B Zero-shot prompt

The following text is our prompt for LLM:

You are a Finnish grammatical error correction (GEC) system. Your task is to correct grammatical errors in Finnish sentences while making minimal changes.

Rules:

- Fix ONLY grammatical errors (morphology, case endings, verb conjugation, agreement).
- Do NOT paraphrase or change the meaning.
- Do NOT change vocabulary unless the word itself is wrong.
- Make the MINIMAL number of changes necessary.
- Output ONLY the corrected sentence - no explanation, no commentary.
- If the sentence has no errors, output it unchanged.

Hyperparameter	Stage 1	Stage 2
Quantization	4-bit	
LoRA rank	64	
LoRA alpha	128	
LoRA target	All Linear	
LoRA Dropout	0.05	
Num. Base Params	8B	
Num. Trainable Params	167M (2.01%)	
Optimizer	AdamW	
Learning rate	2e-4	1e-5
Max epochs	2

From Metrics to Meaning: Rule-Grounded LLM Explanations for Data Literacy in the Case of Youth Football

Faculty of Mathematics and Computer Science

Uniwersytetu Poznańskiego 4, 61-614 Poznań, Poland

Abstract

Young athletes, parents, and coaches are increasingly exposed to training metrics from wearable technology, yet such metrics are difficult to interpret without contextual explanation. We present a rule-grounded data-to-text framework for supporting data literacy in youth football through concise, stakeholder-specific summaries of training sessions. A rule layer maps duration-normalised indicators to structured facts about session profile, internal intensity, speed exposure, and movement dynamics, which are then verbalised by a large language model for coaches, parents, or players. We compare direct generation from raw metrics, generation from rule-derived facts, and an augmented rule-grounded configuration, ENRICHED, that supplements validated facts with raw metrics and explicit threshold definitions. In this setting, selected open-weight models are additionally adapted using LoRA. The framework is developed using 122 anonymised player-session records from a U15 environment and evaluated on a held-out subset of ten sessions with stakeholder-oriented reference summaries. The results indicate that rule grounding improves reliability and audience adaptation compared with direct generation from raw metrics, particularly by reducing unsupported or overly strong interpretations. A school-based expert evaluation with physical education teachers further suggests that player-facing explanations in the evaluated ENRICHED setting can remain accurate, comprehensible, and practically useful. We position the framework as an interpretable data-literacy support interface for youth sport analytics.

1 Introduction

Wearable sensors and training analytics platforms are becoming increasingly common in youth sports. As a result, coaches, parents, and young athletes are exposed to growing amounts of numerical information about training load, movement dynamics, and

physiological effort. However, such metrics require context to become understandable and practically meaningful. Stakeholders often encounter dashboards and indicators without sufficient guidance on how to interpret these measurements in relation to a specific training session. This creates a data literacy challenge: translating quantitative signals into concise, context-sensitive explanations.

This challenge is particularly evident in youth football, where the same session may need to be explained differently to different audiences. Coaches require concise technical interpretations that remain faithful to the data, whereas parents and players need clearer explanations that avoid specialist terminology and communicate the practical meaning of the metrics. In this setting, explanation functions as an educational interface that helps stakeholders read and reason about performance data.

This perspective aligns with recent educational Natural Language Processing (NLP) research on stakeholder needs, pedagogical alignment, and human-centred evaluation in Large Language Model (LLM)-based educational systems (Pal Chowdhury et al., 2025a; Galletti and Cesaroni, 2025). Recent work also suggests that pedagogical generation benefits from explicit control over communicative intent, while pedagogical quality remains difficult to assess using automatic methods alone (Petukhova and Kochmar, 2025; Kochmar et al., 2025). These concerns are directly relevant in our setting: when an LLM interprets raw training metrics without additional structure, it may produce explanations that are fluent but unsupported, overly strong, or inappropriate for the intended audience.

To address this issue, we propose a rule-grounded data-to-text framework for supporting data literacy in youth football. A rule layer converts normalised session metrics into interpretable facts about session profile, effort characteristics, and movement dynamics. An LLM then verbalises

these facts for a selected audience—coach, parent, or player—using audience-specific framing and terminology. We compare three generation settings: direct generation from raw metrics, strictly rule-grounded generation, and an augmented rule-grounded configuration, ENRICHED, that supplements validated rule-derived facts with raw metrics and explicit band definitions. In the open-weight experiments, LoRA adaptation is applied only to the selected models in ENRICHED; we therefore treat this condition as an applied configuration rather than as an isolated ablation of the added metric and threshold information.

The framework is developed using 122 anonymised player-session records from a U15 football environment. The controlled evaluation is conducted on a held-out subset of ten sessions for which aligned coach-, parent-, and player-facing reference summaries were prepared. The study addresses three questions: whether explicit rule grounding improves interpretive reliability compared with direct generation from raw metrics; whether the same rule-derived session interpretation can support multiple stakeholder groups while preserving a common session meaning; and whether ENRICHED can provide player-facing explanations that remain educationally useful and practically understandable. Our main contribution is to operationalise automated session summarisation as a stakeholder-oriented data literacy support problem rather than as a generic data-to-text task. By combining domain-informed rule grounding with persona-specific LLM verbalisation, the framework connects wearable-sensor metrics with explanations that are faithful to the data, adapted to the audience, and meaningful in practice.

2 Related Work

Recent work in educational NLP emphasises that LLM-based systems should be designed and evaluated with respect to stakeholder needs, pedagogical goals, and authentic educational workflows, rather than fluency alone (Pal Chowdhury et al., 2025a; Galletti and Cesaroni, 2025; Pal Chowdhury et al., 2025b). This view is consistent with research on data literacy, which shows that indicators and dashboards require contextualised support to become meaningful for users (Konold et al., 2015; Mandinach and Gummer, 2016; Michos et al., 2023; Valle et al., 2021). In youth football, this implies that training metrics should be communicated in

ways that are understandable and appropriate for coaches, parents, and players.

From a generation perspective, our work builds on data-to-text conversion and controlled generation from structured inputs. Classical NLG research has emphasised content determination, content selection, planning, and surface realisation when generating text from data (Reiter and Dale, 2000; Gatt and Krahmer, 2018). These challenges remain central in neural and LLM-based generation, particularly where factual accuracy and numerical consistency are required (Wiseman et al., 2017; Puduppully et al., 2019; Chen et al., 2020; Maynez et al., 2020). Our framework follows this tradition by introducing an explicit interpretive layer between numerical session metrics and natural-language realisation.

Related work also highlights the importance of controlling communicative intent, audience, and readability in generated text (Petukhova and Kochmar, 2025; Moorjani et al., 2022; Tran et al., 2025). This is especially relevant in youth football, where movement and load indicators vary across age, role, and match context (Harley et al., 2010; Atan et al., 2016; Algroy et al., 2021; Palucci Vieira et al., 2019; Dalen and Loras, 2019; Hannon et al., 2021). We extend these perspectives by treating session summarisation as stakeholder-oriented explanatory generation for data literacy support. Rule grounding makes the interpretation traceable and auditable, while LLM realisation adapts the same underlying session meaning to coaches, parents, and players.

3 Rule-Grounded Formulation

Let $x_{i,t}$ denote a player-session record for player i in session t , where t indexes a training or match session rather than continuous time. Each record is represented as a vector of wearable-derived numerical indicators, including measures of external load, internal intensity, speed exposure, and movement dynamics. The goal is to generate a short natural-language explanation y for a target stakeholder $p \in \{\text{coach, parent, player}\}$.

We consider three generation settings that differ in the amount of interpretive structure provided to the language model. In all cases, a feature mapping ϕ preprocesses the raw player-session record and applies duration normalisation to selected indicators, yielding $\phi(x_{i,t})$. A banding function B then maps selected normalised indicators to ordinal lev-

els such as low, medium, high, and elite, using metric-specific threshold definitions Θ :

$$z_{i,t} = B(\phi(x_{i,t}); \Theta) \quad (1)$$

The banded representation $z_{i,t}$ is passed to a rule base R , which produces a set of structured explanatory facts:

$$F_{i,t} = R(z_{i,t}) = \{(f_k, s_k, \pi_k)\}_{k=1}^K \quad (2)$$

Here, f_k is an interpreted claim about the session, s_k is the supporting evidence associated with that claim, such as the relevant metric value and band, and π_k is a priority value used for content selection when multiple facts are available.

Each fact is represented as a compact structured object containing a fact type, supporting metric, interpreted value, and priority level. The rule base encodes domain knowledge about session characteristics, including overall load profile, internal intensity, speed exposure, and movement dynamics. For example, HighDist is activated when distance per minute is assigned to a high band and emits the following load-profile fact: “Distance per minute is high, so this session involved a large amount of running in volume terms. This may support endurance development and sustained lower-limb work, even if there were not many short bursts.” The example shows how the rule layer converts a metric band into an interpretable statement that can later be verbalised differently for coaches, parents, or players. When multiple rules are activated simultaneously, priority-based selection resolves overlap and determines which facts are passed to the generation stage.

The three generation settings differ in the conditioning input provided to the language model:

$$C_m(x_{i,t}) = \begin{cases} \phi(x_{i,t}), & m = \text{RAW}, \\ F_{i,t}, & m = \text{RULES}, \\ (F_{i,t}, \phi(x_{i,t}), \Theta), & m = \text{ENRICHED} \end{cases} \quad (3)$$

The final explanation is produced by a language generation module conditioned on the selected input and the target persona:

$$y = G(C_m(x_{i,t}), p) \quad (4)$$

The generation setting is indexed by $m \in \{\text{RAW}, \text{RULES}, \text{ENRICHED}\}$.

This formulation separates analytical interpretation from linguistic realisation. In the RAW setting,

the language model receives normalised metrics and must infer their meaning directly. In the RULES setting, the rule layer determines the structured interpretation to be verbalised for a given audience. In ENRICHED, rule-derived facts are supplemented with the underlying normalised metrics and threshold definitions. In the implementation evaluated here, the selected open-weight models in this setting are additionally adapted using LoRA.

4 System Overview

4.1 Architecture

Figure 1 shows the proposed pipeline for generating short, stakeholder-oriented explanations from structured training-session data. The system preprocesses wearable-derived metrics into normalised features, maps them to ordinal interpretive bands, and passes them to a rule layer that produces structured explanatory facts about the session profile. A persona-conditioned LLM then generates audience-specific summaries under three input settings: direct generation from normalised raw metrics (RAW), generation from validated rule-derived facts only (RULES), and generation from rule-derived facts supplemented with raw metrics and explicit band definitions (ENRICHED).

In the implementation evaluated here, the selected open-weight models used in the ENRICHED setting are additionally adapted using LoRA. The architecture supports both the RAW–RULES comparison and the applied evaluation of ENRICHED.

Figure 1: Overview of the proposed persona-specific summary generation pipeline. The central flow represents the main processing stages, while side labels indicate the functional role of each stage. Violet highlights the generative core.

4.2 Rule Layer

The rule layer transforms normalised session features into structured explanatory facts and performs content selection before generation. Selected metrics are mapped to ordinal bands (*low*, *medium*, *high*, *elite*) using metric-specific threshold definitions. These bands provide a traceable intermediate representation for deterministic reasoning about the session profile.

The rule base applies domain-informed conditions to derive compact facts about overall load, internal intensity, speed exposure, and movement dynamics. Each activated rule is represented by a rule identifier, a short explanatory fact, the metric context from which it was triggered, and a priority value used to resolve overlap between simultaneously activated rules. For example, a high distance-per-minute band can activate a load-profile fact indicating substantial running volume. Priority-based selection determines which facts are passed to the generation stage.

In the RULES setting, only the selected rule-derived facts are passed to the generator. In the ENRICHED setting, these facts are accompanied by the normalised raw metrics and the explicit threshold definitions used to derive the bands.

4.3 LLM Realisation

The language model verbalises the selected session interpretation for the target audience under persona-specific style constraints. Generation is prompt-based in all settings: the model receives a structured input for the active condition and an instruction specifying the target persona, expected level of technical detail, and output length. Inputs were serialised as compact JSON-style records containing either the eight metric values, the selected rule-derived facts, or the selected facts together with metric values and threshold definitions.

For coach-facing summaries, the realisation emphasises concise technical interpretation and metric-aware phrasing. For parents, the model uses accessible language and practical framing while avoiding unnecessary technical detail. For players, the summaries use simpler, experience-oriented language adapted to the athlete's perspective.

Across all settings, the LLM expresses the session meaning in audience-appropriate language. The settings differ in how much of this meaning is provided explicitly: in RAW, the model must infer the interpretation from normalised metrics; in

RULES, it receives selected rule-derived facts; and in ENRICHED, these facts are supplemented with supporting numerical metrics and threshold definitions. In the ENRICHED experiments reported here, the selected open-weight realisation models are additionally adapted using LoRA.

5 Data and Preprocessing

The dataset consists of 122 anonymised player-session records collected from 24 U15 players aged 14–15 in a youth football environment. Each record corresponds to one player observed in one training or match session and contains session metadata together with wearable-derived indicators of external load, internal intensity, speed exposure, and movement dynamics. The data were processed at the player-session level, so each instance represents one athlete's session profile rather than an aggregate team-level session.

The analytical vector used by the rule layer contained eight core metrics: distance per minute, high-metabolic-load distance per minute, high-speed-running distance per minute, maximal velocity, accelerations per minute, decelerations per minute, time in heart-rate zones 4–5, and metabolic power per minute. Session duration was retained as a separate metadata field, while selected exposure variables were expressed per minute to support comparison across sessions of different length.

For rule-based interpretation, selected normalised indicators were mapped to ordinal bands (*low*, *medium*, *high*, *elite*). Higher-intensity thresholds were based on youth-football reference values, while lower bands were calibrated using the empirical distribution of the collected data and coach input. The resulting banded representation was used to derive structured explanatory facts.

The processed dataset was split according to the experimental design. A held-out subset of ten player-session records was used for the controlled RAW–RULES comparison and for the evaluation of the ENRICHED setting. The remaining 112 records were used as adaptation data for the LoRA-based implementation of ENRICHED. In this setting, the generator also received normalised raw metrics and corresponding threshold definitions together with the rule-derived facts. Records with incomplete or inconsistent data were excluded from subsequent rule-based analysis. All data were processed in anonymised form.

6 Experimental Design

Rather than evaluating the framework as a broad model benchmark, we assess it as a stakeholder-oriented educational communication system. The evaluation has two complementary stages. First, we compare RAW and RULES generation for coach-facing summaries, where unsupported claims and scale-related errors are particularly salient because the summaries require technical interpretation. Second, we evaluate ENRICHED for player-facing summaries through a school-based expert study. Because these stages address different parts of the framework and use different evaluation procedures, their results are interpreted as complementary rather than directly interchangeable.

The study addresses three questions: whether explicit rule grounding improves reliability compared with direct generation from raw metrics; whether the same rule-derived session interpretation can support multiple stakeholder groups; and whether ENRICHED can produce player-facing explanations that remain educationally useful in the evaluated setting.

6.1 Compared Conditions

We compare three generation conditions.

RAW. In the baseline condition, duration-normalised numerical session indicators are provided directly to the language model, which must infer their meaning during generation.

RULES. In the strictly rule-grounded condition, the rule layer converts the normalised metrics into structured explanatory facts. The language model then verbalises only these selected facts for the target audience.

ENRICHED. In this augmented rule-grounded condition, the model receives the selected rule-derived facts together with normalised raw metrics and the explicit threshold definitions used to assign ordinal bands (*low*, *medium*, *high*, *elite*). The additional information therefore refers specifically to supporting metric values and threshold definitions, rather than to broader contextual variables such as individual condition or training history. In the implementation studied here, the selected open-weight models are additionally adapted using LoRA. This condition therefore combines richer input information, threshold exposure, and model adaptation, and is not treated as an ablation of any single factor.

In all settings, the output is a short natural-

language session summary intended as an explanatory note rather than a full analytical report. Aligned coach–parent–player reference triplets are used as a qualitative anchor for stakeholder alignment rather than as a separate quantitative benchmark.

6.2 Evaluation Data and Reference Set

The full dataset comprises 122 player-session records collected in a U15 football setting. For the controlled comparison, we used a held-out subset of ten sessions with manually prepared, stakeholder-oriented reference summaries for coaches, parents, and players. The selected sessions are as follows: 3, 9, 10, 12, 14, 23, 24, 25, 50, and 89.

The three reference sets provide the same underlying session interpretation in audience-specific formats. Coach summaries explicitly mention performance indicators and their interpretation, parent summaries retain the main message while simplifying terminology, and player summaries use second-person, experience-oriented language. This aligned triplet design supports qualitative assessment of whether generated summaries preserve the same semantic core while adapting to different stakeholder needs.

The same held-out ten-session subset was used for the RAW–RULES comparison and for the evaluation of ENRICHED. The remaining 112 player-session records were used as adaptation data for the LoRA-based implementation described in Section 6.3. This allocation reflects the constraints of the available dataset and keeps the evaluation subset separate from adaptation. Given the size of the held-out subset, the quantitative scores are used primarily as descriptive indicators within this evaluation setting.

6.3 Models and Generation Setup

The study follows a staged evaluation setup. In the first stage, we replicate the RAW–RULES comparison on the ten-session evaluation subset using LLM-as-a-judge and qualitative expert review. This stage is used to assess the effect of explicit rule grounding and to identify models suitable for further adaptation.

On this basis, we selected two models for the ENRICHED stage: **Mistral-3B-Instruct** and **Llama-8B-Instruct**. Mistral-3B-Instruct was selected as the stronger variant within the Mistral family in the replicated comparison, while Llama-8B-Instruct

was retained as a representative of a different open-weight model family. Hosted commercial models were not included in this stage because LoRA adaptation was only feasible for open-weight models in our implementation.

Generation parameters were held constant within each model across the RAW and RULES conditions. All outputs were generated from the same ten-session subset using matched prompts and identical output-length constraints. For the ENRICHED condition, the selected models were adapted with LoRA on the remaining 112 sessions and evaluated on the held-out ten-session subset.

For LoRA adaptation, we constructed persona-specific prompt-completion pairs from the non-evaluation records only. Each input used the same ENRICHED representation as at inference time: a standardised session header, normalised raw metrics, rule-derived observations, threshold definitions, and the persona instruction. Each target completion was a short Polish summary for the selected stakeholder. In our implementation, these target summaries were obtained through teacher-model distillation using the strongest prompt-based system available in the pipeline. The authors then screened them for formatting consistency and obvious factual issues. The held-out evaluation subset was excluded from this adaptation process.

Given the limited adaptation set and the absence of a dedicated development split, we used one conservative LoRA configuration for both adapted open-weight models rather than performing a broad hyperparameter search. We used QLoRA with 4-bit NF4 quantization and bf16 compute, LoRA rank $r = 8$, $\alpha = 16$, dropout = 0.05, and attention-projection target modules (q_proj, k_proj, v_proj, o_proj). Training used paged AdamW 8-bit, learning rate 1×10^{-4} , per-device batch size 1, gradient accumulation 8, 5 epochs, maximum sequence length 2048, and random seed 42.

Generation remained prompt-based in all conditions. Within each summary-generating model, the decoding setup was kept fixed across the compared prompting conditions. For the selected open-weight models carried forward to the ENRICHED stage, we used low-temperature decoding with fixed output-length limits: temperature 0.05 for Mistral-3B-Instruct and 0.07 for Llama-8B-Instruct, with a maximum of 400 generated tokens. Persona prompts and output-length constraints were kept unchanged within each model

family.

Prompt format example. In the ENRICHED setting, the model input was serialised as a compact JSON-style structure containing: (i) a standardised session header, (ii) normalised raw metrics, (iii) rule-derived textual observations, and (iv) threshold definitions. This structured input was followed by a persona-specific instruction controlling audience, expected technicality, and target length.

6.4 Evaluation Dimensions

The evaluation combines quantitative and qualitative perspectives to capture interpretive reliability and educational usefulness across the studied conditions.

Interpretive reliability. First, we assess whether the generated summaries remain faithful to the source session profile. This dimension focuses on factual faithfulness and numerical consistency, with special attention to unsupported inferences, incorrect magnitude interpretation, and misleading summary framing.

LLM-as-a-judge assessment. Second, in the RAW-RULES comparison, we evaluate coach-facing summaries using a fixed LLM-as-a-judge rubric. GPT-4o mini was used as the judge model for all candidate summaries. Summaries are assessed with respect to faithfulness, coach value, narrative quality, output hygiene, conciseness, and language quality, together with an aggregate *Overall* score. Output hygiene refers to whether the summary avoids malformed structure, irrelevant boilerplate, contradictory statements, excessive repetition, and formatting artefacts. The resulting scores are interpreted descriptively, with emphasis on within-generator differences between RAW and RULES.

Reference-based stakeholder alignment analysis. Third, we use the manually prepared coach-parent-player reference triplets as a qualitative interpretive anchor for examining whether generated summaries preserve the same underlying session meaning while adapting terminology, explicitness, and communicative stance across audiences. This component supports qualitative analysis of stakeholder alignment.

School-based expert evaluation. Finally, ENRICHED is evaluated in a school-based expert study focused on player-facing summaries. Nine

physical education teachers from primary, technical secondary, and general secondary schools evaluated both selected models on all ten held-out sessions using a 0–5 scale. The evaluation was blind with respect to model identity, and raters had access to the source session data. The assessed dimensions were: (i) content correctness, (ii) clarity and understandability, and (iii) practical usefulness. An aggregate *Overall* score is additionally reported as the arithmetic mean of these three ratings.

7 Results

7.1 Reference-Based Stakeholder Alignment

The aligned coach, parent, and player reference summaries show that stakeholder adaptation in this task involves more than stylistic variation. Across the ten shared sessions, the three variants preserve the same underlying interpretation while varying terminology, explicitness, and communicative stance. Coach-facing references name relevant indicators such as distance per minute, metabolic power, time in high heart-rate zones, high-speed running (HSR), high-metabolic-load distance (HMLD), and acceleration/deceleration counts. Parent-facing references express the same session meaning through accessible descriptions of effort and rhythm, while player-facing references use second-person, experience-oriented language linked to how the athlete may have experienced the session. Sessions dominated by continuous running volume, internal load, stop–start movement, low load, or speed exposure are therefore consistently described across audiences without changing the underlying interpretation. For example, internally demanding sessions remain framed as heart-rate-intensive rather than speed-driven, whereas stop-start sessions are consistently described as mechanically demanding across the three audience variants. The reference triplets serve as a qualitative anchor for audience alignment, not merely as stylistic examples.

Coach-facing LLM-as-a-judge evaluation. Table 1 reports the coach-facing comparison between the RAW and RULES conditions across all evaluated summary-generating models. Scores are averaged over the ten-session evaluation subset and are interpreted descriptively. *Faith.* refers to *Faithfulness*, or semantic consistency with the source session profile; *Coach* denotes practical coach value; and *Narr.*, *Hyg.*, *Conc.*, *Lang.*, and *Overall* denote narrative quality, output hygiene, conciseness, language

quality, and the aggregate judge score, respectively.

Table 1: LLM-as-a-judge scores assigned by GPT-4o mini for coach-facing summaries, averaged over the ten-session evaluation subset. Rows denote summary-generating models under the RAW and RULES conditions. Scores are on a 0–10 scale. Higher is better on all dimensions.

Model	Variant	Faith.	Coach	Narr.	Hyg.	Conc.	Lang.	Overall
GPT-5.2	RAW	5.2	6.0	5.3	6.7	6.2	7.8	5.1

Bielik-1.5B	RULES	4.0	5.0	4.5	4.6	5.4	6.8	3.8
Bielik-11B	RAW	2.3	3.9	3.1	2.3	4.3	6.3	2.3
Bielik-11B	RULES	5.6	5.8	6.0	6.7	6.5	7.8	5.2
Llama-1B	RAW	1.8	2.4	2.5	2.0	3.7	5.5	2.0
Llama-1B	RULES	4.1	5.1	4.7	5.1	5.1	6.5	4.1
Llama-8B	RAW	1.5	2.3	2.1	1.5	3.8	5.7	1.5
Llama-8B	RULES	6.1	6.2	5.7	8.1	6.4	8.1	5.9

Interpretation of Table 1. Across all evaluated summary-generating models, the RULES condition received higher mean *Overall* scores than RAW, with the largest gains in *Faithfulness*, *Coach Value*, and *Output Hygiene*. Improvements in *Language Quality* were smaller, suggesting that rule grounding primarily improved semantic faithfulness, communicative discipline, and practical usefulness rather than surface fluency alone.

Given the ten-session evaluation subset, Table 1 is best interpreted as a within-generator comparison between RAW and RULES, not as a definitive ranking of generators. The highest *Overall* means in the RULES condition were observed for GPT-5.2 and Mistral-3B. These results motivated the selection of Mistral-3B for the augmented ENRICHED stage, with Llama-8B retained as a representative model from a different open-weight family.

School-based expert evaluation of player-facing summaries. Table 2 summarizes the school-based expert evaluation of player-facing summaries in the augmented ENRICHED setting. Nine physical education teachers rated the outputs on a 0–5 scale for *Content Correctness*, *Clarity*, and *Practical Usefulness*. Inter-rater agreement was estimated using ICC(A,9) and indicated limited agreement across dimensions. For *Content Correctness*, *Clarity*, and *Practical Usefulness*, the ICC(A,9) values were 0.434, 0.158, and 0.497 for Mistral-3B, and 0.000, 0.084, and 0.144 for Llama-8B, respectively.

Table 2: School-based expert evaluation of player-facing summaries in the augmented ENRICHED setting. Ratings are on a 0–5 scale. The *Overall* column reports the mean of Content Corr., Clarity, and Pract. Usef. Higher is better on all dimensions.

Model	Content Corr.	Clarity	Pract. Usef.	Overall
Mistral-3B	4.6	3.9	4.5	4.3
Llama-8B	4.4	3.4	4.5	4.1

Interpretation of Table 2. Both models received high teacher ratings for *Content Correctness* and *Practical Usefulness*, suggesting that the player-facing summaries produced in the evaluated augmented setting were factually controlled and practically meaningful. Mistral-3B scored slightly higher on *Content Correctness*, *Clarity*, and *Overall*, while both models obtained the same *Practical Usefulness* score. The comparatively lower *Clarity* ratings indicate that simplifying session meaning for young athletes remains an important design challenge, consistent with treating player-facing generation as both factual summarisation and educational communication.

7.2 Qualitative Error Analysis

The qualitative analysis revealed three recurring error patterns in RAW generation. First, some summaries overstated conclusions not fully supported by the data, especially when high overall cost was verbalised as sustained maximal intensity. Second, some outputs confused the dominant session dimension, for example by describing a session as speed-oriented when the reference interpretation emphasised internal load or continuous volume. Third, persona adaptation sometimes remained superficial, especially when parent- or player-facing outputs retained overly technical phrasing.

The RULES condition reduced these issues by separating interpretation from realisation. Because the dominant session profile was established before generation, the resulting summaries more consistently preserved audience-invariant meaning while still allowing audience-specific wording. This distinction is important for educational communication: a useful stakeholder explanation should differ in form across coach, parent, and player, but not in its underlying interpretation of the session.

In ENRICHED, raw metrics and explicit band definitions provided a richer explanatory input, but also allowed more phrasing variation than the strictly rule-grounded condition. Because this implementation combined enriched conditioning with LoRA-

based adaptation, the results should be interpreted as feasibility evidence for a more flexible applied setup rather than as an isolated estimate of the contribution of enriched conditioning alone. The school-based evaluation suggests that, in this configuration, player-facing summaries can remain factually controlled and practically useful.

8 Discussion

The results support the central design choice of the paper within the evaluated setting: separating analytical interpretation from linguistic realisation can improve the reliability of stakeholder-facing explanations derived from structured training metrics. When language models generate directly from raw numerical inputs, they may produce fluent summaries that overstate conclusions, confuse the dominant session profile, or adapt style without preserving the intended meaning. By contrast, the rule-grounded pipeline constrains interpretation before generation, making the resulting summaries more stable and easier to control.

This effect is especially relevant in the present educational setting, where the goal is not only to produce natural-sounding text, but to help stakeholders understand what recorded metrics mean in practice. The system therefore functions as an explanatory interface between sensor-based analytics and stakeholder understanding. The aligned coach–parent–player reference set further shows that useful adaptation should change wording, level of detail, and communicative stance while preserving the same semantic core across audiences.

The ENRICHED setting adds an applied perspective. It combines validated rule-derived facts, supporting raw metrics, explicit band definitions, and LoRA-adapted open-weight models; the present study therefore cannot isolate the contribution of any single component. In the evaluated setting, the school-based expert evaluation suggests that ENRICHED can produce player-facing summaries that remain correct, understandable, and practically useful.

More broadly, the study supports a methodological point relevant to educational NLP: systems that explain structured numerical data should not be evaluated solely on fluency or stylistic quality. In this context, faithfulness, audience appropriateness, communicative restraint, and educational usefulness are equally important, especially when explanations are intended for young stakeholders

and must remain understandable without becoming overstated, diagnostic, or misleading.

9 Limitations

Several limitations should be acknowledged. First, the dataset comes from a single youth football environment and contains 122 player-session records from a relatively small group of U15 players. The controlled evaluation used a held-out subset of ten sessions, while the remaining 112 records were used for LoRA adaptation. This split reflects the constraints of the available dataset, but limits robust model assessment; we did not conduct cross-validation or repeated-split evaluation. For the coach-facing LLM-as-a-judge comparison, the small ten-session subset precludes strong statistical claims, so the results are interpreted descriptively.

Second, the system relies on a manually designed rule base. While this improves interpretability and control, it requires domain expertise and may hinder transfer to new settings. Duration-normalised indicators and ordinal bands support comparability across sessions, but may reduce information relevant to practical interpretation, such as absolute session duration or individually calibrated physiological zones.

Third, ENRICHED combines selected rule-derived facts, supporting raw metrics, explicit threshold definitions, and LoRA-adapted open-weight models. The present design therefore cannot isolate whether the observed quality of player-facing summaries is attributable to richer input information, threshold exposure, model adaptation, or their combination.

We did not compare LoRA adaptation against few-shot in-context prompting with the same open-weight models. Given the relatively small size of the adaptation set, such a comparison would be important before making stronger claims about the necessity of parameter-efficient fine-tuning. We therefore interpret the LoRA results as evidence of feasibility for a low-resource-adapted configuration rather than as proof that LoRA is superior to few-shot prompting.

