSTDT are

[2] `http://en.wikipedia.org`

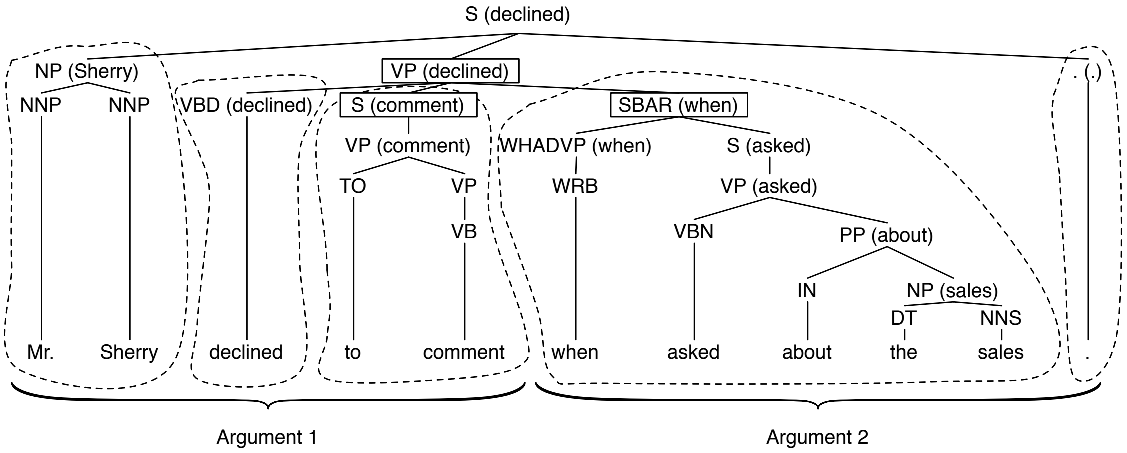

Figure 1: Two arguments of a discourse relation, and the minimum set of subtrees that contain them—lexical heads are indicated between brackets.

employed. For the PDTB classifier, we conform to the guidelines of Prasad et al. (2008b, 5): The portion of the corpus corresponding to sections 2–21 of the WSJ is used for training the classifier, while the portion corresponding to WSJ section 23 is used for testing. In order to extract syntactic features, all training and test data are furthermore aligned with their corresponding parse trees in the Penn Treebank (Marcus et al., 1993).

Because in the PDTB an instance can be annotated with several discourse relations simultaneously—called 'senses' in Prasad et al. (2008b)—for each instance with n senses in the corpus, we create n identical feature vectors, each being labeled by one of the instance's senses. However, in the RST framework, only one relation is allowed to hold between two EDUs. Consequently, each instance from the RSTDT is labeled with a single discourse relation, from which a single feature vector is created. For RSTDT, we extract 25078 training vectors and 1633 test vectors. For PDTB we extract 49748 training vectors and 1688 test vectors. There are 41 classes (relation types) in the RSTDT relation classification task, and 29 classes in the PDTB task. For the PDTB, we selected level-two relations, because they have better expressivity and are not too fine-grained. We experimentally set the entropy-based feature selection parameter to $N = 5000$. With large N values, we must store and process large feature co-occurrence matrices. For example, doubling the number of selected features, N to 10000 did not improve the classification accuracy, although it required 4GB of memory to store the feature co-occurrence matrix.

Figure 2 shows the number of features that occur in test data but not in labeled training data, against the number of training instances. It can be seen from Figure 2 that, with less training data available to the classifier, we can potentially obtain more information regarding features by looking at unlabeled data. However, when the training dataset's size increases, the number of features that only appear in test data decreases rapidly. This inverse relation between the training dataset size and the number of features that only appear in test data can be observed in both RSTDT and PDTB datasets. For a training set of 100 instances, there are 23580 unseen features in the case of RSTDT, and 27757 in the case of PDTB. The number of unseen features is halved for a training set of 1800 instances in the case of RSTDT, and for a training set of 1300 instances in the case of PDTB. Finally, when selecting all available training data, we count only 1365 unseen test features in the case of RSTDT, and 87 in the case of PDTB.

In the following experiments, we use macro-averaged F-scores to evaluate the performance of the proposed discourse relation classifier on test data. Macro-averaged F-score is not influenced by the number of instances that exist in each relation type. It equally weights the performance on both frequent relation types and infrequent relation types. Because we are interested in measuring the overall performance of a discourse relation classifier across all re-

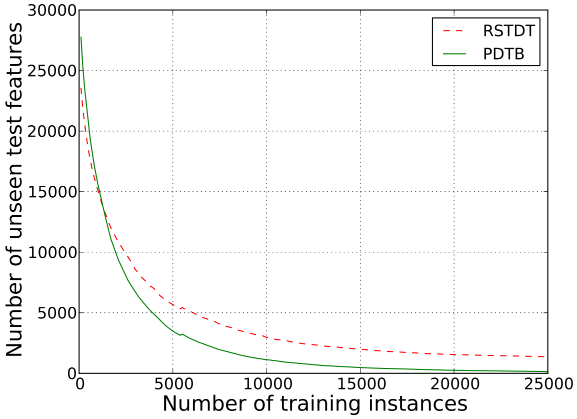

Figure 2: Number of features seen only in the test set, as a function of the number of training instances used.

lation types we use macro-averaged F-score as the preferred evaluation metric for this task.

We train a multi-class logistic regression model without extending the feature vectors as a baseline method. This baseline is expected to show the effect of using the proposed feature vector extension approach for the task of discourse relation learning. Experimental results on RSTDT and PDTB datasets are depicted in Figures 3 and 4. From these figures, we see that the proposed feature extension method outperforms the baseline for both RSTDT and PDTB datasets for the full range of training dataset sizes. However, whereas the difference of scores between the two methods is obvious for small amounts of training data, this difference progressively decreases as we increase the amount of training data. Specifically, with 100 training instances, the difference between baseline and proposed method is the largest: For RSTDT, the baseline has a macro-averaged F-score of 0.084, whereas the the proposed method has a macro-averaged F-score of 0.189 (ca. 119% increase in F-score). For PDTB, the baseline has an F-score of 0.016, while the proposed method has an F-score of 0.089 (459% increase). The difference of scores between the two methods then progressively diminishes as the number of training instances is increased, and fades beyond 10000 training instances. The reason for this behavior is given by Figure 2: For a small number of training instances, the number of unseen features in training data is large. In this case, the feature vector extension process is comprehensive, and score can be increased by the use of unlabeled data. When more training data is progressively used, the number of unseen test features sharply diminishes, which means feature vector extension becomes more limited, and the performance of the proposed method gets progressively closer to the baseline. Note that we plotted PDTB performance up to 25000 training instances, as the number of unseen test features becomes so small past this point that the performances of the proposed method and baseline are identical. Using all PDTB training data (49748 instances), both baseline and proposed method reach a macro-average F-score of 0.308.

Table 1: F-scores for RSTDT relations, using a training set containing #Tr instances of each relation. B. indicates F-score for baseline, P.M. for the proposed method. A boldface indicates the best classifier for each relation.

Although the distribution of discourse relations in RSTDT and PDTB is not uniform, it is possible to study the performance of the proposed method when all relations are made equally rare. We evaluate performance on artificially-created training sets containing an equal amount of each discourse relation. Table 1 contains the F-score for each RSTDT relation, using training sets containing respectively one, two, three, five and seven instances of each relation. For space considerations, only relations with significant results are shown. We observe that, when using respectively one and two instances of each relation, the baseline classifier is unable to detect any relation, and has a macro-average F-score of zero. Contrastingly, the classifier built with feature vector extension reaches in those cases an F-score of 0.06. Furthermore, when employing the proposed method, certain relations have relatively high F-scores even with very little labeled data: With one training instance, ATTRIBUTION[S][N] has an F-score of 0.597, while SUMMARY[N][S] has an F-score of 0.429. With three training instances, ENABLEMENT[N][S] has an F-score of 0.579. When the amount of each relation is increased, the baseline classifier starts detecting more relations. In all cases, the proposed method performs better in terms of accuracy and macro-average F-score. With a training set containing seven instances of each relation, the baseline's macro-average F-score is starting to get closer to the extended classifier's, with superior performances for several relations, such as COMPARISON[N][S], CONDITION[N][S], and TEMPORAL[N][S]. Still, in this case, the extended classifier's accuracy is higher than the baseline (0.213 versus 0.122). Table 2 summarizes the outcome of the same experiments performed on the PDTB dataset. The results exhibit a similar trend, despite the baseline classifier having a relatively high accuracy for each case.

Using the data from Figures 2, 3 and 4, it is possible to calculate the relative score change occurring when using the proposed method, as a function of the number of unseen features found in test data. This graph is plotted in Figure 5. Besides macro-average F-score, we additionally plot accuracy change. In the top subfigure, representing the case of RSTDT, we see that, for the lowest amount of unseen test features, the proposed method does

Table 2: F-scores for PDTB relations.

not bring any change in F-score or accuracy. Indeed, as the number of unknown features is low, feature vector extension is very limited, and does not improve the performance compared to the baseline. Then, a progressive increase of both accuracy and macro-average F-score is observed, as the number of unseen test features is incremented. For instance, for 8500 unseen test features, the macro-average F-score increase (resp. accuracy increase) is 25% (resp. 2.5%), while it is 20% (resp. 1%) for 11000 unseen test instances. These values reach a maximum of 119% macro-average F-score increase, and 66% accuracy increase, when 23500 features unseen during training are present in test data. This situation corresponds in Figures 3 and 4 to the case of very small training sets. The bottom subfigure of Figure 2, for the case of PDTB, reveals a similar tendency. The macro-average F-score increase (resp. accuracy increase) is negligible for 1000 unseen test features, while this increase is 21% for both macro-average F-score and accuracy in the case of 9700 unseen test features, and 459% (resp. 630% for accuracy) when 28000 unseen features are found in test data. This shows that the proposed method is useful when large numbers of features are missing from the training set, which corresponds in practice to small training sets, with few training instances for each relation type. For large training sets, most features are encountered by the classifier during training, and feature vector extension does not bring useful information.

We empirically evaluate the effect of using different amounts of unlabeled data on the performance of the proposed method. We use respectively 100 and 10000 labeled training instances, create feature co-occurrence matrices with different amounts of unlabeled data, and evaluate the performance in relation classification. Experimental results for RSTDT are illustrated in Figure 6 (top). From Figure 6 it appears clearly that macro-average F-scores improve with increased number of unlabeled instances. However, the benefit of using larger amounts of unlabeled data is more pronounced when only a small number of labeled training instances are employed (ca. 100). In fact, with 100 labeled training instances, the maximum improvement in F-score is 119% (corresponds to using all our 100000 unlabeled instances). However, the maximum improvement in F-score with 10000 labeled training instances is small, only 2.5% (corresponds to 10000 unlabeled instances).

The effect of using unlabeled data on PDTB relation classification is illustrated in Figure 6 (bottom). Similarly, we consecutively set the labeled training dataset size to 100 and 10000 instances, and plot the macro-average F-score against the unlabeled dataset size. As in the RSTDT experiment, the benefit of us-

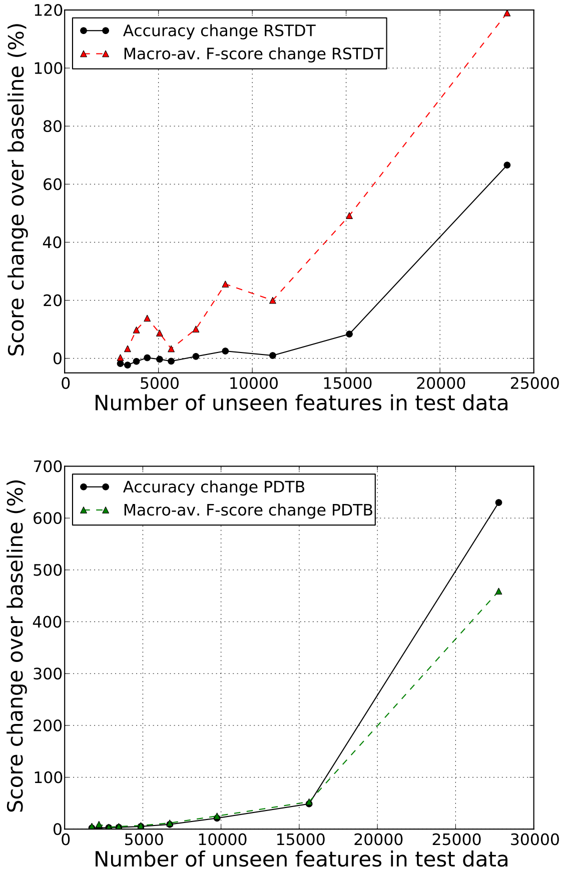

Figure 5: Score change as a function of unseen test features for RSTDT (top) and PDTB (bottom).

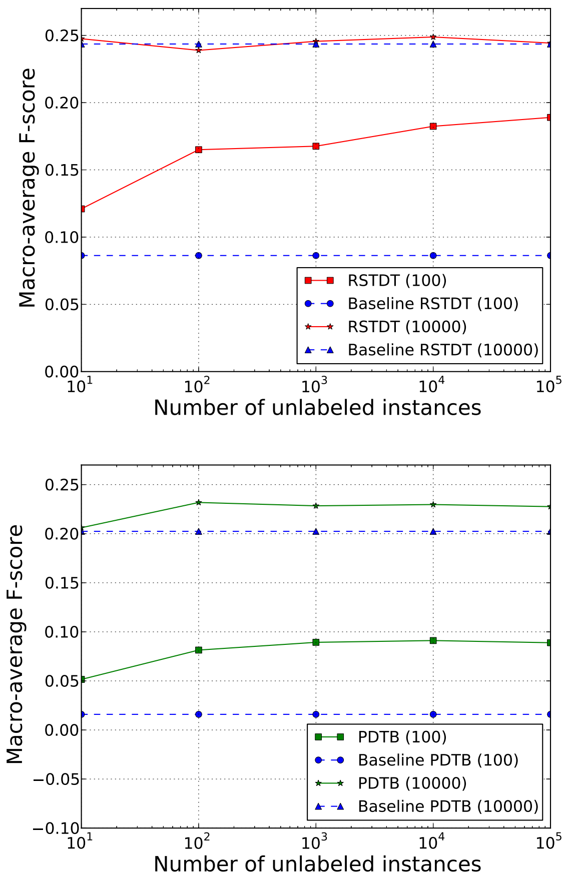

Figure 6: Macro-average F-score for RSTDT (top) and PDTB (bottom), for 100 and 10000 training instances, against the number of unlabeled instances.

ing unlabeled data is more obvious when the number of labeled training instances is small. In particular, with 100 training instances, the maximum improvement in F-score is 459% (corresponds to 100000 unlabeled instances). However, with 10000 labeled training instances the maximum improvement in F-score is 15% (corresponds to 100 unlabeled instances). These results confirm that, on the one hand performance improvement is more prominent for smaller training sets, and that on the other hand, performance is increased when using larger amounts of unlabeled data.

5 Conclusion

We presented a semi-supervised method which exploits the co-occurrence of features in unlabeled data, to extend feature vectors during training and testing in a discourse relation classifier. Despite the simplicity of the proposed method, it significantly improved the macro-average F-score in discourse relation classification for small training datasets, containing low-occurrence relations. We performed an evaluation on two popular datasets, the RSTDT and PDTB. We empirically evaluated the benefit of using a variable amount of unlabeled data for the proposed method. Although the macro-average F-scores of the classifiers described are too low to be used directly as discourse analyzers, the gain in F-score and accuracy for small labeled datasets are a promising perspective for improving classification accuracy for infrequent relation types. In particular, the proposed method can be employed in existing discourse classifiers that work well on popular relations, and be expected to improve the overall accuracy.

Abstract

Language is sensitive to both semantic and pragmatic effects. To capture both effects, we model language use as a cooperative game between two players: a speaker, who generates an utterance, and a listener, who responds with an action. Specifically, we consider the task of generating spatial references to objects, wherein the listener must accurately identify an object described by the speaker. We show that a speaker model that acts optimally with respect to an explicit, embedded listener model substantially outperforms one that is trained to directly generate spatial descriptions.

1 Introduction

Language is about successful communication between a speaker and a listener. For example, if the goal is to reference the target object O1 in Figure 1, a speaker might choose one of the following two utterances:

(a) *right of* O2 $\qquad (b)$ *on* O3

Although both utterances are semantically correct, (a) is ambiguous between O1 and O3, whereas (b) unambiguously identifies O1 as the target object, and should therefore be preferred over (a). In this paper, we present a game-theoretic model that captures this communication-oriented aspect of language interpretation and generation.

Successful communication can be broken down into semantics and pragmatics. Most computational work on interpreting language focuses on compositional semantics (Zettlemoyer and Collins, 2005; Wong and Mooney, 2007; Piantadosi et al., 2008), which is concerned with verifying the truth of a sentence. However, what is missing from this truth-oriented view is the pragmatic aspect of language—that language is used to accomplish an end goal, as exemplified by speech acts (Austin, 1962). Indeed, although both utterances (a) and (b) are semantically valid, only (b) is pragmatically felicitous: (a) is ambiguous and therefore violates the Gricean maxim of manner (Grice, 1975). To capture this maxim, we develop a model of pragmatics based on game theory, in the spirit of Jäger (2008) but extended to the stochastic setting. We show that Gricean maxims

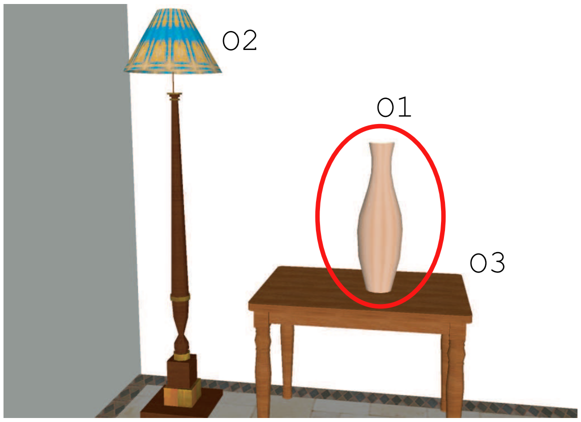

Figure 1: An example of a 3D model of a room. The *speaker*'s goal is to reference the target object O1 by describing its spatial relationship to other object(s). The *listener*'s goal is to guess the object given the speaker's description.

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 410–419,

fall out naturally as consequences of the model.

An effective way to empirically explore the pragmatic aspects of language is to work in the grounded setting, where the basic idea is to map language to some representation of the non-linguistic world (Yu and Ballard, 2004; Feldman and Narayanan, 2004; Fleischman and Roy, 2007; Chen and Mooney, 2008; Frank et al., 2009; Liang et al., 2009). Along similar lines, past work has also focused on interpreting natural language instructions (Branavan et al., 2009; Eisenstein et al., 2009; Kollar et al., 2010), which takes into account the goal of the communication. This work differs from ours in that it does not clarify the formal relationship between pragmatics and the interpretation task. Pragmatics has also been studied in the context of dialog systems. For instance, DeVault and Stone (2007) present a model of collaborative language between multiple agents that takes into account contextual ambiguities.

We present our pragmatic model in a grounded setting where a speaker must describe a target object to a listener via spatial description (such as in the example given above). Though we use some of the techniques from work on the semantics of spatial descriptions (Regier and Carlson, 2001; Gorniak and Roy, 2004; Tellex and Roy, 2009), we empirically demonstrate that having a model of pragmatics enables more successful communication.

2 Language as a Game

To model Grice's cooperative principle (Grice, 1975), we formulate the interaction between a speaker S and a listener L as a cooperative game, that is, one in which S and L share the same utility function. For simplicity, we focus on the production and interpretation of single utterances, where the speaker and listener have access to a shared context. To simplify notation, we suppress writing the dependence on the context.

The Communication Game

1. In order to communicate a *target* o to L, S produces an *utterance* w chosen according to a strategy $p_{\text{S}}(w \mid o)$.
2. L interprets w and responds with a *guess* g according to a strategy $p_{\text{L}}(g \mid w)$.
3. S and L collectively get a utility of $U(o, g)$.

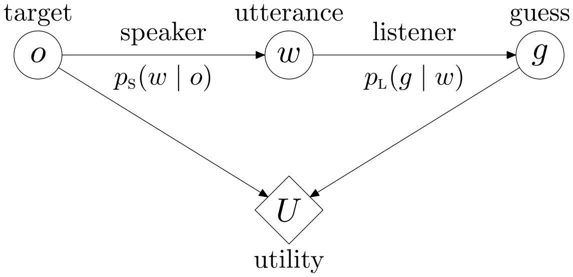

Figure 2: Diagram representing the communication game. A target, o, is given to the speaker that generates an utterance w. Based on this utterance, the listener generates a guess g. If $o = g$, then both the listener and speaker get a utility of 1, otherwise they get a utility of 0.

This communication game is described graphically in Figure 2. Figure 3 shows several instances of the communication game being played for the scenario in Figure 1.

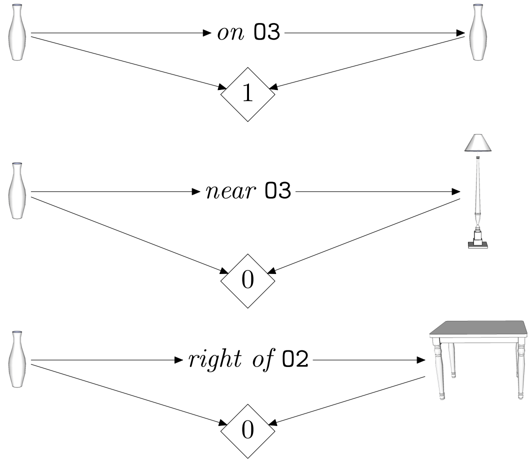

Figure 3: Three instances of the communication game on the scenario in Figure 1. For each instance, the target o, utterance w, guess g, and the resulting utility U are shown in their respective positions. A utility of 1 is awarded only when the guess matches the target.

Grice's maxim of manner encourages utterances to be unambiguous, which motivates the following utility, which we call *(communicative) success*:

$$U(o, g) \overset{\text{def}}{=} \mathbb{I}[o = g], \qquad (1)$$

where the indicator function $\mathbb{I}[o = g]$ is 1 if $o = g$ and 0 otherwise. Hence, a utility-maximizing speaker will attempt to produce unambiguous utterances because they increase the probability that the listener will correctly guess the target.

Given a speaker strategy $p_{\text{S}}(w \mid o)$, a listener strategy $p_{\text{L}}(g \mid w)$, and a prior distribution over targets $p(o)$, the expected utility obtained by S and L is as follows:

$$\begin{aligned} \text{EU}(\text{S},\text{L}) &= \sum_{o,w,g} p(o) p_{\text{S}}(w|o) p_{\text{L}}(g|w) U(o,g) \\ &= \sum_{o,w} p(o) p_{\text{S}}(w|o) p_{\text{L}}(o|w). \qquad (2) \end{aligned}$$

3 From Reflex Speaker to Rational Speaker

Having formalized the language game, we now explore various speaker and listener strategies. First, let us consider *literal* strategies. A literal speaker (denoted S:LITERAL) chooses uniformly from the set of utterances consistent with a target object, i.e., the ones which are semantically valid;[1] a literal listener (denoted L:LITERAL) guesses an object consistent with the utterance uniformly at random.

In the running example (Figure 1), where the target object is O1, there are two semantically valid utterances:

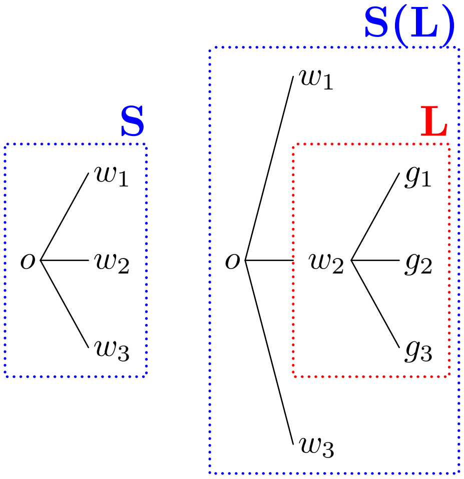
(a) *right of* O2 $\qquad (b)$ *on* O3

S:LITERAL selects (a) or (b) each with probability $\frac{1}{2}$. If S:LITERAL chooses (a), L:LITERAL will guess the target object O1 correctly with probability $\frac{1}{2}$; if S:LITERAL chooses (b), L:LITERAL will guess correctly with probability 1. Therefore, the expected utility EU(S:LITERAL, L:LITERAL) $= \frac{3}{4}$.

We say S:LITERAL is an example of a *reflex* speaker because it chooses an utterance without taking the listener into account. A general reflex speaker is depicted in Figure 4(a), where each edge represents a potential utterance.

Suppose we now have a model of some listener L. Motivated by game theory, we would optimize the expected utility (2) given $p_{\text{L}}(g \mid w)$. We call the resulting speaker S(L) the *rational* speaker with respect to listener L. Solving for this strategy yields:

$$\begin{aligned} p_{\text{S(L)}}(w \mid o) &= \mathbb{I}[w = w^*], \text{ where} \\ w^* &= \operatorname*{argmax}_{w'} p_{\text{L}}(o \mid w'). \qquad (3) \end{aligned}$$



(a) Reflex speaker (b) Rational speaker

Figure 4: (a) A reflex speaker (S) directly selects an utterance based only on the target object. Each edge represents a different choice of utterance. (b) A rational speaker (S(L)) selects an utterance based on an embedded model of the listener (L). Each edge in the first layer represents a different choice the speaker can make, and each edge in the second layer represents a response of the listener.

Intuitively, S(L) chooses an utterance, w^*, such that, if listener L were to interpret w^*, the probability of L guessing the target would be maximized.[2] The rational speaker is depicted in Figure 4(b), where, as before, each edge at the first level represents a possible choice for the speaker, but there is now a second layer representing the response of the listener.

To see how an embedded model of the listener improves communication, again consider our running example in Figure 1. A speaker can describe the target object O1 using either w_1 = *on* O3 or w_2 = *right of* O2. Suppose the embedded listener is L:LITERAL, which chooses uniformly from the set of objects consistent with the given utterance. In this scenario, $p_{\text{L:LITERAL}}(\text{O1} \mid w_1) = 1$ because w_1 unambiguously describes the target object, but $p_{\text{L:LITERAL}}(\text{O1} \mid w_2) = \frac{1}{2}$. The rational speaker S(L:LITERAL) would therefore choose w_1, achieving a utility of 1, which is an improvement over the reflex speaker S:LITERAL's utility of $\frac{3}{4}$.

[1] Semantic validity is approximated by a set of heuristic rules (e.g. *left* is all positions with smaller x-coordinates).

[2] If there are ties, any distribution over the utterances having the same utility is optimal.

4 From Literal Speaker to Learned Speaker

In the previous section, we showed that a literal strategy, one that considers only semantically valid choices, can be used to directly construct a reflex speaker S:LITERAL or an embedded listener in a rational speaker S(L:LITERAL). This section focuses on an orthogonal direction: improving literal strategies with learning. Specifically, we construct learned strategies from log-linear models trained on human annotations. These learned strategies can then be used to construct reflex and rational speaker variants—S:LEARNED and S(L:LEARNED), respectively.

4.1 Training a Log-Linear Speaker/Listener

We train the speaker, S:LEARNED, (similarly, listener, L:LEARNED) on training examples which comprise the utterances produced by the human annotators (see Section 6.1 for details on how this data was collected). Each example consists of a 3D model of a room in a house that specifies the 3D positions of each object and the coordinates of a 3D camera. When training the speaker, each example is a pair (o, w), where o is the input target object and w is the output utterance. When training the listener, each example is (w, g), where w is the input utterance and g is the output guessed object.

For now, an utterance w consists of two parts:

- A spatial preposition $w.r$ (e.g., *right of*) from a set of possible prepositions.[3]
- A reference object $w.o$ (e.g., `O3`) from the set of objects in the room.

We consider more complex utterances in Section 5.

Both S:LEARNED and L:LEARNED are parametrized by log-linear models:

$$p_{\text{S:LEARNED}}(w|o;\theta_{\text{S}}) \propto \exp\{\theta_{\text{S}}^\top \phi(o,w)\} \quad (4)$$

$$p_{\text{L:LEARNED}}(g|w;\theta_{\text{L}}) \propto \exp\{\theta_{\text{L}}^\top \phi(g,w)\} \quad (5)$$

where $\phi(\cdot,\cdot)$ is the feature vector (see below), θ_{S} and θ_{L} are the parameter vectors for speaker and listener. Note that the speaker and listener use the same set of features, but they have different parameters. Furthermore, the first normalization sums over possible utterances w while the second normalization sums over possible objects g in the scene. The two parameter vectors are trained to optimize the log-likelihood of the training data under the respective models.

Features We now describe the features $\phi(o, w)$. These features draw inspiration from Landau and Jackendoff (1993) and Tellex and Roy (2009).

Each object o in the 3D scene is represented by its bounding box, which is the smallest rectangular prism containing o. The following are functions of the camera, target (or guessed object) o, and the reference object $w.o$ in the utterance. The full set of features is obtained by conjoining these functions with indicator functions of the form $\mathbb{I}[w.r = r]$, where r ranges over the set of valid prepositions.