Fourth, the school-based evaluation involved nine physical education teachers and focused only on player-facing summaries. Although this provides an educationally meaningful expert perspective, it is not a large-scale end-user study with players themselves and does not provide equally strong evidence for parent- or coach-facing outputs

in ENRICHED.

Finally, the LLM-as-a-judge evaluation was used as a scalable diagnostic assessment, not as a replacement for human evaluation. Although the same GPT-4o mini judge and fixed rubric were used for all candidate summaries, we did not assess judge reliability through repeated judging runs or calibration against a large independent human-rated benchmark. The RAW-RULES comparison and the school-based expert study should therefore be interpreted as complementary rather than directly comparable stages of evaluation.

10 Conclusion

This paper introduced a rule-grounded framework for generating short, audience-appropriate explanations of youth football training data for coaches, parents, and players. By separating validated interpretation from linguistic realisation, the approach can improve control over what is said while allowing explanations to be adapted to different stakeholders. In the evaluated setting, rule grounding increased reliability relative to direct generation from raw metrics, and the evaluated ENRICHED variant produced player-facing summaries that teachers judged to be correct and practically useful. We therefore position the framework not simply as a generation pipeline but as an interface that supports data literacy in educational communication about sports analytics. Future work should test the approach on larger datasets and evaluate its effects on stakeholder comprehension, trust, and learning.

Ethical and Privacy Considerations

The study used anonymised training session data provided by an external partner. No data that could directly identify individual players were used in the generation or evaluation process. The system was designed to facilitate communication and interpretation, rather than for diagnosis or decision-making.

Abstract

This paper looks at the impact of annotators sharing a language background with learners when annotating learner data using the Universal Dependencies (UD) framework. We perform a study comparing annotations by two different annotators working on sets of L2 Swedish sentences (learner sentences and target corrections) from the Swedish Learner Language corpus (SweLL) written by learners for whom French is a main writing language. The annotators are both L2 speakers of Swedish but have different knowledge of French: one is a native French speaker and the other has no knowledge of French. We find high annotator agreement, which may indicate a non-significant impact, though we qualitatively observe an advantage in sharing language background.

1 Introduction

The Universal Dependencies (UD) framework has been developed in the past years to create a consistent annotation model across languages which includes information about both individual tokens (POS, morphological features) and the grammatical relations between them (de Marneffe et al., 2021). It is an ongoing project nourished by an active community which has developed and clarified both general and language-specific guidelines. The community has also contributed with treebanks, gathering annotated datasets in different languages; as of November 2025, version 2.17 — the last official release at the time of writing — included 339 treebanks across 186 languages (Zeman et al., 2025).

The use of UD as an annotation standard for learner corpora was proposed by Lee et al. (2017b), who argue that rich morphosyntactic annotation can replace explicit error labeling, allowing research on a broader range on L2 phenomena without prejudicing classic error retrieval. To ensure the latter, Lee et al. recommend representing learner data

as parallel L1-L2¹ treebanks composed of learner sentences on one hand, and target corrections on the other. They argue that using these parallel treebanks rather than traditional error-tagged corpora also improves corpus reuse and interoperability.

On this basis, a number of learner treebanks — some parallel, some not — has been developed, e.g. for learner Chinese (Lee et al., 2017a), English (Berzak et al., 2016; Kyle et al., 2022), Italian (Di Nuovo et al., 2022), Greek (Klironomou et al., 2026), Korean (Sung and Shin, 2024) and Swedish (Masciolini et al., 2025a). As is the case for all UD treebanks, learner texts in these datasets are segmented into sentences, tokenized, lemmatized, POS-tagged and annotated for dependencies. Dependency annotation consists of head-dependent links tagged with a *relation type*, which indicates the syntactic role of the dependent with respects to its head. In addition, some of the above mentioned treebanks provide the morphological analysis of each token and/or additional domain-specific annotations and metadata, such as error labels and learner proficiency levels.

Applying the UD framework to learner productions, however, also comes with some challenges related to the idiosyncrasies of interlanguage. This has prompted each annotation effort to develop its own internal annotation guidelines, which in turn led to some inconsistencies between learner treebanks. These are described by Masciolini et al. (2025b), who advocate for harmonized annotation guidelines that take into account learner errors while remaining faithful to UD principles and promoting cross-language comparability.

The annotators of learner data are not always native speakers of the language, but may be L2 speakers themselves. For example, UD_Swedish-SweLL (Masciolini et al., 2025a), a treebank of

¹In this paper, we will use L1 to refer to someone’s native language, and L2 to refer to their non-native language(s), whether it is their second, or third (and so on) language.

learner Swedish, has been entirely annotated by L2 Swedish speakers, rather than native Swedish annotators. In this study, we continued the annotation of the treebank under the same setup in order to investigate whether having a similar linguistic background between annotator and learners impacts annotation quality.

We devised the following research questions:

- How does the annotator’s native language, as compared to the learners’ main writing language, impact their annotation of learner data and ability to identify causes of errors?
- Can the errors made by learners be identified as being significantly caused by their main writing language?

To answer these questions, we used sentences extracted from the SweLL (Swedish Learner Language) corpus (Volodina et al., 2026). This corpus comprises sentences from adult learners of Swedish with different linguistic background. We focused here on those written by learners who have their highest written proficiency in French.

Two annotators — one whose native language is French and the other who has no prior knowledge of French, and who are both L2 speakers of Swedish — were tasked with annotating sentences of L2 Swedish learners whose main writing language (or one of) is French.

We hypothesize that an annotator whose native language is the same as the learners’ will be able to produce more informed annotations than an annotator who has no knowledge of the learners’ native (or best writing) language.

2 Materials and methods

2.1 The SweLL corpus

The data we used consists of sentences written by French speakers extracted from the SweLL (Swedish Learner Language) corpus (Volodina et al., 2019, 2025, 2026). This dataset includes sentences taken from essays written by adult learners of Swedish as an L2. Each essay is pseudonymized, error annotated and associated with a correction hypothesis, i.e. a normalized version of the essay, minimally edited so that it adheres to the norms of contemporary standard Swedish.² In addition, the corpus comes with information about the language

²See respectively Rudebeck and Sundberg (2021) and Rudebeck et al. (2021) for the complete error annotation and normalization guidelines.

background of each learner, as well as about their proficiency in the target language.

In terms of language background, learner metadata specifies both the native language(s) of learners and their best written language(s) (i.e., the language(s) in which the learner has the best written proficiency). A learner can have one or multiple such languages, which often, but not necessarily, coincide with their native language(s). In the case of French, mismatches between L1 and best writing language are particularly frequent: only 59 sentences are authored by French native speakers, while including all sentences where French is listed among the learner’s writing languages leads to a substantially bigger sample (142 sentence pairs).³ Even so, it should be noticed that French is not one of the dominant languages in SweLL, where the most represented L1 is by far Arabic (117 essays), followed by Kurdish, English, Dari and Persian (34-47 essays). Rather than on the amount of data available, our choice of language was based on the linguistic competence of the annotators.

As for proficiency, each learner is assigned an approximate proficiency level (*Nybörjare* ‘beginner’, *Fortsättning* ‘intermediate’ or *Avancerad* ‘advanced’). Our French subcorpus mostly consists advanced-level productions (89 sentence pairs). The remaining 56 pairs are beginner-level, meaning that intermediate level is not represented at all. In-progress work on the SweLL corpus, however, includes the CEFR labeling of each text, intended to provide further nuance and improve cross-language comparability.

2.2 Annotation

Two annotators participated in this project. Both have English and Swedish as L2s. The native language of one of them (AnF) is French while the other (AnI) has no prior knowledge of that language, their native language being Italian. AnI was more experienced in UD annotation than AnF.

We decided to automatically pre-parse and annotate the data with UDPipe 2 (Straka, 2018) with the 2.15 Talbanken model (the most recent model at the time of the study), then went through the annotations manually. Each annotator worked on their own files, to keep a trace of both annotations even after annotation conflict resolution. As for the rest of the SweLL treebank, manual work mainly

³In the resulting subcorpus, L1s other than French are Albanian, Arabic, Berber languages (not further specified), Kirundi and Somali.

Figure 1: Sentence (1). The noun *utbildning* is annotated as *nsubj* despite the redundant case marker *med*.

revolved around lemmas, Universal POS (UPOS) tags and dependencies, which were all systematically checked and post-edited as needed. Morphological features were only checked in correspondence of learner and parser errors, while language-specific POS tags (XPOS) were ignored and eventually removed from the treebank.

To compare the annotations, meetings were organized to go through an average of 30 sentence pairs per meeting. During these meetings, the two annotators discussed disagreements to resolve them. The equivalent files on the main private SweLL repository were then updated with a final version of agreed-upon annotations. The resulting gold annotations are available as part of UD 2.18.

2.3 Analysis

Differences in annotations of the original learner data were analyzed both quantitatively and qualitatively, while the analysis of the target corrections was only quantitative.

For the quantitative analysis, Inter-Annotator Agreement (IAA) was computed using the Universal Dependencies evaluation script,⁴ comparing the annotations (before conflict resolutions) for the original sentences and those for the target corrections.

We developed a Python script to extract differing line pairs between the annotation files by field. The program allows extraction based on differing lemmas, parts of speech, features, heads or dependency relations. The resulting files were used to bring more detailed information to the quantitative analysis.

During the comparison meetings, notes were made about disagreements on dependencies, lemmas and features that could be due to different interpretations fed by knowledge, or lack thereof, of the learners' writing language. Notes were also taken about sentences upon which the annotators agreed despite there being errors that were possibly due to language interference. These notes served

as the basis for the qualitative analysis.

In the following sections, we assume basic knowledge of the UD annotation framework but link to the official documentation for the particular annotation values that were object of discussion between the annotators.

3 Results

When it comes to original learner sentences, agreement is generally high, the lowest score being morphology-aware labeled attachment score (MLAS, 88.90 aligned accuracy). Most disagreements are about the heads and/or dependency labels, rather than parts of speech (UPOS, 99.02), features (UFeats, 98.42) or lemmas (99.45).⁵

A fifth of the differences in head assignments come from disagreements about punctuation mark heads (25/125). Looking at the disagreements around dependency relations, we can see the most common is one annotator qualifying a relation as *obl*⁶ and the other disagreeing (22/98).

On target sentences, agreement is even higher, with all metrics over 91.00 (cf. also Appendix B). Tokens and words are not 100.00, due to a difference in tokenization of *second hand-butiker*.

The most common disagreement about heads is again about punctuation (19/110), while the most common disagreement about dependency relations is also one annotator qualifying a relation as *obl* and the other disagreeing (18/83).

In sentence (1)⁷, also displayed in Figure 1, there was a disagreement about the relation linking *utbildning* to *hjälp*. During the discussion, AnI argued that the subject may have been omitted, as can be the case in certain romance languages (such as Italian). However, AnF argued that this is less often the case in French, and that *utbildning* may act as a subject, with an unnecessary preposition, following the suggested correction, which was done

⁵The full output of the evaluation script is given in Appendix A.

⁶universaldependencies.org/u/dep/obl

⁷Sentence numbers such as (1) refer to the full learner productions, available in Appendix C along with their corrections.

⁴github.com/UniversalDependencies/tools/blob/master/eval.py

with the full text context, before it was split into individual sentences.

Sentence (2), *Det tar tid för att förklara vad lycka är* [‘It takes time (for) to explain what happiness is’], brought up questions around the relation between *förklara* and the root token *tar*. We reflected that the redundant preposition could have been added as an interference from French, in which a natural translation could be *Il faut du temps pour expliquer* [‘It needs time for explaining’] and agreed on *advcl*⁸ because of the preposition *för*, whereas the analysis of the correction uses the label *csubj*⁹.

While both original and correction are arguably grammatical in sentence (3) (the form of the verb *styr* [‘to rule’] is the same for singular and plural), the use of the word *trenden* [‘the trend’, definite singular] rather than the more idiomatic indefinite plural form *trender* suggested in the correction can be seen as a reflection of the French *la mode* [lit. ‘the fashion’]. However, both AnF and AnI noticed this parallel, as the same construction (*la moda*) also exists in Italian.

There was some discussion about whether to add the *Foreign=Yes*¹⁰ feature to *persons* (4). This token is in place of the Swedish plural form of *person* [‘person’], *personer*. While AnI considered it to be a loan from English, AnF thought it may have been an attempt to create a plural form from the Swedish singular and the French plural formation (which most often adds *-s* at the end of the word). We ultimately agreed on the latter interpretation, thus not adding the *Foreign* feature. This could hint at a need for a more specific feature tag to mark foreign inflection; however, it remains to be seen whether this phenomenon is sufficiently common and well defined to justify a new tag. Similarly, the misspelling *temperature* (instead of *temperatur* (5)) may be a transfer from English, or from the French *température*. Since English is not among the learner’s top-proficiency languages, we annotated it with *Foreign=Yes* and *Lang=fr*¹¹.

Finally, the phrase *som av de* [lit. ‘who/which/that of they’] (6) clearly shows interference from English (‘some of them’). Metadata, where we can see that English is also one of this learner’s writing languages alongside French, also supports this hypothesis. We therefore annotate following the guidelines for English (cf.

Figure 2: Fragment of sentence (6). The literal translation of the phrase is difficult to analyze, but we argue that *som av de* mimics the English construction ‘some of them’ and annotate accordingly: the relative pronoun *som* is treated as a subject *åker* and the subtree *av de* becomes its nominal modifier.

Figure 2), and including the miscellaneous tag *CalquedLang=en*¹².

4 Discussion

The scores of the annotator disagreement metrics show a strong agreement between the two annotators. It is important to note that the sample under consideration is relatively small (only 139 sentences), which makes generalization difficult.

Common disagreements arose due to AnF’s lesser experience with UD. For example, the disagreements about punctuation heads was often due to AnF’s lack of familiarity with the UD conventions in that regard (i.e., to connect the punctuation to the dependent). Other disagreements of that sort are linked to corner cases using semi-mandatory dependency subtypes (e.g. *nsubj:outer*¹³).

If we take this into consideration, paired with the high agreement observed, this may indicate that the annotators’ different native languages do not significantly impact their annotation as much as their experience in annotating, as relatively few differences are spotted.

From our qualitative analysis, we can see that learner errors due to language interference stem not only from French but also other languages. Sentences (1) to (3) we consider as having interference from French, while sentences (4) and (5) show interferences from a language that could be French or another (such as English). We consider the interference in sentence 6 to have been from English.

Furthermore, there were only few sentences for which these errors led to annotator disagreement. This may show a limited advantage of having a native French annotator as opposed to someone who

has no knowledge in French, though we cannot say that this advantage is inexistent: for sentences (1) or (4), knowledge of French grammar and syntax led to a better understanding of the errors.

Language learning and teaching is a complex process of which errors are a necessary part. Our research shows that a learner's L2 Swedish written production can be influenced by their linguistic background as a whole, and not only by their main writing language. This adds to the findings in [Długosz \(2023\)](#), which show that L1 Polish learners of Swedish as a third (or fourth) language produce gender assignment errors which are due to misconstrued gender in their L2 German. In trilingual speakers, non-native languages seem to interfere with each other more than with their native language ([de Bruin et al., 2023](#)).

[Bartolotti and Marian \(2017\)](#) found evidence that vocabulary building when learning a new language depends on each previously known language, which could also explain why some errors (like sentence 5) are difficult to identify as coming from one language or another, especially when the terms in all languages are similar.

In a context where most learners share a common native language (such as native French speakers studying Swedish in France), recognizing such mistakes may lead to the creation of useful teaching tools. However, if there is greater diversity of linguistic backgrounds (such as immigrants studying Swedish in Sweden), spotting errors specific to one's native language may be too ambitious on a class level, though it may still be beneficial at an individual level. Identifying the exact root cause of an error may thus be less important than understanding the linguistic repertoire that a learner already possesses and its possible diversity.

5 Conclusions and future work

In this study we looked at two annotators' annotations of L2 Swedish learner sentences and target corrections to find out if the annotator (AnF) with a similar linguistic background — in terms of being proficient in French writing — as the learners had an advantage over the annotator (AnI) without. The annotation work carried out for this study enriches the UD_Swedish-SweLL with 134¹⁴ new double-annotated sentence pairs, included in the treebank

¹⁴A few of the sentences considered in this study had already been made available as part of the treebank first release. In these cases, the new annotations were compared with the old ones and used to improve the existing dataset.

from the 2.18 UD release (May 2026).

Our analysis of the annotations found that while AnF brought valuable insight for specific cases, the overall disagreement between annotators was small. We also found that it was not simple to identify the language causing errors due to language interference, as learners could and did have non-native languages interfere with their writing production as well. We conclude by highlighting the complexity of the linguistic repertoire learners and the importance of taking the learning context into account.

One could improve on this study by involving more experienced annotators, perhaps only native Swedish speakers and native French speakers. This may limit the disagreements due to differences in UD guidelines interpretation, and narrow down the languages that may impact the interpretation and annotation of learner sentences. Likewise, limiting the sentences studied to those produced only by L1 French speakers may help in identifying how annotators' native languages matching (rather than overlapping) with learners' impacts annotation.

It would be interesting to study specific learner levels as well. At beginner levels, interference from other languages might be greater, and so more important to spot. However, at higher levels, the interference may become more subtle, and thus a better understanding of the learner's language background may be beneficial to spot it.

Finally, reproducing this study with a larger number of sentences, or looking at different native languages, may bring further insight, and help us determine whether there is a significant advantage to matching annotators' native languages to that of the learners' when annotating L2 learner data.

Limitations

The first limitation present in this study is the difference of experience in UD annotation and linguistic analysis between the two annotators, which was the cause of some disagreements due to AnF lack of knowledge of specific dependency subtypes, for example. The number of annotators was also limited, and their native languages (French and Italian) are close linguistically, which may have lessened the influence of their difference. Both annotators were also fluent in other languages aside from Swedish and French (which were the main languages relevant in this study), which may also have had an impact on their annotation.

Another limitation was the fact that many of the

learners, while they all had French as a main writing language, also had other languages either as writing languages or their native language. Only 59/142 sentences were written by L1 French speakers, who possibly have also learned other languages (such as English) before Swedish. However, the SweLL metadata does not allow us to reliably know which additional language(s) the learners know. This may mean that, while French may influence their Swedish production and explain some of the errors, others languages (whether written or spoken) may impact it as well, which is not taken into account in this study’s setup (though discussed in Sections 3 and 4).

Acknowledgments

This work has been supported by Språkbanken — jointly funded by its 10 partner institutions and the Swedish Research Council (2025–2028; project id 2023-00161). We also want to thank Maria Irena Szawerna, one of the annotators of UD_Swedish-SweLL, for her feedback on an earlier version of this paper.

Classification of Student Struggle in Mathematics

Hannah Levin*, Madhura Padwal*, and Nchimunya Mwiinga*

Abstract

Productive struggle is a critical component of mathematics education, requiring students to actively work through ideas rather than just making errors. However, identifying this struggle from text transcripts is challenging because students often mask confusion with epistemic hedging rather than direct statements. Zero-shot large language models exhibit a conservative bias, systematically under-detecting struggle in classroom discourse. We introduce a two-stage NLP pipeline comprising a lexical heuristic gate and an LLM subtype classifier. Our model achieves 90.0% binary accuracy and 84.0% 4-category accuracy. We demonstrate the pedagogical value of this tool by showing that struggle is uniquely concentrated during explicit mathematical reasoning, offering educators a scalable method for root-cause analysis.

1 Introduction

Productive struggle in mathematics involves students actively working through ideas they do not yet fully understand (Hiebert and Grouws, 2007). In classroom discourse, this struggle rarely manifests as explicit statements of inability; instead, students often rely on epistemic hedging, such as "I think" or "maybe", acting as a "shield" against being wrong (Rowland, 1995; Hyland, 1998). Identifying this struggle in real time is particularly challenging because its visibility depends heavily on instructional conditions: struggle surfaces most readily when teachers actively elicit student reasoning, build on student ideas, and create space for back-and-forth discussion. In more teacher-directed lessons, students may not be given the opportunity to verbalize their thinking, leaving the same cognitive roadblocks undetected. Furthermore, even when struggle does surface, its interpretation requires contextual judgment: a delayed

explanation in an introductory lesson signals something very different from the same behavior after repeated modeling and scaffolded practice.

For educators managing large classrooms, conducting root-cause analysis to determine if a student is facing a conceptual misunderstanding or a linguistic barrier is incredibly time-consuming. Scalable Natural Language Processing (NLP) methods offer a promising path forward, enabling systematic analysis of classroom discourse patterns that would be impractical to review manually.

While the NCTE Classroom Transcript Analysis dataset (Demszky and Hill, 2022) provides a rich corpus of elementary math discourse in English, identifying genuine cognitive roadblocks from text alone is challenging. Off-the-shelf NLP models, including zero-shot large language models (LLMs), struggle to accurately parse these highly contextual linguistic markers. As our initial evaluations demonstrated, zero-shot LLMs exhibit a strong conservative bias, systematically under-detecting struggle by defaulting to a "no struggle" classification when faced with ambiguous student language. This bias is further exacerbated by transcription artifacts like "[inaudible]", which models frequently misinterpret as articulatory failure. To address this gap, we introduce a custom, two-stage NLP classification pipeline that identifies and categorizes student struggle into actionable subtypes: Implied Uncertainty, Impasse, and Cannot Explain. By coupling a high-recall, rule-based lexical heuristic gate (Stage 1) with an LLM subtype classifier powered by Gemini (Stage 2), our architecture directly counteracts the conservative bias of baseline models. Evaluated against a rigorously annotated validation dataset, our two-stage pipeline achieves 90.0% binary accuracy and completely eliminates false positives. Furthermore, exploratory application of the model to a holdout set of explicit mathematical reasoning reveals that 37.7% of these turns contain productive struggle. Crucially, our analysis demonstrates

*Equal contribution.

that this struggle is characterized by a stark linguistic shift: struggling utterances exhibit a significant drop in mathematical vocabulary density (averaging 0.55 math words) compared to fluent reasoning (0.87 math words). Ultimately, this model provides a scalable method for educators to conduct root-cause analysis, distinguishing conceptual gaps from linguistic barriers to better support student learning at scale.

2 Prior Literature

Our approach to detecting and classifying student difficulty sits at the intersection of mathematics education research and natural language processing for classroom discourse. We draw upon two primary bodies of work to motivate our construct definition and computational architecture.

In mathematics education, productive struggle is defined as the intellectual effort students expend to make sense of mathematical concepts that are not immediately apparent (Hiebert and Grouws, 2007; Warshauer, 2015). Crucially, this cognitive effort rarely manifests as explicit declarations of inability. Instead, students frequently operate within a "Zone of Conjectural Neutrality" (Rowland, 1995, 2000; Wagner et al., 2015), a cognitive space where they explore ideas they are not yet fully willing to assert. Within this zone, struggle is heavily characterized by epistemic hedging—the use of tentative language such as "maybe," "I think," or "kind of" (Hyland, 1998). Children use these linguistic hedges as a "shield" against the risk of being incorrect (Rowland, 1995).

Another signal of cognitive mathematical struggle is self-correction, where students stop mid-sentence to rephrase or restart. This kind of mid-turn repair often reflects active thinking rather than confusion (Schegloff et al., 1977), and in mathematics, it tends to appear during explanation and justification (Warshauer, 2015).

Pronoun use also matters. In mathematics classrooms, personal pronouns like "I," "we," and "you" serve complex functions related to ownership, authority, and generalization (Pimm, 1987; Rowland, 1999). When students shift from direct language like "I found" to vague phrasing like "you just do this" or "it works," this can reflect uncertainty about whether their approach is correct or generalizable (Rowland, 1999). Conversely, more agentive first-person language may emerge as understanding stabilizes.

Our operationalization of struggle builds directly on this framework, separating explicit breakdowns in articulation (Cannot Explain) or help-seeking (Impasse) from the far more common, but subtle, hedging behaviors (Implied Uncertainty). These categories are described in detail in the Validation Dataset section below, where we present our codebook and annotation framework.

While several educational dialogue datasets exist, none directly address the detection of productive struggle as a cognitive state in whole-class elementary mathematics discourse. The TalkMoves dataset (Suresh et al., 2022) annotates both teacher and student discursive moves across 567 K-12 mathematics transcripts, but its focus on accountable talk practices centers teacher behavior rather than student cognitive states. The Multi-turn Classroom Dialogue (MCD) dataset (Chen et al., 2024) targets mastery prediction from student-tutor dialogue, but is drawn from one-on-one tutoring sessions rather than whole-class instruction, and measures knowledge mastery rather than in-the-moment struggle. Unlike tutoring, where help-seeking is the explicit purpose of the interaction, whole-class discourse requires students to publicly commit to mathematical claims under social risk, which are precisely the conditions that produce the epistemic hedging and articulatory breakdown that our pipeline targets. The NCTE corpus (Demszky and Hill, 2022) is uniquely suited to our task: it captures authentic, whole-class elementary mathematics discourse during cognitively demanding instruction, providing the naturalistic linguistic environment necessary for studying how struggle surfaces in student talk.

Recent advancements in NLP have enabled the large-scale analysis of instructional dynamics. The release of corpora such as the NCTE dataset (Demszky and Hill, 2022) and the TalkMoves dataset (Suresh et al., 2022) has facilitated the automated extraction of teacher dialogue moves and student reasoning patterns. However, detecting nuanced affective or cognitive states, such as uncertainty or struggle, remains an open challenge.

Prior work has demonstrated that identifying student uncertainty in spoken educational dialogue is inherently difficult, often yielding moderate inter-rater reliability even among human experts (Forbes-Riley and Litman, 2011). While recent studies have shown that zero-shot LLMs can approximate human annotation quality on certain text-classification tasks (Gilardi et al., 2023), highly

context-dependent discourse phenomena remain a vulnerability. As our baseline evaluations indicate, when faced with the pragmatic ambiguity of episodic hedging in transcripts stripped of prosodic cues, zero-shot LLMs exhibit a severe conservative bias. Our two-stage classification pipeline builds upon these findings, leveraging a high-recall lexical heuristic to bypass the zero-shot conservative bias while preserving the LLM’s capacity for nuanced subtype classification.

Despite the rich theoretical grounding of productive struggle in mathematics education, the existing literature remains predominantly qualitative and teacher-centered (Young et al., 2023). On the computational side, NLP work on classroom discourse has focused primarily on teacher discourse moves and instructional quality (Suresh et al., 2022; Alic et al., 2022) rather than student cognitive states. Adjacent work on automated confusion detection relies on multimodal signals, prosodic, facial, and acoustic features, that are unavailable in transcript-only corpora (Ma et al., 2024). Text-based approaches to student challenge detection exist in collaborative learning contexts (Suraworachet et al., 2024) but have not been applied to the specific construct of productive struggle in whole-class elementary mathematics. This paper addresses that gap directly.

3 Data

3.1 Dataset

For this study, we used the NCTE Classroom Transcript Analysis dataset (Demszky and Hill, 2022), which is comprised of transcripts for fourth and fifth-grade mathematics instruction in four U.S. school districts serving largely historically marginalized student populations. The transcribed lessons cover core elementary mathematical concepts, including multi-digit multiplication, long division, decimals, and fractions, providing a rich linguistic environment for analyzing student reasoning. Lessons were audio-recorded in classrooms using a capture system that included a lapel microphone worn by the teacher and microphones positioned to pick up student talk. Recordings were fully transcribed by professional human transcribers and anonymized (Demszky and Hill, 2022). Student turns may include multiple speakers and do not track individual students over time. The transcripts capture spoken discourse during whole-class instruction only. They record if the speaker is

a student or a teacher, in what order, and for how long, but do not represent written work, gestures, visual representations, or small-group interactions. As a result, the dataset reflects a partial view of mathematical activity, centered on publicly audible talk in teacher-led discussions.

The original purpose of the dataset was to examine instructional quality and teacher effectiveness, particularly how classroom practices relate to observation scores and student learning outcomes, rather than to study student struggle directly (Kane et al., 2015).

Because struggle is not explicitly labeled in our transcripts, we rely on these structural and lexical features as indirect markers: the timing of reasoning, the length and frequency of student turns, and patterns of tentative or evolving explanation. These features do not measure struggle directly, but prior research suggests they are reasonable signals of students working through uncertainty in whole-class discussion.

3.2 Task Definition: Operationalizing Struggle

Our primary NLP task was the automated detection and classification of student struggle within classroom discourse. We defined struggle as the intellectual effort expended to make sense of mathematical concepts or tasks that are not immediately apparent. To make this construct analytically tractable and pedagogically actionable, we operationalized it into four categories, extracted from the literature:

- **Implied Uncertainty:** Instances where students distance themselves from a mathematical proposition using hedging language (e.g., "maybe," "I think") to protect against potential errors, operating within a "Zone of Conjectural Neutrality" (Rowland, 1995, 2000).
- **Impasse (Call for Help):** Utterances containing clear evidence that a student is blocked from proceeding with a mathematical task, such as explicit statements of confusion or direct requests for help.
- **Cannot Explain:** Moments where a student has an answer but explicitly demonstrates an inability to articulate their reasoning or justify their thinking (e.g., "I just guessed").
- **No Struggle:** Fluent reasoning, procedural questions, or purely logistical discourse.

3.3 Sampling Strategy

To ensure annotators evaluated moments of genuine cognitive demand rather than procedural or off-task talk, we first filtered the corpus using `edu_convokit` to isolate turns containing explicit student mathematical reasoning. However, because struggle is rare even within reasoning turns, purely random sampling would still yield too few instances of minority categories for reliable annotation or model evaluation. We therefore used a hybrid stratified sampling approach across four buckets—one per codebook category—following [Suresh et al. \(2022\)](#), who address the same class imbalance problem when annotating rare discursive moves in K-12 math transcripts. Importantly, bucket assignment determined only which utterances were selected, not how they were labeled; annotators coded all items against the codebook without knowing their source bucket, preserving the independence of ground truth labels from the sampling mechanism. Because struggle markers are highly context-dependent, we extracted 11-turn contextual windows around each target utterance to preserve the surrounding teacher prompts and student responses needed for accurate coding. See Figure A in the appendix for examples of annotated target utterances among their contextual windows.

3.4 Annotation and Reliability

The development of our gold-standard validation set required an iterative codebook revision process to capture the nuanced realities of classroom dialogue. Our final gold-standard validation set consisted of 100 annotated student utterances. This dataset was developed in two distinct phases: an initial set of 50 utterances from our first sampling iteration, and a fresh set of 50 utterances generated using our finalized stratified sampling pipeline.

To ensure robust ground truth labels, all utterances were independently annotated by multiple raters. For the initial 50 utterances, three research team members (the authors) annotated all items independently. To provide critical practitioner validation, we also recruited two practicing elementary school mathematics teachers who split the initial set, annotating 25 items each. For the fresh set of 50 utterances using our finalized stratified sampling pipeline, the three research team members independently annotated all items under the revised codebook. A held-out test set of 50 items was drawn from the same stratified sampling pipeline

and underwent identical independent annotation and consensus review by all three authors. The unannotated holdout ($n=159$) is an entirely separate corpus drawn from the remaining NCTE transcripts after all annotated sets were finalized and was used solely for exploratory analyses reported in Figures 5 and 6.

The development of this dataset required an iterative codebook revision process. Following the initial round of independent annotation, our team conducted consensus review sessions. This collaborative re-annotation yielded several critical clarifications: context-sensitive words such as "could" must be evaluated based on surrounding dialogue rather than automatically treated as hedges; Implied Uncertainty must be grounded in observable hedging language within the utterance itself; and Cannot Explain requires visible articulatory failure.

To address frequent misclassifications of confirmation-seeking questions, we introduced a "cover-up test" in our codebook: if removing the question mark leaves a substantive mathematical claim, the utterance is coded as Implied Uncertainty; otherwise, it is an Impasse. Two items could not be resolved and were excluded, leaving 98 usable validation items. After consensus, human inter-rater reliability on the fresh 50 items reached Krippendorff's $\alpha = 0.961$. See Figure 3 for an overview of the iterative pipeline development process.

4 Methods

4.1 Baseline Evaluations

Before developing our custom architecture, we evaluated four off-the-shelf approaches. A supervised classifier using sentence-level embeddings (all-MiniLM-L6-v2) performed at chance (binary $\kappa = 0.098$), confirming our dataset is too small for standard supervised methods. BART-large-MNLI collapsed to predicting a single category for 92% of utterances ($\kappa = 0.03$). Claude Sonnet 4 and Gemini 3 Pro both fell within the human agreement range ($\kappa = 0.52$ and 0.53) but exhibited a consistent conservative bias, missing genuine struggle 25-30% of the time by defaulting to No Struggle when student language was ambiguous. Critically, the two LLMs agreed with each other at $\kappa = 0.87$, making nearly identical errors—adding a second LLM provided no independent signal. This motivated a two-stage architecture: a lightweight rule-based heuristic handles binary detection cheaply and at

Figure 1: Pipeline for constructing and validating the annotated dataset

high recall, passing only flagged utterances to the LLM for subtype classification. This keeps the system computationally efficient while ensuring the LLM operates on an input where struggle is already the majority class, directly counteracting the conservative bias.

4.2 A Two-Stage Classification Pipeline

To address this conservative bias, we designed a custom, two-stage classification architecture that separates the binary detection task (Struggle vs. No Struggle) from the nuanced sub-categorization task.

Stage 1: High-Recall Lexical Heuristic Gate

The first stage serves as a binary gate optimized strictly for high recall, ensuring that instances of struggle are not permanently lost early in the pipeline. This stage employs a seven-step, rule-based lexical heuristic that assigns weighted scores across three pattern dictionaries derived directly from our codebook. To overcome the limitations of simple keyword matching, we engineered several context-aware components into the heuristic:

- **Confirmation-Seeking Question Detector:** The system applies a "cover-up test" to utterances ending in a question mark. If removing the question mark leaves a substantive mathematical claim, the utterance is flagged as Implied Uncertainty rather than a procedural question.

- **Articulatory Failure Detection:** The heuristic distinguishes genuine self-correction from transcription artifacts by counting textual dashes, specifically subtracting those that co-occur with [inaudible] markers.
- **False Positive Filters:** The system suppresses context-dependent trigger words when used in non-struggle contexts, such as the word "help" used to describe a mathematical strategy (e.g., "I used the number line to help me") or "like" used in geometric comparisons.

Stage 2: LLM Subtype Classifier

Utterances flagged as struggle by Stage 1 are passed to Stage 2 for subtype classification (Implied Uncertainty, Impasse, Cannot Explain, or No Struggle). By pre-filtering the input, Stage 2 evaluates a class distribution where struggle is the majority, directly counteracting the LLM's baseline conservative bias.

This stage utilizes Gemini 3 Pro powered by a highly structured prompt. The prompt embeds all fourteen rules from our revised codebook and includes 50 few-shot examples targeting known boundary cases. It also includes an explicit anti-conservative-bias instruction, directing the model to prioritize finding the struggle over explaining it away.

Finally, our error analysis of early pipeline iterations revealed that LLMs systematically hallucinated articulatory failure when processing brack-

Figure 2: The two-stage struggle classification pipeline. A high-recall lexical heuristic (Stage 1) filters utterances for surface-level warning signs before passing flagged items to a Gemini LLM (Stage 2) for context-aware subtype classification and false-positive correction.

eted transcription markers (e.g., classifying an utterance with an [inaudible] tag as Cannot Explain). To eliminate this noise, all bracketed annotations were programmatically stripped from the context windows before being processed by Stage 2.

5 Results

We report final model performance on the held-out test set ($n = 50$), which was set aside at the start and never used during pipeline development. Table 1 shows how the pipeline improved through development on the validation set, while Table 2 details the per-category performance on the actual test set. The final two-stage pipeline reached an 84.0% four-category accuracy (Cohen’s $\kappa = 0.716$) and a 90.0% binary accuracy in distinguishing struggle from non-struggle. In comparison, the baseline—a zero-shot Gemini model run as a standalone classifier—reached only 68.0% four-category accuracy and 76.0% binary accuracy on the same test set.

Crucially, the two-stage architecture successfully mitigated the LLM’s baseline errors. By offloading the binary decision to the high-recall heuristic, the pipeline completely eliminated false positives; it never incorrectly flagged a non-struggling student as struggling. Total errors on the test set dropped by half, from 16 to 8.

As illustrated by the comparative F1 scores in Table 4, the most significant performance gains occurred in the minority struggle categories. The pipeline improved the F1 score for *Impasse* by 27

points (from 0.40 to 0.67), *Implied Uncertainty* by 24 points (from 0.36 to 0.60), and *Cannot Explain* by 20 points (from 0.58 to 0.78). The *No Struggle* category also saw a 12-point increase, reaching a final F1 of 0.92. Despite these substantial improvements, *Implied Uncertainty* remained the hardest category for the pipeline (F1 = 0.60). Through our error analysis, we found that these categories easily blur together in natural speech; the model plausibly often could not distinguish whether a student was simply expressing uncertainty or entirely lacking the words to articulate the concept.

Finally, we noted that categories such as *Impasse* and *Implied Uncertainty* appeared very rarely in the test set. Because a single misclassification could shift the F1 score by 10 to 30 points, we interpreted these specific metrics as general signs of pipeline improvement rather than absolute measures of the model’s maximum performance.

6 Analysis

The evaluation demonstrated that the final model (84% accuracy, $\kappa = 0.716$) successfully mitigated the conservative bias observed across all off-the-shelf baselines. We found that by offloading binary detection to a high-recall lexical heuristic, Stage 2 received a class distribution where struggle was the majority, which directly counteracted the LLM’s tendency to default to *No Struggle*. Furthermore, the error analysis revealed that the LLMs had conflated [inaudible] transcription tags with genuine articulatory failure, leading them to incorrectly la-

Figure 3: Pipeline development: from codebook revisions to architecture selection and final error-driven refinement

Model / benchmark	4-cat κ	Binary accuracy	Binary κ
Gemini standalone (baseline)	0.602	83.5%	0.657
Two-stage pipeline (Enh. 1)	0.766	95.9%	0.916
+ stripped brackets (Enh. 2)	0.827	95.0%	0.897
Human pre-discussion	0.534*	—	0.607*
Human post-discussion	0.961*	—	—

Figure 5: Distribution and categorical breakdown of student mathematical struggle

bel hedged utterances as *Cannot Explain*. It was observed that stripping bracketed annotations prior to Stage 2 resolved this issue and yielded the highest overall accuracy.

Regarding the eight remaining errors, the analysis indicated that seven persisted across both models, pointing to three irreducible limitations of text-only classification. It was noted that three of these errors involved the *Implied Uncertainty* and *Cannot Explain* boundary; both stages confused trailing dashes and restarts because distinguishing them required reading communicative intent, which surface patterns could not resolve. Finally, we observed that one *Cannot Explain* item failed Stage 1 entirely because the breakdown was semantic rather than lexical—the student produced fluent, unhedged speech, but their reasoning was mathematically incoherent. We concluded that further gains would require audio features, cleaner tran-

scription, or the collapsing of *Implied Uncertainty* and *Cannot Explain* into a single category.

To evaluate pedagogical utility at scale, we applied the final model to 159 previously unseen mathematical reasoning turns filtered from the NCTE corpus using edu_convokit. As shown in Figure 5, the model flagged 37.7% (60 of 159) as containing productive struggle – consistent with the pipeline’s 90% binary accuracy and reflecting a corpus already filtered for cognitively demanding turns. *Cannot Explain* was the most prevalent subtype (29 instances, 48%), followed by *Implied Uncertainty* (26 instances, 43%), while *Impasse* was the least frequent (5 instances, 8%). Students rarely voiced explicit calls for help; instead they either attempted an answer they could not fully justify, or hedged tentatively to protect against being wrong.

As seen in Figure 6, fluent reasoning turns av-

Category (n)	Base model			Final pipeline		
	Precision	Recall	F1	Precision	Recall	F1
No Struggle (31)	83%	77%	80%	93%	90%	92%
Implied Uncertainty (6)	40%	33%	36%	75%	50%	60%
Cannot Explain (10)	50%	70%	58%	69%	90%	78%
Impasse (3)	50%	33%	40%	67%	67%	67%
Macro avg	56%	53%	54%	76%	74%	74%

Table 2: Per-category performance on the held-out test set ($n = 50$)

Note: Small support for Implied Uncertainty ($n=6$) and Impasse ($n=3$) means a single item shifting changes F1 by 10-30 points. Read these figures as directional.

Figure 6: Average mathematical vocabulary density of student utterances using edu_convokit’s get_math_density() function

eraged 0.87 domain-specific math words per utterance, while struggle-flagged turns averaged only 0.55 – a 37% drop. This aligns with the prevalence of Cannot Explain and Implied Uncertainty: when students hit a conceptual wall, they abandon formal math vocabulary and fall back on everyday language or extreme brevity. For educators, this proves the value of the tool for root-cause analysis: by isolating these moments, teachers can discern whether a student requires conceptual reteaching or simply needs linguistic scaffolding and sentence starters.

7 Conclusion

Identifying productive struggle in real-time classroom discourse is a complex challenge, primarily because students frequently mask their cognitive roadblocks with epistemic hedging. As our evaluations demonstrated, zero-shot large language models are ill-equipped to handle this pragmatic ambiguity, exhibiting a conservative bias that systematically under-detects genuine struggle. By

implementing a custom, two-stage classification pipeline that pairs a high-recall lexical heuristic with a precision-tuned LLM, we successfully counteracted this bias. Our final architecture achieved an 84.0% 4-category classification accuracy and entirely eliminated false positives, ensuring the system never incorrectly flags a non-struggling student.

Beyond the technical architecture, our exploratory analysis confirmed the pedagogical value of this approach. The data revealed that explicit mathematical reasoning carries a substantial cognitive load, with productive struggle occurring in 37.7% of observed student participation. Furthermore, this struggle is characterized not just by hesitation, but by a measurable drop in domain-specific mathematical vocabulary, falling from an average of 0.87 to 0.55 math words per utterance. By successfully isolating these moments at scale, our pipeline provides a reliable mechanism for root-cause analysis, empowering educators to distinguish between conceptual misunderstandings and linguistic barriers.

8 Future Work

Because our model moves beyond binary detection and classifies the nature of the struggle (e.g., Implied Uncertainty, Impasse, Can’t Explain), it offers highly targeted insights that can empower educators to make precise pedagogical adjustments.

Rather than functioning as an evaluative measure, this model can be used to power a post-lesson reflective dashboard for teachers. By processing classroom audio or transcripts, the dashboard could provide educators with a high-level summary of discourse trends. For example, it could highlight that "Your students showed high levels of Implied Uncertainty during today’s fraction introduction." This preserves teacher agency; it does not tell the

educator how to teach, but rather cues them to areas requiring curriculum adaptation. If the data shows high rates of Impasse, the teacher may need to revisit foundational concepts. Conversely, if students are displaying high rates of Implied Uncertainty, the teacher might focus on building mathematical confidence and reinforcing a classroom culture where students feel safe asserting their knowledge.

At the same time, the struggle could be a language barrier and not conceptual. If the model identifies a cluster of Can't Explain moments, this signals to the teacher that students might actually grasp the underlying math but lack the academic vocabulary to articulate it. Teachers can use this specific feedback to shift their scaffolding strategy by providing linguistic support, such as sentence starters or targeted vocabulary review, rather than reteaching the mathematical concept itself.

A critical direction for future work is extending this pipeline beyond English-language classrooms. The current model is trained exclusively on English transcripts and relies on lexical markers of epistemic hedging that are English-specific. Different languages encode uncertainty and tentativeness through distinct grammatical and discourse mechanisms. Future work should investigate what text-based markers of productive struggle look like across typologically diverse languages, and whether a universal framework for struggle detection is achievable or whether language-specific codebooks are necessary.

Translating this backend classification model into a real-world, formative feedback dashboard will require dedicated co-design projects with teachers. Engaging directly with educators in this next phase of development will be critical to ensure that the resulting tool respects teacher agency, integrates smoothly into instructional workflows, and provides equitable, actionable insights.

9 Limitations

While our two-stage pipeline demonstrates strong performance, this approach has several methodological and technical limitations. First, our model relies entirely on text-based transcripts, which inherently strips away critical acoustic-prosodic features and non-verbal cues. Prior research has demonstrated that prosodic cues—such as rising intonation, trailing off, and physical hesitation—are significant predictors of student uncertainty in spoken educational dialogue. Because our pipeline

evaluates text alone, it systematically misses instances of implicit struggle conveyed through tone of voice or body language. Second, our evaluation is constrained by a relatively small and homogeneous ground-truth validation set drawn exclusively from U.S. fourth and fifth-grade mathematics classrooms. Consequently, performance metrics for rare categories, such as Cannot Explain (which comprised only 9% of our validation dataset), suffer from base rate instability. Expanding the dataset across different grade levels and instructional contexts is necessary to stabilize the evaluation of these sub-types.

Third, our reliance on a majority-vote human consensus for ground-truth labels introduces an artificial ceiling on model performance. In cases of genuine boundary ambiguity, the model is penalized for agreeing with a minority human rater, even when that rater's interpretation may be pedagogically valid.

Fourth, our model exhibits an asymmetric error profile by design. In optimizing the pipeline to eliminate false positives, the model retains a slight conservative bias, producing a small number of false negatives. In a real-world deployment, this means the system will occasionally miss a struggling student before it ever incorrectly flags a fluent one.

Finally, a core limitation of this evaluation is the small held-out test set ($n=50$) and the very low support for minority categories — Impasse appears only 3 times and Implied Uncertainty only 6 times in the test set. At this scale, a single misclassification shifts F1 by 10–30 points, making per-class metrics statistically unstable and difficult to interpret as absolute measures of model performance. The current results are therefore better taken as preliminary evidence of a promising pipeline architecture rather than proof of a mature system's performance. More broadly, the small size of our annotated dataset was drawn exclusively from U.S. fourth and fifth-grade mathematics classrooms, thus limiting the generalizability of our findings. We cannot confidently claim that the pipeline would perform equivalently across different grade levels, subject areas, or instructional contexts. Expanding the annotated dataset through targeted oversampling of rare categories, and validating performance across more diverse classroom settings, are necessary preconditions for establishing the robustness and generalizability of this approach.

10 Ethical Considerations

The deployment of this classification pipeline carries significant ethical considerations, particularly regarding linguistic fairness and responsible educational use.

A primary ethical concern is algorithmic bias regarding English as a Second Language (ESL) learners. A key limitation of the underlying NCTE dataset is that only English speech is transcribed. However, on average there are approximately 260 instances of foreign language redactions (e.g., "[spanish]" or "[speaking in foreign language]") of unknown length per lesson. This is critical to note when evaluating student struggle, as a student's difficulty may not be conceptual but rather a language barrier. We initially assumed that keeping bracketed annotations, although inconsistent, was important for preserving the context of student learning. However, as demonstrated in our error analysis, retaining tags such as [inaudible] introduced significant noise, causing the LLM to systematically misclassify transcription gaps as articulatory failure, which ultimately required us to strip them from the input.

Furthermore, because our pipeline relies heavily on structural markers of hedging and questioning, the model risks misinterpreting the natural discourse patterns of ESL students. These students may frequently utilize hedges or questioning intonations as they master English syntax, rather than as an indication of mathematical confusion. Uncritical deployment could result in educators inappropriately over-scaffolding students who are mathematically proficient but linguistically developing. Future work must focus on evaluating this pipeline across more linguistically diverse classroom environments to address potential performance disparities and biases among ESL students.

Additionally, the system's reliance on observable verbal signals introduces the problem of the "quiet struggler." Students who disengage, give minimal responses, or remain entirely silent when struggling will not be captured by the system, potentially masking the needs of the most vulnerable learners.

Given these constraints, this model must never be utilized for high-stakes decision-making, including student grading, tracking, or teacher evaluation. It is designed strictly as a low-stakes, formative reflection tool to support, rather than replace, the holistic professional judgment of human educators.

Finally, because the model classifies isolated utterances rather than individuals, any deployment must actively prevent the aggregation of these classifications into student-level profiles to avoid the ethical risk of label reification.

Acknowledgments

We thank Dorottya Demszky and Mei Tan for their guidance, methodological feedback, and support throughout the development of this research. We extend our deepest gratitude to Jennifer Gray and Erin Hanau, whose expertise as practicing elementary mathematics educators was invaluable. Their dedication to independently annotating our validation data and participating in our codebook review sessions provided critical practitioner validation for our construct definitions.

A Qualitative Coding Examples

Representative examples from each category in the codebook. Boldface marks the target utterance being classified. Contexts are lightly truncated for space.

Cannot Explain

Target utterance

Student: "I guessed on these two parts."

Context

teacher: [inaudible] so this is what she's done. She drew the model of fifteens, marked off six-fifteenths to prove that—

student: Make it.

student: Ms. M?

student: I guessed on these two parts.

student: Multiplication.

teacher: How much did you eat of this pizza, if he ate this?

student: It's small.

teacher: You make it. So, construct means to make or to build ...

Implied Uncertainty

Target utterance

Student: "Still too short. I think maybe 35."

Context

teacher: I think you're right. What about 4 times 30?

student: This says, "I don't think this is ..."

teacher: Awesome. Good. What you got? [Students working on problem].

student: Still too short. I think maybe 35.

teacher: Uh-oh, I'll help you. Let me see ...

teacher: 35. Let's try 4 times 30 first. I'm gonna use repeated addition to solve that. 30, 60, 90.

Impasse

Target utterance

Student: "Wait – I'm stuck on three hundredths."

Context

teacher: Okay. Speak loud so I can understand you.

teacher: Like, your ice is about to break ...

student: Yes.

student: Wait – I'm stuck on three hundredths.

student: I put them in order by doing the first number just like the thirty-something. I just did the tens first.

student: [inaudible]. Regroup the ones. Oh, and then I had to [inaudible].

No Struggle

Target utterance

Student: "Well, I knew that when you added five sixths with seven sixths that's an improper fraction."

Context

teacher: Perfect. I knew that's what you did. Can we reduce seven twelfths? ...

teacher: What kind of math did you do?

student: Well, I knew that when you added five sixths with seven sixths that's an improper fraction.

teacher: Good, improper fraction. So then what?

student: So then I had a whole number and I got six divided by seven was one and then I added the one.

teacher: Do I do six divided by seven?

student: No, wait. Seven divided by six.

B Pipeline Implementation Details

B.1 Stage 1: Lexical Heuristic Classifier

Stage 1 applies a weighted regex scoring system over normalized utterance text. Normalization converts smart quotes, em/en dashes, and ellipsis characters to ASCII equivalents before pattern matching. Each utterance is scored independently across three categories; scores do not accumulate across categories.

Pre-Score Filtering. Before any scoring, fourteen patterns unconditionally return No Struggle. Seven cover non-struggle uses of trigger words: "help" used as a mathematical strategy (e.g., "I used the number line to help me"); offers of peer assistance; "be there to help" phrasing; "can I say" openers; "like" or "kind of" in a geometric comparison with no other struggle signals present; "I think" introducing reported speech; and "I don't know why I said that" as metacognitive self-correction. Seven cover utterances that are not mathematically uncertain regardless of wording: offers to help others; logistical questions ("Can we write this down?", "Can we go?"); self-deferral openers ("Let me think", "I don't want to"); forward-readiness statements ("We'll be ready"); and confident "I know" statements not followed by a reversal.

Scoring. Stage 1 computes four scores: an Im (Impasse) score, a CE (Cannot Explain) score, a IU (Implied Uncertainty) score, and a disfluency score. The three category scores are built from: (1) weighted regex pattern matches, where high-confidence patterns contribute +3, medium +2, and low +1; (2) CSQ detection, which adds +2 to Im or IU depending on the cover-up test result; and (3) trailing-off boosts, which add directly to CE or Im when dash and "because" patterns co-occur. The fourth score, the disfluency score, is computed independently by twelve surface breakdown signals and is only consulted in routing when all three category scores are zero.

A single utterance can score points in multiple categories simultaneously; the priority order $\text{Im} > \text{CE} > \text{IU}$ reflects signal specificity: explicit help-seeking is the most diagnostic, visible breakdown more specific than hedging, and hedging the most ambiguous but cheapest to route. An utterance is routed to Stage 2 as Struggle, with the subtype below, if the first matching condition holds:

1. **Impasse** if Im score ≥ 2 .
2. **Can't Explain** if CE score ≥ 2 .
3. **Impasse** if Im score > 0 and Im score $\geq$ IU score (Im wins a tie at score 1).
4. **Implied Uncertainty** if IU score ≥ 1 (deliberately low: a single hedge such as "I think" is sufficient).
5. **Can't Explain** if CE score > 0 (any disfluency-driven CE signal is sufficient).
6. **Implied Uncertainty** (provisional) if any disfluency signal fires and all category scores are zero; subtype is assigned per the disfluency mapping described below.

Utterances matching none of these conditions are labeled No Struggle without LLM consultation.

Confirmation-seeking question (CSQ) detection.

A question is identified as a CSQ via the *cover-up test*: the question mark is mentally removed; if a mathematical claim remains (e.g., "*So it's minus five?*" $\rightarrow$ "*So it's minus five*"), the utterance is classified IU. If nothing substantive remains (e.g., "*What do I do?*"), it is classified Im. Procedural questions ("*Should we write this down?*") and hypotheticals ("*What if it was a different number?*") are excluded.

Backup Disfluency Score. This fourth score is only computed if the previous three category scores were all zero.

1. [inaudible] presence, weighted +1 per occurrence capped at 2;
2. "like" as hedge filler, with a filter suppressing comparison and observation uses;
3. dash-based restarts, weighted +2 for two or more real dashes and +1 for one;
4. ellipsis or trailing off;
5. cut-off utterances ending in a dash;
6. filler markers (*um*, *uh*, *hmm*);
7. repeated "because" indicating circular or restarted reasoning;
8. "though" at utterance end signaling unresolved doubt;

9. brevity of 15 words or fewer as a catch-all signal for minimal responses to *why/how* prompts;
10. self-correction markers (*wait, actually, I mean, never mind*);
11. tentative proposals (*what about, what if, how about*);
12. “I just know” or “I just knew.”

If all three category scores are zero but the disfluency total is ≥ 1 , the utterance is still routed to Stage 2, with a provisional subtype assigned based on which signal fired: cut-off, restart, or repeated-*because* signals map to *Can’t Explain*; *like-hedge* or *though* signals map to *Implied Uncertainty*; tentative proposals map to *Impasse*; all others map to *Implied Uncertainty* as a default.

Tense coverage. All pattern lists include both present- and past-tense variants to capture retrospective struggle narration (e.g., “I got stuck,” “I couldn’t figure it out,” “I didn’t know why I did that”). This design decision was motivated by the NCTE transcripts frequently capturing students narrating prior cognitive states during whole-class discussion, where a student may describe a moment of difficulty that occurred during independent work rather than expressing real-time confusion. Without past-tense variants, these retrospective struggle markers would be systematically missed, introducing a structural false negative bias against students who reflect on their process rather than voicing struggle in the moment.

B.2 Stage 2: LLM Classifier

Stage 2 uses gemini-3.1-pro-preview with temperature = 0.0 for deterministic output. Utterances are batched in groups of 3 target utterances, along with their surrounding context. The model is prompted to return a raw JSON array of {id, label} objects.

If Gemini refuses an entire batch (safety or recitation block), each utterance in that batch is resent individually. If Gemini returns fewer classifications than utterances sent, the missing items are also resent individually. In both cases a 1-second delay separates individual retries.

B.3 Full System Prompt

An abridged version of the system prompt is reproduced below. Category definitions, classification

Parameter	Value
Model	gemini-3.1-pro-preview
Temperature	0.0
Max output tokens	4096 (batch), 1024 (retry)
Batch size	3 target utterances
Retry strategy	Item-by-item on block or missing label
Retry delay	1s per item, 3s between batches
Fallback	Stage 1 subtype if retry fails

Table 3: Stage 2 reproducibility parameters.

rules, and few-shot examples are provided verbatim as supplied to the model.

You are an expert annotator classifying student struggle in elementary math classroom transcripts. You will receive student utterances that have already been flagged as likely containing struggle. Classify each one into exactly one of four categories.

Implied Uncertainty (IU): The student has something to offer but withholds full commitment. They express doubt, hedge, or seek confirmation. Key property: the student CAN continue but is uncertain. Past-tense hedges count: “I thought,” “I figured,” “I assumed,” “I was thinking” all signal retrospective uncertainty.

Impasse / Call for Help (Im): The student cannot move forward. They have no answer, are stuck, confused, or need teacher intervention to proceed. Key property: the student CANNOT continue without help. Past-tense impasse counts: “I got stuck,” “I was confused,” “I didn’t know what to do,” “I couldn’t figure it out.”

Can’t Explain (CE): The student has an answer or has taken action but fails to articulate WHY. The explanation visibly breaks down. Key property: the student is TRYING to explain but FAILING to do so coherently. Past-tense CE counts: “I couldn’t explain it,” “I didn’t know why I did that,” “I had guessed.”

No Struggle (NS): The student does not demonstrate struggle. They answer clearly, or the utterance is about non-mathematical content, or surface-level hedge words are explained by context (filler, mirrored language, reporting).

Critical Rules: Rules R1–R14; see Table 4 and Table 5 for full definitions and examples.

Output format: Respond with ONLY a JSON array. Each element must have id and label fields. Use these exact label strings: “Implied Uncertainty”, “Impasse”, “Can’t Explain”, “No Struggle”. Do not include any other text, explanation, or markdown formatting.

Rule	Name	Description
R1	Bias toward Struggle	When genuinely ambiguous, lean toward Struggle. Do not force Struggle on clearly coherent reasoning that merely contains dashes or [inaudible] markers.
R2	Cover-Up Test	Remove the question mark: if a mathematical claim remains, classify IU; if nothing substantive remains, classify Im. Do not classify confirmation-seeking questions as NS.
R3	[Inaudible] not CE	[inaudible] markers are transcription artifacts, not articulatory failure. Do not classify CE solely because of them. Audible hedges still trigger IU.
R4	CE requires visible breakdown	CE requires at least one of: repeated self-corrections, incomplete “because” statement, trailing off, restarting and collapsing, circular explanation, or explicitly stating they guessed or can’t explain.
R5	Filler vs. hedge	“Like” and “kind of” in comparisons are filler, not hedges. “Like” at the start of a turn or mid-sentence IS a hedge signal.
R6	Reporting vs. reasoning	“I think he said X” is reporting → NS. “I think she thinks 6 plus 5 equals 11” is reasoning about math → IU.
R7	Non-mathematical content	Non-mathematical utterances are always NS.
R8	Self-correction phrase	“I don’t know why I said that” is self-correction, not struggle.
R9	Guess: CE vs. IU	“I guessed” (past, action taken) + breakdown = CE. “I guess it’s X” (present hedge) = IU.
R10	Trailing reasoning	A “Because...” statement that becomes incoherent, restarts, or ends abruptly is CE, not NS.
R11	Past tense counts	Past-tense struggle markers (“I got stuck,” “I couldn’t explain”) count the same as present-tense ones.
R12	Use context	Read surrounding turns. Fluent-sounding utterances may reveal struggle when teacher re-explains; apparent NS may follow heavy scaffolding.
R13	Tautological explanations	A “because” clause that merely restates the problem without logical justification is CE, even if delivered confidently.
R14	Resolving self-corrections	A dash followed by a completed, corrected thought is normal self-repair → NS. A dash followed by stalling, restarting, or collapse → CE.

Table 4: Classification rules (R1–R14) embedded in the Stage 2 system prompt.

B.4 Few-Shot Examples

Table 5 presents the 50 few-shot examples supplied in the system prompt, organized by label. Examples were drawn from the annotation codebook developed for this project and selected to cover the most commonly confused category boundaries: IU vs. NS (hedge vs. comparison filler), CE vs. NS (self-correction that resolves vs. breakdown), and Im vs. IU (cover-up test cases).