- *Proximity functions* measure the distance between o and $w.o$. This is implemented as the minimum over all the pairwise Euclidean distances between the corners of the bounding boxes. We also have indicator functions for whether o is the closest object, among the top 5 closest objects, and among the top 10 closest objects to $w.o$.
- *Topological functions* measure containment between o and $w.o$: $vol(o \cap w.o)/vol(o)$ and $vol(o \cap w.o)/vol(w.o)$. To simplify volume computation, we approximate each object by a bounding box that is aligned with the camera axes.
- *Projection functions* measure the relative position of the bounding boxes with respect to one another. Specifically, let v be the vector from the center of $w.o$ to the center of o. There is a function for the projection of v onto each of the axes defined by the camera orientation (see Figure 5). Additionally, there is a set of indicator functions that capture the relative magnitude of these projections. For example, there is a indicator function denoting whether the projection of v onto the camera's x-axis is the largest of all three projections.

[3] We chose 10 prepositions commonly used by people to describe objects in a preliminary data gathering experiment. This list includes multi-word units, which function equivalently to prepositions, such as *left of*.

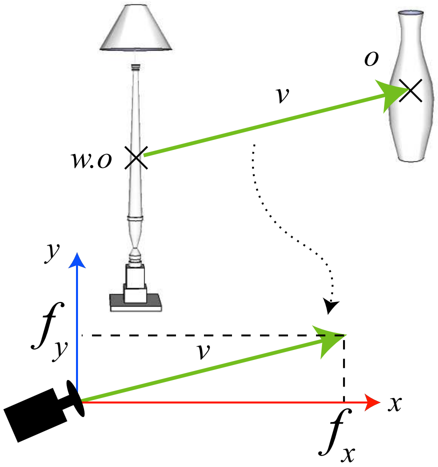


Figure 5: The projection features are computed by projecting a vector v extending from the center of the reference object to the center of the target object onto the camera axes f_x and f_y.

5 Handling Complex Utterances

So far, we have only considered speakers and listeners that deal with utterances consisting of one preposition and one reference object. We now extend these strategies to handle more complex utterances. Specifically, we consider utterances that conform to the following grammar:[4]

[noun]	N	→	*something* | O1 | O2 | · · ·
[relation]	R	→	*in front of* | *on* | · · ·
[conjunction]	NP	→	N RP*
[relativization]	RP	→	R NP

This grammar captures two phenomena of language use, conjunction and relativization.

- Conjunction is useful when one spatial relation is insufficient to disambiguate the target object. For example, in Figure 1, *right of* O2 could refer to the vase or the table, but using the conjunction *right of* O2 *and on* O3 narrows down the target object to just the vase.
- The main purpose of relativization is to refer to objects without a precise nominal descriptor. With complex utterances, it is possible to chain relative prepositional phrases, for example, using *on something right of* O2 to refer to the vase.

Given an utterance w, we define its *complexity* $|w|$ as the number of applications of the relativization rule, RP → R NP, used to produce w. We had only considered utterances of complexity 1 in previous sections.

5.1 Example Utterances

To illustrate the types of utterances available under the grammar, again consider the scene in Figure 1.

Utterances of complexity 2 can be generated either using the relativization rule exclusively, or both the conjunction and relativization rules. The relativization rule can be used to generate the following utterances:

- *on something that is right of* O2
- *right of something that is left of* O3

Applying the conjunction rule leads to the following utterances:

- *right of* O2 *and on* O3
- *right of* O2 *and under* O1
- *left of* O1 *and left of* O3

Note that we inserted the words *that is* after each N and the word *and* between every adjacent pair of RPs generated via the conjunction rule. This is to help a human listener interpret an utterance.

5.2 Extending the Rational Speaker

Suppose we have a rational speaker S(L) defined in terms of an embedded listener L which operates over utterances of complexity 1. We first extend L to interpret arbitrary utterances of our grammar. The rational speaker (defined in (2)) automatically inherits this extension.

Compositional semantics allows us to define the interpretation of complex utterances in terms of simpler ones. Specifically, each node in the parse tree has a *denotation*, which is computed recursively in terms of the node's children via a set of simple rules. Usually, denotations are represented as lambda-calculus functions, but for us, they will be distributions over objects in the scene. As a base case for interpreting utterances of complexity 1, we can use either L:LITERAL or L:LEARNED (defined in Sections 3 and 4).

[4] Naturally, we disallow direct reference to the target object.

Given a subtree w rooted at $u \in \{\texttt{N}, \texttt{NP}, \texttt{RP}\}$, we define the denotation of w, $[\![w]\!]$, to be a distribution over the objects in the scene in which the utterance was generated. The listener strategy $p_{\text{L}}(g|w) = [\![w]\!]$ is recursively as follows:

- If w is rooted at N with a single child x, then $[\![w]\!]$ is the uniform distribution over $\mathcal{N}(x)$, the set of objects consistent with the word x.
- If w is rooted at NP, we recursively compute the distributions over objects g for each child tree, multiply the probabilities, and renormalize (Hinton, 1999).
- If w is rooted at RP with relation r, we recursively compute the distribution over objects g' for the child NP tree. We then appeal to the base case to produce a distribution over objects g which are related to g' via relation r.

This strategy is defined formally as follows:

$$p_{\text{L}}(g \mid w) \propto \begin{cases} \mathbb{I}[g \in \mathcal{N}(x)] & w = (\texttt{N}\, x) \\ \prod_{j=1}^{k} p_{\text{L}}(g \mid w_j) & w = (\texttt{NP}\, w_1 \dots w_k) \\ \sum_{g'} p_{\text{L}}(g \mid (r, g')) p_{\text{L}}(g' \mid w') & w = (\texttt{RP}\, (\texttt{R}\, r)\, w') \end{cases} \tag{6}$$

Figure 6 shows an example of this bottom-up denotation computation for the utterance *on something right of* O2 with respect to the scene in Figure 1. The denotation starts with the lowest NP node $[\![\texttt{O2}]\!]$, which places all the mass on O2 in the scene. Moving up the tree, we compute the denotation of the RP, $[\![$*right of* O2$]\!]$, using the RP case of (6), which results in a distribution that places equal mass on O1 and O3.[5] The denotation of the N node $[\![$*something*$]\!]$ is a flat distribution over all the objects in the scene. Continuing up the tree, the denotation of the NP is computed by taking a product of the object distributions, and turns out to be exactly the same split distribution as its RP child. Finally, the denotation at the root is computed by applying the base case to *on* and the resulting distribution from the previous step.

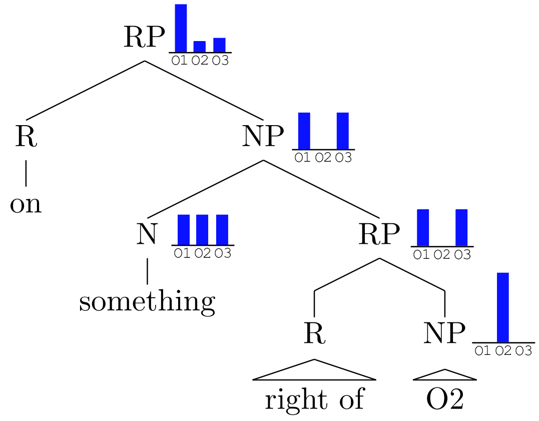

Figure 6: The listener model maps an utterance to a distribution over objects in the room. Each internal NP or RP node is a distribution over objects in the room.

Generation So far, we have defined the listener strategy $p_{\text{L}}(g \mid w)$. Given target o, the rational speaker S(L) with respect to this listener needs to compute $\text{argmax}_w\, p_{\text{L}}(o \mid w)$ as dictated by (3). This maximization is performed by enumerating all utterances of bounded complexity.

5.3 Modeling Listener Confusion

One shortcoming of the previous approach for extending a listener is that it falsely assumes that a listener can reliably interpret a simple utterance just as well as it can a complex utterance.

We now describe a more realistic speaker which is robust to listener confusion. Let $\alpha \in [0, 1]$ be a *focus parameter* which determines the confusion level. Suppose we have a listener L. When presented with an utterance w, for each application of the relativization rule, we have a $1 - \alpha$ probability of losing focus. If we stay focused for the entire utterance (with probability $\alpha^{|w|}$), then we interpret the utterance according to p_{L}. Otherwise (with probability $1 - \alpha^{|w|}$), we guess an object at random according to $p_{\text{rnd}}(g \mid w)$. We then use (3) to define the rational speaker S(L) with respect the following "confused listener" strategy:

$$\tilde{p}_{\text{L}}(g \mid w) = \alpha^{|w|} p_{\text{L}}(g \mid w) + (1 - \alpha^{|w|}) p_{\text{rnd}}(g \mid w). \tag{7}$$

As $\alpha \to 0$, the confused listener is more likely to make a random guess, and thus there is a stronger penalty against using more complex utterances. As

[5] It is worth mentioning that this split distribution between O1 and O3 represents the ambiguity mentioned in Section 3 when discussing the shortcomings of S:LITERAL.

$\alpha \rightarrow 1$, the confused listener converges to p_{L} and the penalty for using complex utterances vanishes.

5.4 The Taboo Setting

Notice that the rational speaker as defined so far does not make full use of our grammar. Specifically, the rational speaker will never use the "wildcard" noun *something* nor the relativization rule in the grammar because an NP headed by the wildcard *something* can always be replaced by the object ID to obtain a higher utility. For instance, in Figure 6, the NP spanning *something right of* O2 can be replaced by O3.

However, it is not realistic to assume that all objects can be referenced directly. To simulate scenarios where some objects cannot be referenced directly (and to fully exercise our grammar), we introduce the *taboo setting*. In this setting, we remove from the lexicon some fraction of the object IDs which are closest to the target object. Since the tabooed objects cannot be referenced directly, a speaker must resort to use of the wildcard *something* and relativization.

For example, in Figure 7, we enable tabooing around the target O1. This prevents the speaker from referring directly to O3, so the speaker is forced to describe O3 via the relativization rule, for example, producing *something right of* O2.

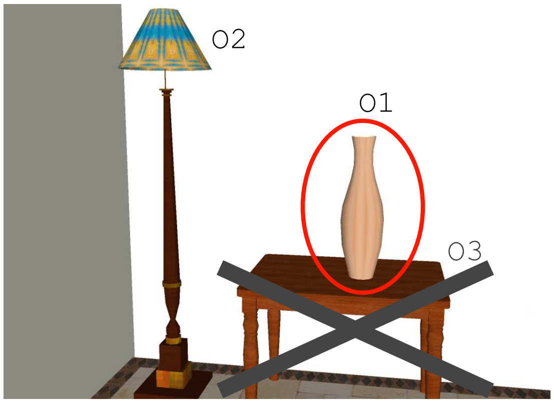

Figure 7: With tabooing enabled around O1, O3 can no longer be referred to directly (represented by an X).

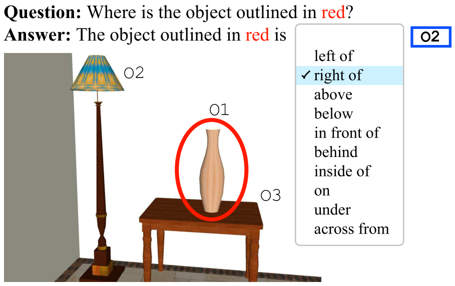
6 Experiments

We now present our empirical results, showing that rational speakers, who have embedded models of listeners, can communicate more successfully than reflex speakers, who do not.



Question: Where is the object outlined in red?
Answer: The object outlined in red is

Figure 8: Mechanical Turk speaker task: Given the target object (e.g., O1), a human speaker must choose an utterance to describe the object (e.g., *right of* O2).

6.1 Setup

We collected 43 scenes (rooms) from the Google Sketchup 3D Warehouse, each containing an average of 22 objects (household items and pieces of furniture arranged in a natural configuration). For each object o in a scene, we create a *scenario*, which represents an instance of the communication game with o as the target object. There are a total of 2,860 scenarios, which we split evenly into a training set (denoted TR) and a test set (denoted TS).

We created the following two Amazon Mechanical Turk tasks, which enable humans to play the language game on the scenarios:

Speaker Task In this task, human annotators play the role of speakers in the language game. They are prompted with a target object o and asked to each produce an utterance w (by selecting a preposition $w.r$ from a dropdown list and clicking on a reference object $w.o$) that best informs a listener of the identity of the target object.

For each training scenario o, we asked three speakers to produce an utterance w. The three resulting (o, w) pairs are used to train the learned reflex speaker (S:LITERAL). These pairs were also used to train the learned reflex listener (L:LITERAL), where the target o is treated as the guessed object. See Section 4.1 for the details of the training procedure.

Listener Task In this task, human annotators play the role of listeners. Given an utterance generated by a speaker (human or not), the human listener must

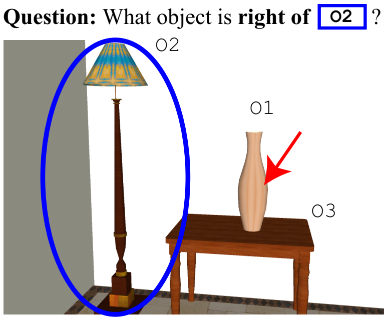


Figure 9: Mechanical Turk listener task: a human listener is prompted with an utterance generated by a speaker (e.g., *right of* O2), and asked to click on an object (shown by the red arrow).

guess the target object that the speaker saw by clicking on an object. The purpose of the listener task is to evaluate speakers, as described in the next section.

6.2 Evaluation

Utility (Communicative Success) We primarily evaluate a speaker by its ability to communicate successfully with a human listener. For each test scenario, we asked three listeners to guess the object. We use $p_{\text{L:HUMAN}}(g \mid w)$ to denote the distribution over guessed objects g given prompt w. For example, if two of the three listeners guessed O1, then $p_{\text{L:HUMAN}}(\texttt{O1} \mid w) = \frac{2}{3}$. The expected utility (2) is then computed by averaging the utility (communicative success) over the test scenarios TS:

$$\begin{aligned}\text{SUCCESS}(\text{S}) &= \text{EU}(\text{S}, \text{L:HUMAN}) \qquad (8)\\ &= \frac{1}{|\text{TS}|}\sum_{o\in\text{TS}}\sum_{w} p_{\text{S}}(w|o)p_{\text{L:HUMAN}}(o|w).\end{aligned}$$

Exact Match As a secondary evaluation metric, we also measure the ability of our speaker to exactly match an utterance produced by a human speaker. Note that since there are many ways of describing an object, exact match is neither necessary nor sufficient for successful communication.

We asked three human speakers to each produce an utterance w given a target o. We use $p_{\text{S:HUMAN}}(w \mid o)$ to denote this distribution; for example, $p_{\text{S:HUMAN}}(\textit{right of}\ \texttt{O2} \mid o) = \frac{1}{3}$ if exactly one of the three speakers uttered *right of* O2. We then define the *exact match* of a speaker S as follows:

Speaker	Success	Exact Match
S:LITERAL [reflex]	4.62%	1.11%
S(L:LITERAL) [rational]	33.65%	2.91%
S:LEARNED [reflex]	38.36%	5.44%
S(L:LEARNED) [rational]	**52.63%**	14.03%
S:HUMAN	41.41%	**19.95%**

Table 1: Comparison of various speakers on communicative success and exact match, where only utterances of complexity 1 are allowed. The rational speakers (with respect to both the literal listener L:LITERAL and the learned listener L:LEARNED) perform better than their reflex counterparts. While the human speaker (composed of three people) has higher exact match (it is better at mimicking itself), the rational speaker S(L:LEARNED) actually achieves higher communicative success than the human listener.

$$\text{MATCH}(\text{S}) = \frac{1}{|\text{TS}|}\sum_{o\in\text{TS}}\sum_{w} p_{\text{S:HUMAN}}(w \mid o)p_{\text{S}}(w \mid o). \qquad (9)$$

6.3 Reflex versus Rational Speakers

We first evaluate speakers in the setting where only utterances of complexity 1 are allowed. Table 1 shows the results on both success and exact match. First, our main result is that the two rational speakers S(L:LITERAL) and S(L:LEARNED), which each model a listener explicitly, perform significantly better than the corresponding reflex speakers, both in terms of success and exact match.

Second, it is natural that the speakers that involve learning (S:LITERAL and S(L:LITERAL)) outperform the speakers that only consider the literal meaning of utterances (S:LEARNED and S(L:LEARNED)), as the former models capture subtler preferences using features.

Finally, we see that in terms of exact match, the human speaker S:HUMAN performs the best (this is not surprising because human exact match is essentially the inter-annotator agreement), but in terms of communicative success, S(L:LEARNED) achieves a higher success rate than S:HUMAN, suggesting that the game-theoretic modeling undertaken by the rational speakers is effective for communication, which is ultimate goal of language.

Note that exact match is low even for the "human speaker", since there are often many equally good

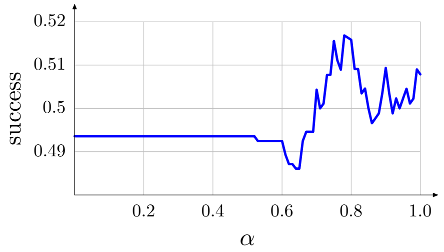

Figure 10: Communicative success as a function of focus parameter α without tabooing on TsDev. The optimal value of α is obtained at 0.79.

ways to evoke an object. At the same time, the success rates for all speakers are rather low, reflecting the fundamental difficulty of the setting: sometimes it is impossible to unambiguously evoke the target object via short utterances. In the next section, we show that we can improve the success rate by allowing the speakers to generate more complex utterances.

6.4 Generating More Complex Utterances

We now evaluate the rational speaker s(L:Learned) when it is allowed to generate utterances of complexity 1 or 2. Recall from Section 5.3 that the speaker depends on a focus parameter α, which governs the embedded listener's ability to interpret the utterance. We divided the test set (Ts) in two halves: TsDev, which we used to tune the value of α and TsFinal, which we used to evaluate success rates.

Figure 10 shows the communicative success as a function of α on TsDev. When α is small, the embedded listener is confused more easily by more complex utterances; therefore the speaker tends to choose mostly utterances of complexity 1. As α increases, the utterances increase in complexity, as does the success rate. However, when α approaches 1, the utterances are too complex and the success rate decreases. The dependence between α and average utterance complexity is shown in Figure 11.

Table 2 shows the success rates on TsFinal for $\alpha \to 0$ (all utterances have complexity 1), $\alpha = 1$ (all utterances have complexity 2), and α tuned to maximize the success rate based on TsDev. Setting α in this manner allows us to effectively balance complexity and ambiguity, resulting in an improvement in the success rate.

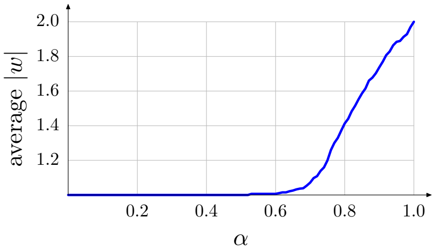

Figure 11: Average utterance complexity as a function of the focus parameter α on TsDev. Higher values of α yield more complex utterances.

Taboo Amount	Success ($\alpha \to 0$)	Success ($\alpha = 1$)	Success ($\alpha = \alpha^*$)	α^*
0%	51.78%	50.99%	54.53%	0.79
5%	38.75%	40.83%	43.12%	0.89
10%	29.57%	29.69%	30.30%	0.80
30%	12.40%	13.04%	12.98%	0.81

Table 2: Communicative success (on TsFinal) of the rational speaker s(L:Learned) for various values of α across different taboo amounts. When the taboo amount is small, small values of α lead to higher success rates. As the taboo amount increases, larger values of α (resulting in more complex utterances) are better.

7 Conclusion

Starting with the view that the purpose of language is successful communication, we developed a game-theoretic model in which a *rational* speaker generates utterances by explicitly taking the listener into account. On the task of generating spatial descriptions, we showed the rational speaker substantially outperforms a baseline reflex speaker that does not have an embedded model. Our results therefore suggest that a model of the pragmatics of communication is an important factor to consider for generation.

Facilitating Translation Using Source Language Paraphrase Lattices

Jinhua Du, Jie Jiang, Andy Way

Abstract

For resource-limited language pairs, coverage of the test set by the parallel corpus is an important factor that affects translation quality in two respects: 1) out of vocabulary words; 2) the same information in an input sentence can be expressed in different ways, while current phrase-based SMT systems cannot automatically select an alternative way to transfer the same information. Therefore, given limited data, in order to facilitate translation from the input side, this paper proposes a novel method to reduce the translation difficulty using source-side lattice-based paraphrases. We utilise the original phrases from the input sentence and the corresponding paraphrases to build a lattice with estimated weights for each edge to improve translation quality. Compared to the baseline system, our method achieves relative improvements of 7.07%, 6.78% and 3.63% in terms of BLEU score on small, medium and large-scale English-to-Chinese translation tasks respectively. The results show that the proposed method is effective not only for resource-limited language pairs, but also for resource-sufficient pairs to some extent.

1 Introduction

In recent years, statistical MT systems have been easy to develop due to the rapid explosion in data availability, especially parallel data. However, in reality there are still many language pairs which lack parallel data, such as Urdu–English, Chinese–Italian, where large amounts of speakers exist for both languages; of course, the problem is far worse for pairs such as Catalan–Irish. For such resource-limited language pairs, sparse amounts of parallel data would cause the word alignment to be inaccurate, which would in turn lead to an inaccurate phrase alignment, and bad translations would result. Callison-Burch et al. (2006) argue that limited amounts of parallel training data can lead to the problem of low coverage in that many phrases encountered at run-time are not observed in the training data and so their translations will not be learned. Thus, in recent years, research on addressing the problem of unknown words or phrases has become more and more evident for resource-limited language pairs.

Callison-Burch et al. (2006) proposed a novel method which substitutes a paraphrase for an unknown source word or phrase in the input sentence, and then proceeds to use the translation of that paraphrase in the production of the target-language result. Their experiments showed that by translating paraphrases a marked improvement was achieved in coverage and translation quality, especially in the case of unknown words which previously had been left untranslated. However, on a large-scale data set, they did not achieve improvements in terms of automatic evaluation.

Nakov (2008) proposed another way to use paraphrases in SMT. He generates nearly-equivalent syntactic paraphrases of the source-side training sentences, then pairs each paraphrased sentence with the target translation associated with the original sentence in the training data. Essentially, this method generates new training data using paraphrases to train a new model and obtain more useful

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 420–429,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

phrase pairs. However, he reported that this method results in bad system performance. By contrast, real improvements can be achieved by merging the phrase tables of the paraphrase model and the original model, giving priority to the latter. Schroeder et al. (2009) presented the use of word lattices for multi-source translation, in which the multiple source input texts are compiled into a compact lattice, over which a single decoding pass is then performed. This lattice-based method achieved positive results across all data conditions.

In this paper, we propose a novel method using paraphrases to facilitate translation, especially for resource-limited languages. Our method does not distinguish unknown words in the input sentence, but uses paraphrases of all possible words and phrases in the source input sentence to build a source-side lattice to provide a diverse and flexible list of source-side candidates to the SMT decoder so that it can search for a best path and deliver the translation with the highest probability. In this case, we neither need to change the phrase table, nor add new features in the log-linear model, nor add new sentences in the training data.

The remainder of this paper is organised as follows. In Section 2, we define the "translation difficulty" from the perspective of the source side, and then examine how well the test set is covered by the phrase table and the parallel training data . Section 3 describes our paraphrase lattice method and discusses how to set the weights for the edges in the lattice network. In Section 4, we report comparative experiments conducted on small, medium and large-scale English-to-Chinese data sets. In Section 5, we analyse the influence of our paraphrase lattice method. Section 6 concludes and gives avenues for future work.

2 What Makes Translation Difficult?

2.1 Translation Difficulty

We use the term "translation difficulty" to explain how difficult it is to translate the source-side sentence in three respects:

- The OOV rates of the source sentences in the test set (Callison-Burch et al., 2006).
- Translatability of a known phrase in the input sentence. Some particular grammatical structures on the source side cannot be directly translated into the corresponding structures on the target side. Nakov (2008) presents an example showing how hard it is to translate an English construction into Spanish. Assume that an English-to-Spanish SMT system has an entry in its phrase table for "*inequality of income*", but not for "*income inequality*". He argues that the latter phrase is hard to translate into Spanish where noun compounds are rare: the correct translation in this case requires a suitable Spanish preposition and a reordering, which are hard for the system to realize properly in the target language (Nakov, 2008).
- Consistency between the reference and the target-side sentence in the training corpus. Nakov (2008) points out that if the target-side sentence in the parallel corpus is inconsistent with the reference of the test set, then in some cases, a test sentence might contain pieces that are equivalent, but syntactically different from the phrases learned in training, which might result in practice in a missed opportunity for a high-quality translation. In this case, if we use paraphrases for these pieces of text, then we might improve the opportunity for the translation to approach the reference, especially in the case where only one reference is available.

2.2 Coverage

As to the first aspect – coverage – we argue that the coverage rate of the new words or unknown words are more and more becoming a "bottleneck" for resource-limited languages. Furthermore, current SMT systems, either phrase-based (Koehn et al., 2003; Chiang, 2005) or syntax-based (Zollmann and Venugopal, 2006), use phrases as the fundamental translation unit, so how much the phrase table and training data can cover the test set is an important factor which influences the translation quality. Table 1 shows the statistics of the coverage of the test set on English-to-Chinese FBIS data, where we can see that the coverage of unigrams is very high, especially when the data is increased to the medium size (200K), where unigram coverage is greater than 90%. Based on the observations of the unknown un-

Table 1: The coverage of the test set by the phrase table and the parallel corpus based on different amount of the training data. "PL" indicates the Phrase Length N, where $\{1 <= N <= 10\}$; "20K" and "200K" represent the sizes of the parallel data for model training and phrase extraction; "Cov." indicates the coverage rate; "Tset" represents the number of unique phrases with the length N in the Test Set; "PT" represents the number of phrases of the Test Set occur in the Phrase Table; "Corpus" indicates the number of phrases of the Test Set appearing in the parallel corpus; "in PT" indicates the coverage of the phrases in the Test Set by the phrase table and correspondingly "in Corpus" represents the coverage of the phrases in the Test Set by the Parallel Corpus.

igrams, we found that most are named entities (NEs) such as person name, location name, etc. From the bigram phrases, the coverage rates begin to significantly decline. It can also be seen that phrases containing more than 5 words rarely appear either in the phrase table or in the parallel corpus, which indicates that data sparseness is severe for long phrases. Even if the size of the corpus is significantly increased (e.g. from 20K to 200K), the coverage of long phrases is still quite low.

With respect to these three aspects of the translation difficulty, especially for data-limited language pairs, we propose a more effective method to make use of the paraphrases to facilitate translation process.

3 Paraphrase Lattice for Input Sentences

In this Section, we propose a novel method to employ paraphrases to reduce the translation difficulty and in so doing increase the translation quality.

3.1 Motivation

Our idea to build a paraphrase lattice for SMT is inspired by the following points:

- Handling unknown words is a challenging issue for SMT, and using paraphrases is an effective way to facilitate this problem (Callison-Burch et al., 2006);
- The method of paraphrase substitution does not show any significant improvement, especially on a large-scale data set in terms of BLEU (Papineni et al., 2002) scores (Callison-Burch et al., 2006);
- Building a paraphrase lattice might provide more translation options to the decoder so that it can flexibly search for the best path.

The major contributions of our method are:

- We consider all N-gram phrases rather than only unknown phrases in the test set, where $\{1 <= N <= 10\}$;
- We utilise lattices rather than simple substitution to facilitate the translation process;
- We propose an empirical weight estimation method to set weights for edges in the word lattice, which is detailed in Section 3.4.

3.2 Paraphrase Acquisition

Paraphrases are alternative ways to express the same or similar meaning given a certain original word, phrase or segment. The paraphrases used in our method are generated from the parallel corpora based on the algorithm in (Bannard and Callison-Burch, 2005), in which paraphrases are identified by pivoting through phrases in another language. In this algorithm, the foreign language translations of an English phrase are identified, all occurrences of those foreign phrases are found, and all English phrases that they translate as are treated as potential paraphrases of the original English phrase (Callison-Burch et al., 2006). A paraphrase has a probability $p(e_2|e_1)$ which is defined as in (2):

$$p(e_2|e_1) = \sum_f p(f|e_1)p(e_2|f) \tag{1}$$

where the probability $p(f|e_1)$ is the probability that the original English phrase e_1 translates as a particular phrase f in the other language, and $p(e_2|f)$ is the probability that the candidate paraphrase e_2 translates as the foreign language phrase.

$p(e_2|f)$ and $p(f|e_1)$ are defined as the translation probabilities which can be calculated straightforwardly using maximum likelihood estimation by counting how often the phrases e and f are aligned in the parallel corpus as in (2) and (3):

$$p(e_2|f) \approx \frac{count(e_2, f)}{\sum_{e_2} count(e_2, f)} \tag{2}$$

$$p(f|e_1) \approx \frac{count(f, e_1)}{\sum_f count(f, e_1)} \tag{3}$$

3.3 Construction of Paraphrase Lattice

To present paraphrase options to the PB-SMT decoder, lattices with paraphrase options are constructed to enrich the source-language sentences. The construction process takes advantage of the correspondence between detected paraphrases and positions of the original words in the input sentence, then creates extra edges in the lattices to allow the decoder to consider paths involving the paraphrase words.

An toy example is illustrated in Figure 1: given a sequence of words $\{w_1, \ldots, w_N\}$ as the input, two phrases $\alpha = \{\alpha_1, \ldots, \alpha_p\}$ and $\beta = \{\beta_1, \ldots, \beta_q\}$ are detected as paraphrases for $S_1 = \{w_x, \ldots, w_y\}$ $(1 \leq x \leq y \leq N)$ and $S_2 = \{w_m, \ldots, w_n\}$ $(1 \leq m \leq n \leq N)$ respectively. The following steps are taken to transform them into word lattices:

1. Transform the original source sentence into word lattices. $N + 1$ nodes $(\theta_k, 0 \leq k \leq N)$ are created, and N edges (referred to as "ORG-E" edges) labeled with w_i $(1 \leq i \leq N)$ are generated to connect them sequentially.