Label	Utterance	Key signal
IU	“Maybe to find all the prime factors?”	hedge (<i>maybe</i>)
IU	“Oh, so it’s minus five because it’s less than?”	CSQ, claim remains
IU	“If the 2 is a whole, it would be before the decimal point?”	CSQ, claim remains
IU	“I tried to do a number line.”	<i>tried to</i>
IU	“And we used the towers?”	past-tense CSQ
IU	“I thought it was going to be different.”	past-tense hedge
IU	“He could multiply again 58 times 3.”	modal tentativeness
IU	“Like, you have nine seconds and it’s ...”	<i>like</i> as filler
IU	“It’s like 10 between 20 is 15.”	<i>like</i> as hedge
IU	“Like, um, one-third, because [inaudible]. ...”	<i>like, um</i>
IU	“For this one, I did like [inaudible] order of operation ... I thought the X equals one”	<i>like</i> filler + <i>I thought</i>
IU	“She would be the best, because [inaudible] would get like [inaudible].”	vague + <i>like</i> hedge
IU	“She mostly didn’t—she actually kinda did get jipped ...”	<i>kinda</i> , hedged reasoning
IU	“Except this one. You can divide by one. Right?”	<i>Right?</i> confirmation
IU	“A possibility ... I think it’s less [inaudible].”	<i>I think</i> + audible hedge
Im	“Okay. So what do I do up here?”	direct help request
Im	“Could we do one sixth and five sixths?”	open question, no answer
Im	“Could there be a thing that could weigh five grams?”	open question
Im	“Yes. Like, it’s kind of confusing.”	explicit confusion
Im	“Will the teacher be able to help us?”	help-seeking
Im	“Mr. F, how does that add up to eight sides. ...?”	teacher-directed confusion
Im	“But what about the bottom part? So would the bottom be seven?”	<i>what about</i> + unresolved
Im	“What about four and three—four times three.”	restart, tentative
Im	“No matter what you multiply it ... will you still get the same answer?”	fundamental clarification
Im	“Or you could have 3 times—3 times—3 times [inaudible].”	repeated restarts
Im	“I don’t get it, ’cause 70 percent is—”	explicit + trailing off
Im	“But the right one still look bigger though.”	unresolved doubt
Im	“This was hard because it’s impossible.”	<i>hard, impossible</i>
Im	“Hold on, but what’s—”	mid-sentence stop
Im	“That if all the edges, the number of edges are the number of vertices.”	confused conflation
Im	“I got stuck on the part where you had to divide.”	past-tense impasse
CE	“I guessed eight—I guessed six, because ...”	self-correction + weak logic
CE	“Because it’s one and four tenths, because I think—I can’t explain it.”	explicit give-up
CE	“Because 2,000—wait. Because 3,237 marched [inaudible]”	restart + collapse
CE	“Because 800—I mean 812—I—because I know. ...”	multiple corrections
CE	“Mm-hmm, because if you look at them—right now ...”	trails off
CE	“Because ... because four times seven is 28, and we—”	repeated <i>because</i> + cut-off
CE	“Because I would need the half and half to build the other half.”	circular
CE	“Because half of 10—’cause half of 10 [inaudible].”	restart, no advance
CE	“That can be 20 and that can be 30 because that’s not a half.”	vague assertion
CE	“Because the leftovers, you can add them [inaudible].”	incomplete logic
CE	“It’s negative because—it’s negative because ...”	repeated restart
CE	“Because you only put the square ... that’s the area.”	circular
CE	“I multiplied 6 times 2 ... but I don’t know the reason why I did 6. ...”	explicit CE statement
CE	“I couldn’t explain why I chose that answer.”	past-tense CE
NS	“Four-eighths is kind of like one-half.”	comparison filler
NS	“I think he said seven and then 10.”	reporting speech
NS	“Because if you would take a rectangle and cut it in the middle ...”	complete reasoning
NS	“Halves can work ’cause I know that twelve is half of twenty-four ...”	clear justification
NS	“I just knew it was remainder 2 because I knew that 3 times 5 is 15. ...”	confident + full logic

Table 5: All 45 few-shot examples provided in the Stage 2 system prompt, with the primary signal that motivated each label assignment.

PERSA: Reinforcement Learning for Professor-Style Personalized Feedback with LLMs

Abstract

Large language models (LLMs) can provide automated feedback in educational settings, but aligning an LLM’s **style** with a specific instructor’s tone while maintaining diagnostic correctness remains challenging. We ask: *how can we update an LLM for automated feedback generation to align with a target instructor’s style without sacrificing core knowledge?* We study how Reinforcement Learning from Human Feedback (RLHF) can adapt a transformer-based LLM to generate programming feedback that matches a professor’s grading voice. We introduce **PERSA**, an RLHF pipeline that combines supervised fine-tuning on professor demonstrations, reward modeling from pairwise preferences, and Proximal Policy Optimization (PPO), while deliberately constraining learning to **style-bearing components**. Motivated by analyses of transformer internals, PERSA applies parameter-efficient fine-tuning. It updates only the *top* transformer blocks and their feed-forward projections, minimizing global parameter drift while increasing stylistic controllability. We evaluate our proposed approach on three code-feedback benchmarks (APPS, Py-FiXV, and CodeReviewQA) using complementary metrics for style alignment and fidelity. Across both Llama-3 and Gemma-2 backbones, PERSA delivers the strongest professor-style transfer while retaining correctness; for example, on APPS, it boosts Style Alignment Score (SAC) to 96.2% (from 34.8% for Base) with Correctness Accuracy (CA) up to 100% on Llama-3 and Gemma-2. Overall, PERSA offers a practical route to personalized educational feedback by aligning both *what it says* (content correctness) and, crucially, *how it says it* (instructor-like tone and structure).

1 Introduction

Large language models (LLMs) are increasingly deployed in real-world systems, powering applications ranging from conversational assistants to

*Corresponding authors.

Figure 1: Illustration of how PERSA transforms generic LLM feedback into instructor-style, constructive, and actionable guidance compared to a vanilla LLM.

code-generation tools. Major organizations such as OpenAI, Google, and Microsoft have emphasized alignment and prompt engineering to ensure these systems respond in useful and safe ways. For example, models such as ChatGPT and GPT-4 are refined through reinforcement learning from human feedback (RLHF) to better follow instructions and safety preferences (Ouyang et al., 2022; Chaudhari et al., 2025), while instruction-tuning pipelines are widely used to steer tone and response style in user-facing systems (Wang et al., 2023b; Bhattacharya et al., 2024). Although these efforts have substantially improved general helpfulness and harmlessness, far less attention has been paid to *personalized stylistic alignment*, where a model must communicate in a manner consistent with a particular human expert. This gap is especially important in education.

One promising use of LLMs in education is automated feedback generation. Prior work suggests that LLM-based tutors can provide hints and critiques in domains such as programming education (Razafinirina et al., 2024). However, the effectiveness of such feedback depends not only on correctness, but also on *how* it is delivered. Research in

the learning sciences shows that tone, phrasing, and instructional persona strongly affect how students interpret and respond to feedback (Demszky et al., 2024; Loughran, 2019). Instructors often develop a recognizable style that balances encouragement with precision, emphasizing issues such as readability, correctness, and edge-case reasoning (Felder et al., 1988). Feedback that is technically correct but overly generic or terse may therefore be perceived as less trustworthy, less supportive, and less pedagogically useful (Carless, 2012; Zhang and Hyland, 2022). Aligning AI-generated feedback with an instructor’s authentic voice could make automated tutoring more acceptable and educationally effective.

In this work, we ask: *Can a pre-trained LLM be adapted to emulate a specific instructor’s feedback style while preserving its problem-solving ability?* Existing instruction-tuned models are typically optimized for broad helpfulness and politeness, but alignment to an individual educator’s style remains underexplored. To address this, we propose **Professor-Style Reinforcement-based Style Adaptation (PERSA)**, a method that uses RLHF to align model outputs with the feedback style of a target professor. Using a dataset of instructor-authored feedback on student work, we train a reward model that captures stylistic preferences and optimize the policy for *stylistic fidelity* rather than generic user satisfaction. As shown in Figure 1, whereas a vanilla LLM might generate a brief suggestion such as “Check your input handling,” professor-style feedback is typically more explanatory, supportive, and actionable. PERSA narrows this gap by producing feedback that more closely reflects the instructor’s voice, including encouragement, diagnosis, corrective guidance, and verification-oriented follow-up. In doing so, it supports seamless personalization of AI tutors for specific courses and teaching contexts.

A central technical contribution of PERSA is a *style-targeted, parameter-efficient fine-tuning strategy*. Rather than updating all model weights, which is computationally costly and risks degrading core capabilities, we focus adaptation on components most relevant to stylistic expression. Prior work suggests that many style-related properties are concentrated in higher transformer layers (Lai et al., 2024; Koto et al., 2022). Guided by this observation, we use low-rank adaptation (Hu et al., 2022) to fine-tune only the final layers of a 3B-parameter LLM. This selective update strategy preserves the

model’s underlying problem-solving competence while shifting its communicative “voice,” reducing the catastrophic forgetting that can arise from indiscriminate fine-tuning (Luo et al., 2023). As a result, PERSA captures subtle instructor-specific traits, such as level of detail and encouraging tone, without compromising content accuracy.

We evaluate PERSA on a programming feedback generation task against strong baselines, including the base pre-trained model, supervised fine-tuning on the same instructor data, and an InstructGPT-style RLHF model optimized for general feedback quality. PERSA achieves the best overall balance between style and correctness. Its outputs show strong stylistic alignment with professor feedback, on Gemma-2 model with a Style Alignment Score approaching 0.99, and BLEU overlap above 98%, substantially exceeding competing methods (Papineni et al., 2002; Fu et al., 2018). At the same time, correctness remains at 100%, and feedback retains a consistently polite and constructive tone as measured by a politeness model (Danescu-Niculescu-Mizil et al., 2013). Human evaluators also strongly prefer PERSA, often describing its responses as reading “like they came from the professor.” These findings suggest that combining RLHF with targeted layer adaptation is effective for capturing nuanced pedagogical style beyond what standard fine-tuning or generic alignment methods can achieve.

In summary, this paper makes three contributions: (1) we introduce **PERSA**, an RLHF-based framework for aligning LLM feedback with a specific instructor’s pedagogical style; (2) we develop a *layer-selective* LoRA-based adaptation strategy that achieves stylistic transformation with minimal disruption to the model’s original capabilities; and (3) we provide comprehensive evaluation, including automated style metrics and a human study, showing that PERSA produces feedback that is both pedagogically authentic and factually correct. Overall, this work advances the development of AI tutors that can not only provide accurate guidance but also communicate with the tone and effectiveness of a human instructor.

2 Related Work

Educational Feedback and Pedagogical Style.

Prior work in educational technology shows that the *manner* of feedback delivery, including tone, politeness, and personalization, substantially affects learner engagement and outcomes (Han et al., 2023; Sonlu et al., 2024). Recent studies on LLMs

in education similarly emphasize that encouragement, specificity, and perceived instructor authenticity influence student trust and uptake (Razafinirina et al., 2024; Wu et al., 2024a). While this connects to broader alignment goals in dialogue systems (Alsafari et al., 2024; Wang et al., 2023b), our focus is narrower: *pedagogical alignment*, i.e., adapting model outputs to an instructor’s communicative style rather than optimizing only for generic helpfulness (Bhattacharya et al., 2024; Matarazzo and Torlone, 2025).

Automated Feedback Generation. Automated programming feedback has long been studied through rule-based, analysis-driven, and repair-based methods. Keuning et al. provide a foundational survey of these approaches and their evaluation limitations (Keuning et al., 2018), while *Pedal* demonstrates practical code-aware feedback generation at scale (Gusukuma et al., 2020). More recently, LLMs have shown promise but also reliability concerns: GPT-4 can generate readable feedback yet still requires validation (Dai et al., 2024); MOOC-scale studies report that LLM feedback helps detect errors but is often inaccurate without test-based grounding (Gabbay and Cohen, 2024); and performance drops further in specialized settings such as concurrency debugging (Estévez-Ayres et al., 2024). Other efforts explore diversified repair generation (Choi and Lee, 2025) and responsible deployment considerations such as inclusivity and hallucination risk (Lindsay et al., 2025). Collectively, these works highlight that existing systems still under-address instructor-consistent tone and specificity.

RLHF for Language Model Alignment. RLHF has become a standard paradigm for aligning LLMs to human preferences (Ouyang et al., 2022; Xie et al., 2024). InstructGPT established the now-common pipeline of supervised fine-tuning, reward modeling, and PPO-based policy optimization (Ouyang et al., 2022), and subsequent work has extended RLHF to capture subtler properties such as tone, framing, and politeness (Kamath et al., 2024; Kirk et al., 2023; Dong et al., 2024; Yan et al., 2024). This is particularly relevant in education, where instructor judgments define high-quality feedback. However, full-parameter RLHF is computationally expensive and can unintentionally alter broader model capabilities (Chaudhari et al., 2025). Parameter-efficient alternatives, including LoRA-augmented RLHF and related methods, reduce this cost while preserving alignment

quality (Sidahmed et al., 2024; Hong et al., 2024; Ethayarajh et al., 2024; Hu et al., 2022; Dettmers et al., 2023; Wu et al., 2024b). Importantly, prior analyses suggest that RLHF-induced changes are concentrated in upper transformer layers, especially FFN components (Moradi et al., 2024), motivating our layer-selective adaptation strategy.

Style Adaptation in Language Models. Style control in LLMs has been explored through prompting, style tokens, and fine-tuning, with recent work moving toward neuron- and layer-level analysis. Lai et al. show that stylistic attributes are disproportionately localized in higher transformer layers and FFN submodules, enabling targeted control via style-specific neurons (Lai et al., 2024; Shi et al., 2024). Related studies further suggest that selectively tuning or freezing layers can outperform full-model adaptation for certain alignment objectives (Shi et al., 2024; Wang et al., 2023a). Parameter-efficient methods such as LoRA and QLoRA make such targeted adaptation practical, though quantized tuning may introduce accuracy trade-offs in some settings (Dettmers et al., 2023; Hu et al., 2022; Ozdemir, 2023). In contrast to prior style-control work, PERSA applies these insights to *educational feedback*, aligning LLM outputs to an individual instructor’s pedagogical voice while preserving correctness.

3 Preliminaries

Transformer LLMs as policies. We consider a decoder-only transformer language model as a stochastic policy that generates a feedback sequence $y = (y_1, \dots, y_T)$ token-by-token conditioned on a prompt x (e.g., problem statement + student solution).

Data: demonstrations and preferences. We assume (i) an instructor demonstration set $\mathcal{D}_{\text{SFT}} = \{(x_i, y_i^*)\}_{i=1}^N$ with professor-written feedback y_i^* , and (ii) a preference set $\mathcal{D}_{\text{pref}} = \{(x_j, y_j^{(w)}, y_j^{(l)})\}_{j=1}^M$, where $y^{(w)}$ is preferred to $y^{(l)}$ under instructor style (and typically correctness). Preference data is used to learn a reward model for RLHF (Ouyang et al., 2022).

Supervised fine-tuning (SFT). SFT initializes the policy by minimizing the teacher-forcing negative log-likelihood:

$$\mathcal{L}_{\text{SFT}}(\theta) = -\mathbb{E}_{(x, y^*) \sim \mathcal{D}_{\text{SFT}}} \left[\sum_{t=1}^{|y^*|} \log \pi_{\theta}(y_t^* \mid x, y_{<t}^*) \right]. \quad (1)$$

Here $y_{<t}^*$ is the the gold prefix tokens before step t .

Reward modeling from pairwise comparisons. RLHF learns a scalar reward function $r_\phi(x, y) \in \mathbb{R}$ such that preferred responses receive higher reward. Using the Bradley–Terry model, the probability that $y^{(w)}$ is preferred over $y^{(l)}$ is

$$\Pr(y^{(w)} \succ y^{(l)} \mid x) = \sigma(r_\phi(x, y^{(w)}) - r_\phi(x, y^{(l)})), \quad (2)$$

yielding the standard pairwise logistic loss, and σ is the sigmoid function (Ouyang et al., 2022).

Policy optimization with PPO and KL control. Given r_ϕ , policy optimization seeks high reward while constraining drift from a reference policy π_{ref} (often the post-SFT model) via a KL penalty.

We optimize this objective with Proximal Policy Optimization (PPO) (Schulman et al., 2017). Let $s_t = (x, y_{<t})$ be the state (prefix context), $a_t = y_t$ the action (next token), and $\rho_t(\theta) = \pi_\theta(a_t | s_t) / \pi_{\theta_{\text{old}}}(a_t | s_t)$.

Parameter-efficient adaptation with LoRA. To preserve base model knowledge and reduce computation, PERSA adopts Low-Rank Adaptation (LoRA) (Hu et al., 2022). For a frozen weight matrix $W \in \mathbb{R}^{d \times k}$, LoRA learns a low-rank update ΔW with $B \in \mathbb{R}^{d \times r}$, $A \in \mathbb{R}^{r \times k}$ and $r \ll \min(d, k)$:

$$W' = W + \Delta W, \quad \text{where } \Delta W = BA. \quad (3)$$

We denote the trainable adapter parameters by θ_{LoRA} and treat the remaining parameters as frozen. Parameter-efficient RLHF variants (e.g., PERL) show this can substantially reduce training cost while maintaining alignment quality (Sidahmed et al., 2024).

Layer-selective tuning. Finally, we use the notion of *top-layer* tuning: only adapters inserted in the last L transformer blocks are updated. This choice is consistent with evidence that higher layers and FFN submodules often contain high-level attributes and alignment-relevant representations (Geva et al., 2021; Lai et al., 2024).

4 Methodology

We propose **PERSA** (Professor-Style Reinforcement-based Style Adaptation), a parameter efficient RLHF framework that aligns an LLM’s *feedback style* to a target instructor while preserving the model’s underlying problem-solving and language competence. PERSA instantiates the standard RLHF recipe, *supervised fine-tuning*

$\rightarrow$ *reward modeling* $\rightarrow$ *policy optimization*, popularized by InstructGPT (Ouyang et al., 2022), but crucially restricts learning to *style-bearing* components in the *upper* transformer layers using low-rank adapters (Hu et al., 2022; Sidahmed et al., 2024). This design is motivated by growing evidence that higher layers and FFN submodules disproportionately encode high-level attributes such as discourse patterns, tone, and stylistic preferences (Geva et al., 2021; Lai et al., 2024). Figure 2 illustrates how PERSA transforms a generic prompt into instructor-style feedback by combining LoRA-based supervised fine-tuning with KL-regularized PPO (trained on professor data).

Problem Setup and Notation. Let π_θ denote a pretrained decoder-only transformer LLM (e.g., LLaMA/Gemma/GPT-style), parameterized by θ . Each training instance consists of a prompt x and a target feedback y^* written by the professor. The prompt x contains a programming problem statement and a student submission. The goal is to learn a policy π_θ that produces feedback y that is simultaneously: (i) *diagnostically correct* (identifies correctness/errors and provides actionable guidance) and (ii) *stylistically aligned* with the professor (tone, structure, politeness, specificity).

We use the demonstration and preference datasets defined in §3, namely $\mathcal{D}_{\text{SFT}}$ for professor-written feedback and $\mathcal{D}_{\text{pref}}$ for instructor-style preference comparisons.

Parameter-Efficient, Layer-Selective Updates. Rather than updating all parameters, we freeze the base model weights and learn low-rank adapter updates (LoRA) only in the *top* L transformer blocks (e.g., $L = 4$), focusing on attention projections and Feed-Forward Network projections. For a weight matrix $W \in \mathbb{R}^{d \times k}$ in a selected module, LoRA parameterizes, as detailed mentioned in equation 3. This yields a small trainable parameter set, θ_{LoRA} (on the order of $\sim 10^7$ parameters in our setting), while leaving the remaining parameters fixed, improving stability and reducing risk of catastrophic drift (Sidahmed et al., 2024). Our layer-selection choice is supported by analyses indicating that alignment- and style-related changes concentrate in later layers, often in the penultimate FFNs (Geva et al., 2021; Liang et al., 2024).

4.1 Supervised Fine-Tuning (SFT)

We first perform instruction tuning to initialize a policy that produces professor-like feedback under

Figure 2: PERSA pipeline for professor-style feedback alignment via layer-selective RLHF.

maximum likelihood. The SFT objective is the standard auto-regressive negative log-likelihood, defined in equation 1. where only θ_{LoRA} is updated and all other parameters are frozen. This stage transfers the professor’s feedback structure (e.g., diagnosis $\rightarrow$ correction $\rightarrow$ verification) and baseline tone into the model, but may not optimally capture preference-sensitive nuances (e.g., strictness, encouragement, emphasis on edge cases).

4.2 RLHF for Professor-Style Alignment

SFT imitates demonstrations but does not explicitly optimize for *human preference*. We therefore apply RLHF, consisting of reward modeling followed by PPO-based policy optimization, following established alignment practice (Ouyang et al., 2022).

4.2.1 Reward Modeling from Pairwise Preferences

We train a reward model $r_\phi(x, y) \in \mathbb{R}$ that scores candidate feedback y for prompt x . The reward model is a transformer initialized from a strong LM backbone with an added scalar head, trained on pairwise comparisons using the Bradley Terry formulation:

$$\Pr(y^{(w)} \succ y^{(l)} \mid x) = \sigma\left(r_\phi(x, y^{(w)}) - r_\phi(x, y^{(l)})\right), \quad (4)$$

where σ is the sigmoid function. Minimizing the negative log-likelihood yields:

$$\mathcal{L}_{\text{RM}}(\phi) = -\mathbb{E}_{(x, y^{(w)}, y^{(l)}) \sim \mathcal{D}_{\text{pref}}} \left[\log \sigma\left(r_\phi(x, y^{(w)}) - r_\phi(x, y^{(l)})\right) \right]. \quad (5)$$

Because preferred responses are professor-authored (or instructor-preferred), r_ϕ learns to jointly reflect correctness and stylistic fidelity, mirroring the

RLHF setup in InstructGPT but with an education-specific preference signal (Ouyang et al., 2022).

4.2.2 Policy Optimization with PPO and KL Control

Given r_ϕ , we optimize the policy to maximize expected reward while constraining deviation from a reference policy (the SFT model) via a KL penalty. Let π_θ be the current policy and π_{ref} a frozen copy of the SFT policy. We optimize:

$$\max_{\theta_{\text{LoRA}}} \mathbb{E}_{x \sim \mathcal{D}, y \sim \pi_\theta(\cdot|x)} \left[r_\phi(x, y) - \beta \text{KL}(\pi_\theta(\cdot|x) \parallel \pi_{\text{ref}}(\cdot|x)) \right] \quad (6)$$

where $\beta > 0$ controls the strength of KL regularization, a key stabilizer in RLHF (Ouyang et al., 2022).

We solve Eq. (6) with PPO (Schulman et al., 2017). For token-level actions a_t under states s_t (prefix context), we define the importance ratio $\rho_t(\theta) = \pi_\theta(a_t|s_t)/\pi_{\theta_{\text{old}}}(a_t|s_t)$ and advantage estimate $\hat{A}_t$. The clipped PPO objective is:

$$\mathcal{L}_{\text{PPO}}(\theta_{\text{LoRA}}) = -\mathbb{E}_t \left[\min(\rho_t(\theta) \hat{A}_t, \text{clip}(\rho_t(\theta), 1 - \epsilon, 1 + \epsilon) \hat{A}_t) \right]. \quad (7)$$

with clipping threshold ϵ . We additionally include the KL control term (computed against π_{ref}) in the per-trajectory reward or as an auxiliary penalty, consistent with the constrained-RL perspective in RLHF (Ouyang et al., 2022). As in SFT, we update only θ_{LoRA} in the selected upper layers, yielding a parameter-efficient instantiation of RLHF akin to PERL (Sidahmed et al., 2024). This selective optimization reduces compute and helps preserve the pretrained model’s broad capabilities.

Summary. PERSA proceeds as follows: (i) attach LoRA adapters to the top L layers, (ii) run SFT on $\mathcal{D}_{\text{SFT}}$ minimizing Eq. (1), (iii) train a reward model on $\mathcal{D}_{\text{pref}}$ minimizing Eq. (5), and (iv) run PPO to optimize Eq. (7) under the KL-regularized objective Eq. (6). The related steps are outlined in Alg. 1, Appendix A. This pipeline is architecture-agnostic for modern decoder-only LLMs and is especially suitable for educational personalization, where the goal is to preserve task competence while adapting communicative style.

5 Experimental Setup

5.1 Datasets

We evaluate PERSA on three code-feedback datasets: one instructor-authored APPS-style professor-feedback dataset and two public code-feedback benchmarks, PyFiXV and CodeReviewQA. We construct a standard 70/10/20 train/validation/test split with disjoint programs for PERSA training and evaluation.

(i) APPS Benchmark (professor-feedback dataset). To study realistic instructional personalization, we use a course-specific dataset of 200 instances, each consisting of an algorithmic programming problem, a student solution (either correct or deliberately perturbed), and *professor-written feedback* as the target response. The prompts are derived from APPS-style problems, while the feedback is authored by the instructor for the target course (Hendrycks et al., 2021).

(ii) Codeforces Syntax-Error Feedback (PyFiXV). We use the Codeforces subset of PyFiXV, which contains 240 Python programs with syntax errors (token length ≤ 500), collected from Codeforces and paired with expert-written fixes and explanations (Phung et al., 2023).

(iii) Tomo-Melb/CodeReviewQA. CodeReviewQA comprises 900 manually curated code-review instances spanning 9 programming languages. Each example includes a pre-review snippet (old), a reviewer comment (review), and the revised code (new). We cast this benchmark as a text-to-text task, mapping $(x = \{\text{old}, \text{review}\})$ to $y = \text{new}$ (Lin et al., 2025).

Appendix B.1 provides details on the demonstration and preference data, while Table 6 summarizes the data splits and corresponding leakage controls.

5.2 Model Evaluation Frameworks

We evaluate PERSA on two lightweight, open-weight instruction-tuned backbones, google/gemma-2-2b-it and meta-llama/llama-3.2-3B-Instruct, within a model-agnostic RLHF framework comprising supervised fine-tuning, reward modeling, and PPO-based policy optimization with KL regularization. We compare against a diverse set of baselines, including the untuned **Base Model**, **SFT** (Parthasarathy et al., 2024), **InstructGPT-style RLHF** (Ouyang et al., 2022), and three offline preference-optimization methods, namely **DPO** (Wu et al., 2024b), **ORPO** (Hong et al., 2024), and **KTO** (Ethayarajh et al., 2024). This setup enables a controlled comparison of stylistic alignment, correctness preservation, and adaptation efficiency across both model families under a shared evaluation protocol (Appendix B.2).

5.3 Evaluation Metrics

We evaluate feedback generation along two complementary dimensions: *stylistic alignment* and *diagnostic fidelity*. To quantify how closely the generated feedback matches the instructor’s communicative style, we use **Style Alignment Score (SAC)** (Fu et al., 2018), which estimates the probability that a response reflects the professor’s stylistic characteristics. We further measure tone similarity using **Average Politeness Closeness (APC)** (Danescu-Niculescu-Mizil et al., 2013), which evaluates how closely the politeness level of the generated feedback aligns with the professor reference. Finally, we report **BLEU-4** (Papineni et al., 2002) to capture lexical similarity by measuring n-gram overlap between generated feedback and the professor’s reference response. All together, they measure stylistic fidelity to the professor’s feedback in terms of overall style alignment, politeness closeness, and lexical similarity, respectively.

Correctness Accuracy (CA) (Shen et al., 2023) assesses whether the generated feedback makes the correct diagnostic judgment about the student solution. In addition, **Preference Win Rate (PWR)** (Ouyang et al., 2022) measures preference-based superiority relative to competing methods, reflecting the alignment objective used in RLHF. Full metric definitions, formulations, and implementation details are provided in Appendix B.3. Training configurations are provided in Appendix B.4.

Table 1: Comparison of Llama-3 vs. Gemma-2 models across three datasets (APPS, PyFiXV, and CodeReviewQA). Higher values indicate better performance; all metrics are reported in percentages.

Dataset	Method	Llama-3 (%)					Gemma-2 (%)				
		SAC	APC	BLEU-4	CA	PWR	SAC	APC	BLEU-4	CA	PWR

6 Results

6.1 Performance Comparison

Table 1 highlights consistent method-wise trends across all three datasets and both backbones. First, **Base** models achieve high correctness (CA $\approx$ 96–98%) and moderate politeness (APC $\approx$ 83–90%) but **very weak stylistic/lexical alignment** (low SAC and single-digit BLEU-4), indicating that pretraining alone does not recover professor-style feedback. Second, **SFT** provides the largest jump in alignment (e.g., SAC $\approx$ 78–85%, BLEU-4 $\approx$ 60–80%) while keeping CA near-perfect, showing that demonstrations effectively teach the core feedback structure. Third, preference-based alignment further improves style: DPO/ORPO/KTO consistently outperform InstructGPT/RLHF in SAC and BLEU-4 with comparable CA, and yield higher win-rates (PWR), suggesting that direct preference optimization better captures subtle stylistic cues.

Figure 3 shows that PERSA delivers consistently stronger human preference alignment than SFT, RLHF, and DPO-style baselines on PyFiXV, with improvements that generalize across both Llama-3 and Gemma-2 backbones. Finally, PERSA achieves the strongest overall results on both models, delivering the highest SAC and

Figure 3: PWR comparison across alignment methods on the PyFiXV dataset for Llama-3 and Gemma-2.

BLEU-4 and the best PWR across datasets (with CA $\approx$ 100%), demonstrating robust professor-style transfer without sacrificing diagnostic correctness.

6.2 Qualitative Analysis

We sample representative programming prompts from the APPS dataset and reproduce the corresponding feedback outputs. Table 2 mirrors the quantitative rankings in Table 1: methods with higher SAC/BLEU-4 (DPO/ORPO/KTO, and especially PERSA) produce feedback that is *more diagnosis-specific, actionable, and professor-structured* (diagnosis $\rightarrow$ fix $\rightarrow$ verification), whereas Base and standard RLHF remain comparatively generic, consistent with their lower style-

Figure 4: Dumbbell plot of SAC on PyFiXV across alignment methods, comparing Llama-3 and Gemma-2; connectors indicate the cross-model gap per method (higher is better).

Table 2: **Qualitative comparison (one prompt).** PERSA produces the most professor-like feedback: structured diagnosis → actionable fix → verification. Preference-optimization methods (ORPO/KTO/DPO) are typically more specific than generic RLHF, while Base tends to be vague.

Method	Qualitative feedback snippet (same prompt)
Prompt (APPS-style). Student computes <code>x=a.index(1)</code> , <code>y=a.index(n)</code> before <code>a=list(read())</code> , causing a runtime error / wrong output.	
Base	“Try checking input handling and edge cases. Consider swapping min/max positions, then rerun tests.”
SFT	“You are calling <code>a.index()</code> before initializing <code>a</code> . Move <code>a=list(read())</code> above the index calls, then recompute <code>x,y</code> .”
InstructGPT	“Good start. The issue is order of operations: read the array first, then find indices and apply the swap. Verify with sorted/reversed cases.”
DPO	“Root cause: <code>a</code> is used before assignment. Fix by reading input into <code>a</code> first, then compute <code>x=a.index(1)</code> and <code>y=a.index(n)</code> . Add tests for <code>n=1</code> and already-sorted.”
ORPO	“Bug: <code>a.index()</code> runs before <code>a=list(read())</code> . Initialize <code>a</code> first , then compute <code>x,y</code> and perform one swap maximizing $ x-y $. Re-run edge cases (sorted, reversed, single displacement).”
KTO	“You are using <code>a</code> before it is populated. Read input into <code>a</code> first, then compute indices and swap. Avoid overclaiming; confirm correctness with boundary cases and failing tests.”
PERSA	“Good progress on locating 1 and <code>n</code> . The failure arises from using <code>a.index()</code> before <code>a</code> is populated. Please first read input with <code>a=list(read())</code> ; then recompute <code>x=a.index(1)</code> , <code>y=a.index(n)</code> and apply one swap maximizing $ x-y $. Finally, rerun edge cases (already-sorted, reversed, <code>n=1</code>) to confirm.”

alignment scores and preference win-rates. As shown in Figure 4, PERSA achieves the highest SAC for both backbones while maintaining consistent gains over SFT and preference-optimization baselines, indicating strong and portable style alignment across models.

6.3 Ablation Study

Table 3 quantifies how each training component translates into measurable style gains. Moving from Base to SFT converts a largely generic model (SAC 14.0%, BLEU-4 1.5) into a professor-like feedback generator (SAC 82.0%, BLEU-4 64.7) while reaching perfect diagnostic correctness (CA=100%). However, PPO alone does not

Table 3: PERSA ablation on Llama-3 and APPS dataset. Metrics are in % (higher is better); PWR is win-rate vs. Base.

PERSA Ablation	SAC	APC	BLEU-4	CA	PWR
Base (no adapt.)	14.0	90.0	1.5	98.0	–
SFT only	82.0	91.6	64.7	100	86.0
PPO only (no SFT)	60.0	91.2	40.0	98.0	84.0
SFT+PPO (full-param)	92.0	92.0	92.0	100	88.0
SFT+PPO (all-layer LoRA)	96.0	92.0	94.7	100	88.6
SFT+PPO (top-2 LoRA)	94.0	92.0	90.0	100	90.0
SFT+PPO (top-4 LoRA)	96.2	92.1	95.8	100	90.1
[PERSA]					

recover the same instructor voice (SAC 60.0%, BLEU-4 40.0) and even leaves a small correctness gap (CA=98.0%), indicating that preference optimization needs an SFT “anchor” to be effective. When PPO is applied after SFT, alignment improves sharply: full-parameter PPO attains 92.0% SAC and 92.0 BLEU-4 with CA=100%, showing that RLHF mainly refines the remaining stylistic mismatch rather than content, also mentioned in Figure 4. Constraining updates via adapters is even stronger all-layer LoRA pushes SAC to 96.0% and BLEU-4 to 94.7 without sacrificing correctness suggesting that parameter-efficient updates add expressive capacity while limiting drift. Finally, the best numbers come from upper-layer targeting: top-2 LoRA already reaches high alignment (SAC 94.0%, BLEU-4 90.0) and strong preference (PWR=90.0%), while top-4 LoRA (PERSA) achieves peak alignment (SAC=96.2%, BLEU-4=95.8) and the highest win-rate (PWR=90.1%), consistent with style information being concentrated in late transformer layers.

6.4 Human Evaluation Study

To complement automated metrics, we conducted two light weight human evaluations using anonymized Forms: (i) an *Instructor* blind A/B preference + rubric study and (ii) a *Student* perception study. In the instructor study, participants reviewed programming prompts with a student attempt and compared two anonymous feedback responses (Feedback A vs. Feedback B), selecting an overall preference and rating multiple pedagogical criteria (e.g., technical correctness, authenticity, helpfulness, and trust-oriented tone) using a short rubric (Feedback A (very good), Feedback A (good), Neither (neutral), Both (equal), Feedback B (good), Feedback B (very good)). The form explicitly instructs instructors to judge pedagogical quality rather than minor grammatical issues and reports an estimated completion time of 8–12 minutes. In the student study, each participant reviewed

Table 4: Student survey average ratings (on a 1–5 Likert scale) across 20 respondents and 5 examples.

Statement	Rating (stdev)
The feedback was clear.	4.34 (1.05)
The feedback was helpful.	4.37 (1.04)
I trust this feedback.	4.31 (0.97)
It includes a full solution/code I could copy directly.	2.55 (1.49)
I know what the issue is after reading the feedback.	4.27 (1.07)
It sounds like a real instructor.	3.87 (1.34)

Table 5: Instructor survey across 12 respondents (blind A/B). Percentage of cases where feedback A (PERSA) was preferred over Feedback B (vanilla LLM); tie aggregates “Both”/“Neither” responses.

Statement	A (%)	B (%)	Tie (%)
Overall preference	83.6	1.8	14.6
Helpfulness / actionability	85.5	1.8	12.7
Authenticity (human instructor)	74.5	1.8	23.7
Trust-oriented tone	87.3	3.6	9.1
Technical correctness	61.8	5.5	32.7
Gives too much solution	27.3	27.3	45.4

five feedback instances and reported an evaluation of different features of the feedback on a Likert (1–5) scale.

Human-study interpretation. Tables 4 and 5 summarize our blind human evaluation comparing **PERSA** (Feedback A) to a vanilla LLM (Feedback B) across diverse respondents, including university instructors with varying teaching experience and students spanning beginner to advanced programming backgrounds. We used short, consistent rubrics that asked participants to judge clarity, helpfulness / action-ability, trust, and instructor-likeness (rather than minor grammar). We observe converging evidence that **PERSA**’s professor-style alignment improves perceived feedback quality beyond the baseline. Students report high ratings for clarity, helpfulness, trust, and understanding (4.27–4.37/5), while the lower score on “includes a full solution” (2.55) suggests the feedback typically supports revision without excessive solution dumping. Instructors similarly prefer **PERSA** (83.6%) and rate it higher on helpfulness/actionability (85.5%) and trust-oriented tone (87.3%), with substantially stronger perceived authenticity (74.5%) than the vanilla LLM.

To complement our automated evaluation, we conducted a human study involving 32 participants (comprising faculty and students) across 8 univer-

Figure 5: Human-study outcomes comparing **PERSA** against a vanilla LLM.

sities. This study compares **PERSA** against a vanilla LLM baseline to evaluate perceived pedagogical quality and alignment with instructor-like behavior. As shown in Figure 5, respondents consistently preferred **PERSA** over the vanilla baseline in both overall preference and human-like, instructor-style feedback, providing direct human-centered evidence that **PERSA** produces responses that are more authentic, supportive, and pedagogically aligned. Details of the study design are provided in Appendix C.

7 Conclusion

We presented **PERSA**, a professor-style reinforcement learning framework that adapts LLM-generated programming feedback to an instructor’s communicative voice while maintaining diagnostic correctness. **PERSA** follows an RLHF recipe, supervised fine-tuning, preference-based reward modeling, and PPO optimization, but makes adaptation practical and controllable by restricting learning to style-relevant parameters through *layer-selective*, parameter-efficient LoRA updates concentrated in the upper transformer layers. Across datasets and model backbones, **PERSA** achieves the strongest overall alignment, reaching near-ceiling style and lexical similarity (e.g., SAC/BLEU) without degrading correctness accuracy, and producing feedback that is consistently more structured, specific, and pedagogically actionable in qualitative analyses. Taken together, our results suggest that “instructor voice” behaves as a largely separable and optimizable attribute that can be injected via targeted adaptation rather than full-model retraining, enabling more trustworthy, authentic, and deployable AI feedback systems for education.

Limitations

PERSA is evaluated on a limited set of instructors, programming tasks, and feedback distributions, so its gains in stylistic alignment may not directly transfer to new courses, grading philosophies, or broader educational settings without additional preference data and recalibration. Moreover, because the reward model is learned from a specific instructor cohort and prompting setup, it may capture dataset-specific biases or stylistic artifacts, and, like RLHF more broadly, it remains vulnerable to reward misclassifications and over-optimization. Detailed discussion, limitations, and future directions are provided in Appendix D.

Ethical Considerations

We carefully considered the ethical responsibilities associated with this work, particularly the human evaluation component. The study was conducted in accordance with standard institutional and legal expectations for voluntary human participation, including anonymized response collection, minimal-risk survey design, and analysis in aggregate form without storing personally identifiable information.

Appendix

A Pseudo Code

Algorithm 1: PERSA: Layer-Selective LoRA + RLHF

Input : Base LLM π_θ ; demos $\mathcal{D}_{\text{SFT}}$; prefs $\mathcal{D}_{\text{pref}}$; top layers L ; LoRA rank r ; KL β ; PPO steps T

Output : Style-aligned policy $\pi_{\theta'}$

Freeze θ ; insert LoRA (rank r) in top L layers; trainable params θ_{LoRA} ;

SFT;;

$\theta_{\text{LoRA}} \leftarrow \arg \min_{\theta_{\text{LoRA}}} \mathbb{E}_{(x, y^*) \sim \mathcal{D}_{\text{SFT}}} [-\sum_t \log \pi_\theta(y_t^* | x, y_{<t}^*)]$;

Set reference $\pi_{\text{ref}} \leftarrow \pi_\theta$ (frozen);

RM;;

Train reward r_ϕ on $\mathcal{D}_{\text{pref}}$ with

$\mathcal{L}_{\text{RM}} = -\mathbb{E} [\log \sigma(r_\phi(x, y^{(w)}) - r_\phi(x, y^{(l)}))]$;

PPO;;

for $t = 1$ **to** T **do**

Sample x ; generate $y \sim \pi_\theta(\cdot | x)$; compute

$\tilde{R} = r_\phi(x, y) - \beta \text{KL}(\pi_\theta \| \pi_{\text{ref}})$;

Update θ_{LoRA} by PPO using reward $\tilde{R}$ (clipped ratio);

return $\pi_{\theta'}$ (base + trained LoRA);

B Detailed Experimental Settings

B.1 Data Splits & Leakage Controls.

To prevent train-test contamination and inflated SAC/BLEU scores from near-duplicate examples, we employ leakage-aware splits and explicit overlap audits. In addition to a standard *instance-level* split, we evaluate on a stricter *New-Problems* split that withholds entire problem IDs from training. Before splitting, we remove exact duplicates using hashes over {problem, solution, reference feedback} and filter near-duplicates via Min-Hash/Jaccard similarity on problem text and reference feedback. After splitting, we compute each test example’s maximum similarity to the training set and verify that all remain below a conservative threshold. To further reduce dependence on surface-level overlap, we also report paraphrase-robust SAC and diversity statistics. Table 6 summarizes these controls.

Preference data. The same three datasets are used to construct both $\mathcal{D}_{\text{SFT}}$ and $\mathcal{D}_{\text{pref}}$. For $\mathcal{D}_{\text{SFT}}$, each example is a prompt-reference pair (x, y^*) , where y^* is the professor or expert-written feedback. For $\mathcal{D}_{\text{pref}}$, we form pairwise comparisons $(x, y^{(w)}, y^{(l)})$ using the same training prompts: the preferred response $y^{(w)}$ is the professor/expert feedback, and the rejected response $y^{(l)}$ is feedback gen-

Table 6: Leakage-aware splits & overlap audits.

Audit / Split		Std. New-Problems	
Split key		inst.	prob. ID
Exact dups rm. (%) ↓		1.2	1.2
Near-dups rm. (%) ↓		6.5	6.5
Max train-test (problem) ↓	sim.	0.23	0.19
Max train-test (ref. fb) ↓	sim.	0.18	0.15
# test items >0.8 (Jaccard) ↓		0	0
Paraphrase SAC (%) ↑	agr.	94.0	91.5
BERTScore (F1) ↑		0.92	0.90
Self-BLEU ↓		0.54	0.50
Distinct-2 ↑		0.21	0.24

Table 7: Method footprint. PERSA retains an RLHF pipeline but updates only Top- L LoRA adapters (layer-selective PEFT), improving efficiency and style fidelity.

Method	Obj.	RM	On-pol.	Trainable	Scope	Pros
Base	–	N	N	0%	Frozen	No cost
SFT	SFT	N	N	Full	All	Stable, simple
RLHF	PPO	Y	Y	Full	All	Strong align; costly
DPO	DPO	N	N	Full	All	Offline, stable
ORPO	ORPO	N	N	Full	All	Efficient prefs
KTO	KTO	N	N	Full	All	Robust prefs
PERSA	SFT+PPO	Y	Y	Top- L LoRA	Top- L	Style + low drift

erated by the vanilla backbone or a weaker baseline under the same prompt. Preference pairs are created only from the training split to avoid train-test leakage.

B.2 Model Evaluation Framework

We use lightweight, open-weight instruction-tuned LLMs as backbones so that PERSA (SFT + reward modeling + PPO) can run in a single-GPU setting. **Vanilla LLM baseline.** Unless otherwise stated, “vanilla LLM” refers to the instruction-tuned backbone used without task-specific fine-tuning or preference optimization. In our experiments, this corresponds to google/gemma-2-2b-it or meta-llama/Llama-3.2-3B-Instruct, evaluated with the same prompts and decoding configuration as the adapted models.

Primary backbone: Gemma 2 2B Instruct. We use google /gemma-2-2b-it as the main policy model due to its strong instruction-following behavior at a practical size, enabling parameter-efficient RLHF in constrained compute (Team et al., 2024). **Secondary backbone: Llama 3.2 3B Instruct.** We additionally evaluate meta-llama/Llama-3.2-3B-Instruct to test

cross-family robustness (Meta vs. Google) while keeping the model small enough for Colab-scale tuning (Dubey et al., 2024). **General recipe (model-agnostic).** All experiments treat the LLM as a conditional policy $\pi_\theta(y \mid x)$ over feedback tokens; we apply (1) supervised fine-tuning on instructor demonstrations, (2) reward modeling from pairwise preferences, and (3) PPO-based policy optimization with a KL constraint to preserve base knowledge. This structure is compatible with any decoder-only LLM that supports PEFT adapters (Ouyang et al., 2022; Schulman et al., 2017).

Methods Compared: We compare PERSA against strong baselines spanning supervised imitation and preference-based alignment to assess their ability to generate professor-like programming feedback while preserving correctness. (1) **Base Model** denotes the instruction-tuned backbone (Gemma-2-2B-IT or Llama-3.2-3B-Instruct) used *without* any task-specific adaptation. (2) **Supervised Fine-Tuning (SFT)** fine-tunes the backbone on professor-authored demonstrations using a maximum-likelihood objective. (3) **InstructGPT-style RLHF** follows the standard RLHF recipe of reward modeling from preferences and policy optimization with PPO and KL control (Ouyang et al., 2022). To reflect recent state-of-the-art alternatives to PPO-based RLHF, we additionally include three *offline* preference optimization methods trained on the same professor preference pairs: (4) **DPO** (Direct Preference Optimization), which directly optimizes the policy from preference comparisons without an explicit reward model (Wu et al., 2024b), (5) **ORPO** (Odds Ratio Preference Optimization), which integrates preference signals into an SFT-like objective (Hong et al., 2024), and (6) **KTO** (Kahneman–Tversky Optimization), a robust preference based objective inspired by prospect theory (Ethayarajh et al., 2024). Finally, (7) **PERSA** is our proposed framework that combines SFT initialization with *layer-selective, parameter-efficient* preference alignment (LoRA on upper layers) to target instructor style while minimizing drift in core capabilities. **Table 7 columns.** We report each method’s optimization objective (*Obj.*), whether it requires an explicit reward model (*RM*) and on-policy rollouts (*On-pol.*), the fraction of trainable parameters (*Trainable*), and update scope across layers (*Scope*), highlighting that offline preference methods (DPO/ORPO/KTO) train full weights without RM/rollouts, while **PERSA** follows an RLHF pipeline (RM+on-policy) but updates only Top- L

LoRA adapters for efficient, style-focused alignment. All approaches are evaluated under the same prompts, data splits, and decoding settings, enabling a controlled comparison of stylistic alignment and content fidelity.

B.3 Evaluation Metric

We evaluate PERSA on two complementary dimensions: *style alignment* (how feedback is phrased) and *diagnostic fidelity* (whether feedback is correct). All metrics are reported on the held-out test set as means.

Style Alignment Score (SAC). We train a calibrated binary style classifier (professor vs. non-professor feedback) and compute

$$\text{SAC} = \frac{1}{N} \sum_{i=1}^N C(\hat{y}_i), \quad (8)$$

where $C(\hat{y}_i) \in [0, 1]$ is the posterior for the professor label; higher is better (Fu et al., 2018).

Average Politeness Closeness (APC). Using a politeness scorer $p(\cdot) \in [0, 1]$ (Danescu-Niculescu-Mizil et al., 2013), we measure tone closeness to the professor reference:

$$\text{APC} = \frac{1}{N} \sum_{i=1}^N \left(1 - |p(\hat{y}_i) - p(y_i^*)|\right). \quad (9)$$

BLEU-4. We report corpus BLEU-4 (with smoothing) to quantify n -gram overlap in phrasing with the professor feedback (Papineni et al., 2002).

Correctness Accuracy (CA). CA measures whether the feedback correctly identifies solution correctness. Let z_i be the unit-test label and $\hat{z}_i$ the judgment extracted from $\hat{y}_i$; then

$$\text{CA} = \frac{1}{N} \sum_{i=1}^N \mathbb{I}[\hat{z}_i = z_i], \quad (10)$$

with higher indicating more reliable feedback (Shen et al., 2023). We interpret CA as a preservation check rather than the main source of improvement.

Preference Win Rate (PWR). To reflect RLHF objectives, we report the fraction of prompts where PERSA is preferred over a baseline under the same rater:

$$\text{PWR} = \frac{1}{N} \sum_{i=1}^N \mathbb{I} \left[r_\phi(x_i, \hat{y}_i^{\text{PERSA}}) > r_\phi(x_i, \hat{y}_i^{\text{BASE}}) \right]. \quad (11)$$

a standard RLHF evaluation signal (Ouyang et al., 2022).

Metric reliability. We treat SAC and APC as automatic proxies rather than definitive measures of pedagogical quality. To check reliability, we calibrate the SAC classifier on held-out professor/non-professor feedback. For APC, we report correlation with human judgments of tone/trust-oriented feedback. These checks are intended to ensure that automatic metrics track human-perceived style dimensions rather than only surface lexical overlap.

B.4 Configurations

We summarize key hyperparameter for reproducible local-scale training; values below are defaults and can be scaled with model size.

Input formatting. We serialize each example as: *Problem + Student code + optional tests/constraints* $\rightarrow$ *Feedback*. We cap the input length (e.g., 1 2k tokens) and truncate from the left (oldest context) when needed.

Parameter-efficient tuning (LoRA/QLoRA). We inject LoRA adapters into attention and MLP projections (e.g., `q_proj`, `k_proj`, `v_proj`, `o_proj`, `up_proj`, `down_proj`, `gate_proj`) and update only the *top L transformer blocks* (layer-selective adaptation). Typical settings: rank $r \in \{8, 16\}$, $\alpha \in \{16, 32\}$, dropout $p = 0.05$. For coding environments, we use 4-bit NF4 quantization with double-quantization when available (QLoRA). (Hu et al., 2022; Detrmers et al., 2023)

SFT. Optimizer: AdamW; learning rate $1e-5$ $2e-5$; epochs 3 10 (smaller for CodeReviewQA, larger for the 200-example instructor set); effective batch size via gradient accumulation; warmup 3 5%; weight decay 0.0 0.1; label smoothing optional (0.0 0.1).

Reward model (RM). We train a reward model $r_\phi(x, y)$ on preference pairs with a Bradley Terry / logistic loss; batch size 8 32; 1 3 epochs; early stopping on validation preference accuracy (Ouyang et al., 2022).

PPO (RLHF). We optimize the KL-regularized objective with PPO using: rollout batch 32 128 prompts, 1-4 PPO epochs per iteration, clipping $\epsilon = 0.2$, KL coefficient $\beta \in [0.005, 0.05]$, and a reference policy π_{ref} set to the post-SFT model. We keep generation short for feedback (e.g., max new tokens 128 256) to stabilize advantage estimates. (Schulman et al., 2017; Ouyang et al., 2022)

Figure 6: Overview of the human evaluation design used for instructor and student studies.

Compute and reproducibility. All runs fix random seeds, log training curves, and report mean $\pm$ std over 3 seeds when feasible. On GPUs (A100), Gemma-2-2B with 4-bit LoRA typically fits in memory with moderate batch sizes; Llama-3.2-3B may require smaller rollouts or more accumulation.

C Human Study Design

Figure 6 summarizes our human evaluation protocol, showing the participating groups (instructors and students), the shared evaluation criteria (overall preference, clarity, helpfulness, and trust), and the blind A/B comparison between PERSA-generated feedback and vanilla LLM feedback used in both surveys.

Our instructor student **human evaluation section C**, provides direct evidence that PERSA’s RLHF objective translates into perceived pedagogical gains participants overwhelmingly preferred the PERSA outputs over a vanilla LLM thereby validating that the learned preference signal improves feedback quality beyond automated style metrics. **Figure 5** states that across instructor and student respondents, PERSA is preferred over the vanilla LLM (92% vs. 8%) and is judged to better match a human-instructor feedback style (94.3%), providing human-centered validation of PERSA’s RLHF-based style alignment.

D Discussion

PERSA demonstrates that *personalized pedagogical alignment* can be achieved by tuning *how* feedback is delivered (tone, structure, and phrasing) without degrading *what* is delivered (diagnostic correctness). Across three datasets and two model families, we observe a consistent separation between *style* and *substance*: base instruction-tuned models retain high correctness (CA) but exhibit weak professor-style fidelity (low SAC/BLEU),

while preference-based methods systematically improve stylistic alignment with minimal impact on CA. Crucially, PERSA achieves the strongest overall alignment (near-ceiling SAC/BLEU with $CA \approx 100\%$), indicating that instructor voice is an optimizable target distinct from generic “helpfulness” alignment.

Why each component matters. PERSA’s performance is not due to a single stage, but to the complementary roles of its components. **SFT** provides a stable initialization that learns the instructor’s canonical feedback template (e.g., encouragement → diagnosis → fix → verification), yielding the largest first jump in SAC/BLEU and perfect CA, but it does not fully capture nuanced preferences such as strictness, specificity, and emphasis on edge cases. **Reward modeling** operationalizes these nuanced stylistic and pedagogical preferences from pairwise comparisons, producing a scalar signal that encodes instructor-specific judgments beyond likelihood matching. **PPO with KL control** then refines the policy to maximize preference reward while preventing broad drift from the SFT reference, which is essential for preserving the backbone’s general coding competence and avoiding capability regressions.

Why layer-selective LoRA is central. A key insight behind PERSA is that updating *all* parameters is neither necessary nor desirable for style personalization. Motivated by evidence that late transformer layers and FFN submodules disproportionately encode high-level attributes (discourse patterns, tone, and stylistic signatures), PERSA restricts trainable parameters to LoRA adapters in the top layers. This yields two benefits: (i) **efficiency** only a small fraction of parameters (e.g., $\sim 30M$ in the last 4 layers) need to move to achieve large stylistic gains; and (ii) **stability** constraining updates reduces catastrophic drift and preserves correctness, which is critical in educational feedback where factual errors can harm learning. The ablations support this design: PPO without SFT is sample-inefficient for learning instructor voice, and broader updates (full-parameter PPO or all-layer LoRA) improve style but underperform targeted top-layer adaptation, implying that “style-bearing capacity” is concentrated in late layers rather than uniformly distributed.

Relevance and broader implications. PERSA’s results suggest a practical path to **course-level personalization** of AI tutors: rather than training new models per instructor, one can adapt a compact

backbone with a small set of instructor-specific adapters and a preference signal, enabling rapid deployment and easy swapping of styles across courses. This is particularly relevant for educational settings where instructors have distinct grading philosophies (e.g., emphasis on readability vs. correctness vs. edge cases) and where student trust depends on perceived authenticity. Beyond education, the same principle generalizes to domains requiring **persona consistent communication** (e.g., customer support, clinical explanations, legal drafting) where maintaining core competence while matching a specific communication style is essential. Finally, the strong agreement between quantitative alignment metrics and qualitative examples indicates that optimizing for instructor preference can yield feedback that is not only stylistically similar but also more actionable and pedagogically structured, supporting the use of preference based objectives as a reliable mechanism for fine-grained style alignment.

What PERSA adds beyond standard RLHF. PERSA does not claim a new reinforcement learning algorithm; rather, it operationalizes RLHF for a narrower educational alignment problem: instructor-specific feedback style. Its novelty lies in treating professor voice as a distinct optimizable attribute, combining instructor-authored demonstrations, preference modeling, and layer-selective LoRA updates to shift feedback tone, structure, and specificity while limiting parameter drift. This framing differs from generic RLHF, which optimizes broad helpfulness, and from standard SFT, which imitates demonstrations without explicitly optimizing instructor-preference signals.

Limitations. Our evaluation covers a small number of instructors, student feedback distributions, and programming tasks; consequently, the observed style improvements may not directly transfer to new instructors, grading policies, courses, or broader educational settings without additional preference data and validation. In addition, because PERSA is trained with a fixed prompting/template and a specific instructor cohort, the reward model may capture prompt- or dataset-specific artifacts, which can reduce robustness when moving to different assignment formats, programming languages, or institutional contexts unless recalibrated. Finally, as with RLHF more broadly, a learned reward can reflect annotator bias and remains vulnerable to misspecification or over-optimization even with KL regularization, motivating careful monitoring

and human-in-the-loop oversight prior to classroom deployment (Ouyang et al., 2022; Lindsay et al., 2025).

While our human study partially validates the automatic style metrics, we do not yet include an LLM-as-a-judge evaluation for holistic pedagogical style. Future work will compare SAC/APC with expert-calibrated LLM judges that assess authenticity, encouragement, specificity, and instructional tone.

Future Work. We will extend PERSA to multi-instructor and multi-course settings with longitudinal classroom studies, and will explore stronger preference collection and safety controls (e.g., uncertainty-aware rewards and calibration) to ensure style-personalized feedback remains accurate, fair, and robust in real deployments.

Educational outcomes beyond style. to complement style/correctness metrics (SAC/APC/BLEU/CA/PWR), we will evaluate *learning-relevant* outcomes: (i) revision success by measuring whether students can fix the identified issues on a resubmission task (pass@1 / unit-test pass rate improvement), and (ii) error recurrence by tracking whether the same misconception/bug type reappears in a follow-up attempt. In addition, we will assess **action-ability and rubric alignment** using a validated feedback rubric, rated by instructors/TA annotators, rather than preference alone.

Data-lean fine-tuning of models for evaluating teacher performance in a GenAI-led elicitation simulation

Abstract

Recent advances in the capabilities of conversational agents based on large language models make them a very promising tool for role playing K-12 students in order to train educators in conversational teaching practices, such as eliciting student thinking, explaining disciplinary content, and facilitating a classroom discussion. In fact, such simulations can and have been developed relatively quickly and without data to machine-learn from – neither classroom data nor human-simulated data. To enhance the usefulness and effectiveness of such teaching simulations, it is necessary to provide pedagogically sound, timely, and personalized feedback to the educator about their simulation performance. In this study, we present experiments on fine-tuning models to evaluate educator performance in an elicitation teaching simulation. The models are developed with data collected during usability testing of the simulation and evaluated on real user data. We show that even with relatively little fine-tuning data, robust performance can be obtained.

1 Introduction

Digital teaching simulations (**DTS**) have increasingly been integrated into teacher education settings to support educators in learning how to engage in high-leverage teaching practices, such as eliciting student thinking, facilitating productive discussions, and communicating with families, and have been shown to improve educators' skills, knowledge and beliefs (Dalinger et al., 2020; Dieker et al., 2019; Ersozlu et al., 2021; Lee et al., 2024; Mikeska et al., 2025a). One of the most common types of DTS involves educators in conversing with one or more student avatars via an online interface where the avatars appear visually and talk to each other and the educator in real time. In these simulations, there is a human-in-the-loop called a

simulation specialist who has been trained to use specialized technology, such as voice modulation software and game controllers, and to enact various student personas that align with the student avatars' pre-specified personalities, backgrounds, previous experiences, and content understandings (Bondie et al., 2021).

Research has shown that productive simulation-based learning experiences involve instructional or learning cycles whereby teacher educators or professional development facilitators support educators in preparing for, engaging in, and then debriefing and reflecting on their simulation performances (Lottero-Perdue et al., 2023; Mikeska et al., 2023a; Woods et al., 2024). These instructional cycles can also include formative feedback from a teacher educator, coach, educators' peers, or via written feedback reports. Research has suggested that such feedback supports educators in identifying their instructional strengths and areas for growth and in learning how they can apply what they are learning to K-12 classrooms (Cohen et al., 2020; Horn et al., 2023; Mikeska et al., 2023b; Pecore et al., 2023). However, despite the empirical evidence for the efficacy of DTS, they are challenging to scale due to the need for the simulation specialist to power the student avatars during each simulation.

To address this scaling challenge, recent research has begun exploring how generative AI (**GenAI**) can be used to simulate student responses (Marquez-Carpintero et al., 2025; Hong et al., 2025; Liu et al., 2026; Pan et al., 2025; Markel et al., 2023; Lim et al., 2025; Zhang et al., 2026; Zhuang and Zhang, 2025; Lee et al., 2025, 2026; Gíslason, 2026; Ziying et al., 2026; Son, 2025). While users perceive GenAI teaching simulations as useful to support their learning (Lim et al., 2025; Markel et al., 2023; Mikeska et al., 2025b; Zhang et al., 2026) and manual analyses are being applied to explore user activity in a simulation (Lee et al., 2026; Son, 2025), we are not aware of studies focusing

*The author was at ETS at the time of research.

on automated assessment of teacher performance in a GenAI simulation for formative purposes.

Prior work on automated evaluation of teacher performance has been conducted on annotated classroom discussions data, such as mathematics discussions (TalkMoves (Suresh et al., 2022), NCTE (Demszky and Hill, 2023)), ELA discussions (Tran et al., 2024), small-group discussions in DTS (Asano et al., 2025; Nazaretsky et al., 2023), and tutoring dialogues (Cao et al., 2025; Macina et al., 2023). In contrast with at least a hundred teacher performances in each of the above, we explore feasibility of evaluating teacher performance in a newly created GenAI-led simulation with very little development data – only 40 performances, collected during usability testing of the simulation.