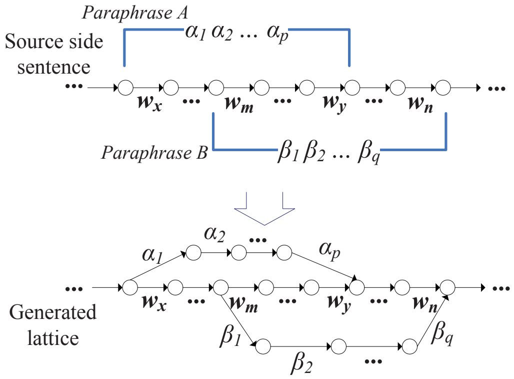

Figure 1: An example of lattice-based paraphrases for an input sentence

2. Generate extra nodes and edges for each of the paraphrases. Taking α as an example, firstly, $p - 1$ nodes are created, and then p edges (referred as "NEW-E" edges) labeled with α_j $(1 \leq j \leq p)$ are generated to connect node θ_{x-1}, $p - 1$ nodes and θ_{y-1}.

Via step 2, word lattices are generated by adding new nodes and edges coming from paraphrases. Note that to build word lattices, paraphrases with multi-words are broken into word sequences, and each of the words produces one extra edge in the word lattices as shown in the bottom part in Figure 1.

Figure 2 shows an example of constructing the word lattice for an input sentence which is from the test set used in our experiments.[1] The top part in Figure 2 represents nodes (double-line circles) and edges (solid lines) that are constructed by the original words from the input sentence, while the bottom part in Figure 2 indicates the final word lattice with the addition of new nodes (single-line circles) and new edges (dashed lines) which come from the paraphrases. We can see that the paraphrase lattice increases the diversity of the source phrases so that it can provide more flexible translation options during the decoding process.

[1] Figure 2 contains paths that are duplicates except for the weights. We plan to handle this in future work.

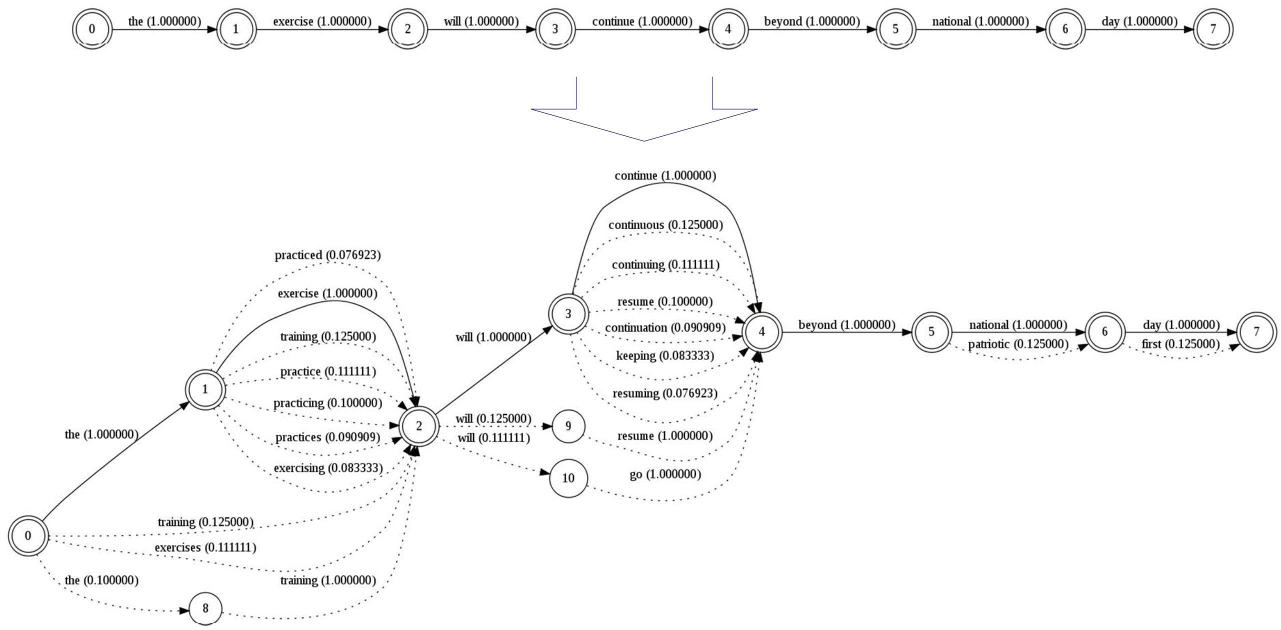

Figure 2: An example of how to build a paraphrase lattice for an input sentence

3.4 Weight Estimation

Estimating and normalising the weight for each edge in the word lattice is a challenging issue when the edges come from different sources. In this section, we propose an empirical method to set the weights for the edges by distinguishing the original ("ORG-E") and new ("NEW-E") edges in the lattices. The aim is to utilize the original sentences as the references to weight the edges from paraphrases, so that decoding paths going through "ORG-E" edges will tend to have higher scores than those which use "NEW-E" ones. The assumption behind this is that the paraphrases are alternatives for the original sentences, so decoding paths going though them ought to be penalised.

Therefore, for all the "ORG-E" edges, their weights in the lattice are set to 1.0 as the reference. Thus, in the log-linear model, decoding paths going though these edges are not penalised because they do not come from the paraphrases.

By contrast, "NEW-E" are divided into two groups for the calculation of weights:

- For "NEW-E" edges which are outgoing edges of the lattice nodes that come from the original sentences, the probabilities $p(e_s|e_i)^2$ of their corresponding paraphrases are utilised to produce empirical weights. Supposing that a set of paraphrases $\mathbf{X} = \{x_1, \ldots, x_k\}$ start at node A which comes from the original sentence, so that $\mathbf{X}$ are sorted descendingly based on the probabilities $p(e_s|e_i)$, their corresponding edges for node A are $\mathbf{G} = \{g_1, \ldots, g_k\}$, then the weights are calculated as in (4):

$$w(e_i) = \frac{1}{k+i} \;\; (1 <= i <= k) \qquad (4)$$

  where k is a predefined parameter to trade off between decoding speed and the number of potential paraphrases being considered. Thus, once a decoding path goes though one of these edges, it will be penalised according to its paraphrase probabilities.

- For all other "NEW-E" edges, their weights are set to 1.0, because the paraphrase penalty has been counted in their preceding "NEW-E" edges.

Figure 2 illustrates the weight estimation results. Nodes coming from the original sentences are drawn in double-line circles (e.g. nodes 0 to 7), while

[2] e_s indicates the source phrase S, e_i represents one of the paraphrases of S.

nodes created from paraphrases are shown in single-line circles (e.g. nodes 8 to 10). "ORG-E" edges are drawn in solid lines and "NEW-E" edges are shown using dashed lines. As specified previously, "ORG-E" edges are all weighted by 1.0 (e.g. edge labeled "the" from node 0 to 1). By contrast, "NEW-E" edges in the first group are weighted by equation (4) (e.g. edges in dashed lines start from node 0 to node 2 and 8), while others in the second group are weighted by 1.0 (e.g. edge labeled "training" from node 8 to 2). Note that penalties of the paths going through paraphrases are counted by equation (4), which is represented by the weights of "NEW-E" edges in the first group. For example, starting from node 2, paths going to node 9 and 10 are penalised because lattice weights are also considered in the log-linear model. However, other edges do not imply penalties since their weights are set to 1.0.

The reason to set all weights for the "ORG-E" edges to a uniform weight (e.g. 1.0) instead of a lower empirical weight is to avoid excessive penalties for the original words. For example, in Figure 2, the original edge from node 3 to 4 (*continue*) has a weight of 1.0, so the paths going though the original edges from node 2 to 4 (*will continue*) have a higher lattice score ($1.0 \times 1.0 = 1.0$) than the paths going through the edges of paraphrases (e.g. *will resume* (score: $0.125 \times 1.0 = 0.125$) and *will go* (score: $0.11 \times 1.0 = 0.11$)), or any other mixed paths that goes through original edges and paraphrase edges, such as *will continuous* (score: $1.0 \times 0.125 = 0.125$). The point is that we should have more trust when translating the original words, but if we penalise (set weights < 1.0) the "ORG-E" edges whenever there is a paraphrase for them, then when considering the context of the lattice, paraphrases will be favoured systematically. That is why we just penalise the "NEW-E" edges in the first group and set other weights to 1.0.

As to unknown words in the input sentence, even if we give them a prioritised weight, they would be severely penalised in the decoding process. So we do not need to distinguish unknown words when building and weighting the paraphrase lattice.

4 Experiments

4.1 System and Data Preparation

For our experiments, we use Moses (Koehn et al., 2007) as the baseline system which can support lattice decoding. We also realise a paraphrase substitution-based system (Para-Sub)[3] based on the method in (Callison-Burch, 2006) to compare with the baseline system and our proposed paraphrase lattice-based (Lattice) system.

The alignment is carried out by GIZA++ (Och and Ney, 2003) and then we symmetrized the word alignment using the grow-diag-final heuristic. The maximum phrase length is 10 words. Parameter tuning is performed using Minimum Error Rate Training (Och, 2003).

The experiments are conducted on English-to-Chinese translation. In order to fully compare our proposed method with the baseline and the "Para-Sub" system, we perform the experiments on three different sizes of training data: 20K, 200K and 2.1 million pairs of sentences. The former two sizes of data are derived from FBIS,[4] and the latter size of data consists of part of HK parallel corpus,[5] ISI parallel data,[6] other news data and parallel dictionaries from LDC. All the language models are 5-gram which are trained on the monolingual part of parallel data.

The development set (devset) and the test set for experiments using 20K and 200K data sets are randomly extracted from the FBIS data. Each set includes 1,200 sentences and each source sentence has one reference. For the 2.1 million data set, we use a different devset and test set in order to verify whether our proposed method can work on a language pair with sufficient resources. The devset is the NIST 2005 Chinese-English current set which has only one reference for each source sentence and the test set is the NIST 2003 English-to-Chinese current set which contains four references for each source sentence. All results are reported in BLEU and TER (Snover et al., 2006) scores.

[3] We use "Para-Sub" to represent their system in the rest of this paper.

[4] This is a multilingual paragraph-aligned corpus with LDC resource number LDC2003E14.

[5] LDC number: LDC2004T08.

[6] LDC number: LDC2007T09.

Lattice	**15.44**	[-0.85, +0.84]	[+0.74, +1.30]	**73.06**	**25.20**	[-1.11, +1.15]	[+1.19, +2.01]	**62.37**

Table 2: Comparison between the baseline, "Para-Sub" and our "Lattice" (paraphrase lattice) method.

The paraphrase data set used in our lattice-based and the "Para-Sub" systems is same which is derived from the "Paraphrase Phrase Table"[7] of TER-Plus (Snover et al., 2009). The parameter k in equation 4 is set to 7.

4.2 Paraphrase Filtering

The more edges there are in a lattice, the more complicated the decoding is in the search process. Therefore, in order to reduce the complexity of the lattice and increase decoding speed, we must filter out some potential noise in the paraphrase table. Two measures are taken to optimise the paraphrases when building a paraphrase lattice:

- Firstly, we filter out all the paraphrases whose probability is less than 0.01;
- Secondly, given a source-side input sentence, we retrieve all possible paraphrases and their probabilities for source-side phrases which appear in the paraphrase table. Then we remove the paraphrases which are not occurred in the "phrase table" of the SMT system. This measure intends to avoid adding new "unknown words" to the source-side sentence. After this measure, we can acquire the final paraphrases which can be denoted as a quadruple $< SEN\_ID, Span, Para, Prob >$, where "SEN_ID" indicates the ID of the input sentence, "Span" represents the span of the source-side phrase in the original input sentence, "Para" indicates the paraphrase of the source-side phrase, and "Prob" represents the probability between the source-side phrase and its paraphrase, which is used to set the weight of the edge in the lattice. The quadruple is used to construct the weighted lattice.

4.3 Experimental Results

The experimental results conducted on small and medium-sized data sets are shown in Table 2. The 95% confidence intervals (CI) for BLEU scores are independently computed on each of three systems, while the "pair-CI 95%" are computed relative to the baseline system only for "Para-Sub" and "Lattice" systems. All the significance tests use bootstrap and paired-bootstrap resampling normal approximation methods (Zhang and Vogel, 2004).[8] Improvements are considered to be significant if the left boundary of the confidence interval is larger than zero in terms of the "pair-CI 95%". It can be seen that 1) our "Lattice" system outperforms the baseline by 1.02 and 1.6 absolute (7.07% and 6.78% relative) BLEU points in terms of the 20K and 200K data sets respectively, and our system also decreases the TER scores by 2.24 and 1.19 (2.97% and 1.87% relative) points than the baseline system. In terms of the "pair-CI 95%", the left boundaries for 20K and 200K data are respectively "+0.74" and "+1.19", which indicate that the "Lattice" system is significantly better than the baseline system on these two data sets. 2) The "Para-Sub" system performs slightly better (0.36 absolute BLEU points) than the baseline system on the 20K data set, but slightly worse (0.19 absolute BLEU points) than the baseline on the 200K data set, which indicates that the paraphrase substitution method used in (Callison-Burch et al., 2006) does not work on resource-sufficient data sets. In terms of the "pair-CI 95%", the left boundary for 20K data is "+0.13", which indicates that it is significantly better than the baseline system, while the left boundary is "-0.46" for 200K data, which indicates that the "Para-Sub" system is significantly worse than the baseline system. 3) comparing the "Lattice" system with the "Para-Sub"

SYS	BLEU	CI 95%	pair-CI 95%	NIST	TER
Baseline	14.04	[-0.73, +0.40]	–	6.50	74.88
Para-Sub	14.13	[-0.56, +0.56]	[-0.18, +0.40]	6.52	74.43
Lattice	**14.55**	[-0.75, +0.32]	[+0.15,+0.83]	**6.55**	**73.28**

Table 3: Comparison between the baseline and our paraphrase lattice method on a large-scale data set.

system, the "pair-CI 95%" for 20K and 200K data are respectively [+0.41, +0.92] and [+1.40, +2.17], which indicates that the "Lattice" system is significantly better than the "Para-Sub" system on these two data sets as well. 4) In terms of the two metrics, our proposed method achieves the best performance, which shows that our method is effective and consistent on different sizes of data.

In order to verify our method on large-scale data, we also perform experiments on 2.1 million sentence-pairs of English-to-Chinese data as described in Section 4.1. The results are shown in Table 3. From Table 3, it can be seen that the "Lattice" system achieves an improvement of 0.51 absolute (3.63% relative) BLEU points and a decrease of 1.6 absolute (2.14% relative) TER points compared to the baseline. In terms of the "pair-CI 95%", the left boundary for the "Lattice" system is "+0.15" which indicates that it is significantly better than the baseline system in terms of BLEU. Interestingly, in our experiment, the "Para-Sub" system also outperforms the baseline on those three automatic metrics. However, in terms of the "pair-CI 95%", the left boundary for the "Para-Sub" system is "-0.18" which indicates that it is not significantly better than the baseline system in terms of BLEU. The results also show that our proposed method is effective and consistent even on a large-scale data set.

It also can be seen that the improvement on 2.1 million sentence-pairs is less than that of the 20K and 200K data sets. That is, as the size of the training data increases, the problems of data sparseness decrease, so that the coverage of the test set by the parallel corpus will correspondingly increase. In this case, the role of paraphrases in decoding becomes a little weaker. On the other hand, it might become a kind of noise to interfere with the exact translation of the original source-side phrases when decoding. Therefore, our proposed method may be more appropriate for language pairs with limited resources.

5 Analysis

5.1 Coverage of Paraphrase Test Set

The coverage rate of the test set by the phrase table is an important factor that could influence the translation result, so in this section we examine the characteristics of the updated test set that adds in the paraphrases. We take the 200K data set to examine the coverage issue. Table 4 is an illustration to compare the new coverage and the old coverage (without paraphrases) on medium sized training data.

PL	Tset	PT	New Cov.(%)	Old Cov.(%)
1	9,264	8,994	**97.09**	92.03
2	32,805	25,796	**78.63**	68.40
3	39,918	15,708	**39.35**	34.55
4	42,247	6,479	**15.34**	14.29
5	43,088	2,670	**6.20**	5.99
6	43,066	1,204	**2.80**	2.77
7	42,602	582	1.37	1.36
8	41,865	319	0.76	0.76
9	40,984	233	0.57	0.57
10	40,002	135	0.34	0.34

Table 4: The coverage of the paraphrase-added test set by the phrase table on medium size of the training data.

From Table 4, we can see that the coverage of unigrams, bigrams, trigrams and 4-grams goes up by about 5%, 10%, 5% and 1%, while from 5-grams there is only a slight or no increase in coverage. These results show that 1) most of the paraphrases that are added in are lower-order n-grams; 2) the paraphrases can increase the coverage of the input by handling the unknown words to some extent.

However, we observed that most untranslated words in the "Para-Sub" and "Lattice" systems are still NEs, which shows that in our paraphrase table, there are few paraphrases for the NEs. Therefore, to further improve the translation quality using paraphrases, we also need to acquire the paraphrases for NEs to increase the coverage of unknown words.

Baseline: 不管 阿 叛乱 分子 才 能 真正 disarmed 完全 是 北约 的 主要 挑战 。

Para-Sub: 能否 阿族 叛乱 分子 可以 真正 裁军 完全 是 北约 的 主要 挑战 。

Lattice: 能否 真正 阿族 叛乱 分子 可以 完全 非 军事 武装 是 北约 的 主要 挑战 。

Figure 3: An example from three systems to compare the processing of OOVs

5.2 Analysis on Translation Results

In this section, we give an example to show the effectiveness of using paraphrase lattices to deal with unknown words. The example is evaluated according to both automatic evaluation and human evaluation at sentence level.

See Figure 3 as an illustration of how the paraphrase-based systems process unknown words. According to the word alignments between the source-side sentence and the reference, the word “disarmed” is translated into two Chinese words “解除” and “武装”. These two Chinese words are discontinuous in the reference, so it is difficult for the PB-SMT system to correctly translate the single English word into a discontinuous Chinese phrase. In fact in this example, “disarmed” is an unknown word and it is kept untranslated in the result of the baseline system. In the “Para-Sub” system, it is translated into “裁军” based on a paraphrase pair PP_1 = “disarmed || disarmament || 0.087” and its translation pair T_1 = “disarmament || 裁军”. The number “0.087” is the probability p_1 that indicates to what extent these two words are paraphrases. It can be seen that although “裁军” is quite different from the meaning of “disarmed”, it is understandable for human in some sense. In the “Lattice” system, the word “disarmed” is translated into three Chinese words “非 军事 武装” based on a paraphrase pair PP_2 = “disarmed || demilitarized || 0.099” and its translation pair T_2 = “demilitarized || 非 军事 武装”. The probability p_2 is slightly greater than p_1.

We argue that the reason that the “Lattice” system selects PP_2 and T_2 rather than PP_1 and T_1 is because of the weight estimation in the lattice. That is, PP_2 is more prioritised, while PP_1 is more penalised based on equation (4).

From the viewpoint of human evaluation, the paraphrase pair PP_2 is more appropriate than PP_1, and the translation T_2 is more similar to the original meaning than T_1. The sentence-level automatic evaluation scores for this example in terms of BLEU and TER metrics are shown in Table 5.

SYS	BLEU	TER
Baseline	20.33	66.67
Para-Sub	21.78	**53.33**
Lattice	**23.51**	**53.33**

Table 5: Comparison on sentence-level scores in terms of BLEU and TER metrics.

The BLEU score of the “Lattice” system is much higher than the baseline, and the TER score is quite a bit lower than the baseline. Therefore, from the viewpoint of automatic evaluation, the translation from the “Lattice” system is also better than those from the baseline and “Para-Sub” systems.

6 Conclusions and Future Work

In this paper, we proposed a novel method using paraphrase lattices to facilitate the translation process in SMT. Given an input sentence, our method firstly discovers all possible paraphrases from a paraphrase database for N-grams ($1 <= N <= 10$) in the test set, and then filters out the paraphrases which do not appear in the phrase table in order to avoid adding new unknown words on the input side. We then use the original words and the paraphrases to build a word lattice, and set the weights to prioritise the original edges and penalise the paraphrase edges. Finally, we import the lattice into the decoder to perform lattice decoding. The experiments are conducted on English-to-Chinese translation using the FBIS data set with small and medium-sized amounts of data, and on a large-scale corpus of 2.1

million sentence pairs. We also performed comparative experiments for the baseline, the "Para-Sub" system and our paraphrase lattice-based system. The experimental results show that our proposed system significantly outperforms the baseline and the "Para-Sub" system, and the effectiveness is consistent on the small, medium and large-scale data sets.

As for future work, firstly we plan to propose a pruning algorithm for the duplicate paths in the lattice, which will track the edge generation with respect to the path span, and thus eliminate duplicate paths. Secondly, we plan to experiment with another feature function in the log-linear model to discount words derived from paraphrases, and use MERT to assign an appropriate weight to this feature function.

Abstract

This paper studies the problem of mining entity translation, specifically, mining English and Chinese name pairs. Existing efforts can be categorized into (a) a transliteration-based approach leveraging phonetic similarity and (b) a corpus-based approach exploiting bilingual co-occurrences, each of which suffers from inaccuracy and scarcity respectively. In clear contrast, we use unleveraged resources of monolingual entity co-occurrences, crawled from entity search engines, represented as two entity-relationship graphs extracted from two language corpora respectively. Our problem is then abstracted as finding correct mappings across two graphs. To achieve this goal, we propose a holistic approach, of exploiting both transliteration similarity and monolingual co-occurrences. This approach, building upon monolingual corpora, complements existing corpus-based work, requiring scarce resources of parallel or comparable corpus, while significantly boosting the accuracy of transliteration-based work. We validate our proposed system using real-life datasets.

1 Introduction

Entity translation aims at mapping the entity names (*e.g.*, people, locations, and organizations) in source language into their corresponding names in target language. While high quality entity translation is essential in cross-lingual information access and translation, it is non-trivial to achieve, due to the challenge that entity translation, though typically bearing pronunciation similarity, can also be arbitrary, *e.g.*, Jackie Chan and 成龙 (pronounced Cheng Long). Existing efforts to address these challenges can be categorized into transliteration- and corpus-based approaches. Transliteration-based approaches (Wan and Verspoor, 1998; Knight and Graehl, 1998) identify translations based on pronunciation similarity, while corpus-based approaches mine bilingual co-occurrences of translation pairs obtained from parallel (Kupiec, 1993; Feng et al., 2004) or comparable (Fung and Yee, 1998) corpora, or alternatively mined from bilingual sentences (Lin et al., 2008; Jiang et al., 2009). These two approaches have complementary strength– transliteration-based similarity can be computed for any name pair but cannot mine translations of little (or none) phonetic similarity. Corpus-based similarity can support arbitrary translations, but require highly scarce resources of bilingual co-occurrences, obtained from parallel or comparable bilingual corpora.

In this paper, we propose a holistic approach, leveraging both transliteration- and corpus-based similarity. Our key contribution is to replace the use of scarce resources of bilingual co-occurrences with the use of untapped and significantly larger resources of monolingual co-occurrences for translation. In particular, we extract monolingual co-occurrences of entities from English and Chinese Web corpora, which are readily available from entity search engines such as PeopleEntityCube[1], deployed by Microsoft Research Asia. Such engine

automatically extracts people names from text and their co-occurrences to retrieve related entities based on co-occurrences. To illustrate, Figure 1(a) demonstrates the query result for “Bill Gates,” retrieving and visualizing the “entity-relationship graph” of related people names that frequently co-occur with Bill in English corpus. Similarly, entity-relationship graphs can be built over other language corpora, as Figure 1(b) demonstrates the corresponding results for the same query, from Renlifang[2] on Chinese Web corpus. From this point on, for the sake of simplicity, we refer to English and Chinese graphs, simply as G_e and G_c respectively. Though we illustrate with English-Chinese pairs in the paper, our method can be easily adapted to other language pairs.

In particular, we propose a novel approach of abstracting entity translation as a graph matching problem of two graphs G_e and G_c in Figures 1(a) and (b). Specifically, the similarity between two nodes v_e and v_c in G_e and G_c is initialized as their transliteration similarity, which is iteratively refined based on relational similarity obtained from monolingual co-occurrences. To illustrate this, an English news article mentioning “Bill Gates” and “Melinda Gates” evidences a relationship between the two entities, which can be quantified from their co-occurrences in the entire English Web corpus. Similarly, we can mine Chinese news articles to obtain the relationships between “比尔·盖茨” and “梅琳达·盖茨”. Once these two bilingual graphs of people and their relationships are harvested, entity translation can leverage these parallel relationships to further evidence the mapping between translation pairs, as Figure 1(c) illustrates.

To highlight the advantage of our proposed approach, we compare our results with commercial machine translators (1) Engkoo[3] developed in Microsoft Research Asia and (2) Google Translator[4]. In particular, Figure 2 reports the precision for two groups– “heads” that belong to top-100 popular people (determined by the number of hits), among randomly sampled 304 people names[5] from six graph pairs of size 1,000 each, and the remaining “tails”. Commercial translators such as Google, leveraging bilingual co-occurrences that are scarce for tails, show significantly lower precision for tails. Meanwhile, our work, depending solely on monolingual co-occurrences, shows high precision, for both heads and tails.

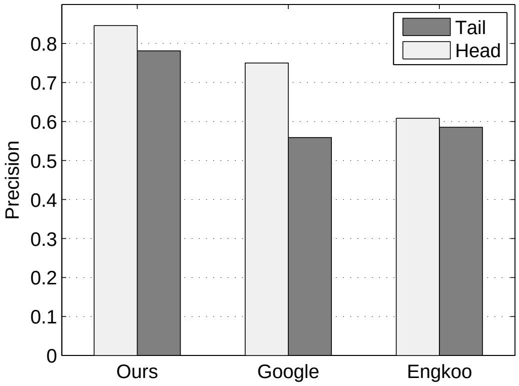

Figure 2: Comparison for Head and Tail datasets

Our focus is to boost translation accuracy for long tails with non-trivial Web occurrences in each monolingual corpus, but not with much bilingual co-occurrences, *e.g.*, researchers publishing actively in two languages but not famous enough to be featured in multi-lingual Wikipedia entries or news articles. As existing translators are already highly accurate for popular heads, this focus well addresses the remaining challenges for entity translation.

To summarize, we believe that this paper has the following contributions:

- We abstract entity translation problem as a graph mapping between entity-relationship graphs in two languages.
- We develop an effective matching algorithm leveraging both pronunciation and co-occurrence similarity. This holistic approach complements existing approaches and enhances the translation coverage and accuracy.
- We validate the effectiveness of our approach using various real-life datasets.

The rest of this paper is organized as follows. Section 2 reviews existing work. Section 3 then develops our framework. Section 4 reports experimental results and Section 5 concludes our work.

2 Related Work

In this section, we first survey related efforts, categorized into transliteration-based and corpus-based approaches. Our approach leveraging both is complementary to these efforts.

2.1 Transliteration-based Approaches

Many name translations are loosely based on phonetic similarity, which naturally inspires transliteration-based translation of finding the translation with the closest pronunciation similarity, using either rule-based (Wan and Verspoor, 1998) or statistical (Knight and Graehl, 1998; Li et al., 2004) approaches. However, people are free to designate arbitrary bilingual names of little (or none) phonetic similarity, for which the transliteration-based approach is not effective.

2.2 Corpus-based Approaches

Corpus-based approach can mine arbitrary translation pairs, by mining bilingual co-occurrences from parallel and comparable bilingual corpora. Using parallel corpora (Kupiec, 1993; Feng et al., 2004), *e.g.*, bilingual Wikipedia entries on the same person, renders high accuracy but suffers from high scarcity. To alleviate such scarcity, (Fung and Yee, 1998; Shao and Ng, 2004) explore a more vast resource of comparable corpora, which share no parallel document- or sentence-alignments as in parallel corpora but describe similar contents in two languages, *e.g.*, news articles on the same event. Alternatively, (Lin et al., 2008) extracts bilingual co-occurrences from bilingual sentences, such as annotating terms with their corresponding translations in English inside parentheses. Similarly, (Jiang et al., 2009) identifies potential translation pairs from bilingual sentences using lexical pattern analysis.

2.3 Holistic Approaches

The complementary strength of the above two approaches naturally calls for a holistic approach, such as recent work combining transliteration- and corpus-based similarity mining bilingual co-occurrences using general search engines. Specifically, (Al-Onaizan and Knight, 2002) uses transliteration to generate candidates and then web corpora to identify translations. Later, (Jiang et al., 2007) enhances to use transliteration to guide web mining.

Our work is also a holistic approach, but leveraging significantly larger corpora, specifically by exploiting monolingual co-occurrences. Such expansion enables to translate "long-tail" people entities with non-trivial Web occurrences in each monolingual corpus, but not much bilingual co-occurrences. Specifically, we initialize name pair similarity using transliteration-based approach, and iteratively reinforces base similarity using relational similarity.