2 Related work

A variety of constructs related to effective teaching have been modeled computationally based on human-annotated datasets, predominantly of real or simulated classroom discussions and tutorial dialogues. These include specific teaching actions such as asking effective questions (Alic et al., 2022; Jensen et al., 2020; Kelly et al., 2018), encouraging students' interaction (Ilagan et al., 2024), supporting student motivation (Hunkins et al., 2022), enacting conversational uptake (Demszky et al., 2021; Jensen et al., 2020); more comprehensive analyses of various teacher and student "talk moves", common types of teacher and student contributions to classroom discourse (Suresh et al., 2022; Tran et al., 2024; Cao et al., 2025; Wang et al., 2025), as well as holistic characteristics of discussions such as coherence (Asano et al., 2025), extent of instructional support (Whitehill and LoCasale-Crouch, 2024), and instructional quality (Xu et al., 2024).

Methods used for automated analyses of educational discourse ranged from feature-based machine learning (Donnelly et al., 2017; Jensen et al., 2020; Kelly et al., 2018; Hunkins et al., 2022; Samei et al., 2014), to deep neural networks, including transformers (Demszky et al., 2021; Schlotterbeck et al., 2021; Kupor et al., 2023; Nazaretsky et al., 2023; Alic et al., 2022; Xu et al., 2024; Ilagan et al., 2024), to large language models (LLMs) using techniques such as few-shot prompting, chain-of-thought, and parameter-efficient fine-tuning (Wang and Demszky, 2023; Kupor et al., 2023; Whitehill and LoCasale-Crouch, 2024; Hou et al., 2024; Wang et al., 2025; Cao et al., 2025).

Wang et al. (2025) compared LLM prompt-engineering, full fine-tuning with BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), and parameter-efficient fine-tuning (PEFT) of LLMs on the TalkMoves dataset. They found that PEFT approaches were stronger on the talk moves Restating and Revoicing of the students' utterances but performed comparably to RoBERTa on the other constructs. However, these findings were obtained with fine-tuning on hundreds of transcripts totaling about 1.5M teacher words. Beigman Klebanov et al. (2025) studied few-shot vs fine-tuned models on about 1K teacher utterances in small-group discussion DTS and found fine-tuned models to be superior; however, the annotated data included only select, clear-cut utterances per transcript. Tran et al. (2024) evaluated both fine-tuned BERT and few-shot LLMs on detecting productive teaching moves and found that fine-tuned models were generally competitive though yielded to LLMs in certain configurations. Focusing specifically on the amount of fine-tuning data in the broader context of text classification, Zhang et al. (2025) compared BERT-like fine-tuned models, zero-shot LLMs, and LLM-internal-states-based methods on six text classification tasks and concluded that BERT-like models were stronger for what the authors termed "general text classification," but the strong performance of BERTs was predicated on tuning on moderate to abundant data. When data size was reduced to a few hundred (up to 450 instances, comparable to our scenario), they sank below GPT-4o results for the three datasets on which both model types of evaluated. In the current study, we investigate a data-lean scenario focusing on fine-tuned models, with an LLM-based few-shot model as a baseline.

3 The GenAI-led teaching simulation

The simulation was designed to support elementary pre-service and in-service teachers and paraeducators in developing the teaching competency of eliciting student thinking in elementary mathematics. During the simulation, teachers engaged in voice conversation with the Cecilia chatbot. Cecilia's responses were generated in accordance with a predefined student profile (section 3.1), allowing teachers to practice instructional strategies to elicit Cecilia's method for solving the addition word problem and her understandings and misunderstandings around addition. Cecilia was designed to respond to the teacher's questions with

Figure 1: Interface of the GenAI teaching simulation.

the minimal amount of information that was responsive to the question, thus allowing the teacher to practice elicitation. That is, when asked a question like ‘What did you do to solve the problem?’, Cecilia would describe the first step but not the full process and would not divulge her reasoning unless explicitly prompted to do so by the teacher.

3.1 The strategies for adding task

The Strategies for Adding task is based on design criteria for elicitation tasks (Qi and Sykes, 2016). Cecilia’s knowledge profile specifies both her understanding and gaps in knowledge when solving addition problems. In this task, Cecilia solved the word problem: “Mike has 6 crayons. Ann has 2 crayons. How many crayons do Mike and Ann have in all?” Cecilia solved this problem and showed her understanding in her written work (Figure 1 bottom right). She understands that 6 represents Mike’s crayons, 2 represents Ann’s crayons, and 8 represents the total. Cecilia counts on from the first addend and uses models (e.g., drawings) to represent and solve the problem. However, she cannot add numbers fluently. She does not understand that counting on from the larger addend (regardless of the position) is more efficient. She is not familiar with any strategies besides drawing and counting for addition and she does not understand the commutative property. This knowledge profile represents a step in a typical progression of learning addition for early elementary students.

In the simulation, teachers were not provided with detailed information about Cecilia’s conceptual understanding. They were instructed to elicit what Cecilia did and did not understand regarding addition (top right – ‘Your Goals’ – in Figure 1). A 10-minute preparation time was provided, allowing teachers to consider their elicitation strategies.

3.2 Implementation of the simulation

Chatbot default dialogue responses were generated using Azure OpenAI’s GPT-4o model (v2024-08-06) via Microsoft Azure’s Chat Completions API. Each request was issued as a single-turn completion conditioned on a system prompt that encoded the knowledge profile of the simulated student, instructional constraints, and worked examples along with few-shot dialog examples and the full conversation history.

Response generation followed a hybrid pipeline combining LLM-based dialogue generation with deterministic validation and filtering. Mathematical expressions in user input were normalized using GPT-4o, then parsed and evaluated using Python’s Abstract Syntax Tree (AST) library to enforce structural constraints on practice problems (i.e., a single addition operation with two operands and a sum of up to 20). Inputs that failed the structural requirements triggered replacement of the initial response with predefined messages (e.g., “Oops! I don’t understand this!”).

In addition to structural validation on user input, regular expression-based checks were applied to detect mathematical vocabulary that Cecilia should not be familiar with (e.g., equation) and out-of-range numerical values (i.e., any number greater than 20), with violations resulting in appropriate canned responses (e.g., “I don’t know what that means” and “That’s too many to draw”, respectively). If no constraints were violated, a final LLM-based simplification step adjusted lexical complexity and limited responses to a single procedural step. A more comprehensive description of the implementation of the chatbot and the evaluation of the accuracy of Cecilia’s responses in terms of responsiveness to the teacher’s questions; appropriateness in age, emotional tone, amount of information provided, and coherence with respect to prior conversation; and alignment with the student’s knowledge profile can be found in Mikeska et al. (2025b).

4 Data

4.1 Participants

Study 1: A total of 45 educators (paraeducators, in-service teachers, and principals) participated in a usability study to test the simulation. The age range was 25 to 64 years. Among them, 67% identified as White, 18% as Hispanic or Latino, 13% as Black or African American, and 4% as Asian or Asian American. The majority of educators were

female (82%). Regarding educational background, 67% held a Master's degree, 13% a Bachelor's degree, 11% a Doctoral degree, 7% other degrees, and 2% a high school diploma. Additionally, 76% of the educators had prior experience in teaching mathematics. Their familiarity with digital teaching simulations varied: 11% of were very familiar, 31% were somewhat familiar, 38% were a little familiar, and 20% were not familiar. We collected data from 45 participants; however, due to technical issues, we had to exclude 5 transcripts from the analysis. The 40 transcripts collected in this study comprised the **development** dataset.

Study 2: This study was the first implementation pilot of the simulation within a teacher education context. The data was collected from 10 pre-service teachers (PSTs) enrolled in a mathematics method course at a private college in the Northeastern USA. PSTs were aged 18-24. At the time of data collection, 90% of them had obtained a high school diploma. Half of the participants had experience as substitute teachers or in other teaching capacities. In terms of familiarity with digital teaching simulations, 50% were not familiar, 30% were somewhat familiar, and 20% were a little familiar. The gender and ethnicity data for PSTs were not collected.

In this study, as part of the coursework, PSTs participated in two instructional cycles using the Strategies for Adding simulation. During the first cycle, PSTs prepared for the simulation by reviewing the simulation's goal and the scenario's background. The 10-minute preparation phase included reviewing Cecilia's written work and considering questions or prompts to use to elicit her problem-solving process and conceptual understanding of addition. Next, they engaged in the simulation, followed by a reflection session during their 50-minute class time. Their mathematics methods teacher educator facilitated the reflection activity, during which PSTs reviewed [Hallman-Thrasher et al. \(2020\)](#) categorization of questions by purpose and analyzed their own transcript. Each PST then compared their transcript with a partner's to further reflect on how to elicit Cecilia's thinking and modify their questioning strategy in the future.

After one week, the second instructional cycle took place. After the second simulation, PSTs engaged in a reflection activity and categorized their questions again. In this reflection, they focused on the information each question gathered about Cecilia's mathematical understanding. They participated in a whole-class discussion where PSTs

analyzed Cecilia's conceptual understanding and knowledge gaps based on their simulation experiences. Afterward, they completed a debrief assignment to reflect on their elicitation techniques. The 20 transcripts collected in this study comprised the **test** dataset.

4.2 Annotation of aspects of teaching quality

Facilitating productive talk in classrooms with and between students requires that teachers use specific instructional moves to gauge students' initial and developing ideas and prompt them to share their thinking and understanding ([Michaels and O'Connor, 2015](#); [Wei et al., 2018](#)). Eliciting student thinking requires teachers to attend to specific student ideas, ask follow-up questions, and explain their reasoning ([Estapa and Davis, 2023](#); [Shaughnessy and Boerst, 2018](#)). In this study, we focus on three key constructs related to the practice of eliciting student thinking summarized in Table 1.

Construct	Description
ASI	Attends to Specific Ideas
AQTA	Asks Questions Tied to Actions
SWE	Show Work and Explain

Table 1: Summary of elicitation constructs.

Two raters with content analysis expertise participated in the annotation. Each teacher turn was annotated for each of the three constructs. The development set was used for developing rubrics, rater training, joint coding, individual coding, and double coding to monitor agreement. For the test set, one transcript was coded jointly and discussed, while the remaining 19 transcripts (266 teacher turns in all) were coded independently to evaluate inter-annotator agreement. The coding was reliable, achieving Cohen's κ of 0.88, 0.86, and 0.93, for AQTA, ASI, and SWE, respectively.

Table 2 exemplifies the flow of the conversation and the annotations of the teacher's utterances.

The first four teacher utterances contain at least one effective elicitation move each. The first two include asking Cecilia about something that she has done (provided the answer 8 in utterance#1, drew circles in utterance#3; AQTA = 1), specifically to explain the process ('how did you...') or reasoning ('why did you...'), respectively (SWE = 1). The third teacher's utterance (#5 in the Table) includes asking for Cecilia's reasoning about what she has just done (AQTA = 1, SWE = 1), following up

U#	Speaker	Utterance	Classifications		
			ASI	AQTA	SWE
1	Teacher	Cecilio, how did you come up with the answer of eight?	0	1	1
2	Cecilia	When we asked. About the crayons. I drew circles for the crayons. Mike had 6 and Ann had 2. I counted 6,7,8.			
3	Teacher	That's great. I noticed. I noticed when you drew your circles that you have three circles. With a dot inside of them. Why did you put the dot inside those three circles?	0	1	1
4	Cecilia	I put dots to show where I started counting Ann's crayons.	1	1	1
5	Teacher	So why do you have. Three dots instead of just two dots. If Anne only has two crayons.			
6	Cecilia	The first dot is where I started counting from Mike's crayons.	1	0	0
7	Teacher	Do you worry that you might get confused by having three dots to represent Anne's two? Crayons.			
8	Cecilia	Nope! I know which dots go to Ann's crayons because I still count them starting at Mike's crayons.	0	0	0
9	Teacher	You were able to come up. With the correct answer, Cecilia. But I worry in the future. Your extra dot might cause some confusion.			
10	Cecilia	Okay. I'll try to remember that.	0	0	0
11	Teacher	Maybe. A helpful strategy going forward would be to put the number one. In the circle where you started instead of using dots.			
12	Cecilia	Okay, I'll try that!			

Table 2: An excerpt from a conversation between the Teacher (human participant) and Cecilia (the GenAI powered student). Data is shown as it appears in the automated transcription. Human classifications of each teacher utterance for the three constructs are shown in the last three columns.

on Cecilia's idea of putting the dots where she starts counting Ann's crayons (ASI = 1). The next teacher utterance continues the follow-up on Cecilia's three dots idea (ASI = 1), though not about a specific action just performed (AQTA = 0) and not asking a process or reasoning question, but an attitude question ('do you worry...', SWE = 0). The last two teacher utterances do not contain any of the effective moves. The final utterance, specifically, is the teacher's attempt to teach Cecilia to improve her strategy for adding – which is out of scope for the simulation that focuses on eliciting the student's ideas rather than on changing them. A more effective elicitation strategy would have been to move on after the first three exchanges and ask Cecilia to solve a different problem that would help the teacher further explore Cecilia's mathematical understanding, for example, asking her to add more than two numbers or bigger numbers, or checking if she is familiar with the commutative property by solving 2+6 instead of 6+2.

4.3 Datasets

Table 3 shows the descriptive statistics of the data.

Development set				Test set		
#Pa	40			10		
#Tr	40			20		
#Ut	630			275		
#W	11K			3.6K		
	ASI	AQTA	SWE	ASI	AQTA	SWE
%1	28	26	23	27	40	29

Table 3: Descriptive statistics of the datasets. #Pa: Participants. #Tr: Transcripts. #Ut: Teacher utterances. #W: Total word count of all teacher utterances. %1: Percentage of teacher utterances labeled as class 1.

5 Models for evaluating teacher discourse

The goal of the evaluation models is to power formative feedback to teachers immediately following the simulation. Two types of feedback are created. First, for every construct, we show up to 3

utterances where the teacher engaged in the target behavior and up to 3 utterances where they did not. As an additional resource, examples from other teacher’s performances are provided. Second, for every construct, we show the overall frequency of occurrence of utterances where the target behavior occurred, and compare it to the range calculated using data from well-performing teachers. To support both types of feedback, the evaluation models are implemented as classifiers. For each construct, we classify each teacher utterance as showing the target behavior (class 1) or not (class 0).

5.1 Baselines

5.1.1 Few-shot models

Each construct was evaluated through LLM prompting using Azure OpenAI GPT-4o structured outputs. Each prompt instructed the model to identify and extract exact conversational turns from the transcript containing evidence for a single construct. Structured output returned verbatim excerpts with original role (i.e., student or teacher), message string, and turn identifier fields, enabling turn-level binary classification downstream. An empty list was returned when no evidence was found. All prompts were constructed as single system messages containing task instructions, the standardized problem context, construct-specific requirements with between two and five positive and negative examples picked by the subject matter expert on the team, and the full chat history transcript. Appendix B provides the prompts.

5.1.2 Fine-tuned baseline

As a baseline encoder model, we used DeBERTa (He et al., 2021) model deberta-v3-base¹ (He et al., 2023) from HuggingFace’s Transformers library (Wolf et al., 2020). We picked DeBERTa as it was the latest widely used iteration of BERT-style family of models (at the time of analysis) that achieved state-of-the-art performance on natural language understanding benchmarks like MNLI (Williams et al., 2018) and SQuAD v2.0 (Rajpurkar et al., 2018), improving on both BERT and RoBERTa models (He et al., 2021). The model has 12 layers and a hidden size of 768, 86M backbone parameters with a vocabulary of 128K tokens. This model was pre-trained using 160GB of data. For fine-tuning for our classification task, the learning rate was set to 5e-5, trained for 20 epochs. Only the

current teacher utterance were used as input to classify the utterance. We fine-tuned the model on data from four development set folds and evaluated on the fifth fold, in a 5-fold cross-validation design.

5.2 Experimental model

Using the development set, we explored a number of strategies for improving the baseline fine-tuned classifier. We used 5-fold cross-validation on the development set to evaluate the effectiveness of the strategies, separately and in combination. We discuss each strategy in turn.

Weighted loss to account for category imbalance (WB): As can be seen in Table 3, the class distribution is somewhat skewed, with class 1 accounting for fewer than 30% of the teacher utterances for each construct in the development data. In weighted loss, the weights were inversely proportional to the class frequencies.

Context (CO): Prior research has shown that incorporating a limited context of a few utterances can be effective (Tran et al., 2024; Cao et al., 2025). We experimented with a sliding window of three utterances, from three utterances proceeding the current one, two proceeding and one subsequent, all the way to three subsequent utterances as context. Based on the results on the development set, we selected the scheme with one utterance proceeding the current one (the student’s utterance right before the current teacher utterance) and two utterances following the current one (the student’s response and the teacher’s next utterance) as context.

Pre-training using real classroom discussion transcripts (CD): In order to attune the model to teacher-student educational discourse, we pre-trained on the publicly available data of classroom discussion transcripts from the NCTE corpus (Demszky and Hill, 2023). The corpus contains 1,660 transcripts of 45-60 minute 4th and 5th grade mathematics lessons collected by the National Center for Teacher Effectiveness. Cao et al. (2025) found that pre-training on classroom discussion data was useful for developing better classifiers of the same talk moves in tutorial dialogues. Our data isn’t tutoring, in the sense that the teacher’s goal isn’t to help the student learn, but to elicit the students’ current state of knowledge; nevertheless, classroom discourse in the domain of mathematics could be useful pre-training material. We experimented with 1, 5, 10, and 15-epoch pre-training and found that 10-epoch pre-training was the most effective.

¹<https://huggingface.co/microsoft/deberta-v3-base>

Multi-label classification (ML): We observed that while the three teaching constructs capture different aspects of a high quality teacher performance in the simulation, they sometimes happen in the same teacher utterance; see, for example, the conversation excerpt shown in Table 2. Quantitatively, we found that Pearson’s correlation between the list of binary labels for AQTA and SWE across the 630 teacher utterances in the 40 development set simulations was $r = 0.59$, suggesting a tendency to occur in the same utterances. The other correlations were weaker but still significant: $r = 0.37$ for AQTA and ASI and $r = 0.25$ for ASI and SWE. We implemented a multi-label classification with zero to three labels for each teacher utterance.

Selecting the final model for benchmarking: Table 4 shows the results for each strategy on its own (rows WB through CD), using 5-fold cross-validation on the development set. In addition to the four evaluation metrics (see section 5.3) for each of the three constructs, yielding $4 \times 3 = 12$ numbers for each model, we also provide a summary evaluation in the form of the count of cases, out of 12, where the result was substantially better ($\uparrow$) or worse ($\downarrow$) than the fine-tuned baseline, using a change of 0.04 or more as a cutoff. We observe that all strategies were net-positive, namely, increases outnumbered decreases, but (a) all incurred some decreases, and (b) the best net result was only 2 out of 12, suggesting overall mild positive impact. We experimented with combining strategies and picked the best combination, shown in row F(final): The model that included pre-training on the classroom (NCTE) data, multi-label learning, and context. That model achieved a net effect of 8 out of 12, without incurring any decreases. We call this model **FT-Exp** henceforth and benchmark it against the baselines on the test set to evaluate whether the improvement potential is realized on a new set of transcripts unseen during development.

5.3 Model evaluation

To evaluate the models for their ability to identify teacher utterances that realize the given teaching construct, we use both a retrieval paradigm (precision, recall, and F1 scores for the rarer positive class) and a classification paradigm (Cohen’s κ).

For each of the fine-tuned models (FT-BL and FT-Exp), we used five models that we fine-tuned on four out of the five cross-validation folds each. We compute the evaluation metrics for each model on the test set and show the average performance

Mod.	Met.	ASI	AQTA	SWE	$\uparrow$	$\downarrow$
BL	Prec.	.54	.74	.61		
	Rec.	.58	.72	.72		
	F1	.55	.73	.64		
	κ	.37	.62	.52		
WB	Prec.	.58	.68	.58	1	1
	Rec.	.61	.79	.75	1	
	F1	.56	.73	.65		
	κ	.41	.61	.52	1	
CO	Prec.	.58	.66	.63	1	1
	Rec.	.60	.64	.72		1
	F1	.59	.72	.65	1	
	κ	.42	.60	.54	1	
ML	Prec.	.52	.70	.66	1	1
	Rec.	.70	.76	.70	2	
	F1	.58	.71	.65		
	κ	.39	.60	.54		
CD	Prec.	.55	.69	.64		1
	Rec.	.73	.83	.67	2	1
	F1	.62	.74	.62	1	
	κ	.44	.63	.50	1	
F	Prec.	.58	.76	.67	2	
	Rec.	.70	.76	.69	2	
	F1	.61	.76	.67	1	
	κ	.44	.66	.56	3	

Table 4: Dev-set performance of the baseline (BL), each strategy on its own (WB: Weight Balance; CO: Context; ML: Multi-Label; CD: Classroom Discourse) and the final selected model (F). The last two columns count the number of metrics with increase ($\uparrow$) and decrease ($\downarrow$) of at least 0.04 wrt BL.

as the final test set evaluation. In addition, we show the evaluation metrics on the test set for the best aggregate model, as explained in the next section.

5.4 Robustness through aggregation

Due to non-determinism, it is common practice to train multiple times and aggregate the results. It is also possible to intentionally diversify the models by training multiple models on various sub-samples of the data. Aggregation of predictions from multiple such models could improve robustness. Requiring more models to agree is likely to improve precision but hurt recall, while using a permissive aggregation, e.g., positive if at least one model predicts positive, could help recall but hurt precision.

To gauge the optimal aggregation strategy, one ideally would train multiple models based on different subsets of the fine-tuning data for each of the cross-validation folds, resulting in $5 \times 5 = 25$ dif-

ferent models. This would require sub-partitioning of each fold into 80% and 20% again; given that a fold already contains only 8 transcripts, this design would further reduce the training data and result in a small evaluation set for the aggregation models. We therefore opted for a different design to gauge the optimal aggregation strategy: We randomly picked one of the FT-Exp models fine-tuned on four development folds and re-tuned it with four different random seeds. This created some variation in the models, and we considered how many positive votes we should require for the best balance of precision and recall. The results are shown in Table 6 in Appendix A. The results showed that while the most permissive model has the best recall and the most conservative had the best precision, as expected, the best precision and recall combination is achieved by a majority vote – requiring three out of the five models to assign the teacher utterance to class 1 in order for the aggregate to be class 1.

Based on these findings, for the test set, we will provide the results of the majority aggregation of five models (Agg FT-Exp), each fine-tuned on four out of five development set folds.

6 Results

Table 5 shows the results. We observe that fine-tuning was quite effective, the small number of transcripts notwithstanding. Both FT models improved over the Few Shot baseline on all metrics, on average across the three target constructs.

Next, we observe that FT-Exp gained in recall (+0.12) more than it lost in precision (-0.06) with respect to FT-BL, on average across constructs, resulting in improvements in F1 and κ scores, both on average and for each of the constructs.

Let us next compare the results for FT-Exp, shown as average performance on the test set across five models trained on four out of five development folds, to Agg FT-Exp, namely, a single system that aggregates the classifications generated by the five systems above using a majority vote. The results show clearly that the aggregated model is similar or better than the average single model.

7 Discussion

Overall, there is no reason to prefer few-shot (FS) models over fine-tuned (FT) ones, as the only cases of lower scores for FT models are recall for ASI for FT-BL and precision for ASI for FT-Exp, but, in both cases, these were compensated by a larger in-

Model	Metric	ASI	AQTA	SWE	Av.
Few Shot	Prec.	.53	.65	.73	.64
	Recall	.45	.59	.61	.55
	F1	.49	.62	.67	.59
	κ	.29	.41	.53	.41
FT BL	Prec.	.68	.82	.71	.74
	Recall	.41	.71	.70	.61
	F1	.48	.75	.71	.65
	κ	.36	.60	.59	.52
FT Exp.	Prec.	.50	.85	.70	.68
	Recall	.71	.72	.77	.73
	F1	.58	.78	.73	.70
	κ	.38	.64	.61	.54
Agg. FT Exp.	Prec.	.54	.84	.70	.69
	Recall	.81	.77	.78	.79
	F1	.65	.81	.74	.73
	κ	.48	.69	.60	.59

Table 5: Test-set performance of the two baselines and the best experimental models.

crease in precision and recall, respectively, showing overall gains in κ and similar or better F1 scores. For AQTA and SWE, the FT-Exp model crossed the $\kappa \geq 0.60$ threshold that is often taken to be sufficient for formative purposes, showing that fine-tuning, even with relatively little data, can result in usable models. That said, one of the constructs – ASI – remained challenging for all the models.

The FT-Exp model is the most promising, not only due to quality of performance, but also in terms of maintenance and cost of exploitation. Since FT-Exp employs multi-label learning, there is just one model dealing with all the three constructs. Being a relatively small BERT-family model, it can be installed locally and avoid incurring cost per query, as do the larger and more powerful LLMs, like GPT-4o used here for the few-shot model.

Our results also suggest that it may be beneficial to introduce some variation in the models by fine-tuning multiple models on somewhat different subsets of the fine-tuning data. In particular, majority aggregation of five such models results in improved recall across the board, without paying a price in precision. A different aggregation strategy to prioritize recall or precision could be devised, as well as optimizing the number of models and the extent of difference between them; more development data would be necessary for this optimization task. Our results show that a strategy evaluated on development set using a model variation method

that does not require data sub-partitioning resulted in a robust aggregation strategy that generalized to a blind test set with a different model variation method. While using multiple models to attain more robust performance is not a new finding in the LLM world, our results show that model aggregation can be successfully developed and evaluated using relatively little data.

Limitations

Although our results cover multiple effective elicitation moves, they are all studied in the context of a single task. Additional elicitation tasks in upper elementary mathematics and science are currently under development. We intend to replicate the study design when early data become available.

In addition, while the test set contained data from the target population of users and was collected in the target context of use of the simulation, the data come from a small number of pre-service teachers. As the simulation is used in subsequent data collections, we will examine the performance of the automated evaluation models on additional data to gauge the model’s generalization.

We note that the focus of the current paper is the evaluation of teacher performance in the simulation. The usefulness of an evaluation like this is related but not fully determined by the simulation itself constituting an effective practice based *learning* opportunity for educators. In particular, even if the simulation has some deficiency in terms of the realism of the simulated student’s discourse (Scarlatos et al., 2026), automated evaluation of the teacher’s performance could still be an efficient way to gauge the teacher’s current skill with elicitation strategies, if validated for this purpose. We thank a BEA reviewer for bringing this issue up.

Due to team capacity limitation, we explored only one of the most powerful LLMs available (at the time when the few-shot baselines were developed, GPT 4.0 was the top model). It is possible that few shot learning results would be better with the newer GPT model and/or with other LLMs such as Claude. It is also possible that open-source LLMs such as LLama can also be effectively fine-tuned in a parameter-efficient way (Wang et al., 2025), though, as Tran et al. (2024), we note that the data sizes are most likely too small to move the needle for these models. We leave it to future work to explore other LLMs, especially for the ASI construct for which we do not yet have a satisfac-

tory model. We believe our findings regarding the effectiveness of pre-training using classroom data, of flexible context that may include looking ahead in the conversation, of utilizing the teacher’s ability to include more than one effective strategy in a single utterance, and model variation and aggregation methods are a good starting point for further research in automated evaluation of teacher performance.

Ethics statement

The data collections that yielded the data used in this study were conducted with the approval of the IRB of the authors’ institution.

Feedback to the user in newly developed tasks is an inherently complicated proposition. This is because for the feedback to be most pedagogically appropriate, it needs to take into account how users typically behave in the activity, what strong and weak performances look like, and what properties of the performances best differentiate between the two. This is very hard to do with only usability data that may not even come from the target demographic and/or the target use settings. Therefore, provision of feedback is often delayed until well-performing feedback models can be built, which may deprive the early users of some of the potential benefit of participating in the simulation. Our results are quite optimistic in this respect: With only 40 development transcripts obtained through a usability study, we attained acceptable performance for two out of the three target constructs, suggesting that feedback along these two dimensions can now be responsibly provided to subsequent users.

A Aggregation Schemes Evaluation

#1s	Metric	ASI	AQTA	SWE	Av.
1	Prec.	.53	.68	.65	.62
	Recall	.78	.81	.82	.80
	F1	.63	.74	.72	.70
2	Prec.	.55	.70	.66	.64
	Recall	.77	.80	.80	.79
	F1	.64	.75	.73	.71
3	Prec.	.57	.71	.67	.65
	Recall	.75	.80	.80	.78
	F1	.65	.75	.73	.71
4	Prec.	.58	.71	.67	.65
	Recall	.72	.80	.78	.77
	F1	.64	.75	.72	.70
5	Prec.	.57	.73	.67	.66
	Recall	.65	.78	.75	.73
	F1	.60	.76	.71	.69

Table 6: Development set performance of aggregation schemes for five FT-Exp models fine-tuned with different seeds. The first column shows the number of class 1 classifications across the five models for the aggregate to be class 1. Thus, models requiring only one class 1 vote have the highest recall (0.80, on average across the three constructs), whereas models requiring full agreement - five class 1 votes - have the highest precision (0.66, on average across the three constructs).

B Feedback Evaluation Module

The feedback module evaluates educator–student conversation transcripts against pedagogical criteria using structured output parsing. A single LLM call is issued per elicitation construct (see Table 1), with the model parameters shown in Table 7.

Table 7: Model parameters for the feedback module

Parameter	Value
Temperature	0
Max Tokens	16,000
Seed	42
Response Format	Structured (Evidence)
Model	GPT-4o (v2024-08-06)

Note. The Evidence response format is a structured output schema containing a list of evidence sequences, each comprising consecutive conversational turns with role, content, and turn identifier fields. The same model deployment and parameters are used for all constructs.

For each construct, the prompt is sent as a single system message. The prompt follows a shared template: a task description specifying the construct name, a shared math problem context describing the student’s work, construct-specific evidence requirements with examples and non-examples, and a transcript placeholder where the full conversation history is inserted at runtime. The response is parsed into a structured Evidence object via the OpenAI structured output API.

The task description is as follows:

Your task is to collect evidence on whether the educator’s questions, prompts, and tasks are conducive to eliciting student thinking in the following criterion: *[construct name]* Return your answer as an Evidence object with lists of examples from the user (educator) from the transcript. Provide excerpts from chat history to give sufficient context for evidence. Follow the examples closely, they must be nearly identical. Return an empty list if nothing is similar to the given examples. All evidence must be written exactly as is from the transcript. Never invent or copy examples.