3 Our Framework

Given two graphs $G_e = (V_e, E_e)$ and $G_c = (V_c, E_c)$ harvested from English and Chinese corpora respectively, our goal is to find translation pairs, or a set S of matching node pairs such that $S \subseteq V_e \times V_c$. Let R be a $|V_e|$-by-$|V_c|$ matrix where each R_{ij} denotes the similarity between two nodes $i \in V_e$ and $j \in V_c$.

Overall, with the matrix R, our approach consists of the following three steps, as we will discuss in the following three sections respectively:

1. **Initialization:** computing base translation similarities R_{ij} between two entity nodes using transliteration similarity

2. **Reinforcement model:** reinforcing the translation similarities R_{ij} by exploiting the monolingual co-occurrences

3. **Matching extraction:** extracting the matching pairs from the final translation similarities R_{ij}

3.1 Initialization with Transliteration

We initialize the translation similarity R_{ij} as the transliteration similarity. This section explains how to get the transliteration similarity between English and Chinese names using an unsupervised approach.

Formally, let an English name $N_e = (e_1, e_2, \cdots, e_n)$ and a Chinese name $N_c = (c_1, c_2, \cdots, c_m)$ be given, where e_i is an English word and N_e is a sequence of the words, and c_i is a Chinese character and N_c is a sequence of the characters. Our goal is to compute a score indicating the similarity between the pronunciations of the two names.

We first convert N_c into its Pinyin representation $PY_c = (s_1, s_2, \cdots, s_m)$, where s_i is the Pinyin representation of c_i. Pinyin is the romanization representation of pronunciation of Chinese character. For example, the Pinyin representation of $N_e =$ ("Barack", "Obama") is $PY_c =$("ba", "la", "ke", "ao", "ba", "ma"). The Pinyin representations of Chinese characters can be easily obtained from Chinese character pronunciation dictionary. In our experiments, we use an in-house dictionary, which contains pronunciations of $20,774$ Chinese characters. For the Chinese characters having multiple pronunciations, we only use the most popular one.

Calculation of transliteration similarity between N_e and N_c is now transformed to calculation of pronunciation similarity between N_e and PY_c. Because letters in Chinese Pinyins and English strings are pronounced similarly, we can further approximate pronunciation similarity between N_e and PY_c using their spelling similarity. In this paper, we use Edit Distance (ED) to measure the spelling similarity. Moreover, since words in N_e are transliterated into characters in PY_c independently, it is more accurate to compute the ED between N_e and PY_c, *i.e.*, $ED_{name}(N_e, PY_c)$, as the sum of the EDs of all component transliteration pairs, *i.e.*, every e_i in N_e and its corresponding transliteration (s_i) in PY_c. In other words, we need to first align all s_j's in PY_c with corresponding e_i in N_e based on whether they are translations of each other. Then based on the alignment, we can calculate $ED_{name}(N_e, PY_c)$ using the following formula.

$$ED_{name}(N_e, PY_c) = \sum_i ED(e_i, es_i) \quad (1)$$

where es_i is a string generated by concatenating all s_i's that are aligned to e_i and $ED(e_i, es_i)$ is the Edit Distance between e_i and es_i, *i.e.*, the minimum number of edit operations (including insertion, deletion and substitution) needed to transform e_i into es_i. Because an English word usually consists of multiple syllables but every Chinese character consists of only one syllable, when aligning e_i's with s_j's, we add the constraint that each e_i is allowed to be aligned with 0 to 4 s_i's but each s_i can only be aligned with 0 to 1 e_i. To get the alignment between PY_c and N_e which has the minimal $ED_{name}(N_e, PY_c)$, we use a Dynamic Programming based algorithm as defined in the following formula:

$$\begin{aligned}
&ED_{name}(N_e^{1,i}, PY_c^{1,j}) = \min(\\
&\quad ED_{name}(N_e^{1,i-1}, PY_c^{1,j}) + Len(e_i), \\
&\quad ED_{name}(N_e^{1,i}, PY_c^{1,j-1}) + Len(s_j), \\
&\quad ED_{name}(N_e^{1,i-1}, PY_c^{1,j-1}) + ED(e_i, s_j), \\
&\quad ED_{name}(N_e^{1,i-1}, PY_c^{1,j-2}) + ED(e_i, PY_c^{j-1,j}), \\
&\quad ED_{name}(N_e^{1,i-1}, PY_c^{1,j-3}) + ED(e_i, PY_c^{j-2,j}), \\
&\quad ED_{name}(N_e^{1,i-1}, PY_c^{1,j-4}) + ED(e_i, PY_c^{j-3,j}))
\end{aligned}$$

where, given a sequence $X = (x_1, x_2, \cdots)$ such that x_i is a word, $X^{i,j}$ is the subsequence $(x_i, x_{i+1}, \cdots, x_j)$ of X and $Len(X)$ is the number of letters except spaces in the sequence X. For instance, the minimal Edit Distance between the English name "Barack Obama" and the Chinese Pinyin representation "ba la ke ao ba ma" is 4, as the best alignment is: "Barack" ↔ "ba la ke" (ED: 3), "Obama" ↔ "ao ba ma" (ED: 1). Finally the transliteration similarity between N_c and N_e is calculated using the following formula.

$$Sim_{tl}(N_c, N_e) = 1 - \frac{ED_{name}(N_e, PY_c)}{Len(PY_c) + Len(N_e)} \quad (2)$$

For example, Sim_{tl}("Barack Obama", "巴拉克·奥巴马") is $1 - \frac{4}{11+12} = 0.826$.

3.2 Reinforcement Model

From the initial similarity, we model our problem as an iterative approach that iteratively reinforces the similarity R_{ij} of the nodes i and j from the matching similarities of their neighbor nodes u and v.

The basic intuition is built on exploiting the similarity between monolingual co-occurrences of two different languages. In particular, we assume two entities with strong relationship co-occur frequently in both corpora. In order to express this intuition, we formally define an iterative reinforcement model as follows. Let R_{ij}^t denote the similarity of nodes i and j at t-th iteration:

$$R_{ij}^{t+1} = \lambda \sum_{(u,v)_k \in B^t(i,j,\theta)} \frac{R_{uv}^t}{2^k} + (1-\lambda) R_{ij}^0 \quad (3)$$

The model is expressed as a linear combination of (a) the relational similarity $\sum R_{uv}^t / 2^k$ and (b) transliteration similarity R_{ij}^0. (λ is the coefficient for interpolating two similarities.)

In the relational similarity, $B^t(i,j,\theta)$ is an ordered set of the best matching pairs between neighbor nodes of i and ones of j such that $\forall (u,v)_k \in B^t(i,j,\theta), R_{uv}^t \geq \theta$, where $(u,v)_k$ is the matching pair with k-th highest similarity score. We consider (u,v) with similarity over some threshold θ, or $R_{uv}^t \geq \theta$, as a matching pair. In this neighbor matching process, if many-to-many matches exist, we select only one with the greatest matching score. Figure 3 describes such matching process more formally. $N(i)$ and $N(j)$ are the sets of neighbor nodes of i and j, respectively, and H is a priority queue sorting pairs in the decreasing order of similarity scores.

Meanwhile, note that, in order to express that the confidence for matching (i,j) progressively converges as the number of matched neighbors increases, we empirically use decaying coefficient $1/2^k$ for R_{uv}^t, because $\sum_{k=1}^{\infty} 1/2^k = 1$.

3.3 Matching Extraction

After the convergence of the above model, we get the $|V_e|$-by-$|V_c|$ similarity matrix R^{∞}. From this matrix, we extract one-to-one matches maximizing the overall similarity.

More formally, this problem can be stated as the *maximum weighted bipartite matching* (West,

```
$B^t(i,j,\theta) \leftarrow \{\}$
$\forall u \in N(i), \forall v \in N(j) : H.push(u,v;R^t_{uv})$
while $H$ is not empty do
    $(u,v;s) \leftarrow H.pop()$
    if $s < \theta$ then
        break
    end if
    if neither $u$ nor $v$ are matched yet then
        $B^t(i,j,\theta) \leftarrow B^t(i,j,\theta) \cup \{(u,v)\}$
    end if
end while
return $B^t(i,j,\theta)$
```

Figure 3: How to get the ordered set $B^t(i,j,\theta)$

2000)– Given two groups of entities V_e and V_c from the two graphs G_e and G_c, we can build a *weighted bipartite graph* is $G = (V,E)$, where $V = V_e \cup V_c$ and E is a set of edges (u,v) with weight R^∞_{uv}. To filter out null alignment, we construct only the edges with weight $R^\infty_{uv} \geq \delta$. From this bipartite graph, the maximum weighted bipartite matching problem finds a set of pairwise non-adjacent edges $S \subseteq E$ such that $\sum_{(u,v)\in S} R^\infty_{uv}$ is the maximum. Well-known algorithms include Hungarian algorithm with time complexity of $O(|V|^2 \log |V| + |V||E|)$ (West, 2000).

In this paper, to speed up processing, we consider a greedy alternative with the following steps– (1) choose the pair with the highest similarity score, (2) remove the corresponding row and column from the matrix, and (3) repeat (1) and (2) until their matching scores are over a specific threshold δ.

4 Experiments

This section reports our experimental results to evaluate our proposed approach. First, we report our experimental setting in Section 4.1. Second, we validate the effectiveness and the scalability of our approach over a real-life dataset in Section 4.2.

4.1 Experimental Settings

This section describes (1) how we collect the English and Chinese EntityCube datasets, (2) how to build ground-truth test datasets for evaluating our framework, and (3) how to set up three parameters λ, θ, and δ.

First, we crawled $G_e = (V_e, E_e)$ and $G_c = (V_c, E_c)$ from English and Chinese EntityCubes. Specifically, we built a graph pairs (G_e, G_c) expanding from a "seed pair" of nodes $s_e \in V_e$ and $s_c \in V_c$ until the number of nodes for each graph becomes 1,000[6]. More specifically, when we build a graph G_e by expanding from s_e, we use a queue Q. We first initialize Q by pushing the seed node s_e. We then iteratively pop a node v_e from Q, save v_e into V_e, and push its neighbor nodes in decreasing order of co-occurrence scores with v_e. Similarly, we can get G_c from a counterpart seed node v_c. By using this procedure, we built six graph pairs from six different seed pairs. In particular, the six seed nodes are English names and its corresponding Chinese names representing a wide range of occupation domains (*e.g.*, 'Barack Obama,' 'Bill Gates,' 'Britney Spears,' 'Bruno Senna,' 'Chris Paul,' and 'Eminem') as Table 1 depicts. Meanwhile, though we demonstrate the effectiveness of the proposed method for mining name translations in Chinese and English languages, the method can be easily adapted to other language pairs.

Table 1: Summary for graphs and test datasets obtained from each seed pair

i	$\lvert V_e \rvert, \lvert V_c \rvert$	$\lvert T_i \rvert$	English Name	Chinese Name
1	1,000	51	Barack Obama	巴拉克·奥巴马
2	1,000	52	Bill Gates	比尔·盖茨
3	1,000	40	Britney Spears	布兰妮·斯皮尔斯
4	1,000	53	Bruno Senna	布鲁诺·塞纳
5	1,000	51	Chris Paul	克里斯·保罗
6	1,000	57	Eminem	艾米纳姆

Second, we manually searched for about 50 "ground-truth" matched translations for each graph pair to build test datasets T_i, by randomly selecting nodes within two hops[7] from the seed pair (s_e, s_c), since nodes outside two hops may include nodes whose neighbors are not fully crawled. More specifically, due to our crawling process expanding to add neighbors from the seed, the nodes close to the seed have all the neighbors they would have in the full graph, while those far from the node may not. In order to pick the nodes that well represent the actual

[6] Note, this is just a default setting, which we later increase for scalability evaluation in Figure 6.

[7] Note that the numbers of nodes within two hops in G_e and G_c are 327 and 399 on average respectively.

neighbors, we built test datasets among those within two hops. However, this crawling is used for the evaluation sake only, and thus does not suggest the bias in our proposed framework. Table 1 describes the size of such test dataset for each graph pair.

Lastly, we set up the three parameters λ, θ, and δ using 6-fold cross validation with 6 test datasets T_i's of the graphs. More specifically, for each dataset T_i, we decide λ_i and θ_i such that average MRR for the other 5 test datasets is maximized. (About MRR, see more details of Equation (4) in Section 4.2.) We then decide δ_i such that average F1-score is maximized. Figure 4 shows the average MRR for λ_i and θ_i with default values $\theta = 0.66$ and $\lambda = 0.2$. Based on these results, we set λ_i with values $\{0.2, 0.15, 0.2, 0.15, 0.2, 0.15\}$ that optimize MRR in datasets $T_1, \ldots T_6$, and similarly θ_i with $\{0.67, 0.65, 0.67, 0.67, 0.65, 0.67\}$. We also set δ_i with values $\{0.63, 0.63, 0.61, 0.61, 0.61, 0.61\}$ optimizing F1-score with the same default values $\lambda = 0.2$ and $\theta = 0.66$. We can observe the variances of optimal parameter setting values are low, which suggests the robustness of our framework.

4.2 Experimental Results

This section reports our experimental results using the evaluation datasets explained in previous section. For each graph pair, we evaluated the effectiveness of (1) reinforcement model using MRR measure in Section 4.2.1 and (2) overall framework using precision, recall, and F1 measures in Section 4.2.2. We also validated (3) scalability of our framework over larger scale of graphs (with up to five thousand nodes) in Section 4.2.3. (In all experimental results, **Bold numbers** indicate the best performance for each metric.)

4.2.1 Effectiveness of reinforcement model

We evaluated the reinforcement model over MRR (Voorhees, 2001), the average of the reciprocal ranks of the query results as the following formula:

$$\text{MRR} = \frac{1}{|Q|} \sum_{q \in Q} \frac{1}{rank_q} \tag{4}$$

Each q is a ground-truth matched pair (u, v) such that $u \in V_e$ and $v \in V_c$, and $rank_q$ is the rank of the similarity score of R_{uv} among all R_{uk}'s such that $k \in V_c$. Q is a set of such queries. By comparing MRRs for two matrices R^0 and R^∞, we can validate the effectiveness of the reinforcement model.

- Baseline matrix (R^0): using only the transliteration similarity score, *i.e.*, without reinforcement
- Reinforced matrix (R^∞): using the reinforced similarity score obtained from Equation (3)

Table 2: MRR of baseline and reinforced matrices

Set	MRR	
	Baseline R^0	Reinforced R^∞
T_1	0.6964	**0.8377**
T_2	0.6213	**0.7581**
T_3	0.7095	**0.7989**
T_4	0.8159	**0.8378**
T_5	0.6984	**0.8158**
T_6	0.5982	**0.8011**
Average	0.6900	**0.8082**

We empirically observed that the iterative model converges within 5 iterations. In all experiments, we used 5 iterations for the reinforcement.

Table 2 summarizes our experimental results. As these figures show, MRR scores significantly increase after applying our reinforcement model except for the set T_4 (on average from 69% to 81%), which indirectly shows the effectiveness of our reinforcement model.

4.2.2 Effectiveness of overall framework

Based on the reinforced matrix, we evaluated the effectiveness of our overall matching framework using the following three measures–(1) **precision**: how accurately the method returns matching pairs, (2) **recall**: how many the method returns correct matching pairs, and (3) **F1-score**: the harmonic mean of precision and recall. We compared our approach with a baseline, mapping two graphs with only transliteration similarity.

- Baseline: in matching extraction, using R^0 as the similarity matrix by bypassing the reinforcement step
- Ours: using R^∞, the similarity matrix converged by Equation (3)

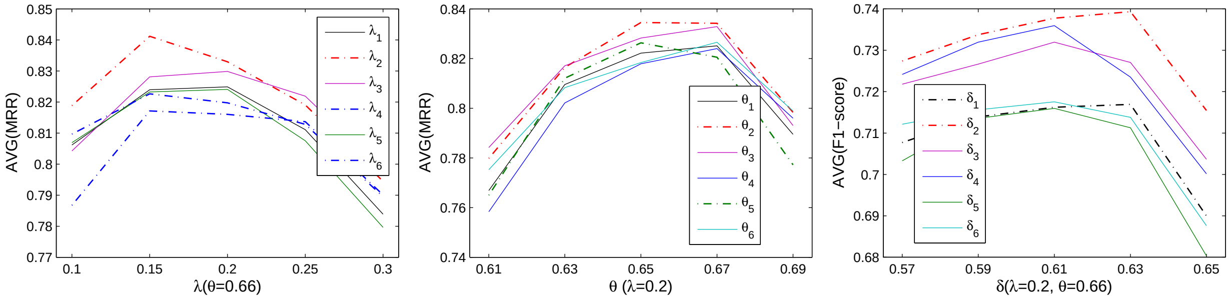

Figure 4: Parameter setup for λ, θ, and δ

In addition, we compared ours with the machine translators of Engkoo and Google. Table 3 summarizes our experimental results.

As this table shows, our approach results in the highest precision (about 80% on average) without compromising the best recall of Google, *i.e.*, 61% of Google vs. 63% of ours. Overall, our approach outperforms others in all three measures.

Meanwhile, in order to validate the translation accuracy over popular head and long-tail, as discussed in Section 1, we separated the test data into two groups and analyzed the effectiveness separately. Figure 5 plots the number of hits returned for the names from Google search engine. According to the distribution, we separate the test data into top-100 popular people with the highest hits and the remaining, denoted *head* and *tail*, respectively.

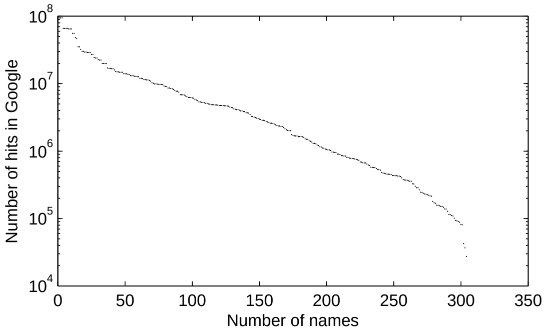

Figure 5: Distribution over number of hits

Table 4 shows the effectiveness with both datasets, respectively. As difference of the effectiveness between tail and head (denoted *diff*) with respect to three measures shows, our approach shows stably high precision, for both heads and tails.

4.2.3 Scalability

To validate the scalability of our approach, we evaluated the effectiveness of our approach over the number of nodes in two graphs. We built larger six graph pairs (G_e, G_c) by expanding them from the seed pairs further until the number of nodes reaches 5,000. Figure 6 shows the number of matched translations according to such increase. Overall, the number of matched pairs linearly increases as the number of nodes increases, which suggests scalability. The ratio of node overlap in two graphs is about between 7% and 9% of total node size.

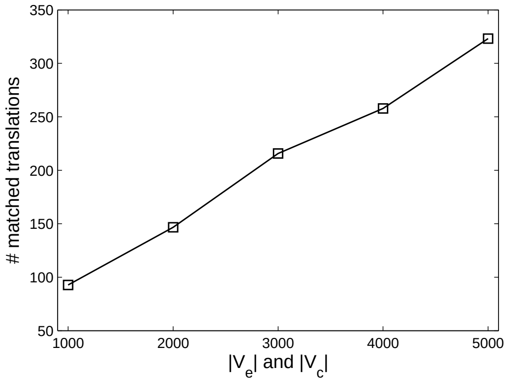

Figure 6: Matched translations over $|V_e|$ and $|V_c|$

5 Conclusion

This paper abstracted name translation problem as a matching problem of two entity-relationship graphs. This novel approach complements existing name translation work, by not requiring rare resources of parallel or comparable corpus yet outperforming the state-of-the-art. More specifically, we combine bilingual phonetic similarity and monolingual Web co-occurrence similarity, to compute a holistic notion of entity similarity. To achieve this goal, we de-

Abstract

This paper studies two issues, non-isomorphic structure translation and target syntactic structure usage, for statistical machine translation in the context of forest-based tree to tree sequence translation. For the first issue, we propose a novel non-isomorphic translation framework to capture more non-isomorphic structure mappings than traditional tree-based and tree-sequence-based translation methods. For the second issue, we propose a parallel space searching method to generate hypothesis using tree-to-string model and evaluate its syntactic goodness using tree-to-tree/tree sequence model. This not only reduces the search complexity by merging spurious-ambiguity translation paths and solves the data sparseness issue in training, but also serves as a syntax-based target language model for better grammatical generation. Experiment results on the benchmark data show our proposed two solutions are very effective, achieving significant performance improvement over baselines when applying to different translation models.

1 Introduction

Recently syntax-based methods have achieved very promising results and attracted increasing interests in statistical machine translation (SMT) research community due to their ability to provide informative context structure information and convenience in carrying out word transformation and sub-span reordering. Fundamentally, syntax-based SMT views translation as a structural transformation process. Generally speaking, from modeling viewpoint, a syntax-based model tries to convert the source structures into target structures iteratively and recursively while from decoding viewpoint a syntax-based system segments an input tree/forest into many sub-fragments, translates each of them separately, combines the translated sub-fragments and then finds out the best combinations. Therefore, from bilingual viewpoint, we face two fundamental problems: the mapping between bilingual structures and the way of carrying out the target structures combination.

For the first issue, a number of models have been proposed to model the structure mapping between tree and string (Galley *et al.*, 2004; Liu *et al.*, 2006; Yamada and Knight, 2001; DeNeefe and Knight, 2009) and between tree and tree (Eisner, 2003; Zhang *et al.*, 2007 & 2008; Liu *et al.*, 2009). However, one of the major challenges is that all the current models only allow one-to-one mapping from one source frontier non-terminal node (Galley *et al.*, 2004) to one target frontier non-terminal node in a bilingual translation rule. Therefore, all those translation equivalents with one-to-many frontier non-terminal node mapping cannot be covered by the current state-of-the-art models. This may largely compromise the modeling ability of translation rules.

For the second problem, currently, the combination is driven by only the source side (both tree-to-string model and tree-to-tree model only check the source span compatibility when combining different target structures in decoding) or only the

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 440–450,

target side (string to tree model). There is no well study in considering both the source side information and the compatibility between different target syntactic structures during combination. In addition, it is well known that the traditional tree-to-tree models suffer heavily from the data sparseness issue in training and the spurious-ambiguity translation path issue (the same translation with different syntactic structures) in decoding.

In addition, because of the performance limitation of automatic syntactic parser, researchers propose using packed forest (Tomita, 1987; Klein and Manning, 2001; Huang, 2008)[1] instead of 1-best parse tree to carry out training (Mi and Huang, 2008) and decoding (Mi *et al.*, 2008) in order to reduce the side effect caused by parsing errors of the one-best tree. However, when we apply the tree-to-tree model to the bilingual forest structures, both training and decoding become very complicated.

In this paper, to address the first issue, we propose a framework to model the non-isomorphic translation process from source tree fragment to target tree sequence, allowing any one source frontier non-terminal node to be translated into any number of target frontier non-terminal nodes. For the second issue, we propose a technology to model the combination task by considering both sides' syntactic structure information. We evaluate and integrate the two technologies into forest-based tree to tree sequence translation. Experimental results on the NIST-2003 and NIST-2005 Chinese-English translation tasks show that our methods significantly outperform the forest-based tree to string and previous tree to tree models as well as the phrase-based model.

The remaining of the paper is organized as following. Section 2 reviews the related work. In section 3 and section 4, we discuss the proposed forest-based rule extraction (non-isomorphic mapping) and decoding algorithms (target syntax information usage). Finally we report the experimental results in section 5 and conclude the paper in section 6.

2 Related Work

Much effort has been done in the syntax-based translation modeling. Yamada and Knight (2001) propose a string to tree model. Galley *et al.* (2004) propose the GHKM scheme to model the string-to-tree mapping. Liu *et al.* (2006) propose a tree-to-string translation model. Liu *et al.* (2007) propose the tree sequence to string model to capture rules covered by continuous sequence of trees. Shieber (2007), DeNeefe and Knight (2009) and Carreras and Collins (2009) propose synchronous tree adjoin grammar to capture more tree-string mapping beyond the GHKM scheme. Zhang *et al.* (2009a) propose the concept of virtual node to reform a tree sequence as a tree, and design efficient algorithms for tree sequence model in forest context. All these works only consider either the source side or the target side syntax information.

To capture both side syntax contexts, Eisner (2003) studies the bilingual dependency tree-to-tree mapping in conceptual level. Zhang *et al.* (2008) propose tree sequence-based tree-to-tree modeling. Liu *et al.* (2009) propose efficient algorithms for tree-to-tree model in the forest-based training and decoding scheme. One common limitation of the above works is they only allow the one-to-one mapping between each non-terminal frontier node, and thus they suffer from the issue of rule coverage. On the other hand, due to the data sparseness issue and model coverage issue, previous tree-to-tree (Zhang *et al.*, 2008; Liu *et al.*, 2009) decoder has to rely solely on the span information or source side information to combine the target syntactic structures, without checking the compatibility of the merging nodes, in order not to fail many translation paths. Thus, this solution fails to effectively utilize the target structure information.

To address this issue, tree sequence (Liu *et al.*, 2007; Zhang *et al.*, 2008) and virtual node (Zhang *et al.*, 2009a) are two concepts with promising results reported. In this paper, with the help of these two concepts, we propose a novel framework to solve the one-to-many non-isomorphic mapping issue. In addition, our proposed solution of using target syntax information enables our forest-based tree-to-tree sequence translation decoding algorithm to not only capture bilingual forest information but also have almost the same complexity as forest-based tree-to-string translation. This reduces the time/space complexity exponentially.

3 Tree to Tree Sequence Rules

The motivation of introducing tree to tree sequence rules is to add target syntax information to tree-to-string rules. Following, we first briefly review the definition of tree-to-string rules, and then describe the tree-to-tree sequence rules.

[1] A packed forest is a compact representation of a set of trees with sharing substructures; formally, it is defined as a triple a triple$< V,E,S >$, where V is non-terminal node set, E is hyper-edge set and S is leaf node set (i.e. all sentence words). Every node in V covers a consecutive sequence of leaf, every hyper-edge in E connect the father node to its children nodes as in a tree. Figure 8 is a packed forest contains two trees.

3.1 Tree to String Rules

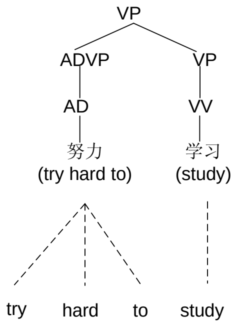

Fig. 1. A word-aligned sentence pair with source tree

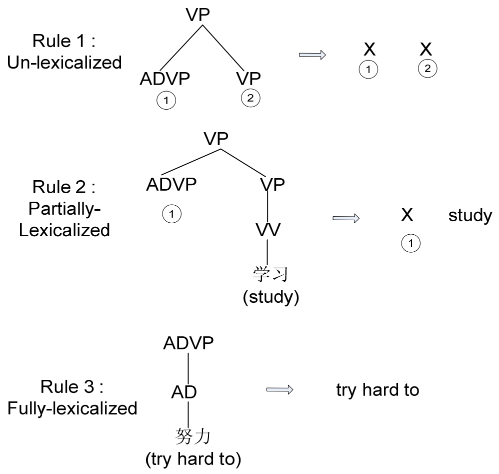

Fig. 2 Examples of tree to string rules

Fig. 2 illustrates the examples of tree to string rules extracted from Fig. 1. The tree-to-string rule is very simple. Its source side is a sub-tree of source parse tree and its target side is a string with only one variable/non-terminal X. The source side and the target side is translation of each other with the constraint of word alignments. Please note that there is no any target syntactic or linguistic information used in the tree-to-string model.

3.2 Tree to Tree Sequence Rules

It is more challenging when extracting rules with target tree structure as constraint. Fig. 3 extends Fig. 1 with target tree structure. The problem is that, given a source tree node, we are able to find its target string translation, but these target string may not form a linguistic sub-tree. For example, in Fig. 3, the source tree node "ADVP" in solid eclipse is translated to "try hard to" in the target sentence, but there is no corresponding sub-tree covering and only covering it in the target side.

Given the example rules in Fig. 2, what are their corresponding rules with target syntax information? The answer is that the previous tree or tree sequence-based models fail to model the Rule 1 and Rule 2 at Fig. 2, since at frontier node level they only allow one-to-one node mapping but the solution is one-to-many non-terminal frontier node mapping. The concept of "virtual node" (Zhang *et al.* 2009a) is a solution to this issue. To facilitate discussion, we first introduce three concepts.

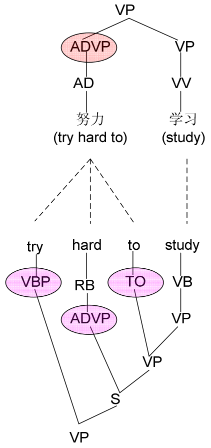

Fig. 3. A word-aligned bi-parsed tree

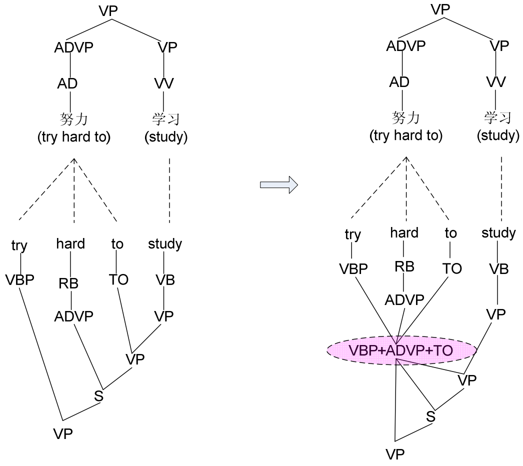

Fig. 4. A restructured tree with a virtual span root

- **Def. 1**. The ***"node sequence"*** is a sequence of nodes (either leaf or internal nodes) covering a consecutive span. For example, in Fig 3, "VBP RB TO" and "VBP ADVP TO" are two "node sequence" covering the same span "try hard to".

- **Def. 2**. The "***root node sequence***" of a span is such a node sequence that any node in this sequence could not be a child of a node in other node sequence of the span. Intuitively, the "*root node sequence*" of a span is the node sequence with the highest topology level. For example, "VBP ADVP TO" is the "root node sequence" of the span of "try hard to". It is easy to prove that given any span, there exist one and only one "*root node sequence*".

- **Def. 3**. The "***span root***" of a span is such a node that if the "*root node sequence*" contains only one tree node, then the "*span root*" is this tree node; otherwise, the "*span root*" is the virtual father node (Zhang *et al*., 2009a) of the "*root node sequence*". Fig. 4 illustrates the reformed Fig. 3 by introducing the virtual node "VBP+ADVP+TO" as the "span root" of the span of "try hard to".

The "*span root*" facilitates us to extract rules with target side structure information. Given a sub-tree of the source tree, we have a set of non-terminal frontier nodes. For each such frontier node, we can find its corresponding target "*span root*". If the "*span root*" is a virtual node, then we add it into the target tree as a virtual segmentation joint point. After adding the "span root" as joint point, we are able to ensure that each frontier source node has only one corresponding target node, then we can use any traditional rule extraction algorithm to extract rules, including those rules with one-to-many non-terminal frontier mappings.

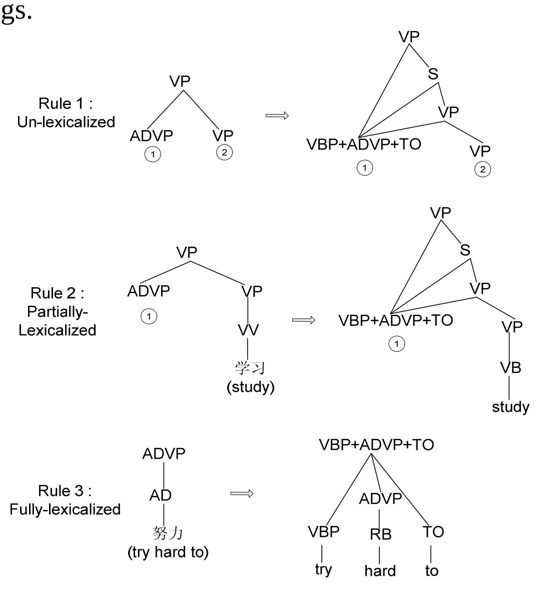

Fig. 5. Tree-to-tree sequence rules

Fig. 5 lists the corresponding rules with target structure information of the tree-to-string rules in Fig 2. All the three rules cannot be extracted by previous tree-to-tree mapping methods (Liu *et al*., 2009). The previous tree-sequence-based methods (Zhang *et al*., 2008; Zhang *et al*., 2009a) can extracted rule 3 since they allow one-to-many mapping in root node level. But they cannot extract rule 1 and rule 2. Therefore, for any tree-to-string rule, our method can always find the corresponding tree-to-tree sequence rule. As a result, our rule coverage is the same as tree-to-string framework while our rules contain more informative target syntax information. Later we will show that using our decoding algorithm the tree-to-tree sequence search space is exponentially reduced to the same as tree-to-string search space. That is to say, we do not need to worry about the exponential search space issue of tree-to-tree sequence model existing in previous work.

3.3 Rule Extraction in Tree Context

Given a word aligned tree pair, we first extract the set of minimum tree to string rules (Galley *et al.* 2004), then for each tree-to-string rule, we can easily extract its corresponding tree-to-tree sequence rule by introducing the virtual span root node. After that, we generate the composite rules by iteratively combining small rules.

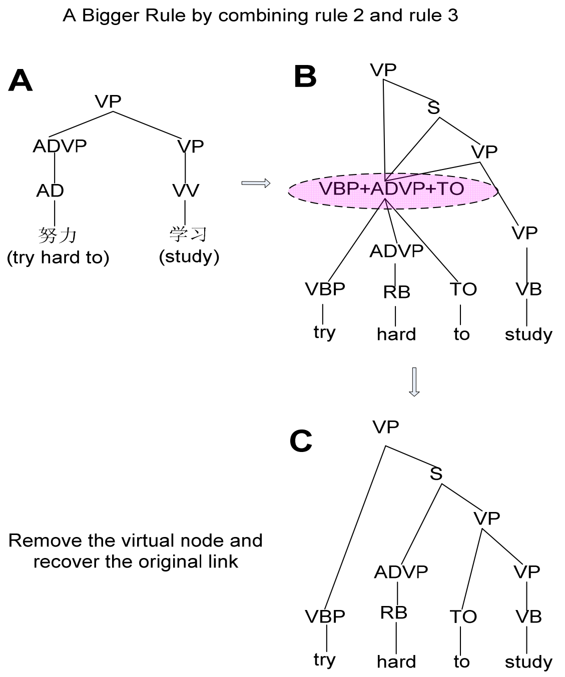

Fig. 6. Rule combination and virtual node removing

Please note that in generating composite rules, if the joint node is a virtual node, we have to recover the original link and remove this virtual node to avoid unnecessary ambiguity. Fig. 6 illustrates the combination process of rule 2 and rule 3 in Fig. 5. As a result, all of our extract rules do not contain any internal virtual nodes.

3.4 Rule Extraction in Forest Context

In forest pair context, we also first generate the minimum tree-to-string rule set as Mi *et al.* (2008), and for each tree-to-string rule, we find its corresponding tree-to-tree sequence rules, and then do rule composition.

In tree pair context, given a tree-to-string rule, there is one and only one corresponding tree-to-tree sequence rule. But in forest pair context, given one such tree-to-string rule, there are many corresponding tree-to-tree sequence rules. All these sub-trees form one or more sub-forests[2] of the entire big target forest. If we can identify the sub-forests, i.e., all of the hyper-edges of the sub-forests, we can retrieve all the sub-trees from the sub-forests as the target sides of the corresponding tree-to-tree sequence rules.

Given a source sub-tree, we can obtain the target root span where the target sub-forests start and the frontier spans where the target sub-forests stop. To indentify all the hyper-edges in the sub-forests, we start from every node covering the root span, traverse from top to down, mark all the hyper-edges visited and stop at the node if its span is a sub-span of one of the forest frontier spans or if it is a word node. The reason we stop at the node once it fell into a frontier span (i.e. the span of the node is a sub-span of the frontier span) is to guarantee that given any frontier span, we could stop at the "*root node sequence*" of this span by **Def.** 2.

For example, Fig. 7 is a source sub-tree of rule 2 in Fig. 5 and the circled part in Fig. 8 is one of its corresponding target sub-forests. Its corresponding target root span is [1,4] (corresponding to source root "VP") and its corresponding target frontier span is {[1,3], study[4,4]}. Now given the target forest, we start from node VP[1,4] and traverse from top to down, finally stop at following nodes: VBP[1,1], ADVP[2,2], TO[3,3], study .

Please note that the starting root node must be a single node, being either a normal forest node or a virtual "span root" node. The virtual "span root" node serves as the frontier node of upper rules and root node of the currently being extracted rules. Because we extract rules in a top-to-down manner, the necessary virtual "span root" node for current sub-forest has already been added into the global forest when extracting upper level rules.

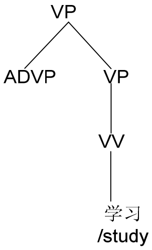

Figure 7. A source sub-tree in rule 2

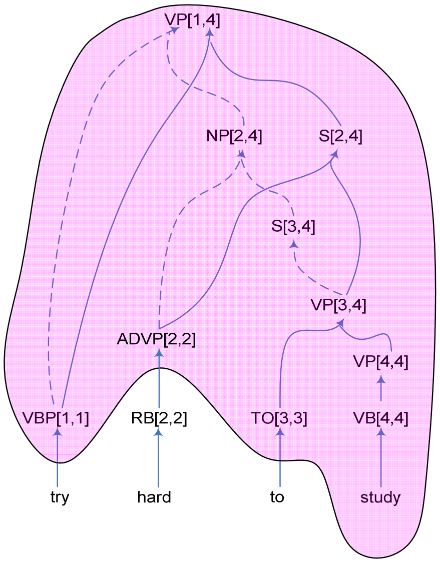

Fig. 8. The corresponding target sub-forest for the tree of Figure 7.

3.5 Fractional Count of Rule

Following Mi and Huang (2008) and Liu *et al.* (2009), we assign a fractional count to a rule to measure how likely it appears given the context of the forest pair. In following equation, "S" means source sub-tree, "T" means target sub-tree, "SF" is source forest and "TF" is the target forest.

$$P(S,T\,|SF,TF) \cong P(S|SF,TF) * P(T|SF,TF)$$
$$\cong P(S|SF) * P(T|TF)$$

[2] All the sub-forests cover the same span. But their roots have different grammar tags as the roots' names. The root may be a virtual span root node in the case of the one-to-many frontier non-terminal node mappings.

The above equation means the fractional count of a source-target tree pair is just the product of each of their fractional count in corresponding forest context in following equation.

$$P(subtree\ |Forest) = \frac{\alpha\beta(subtree)}{\alpha\beta(forest\ root)}$$
$$= \frac{\alpha(subtree\ root) * \prod_{h \in subtree} P(h) * \prod_{v \in leaves(subtree)} \beta(v)}{\alpha\beta(forest\ root)}$$

where α and β are the outside and inside probabilities. In addition, if a sub-tree root is a virtual node (formed by a root node sequence), then we use following equation to approximate the outside probability of the virtual node.

$$\alpha(node\ sequence\ ns) = \sqrt[\#\ of\ nodes\ in\ ns]{\prod_{n \in ns} \alpha(n)}$$

4 Decoding

4.1 Traditional Forest-based Decoding

A typical translation process of a forest-based system is to first convert the source packed forest into a target translation forest, and then apply search algorithm to find the best translation result from this target translation forest (Mi *et al.*, 2008).

For the tree-to-string model, the forest conversion process is as following: given an input packed forest, we do pattern matching (Zhang *et al.*, 2009b) with the source side structures in the rule set. For each matched rule, we establish its target side as a hyper-edge in the target forest.

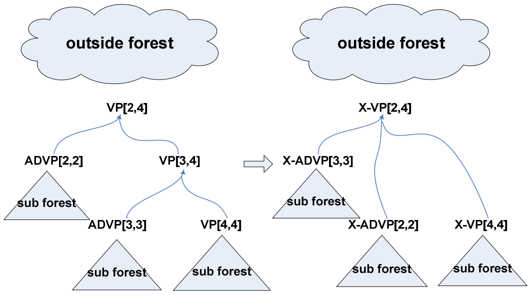

Fig. 9. A forest conversion step in a tree to string model

Fig. 9 exemplifies a conversion step in the tree to string model. A sub-tree structure with two hyper-edge "*VP[2,4] => ADVP[2,2] VP[3,4]*" and "*VP[3,4] => ADVP[3,4] VP[4,4]*" is converted into a target hyper-edge "*X-VP[2,4] => X-ADVP[3,3] X-ADVP[2,2] X-VP[4,4]* ". The node "*X-VP[4,4]*" in the target forest means that its syntactic label in target forest is "X" and it is translated from the source node "VP[4,4]" in the source forest. In this target hyper-edge, "*X-ADVP[3,3] X-ADVP[2,2]*" means the translation from source node "*ADVP[3,3]*" is put before the translation from "*ADVP[2,2]*", representing a structure reordering.

4.2 Toward Bilingual Syntax-aware Translation Generation

As we could see in section 4.1, there is only one kind of non-terminal symbol "X" in the target side. It is a big challenge to rely on such a coarse label to generate a translation with fine syntactic quality. For example, a source node may be translated into a "NP" (noun phrase) in target side. However, in this rule set with the only symbol "X", it may be merged with upper structure as a "VP" (verb phrase) instead, because there is no way to favor one over another. In this case, the target tree does not well model the translation syntactically. In addition, all of the internal structure information in the target side is ignored by the tree-to-string rules.

One natural solution to the above issue is to use the tree to tree/tree sequence model, which have richer target syntax structures for more discriminative probability and finer labels to guide the combination process. However, the tree to tree/tree sequence model may face very severe computational problem and so-called "spurious ambiguities" issue.

Theoretically, if in the tree-to-tree sequence model-based decoding, we just give a penalty to the incompatible-node combinations instead of pruning out the translation paths, then the set of sentences generated by the tree-to-tree sequence model is identical to that of the tree-to-string model since every tree-to-tree sequence rule can be projected into a tree-to-string rule. Motivated by this, we propose a solution call parallel hypothesis spaces searching to solve the computational and "spurious ambiguities" issues mentioned above. In the meanwhile, we can fully utilize the target structure information to guide translation.

We restructure the tree-to-tree sequence rule set by grouping all the rules according to their corresponding tree-to-string rules. This behaves like a "tree-to-forest" rule. The "forest" encodes all the tree sequences with same corresponding string. With the re-constructed rule set, during decoding, we generate two target translation hypothesis spaces (in the form of packed forests) synchronously by the tree-to-string rules and tree-to-tree sequence rules, and maintain the projection between them. In other words, we generate hypothesis (searching) from the tree-to-string forest and calculate the probability (evaluating syntax goodness) for each hypothesis by the hyper-edges in the tree-to-tree sequence forest.

4.3 Parallel Hypothesis Spaces

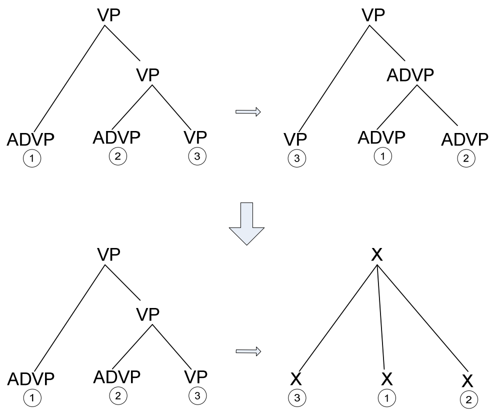

Fig. 10. Mapping from tree-to-tree sequence into tree-to-string rule

In this subsection, we describe what the parallel search spaces are and how to construct them. As shown at Fig. 10, given a tree-to-tree sequence rule, it is easy to find its corresponding tree-to-string rule by simply ignoring the target inside structure and renaming the root and leaves non-terminal labels into “X”. We iterate through the tree-to-tree sequence rule set, find its corresponding tree-to-string rule and then group those rules with the same tree-to-string projection. After that, the original tree-to-tree sequence rule set becomes a set of smaller rule sets. Each of them is indexed by a unique tree-to-string rule.

We apply the tree-to-string rules to generate an explicit target translation forest to represent the target sentences space. At the same time, whenever a tree-to-string rule is applied, we also retrieve its corresponding tree-to-tree sequence rule set and generate a set of latent hyper-edges with fine-grained syntax information. In this case, we have two parallel forests, one with coarse explicit hyper-edges and the other fine and latent. Given a hyper-edge (or a node) in the coarse forest, there are a group of corresponding latent hyper-edges (or nodes) with finer syntax labels in the fine forest. Accordingly, given a tree in the coarse forest, there is a corresponding sub-forest in the latent fine forest. We can view the latent fine forest as imbedded inside the explicit coarse forest. If an explicit hyper-edge is viewed as a big cable, then the group of its corresponding latent hyper-edges is the small wires inside it.

We rely on the explicit hyper-edges to enumerate possible hypothesis while using the latent hyper-edges to measure its translation probability and syntax goodness. Thus, the complexity of the search space is reduced into the tree-to-string model level, while keeping the target language generation syntactic aware. More importantly, we thoroughly avoid those spurious ambiguities introduced by the tree-to-tree sequence rules.

4.4 Decoding with Parallel Hypothesis Spaces

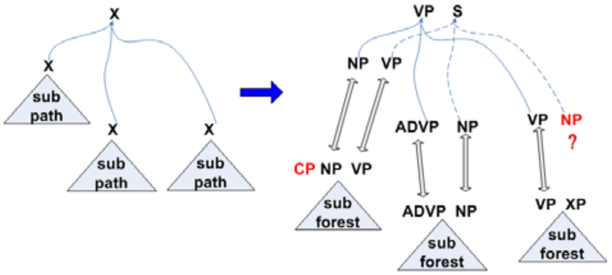

Fig. 11. Derivation path and derivation forest

In this subsection, we show exactly how our decoder finds the best result from the parallel spaces. We generate hypothesis by traversing the coarse forest in the parallel spaces with cube-pruning (Huang and Chiang, 2007). Given a newly generated hypothesis, it is affiliated with a derivation path (tree) in the coarse forest and a group of derivation paths (sub-forest) in the finer forest. As shown in Fig. 11, the left part is the derivation path formed by a coarse hyper-edge, consisting the newly-generated sub-tree “X => X X X” connecting with three previously-generated sub paths while the right part is the derivation forest formed by newly-generated finer hyper-edges rooted at “VP” and “S”, and previously-generated sub-forests.

In this paper, we use the sum of probabilities of all the derivation paths in the finer forest to measure the quality of the candidate translation suggested by the hypothesis. From Fig. 11, we can see there may be more than one corresponding finer forests, it is easy to understand that the sum of all the trees’ probabilities in these finer forests is equal to the sum of the inside probability of all these root nodes of these finer forests. We adopt the dynamic programming to compute the probability of the finer forest: whenever we generate a new hypothesis by concatenating a coarse hyper-edge and its sub-path, we find its corresponding finer hyper-edges and sub-forests, do the combination and accumulate probabilities from bottom to up. For the coarse hyper-edge, because there is only one label "X", any sub-path could be easily concatenated with upper structure covering the same sub-span without the need of checking label compatibility. While for the finer hyper-edges, we only link the root nodes of sub-forests to upper hyper-edges with the same linking node label. This is to guarantee syntactic goodness. In case there are some leaf nodes of the upper hyper-edges fail to find corresponding sub-forest roots with the same label (e.g. the "NP" in red color in the rightmost of Fig 11), we simply link it into the nodes with the least inside probability (among these sub-forests), and at the same time give a penalty score to this combination. If some root nodes of some sub-forest still cannot find upper leaf nodes to concatenate (e.g. the "CP" in red color in Fig. 11), we simply ignore them. After the combination process, it is straightforward to accumulate the inside probability dynamically from bottom up.

5 Experiment

5.1 Experimental Settings

We evaluate our method on the Chinese-English translation task. We first carry out a series empirical study on a set of parallel data with 30K sentence pairs, and then do experiment on a larger data set to ensure that the effectiveness of our method is consistent across data set of different size. We use the NIST 2002 test set as our dev set, and NIST 2003 and NIST 2005 test sets as our test set. A 3-gram language model is trained on the target side of the training data by the SRILM Toolkits (Stolcke, 2002) with modified Kneser-Ney smoothing (Kneser and Ney, 1995). We train Charniak's parser (Charniak, 2000) on CTB5.0 for Chinese and ETB3.0 for English and modify it to output packed forest. GIZA++ (Och and Ney, 2003) and the heuristics "grow-diag-final-and" are used to generate *m-to-n* word alignments. For the MER training (Och, 2003), Koehn's MER trainer (Koehn, 2007) is modified for our system. For significance test, we use Zhang *et al.*'s implementation (Zhang *et al*, 2004). Our evaluation metrics is *case-sensitive closest* BLEU-4 (Papineni *et al.*, 2002). We use following features in our systems: 1) bidirectional tree-to-tree sequence probability, 2) bidirectional tree-to-string probability, 3) bidirectional lexical translation probability, 4) target language model, 5) source tree probability 6) the average number of unmatched nodes in the target forest. 7) the length of the target translation, 8) the number of glue rules used.

5.2 Empirical Study on Small Data

We set forest pruning threshold (Mi *et al*., 2008) to 8 on both source and target forests for rule extraction. For each source sub-tree, we set its height up to 3, width up to 7 and extract up to 10-best target structures. In decoding, we set the pruning threshold to 10 for the input source forest. Table 1 compares the performance in NIST 2003 data set of our method and several state-of-the-art systems as our baseline.

1) **MOSES**: phrase-based system (Koehn *et al*., 2007)
2) **FT2S**: forest-based tree-to-string system (Mi and Huang, 2008; Mi *et al*., 2008)
3) **FT2T**: forest-based tree-to-tree system (Liu *et al*., 2009).
4) **FT2TS (1to1)**: our forest-based tree-to-tree sequence system, where 1to1 means only one-to-one frontier non-terminal node mapping is allowed, thus the system does not follow our non-isomorphic mapping framework.
5) **FT2TS (1toN)**: our forest-based tree-to-tree sequence system that allows one-to-many frontier non-terminal node mapping by following our non-isomorphic mapping framework

In addition, our proposed parallel searching space (**PSS**) technology can be applied to both tree to tree and tree to sequence systems. Thus in table 1, for the tree-to-tree/tree sequence systems, we report two BLEU scores, one uses this technology (withPSS) and one does not (noPSS).

Model		**BLEU-4**
MOSES		23.39
FT2S		26.10
FT2T	noPSS	23.40
	withPSS	24.46
FT2TS (1to1)	noPSS	25.39
	withPSS	26.58
FT2TS (1toN)	noPSS	26.30
	withPSS	**27.70**

Table 1. Performance comparison of different methods

From Table 1, we can see that:

1) All the syntax-based systems (except FT2T (noPSS) (23.40)) consistently outperform the phrase-based system MOSES significantly ($p < 0.01$), indicating that syntactic knowledge is very useful to SMT.
2) The PSS technology shows significant performance improvement ($p < 0.01$) in all models, which clearly shows effectiveness of the PSS technology in utilizing target structures for target language generation.
3) FT2TS (1toN) significantly outperforms ($p < 0.01$) FT2TS (1to1) in both cases (noPSS and withPSS). This convincingly shows the effectiveness of our non-isomorphic mapping framework in capturing the non-isomorphic structure translation equivalences.
4) Both FT2TS systems significantly outperform FT2T($p < 0.01$). This verifies the effectiveness of tree sequence rules.
5) FT2TS shows different level of performance improvements over FT2S with the best case having 1.6 (27.70-26.10) BLEU score improvement over FT2S. This suggests that the target structure information is very useful, but we need to find a correct way to effectively utilize it.

1to1	1toN	ratio
1735871	2363771	1:1.36

Table 2. Statistics on node mapping in forest, where “1to1” means the number of nodes in source forest that can be translated into one node in target forest and “1toN” means the number of nodes in source forest that have to be translated into more than one node in target forest, where the node refers to non-terminal nodes only

Model	# of rules	T2S covered
FT2T	295732	26.8%
FT2TS(1to1)	631487	57.1%
FT2TS (1toN)	1945168	100%

Table 3. Statistics of rule coverage, where “T2S covered” means the percentage of tree-to-string rules that can be covered by the model

Table 2 studies the node isomorphism between bilingual forest pair. We can see that the non-isomorphic node translation mapping (1toN) accounts for 57.6% (=1.36/(1+1.36)) of all the forest non-terminal nodes with target translation. This means that the one-to-many node mapping is a major issue in structure transformation. It also empirically justifies the importance of our non-isomorphic mapping framework.

Table 3 shows the rule coverage of different bilingual structure mapping model. FT2T only covers 26.8% tree-to-string rules, so it performs worse than FT2S as shown in Table 1. FT2TS (1to1) does not allow one-to-many frontier node mapping, so it could only recover the non-isomorphic node mapping in the root level, while FT2TS (1toN) could make it at both root and leaf levels. Therefore, it is not surprising that in Table 3, FT2TS (1toN) cover many more rules than FT2TS (1to1) because given a source tree, there are many leaves, if any one of them is non-isomorphic, then it could not be covered by the FT2TS (1to1).

Decoding Method	BLEU-4	Speed (sec/sent)
Traditional: FT2TS (1toN) (**noPPS**)	26.30	152.6
Ours: FT2TS (1toN) (**withPPS**)	**27.70**	5.22

Table 4. Performance and speed comparison

Table 4 clearly shows the advantage of our decoder over the traditional one. Ours could not only generate better translation result, but also be 152.6/5.22>30 times faster. This mainly attributes to two reasons: 1) one-to-many frontier node mapping equipments the model with more ability to capture more non-isomorphic structure mappings than traditional models, and 2) “parallel search space” enables the decoder to fully utilize target syntactic information, but keeping the size of search space the same as that a “tree to string” model explores.

5.3 Results on Larger Data Set

We also carry out experiment on a larger dataset consisting of the small dataset used in last section and the FBIS corpus. In total, there are 280K parallel sentence pairs with 9.3M Chinese words and 11.8M English words. A 3-gram language model is trained on the target side of the parallel corpus and the GIGA3 Xinhua portion. We compare our system (FT2TS with 1toN and withPPS) with two state-of-the-art baselines: the phrase-based system MOSES and the forest-based tree-to-string system implemented by us. Table 5 clearly shows the effectiveness of our method is consistent across small and larger corpora, outperforming FT2S by 1.6-1.8 BLEU and the MOSES by 3.3-4.0 BLEU statistically significantly (p<0.01).

Model	**BLEU**	
	NIST2003	**NIST2005**
MOSES	29.51	27.53
FT2S	31.21	29.72
FT2TS	**32.88**	**31.50**

Table 5. Performance on larger data set

6 Conclusions

In this paper, we propose a framework to address the issue of bilingual non-isomorphic structure mapping and a novel parallel searching space scheme to effectively utilize target syntactic structure information in the context of forest-based tree to tree sequence machine translation. Based on this framework, we design an efficient algorithm to extract tree-to-tree sequence translation rules from word aligned bilingual forest pairs. We also elaborate the parallel searching space-based decoding algorithm and the node label checking scheme, which leads to very efficient decoding speed as fast as the forest-based tree-to-string model does, at the same time is able to utilize informative target structure knowledge. We evaluate our methods on both small and large training data sets and two NIST test sets. Experimental results show our methods statistically significantly outperform the state-of-the-art models across different size of corpora and different test sets. In the future, we are interested in testing our algorithm at forest-based tree sequence to tree sequence translation.

Discriminative Instance Weighting for Domain Adaptation in Statistical Machine Translation

Abstract

We describe a new approach to SMT adaptation that weights out-of-domain phrase pairs according to their relevance to the target domain, determined by both how similar to it they appear to be, and whether they belong to general language or not. This extends previous work on discriminative weighting by using a finer granularity, focusing on the properties of instances rather than corpus components, and using a simpler training procedure. We incorporate instance weighting into a mixture-model framework, and find that it yields consistent improvements over a wide range of baselines.

1 Introduction

Domain adaptation is a common concern when optimizing empirical NLP applications. Even when there is training data available in the domain of interest, there is often additional data from other domains that could in principle be used to improve performance. Realizing gains in practice can be challenging, however, particularly when the target domain is distant from the background data. For developers of Statistical Machine Translation (SMT) systems, an additional complication is the heterogeneous nature of SMT components (word-alignment model, language model, translation model, etc.), which precludes a single universal approach to adaptation.

In this paper we study the problem of using a parallel corpus from a background domain (OUT) to improve performance on a target domain (IN) for which a smaller amount of parallel training material—though adequate for reasonable performance—is also available. This is a standard adaptation problem for SMT. It is difficult when IN and OUT are dissimilar, as they are in the cases we study. For simplicity, we assume that OUT is homogeneous. The techniques we develop can be extended in a relatively straightforward manner to the more general case when OUT consists of multiple sub-domains.

There is a fairly large body of work on SMT adaptation. We introduce several new ideas. First, we aim to explicitly characterize examples from OUT as belonging to general language or not. Previous approaches have tried to find examples that are similar to the target domain. This is less effective in our setting, where IN and OUT are disparate. The idea of distinguishing between general and domain-specific examples is due to Daumé and Marcu (2006), who used a maximum-entropy model with latent variables to capture the degree of specificity. Daumé (2007) applies a related idea in a simpler way, by splitting features into general and domain-specific versions. This highly effective approach is not directly applicable to the multinomial models used for core SMT components, which have no natural method for combining split features, so we rely on an instance-weighting approach (Jiang and Zhai, 2007) to downweight domain-specific examples in OUT. Within this framework, we use features intended to capture degree of generality, including the output from an SVM classifier that uses the intersection between IN and OUT as positive examples.

Our second contribution is to apply instance

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 451–459,
MIT, Massachusetts, USA, 9-11 October 2010.

weighting at the level of phrase pairs. Sentence pairs are the natural instances for SMT, but sentences often contain a mix of domain-specific and general language. For instance, the sentence *Similar improvements in haemoglobin levels were reported in the scientific literature for other epoetins* would likely be considered domain-specific despite the presence of general phrases like *were reported in*. Phrase-level granularity distinguishes our work from previous work by Matsoukas et al (2009), who weight sentences according to sub-corpus and genre membership.

Finally, we make some improvements to baseline approaches. We train linear mixture models for conditional phrase pair probabilities over IN and OUT so as to maximize the likelihood of an empirical joint phrase-pair distribution extracted from a development set. This is a simple and effective alternative to setting weights discriminatively to maximize a metric such as BLEU. A similar maximum-likelihood approach was used by Foster and Kuhn (2007), but for language models only. For comparison to information-retrieval inspired baselines, eg (Lü et al., 2007), we select sentences from OUT using language model perplexities from IN. This is a straightforward technique that is arguably better suited to the adaptation task than the standard method of treating representative IN sentences as queries, then pooling the match results.