The shared math problem context included in each prompt is:

The discussion is about how the student solved a problem by completing the following steps on a math worksheet:

1. The student drew 6 circles representing Mike's crayons while saying out loud what they were drawing. The circles are drawn in the same pattern as the six-face of a six-sided dice.
2. The student drew 2 crayons representing Ann's crayons
3. The student continued counting, starting where they left off with Mike's crayons, and continuing by counting Ann's crayons. They did not start counting from 1. They drew a dot on Mike's 6th crayon, and then dots on Ann's two crayons as they counted.
4. After solving the problem, the student wrote the numbers 6, 2, and 8 in boxes on the worksheet to complete $6 + 2 = 8$.

The construct-specific sections of each prompt are presented in sections [B.1](#)- [B.3](#). For evaluation purposes, all and only teacher (User) utterances that are returned as part of the evidence for a particular construct are labeled 1 for that construct.

B.1 Attends to Specific Ideas

Evidence Requirements

- To count as evidence for this criterion, the teacher needs to ask a follow up probing question based on a specific idea that the student shared about their problem solving process or math understanding (could be about the given math problem or new problems that the teacher includes in the conversation). The follow up probing question should require the student to explain why they engage in specific steps or to explain their understanding related to the math problem or concepts.
- If it is the first time that the teacher is asking about something the student did (e.g., Why did you draw three circles with dots in them?), that would not count as evidence. But a follow up question based on the student's initial response (e.g., about the three circles with dots)

would count as evidence. Essentially the student needs to say something about a specific idea before the teacher's follow up prompt can be tagged as evidence for this criterion.

- The follow up prompt does not need to be linked to the immediate preceding utterance. The teacher could be following up on something that the student said earlier in the conversation and that would still count as evidence for this criterion.

Examples of Evidence

Example 1:

User: I see that there are eight crayons in all. Can you tell me why you put a dot in three of the grains.

Assistant: I didn't put a dot in three, I put them on the last three I counted.

User: Okay. So how many crayons did Mike have?

Assistant: 6 crayons.

User: So you drew six grands for Mike? And how many crayons did Anne have?

Assistant: Ann had two crayons.

User: Ann had two crayons. So why did you put a dot in the last three, the two circles?

Assistant: I put a dot on Mike's last crayon and Ann's two crayons when I counted them to make 7 and 8.

Example 2:

User: What are the dots in the middle of the circles? What do those represent?

Assistant: The dots are for counting.

User: So why did you only count three of them?

Example 3:

User: Okay, I see that. And why are there dots in three of the circles?

Assistant: I put dots when I count the crayons.

User: Okay, so why are there not dots in the first five?

Example 4:

User: Well, how do you know that's how many crowns they have altogether?

Assistant: I drew 6 for Mike and 2 for Ann. Then I counted, 6, 7, 8.

User: And why did you count? Six, seven, eight.

The following would NOT count as evidence:

- If the teacher restates the student's idea without probing further (only restates to clarify that is what the student said).

- If the teacher asks the students to recall the steps they used to solve the given addition word problem.

Non-Examples

Non-Example 1:

User: So if you remember, here is where normally. I would have manipulatives. For example, maybe some markers. Let's pretend that these markers are crayons, like the circles you drew. So. You first drew six circles. Like this for? Mike's crayons, right?

Assistant: Yes.

Non-Example 2:

User: You drew two circles next because Ann has 2 crayons, right?

Assistant: Yes!

B.2 Asks Questions Tied to Actions

Evidence Requirements

- To count as evidence for this criterion, the teacher needs to ask questions about what the student did or about why the student did specific things to solve the given addition word problem or to solve new addition or subtraction number sentences or word problems.
- These questions do not need to link to the student's preceding comment or utterance.
- If the teacher asks the student a question to confirm or clarify about what they did (something that the student already mentioned earlier in the conversation), that would count as evidence for this criterion.

Examples of Evidence

Example 1:

User: So why did you draw eight circles?

Assistant: I drew 6 circles for Mike's crayons and 2 for Ann's crayons.

Example 2:

User: I'd really like to learn too. Can you show me how you're working this? Problem. What's the first step?

Assistant: First, I draw circles.

Example 3:

User: Can you explain to me? Why? You did, the steps that you did.

Assistant: I drew circles to show the crayons for Mike and Ann. Then I counted 6, 7, 8.

Example 4:

User: Okay, so I see three circles. With a dot on the inside. I'm wondering what made you draw a third circle.

Assistant: I drew two circles for Ann and put dots as I counted.

Example 5:

User: Why did you choose that strategy?

Assistant: That's how I show the crayons.

The following would NOT count as evidence:

- If the teacher's question focuses on what the student understands and is not related to something specific they did to solve the given addition word problem or new addition or subtraction number sentences or word problems. For example, "What does addition mean?", "What does it mean to count on?"
- If the teacher's question asks the student to answer a factual (recall) question related to the given addition word problem.
- If the teacher's questions asks the student what they would do in solving additional problems or what they would do in the future. For example, gives them a new problem and asks them to solve it.

Non-Examples

Non-Example 1:

User: What does the plus sign mean?

Assistant: The plus sign means you add things together.

Non-Example 2:

User: What do you know about how commutative property can be used to solve addition problems?

Assistant: I'm not sure.

Non-Example 3:

User: How is addition similar to multiplication?

Assistant: I just know addition.

Non-Example 4:

User: How many crayons did Mike have?

Assistant: Mike had 6 crayons.

B.3 Shows Work and Explains

Evidence Requirements

- To count as evidence for this criterion, the teacher needs to prompt the student to reference or discuss one or more aspects of their

written work AND explain what they did in that written work or why the written work is the way it is.

Examples of Evidence

Example 1:

User: Which crayons were Mike? How did you show Mike's crayons?

Assistant: I drew 6 circles for Mike's crayons.

Example 2:

User: Excellent. So tell me, how did you count on from six?

Assistant: I started at 6 and then counted 7, 8.

Example 3:

User: So what was the first thing you did to solve the problem?

Assistant: I drew 6 circles for Mike's crayons.

The following would NOT count as evidence:

- If the teacher restates an idea that the student already shared.
- If the teacher asks the students to recall the steps they used to solve the given addition word problem
- If the teacher's question asks the student what they would do in solving additional problems or what they would do in the future (e.g., gives them a new problem and asks them to solve it)

Non-Examples

Non-Example 1:

User: Now I can understand. You started at six, and then you added two more, so that's how you got to. Eight. Is that right?

Assistant: Yes.

Non-Example 2:

User: So if you remember, here is where normally. I would have manipulatives. For example, maybe some markers. Let's pretend that these markers are crayons, like the circles you drew. So. You first drew six circles. Like this for? Mike's crayons, right?

Assistant: Yes.

Multi-component student writing profiles for expert-aligned automated evaluation of English learner essays.

Abstract

Automated Writing Evaluation (AWE) platforms have become common, but a significant gap remains between automated assessment and expert human feedback. We address this gap by introducing a supervised learning method that uses a multi-component student writing profile (comprising estimated CEFR level, grammatical error rates, and vocabulary distribution) to align AI scoring with expert human judgements. In the context of an online essay-writing platform for second language learners of English, our model achieves a 36% reduction in RMSE for holistic essay scoring and an 84% improvement in similarity to human-expert analysis of grammatical errors compared to automarker scores (26% and 57% improvement from the best-performing comparable earlier work, by Zaidi et al., 2019). Furthermore, we demonstrate that the model can predict a student’s profile for a final-version essay from earlier drafts and that predictions generalise to a subsequent task, offering new possibilities for automated curriculum planning. Finally, we introduce a visualisation tool that provides educators with clear expert-aligned longitudinal views of student development.

1 Introduction

Automated Writing Evaluation (AWE) platforms typically allow learners to submit a sequence of revised essays which incorporate system-generated suggestions for improving spelling, vocabulary and grammar. However, these platforms fail to provide the depth of feedback found in human instruction.

Standard metrics for assessing essay quality (e.g., TTR, MTLD, error-free-clause-ratio, grammatical error density, Flesch-Kincaid grade level) offer coarse-grained statistics, but they sacrifice nuance for summarisation. In this work we move beyond such metrics by representing texts as a richer *writing profile* object. This profile comprises sub-components for holistic proficiency, grammatical

Figure 1: The *writing profile* concept; rather than a single score, a student’s writing is represented by a profile with an estimated CEFR level, grammatical error rates (GER) and a profile of vocabulary usage (VOCAB).

error rates and vocabulary use; this provides a more granular view of student development and captures elements that the student *can do* (vocabulary usage) as well as elements that the student is struggling with (grammatical error rates). The concept is illustrated in Figure 1.

Writing profiles provide a dual-purpose representation that is simultaneously human-interpretable (offering pedagogical reference for educators) and machine-readable (as required for automated scoring). In this work, the profiles integrate a holistic essay score mapped to the CEFR¹ (North, 2005), with granular diagnostic actionable data. Specifically, the grammatical error rates are mapped to 26 error categories that are displayed by the platform, and are actionable by a language teacher; while the vocabulary usage data can be visualised as a histogram depicting vocabulary range and distribution, which aligns with standardised exam-marking

¹<https://www.coe.int/en/web/common-european-framework-reference-languages/level-descriptions>

rubric requirements.^{2,3} Together the components constitute a multi-dimensional linguistic signature of a learner’s essay, expressing holistic proficiency, specific aptitude and the areas for improvement.

We source our essays from the *Write & Improve Corpus 2024* (WI_CORPUS) (Nicholls et al., 2024), a public dataset sourced from a major online essay practice platform, *Write & Improve*⁴ (Andersen et al., 2013; Yannakoudakis et al., 2018). This dataset comprises sequences of revisions of learner essays. The final version of each essay is scored by a human expert and mapped to a CEFR-level; the essay is also manually corrected for grammatical (morpho-syntactic) errors. The holistic score, the distribution of the errors, and the vocabulary-usage in the corrected version provides a high-fidelity *expert profile* which can be used as the gold-standard for computer-generated *auto profiles*.

Auto profiles derived using popular NLP tools (*Language Tool*, *ERRANT*, *spaCy*) do not align closely with these expert profiles. To calibrate the auto-profiles, and significantly enhance their alignment with the human experts, we train a neural model using the expert profiles as target data. Beyond this calibration task, we demonstrate that the same model can be used to accurately forecast a student’s final submission profile from an initial draft. Furthermore, we show that the model can also generalise, accurately predicting the writing profile for a subsequent task (which opens possibilities for long-term curriculum planning).

In summary, the contributions of this work are as follows: (1) High-fidelity calibration: a model for accurately aligning automated CEFR-level assignments and grammatical error rates with expert judgments; (2) Vocabulary forecasting: predictions of a learner’s exhibition of vocabulary-usage on a task; (3) Predictive modeling: a model to predict a student’s performance in the final version of the current task from an early draft; and (4) Longitudinal predictions: a model to predict a student’s performance in a subsequent task.

2 Related Work

Accurate modeling of longitudinal skill acquisition is key for adaptive, personalised tutoring systems (Corbett and Anderson, 1994; Anderson et al., 1995). These systems typically rely on a well-defined taxonomy of skills (or *knowledge components* – Koedinger et al. 2012) with a particular acquisition model such as that in Cen et al. (2006) and Pavlik Jr et al. (2009), although implementations vary widely.

In language learning, knowledge components tend to be less clearly defined than in STEM subjects. Resources such as the *English Vocabulary Profile*⁵ or the *English Grammar Profile* (O’Keeffe and Mark, 2017) describe components in a qualitative way, but not as directly machine-readable rules. Consequently, many AWE platforms prioritise identification of errors over an analysis of correct usage.

The tasks of Grammatical error detection (GED) and correction (GEC) have been tackled using a range of methods including feature-based classification and machine-translation (for a survey see Bryant et al., 2023). There are several widely-used, annotated corpora for this task but the error typing within them is not consistent. We opt to use the *ERRANT* tool that has an independent error typology that can be used with any such annotated corpora (Bryant et al., 2017).

In our work, Automated Essay Scoring (AES) becomes a sub-task of AWE. AES typically refers to the task of predicting a holistic grade or analytic grades for an essay without interpretable diagnostics. Recent preferred methods for AES function as “black boxes” (e.g. Mayfield and Black, 2020 and Mansour et al., 2024). By training a model on writing profiles, which are interpretable (as required by legislation⁶) we remove the black-box limitations but retain the accuracy of neural models.

To our knowledge only Zaidi et al. (2019) has attempted a similar prediction task on comparable data from the *Write & Improve* platform, and our work draws comparisons with that study as part of our evaluation.

3 Write & Improve Corpus 2024

The *Write & Improve* platform has a publicly available dataset (WI_CORPUS) used in this work (Nicholls et al., 2024). This logs the essay-writing activities of English language learners, against prompts covering typical topics such as pets, holidays, etc. For each essay submitted, the *Write & Improve* automarker assigns a level on the CEFR scale (see A.3) and gives feedback on errors in the text, inviting the student to correct and resubmit. Hence there is a sequence of submissions for each student-prompt pair. The student chooses when a task is complete and it is time to move on to another prompt.

As well as the platform scores, the WI_CORPUS dataset includes annotations from a human expert for the final version of each essay: this consists of the human-judged CEFR level, and a human-corrected version of the text. This expert information is used to create *expert profiles*, which form the prediction targets for our neural model.

We define our own validation and test folds, removing a subset of samples where the expert human-corrected versions are not currently publicly available. There are 679 users responding to 50 prompts in the filtered dataset, and 23k submissions. 95% of drafting series are between 2 and 16 submissions long, median=3, mean=4.48. The mean Levenshtein ratio (Levenshtein, 1966) for final draft to human-corrected text is 0.96. For all drafts to human-corrected text it is 0.91. Between pairs of drafts it is 0.97. Prompts in the dataset are assigned to one of three difficulty levels: *beginner*, *intermediate*, or *advanced*.

4 Expert Profile Prediction

The main objective (Task 1) for this work is to improve the auto profiles so that they are more in line with the expert profiles. The secondary objective (Task 2) is forward prediction, where we attempt to predict the final draft’s human profile from an earlier version. The tertiary objective (Task 3) is a combination of these – we take the user automarker features from their final attempt at prompt i and try to forward predict the final profile for prompt $i + 1$, to see how well the final user features from prompt i generalise to other prompts on the platform.

4.1 Automatic Writing Profiles

In order to work with writing profiles, we must first extract them. In WI_CORPUS, only the final drafts

Figure 2: *Auto profile* generation. *W&I* is the *Write & Improve* automarker, *LT* is Language Tool. *EVP* is English Vocabulary Profile. *ERRANT* is the ERRANT grammar annotator. The gray text boxes denote components of the resultant profile. (See section 4.4)

are paired with human CEFR scores and human-corrected texts – these can be used directly in expert profile extraction. For earlier drafts we must approximate some aspects. The dataset already contains an auto-marked CEFR level for every draft. To get an estimated distribution of grammatical errors we must auto-correct the text and compare back to the original using ERRANT (the process is described in section 4.4.3). We also get the distribution of vocabulary used in the draft, by looking up the CEFR level of each content word (see section 4.4.4). These three components together form the *auto profile* of an essay attempt. See Figure 2.

4.2 Neural Network Architecture

Figure 3: Neural network architecture. A feedforward network with three branches for each component of the predicted output.

The architecture of our neural system can be seen

in Figure 3. The system is feature-based and takes user features $\mathbf{u} = (u_0, \dots, u_n)$ and task features $\mathbf{t} = (t_0, \dots, t_m)$. These features are concatenated for each sample to get vectors $\mathbf{c}_u, \mathbf{c}_t$. For the Grammatical Error Rate predictions, the concatenated inputs are converted into a pair of 26-dimensional vectors by a matrix product, which are then combined as follows:

$$\begin{aligned} u_{GER} &= W_{gu} \cdot D(\mathbf{c}_u) \\ t_{GER} &= W_{gt} \cdot D(\mathbf{c}_t) \\ \widehat{GER} &= \sigma(u_{GER} \oplus t_{GER}) \end{aligned}$$

where $D(\cdot)$ is a dropout layer with possible *rate* $\in [10^{-10}, 1]$ and σ is the *logistic sigmoid* activation function, $\sigma(z) = 1/(1 + e^{-z})$. The elementwise addition $\oplus$ combines the propensity for user error (u_{GER}) with the intrinsic opportunities for error in the exercise (t_{GER}). The sigmoid ensures that these are always in the $[0, 1]$ range – that is, rates are expressed as a per-category *Rasch model* (Rasch, 1980).

For CEFR level, the outputs of the matrix products are a single number, and there is no sigmoid since the target range is $[0, 12]$:

$$\begin{aligned} u_{CEFR} &= W_{cu} \cdot D(\mathbf{c}_u) \\ t_{CEFR} &= W_{ct} \cdot D(\mathbf{c}_t) \\ \widehat{CEFR} &= u_{CEFR} \oplus t_{CEFR} \end{aligned}$$

For the Vocabulary Profile predictions, the histogram estimate is constructed in a similar manner to other outputs, but it is normalised using a *softmax* activation function (Bridle, 1990):

$$\begin{aligned} u_{VOCAB} &= W_{vu} \cdot D(\mathbf{c}_u) \\ t_{VOCAB} &= W_{vt} \cdot D(\mathbf{c}_t) \\ \widehat{VOCAB} &= softmax(u_{VOCAB} \oplus t_{VOCAB}) \end{aligned}$$

The outputs from the neural network are then returned as a triple with element dimensions (26,1,7):

$$OUT = (\widehat{GER}, \widehat{CEFR}, \widehat{VOCAB})$$

Implementation was in *Keras* (Chollet et al., 2015) on *Tensorflow* backend (Abadi et al., 2015) using utilities from *scikit-learn* (Pedregosa et al., 2011).

4.3 Loss functions

System loss is the sum of three loss functions:

4.3.1 Grammar Error Rates

For grammatical error rate vectors we use *Euclidean distance* as a loss to minimise the overall distance between prediction and target:

$$L_{GER} = \frac{1}{N} \sum_{i=1}^N \sqrt{\sum_k (x_k - y_k)^2}$$

where the index k spans across the components of the vector, and i spans across the N samples in the dataset. *Mean squared error* loss can be used, but Euclidean distance gives slightly better results.

4.3.2 CEFR Level

CEFR level is modelled as a scalar and for this we use *mean squared error* as a loss:

$$L_{CEFR} = \text{MSE} = \frac{1}{N} \sum_{i=1}^N (x_i - y_i)^2$$

where x_i is the predicted value, y_i is the actual value, and N is the number of samples.

4.3.3 Vocabulary

Vocabulary use is represented as an empirical probability distribution, so we can use *cross-entropy loss* as an appropriate loss function:

$$L_{VOCAB} = -\frac{1}{N} \sum_{i=1}^N \sum_{c \in C} y_c \log(x_c)$$

where C is the number of classes (*i.e.* CEFR levels), y_c is the true likelihood of class c , and x_c is the predicted likelihood of class c . Both $x_c, y_c \in [0, 1]$ and $\sum_c x_c = \sum_c y_c = 1$.

4.4 Input Features

The WI_CORPUS dataset contains textual and metadata features for student essays. In this section we outline the input features and the pre-processing required to obtain them. For more information on dimensions and types, see A.4.

4.4.1 Auto CEFR Level

This is the CEFR level reported by the *Write & Improve* auto-marker for each essay submission, expressed as an integer in range $[0, 12]$.

4.4.2 Best-essay flags

This *best-essay* feature consists of two binary flags: one indicates the best draft submitted by the user on this task (*task-best*), and one shows the best draft submitted by the user in the whole dataset

```

S Everything seem quite meaningless to me .
C Everything seems quite meaningless to me .
A 0 1 ||R:SPELL||Everything||REQUIRED||-NONE-||0
A 1 2 ||R:VERB:SVA||seems||REQUIRED||-NONE-||0

```

Figure 4: ERRANT-style annotations. S is the original sentence, C is the corrected sentence, Rows marked A are annotations suggested by ERRANT - here a replacement spelling (R:SPELL) and a replacement on the verb to change the subject-verb-agreement (R:VERB:SVA).

(*user-best*). The motivation behind this feature is to provide a signal about the level of this draft relative to previous drafts, on the basis that the task-best and user-best drafts are more reflective of the upper bound of the student’s ability. We use the student’s automarked CEFR history to set these values.

4.4.3 Grammatical Error Rates

A learner’s grammatical ability is expressed as a *grammatical error rates* (GER) object, a vector where each element corresponds to a type of grammatical error. Elements are real-valued and show the per-token rate of occurrence of that error type within a draft. For the main GER objects, the text written by a student is analyzed using *Language Tool* (LT), a widely-used grammatical error detection and correction system (Milkowski, 2010). This system returns a list of probable corrections that are then applied to the student text, to get the LT-corrected text. This is then compared to the original in ERRANT to get the corrections categorised as ERRANT edit codes.

Figure 4 gives an example of ERRANT-style annotation. The red highlights in the first S(entence) line show the words that ERRANT has tagged as edits. The second line is the C(orrection) by a human expert. The third and fourth A(nnotation) lines show token spans for corrections (in blue). The strings highlighted in green are the error types (e.g., R:SPELL is a spelling error; R:VERB:SVA is a subject-verb agreement error).

ERRANTised GER vectors are simplified by collapsing the R/M/U prefixes (for *replace*, *missing*, *unnecessary*) to get 26 categories (see appendix A.2). Note that in the target data, GERs are only available as ERRANT-type vectors, since they are derived from human corrections. ERRANT GER vectors are called **uGER** in the results.

As well as creating ERRANT-style GER vectors, it is possible to create a similar object for LT output directly. Although LT has hundreds of rules to identify errors, it groups them into categories of

which 15 appear in WI_CORPUSS. Counts are summed and normalised as before. LT GER vectors are denoted **uGER.LT** in the results.

4.4.4 Vocabulary Histogram (uVOCAB)

This feature is a histogram of the proportion of words in a draft that fall into each of the CEFR vocabulary difficulty levels, as defined by the *English Vocabulary Profile* (EVP) (Capel, 2015). These levels cover the same range as the CEFR – for vocabulary each token is categorised to a level and counted in the histogram. As well as A1–C2 there is also an unknown (UNK) category. The EVP level for a word is dependent on the word-class and word-sense of the usage. To ascertain word-class (noun, verb *etc.*) we use the *spaCy* *part-of-speech* tagger (Montani et al., 2023) and we select from the EVP the CEFR level for that class. If no such word-class is recorded, we assume the lowest CEFR level for that word as in Tyen et al. (2022). The EVP look-up uses both US and UK English gazetteers. We do not attempt to disambiguate word senses: a word-sense disambiguation model could be trialed in future work.

4.4.5 Essay statistics

Included in the feature set is the number of tokens in the essay (known to correlate with proficiency level) and the revision number (as a raw count).

4.4.6 Profile averages (tCEFR, tGER, tVOCAB)

To help provide a central value against which to measure the offset of grammatical and proficiency scores, we optionally include the mean values for CEFR level, GER and VOCAB for each task.

4.4.7 Avg. Error Deltas (dGER.LT, dCEFR)

These values measure average change in uGER.LT and uCEFR level per submission for each task t .

4.5 Feature and hyperparameter search

The features given in Section 4.4 are filtered to select a subset with high performance. We use *Bayesian optimisation* (Pelikan, 2005) with five-fold cross validation. Specifically, features are selected, and applied uniformly across all five folds. The mean of the validation losses is used in the selection optimisation step. This prevents coincidental outlier scores on particular folds from dominating the tuning process. Hyperparameter search was carried out as part of the same process. Hyperparameters include dropout rate $\in [10^{-10}, 1]$

for each dense layer, number of dense layers on each branch $\in [0, 5]$, width of dense hidden layers $\in [5, 200]$, and choice of activation functions $\in [\text{sigmoid}, \text{linear}, \text{ReLU}]$. In practice, no hidden layers are needed to get good results, and dropout rates are best when small ($< 10^{-3}$).

4.6 Evaluation

We simultaneously predict three targets (the expert assigned values of CEFR level, GER and VOCAB). This section outlines the evaluation for each. For more information on target dimensions and types see A.5.

4.6.1 Evaluation of CEFR level predictions

For the evaluation of CEFR level prediction, we use *Root Mean Squared Error* (RMSE) to provide a measure that can be compared directly to the CEFR. This is calculated globally with equal weighting across all data points (Pelánek, 2018).

4.6.2 Evaluation of GER predictions

We can compare true and predicted GER vector values $\mathbf{g}$ and $\hat{\mathbf{g}}$ using *cosine proximity*:

$$\text{CosProx}(\mathbf{g}, \hat{\mathbf{g}}) = \frac{\sum_k g_k^2 \hat{g}_k^2}{\sqrt{\sum_k g_k^2} \sqrt{\sum_k \hat{g}_k^2}}$$

For positive valued vectors like GER profiles, cosine proximity ranges from $[0, 1]$ with 1 being a perfect match. The use of cosine proximity is based on Zaidi et al. (2019) and it measures the directional similarity of the vectors (*i.e.*, the relative distribution of the magnitudes of components), but it does not take into account vector magnitude. We use *Root Mean Squared Error* (RMSE) as a secondary measure, to check that rates are at the correct levels as well as being distributed in the same way.

4.6.3 Evaluation of vocabulary distributions

Vocabulary distributions are empirical frequency distributions, so our interest is in how similar the histogram is as a whole. We use *Earth Mover Distance* (EMD). For histogram vectors with true value $\mathbf{h}$ and prediction $\hat{\mathbf{h}}$ we have:

$$\begin{aligned} \text{EMD}_0 &= 0 \\ \text{EMD}_{i+1} &= h_i + \text{EMD}_i - \hat{h}_i \\ \text{EMD}(\mathbf{h}, \hat{\mathbf{h}}) &= \sum_{c=1}^{|C|} |\text{EMD}_c| \end{aligned}$$

where there are C classes in each histogram. $\text{EMD} \in [0, 1]$ where 0 is a perfect match.

4.7 Testing

Testing is carried out with a separate held-out test set for each of the five validation folds. In each case, data is partitioned by student, so any student in the test set will not have appeared in either the training or validation data. This ensures that we are measuring generalisable performance and not just re-using samples that have been encountered during training.

5 Results

Table 1 summarises the results of this work, subdivided into the three tasks; for Task 1 we also provide single-feature scoring and best-performing combinations. We also include baseline scores for Zaidi et al. (2019) and the results of our attempts to reproduce this approach.

The first line for Task 1 shows that the *Write & Improve* automarker predicts the expert CEFR level with mean RMSE of 1.403 (where a unit is half a CEFR level). The LT automarker creates GER vectors that are 0.363 cosine proximal to the expert versions. Vocabulary extractions are good predictors, with a mean EMD of 0.012 (out of 1.0) from the expert-corrected case.

We consider three categories (user-essay features comprising Document Basics and Auto Profiles; and Prompt Features) on their own and in combinations. The listing in Table 1 represents a breakdown of the best combinations found by feature filtering.

Some features are clearly more promising than others. In the *Document Basics*, the best try flag achieves the best CEFR prediction with 1.742 RMSE and the *deltas* achieve the best cosine proximity (0.644). For vocabulary distribution the EMD scores are good (0.034-0.035) but vocabulary features are needed to improve this further.

In the *Auto Profile Features* category, uCEFR is the strongest single feature for the CEFR target with 1.050 RMSE, but it is otherwise unremarkable. uVOCAB is the only good predictor of the final vocabulary distribution, dropping the EMD from at best 0.034 to 0.012.

In the *Prompt Features*, we see that tCEFR and tGER have the greatest influence on their respective targets: if we include tCEFR, CEFR RMSE drops to 1.084, so the mean CEFR is a strong indicator as we might expect. Similarly, for tGER alone, GER cos. prox. is good at 0.650 but for other targets it is less strong. The *deltas* alone look promising but are less effective in combination with other features.

	CEFR level	GER	VOCAB
Task 1: Improving profiles	RMSE↓	Cos.Prox.↑	EMD↓
Automarker performance	1.403	0.363	0.007
(Document Basics)			
best.try	1.742	0.643	0.007
n.tokens	1.784	0.640	0.007
version	1.910	0.640	0.007
deltas	1.852	<u>0.644</u>	0.007
best.try+n.tokens+version	<u>1.103</u>	0.623	<u>0.007</u>
best.try+n.tokens+version+deltas	1.106	0.585	0.008
(Auto Profile Features)			
uCEFR	1.050	0.622	0.007
uGER	1.707	0.661	0.007
uGER.LT	1.708	0.657	0.007
uVOCAB	1.297	0.648	0.007
All auto profile features (uALL)	<u>0.932</u>	<u>0.663</u>	<u>0.007</u>
(Prompt Features)			
tCEFR	1.084	0.626	0.007
tGER	1.595	0.650	0.007
tVOCAB	1.267	0.649	0.007
All prompt features (tALL)	<u>1.076</u>	<u>0.650</u>	<u>0.007</u>
(Replicating Zaidi et al., 2019)			
Prev. Baseline	1.383	-	-
Prev. Best	1.093	0.426	-
Closest (uGER+best)	1.045	0.639	0.007
uALL+tALL (excl. VOCAB)	0.848	0.664	0.007
uALL+tALL+best.try (excl. VOCAB)	<u>0.838</u>	<u>0.665</u>	<u>0.007</u>
(Best Overall Combinations)			
uALL+tALL	0.817	0.670	0.007
uALL+tALL+n.tokens	0.816	0.664	0.007
uALL+tALL+deltas	0.817	0.664	0.007
uALL+tALL+best.try	0.809	0.670	0.007
Task 2: Forward prediction			
Automarker performance	1.426	0.339	0.006
Best from Task 1	0.874	0.659	0.006
Task 3: Generalisation			
Automarker performance	1.913	0.283	0.007
Best from Task 1	0.963	0.649	0.007

Table 1: Results for predicting human expert profile scores from auto profiles. Best features or combinations for each subclass are underlined, best combinations for each Task are in **bold**. ↑=higher is better; ↓=lower is better.

The most performant combination is all *Auto Profile* and *Prompt* features, with the best.try metric. This results in CEFR RMSE of 0.809, GER cos. prox. 0.670 and VOCAB EMD of 0.011.

For comparison with previous work we include a baseline and best score from Zaidi et al. (2019), which is the closest precedent to our Task 1. No baseline grammar scores were given and vocabulary was not included in that paper. In Zaidi et al.

the highest performing configuration used just GER profile and best.try metric – with these features we achieve CEFR RMSE of 1.045 and GER cos. prox. of 0.639, both better than the earlier work. With our best configurations, but excluding VOCAB entirely (as per Zaidi et al.) we do better still, with CEFR RMSE of 0.838 and GER cos. prox. of 0.665.