The paper is structured as follows. Section 2 describes our baseline techniques for SMT adaptation, and section 3 describes the instance-weighting approach. Experiments are presented in section 4. Section 5 covers relevant previous work on SMT adaptation, and section 6 concludes.

2 Baseline SMT Adaptation Techniques

Standard SMT systems have a hierarchical parameter structure: top-level log-linear weights are used to combine a small set of complex features, interpreted as log probabilities, many of which have their own internal parameters and objectives. The top-level weights are trained to maximize a metric such as BLEU on a small development set of approximately 1000 sentence pairs. Thus, provided at least this amount of IN data is available—as it is in our setting—adapting these weights is straightforward. We focus here instead on adapting the two most important features: the language model (LM), which estimates the probability $p(w|h)$ of a target word w following an ngram h; and the translation models (TM) $p(s|t)$ and $p(t|s)$, which give the probability of source phrase s translating to target phrase t, and vice versa. We do not adapt the alignment procedure for generating the phrase table from which the TM distributions are derived.

2.1 Simple Baselines

The natural baseline approach is to concatenate data from IN and OUT. Its success depends on the two domains being relatively close, and on the OUT corpus not being so large as to overwhelm the contribution of IN.

When OUT is large and distinct, its contribution can be controlled by training separate IN and OUT models, and weighting their combination. An easy way to achieve this is to put the domain-specific LMs and TMs into the top-level log-linear model and learn optimal weights with MERT (Och, 2003). This has the potential drawback of increasing the number of features, which can make MERT less stable (Foster and Kuhn, 2009).

2.2 Linear Combinations

Apart from MERT difficulties, a conceptual problem with log-linear combination is that it multiplies feature probabilities, essentially forcing different features to agree on high-scoring candidates. This is appropriate in cases where it is sanctioned by Bayes' law, such as multiplying LM and TM probabilities, but for adaptation a more suitable framework is often a mixture model in which each event may be generated from some domain. This leads to a linear combination of domain-specific probabilities, with weights in $[0, 1]$, normalized to sum to 1.

Linear weights are difficult to incorporate into the standard MERT procedure because they are "hidden" within a top-level probability that represents the linear combination.[1] Following previous work (Foster and Kuhn, 2007), we circumvent this problem by choosing weights to optimize corpus log-likelihood, which is roughly speaking the training criterion used by the LM and TM themselves.

[1] This precludes the use of exact line-maximization within Powell's algorithm (Och, 2003), for instance.

For the LM, adaptive weights are set as follows:

$$\hat{\alpha} = \underset{\alpha}{\operatorname{argmax}} \sum_{w,h} \tilde{p}(w,h) \log \sum_i \alpha_i p_i(w|h), \quad (1)$$

where α is a weight vector containing an element α_i for each domain (just IN and OUT in our case), p_i are the corresponding domain-specific models, and $\tilde{p}(w,h)$ is an empirical distribution from a target-language training corpus—we used the IN dev set for this.

It is not immediately obvious how to formulate an equivalent to equation (1) for an adapted TM, because there is no well-defined objective for learning TMs from parallel corpora. This has led previous workers to adopt ad hoc linear weighting schemes (Finch and Sumita, 2008; Foster and Kuhn, 2007; Lü et al., 2007). However, we note that the final conditional estimates $p(s|t)$ from a given phrase table maximize the likelihood of joint empirical phrase pair counts over a word-aligned corpus. This suggests a direct parallel to (1):

$$\hat{\alpha} = \underset{\alpha}{\operatorname{argmax}} \sum_{s,t} \tilde{p}(s,t) \log \sum_i \alpha_i p_i(s|t), \quad (2)$$

where $\tilde{p}(s,t)$ is a joint empirical distribution extracted from the IN dev set using the standard procedure.[2]

An alternative form of linear combination is a *maximum a posteriori* (MAP) combination (Bacchiani et al., 2004). For the TM, this is:

$$p(s|t) = \frac{c_I(s,t) + \beta\, p_o(s|t)}{c_I(t) + \beta}, \quad (3)$$

where $c_I(s,t)$ is the count in the IN phrase table of pair (s,t), $p_o(s|t)$ is its probability under the OUT TM, and $c_I(t) = \sum_{s'} c_I(s',t)$. This is motivated by taking $\beta\, p_o(s|t)$ to be the parameters of a Dirichlet prior on phrase probabilities, then maximizing posterior estimates $p(s|t)$ given the IN corpus. Intuitively, it places more weight on OUT when less evidence from IN is available. To set β, we used the same criterion as for α, over a dev corpus:

$$\hat{\beta} = \underset{\beta}{\operatorname{argmax}} \sum_{s,t} \tilde{p}(s,t) \log \frac{c_I(s,t) + \beta\, p_o(s|t)}{c_I(t) + \beta}.$$

The MAP combination was used for TM probabilities only, in part due to a technical difficulty in formulating coherent counts when using standard LM smoothing techniques (Kneser and Ney, 1995).[3]

2.3 Sentence Selection

Motivated by information retrieval, a number of approaches choose "relevant" sentence pairs from OUT by matching individual source sentences from IN (Hildebrand et al., 2005; Lü et al., 2007), or individual target hypotheses (Zhao et al., 2004). The matching sentence pairs are then added to the IN corpus, and the system is re-trained. Although matching is done at the sentence level, this information is subsequently discarded when all matches are pooled.

To approximate these baselines, we implemented a very simple sentence selection algorithm in which parallel sentence pairs from OUT are ranked by the perplexity of their target half according to the IN language model. The number of top-ranked pairs to retain is chosen to optimize dev-set BLEU score.

3 Instance Weighting

The sentence-selection approach is crude in that it imposes a binary distinction between useful and non-useful parts of OUT. Matsoukas et al (2009) generalize it by learning weights on sentence pairs that are used when estimating relative-frequency phrase-pair probabilities. The weight on each sentence is a value in $[0,1]$ computed by a perceptron with Boolean features that indicate collection and genre membership.

We extend the Matsoukas et al approach in several ways. First, we learn weights on individual phrase pairs rather than sentences. Intuitively, as suggested by the example in the introduction, this is the right granularity to capture domain effects. Second, rather than relying on a division of the corpus into manually-assigned portions, we use features intended to capture the usefulness of each phrase pair. Finally, we incorporate the instance-weighting model into a general linear combination, and learn weights and mixing parameters simultaneously.

[2] Using non-adapted IBM models trained on all available IN and OUT data.

[3] Bacchiani et al (2004) solve this problem by reconstituting joint counts from smoothed conditional estimates and unsmoothed marginals, but this seems somewhat unsatisfactory.

3.1 Model

The overall adapted TM is a combination of the form:

$$p(s|t) = \alpha_t \, p_I(s|t) + (1 - \alpha_t) \, p_o(s|t), \tag{4}$$

where $p_I(s|t)$ is derived from the IN corpus using relative-frequency estimates, and $p_o(s|t)$ is an instance-weighted model derived from the OUT corpus. This combination generalizes (2) and (3): we use either $\alpha_t = \alpha$ to obtain a fixed-weight linear combination, or $\alpha_t = c_I(t)/(c_I(t) + \beta)$ to obtain a MAP combination.

We model $p_o(s|t)$ using a MAP criterion over weighted phrase-pair counts:

$$p_o(s|t) = \frac{c_\lambda(s,t) + \gamma u(s|t)}{\sum_{s'} c_\lambda(s',t) + \gamma} \tag{5}$$

where $c_\lambda(s,t)$ is a modified count for pair (s,t) in OUT, $u(s|t)$ is a prior distribution, and γ is a prior weight. The original OUT counts $c_o(s,t)$ are weighted by a logistic function $w_\lambda(s,t)$:

$$\begin{aligned} c_\lambda(s,t) &= c_o(s,t) \; w_\lambda(s,t) \qquad (6) \\ &= c_o(s,t) \; [1 + \exp(-\sum_i \lambda_i f_i(s,t))]^{-1}, \end{aligned}$$

where each $f_i(s,t)$ is a feature intended to characterize the usefulness of (s,t), weighted by λ_i.

The mixing parameters and feature weights (collectively ϕ) are optimized simultaneously using dev-set maximum likelihood as before:

$$\hat{\phi} = \operatorname*{argmax}_{\phi} \sum_{s,t} \tilde{p}(s,t) \log p(s|t;\phi). \tag{7}$$

This is a somewhat less direct objective than used by Matsoukas et al, who make an iterative approximation to expected TER. However, it is robust, efficient, and easy to implement.[4]

To perform the maximization in (7), we used the popular L-BFGS algorithm (Liu and Nocedal, 1989), which requires gradient information. Dropping the conditioning on ϕ for brevity, and letting $\bar{c}_\lambda(s,t) = c_\lambda(s,t) + \gamma u(s|t)$, and $\bar{c}_\lambda(t) = \sum_{s'} \bar{c}_\lambda(s',t)$:

$$\begin{aligned} \frac{\partial \log p(s|t)}{\partial \alpha_t} &= k_t \left[\frac{p_I(s|t)}{p(s|t)} - \frac{p_o(s|t)}{p(s|t)} \right] \\ \frac{\partial \log p(s|t)}{\partial \gamma} &= \frac{1-\alpha_t}{p(s|t)} \left[\frac{u(s|t)}{\bar{c}_\lambda(t)} - \frac{\bar{c}_\lambda(s,t)}{\bar{c}_\lambda(t)^2} \right] \\ \frac{\partial \log p(s|t)}{\partial \lambda_i} &= \frac{1-\alpha_t}{p(s|t)} \left[\frac{c_{\lambda'_i}(s,t)}{\bar{c}_\lambda(t)} - \frac{\bar{c}_\lambda(s,t) c_{\lambda'_i}(t)}{\bar{c}_\lambda(t)^2} \right] \end{aligned}$$

where:

$$k_t = \begin{cases} 1 & \text{fixed weight} \\ -c_I(t)/(c_I(t)+\beta)^2 & \text{MAP} \end{cases}$$

$$c_{\lambda'_i}(s,t) = f_i(s,t)(1 - w_\lambda(s,t))c_\lambda(s,t)$$

and:

$$c_{\lambda'_i}(t) = \sum_{s'} c_{\lambda'_i}(s',t).$$

3.2 Interpretation and Variants

To motivate weighting joint OUT counts as in (6), we begin with the "ideal" objective for setting multinomial phrase probabilities $\theta = \{p(s|t), \forall st\}$, which is the likelihood with respect to the true IN distribution $p_{\hat{I}}(s,t)$. Jiang and Zhai (2007) suggest the following derivation, making use of the true OUT distribution $p_{\hat{o}}(s,t)$:

$$\begin{aligned} \hat{\theta} &= \operatorname*{argmax}_{\theta} \sum_{s,t} p_{\hat{I}}(s,t) \log p_\theta(s|t) \qquad (8) \\ &= \operatorname*{argmax}_{\theta} \sum_{s,t} \frac{p_{\hat{I}}(s,t)}{p_{\hat{o}}(s,t)} p_{\hat{o}}(s,t) \log p_\theta(s|t) \\ &\approx \operatorname*{argmax}_{\theta} \sum_{s,t} \frac{p_{\hat{I}}(s,t)}{p_{\hat{o}}(s,t)} c_o(s,t) \log p_\theta(s|t), \end{aligned}$$

where $c_o(s,t)$ are the counts from OUT, as in (6). This has solutions:

$$p_{\hat{\theta}}(s|t) = \frac{p_{\hat{I}}(s,t)}{p_{\hat{o}}(s,t)} c_o(s,t) / \sum_{s'} \frac{p_{\hat{I}}(s',t)}{p_{\hat{o}}(s',t)} c_o(s',t),$$

and from the similarity to (5), assuming $\gamma = 0$, we see that $w_\lambda(s,t)$ can be interpreted as approximating $p_{\hat{I}}(s,t)/p_{\hat{o}}(s,t)$. The logistic function, whose outputs are in $[0,1]$, forces $p_{\hat{I}}(s,t) \leq p_{\hat{o}}(s,t)$. This is not unreasonable given the application to phrase pairs from OUT, but it suggests that an interesting alternative might be to use a plain log-linear weighting

[4] Note that the probabilities in (7) need only be evaluated over the support of $\tilde{p}(s,t)$, which is quite small when this distribution is derived from a dev set. Maximizing (7) is thus much faster than a typical MERT run.

function $\exp(\sum_i \lambda_i f_i(s,t))$, with outputs in $[0,\infty]$. We have not yet tried this.

An alternate approximation to (8) would be to let $w_\lambda(s,t)$ directly approximate $p_{\hat{I}}(s,t)$. With the additional assumption that (s,t) can be restricted to the support of $c_o(s,t)$, this is equivalent to a "flat" alternative to (6) in which each non-zero $c_o(s,t)$ is set to one. This variant is tested in the experiments below.

A final alternate approach would be to combine weighted joint frequencies rather than conditional estimates, ie: $c_I(s,t) + w_\lambda(s,t)c_o(,s,t)$, suitably normalized.[5] Such an approach could be simulated by a MAP-style combination in which separate $\beta(t)$ values were maintained for each t. This would make the model more powerful, but at the cost of having to learn to downweight OUT separately for each t, which we suspect would require more training data for reliable performance. We have not explored this strategy.

3.3 Simple Features

We used 22 features for the logistic weighting model, divided into two groups: one intended to reflect the degree to which a phrase pair belongs to general language, and one intended to capture similarity to the IN domain.

The 14 general-language features embody straightforward cues: frequency, "centrality" as reflected in model scores, and lack of burstiness. They are:

- total number of tokens in the phrase pair (1);
- OUT corpus frequency (1);
- OUT-corpus frequencies of rarest source and target words (2);
- perplexities for OUT IBM1 models, in both directions (2);
- average and minimum source and target word "document frequencies" in the OUT corpus, using successive 100-line pseudo-documents[6] (4); and
- average and minimum source and target word values from the OUT corpus of the following statistic, intended to reflect degree of burstiness (higher values indicate less bursty behaviour): $g/(L - L/(l+1) + \epsilon)$, where g is the sum over all sentences containing the word of the distance (number of sentences) to the nearest sentence that also contains the word, L is the total number of sentences, l is the number of sentences that contain the word, and ϵ is a small constant (4).

The 8 similarity-to-IN features are based on word frequencies and scores from various models trained on the IN corpus:

- 1gram and 2gram source and target perplexities according to the IN LM (4);[7]
- source and target OOV counts with respect to IN (2); and
- perplexities for IN IBM1 models, in both directions (2).

To avoid numerical problems, each feature was normalized by subtracting its mean and dividing by its standard deviation.

3.4 SVM Feature

In addition to using the simple features directly, we also trained an SVM classifier with these features to distinguish between IN and OUT phrase pairs. Phrase tables were extracted from the IN and OUT training corpora (not the dev as was used for instance weighting models), and phrase pairs in the intersection of the IN and OUT phrase tables were used as positive examples, with two alternate definitions of negative examples:

1. Pairs from OUT that are not in IN, but whose source phrase is.
2. Pairs from OUT that are not in IN, but whose source phrase is, and where the intersection of IN and OUT translations for that source phrase is empty.

[5] We are grateful to an anonymous reviewer for pointing this out.

[6] One of our experimental settings lacks document boundaries, and we used this approximation in both settings for consistency.

[7] In the case of the Chinese experiments below, source LMs were trained using text segmented with the LDC segmenter, as were the other Chinese models in our system.

The classifier trained using the 2nd definition had higher accuracy on a development set. We used it to score all phrase pairs in the OUT table, in order to provide a feature for the instance-weighting model.

4 Experiments

4.1 Corpora and System

We carried out translation experiments in two different settings. The first setting uses the European Medicines Agency (EMEA) corpus (Tiedemann, 2009) as IN, and the Europarl (EP) corpus (`www.statmt.org/europarl`) as OUT, for English/French translation in both directions. The dev and test sets were randomly chosen from the EMEA corpus. Figure 1 shows sample sentences from these domains, which are widely divergent.

The second setting uses the news-related subcorpora for the NIST09 MT Chinese to English evaluation[8] as IN, and the remaining NIST parallel Chinese/English corpora (UN, Hong Kong Laws, and Hong Kong Hansard) as OUT. The dev corpus was taken from the NIST05 evaluation set, augmented with some randomly-selected material reserved from the training set. The NIST06 and NIST08 evaluation sets were used for testing. (Thus the domain of the dev and test corpora matches IN.) Compared to the EMEA/EP setting, the two domains in the NIST setting are less homogeneous and more similar to each other; there is also considerably more IN text available.

The corpora for both settings are summarized in table 1.

corpus	sentence pairs
Europarl	1,328,360
EMEA train	11,770
EMEA dev	1,533
EMEA test	1,522
NIST OUT	6,677,729
NIST IN train	2,103,827
NIST IN dev	1,894
NIST06 test	1,664
NIST08 test	1,357

Table 1: Corpora

The reference medicine for Silapo is EPREX/ERYPO, which contains epoetin alfa.
Le médicament de référence de Silapo est EPREX/ERYPO, qui contient de l'époétine alfa.
—
I would also like to point out to commissioner Liikanen that it is not easy to take a matter to a national court.
Je voudrais préciser, à l'adresse du commissaire Liikanen, qu'il n'est pas aisé de recourir aux tribunaux nationaux.

Figure 1: Sentence pairs from EMEA (top) and Europarl text.

We used a standard one-pass phrase-based system (Koehn et al., 2003), with the following features: relative-frequency TM probabilities in both directions; a 4-gram LM with Kneser-Ney smoothing; word-displacement distortion model; and word count. Feature weights were set using Och's MERT algorithm (Och, 2003). The corpus was word-aligned using both HMM and IBM2 models, and the phrase table was the union of phrases extracted from these separate alignments, with a length limit of 7. It was filtered to retain the top 30 translations for each source phrase using the TM part of the current log-linear model.

4.2 Results

Table 2 shows results for both settings and all methods described in sections 2 and 3. The 1st block contains the simple baselines from section 2.1. The natural baseline (*baseline*) outperforms the pure IN system only for EMEA/EP fren. Log-linear combination (*loglin*) improves on this in all cases, and also beats the pure IN system.

The 2nd block contains the IR system, which was tuned by selecting text in multiples of the size of the EMEA training corpus, according to dev set performance. This significantly underperforms log-linear combination.

The 3rd block contains the mixture baselines. The linear LM (*lin lm*), TM (*lin tm*) and MAP TM (*map tm*) used with non-adapted counterparts perform in all cases slightly worse than the log-linear combination, which adapts both LM and TM components. However, when the linear LM is combined with a

Table 2: Results, for EMEA/EP translation into English (fren) and French (enfr); and for NIST Chinese to English translation with NIST06 and NIST08 evaluation sets. Numbers are BLEU scores.

linear TM (*lm+lin tm*) or MAP TM (*lm+map TM*), the results are much better than a log-linear combination for the EMEA setting, and on a par for NIST. This is consistent with the nature of these two settings: log-linear combination, which effectively takes the intersection of IN and OUT, does relatively better on NIST, where the domains are broader and closer together. Somewhat surprisingly, there do not appear to be large systematic differences between linear and MAP combinations.

The 4th block contains instance-weighting models trained on all features, used within a MAP TM combination, and with a linear LM mixture. The *iw all map* variant uses a non-0 γ weight on a uniform prior in $p_o(s|t)$, and outperforms a version with $\gamma = 0$ (*iw all*) and the "flattened" variant described in section 3.2. Clearly, retaining the original frequencies is important for good performance, and globally smoothing the final weighted frequencies is crucial. This best instance-weighting model beats the equivalant model without instance weights by between 0.6 BLEU and 1.8 BLEU, and beats the log-linear baseline by a large margin.

The final block in table 2 shows models trained on feature subsets and on the SVM feature described in 3.4. The general-language features have a slight advantage over the similarity features, and both are better than the SVM feature.

5 Related Work

We have already mentioned the closely related work by Matsoukas et al (2009) on discriminative corpus weighting, and Jiang and Zhai (2007) on (non-discriminative) instance weighting. It is difficult to directly compare the Matsoukas et al results with ours, since our out-of-domain corpus is homogeneous; given heterogeneous training data, however, it would be trivial to include Matsoukas-style identity features in our instance-weighting model. Although these authors report better gains than ours, they are with respect to a non-adapted baseline. Finally, we note that Jiang's instance-weighting framework is broader than we have presented above, encompassing among other possibilities the use of unlabelled IN data, which is applicable to SMT settings where source-only IN corpora are available.

It is also worth pointing out a connection with Daumé's (2007) work that splits each feature into domain-specific and general copies. At first glance, this seems only peripherally related to our work, since the specific/general distinction is made for features rather than instances. However, for multinomial models like our LMs and TMs, there is a one to one correspondence between instances and features, eg the correspondence between a phrase pair (s, t) and its conditional multinomial probability $p(s|t)$. As mentioned above, it is not obvious how to apply Daumé's approach to multinomials, which do not have a mechanism for combining split features. Recent work by Finkel and Manning (2009) which re-casts Daumé's approach in a hierarchical MAP framework may be applicable to this problem.

Moving beyond directly related work, major themes in SMT adaptation include the IR (Hildebrand et al., 2005; Lü et al., 2007; Zhao et al., 2004) and mixture (Finch and Sumita, 2008; Foster and Kuhn, 2007; Koehn and Schroeder, 2007; Lü et al., 2007) approaches for LMs and TMs described above, as well as methods for exploiting monolingual in-domain text, typically by translating it automatically and then performing self training (Bertoldi and Federico, 2009; Ueffing et al., 2007; Schwenk and Senellart, 2009). There has also been some work on adapting the word alignment model prior to phrase extraction (Civera and Juan, 2007; Wu et al., 2005), and on dynamically choosing a dev set (Xu et al., 2007). Other work includes transferring latent topic distributions from source to target language for LM adaptation, (Tam et al., 2007) and adapting features at the sentence level to different categories of sentence (Finch and Sumita, 2008).

6 Conclusion

In this paper we have proposed an approach for instance-weighting phrase pairs in an out-of-domain corpus in order to improve in-domain performance. Each out-of-domain phrase pair is characterized by a set of simple features intended to reflect how useful it will be. The features are weighted within a logistic model to give an overall weight that is applied to the phrase pair's frequency prior to making MAP-smoothed relative-frequency estimates (different weights are learned for each conditioning direction). These estimates are in turn combined linearly with relative-frequency estimates from an in-domain phrase table. Mixing, smoothing, and instance-feature weights are learned at the same time using an efficient maximum-likelihood procedure that relies on only a small in-domain development corpus.

We obtained positive results using a very simple phrase-based system in two different adaptation settings: using English/French Europarl to improve a performance on a small, specialized medical domain; and using non-news portions of the NIST09 training material to improve performance on the news-related corpora. In both cases, the instance-weighting approach improved over a wide range of baselines, giving gains of over 2 BLEU points over the best non-adapted baseline, and gains of between 0.6 and 1.8 over an equivalent mixture model (with an identical training procedure but without instance weighting).

In future work we plan to try this approach with more competitive SMT systems, and to extend instance weighting to other standard SMT components such as the LM, lexical phrase weights, and lexicalized distortion. We will also directly compare with a baseline similar to the Matsoukas et al approach in order to measure the benefit from weighting phrase pairs (or ngrams) rather than full sentences. Finally, we intend to explore more sophisticated instance-weighting features for capturing the degree of generality of phrase pairs.

NLP on Spoken Documents without ASR

Abstract

There is considerable interest in interdisciplinary combinations of automatic speech recognition (ASR), machine learning, natural language processing, text classification and information retrieval. Many of these boxes, especially ASR, are often based on considerable linguistic resources. We would like to be able to process spoken documents with few (if any) resources. Moreover, connecting black boxes in series tends to multiply errors, especially when the key terms are out-of-vocabulary (OOV). The proposed alternative applies text processing directly to the speech without a dependency on ASR. The method finds long (~ 1 sec) repetitions in speech, and clusters them into pseudo-terms (roughly phrases). Document clustering and classification work surprisingly well on pseudo-terms; performance on a Switchboard task approaches a baseline using gold standard manual transcriptions.

1 Introduction

Can we do IR-like tasks without ASR? Information retrieval (IR) typically makes use of simple features that count terms within/across documents such as term frequency (tf) and inverse document frequency (IDF). Crucially, to compute these features, it is sufficient to count repetitions of a term. In particular, for many IR-like tasks, there is no need for an automatic speech recognition (ASR) system to label terms with phonemes and/or words.

This paper builds on Jansen et al. (2010), a method for discovering terms with zero resources. This approach identifies long, faithfully repeated patterns in the acoustic signal. These acoustic repetitions often correspond to terms useful for information retrieval tasks. Critically, this method does not require a phonetically interpretable acoustic model or knowledge of the target language.

By analyzing a large untranscribed corpus of speech, this discovery procedure identifies a vast number of repeated regions that are subsequently grouped using a simple graph-based clustering method. We call the resulting groups pseudo-terms since they typically represent a single word or phrase spoken at multiple points throughout the corpus. Each pseudo-term takes the place of a word or phrase in bag of terms vector space model of a text document, allowing us to apply standard NLP algorithms. We show that despite the fully automated and noisy method by which the pseudo-terms are created, we can still successfully apply NLP algorithms with performance approaching that achieved with the gold standard manual transcription.

Natural language processing tools can play a key role in understanding text document collections. Given a large collection of text, NLP tools can classify documents by category (classification) and organize documents into similar groups for a high level view of the collection (clustering). For example, given a collection of news articles, these tools can be applied so that the user can quickly see the topics covered in the news articles, and organize the collection to find all articles on a given topic. These tools require little or no human input (annotation) and work across languages.

Given a large collection of speech, we would like

Proceedings of the 2010 Conference on Empirical Methods in Natural Language Processing, pages 460–470,
MIT, Massachusetts, USA, 9-11 October 2010. ©2010 Association for Computational Linguistics

tools that perform many of the same tasks, allowing the user to understand the contents of the collection while listening to only small portions of the audio. Previous work has applied these NLP tools to speech corpora with similar results (see Hazen et al. (2007) and the references therein.) However, unlike text, which requires little or no preprocessing, audio files are typically first transcribed into text before applying standard NLP tools. Automatic speech recognition (ASR) solutions, such as large vocabulary continuous speech recognition (LVCSR) systems, can produce an automatic transcript from speech, but they require significant development efforts and training resources, typically hundreds of hours of manually transcribed speech. Moreover, the terms that may be most distinctive in particular spoken documents often lie outside the predefined vocabulary of an off-the-shelf LVCSR system. This means that unlike with text, where many tools can be applied to new languages and domains with minimal effort, the equivalent tools for speech corpora often require a significant investment. This greatly raises the entry threshold for constructing even a minimal tool set for speech corpora analysis.

The paper proceeds as follows. After a review of related work, we describe Jansen et al. (2010), a method for finding repetitions in speech. We then explain how these repetitions are grouped into pseudo-terms. Document clustering and classification work surprisingly well on pseudo-terms; performance on a Switchboard task approaches a baseline based on gold standard manual transcriptions.

2 Related Work

In the *low resource* speech recognition regime, most approaches have focused on coupling small amounts of orthographically transcribed speech (10s of hours) with much larger collections of untranscribed speech (100s or 1000s of hours) to train accurate acoustic models with semi-supervised methods (Novotney and Schwartz, 2009). In these efforts, the goal is to reduce the annotation requirements for the construction of competent LVCSR systems. This semi-supervised paradigm was relaxed even further with the pursuit of self organizing units (SOUs), phone-like units for which acoustic models are trained with completely unsupervised methods (Garcia and Gish, 2006). Even though the move away from phonetic acoustic models improves the universality of the architecture, small amounts of orthographic transcription are still required to connect the SOUs with the lexicon.

The segmental dynamic time warping (S-DTW) algorithm (Park and Glass, 2008) was the first truly zero resource effort, designed to discover portions of the lexicon directly by searching for repeated acoustic patterns in the speech signal. This work implicitly defined a new direction for speech processing research: unsupervised spoken term discovery, the entry point of our speech corpora analysis system. Subsequent extensions of S-DTW (Jansen et al., 2010) permit applications to much larger speech collections, a flexibility that is vital to our efforts.

As mentioned above, the application of NLP methods to speech corpora have traditionally relied on high resource ASR systems to provide automatic word or phonetic transcripts. Spoken document topic classification has been an application of particular interest (Hazen et al., 2007), for which the recognized words or phone n-grams are used to characterize the documents. These efforts have produced admirable results, with ASR transcript-based performance approached that obtained using the gold standard manual transcripts. Early efforts to perform automatic topic segmentation of speech input without the aid of ASR systems have been promising (Malioutov et al., 2007), but have yet to exploit the full the range of NLP tools.

3 Identifying Matched Regions

Our goal is to identify pairs of intervals within and across utterances of several speakers that contain the same linguistic content, preferably meaningful words or terms.

The spoken term discovery algorithm of Jansen et al. (2010) efficiently searches the space of $\binom{n}{2}$ intervals, where n is the number of speech frames.[1] Jansen et al. (2010) is based on dotplots (Church and Helfman, 1993), a method borrowed from bioinformatics for finding repetitions in DNA sequences.

[1] Typically, each frame represents a 25 or 30 ms window of speech sampled every 10 ms

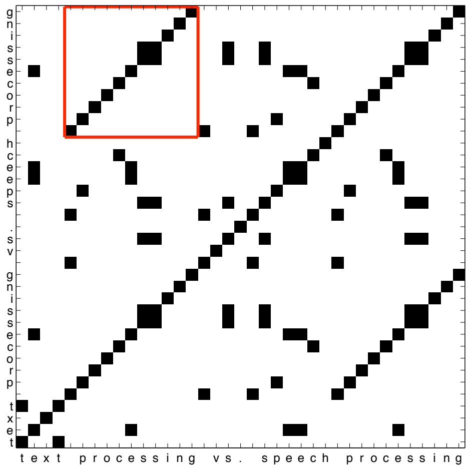

Figure 1: An example of a dotplot for the string "text processing vs. speech processing" plotted against itself. The box calls out the repeated substring: "processing."

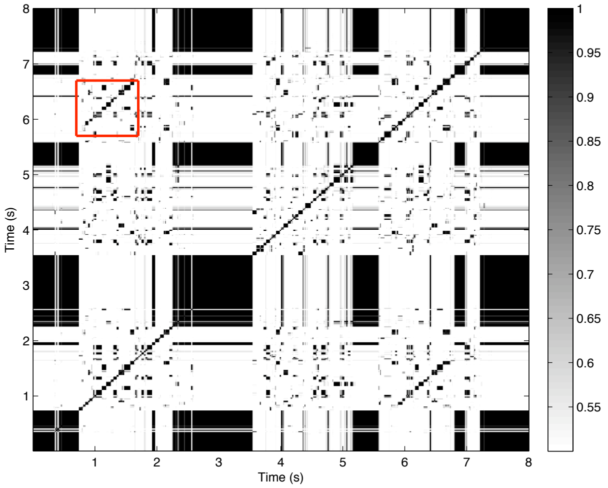

Figure 2: An example of an acoustic dotplot for 8 seconds of speech (posteriorgrams) plotted against itself. The box calls out a repetition of interest.

3.1 Acoustic Dotplots

When applied to text, the dotplot construct is remarkably simple: given character strings s_1 and s_2, the dotplot is a Boolean similarity matrix $K(s_1, s_2)$ defined as

$$K_{ij}(s_1, s_2) = \delta(s_1[i], s_2[j]).$$

Substrings common to s_1 and s_2 manifest themselves as diagonal line segments in the visualization of K. Figure 1 shows an example text dotplot where both $s1$ and $s2$ are taken to be the string "text processing vs. speech processing." The boxed diagonal line segment arises from the repeat of the word "processing," while the main diagonal line trivially arises from self-similarity. Thus, the search for line segments in K off the main diagonal provides a simple algorithmic means to identify repeated terms of possible interest, albeit sometimes partial, in a collection of text documents. The challenge is to generalize these dotplot techniques for application to speech, an inherently noisy, real-valued data stream.

The strategy is to replace character strings with frame-based speech representations of the form $\mathbf{x} = x_1, x_2, \ldots x_N$, where each $x_i \in \mathbb{R}^d$ is a d-dimensional vector space representation of the i^{th} overlapping window of the signal. Given vector time series $\mathbf{x} = x_1, x_2, \ldots x_N$ and $\mathbf{y} = y_1, y_2, \ldots y_M$ for two spoken documents, the acoustic dotplot is the real-valued $N \times M$ cosine similarity matrix $K(\mathbf{x}, \mathbf{y})$ defined as

$$K_{ij}(\mathbf{x}, \mathbf{y}) = \frac{1}{2}\left[1 + \frac{\langle x_i, y_j \rangle}{\|x_i\|\|y_j\|}\right]. \qquad (1)$$

Even though the application to speech is a distinctly noisier endeavor, sequences of frames repeated between the two audio clips will still produce approximate diagonal lines in the visualization of the matrix. The search for matched regions thus reduces to the robust search for diagonal line segments in K, which can be efficiently performed with standard image processing techniques.

Included in this procedure is the application of a diagonal median filter of duration κ seconds. The choice of κ determines an approximate threshold on the duration of the matched regions discovered. Large κ values ($\sim$ 1 sec) will produce a relatively sparse list of matches corresponding to long words or short phrases; smaller κ values ($<$ 0.5 sec) will admit shorter words and syllables that may be less informative from a document analysis perspective. Given the approximate nature of the procedure, shorter κ values also admit less reliable matches.

3.2 Posteriorgram Representation

The acoustic dotplot technique can operate on any vector time series representation of the speech signal, including a standard spectrogram. However, at the individual frame level, the cosine similarities between frequency spectra of distinct speakers producing the same phoneme are not guaranteed to be high.

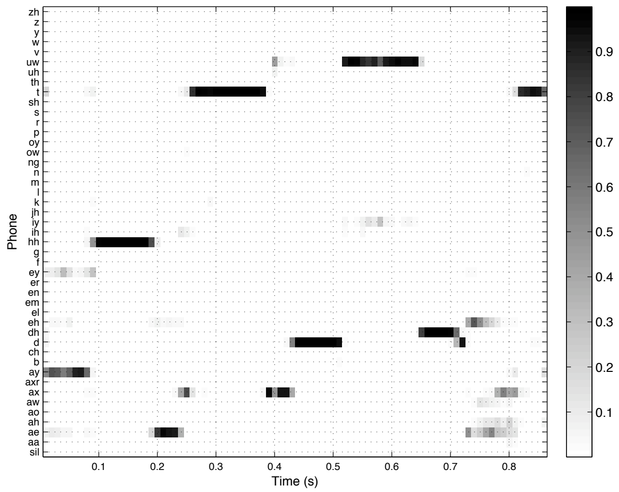

Figure 3: An example of a posteriorgram.

Thus, to perform term discovery across a multi-speaker corpus, we require a *speaker-independent* representation. Phonetic posteriorgrams are a suitable choice, as each frame is represented as the posterior probability distribution over a set of speech sounds given the speech observed at the particular point in time, which is largely speaker-independent by construction. Figure 3 shows an example posteriorgram for the utterance "I had to do that," computed with a multi-layer perceptron (MLP)-based English phonetic acoustic model (see Section 5 for details). Each row of the figure represents the posterior probability of the given phone as a function of time through the utterance and each column represents the posterior distribution over the phone set at that particular point in time.

The construction of speaker independent acoustic models typically requires a significant amount of transcribed speech. Our proposed strategy is to employ a speaker independent acoustic model trained in a high resource language or domain to interpret multi-speaker data in the zero resource target setting.[2] Indeed, we do not need to know a language to detect when a word of sufficient length has been repeated in it.[3] By computing cosine similarities of phonetic posterior distribution vectors (as opposed to reducing the speech to a one-best phonetic token sequence), the phone set used need not be matched to the target language. With this approach, a speaker-independent model trained on the phone set of a reference language may be used to perform speaker independent term discovery in any other.

In addition to speaker independence, the use of phonetic posteriorgrams introduces representational sparsity that permits efficient dotplot computation and storage. Notice that the posteriorgram displayed in Figure 3 consists of mostly near-zero values. Since cosine similarity (Equation 1) between two frames can only be high if they have significant mass on the same phone, most comparisons need not be made. Instead, we can apply a threshold and store each posteriorgram as an inverted file, performing inner product multiplies and adds only when they contribute. Using a grid of approximately 100 cores, we were able to perform the $O(n^2)$ dotplot computation and line segment search for 60+ hours of speech (corresponding to a 500 terapixel dotplot) in approximately 5 hours.

Figure 2 displays the posteriorgram dotplot for 8 seconds of speech against itself (i.e., $\mathbf{x} = \mathbf{y}$). The prominent main diagonal line results from self-similarity, and thus is ignored in the search. The boxed diagonal line segment results from two distinct occurrences of the term *one million dollars*. The large black boxes in the image result from long stretches of silence of filled pauses; fortunately, these are easily filtered with speech activity detection or simple measures of posteriorgram stability.

4 Creating Pseudo-Terms

Spoken documents will be represented as bags of pseudo-terms, where pseudo-terms are computed from acoustic repetitions described in the previous section. Let $\mathcal{M}$ be a set of matched regions (m), each consisting of a pair of speech intervals contained in the corpus ($m = [t_1^{(i)}, t_2^{(i)}], [t_1^{(j)}, t_2^{(j)}]$ indicates the speech from $t_1^{(i)}$ to $t_2^{(i)}$ is an acoustic match to the speech from $t_1^{(j)}$ to $t_2^{(j)}$). If a particular term occurs k times, the set $\mathcal{M}$ can include as many as $\binom{k}{2}$ distinct elements corresponding to that term, so we require a procedure to group them into clusters. We call the resulting clusters pseudo-terms since each

[2] A similarly-minded approach was taken in Hazen et al. (2007) and extended in Hazen and Margolis (2008), where the authors use Hungarian phonetic trigrams features to characterize English spoken documents for a topic classification task.

[3] While in this paper our acoustic model is based on our evaluation corpus, this is not a requirement of our approach. Future work will investigate performance of other acoustic models.

cluster is a placeholder for a term (word or phrase) spoken in the collection. Given the match list $\mathcal{M}$ and the pseudo-term clusters, it is relatively straightforward to represent spoken documents as bags of pseudo-terms.

To perform this pseudo-term clustering we represented matched regions as vertices in a graph with edges representing similarities between these regions. We employ a graph-clustering algorithm that extracts connected components. Let $G = (V, E)$ be an unweighted, undirected graph with vertex set V and edge set E. Each $v_i \in V$ corresponds to a single speech interval ($[t_1^{(i)}, t_2^{(i)}]$) present in $\mathcal{M}$ (each $m \in \mathcal{M}$ has a pair of such intervals, so $|V| = 2|\mathcal{M}|$) and each $e_{ij} \in E$ is an edge between vertex v_i and v_j.

The set E consists of two types of edges. The first represents repeated speech at distinct points in the corpus as determined by the match list $\mathcal{M}$. The second represents near-identical intervals in the same utterance (i.e. the same speech) since a single interval can show up in several matches in $\mathcal{M}$ and the algorithm in Section 3 explicitly ignores self-similarity. Given the intervals $[t_1^{(i)}, t_2^{(i)}]$ and $[t_1^{(j)}, t_2^{(j)}]$ contained in the same utterance and with corresponding vertices $v_i, v_j \in V$, we introduce an edge e_{ij} if fractional overlap f_{ij} exceeds some threshold τ, where $f_{ij} = \max(0, r_{ij})$ and

$$r_{ij} = \frac{(t_2^{(i)} - t_1^{(i)}) + (t_2^{(j)} - t_1^{(j)})}{\max(t_2^{(i)}, t_2^{(j)}) - \min(t_1^{(i)}, t_1^{(j)})} - 1. \quad (2)$$

From the graph G, we produce one pseudo-term for each connected component. More sophisticated edge weighting schemes would likely provide benefit. In particular, we expect improved clustering by introducing weights that reflect acoustic similarity between match intervals, rather than relying solely upon the term discovery algorithm to make a hard decision. Such confidence weights would allow even shorter pseudo-terms to be considered (by reducing κ) without greatly increasing false alarms. With such a shift, more sophisticated graph-clustering mechanisms would be warranted (e.g. Clauset et al. (2004)). We plan to pursue this in future work.

Counts	*Terms*
5	keep track of
5	once a month
2	life insurance
2	capital punishment
9	paper; newspaper
3	talking to you

Table 1: Pseudo-terms resulting from a graph clustering of matched regions ($\kappa = 0.75$, $\tau = 0.95$). Counts indicate the number of times the times the pseudo-terms appear across 360 conversation sides in development data.

Table 1 contains several examples of pseudo-terms and the matched regions included in each group. The orthographic forms are taken from the transcripts in the data (see Section 5). Note that for some pseudo-terms, the words match exactly, while for others, the phrases are distinct but phonetically similar. However, even in this case, there is often substantial overlap in the spoken terms.

5 Data

For our experiments we used the Switchboard Telephone Speech Corpus (Godfrey et al., 1992). Switchboard is a collection of roughly 2,400 two-sided telephone conversations with a single participant per side. Over 500 participants were randomly paired and prompted with a topic for discussion. Each conversation belongs to one of 70 pre-selected topics with the two sides restricted to separate channels of the audio.

To develop and evaluate our methods, we created three data sets from the Switchboard corpus: a development data set, a held out tuning data set and an evaluation data set. The development data set was created by selecting the six most commonly prompted topics (recycling, capital punishment, drug testing, family finance, job benefits, car buying) and randomly selecting 60 sides of conversations evenly across the topics (total 360 conversation sides.) This corresponds to 35.7 hours of audio. Note that each participant contributed at most one conversation side per topic, so these 360 conversation sides represent 360 distinct speakers. All algorithm development and experimentation was conducted exclusively on the development data.

For the tuning data set, we selected an additional 60 sides of conversations evenly across the same six topics used for development, for a total of 360 conversations and 37.5 hours of audio. This data was used to validate our experiments on the development data by confirming the heuristic used to select algorithmic parameters, as described below. This data was not used for algorithm development. The evaluation data set was created once parameters had been selected for a final evaluation of our methods. We selected this data by sampling 100 conversation sides from the next six most popular conversation topics (family life, news media, public education, exercise/fitness, pets, taxes), yielding 600 conversation sides containing 61.6 hours of audio.

In our experiments below, we varied the match duration κ between 0.6 s and 1.0 s and the overlap threshold τ between 0.75 and 1.0. We measured the resulting effects on the number of unique pseudo-terms generated by the process. In general, decreasing κ results in more matched regions increasing the number of pseudo-terms. Similarly, increasing τ forces fewer regions to be merged, increasing the total number of pseudo-terms. Table 2 shows how these parameters change the number of pseudo-terms (features) per document and the average number of occurrences of each pseudo-term. The user could tune these parameters to select pseudo-terms that were long and occurred in many documents. In the next sections, we consider how these parameters effect performance of various learning settings.

To provide the requisite speaker independent acoustic model, we compute English phone posteriorgrams using the multi-stream multi-layer perceptron-based architecture of Thomas et al. (2009), trained on 300 hours of conversational telephone speech. While this is admittedly a large amount of supervision, it is important to emphasize our zero resource term discovery algorithm does not rely on the phonetic interpretability of this reference acoustic model. The only requirement is that the same target language phoneme spoken by distinct speakers map to similar posterior distributions over the reference language phoneme set. Thus, even though we evaluate the system on matched-language Switchboard data, it can be just as easily applied to any target language with no language-specific knowledge or training resources required.[4]

6 Document Clustering

We begin by considering document clustering, a popular approach to discovering latent structure in document collections. Unsupervised clustering algorithms sort examples into groups, where each group contains documents that are similar. A user exploring a corpus can look at a few documents in each cluster to gain an overview of the content discussed in the corpus. For example, clustering methods can be used on search results to provide quick insight into the coverage of the returned documents (Zeng et al., 2004).

Typically, documents are clustered based on a bag of words representation. In the case of clustering conversations in our collection, we would normally obtain a transcript of the conversation and then extract a bag of words representation for clustering. The resulting clusters may represent topics, such as the six topics used in our switchboard data. Such groupings, available with no topic labeled training data, can be a valuable tool for understanding the contents of a speech data collection. We would like to know if similar clustering results can be obtained without the use of a manual or automatic transcript. In our case, we substitute the pseudo-terms discovered in a conversation for the transcript, representing

[4] The generalization of the speaker independence of acoustic models across languages is not well understood. Indeed, the performance of our proposed system would depend to some extent on the phonetic similarity of the target and reference language. Unsupervised learning of speaker independent acoustic models remains an important area of future research.

the document as a bag of pseudo-terms instead of actual words. Can a clustering algorithm achieve similar results along topical groups with our transcript-free representation as it can with a full transcript?

In our experiments, we use the six topic labels provided by Switchboard as the clustering labels. The goal is to cluster the data into six balanced groups according to these topics. While Switchboard topics are relatively straightforward to identify since the conversations were prompted with specific topics, we believe this task can still demonstrate the effectiveness of our representation relative to the baseline methods. After all, topic classification without ASR is still a difficult task.

6.1 Evaluation Metrics

There are numerous approaches to evaluating clustering algorithms. We consider several methods: Purity, Entropy and B-Cubed. For a full treatment of these metrics, see Amigó et al. (2009).

Purity measures the precision of each cluster, i.e., how many examples in each cluster belong to the same true topic. Purity ranges between zero and one, with one being optimal. While optimal purity can be obtained by putting each document in its own cluster, we fix the number of clusters in all experiments so purity numbers are comparable. The purity of a cluster is defined as the largest percentage of examples in a cluster that have the same topic label. Purity of the entire clustering is the average purity of each cluster:

$$\text{purity}(C, L) = \frac{1}{N} \sum_{c_i \in C} \max_{l_j \in L} |c_i \cap l_j| \qquad (3)$$

where C is the clustering, L is the reference labeling, and N are the number of examples. Following this notation, c_i is a specific cluster and l_j is a specific true label.

Entropy measures how the members of a cluster are distributed amongst the true labels. The global metric is computed by taking the weighted average of the entropy of the members of each cluster. Specifically, entropy(C, L) is given by:

$$-\sum_{c_i \in C} \frac{N_i}{N} \sum_{l_j \in L} P(c_i, l_j) \log_2 P(c_i, l_j) \qquad (4)$$

where N_i is the number of instances in cluster i, $P(c_i, l_j)$ is the probability of seeing label l_j in cluster c_i and the other variables are defined as above.

B-Cubed measures clustering effectiveness from the perspective of a user's inspecting the clustering results (Bagga and Baldwin, 1998). B-Cubed precision can be defined as an algorithm as follows: suppose a user randomly selects a single example. She then proceeds to inspect every other example that occurs in the same cluster. How many of these items will have the same true label as the selected example (precision)? B-Cubed recall operates in a similar fashion, but it measures what percentage of all examples that share the same label as the selected example will appear in the selected cluster. Since B-Cubed averages its evaluation over each document and not each cluster, it is less sensitive to small errors in large clusters as opposed to many small errors in small clusters. We include results for B-Cubed F1, the harmonic mean of precision and recall.

6.2 Clustering Algorithms

We considered several clustering algorithms: repeated bisection, globally optimal repeated bisection, and agglomerative clustering (see Karypis (2003) for implementation details). Each bisection algorithm is run 10 times and the optimal clustering is selected according to a provided criteria function (no true labels needed). For each clustering method, we evaluated several criteria functions. Additionally, we considered different scalings of the feature values (the number of times the pseudo-terms appear in each document). We found that scaling each feature by the inverse document frequency, effectively TFIDF, produced the best results, so we use that scaling in all of our experiments. We also explored various similarity metrics and found cosine similarity to be the most effective.

We used the Cluto clustering library for all clustering experiments (Karypis, 2003). In the following section, we report results for the optimal clustering configuration based on experiments on the development data.

6.3 Baselines

We compared our pseudo-term feature set performance to two baselines: (1) Phone Trigrams and

(2) Word Transcripts. The Phone Trigram baseline is derived automatically using an approach similar to Hazen et al. (2007). This baseline is based on a vanilla phone recognizer on top of the same MLP-based acoustic model (see Section 5 and the references therein for details) used to discover the pseudo-terms. In particular, the phone posteriorgrams were transformed to frame-level monophone state likelihoods (through division by the frame-level priors). These state likelihoods were then used along with frame-level phone transition probabilities to Viterbi decode each conversation side. It is important to emphasize that the reliability of phone recognizers depends on the phone set matching the application language. Using the English acoustic model in this manner on another language will significantly degrade the performance numbers reported below.

The Word Transcript baseline starts with Switchboard transcripts. This baseline serves as an upper bound of what large vocabulary recognition can provide for this task. n-gram features are computed from the transcript. Performance is reported separately for unigrams, bigrams and trigrams.

6.4 Results

To optimize parameter settings, match duration (κ) and overlap threshold (τ) were swept over a wide range ($0.6 < \kappa < 1.0$ and $0.75 < \tau < 1.0$) using a variety of clustering algorithms and training criteria. Initial results on development data showed promising performance for the default $\mathcal{I}_2$ criteria in Cluto (repeated bisection set to maximize the square root of within cluster similarity). Representative results on development data with various parameter settings for this clustering configuration appear in Table 3.

Pseudo-term Results

Table 3: Clustering results on development data using globally optimal repeated bisection and $\mathcal{I}_2$ criteria. The best results over the manual word transcript baselines and for each match duration (κ) are highlighted in bold. Pseudo-term results are better than the phonetic baseline and almost as good as the transcript baseline.

A few observations about results on development data. First, the three evaluation metrics are strongly correlated. Second, for each κ the same narrow range of τ values achieve good results. In general, settings of $\tau > 0.9$ were all comparable. Essentially, setting a high threshold for merging matched regions was sufficient without further tuning. Third, we observed that decreasing κ meant more features, but that these additional features did not necessarily lead to more useful features for clustering. For example, $\kappa = 0.70$ gave a small number of reasonably good features, while $\kappa = 0.60$ can give an order of magnitude more features without much of a change in clustering performance. Finally, while pseudo-term results are not as good as with the manual transcripts (unigrams), they achieve similar results. Compared with the phone trigram features determined by the phone recognizer output, the pseudo-terms perform significantly better. Note that these two automatic approaches were built using the identical MLP-based phonetic acoustic model.

We sought to select the optimal parameter settings for running on the evaluation data using the development data and the held out tuning data. We defined the following heuristic to select the optimal parameters. We choose settings for κ, τ and the clustering parameters that independently maximize the performance averaged over all runs on development data. We then selected the single run corresponding to these parameter settings and checked the result on the held out tuning data. This setting was also the best performer on the held out set, so we used these parameters for evaluation. The best performing parameters were globally optimal repeated

κ	τ	*Features*	*Purity*	*Entropy*	B^3 F1

Table 5: Results on evaluation data. The parameters (globally optimal repeated bisection clustering with $\mathcal{I}_2$ criteria, $\kappa = 0.7$ seconds and $\tau = 0.98$) were selected using the development data and validated on tuning data.

bisection clustering with $\mathcal{I}_2$ criteria, $\kappa = 0.7$ s and $\tau = 0.98$. Note that examining Table 3 alone may suggest other parameters, but we found our selection method to yield optimal results on the tuning data.

Results on held out tuning and evaluation data for this setting compared to the manual word transcripts and phone recognizer output are shown in Tables 4 and 5. On both the tuning data and evaluation data, we obtain similar results as on the development data. While the manual transcript baseline is better than our pseudo-term representations, the results are quite competitive. This demonstrates that useful clustering results can be obtained without a full-blown word recognizer. Notice also that the pseudo-term performance remains significantly higher than the phone recognizer baseline on both sets.

7 Supervised Document Classification

Unsupervised clustering methods are attractive since they require no human annotations. However, obtaining a few labeled examples for a simple labeling task can be done quickly, especially with crowd sourcing systems such as CrowdFlower and Amazon's Mechanical Turk (Snow et al., 2008; Callison-Burch and Dredze, 2010). In this setting, a user may listen to a few conversations and label them by topic. A supervised classification algorithm can then be trained on these labeled examples and used to automatically categorize the rest of the data. In this section, we evaluate if supervised algorithms can be trained using the pseudo-term representation of the speech.

We set up a multi-class supervised classification task, where each document is labeled using one of the six Switchboard topics. A supervised learning algorithm is trained on a sample of labeled documents and is then asked to label some test data. Results are measured in terms of accuracy. Since the documents are a balanced sample of the six topics, random guessing would yield an accuracy of 0.1667.

We proceed as with the clustering experiments. We evaluate different representations for various settings of κ and τ and different classifier parameters on the development data. We then select the optimal parameter settings and validate this selection on the held out tuning data, before generating the final representations for the evaluation once the optimal parameters have been selected.

For learning we require a multi-class classifier training algorithm. We evaluated four popular learning algorithms: a) MIRA—a large margin online learning algorithm (Crammer et al., 2006); b) Confidence Weighted (CW) learning—a probabilistic large margin online learning algorithm (Dredze et al., 2008; Crammer et al., 2009); c) Maximum Entropy—a log-linear discriminative classifier (Berger et al., 1996); and d) Support Vector Machines (SVM)—a large margin discriminator (Joachims, 1998).[5] For each experiment, we used default settings of the parameters (tuning did not significantly change the results) and 10 online iterations for the online methods (MIRA, CW). Each reported result is based on 10-fold cross validation.

Table 6 shows results for various parameter settings and the four learning algorithms on development data. As before, we observe that values for $\tau > 0.9$ tend to do well. The CW learning algorithm performs the best on this data, followed by Maximum Entropy, MIRA and SVM. The optimal κ for classification is 0.75, close to the 0.7 value selected in clustering. As before, pseudo-terms do

[5] We used the "variance" formulation with $k = 1$ for CW learning, Gaussian regularization for the Maximum Entropy classifier, and a linear kernel for the SVM.

Table 6: The top 15 results (measured as average accuracy across the 4 algorithms) for pseudo-terms on development data. The best pseudo-term and manual transcript results for each algorithm are bolded. All results are based on 10-fold cross validation. Pseudo-term results are better than the phonetic baseline and almost as good as the transcript baseline.

well, though not as well as the upper bound based on manual transcripts. The performance for pseudo-terms and phone trigrams are roughly comparable, though we expect pseudo-terms to be more robust across languages.

Using the same selection heuristic as in clustering, we select the optimal parameter settings, validate them on the held out tuning data, and compute results on evaluation data. The best performing configuration was for $\kappa = 0.75$ seconds and $\tau = 0.97$. Notice these parameters are very similar to the best parameters selected for clustering. Results on held out tuning and evaluation data for this setting compared to the manual transcripts are shown in Tables 7 and 8. As with clustering, we see good overall performance as compared with manual transcripts. While the performance drops, results suggest that useful output can be obtained without a transcript.

8 Conclusions

We have presented a new strategy for applying standard NLP tools to speech corpora without the aid of a large vocabulary word recognizer. Built instead on top of the unsupervised discovery of term-like units in the speech, we perform unsupervised topic clustering as well as supervised classification of spoken documents with performance approaching that achieved with the manual word transcripts, and generally matching or exceeding that achieved with a phonetic recognizer. Our study identified several opportunities and challenges in the development of NLP tools for spoken documents that rely on little or no linguistic resources such as dictionaries and training corpora.

Fusing Eye Gaze with Speech Recognition Hypotheses to Resolve Exophoric References in Situated Dialogue

Zahar Prasov and Joyce Y. Chai
Department of Computer Science and Engineering
Michigan State University
East Lansing, MI 48824, USA
{prasovza,jchai}@cse.msu.edu

Abstract

In situated dialogue humans often utter linguistic expressions that refer to extralinguistic entities in the environment. Correctly resolving these references is critical yet challenging for artificial agents partly due to their limited speech recognition and language understanding capabilities. Motivated by psycholinguistic studies demonstrating a tight link between language production and human eye gaze, we have developed approaches that integrate naturally occurring human eye gaze with speech recognition hypotheses to resolve exophoric references in situated dialogue in a virtual world. In addition to incorporating eye gaze with the best recognized spoken hypothesis, we developed an algorithm to also handle multiple hypotheses modeled as word confusion networks. Our empirical results demonstrate that incorporating eye gaze with recognition hypotheses consistently outperforms the results obtained from processing recognition hypotheses alone. Incorporating eye gaze with word confusion networks further improves performance.

1 Introduction

Given a rapid growth in virtual world applications for tutoring and training, video games and simulations, and assistive technology, enabling situated dialogue in virtual worlds has become increasingly important. Situated dialogue allows human users to navigate in a spatially rich environment and carry a conversation with artificial agents to achieve specific tasks pertinent to the environment. Different from traditional telephony-based spoken dialogue systems and multimodal conversational interfaces, situated dialogue supports immersion and mobility in a visually rich environment and encourages social and collaborative language use (Byron et al., 2005; Gorniak et al., 2006). In situated dialogue, human users often need to make linguistic references, known as exophoric referring expressions (e.g., `the book to the right`), to extralinguistic entities in the environment. Reliably resolving these references is critical for dialogue success. However, reference resolution remains a challenging problem, partly due to limited speech and language processing capabilities caused by poor speech recognition (ASR), ambiguous language, and insufficient pragmatic knowledge.

To address this problem, motivated by psycholinguistic studies demonstrating a close relationship between language production and eye gaze, our previous work has incorporated naturally occurring eye gaze in reference resolution (Prasov and Chai, 2008). Our findings have shown that eye gaze can partially compensate for limited language processing and domain modeling. However, this work was conducted in a setting where users only spoke to a static visual interface. In situated dialogue, human speech and eye gaze patterns are much more complex. The dynamic nature of the environment and the complexity of spatially rich tasks have a massive influence on what the user will look at and say. It is not clear to what degree prior findings can generalize to situated dialogue. Therefore, this paper explores new studies on incorporating eye gaze for exophoric reference resolution in a fully situated virtual envi-

ronment — a more realistic approximation of real world interaction. In addition to incorporating eye gaze with the best recognized spoken hypothesis, we developed an algorithm to also handle multiple hypotheses modeled as word confusion networks.

Our empirical results have demonstrated the utility of eye gaze for reference resolution in situated dialogue. Although eye gaze is much more noisy given the mobility of the user, our results have shown that incorporating eye gaze with recognition hypotheses consistently outperform the results obtained from processing recognition hypotheses alone. In addition, incorporating eye gaze with word confusion networks further improves performance. Our analysis also indicates that, although a word confusion network appears to be more complicated, the time complexity of its integration with eye gaze is well within the acceptable range for real-time applications.

2 Related Work

Prior work in reference resolution within situated dialogue has focused on using visual context to assist reference resolution during interaction. In (Kelleher and van Genabith, 2004) and (Byron et al., 2005), visual features of objects are used to model the focus of attention. This attention modeling is subsequently used to resolve references. In contrast to this line of research, here we explore the use of human eye gaze during real-time interaction to model attention and facilitate reference resolution. Eye gaze provides a richer medium for attentional information, but requires processing of a potentially noisy signal.

Eye gaze has been used to facilitate human machine conversation and automated language processing. For example, eye gaze has been studied in embodied conversational discourse as a mechanism to gather visual information, aid in thinking, or facilitate turn taking and engagement (Nakano et al., 2003; Bickmore and Cassell, 2004; Sidner et al., 2004; Morency et al., 2006; Bee et al., 2009). Recent work has explored incorporating eye gaze into automated language understanding such as automated speech recognition (Qu and Chai, 2007; Cooke and Russell, 2008), automated vocabulary acquisition (Liu et al., 2007; Qu and Chai, 2010), attention prediction (Qvarfordt and Zhai, 2005; Fang et al., 2009).

Motivated by previous psycholinguistic findings that eye gaze is tightly linked with language processing (Just and Carpenter, 1976; Tanenhous et al., 1995; Meyer and Levelt, 1998; Griffin and Bock, 2000), our prior work incorporates eye gaze into reference resolution. Our results demonstrate that such use of eye gaze can potentially compensate for a conversational systems limited language processing and domain modeling capability (Prasov and Chai, 2008). However, this work is conducted in a static visual environment and evaluated only on transcribed spoken utterances. In situated dialogue, eye gaze behavior is much more complex. Here, gaze fixations may be made for the purpose of navigation or scanning the environment rather than referring to a particular object. Referring expressions can be made to objects that are not in the user's field of view, but were previously visible on the interface. Additionally, users may make egocentric spatial references (e.g. "the chair on the left") which require contextual knowledge (e.g. the users position in the environment) in order to resolve. Therefore, the focus of our work here is on exploring these complex user behaviors in situated dialogue and examining how to combine eye gaze with ASR hypotheses for improved reference resolution.

Alternative ASR hypotheses have been used in many different ways in speech driven systems. Particularly, in (Mangu et al., 2000) multiple lattice alignment is used for construction of word confusion networks and in (Hakkani-Tür et al., 2006) word confusion networks are used for named entity detection. In the study presented here, we apply word confusion networks (to represent ASR hypotheses) along with eye gaze to the problem of reference resolution.

3 Data Collection

In this investigation, we created a 3D virtual world (using the Irrlicht game engine[1]) to support situated dialogue. We conducted a Wizard of Oz study in which the user must collaborate with a remote artificial agent cohort (controlled by a human) to solve a treasure hunting task. The cohort is an "expert" in treasure hunting and has some knowledge regard-

[1] http://irrlicht.sourceforge.net/

ing the locations of the treasure items, but cannot see the virtual environment. The user, immersed in the virtual world, must navigate the environment and conduct a mixed-initiative dialogue with the agent to find the hidden treasures. During the experiments, a noise-canceling microphone was used to record user speech and the Tobii 1750 display-mounted eye tracker was used to record user eye movements.

A snapshot of user interaction with the treasure hunting environment is shown in Figure 1. Here, the user's eye fixation is represented by the white dot and saccades (eye movements) are represented by white lines. The virtual world contains 10 rooms with a total of 155 unique objects that encompass 74 different object types (e.g. chair or plant).

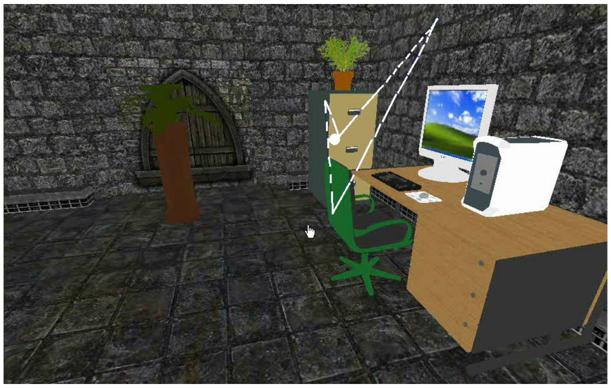

Figure 1: Snapshot of the situated treasure hunting environment

Table 1 shows a portion of a sample dialogue between a user and the expert. Each S_i represents a system utterance and each U_i represents a user utterance. We focus on resolving exophoric referring expressions, which are enclosed in brackets here. In our dataset, an exophoric referring expression is a non-pronominal noun phrase that refers to an entity in the extralinguistic environment. It may be an evoking reference that initially refers to a new object in the virtual world (e.g. `an axe` in utterance U_2) or a subsequent reference to an entity in the virtual world which has previously been mentioned in the dialogue (e.g. `an axe` in utterance U_3). In our study we focus on resolving exophoric referring expressions because they are tightly coupled with a user's eye gaze behavior.

From this study, we constructed a parallel spoken utterance and eye gaze corpus. Utterances, which are separated by a long pause (500 ms) in speech, are automatically recognized using the Microsoft Speech SDK. Gaze fixations are characterized by objects in the virtual world that are fixated via a user's eye gaze. When a fixation points to multiple spatially overlapping objects, only the one in the forefront is deemed to be fixated. The data corpus was transcribed and annotated with 2204 exophoric referring expressions amongst 2052 utterances from 15 users.

S_1	Describe what you're doing.
U_1	I just came out from the room that I started and i see **[one long sword]**
U_2	**[one short sword]** and **[an axe]**
S_2	Compare these objects.
U_3	one of them is long and one of them is really short, and i see **[an axe]**

Table 2: Sample n-best list of recognition hypotheses

4 Word Confusion Networks

For each user utterance in our dataset, an n-best list (with $n = 100$) of recognition hypotheses ranked in order of likelihood is produced by the Microsoft Speech SDK. One way to use the speech recognition results (as in most speech applications) is to use the top ranked recognition hypothesis. This may not be the best solution because a large amount of information is being ignored. Table 2 demonstrates this problem. Here, the number after the underscore denotes a timestamp associated with each recognized spoken word. The strings enclosed in brackets denote recognized referring expressions. In this example, the manual transcription of the original utterance is shown by H_t. In this case, the system must first identify `one long sword` as a referring expression and then resolve it to the correct set of entities in the virtual world. However, not until the twenty fifth ranked recognition hypothesis H_{25}, do we see a referring expression closest to the actual uttered referring expression. Moreover, in utterances with multiple referring expressions, there may not be a single recognition hypothesis that contains all referring expressions, but each referring expression may be contained in some recognition hypothesis. Thus, it is desirable to consider the entire n-best list of hypotheses.

To address this issue, we adopted the word confusion network (WCN): a compact representation of a word lattice or n-best list (Mangu et al., 2000). A WCN captures alternative word hypotheses and their corresponding posterior probabilities in time-ordered sets. In addition to being compact, an important feature for efficient post-processing of recognition hypotheses for real-time systems, WCNs are capable of representing more competing hypotheses than either n-best lists or word lattices. Figure 2 shows an example of a WCN for the utterance "...I see one long sword" along with a timeline (in milliseconds) depicting the eye gaze fixations to potential referent objects that correspond to the utterance. The confusion network shows competing word hypotheses along with corresponding probabilities in log scale.

Using our data set, we can show that word confusion networks contain significantly more words that can compose a referring expression than the top recognition hypothesis. The confusion network keyword error rate (KWER) is 0.192 compared to a 1-best list KWER of 0.318, where a keyword is a word that can be contained in a referring expression. The overall WER for word confusion networks and 1-best lists are 0.315 and 0.460, respectively. The reported WCN word error rates are all oracle word error rates reflecting the best WER that can be attained using any path in the confusion network. One more important feature of word confusion networks is that they provide time alignment for words that occur at approximately the same time interval in competing hypotheses. This is not only useful for efficient syntactic parsing, which is necessary for identifying referring expressions, but also critical for integration with time aligned gaze streams.

5 Reference Resolution Algorithm

We have developed an algorithm that combines an n-best list of speech recognition hypotheses with dialogue, domain, and eye-gaze information to resolve exophoric referring expressions. There are three inputs to the multimodal reference resolution algorithm for each utterance: (1) an n-best list of alternative speech recognition hypotheses ($n = 100$ for a WCN and $n = 1$ for the top recognized hypothesis), (2) a list of fixated objects (by eye gaze) that temporally correspond to the spoken utterance and (3) a set of potential referent objects. Since during the treasure hunting task people typically only speak about objects that are visible or have recently been visible on the screen, an object is considered to be a potential referent if it is present within a close proximity (in the same room) of the user while an utterance is spoken.

The multimodal reference resolution algorithm proceeds with the following four steps:

Step 1: construct word confusion network A word confusion network is constructed out of the input n-best list of alternative recognition hypotheses with the SRI Language Modeling (SRILM) toolkit (Stolcke, 2002) using the procedure described in (Mangu et al., 2000). This procedure aligns words from the n-best list into equivalence classes. First, instances of the same word containing approximately the same starting and ending timestamps are clustered. Then, equivalence classes with common time ranges are merged. For each competing word hypothesis its probability is computed by summing the posteriors of all utterance hypotheses containing this word. In our work, instead of using the actual posterior probability of each utterance hypothesis (which was not available), we assigned each utterance hypothesis a probability based on its position in the ranked list. Figure 2 depicts a portion of the resulting word confusion network (showing competing word hypotheses and their probabilities in log scale) constructed from the n-best list in Table 2.

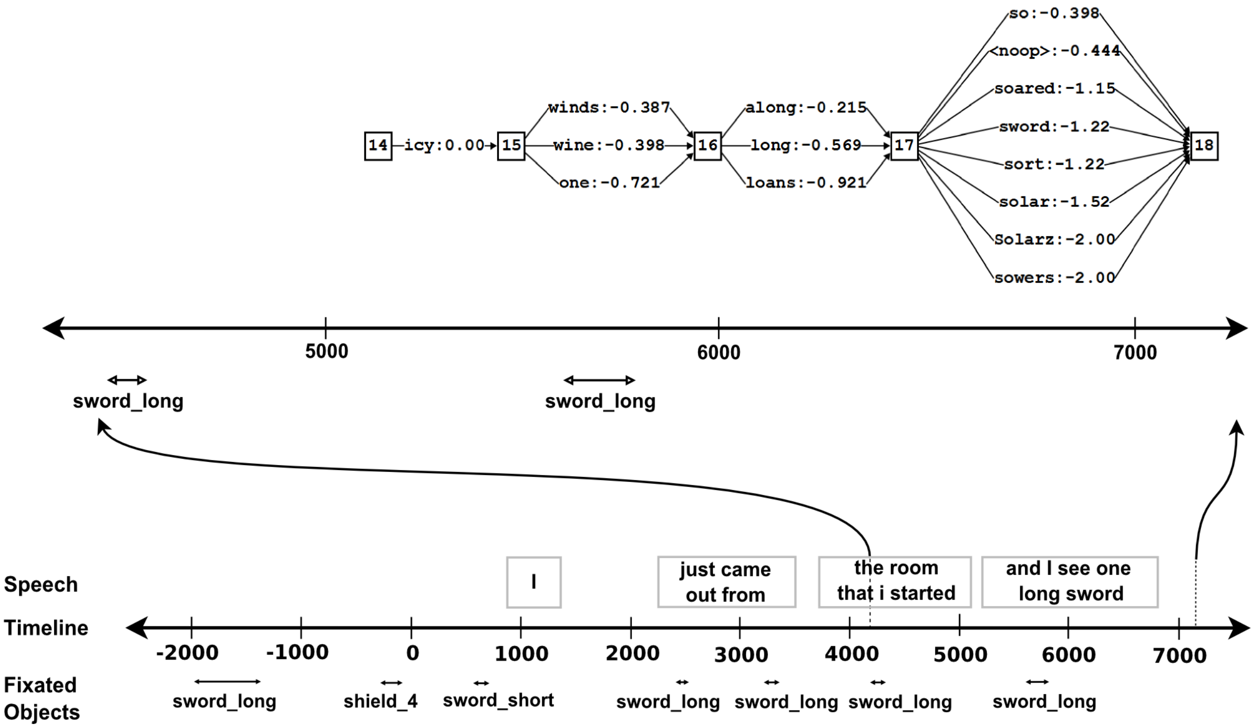

Figure 2: Sample parallel speech and eye gaze data streams, including a portion of the sample WCN

Step 2: extract referring expressions from WCN The word confusion network is syntactically parsed using a modified version of the CYK (Cooke and Schwartz, 1970; Kasami, 1965; Younger, 1967) parsing algorithm that is capable of taking a word confusion network as input rather than a single string. We call this the CYK-WCN algorithm. To do the parsing, we applied a set of grammar rules largely derived from a different domain in our previous work (Prasov and Chai, 2008). A parse chart of the sample word confusion network is shown in Table 3. Here, just as in the CYK algorithm the chart is filled in from left to right then bottom to top. The difference is that the chart has an added dimension for competing word hypotheses. This is demonstrated in position 15 of the WCN, where `one` and `wine` are two nouns that constitute competing words. Note that some words from the confusion network are not in the chart (e.g. `winds`) because they are out of vocabulary. The result of the syntactic parsing is that the parts of speech of all sub-phrases in the confusion network are identified. Next, a set of all exophoric referring expressions (i.e. non-pronominal noun phrases) found in the word confusion network are extracted. Each referring expression has a corresponding confidence score, which can be computed in many many different ways. Currently, we simply take the mean of the probability scores of the expression's constituent words. The sample WCN has four such phrases (shown in bold in Table 3): `wine` at position 15 with length 1, `one long sword` at position 15 with length 3, `long sword` at position 16 with length 2, and `sword` at position 17 with length 1.

Step 3: resolve referring expressions Each referring expression r_j is resolved to the top k potential referent objects according to the probability $P(o_i|r_j)$, where k is determined by information from the linguistic expressions. $P(o_i|r_j)$ is determined using the following expression:

$$P(o_i|r_j) = \frac{AS(o_i)^{\alpha} \times Compat(o_i, r_j)^{1-\alpha}}{\sum_i AS(o_i)^{\alpha} \times Compat(o_i, r_j)^{1-\alpha}} \tag{1}$$

In this equation,

- AS: Attentional salience score of a particu-

length	...						
	5						
	4						
	3		**NP → NUM Adj-NP**				
	2			Adj-NP → ADJ N, **NP → Adj-NP**

	...	14	15	16	17	18	...
	WCN position						

Table 3: Syntactic parsing of word confusion network

lar object o_i, which is determined based on the gaze *fixation intensity* of an object at the start time of referring expression r_j. The fixation intensity of an object is defined as the amount of time that the object is fixated during a predefined time window W (Prasov and Chai, 2008). As in (Prasov and Chai, 2008), we set $W = [-1500..0]$ ms relative to the beginning of referring expression r_j.

- $Compat$: Compatibility score, which specifies whether the object o_i is compatible with the information specified by the referring expression r_j. Currently, the compatibility score is set to 1 if referring expression r_j and object o_i have the same object type (e.g. chair), and 0 otherwise.

- α: Importance weight, in the range $[0..1]$, of attentional salience relative to compatibility. A high α value indicates that the attentional salience score based on eye gaze carries more weight in deciding referents, while a low α value indicates that compatibility carries more weight. In this work, we set $\alpha = 0.5$ to indicate equal weighting between attentional salience and compatibility. If we do not want to integrate eye gaze in reference resolution, we can set $\alpha = 0.0$. In this case, reference resolution will be purely based on compatibility between visual objects and information specified via linguistic expressions.

Once all probabilities are calculated, each referring expression is resolved to a set of referent objects. Finally, this results in a set of *(referring expression, referent object set)* pairs with confidence scores, which are determined by two components. The first component is the confidence score of the referring expression, which is explained in the Step 1 of the algorithm. The second component is the probability that the referent object set is indeed the referent of this expression (which is determined by Equation 1). There are various ways to combine these two components together to form an overall confidence score for the pair. Here we simply multiply the two components. The confidence score for the pair is used in the following step to prune unlikely referring expressions.

Step 4: post-prune The resulting set of *(referring expression, referent object set)* pairs is pruned to remove pairs that fall under one of the following two conditions: (1) the pair has a confidence score equal to or below a predefined threshold ϵ (currently, the threshold is set to 0 and thus keeps all resolved pairs) and (2) the pair temporally overlaps with a higher confidence pair. For example, in Table 3, the referring expressions `one long sword` and `wine` overlap in position 15. Finally, the resulting *(referring expression, referent object set)* pairs are sorted in ascending order according to their constituent referring expression timestamps.

6 Experimental Results

Using our data, described in Section 3, we applied the multimodal reference resolution algorithm described in Section 5. All of the data is used to report the experimental results. Reference resolution model parameters are set based on our prior work in a different domain (Prasov and Chai, 2008). For each utterance we compare the reference resolution performance with and without the integration of eye gaze information. We also evaluate using a word confusion network compared to a 1-best list to model speech recognition hypotheses. For perspective, reference resolution with recognized speech input is compared with transcribed speech.

6.1 Evaluation Metrics

The reference resolution algorithm outputs a list of *(referring expression, referent object set)* pairs for each utterance. We evaluate the algorithm by comparing the generated pairs to the annotated "gold standard" pairs using F-measure. We perform the following two types of evaluation:

- Lenient Evaluation: Due to speech recognition errors, there are many cases in which the algorithm may not return a referring expression that exactly matches the gold standard referring expression. It may only match based on the object type. For example, the expressions `one long sword` and `sword` are different, but they match in terms of the intended object type. For applications in which it is critical to identify the objects referred to by the user, precisely identifying uttered referring expressions may be unnecessary. Thus, we evaluate the reference resolution algorithm with a lenient comparison of *(referring expression, referent object set)* pairs. In this case, two pairs are considered a match if at least the object types specified via the referring expressions match each other and the referent object sets are identical.

- Strict Evaluation: For some applications it may be important to identify exact referring expressions in addition to the objects they refer to. This is important for applications that attempt to learn a relationship between referring expressions and referenced objects. For example, in automated vocabulary acquisition, words other than object types must be identified so the system can learn to associate these words with referenced objects. Similarly, in systems that apply priming for language generation, identification of the exact referring expressions from human users could be important. Thus, we also evaluate the reference resolution algorithm with a strict comparison of *(referring expression, referent object set)* pairs. In this case, a referring expression from the system output needs to exactly match the corresponding expression from the gold standard.

6.2 Role of Eye Gaze

We evaluate the effect of incorporating eye gaze information into the reference resolution algorithm using the top best recognition hypothesis (*1-best*), the word confusion network (*WCN*), and the manual speech transcription (*Transcription*). Speech transcription, which contains no recognition errors, demonstrates the upper bound performance of our approach. When no gaze information is used, reference resolution solely depends on linguistic and semantic processing of referring expressions. Table 4 shows the lenient reference resolution evaluation using F-measure. This table demonstrates that lenient reference resolution is improved by incorporating eye gaze information. This effect is statistically significant in the case of transcription and 1-best ($p < 0.0001$ and $p < 0.009$, respectively) and marginal ($p < 0.07$) in the case of WCN.

Configuration	Without Gaze	With Gaze
Transcription	0.619	0.676
WCN	0.524	0.552
1-best	0.471	0.514

Table 4: Lenient F-measure Evaluation

Configuration	Without Gaze	With Gaze
Transcription	0.584	0.627
WCN	0.309	0.333
1-best	0.039	0.035

Table 5: Strict F-measure Evaluation

Table 5 shows the strict reference resolution evaluation using F-measure. As can be seen in the table, incorporating eye gaze information significantly ($p < 0.0024$) improves reference resolution performance when using transcription and marginally ($p < 0.113$) in the case of WCN optimized for strict evaluation. However there is no difference for the 1-best hypotheses which result in extremely low performance. This observation is not surprising since 1-best hypotheses are quite error prone and less likely to produce the exact expressions.

Since eye gaze can be used to direct navigation in a mobile environment as in situated dialogue, there could be situations where eye gaze does not reflect the content of the corresponding speech. In such situations, integrating eye gaze in reference resolution could be detrimental. To further understand the role of eye gaze in reference resolution, we applied our reference resolution algorithm only to utterances where speech and eye gaze are considered closely coupled (i.e., eye gaze reflects the content of speech). More specifically, following the previous work (Qu and Chai, 2010), we define a *closely coupled* utterance as one in which at least one noun or adjective describes an object that has been fixated by the corresponding gaze stream.

Table 6 and Table 7 show the performance based on closely coupled utterances using lenient and strict evaluation, respectively. In the lenient evaluation, reference resolution performance is significantly improved for all input configurations when eye gaze information is incorporated ($p < 0.0001$ for transcription, $p < 0.015$ for WCN, and $p < 0.0022$ for 1-best). In each case the closely coupled utterances achieve higher performance than the entire set of utterances evaluated in Table 5. Aside from the 1-best case, the same is true when using strict evaluation ($p < 0.0006$ for transcription and $p < 0.046$ for WCN optimized for strict evaluation). This observation indicates that in situated dialogue, some mechanism to predict whether a gaze stream is closely coupled with the corresponding speech content can be beneficial in further improving reference resolution performance.

Configuration	Without Gaze	With Gaze
Transcription	0.616	0.700
WCN	0.523	0.570
1-best	0.473	0.537

Table 6: Lenient F-measure Evaluation for Closely Coupled Utterances

6.3 Role of Word Confusion Network

The effect of incorporating eye gaze with WCNs rather than 1-best recognition hypotheses into reference resolution can also be seen in Tables 4 and 5. Table 4 shows a significant improvement when using WCNs rather than 1-best hypotheses for both with ($p < 0.015$) and without ($p < 0.0012$) eye gaze configurations. Similarly, Table 5 shows a significant improvement in strict evaluation when using WCNs rather than 1-best hypotheses for both with ($p < 0.0001$) and without ($p < 0.0001$) eye gaze configurations. These results indicate that using word confusion networks improves both lenient and strict reference resolution. This observation is not surprising since identifying correct linguistic expressions will enable better search for semantically matching referent objects.

Configuration	Without Gaze	With Gaze
Transcription	0.579	0.644
WCN	0.307	0.345
1-best	0.045	0.038

Table 7: Strict F-measure Evaluation for Closely Coupled Utterances

Although WCNs lead to better performance, utilizing WCNs is more computationally expensive compared to 1-best recognition hypotheses. Nevertheless, in practice, WCN depth, which specifies the maximum number of competing word hypotheses in any position of the word confusion network, can be limited to a certain value $|d|$. For example, in Figure 2 the depth of the shown WCN is 8 (there are 8 competing word hypotheses in position 17 of the WCN). The WCN depth can be limited by pruning word alternatives with low probabilities until, at most, the top $|d|$ words remain in each position of the WCN. It is interesting to observe how limiting WCN depth can affect reference resolution performance. Figure 3 demonstrates this observation. In this figure the resolution performance (in terms of lenient evaluation) for WCNs of varying depth is shown as dashed lines for with and without eye gaze configurations. As a reference point, the performance when utilizing 1-best recognition hypotheses is shown as solid lines. It can be seen that as the depth increases, the performance also increases until the depth reaches 8. After that, there is no performance improvement.

7 Discussion

In Section 6.2 we have shown that incorporating eye gaze information improves reference resolution performance. Eye-gaze information is particu-

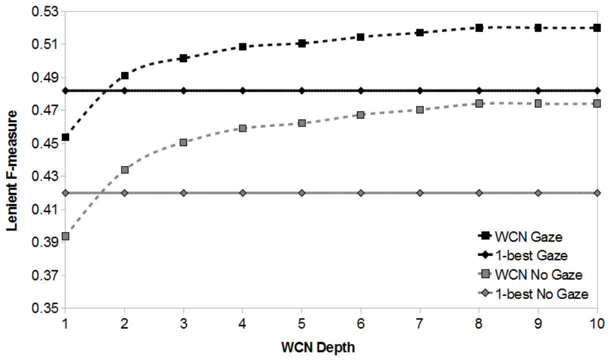

Figure 3: Lenient F-measure at each WCN Depth

larly helpful for resolving referring expressions that are ambiguous from the perspective of the artificial agent. Consider a scenario where the user utters a referring expression that has an equivalent semantic compatibility with multiple potential referent objects. For example, in a room with multiple books, the user utters "the open book to the right", but only the phrase "the book" is recognized by the ASR. If a particular book is fixated during interaction, there is a high probability that it is indeed being referred to by the user. Without eye gaze information, the semantic compatibility alone could be insufficient to resolve this referring expression. Thus, when eye gaze information is incorporated, the main source of performance improvement comes from better identification of potential referent objects.

In Section 6.3 we have shown that incorporating multiple speech recognition hypotheses in the form of a word confusion network further improves reference resolution performance. This is especially true when exact referring expression identification is required (F-measure of 0.309 from WCNs compared to F-measure of 0.039 from 1-best hypotheses). Using a WCN improves identification of low-probability referring expressions. Consider a scenario where the top recognition hypothesis of an utterance contains no referring expressions or an incorrect referring expression that has no semantically compatible potential referent objects. If a referring expression with a high compatibility value to some potential referent object is present in a lower probability hypothesis, this referring expression can only be identified when a WCN rather than a 1-best hypothesis is utilized. Thus, when word confusion networks are incorporated, the main source of performance improvement comes from better referring expression identification.

7.1 Computational Complexity

One potential concern of using word confusion networks rather than 1-best hypotheses is that they are more computationally expensive to process. The asymptotic computational complexity for resolving the referring expressions using the algorithm presented in this work with a WCN is the summation of three components: (1) $O(|G| \cdot |d|^2 \cdot |w|^3)$ for confusion network construction and parsing, (2) $O(|r| \cdot |O| \cdot log(|O|))$ for reference resolution, and (3) $O(|r|^2)$ for selection of *(referring expression, referent object set)* pairs. Here, $|w|$ is the number of words in the input speech signal (or, more precisely, the number of words in the longest ASR hypothesis for a given utterance); $|G|$ is the size of the parsing grammar; $|d|$ is the depth of the constructed word confusion network; $|O|$ is the number of potential referent objects for each utterance; and $|r|$ is the number of referring expressions that are extracted from the word confusion network.

The complexity is dominated by the word confusion network construction and parsing. Also, both the number of words in an input utterance ASR hypothesis $|w|$ and the number of referring expressions in a word confusion network $|r|$ are dependent on utterance length. In our study, interactive dialogue is encouraged and, thus, utterances are typically short; with a mean length of 6.41 words and standard deviation of 4.35 words. The longest utterances in our data set has 31 words. WCN depth $|d|$ has a mean of 10.1, a standard deviation of 8.1, and a maximum 89 words. In practice, as shown in Section 6.3, limiting $|d|$ to 8 words achieves comparable reference resolution results as using a full word confusion network.

To demonstrate the applicability of our reference resolution algorithm for real-time processing, we applied it on the data corpus presented in Section 3. This corpus contains utterances with a mean input time of 2927.5 ms and standard deviation of 1903.8 ms. On a 2.4 GHz AMD Athlon(tm) 64 X2 Dual Core Processor, the runtimes resulted in a real time factor of 0.0153 on average. Thus, on average, an utterance from this corpus can be processed in just under 45 ms, which is well within the range of acceptable real-time performance.

7.2 Error Analysis

As can be seen in Section 6, even when using transcribed data, reference resolution performance still has room for improvement (achieving the highest lenient F-measure of 0.700 when eye gaze is utilized for resolving closely coupled utterances). In this section, we elaborate on the potential error sources. Specifically, we discuss two types of error: (1) a referring expression is incorrectly recognized or (2) a recognized referring expression is not resolved to a correct referent object set.

Given transcribed data, which simulates perfectly recognized utterances, all referring expression recognition errors arise due to incorrect language processing. Most of these errors occur because an incorrect part of speech (POS) tag is assigned to a word, or an out-of-vocabulary (OOV) word is encountered, or the parsing grammar has insufficient coverage. A particularly interesting parsing problem occurs due to the nature of spoken language. Since punctuation is sometimes unavailable, given an utterance with several consecutive nouns, it is unclear which of these nouns should be treated as head nouns and which should be treated as noun modifiers. For example, in the utterance "there is *a desk lamp* table and two chairs" it is unclear if the italicized expression should be parsed as a single phrase or as a list of (two) phrases `a desk` and `lamp`. Thus, some timing information should be used for disambiguation.

Object set identification errors are more prevalent than referring expression recognition errors. The majority of these errors occur because a referring expression is ambiguous from the perspective of the conversational system and there is not enough information to choose amongst multiple potential referent objects due to limited speech recognition and domain modeling. One reason for this is that a referring expression may be resolved to an incorrect number of referent objects. Another reason is that a pertinent object attribute or a distinguishing spatial relationship between objects specified by the user cannot be established by the system. For example, during the utterance "I see *a vase* left of the table" there are two vases visible on the screen creating an ambiguity if the phrase `left of` is not processed correctly. This is caused by an inadequate representation of spatial relationships and processing of spatial language. One more reason for potential ambiguity is the lack of pragmatic knowledge that can support adequate inference. For example, when the user refers to two *sofa* objects using the phrase "*an armchair* and *a sofa*", the system lacks pragmatic knowledge to indicate that `arm chair` refers to the smaller of the two objects. Some of these errors can be avoided when eye gaze information is available to the system. However, due to the noisy nature of eye gaze data, many such referring expressions remain ambiguous even when eye gaze information is considered.

8 Conclusion

In this work, we have examined the utility of eye gaze and word confusion networks for reference resolution in situated dialogue within a virtual world. Our empirical results indicate that incorporating eye gaze information with recognition hypotheses is beneficial for the reference resolution task compared to only using recognition hypotheses. Furthermore, using a word confusion network rather than the top best recognition hypothesis further improves reference resolution performance. Our findings also demonstrate that the processing speed necessary to integrate word confusion networks with eye gaze information is well within the acceptable range for real-time applications.