In Task 2, we attempt to predict the final expert profile, using auto profiles from earlier drafts. Here,

using the best configuration from Task 1, we see CEFR RMSE of 0.874 and GER cos. prox. of 0.659. VOCAB EMD is 0.014. These scores are slightly worse than for Task 1, although still beating the Task 1 automarkers.

In Task 3, we attempt to predict the expert profile for the final draft of the *next* series that the student will undertake. In this task we see CEFR RMSE of 0.963 and GER cos. prox. of 0.649. Vocabulary scores, although low in the full range of EMD, are half as good as in other tasks, with EMD 0.028.

6 Discussion

The multi-task learning configuration used in this work is currently the best recorded in this class of task and data. In Zaidi et al. (2019) a larger, private data set is used but the best performance (using an ERRANTised GER vector and the best-essay flags to target CEFR level) is weaker in terms of both CEFR level prediction and GER cosine proximity (1.093 to 0.809 RMSE and 0.426 to 0.669 cos. prox. respectively).

The implication is that a richer target is just as important as having richer input features (which are tested without leading to any improvement in Zaidi et al.). The 84% increase in GER cosine proximity is a key result, but consistent GER RMSE of 0.006-0.007 is also better than we might expect, thanks to the choice of loss function. Retrained with negative cosine proximity as the loss, our best system returns similar cosine proximity but GER RMSE 0.332, much worse than with Euclidean loss.

Outside of prediction, we can inspect the internal representations output by the interior branches of the network. For instance we can extract and concatenate the CEFR, GER and VOCAB activations just for the *user* branches. This is shown for 200 randomly selected students (at submission of final essay) projected to 2D using MDS (Kruskal, 1964) in Figure 5. Colours are (a) expert CEFR and (b) the user's choice of prompt difficulty. Neither of these is used in training, but banded clustering is evident for both, which suggests these representations could be used to apply adaptive pedagogical policies, such as changing a student's prompt group when their characteristics do not fit their current grouping.

7 Visualiser

We make the data from this work available in a visualisation tool⁷ (See figure 6). For each student the tool presents personalised profile data: (1) Student learning statistics, including average human and automarker CEFR level, ranks in cohort, average number of drafts, and rate of change of CEFR and average GER per draft. (2) CEFR level time series. (3) Average grammatical error rate (GER) time series. (4) Grammatical error rate (GER) summary. (5) Vocabulary distribution (VOCAB) summary. In the time series and grammar charts, the gold line shows our predicted score, teal shows the human expert scores and cyan shows the automarker scores.

8 Limitations and Future Work

The technique described in this work is simple and fast to train, but it is *Markovian* and assumes that the effect of history has been incorporated into the features seen at each timestep. While it may be reasonable to model skill as cumulative in this way, it may be better to include history explicitly using a method such as Knowledge Tracing (Corbett and Anderson, 1994; Piech et al., 2015). This is scheduled for future work. Another limitation is that this study has been restricted to a single data-set and platform but this is hard to rectify since there is a scarcity of such corpora.

9 Conclusion

We introduce interpretable multi-component vectors, *writing profiles*, that describe a learner's writing in terms of CEFR level, and vocabulary usage alongside their grammatical errors. Using a neural model, we effectively align automatically generated writing profiles with high-quality human-expert profiles, enhancing AES performance. Further, the neural model is shown to generalise across essay drafts and future tasks; paving the way for future work in longitudinal curriculum planning. Lastly, we make writing profile data explorable within our longitudinal visualisation tool.

Figure 5: Representations of students from the test set, concatenated from the branches of the neural network associated with the user only. These are projected into 2D by MDS, and coloured by (a) expert CEFR and (b) prompt (difficulty) levels. These colour groupings are not known to the system, so the scatters reveal that this structure has been learned independently. This may be helpful in supporting pedagogical adaptivity such as deciding which prompt group a student should actually belong to.

Figure 6: Visualiser Screenshot - student detail view. For each student the tool presents: (1) Student learning statistics. (2) Student CEFR level time series. (3) Student average grammatical error rates time series. (4) Grammatical error summary. (5) Vocabulary usage summary. In the time series and grammar summary charts, the gold line represents our predicted score, dark teal is expert score, cyan is automarker score.

Abstract

This study examines automated scoring fairness in a formative assessment context: the automated evaluation of medical students' communication skills. Building on the premise that definitions of fairness are value-dependent, we investigate how conclusions about group differences may vary under different weighting schemes for false positives (FPs) and false negatives (FNs). Results show that when errors are treated symmetrically, no statistically significant differences are observed across demographic groups based on race or gender. This pattern remains stable when error weights are varied, with no consistent or robust disparities emerging. A small number of isolated differences appear under moderate FN weighting. Overall, the findings suggest that fairness conclusions in this setting are relatively robust to variations in error weighting. At the same time, the study highlights the importance of making value assumptions explicit when evaluating automated scoring systems, particularly in formative contexts where error trade-offs carry pedagogical implications for feedback, learner engagement, and educational equity.

1 Introduction

Automated scoring systems are increasingly used in educational settings to evaluate constructed responses at scale (Flores et al., 2025). They can reduce scoring burden and support timely feedback, but they also raise an important question: does the system behave differently across demographic groups in ways that reflect construct-irrelevant factors? This concern is especially important in cases where scores may affect learning opportunities, consequential decisions, and perceptions of competence.

Fairness is an inherent concern in algorithmic classification, and a consistent finding across the literature is that fairness is not a single, unified concept. Notable papers such as “On the

(im)possibility of fairness” (Friedler et al., 2021) showcase how different notions of fairness reflect different underlying value systems, and no single classification system can satisfy all of them simultaneously.

This challenge is equally present in research on automated scoring in education (Johnson and McCaffrey, 2023). In this field, a fair test is one in which differences in scores among test-takers reflect only variations in the skills defined by the construct. Systematic score differences between non-random groups that arise from factors unrelated to the construct (i.e., construct-irrelevant factors) may signal potential unfairness in the assessment (Litman et al., 2021; Schaller et al., 2024; Andersen et al., 2025). To illustrate these competing perspectives, Loukina et al. (2019) distinguish three aspects of fairness: (1) whether scores are equally accurate across groups, (2) whether scores systematically differ from human scores for certain groups, and (3) whether such discrepancies persist when individuals have comparable ability. Empirical findings corroborate that fully satisfying all criteria simultaneously is rarely feasible.

While prior work on fairness in automated scoring has primarily focused on *summative assessment*, particularly for essay scoring and short-answer grading (Johnson et al., 2022), this paper examines fairness in *formative assessment* and in a different domain: the automated evaluation of medical students' communication skills with patients.

When discussing fairness in automated scoring in learning tools, there could be different value systems that govern the definition and subsequent evaluation of fairness. In the present setting, our automated scoring system makes binary decisions about whether specific behaviors are present in a learner response. In this setting, one key consideration is the relative importance of false positives (FPs) versus false negatives (FNs), as discussed in several key studies (Dey et al., 2024; Ernst et al.,

2025). In formative assessment, these trade-offs have pedagogical consequences: FNs may undermine learner confidence, while FPs can obscure learning gaps. Some value systems treat errors symmetrically, prioritizing overall accuracy; others emphasize minimizing FPs, ensuring positive evaluations reflect demonstrated competence; still others prioritize minimizing FNs to avoid discouraging learners or overlooking emerging skills. For example, Li et al. (2023) examine the effects of FPs (incorrect answers marked correct) and FNs (correct answers marked incorrect) in an AI autograder for short-answer tasks. The findings show that FPs can harm learning, largely because students fail to detect them and disengage after receiving positive feedback. FNs have more variable effects, with evidence that deeper engagement can mitigate their impact. In another study, Dey et al. (2024) find that the odds of addressing a FP feedback was 99% lower than addressing a FN feedback, representing significant missed opportunities for revision and learning. Thus, evaluation criteria reflect not only technical choices but also assumptions about which errors are most consequential for learning.

This study examines how fairness across demographic groups may vary under these different error-weighting approaches. If one type of error disproportionately affects certain learners, feedback may be misleading, impacting motivation and learning outcomes. Understanding these dynamics is crucial for designing automated scoring systems that are both accurate and educationally equitable. The paper makes the following original contributions:

- Examines fairness in automated scoring of medical students' communication skills in a formative context.
- Investigates the impact of error-weighting on fairness across demographic groups.
- Highlights the pedagogical implications of error asymmetries for feedback quality, learner motivation, and educational equity.

2 Data

Context: The context for this study is the Communication Learning Assessment (CLA) learning tool¹. CLA is a formative, digital tool designed to support medical students in developing communication skills for effective interaction with patients. CLA presents learners with video-based patient

Group	Sample size (<i>n</i>)	PCB rate (%)
<i>Gender</i>		
Female	837	61.4
Male	522	60.7
Non-binary	16	56.3
Other gender	8	87.5
<i>race</i>		
White/Caucasian	799	60.8
Asian	322	59.9
African American	150	63.3
Multiracial	56	58.9

Table 1: Dataset summary: subgroup sizes and annotation PCB prevalence ($N = 1,383$).

scenarios that describe a clinical case. Each case ends with a question or statement from the patient. The learner can then record a verbal response of up to two minutes addressing the patient, where they strive to exemplify appropriate communication skills. The three main categories of skills practiced via these cases include 1) responding to emotions, 2) providing information, and 3) fostering the relationship. Within each of these categories, the learner is expected to demonstrate appropriate communication behaviors within the specific clinical case they are given, which are called *patient-centered behaviors* (PCBs). For example, when responding to emotions in a case about a patient sharing discouragement that their weight loss journey has plateaued, an appropriate PCB might be “*I am sorry to hear this, it must be truly frustrating after all these efforts*”. Notably, these PCBs can vary widely among learners and cases, which makes PCB annotation and, subsequently, detection, a non-trivial task. In CLA, automated detection of case-specific PCBs is used to generate scores and those scores can form a basis of individualized feedback for learners.

Learners: The learners in our dataset were 3rd and 4th year US medical students who had successfully passed the USMLE® Step 1 exam² and used the CLA tool for practicing their communication skills. The dataset includes self-reported gender and race for each learner.

Annotation: Responses from 223 learners across 8 clinical cases were annotated for PCBs, although not every learner responded to every case. Annotation was performed by a team of four NBME staff members trained in clinical communication assessment. Annotations were guided by a detailed rubric (see Appendix A), capturing

¹<https://www.nbme.org/cla>

²<https://www.usmle.org/step-exams/step-1>

PCBs essential for effective physician-patient interactions, such as *acknowledgment of patient concerns*, *provision of clear explanations*, *demonstration of empathy*, and *reinforcement of positive behaviors*. This rubric included 25 unique PCBs, each associated exclusively with one of the 8 clinical cases, with each case containing between 1 and 4 distinct PCBs. Annotators were instructed to precisely identify text spans corresponding to each PCB by providing exact character-level indices. Negative samples for each PCB were systematically derived by listing all learner responses from the same clinical case that were not annotated as reflecting that specific PCB.

Annotators scored de-identified transcripts, were blind to learner demographics, and received explicit bias training. We therefore use human annotations as the reference standard for PCB presence, while recognizing that this does not rule out all sources of annotation bias.

Automated scoring system: The automated scoring of PCBs was performed by training ACTA (Rezayi et al., 2025) – an encoder-based transformer scoring model built on DeBERTa used operationally within CLA – on a cross-validated set of learner responses. Average binary F1 score for each PCB was 0.92 (min = 0.86, max = 0.97). Fairness was evaluated using out-of-fold predictions from 5-fold cross-validation on the annotated dataset.

Dataset: The resulting dataset consists of 1,383 records. Each record includes self-reported learner demographics, human PCB annotations, and ACTA predictions by learner response (encounter) and PCB type. Each prediction is assigned TP/TN/FP/FN labels after a careful error analysis by the annotation team. Each record includes the clinical communication text, a PCB label, and identifiers (case_id, encounter_id).

Table 1 reports subgroup sizes and human annotation prevalence (PCB rate). The largest groups are Female and White/Caucasian learners. Importantly, annotation PCB prevalence is nearly constant across high-volume groups (approximately 59–63%). Smaller groups (e.g., non-binary and other gender identities) have limited sample size and are therefore reported descriptively.

Looking at individual clinical cases (Table 4 in Appendix B), some cases show differences in PCB prevalence rates, but these differences are not statistically significant. In case 180, the PCB prevalence rate for the White/Caucasian group is around 10%

lower than for the other two high-volume groups, while case 192 shows the reverse pattern. This suggests that differences in individual cases may reflect factors other than annotation bias.

3 Methodology

We use prediction scores from the operationally deployed ACTA model. ACTA produces binary PCB-level decisions for each clinical encounter (learner-case interaction), and a single encounter may contain multiple PCBs. Because these decisions are clustered within encounter, we use the encounter as the unit of analysis rather than treating PCB-level observations as independent.

For encounter e we define a policy-sensitive error score by summing weighted false negatives and false positives across all PCBs associated with the encounter’s case:

$$L(e) = \sum_{c \in \mathcal{C}_{v(e)}} [w^{\text{FN}} \text{fn}_{e,c} + w^{\text{FP}} \text{fp}_{e,c}] \quad (1)$$

Here $\text{fn}_{e,c}$ and $\text{fp}_{e,c}$ are binary indicators of FN and FP errors for PCB c , and w^{FN} and w^{FP} control their relative importance. These weights are part of the evaluation, not the model.

To compare demographic groups, we compare case-adjusted disparity in mean encounter-level error. For groups a and a' ,

$$\Delta(a, a') = \sum_v \pi(v) \left| \mathbb{E}[L(e) \mid A=a, V=v] - \mathbb{E}[L(e) \mid A=a', V=v] \right| \quad (2)$$

where V is the vignette and $\pi(v)$ is the proportion of encounters in the full dataset that belong to vignette v , where $\sum_v \pi(v) = 1$.

4 Experiments

We evaluate ACTA with two views of fairness. First, we report PCB-level metrics by demographic group: recall, precision, F1, and positive prediction rate. Second, we compute the encounter-level disparity measure $\Delta(a, a')$ under multiple FN/FP weight ratios to test whether fairness conclusions are stable to different error priorities. Uncertainty is estimated with 1,000 bootstrap resamples at the encounter level, stratified by case so that case composition is preserved.

Figure 1: Absolute encounter-level disparity across different FN and FP weightings. The x-axis shows the FN/FP weight ratio, and the y-axis shows the absolute disparity estimate for each pairwise comparison.

Attribute	Group	Recall	Prec.	F1	PPR
Gender	Female	0.963	0.926	0.944	0.661
Gender	Male	0.960	0.908	0.933	0.633
Race	White/Caucasian	0.967	0.928	0.947	0.637
Race	Asian	0.931	0.915	0.923	0.637
Race	African American	0.979	0.906	0.941	0.677

Table 2: PCB-level performance metrics for the high-volume demographic groups in CLA.

Table 2 shows that the PCB-level metrics are broadly similar across the high-volume groups, with only small gender differences. Race shows somewhat more descriptive variation, especially in recall for comparisons involving Asian students, but none of the pairwise group differences is statistically significant after Bonferroni correction. Table 3 shows that the same general pattern holds for the encounter-level disparity measure under equal weighting of FNs and FPs: none of the pairwise comparisons is significant after correction, although the largest baseline disparity is observed for the White-Asian comparison.

Figure 1 shows that this baseline view is not fully stable across error-priority settings. As the relative weight assigned to FNs increases, absolute encounter-level disparity increases for all four pairwise comparisons. This indicates that group differences become larger when missed credit is treated as more costly than undeserved credit. At the same time, the comparisons do not behave identically: the White-Asian disparity is the only one that reaches significance anywhere in the sweep, doing so at the 2:1 and 3:1 FN:FP settings, while the remaining comparisons remain below the pairwise significance threshold. The White/Caucasian–Asian result seems to be mainly about false negatives. In Table 2, the Asian subgroup has lower recall than the White/Caucasian subgroup, while precision is more similar. This means the model misses more true PCBs for Asian learners, but it does not show an equally large difference in false positives. Because of that, the group difference becomes larger when false negatives are

Pair tested	$\Delta(a, a')$	95% CI	p-value
Female vs Male	0.016	[0.000, 0.108]	0.723
White/Caucasian vs Asian	0.090	[0.015, 0.182]	0.082
White/Caucasian vs African American	0.021	[0.000, 0.160]	0.748
Asian vs African American	0.055	[0.000, 0.205]	0.478

Table 3: Encounter-level disparity estimates under equal weighting of FNs and FPs. None of the pairwise comparisons were statistically significant.

given more weight. We cannot say from this analysis why those missed detections happen. For this reason, we interpret the result cautiously as a local sensitivity to FN weighting, not as evidence of a broad or stable demographic disparity.

5 Discussion

The main finding from this study is that when errors are treated symmetrically—i.e., when FPs and FNs are assigned equal weight—the empirical results indicate no statistically significant differences across demographic groups. This suggests that, under a value framework in which both types of errors are considered equally consequential, the scoring system performs comparably across groups. This finding is particularly relevant because many intended uses of these scores assume such symmetry in error costs.

Next, we investigate patterns when weights on different types of errors are disproportionately increased. When increasing the weights on FPs up to fivefold, no statistically significant differences between groups are observed, suggesting that under a value framework that emphasizes high accuracy, the system performs equitably. A similar pattern holds when increasing the weights of FNs, with one exception: statistically significant differences emerge when FNs are assigned two- or threefold weights in the White–Asian comparison. We emphasize that we do not currently have a clear theoretical explanation for this pattern, and thus interpret it with caution, particularly in light of the fact that the effect disappears at higher weights (e.g., four- or fivefold). One possible account is that it

may be an example of Type I error resulting from multiple comparisons, despite the application of Bonferroni correction. It may also reflect a combination of sampling variability, subgroup imbalances, and underlying distributional differences in scores that render certain comparisons more sensitive to moderate changes in FN weighting. In particular, such reweighting may disproportionately affect borderline cases, producing localized effects. Overall, these findings point to a complex interaction between data characteristics and metric design, with a likely minimal practical effect.

6 Limitations and Ethical Considerations

Several limitations should be considered when interpreting the findings of this work.

First, the dataset is relatively limited in size, particularly for certain subgroup comparisons. This constrains statistical power and reduces the ability to detect small but potentially meaningful differences across demographic groups. This limitation is especially relevant for intersectional analyses, where subgroup counts become even smaller.

Second, the analysis is conducted within the specific context of the ACTA scoring system and the CLA learning tool. While these provide a valuable and realistic testbed, they represent a particular type of automated scoring application with its own design choices and use cases. Consequently, the findings may not generalize to other automated scoring settings, such as those involving different constructs, item formats, model architectures, or deployment contexts. Replication across diverse systems and domains is necessary to establish the broader applicability of these results.

Third, the weighting schemes used in this study are intentionally simple, focusing on systematically varying the relative importance of FPs and FNs. While this approach is useful for conducting sensitivity analyses and illustrating how fairness conclusions shift under different value assumptions, it does not fully capture the complexity of real-world assessment policies. In practice, decisions about error costs may depend on a wider range of factors, including the stakes of the assessment, the distribution of scores, downstream decision-making processes, and stakeholder priorities. More nuanced or context-specific cost functions could lead to different patterns of results.

In terms of ethical considerations, institutions deploying automated scoring systems have a respon-

sibility to examine disaggregated error patterns, assess the potential harms associated with different error types, and ensure that mechanisms exist for identifying and correcting erroneous scores. Such analyses help ensure that automated scoring systems do not introduce or amplify inequities through the unequal distribution of scoring errors.

A key consideration is that while most investigations of group differences treat FP and FN errors as equally important, the intended use of an assessment should guide the relative weight of these errors. The consequences of awarding credit without merit (FP) or withholding credit when it's deserved (FN) can differ substantially in low vs. high stakes and formative vs. summative assessments. For example, in a high-stakes context like a medical licensure exam, incorrectly passing an unqualified physician (FP) can potentially result in risk to real patients. In this case, minimizing FP errors might be prioritized. In contrast, for low-stakes formative tools, such as CLA, failing to award credit when it's deserved (FN) can affect a learner's confidence and motivation, ultimately undermining the main purpose of the learning tool.

These differences underscore that error weighting is fundamentally a value-laden decision, tied to the goals and consequences of the assessment. Treating FP and FN errors symmetrically may be appropriate in some cases, but it should not be assumed as a default. Instead, evaluation frameworks should explicitly align error trade-offs with the intended use of the assessment, as different choices can lead to materially different conclusions about system performance and fairness across groups.

A remaining source of uncertainty is that both human annotation and automated scoring operate on the same de-identified text. As a result, construct-irrelevant linguistic variation correlated with demographic group could affect both human labels and model predictions. Potential sources include subgroup differences in lexical, grammatical, or discourse patterns, as well as uneven subgroup representation in model training.

A Annotation Guideline

1. **Annotate Complete Components.** Ensure each annotation captures the complete text relevant to the label, even if the sentence is grammatically incomplete.
2. **Annotate all instances of a concept or label.** More variations of a label or concept will better train the automated scoring model.
3. **Include Filler Words Within a Text Span.** Stutters, repetitions, false starts, and filler words such as ‘um,’ ‘ok,’ or ‘like’ should be included only if they are in the middle of a text span. Do not annotate them if they are at the beginning or end.
4. **Do Not Infer Beyond the Text.** Annotate only what is explicitly stated. Avoid making assumptions or interpretations beyond the text.
5. **Maintain Neutrality.** Do not let personal opinions or interpretations influence the annotation. Focus solely on the content and structure. Transcripts are not being scored; they serve as a source of information to train an automated scoring engine.
6. **Follow Label Definitions Strictly.** Always refer to the label definitions provided. If a segment doesn’t clearly fit a label, leave it unannotated or flag it for review.
7. **Parsimony.** Annotate only the minimal number of words necessary to accurately represent the label, avoiding extraneous or redundant text to maintain clarity and consistency across annotations.
8. **Separate Labels for Adjacent Components.** When two adjacent statements or questions both correspond to the same label, annotate each one separately.
9. **Punctuation Does Not Affect Annotation.** Include or exclude it as needed, focusing instead on accurately capturing the relevant words for the label.
10. **Avoid Overlap.** Annotations can sometimes seem to have similar concepts. However, if there is overlap in the annotation, double-check the label definition and/or flag for review, as there should be a distinction and minimal overlap.

Asian	21 (54%)	11 (100%)	27 (56%)	32 (73%)	15 (38%)	22 (67%)	34 (71%)	31 (52%)
African American	8 (44%)	6 (100%)	10 (56%)	26 (72%)	2 (33%)	12 (67%)	24 (75%)	7 (44%)

Table 4: Number of encounters, and PCBs, and positive annotations by case, gender, and ethnicity.

B Data Statistics

Table 4 summarizes the eight cases included in the analysis. The number of encounters is similar across cases, ranging from 46 to 59, while the number of PCBs ranges from 1 to 4. Positive annotation rates vary across cases, but differences by gender and ethnicity within each case are generally small.

Noise Steering for Controlled Text Generation: Improving Diversity and Reading-Level Fidelity in Arabic Educational Story Generation

Abstract

Generating diverse, pedagogically valid stories for Arabic early-grade reading assessments requires balancing tight constraints on vocabulary, reading level, and narrative structure against the need to avoid repetitive plots that undermine assessment validity. We investigate *noise steering*, injecting calibrated Gaussian perturbations into the internal representations of transformer models at inference time, as a training-free diversity method evaluated across five small Arabic-centric language models (7–9B parameters). We compare four injection strategies against high-temperature sampling baselines, measuring diversity, quality, constraint adherence, and reading grade level. Residual stream noise consistently improves narrative diversity with minimal quality or constraint cost and preserves early-grade reading level across all Arabic-centric models. Attention entropy noise injection (AENI) stabilizes the otherwise unreliable attention-logit noise while recovering quality. High-temperature sampling inflates reading grade level and causes catastrophic collapse on several models. We find internal representation-level perturbation to be a more suitable diversity strategy than output-level stochasticity for constrained educational content generation.

1 Introduction

The Early Grade Reading Assessment (EGRA) is a widely used framework for evaluating foundational reading skills in young learners (Dubeck and Gove, 2015). A key component involves short narrative passages that must satisfy strict pedagogical constraints: controlled vocabulary, appropriate reading level, clear narrative structure, and cultural neutrality. Manually producing such passages at scale is labor-intensive, making automatic generation an attractive alternative, particularly in Arabic, where rich morphology, orthographic variation, and diglossia introduce additional linguistic complexity (Habash, 2010). Recent work has

shown that large language models can generate fluent Arabic stories aligned with EGRA criteria, but two tensions persist (Abdelghafur et al., 2025; Rai et al., 2024). First, *diversity vs. constraint adherence*: increasing output variety risks violating the tight pedagogical requirements that make EGRA passages valid assessment instruments (Holtzman et al., 2020). Second, practical deployment in under-resourced educational settings favors small language models (SLMs) of 7–9 billion parameters over large frontier models. Yet, these smaller Arabic-centric models are more susceptible to generation instability when diversity is pushed. We address both tensions by investigating *noise steering*: injecting calibrated Gaussian perturbations into the internal representations of transformer models at inference time, without any fine-tuning. We evaluate four injection strategies across five Arabic SLMs and show that residual stream noise and attention entropy noise injection (AENI) consistently improve narrative diversity while preserving reading grade level and constraint adherence, outperforming output-level approaches such as high-temperature sampling that raise diversity at the cost of pedagogical validity.

2 Background

2.1 EGRA Constraints

EGRA-aligned texts are constructed under strict pedagogical and linguistic constraints (Dubeck and Gove, 2015). These include controlled passage length, age-appropriate vocabulary, a clear narrative structure, limited characters, grammatical correctness, and cultural neutrality. These constraints ensure comparability across assessments and support the generation of both literal and inferential comprehension questions. However, manually creating such passages is labor-intensive and requires domain expertise, limiting scalability (Abdelghafur et al., 2025).

2.2 Challenges in Arabic EGRA Generation

Generating EGRA-aligned content in Arabic introduces additional challenges due to the language’s rich morphology, orthographic ambiguity, and diglossia between Modern Standard Arabic and dialectal varieties, compounded by the limited availability of high-quality annotated datasets for children’s literature (Habash, 2010; Abdelghafur et al., 2025). While recent work has shown that models such as GPT-4 and Jais can generate fluent, EGRA-aligned stories, inconsistencies in narrative structure, deviations from target word counts, and repetitive outputs with minimal structural variation remain persistent issues (Abdelghafur et al., 2025; Rai et al., 2024; El-Shangiti et al., 2024).

2.3 Diversity vs. Constraint Trade-off

A central challenge in EGRA-based generation is balancing diversity with constraint satisfaction. Increasing diversity through stochastic decoding can lead to output degeneration and reduced control over pedagogical requirements (Holtzman et al., 2020), while overly constrained prompting often results in repetitive and structurally similar outputs (Rai et al., 2024).

Recent approaches attempt to address this trade-off. Shankarnarayanan et al. (2024) show that inspiration-based prompting can improve narrative diversity, while Madaan et al. (2023) demonstrate that iterative self-refinement can enhance output quality without model fine-tuning. Despite these advances, achieving consistent diversity while maintaining strict adherence to EGRA constraints remains unresolved, particularly in Arabic.

3 Related Works

3.1 Output-Level Diversity: Stochastic Decoding Strategies

A common approach to diversity in LLM generation is stochastic decoding, which modifies the token probability distribution at each step. Temperature scaling (Ackley et al., 1985) flattens or sharpens this distribution, while top- k sampling (Fan et al., 2018) restricts candidates to the k most probable tokens, and nucleus (top- p) sampling (Holtzman et al., 2020) selects the smallest token set whose cumulative probability exceeds a threshold. These methods trade output quality for diversity as their parameters increase, yet they share a fundamental limitation: all intervention occurs at the final vocabulary logit, leaving the model’s

internal computations, embeddings, attention patterns, and intermediate representations entirely unchanged. Locally Typical Sampling (Meister et al., 2023) approaches diversity differently by selecting tokens whose information content stays close to the conditional entropy of the model, reducing degenerate repetition while preserving fluency. A complementary line of work intervenes on the output vocabulary itself: Dineen et al. (2026) randomly mask logits during self-play training to stop the model from collapsing onto a narrow set of token sequences. Their mask is applied during RL training, while ours is applied at inference, making the two approaches complementary. We use temperature, top- p , top- k primary decoding baselines. Our internal noise methods are independent to all of them and can be combined with any output-level sampler.

3.2 Internal Noise Injection in Transformers

A smaller but closely related body of work explores injecting perturbations into the internal representations of transformer models rather than into the output distribution. Kang et al. (2024) is the most directly comparable prior work, they apply input-dependent Gaussian noise to the hidden states of early LLM layers during *fine-tuning* to produce diverse paraphrases of training examples for knowledge injection. Kang et al. (2024) demonstrate that latent-level perturbation yields more semantically diverse augmentations than data-level paraphrasing alone. This finding motivates our hypothesis that similar perturbations at *inference time* can promote creative diversity in generation. Unlike Kang et al. (2024)’s method of applying noise during training to improve knowledge retention, our methods apply noise at inference time to diversify outputs without modifying model weights.

The residual stream framework of Elhage et al. (2021) motivates our choice of injection sites. Embeddings, attention logits, and block outputs each represent distinct points at which information is written to the model’s shared communication channel, producing qualitatively different perturbation effects.

3.3 Entropy-Aware Generation

Several works use the model’s own uncertainty as a signal for adaptive decoding. EDT (Zhang et al., 2024) raises temperature when the output vocabulary entropy is low, encouraging exploration precisely when the model is overconfident. Our atten-

tion entropy-based method shares this motivation but monitors entropy over attention distributions rather than output logits, intervening at the attention level, before the model’s repetitive tendencies manifest in the output distribution.

3.4 Constrained Generation and Arabic Educational LLMs

Constrained decoding methods (Willard and Louf, 2023) enforce formal output constraints by masking invalid tokens at each step, but do so at the cost of forcing the model toward low-probability and often repetitive continuations. This phenomenon is seen clearly in Early-Grade Reading Assessment (EGRA) story generation (RTI International, 2016; Zuolkernan and Shapsough, 2024), where tight vocabulary and structural constraints narrow the valid token set and exacerbate the repetitive nature of outputs. Noise injection has been shown to systematically degrade a model’s ability to follow constraints and guidelines (Shahani et al., 2025), motivating careful calibration. Our noise decay strategy addresses this directly by reducing perturbation magnitude as generation progresses, allowing the model to explore creative directions early in the story while gradually restoring constraint following behaviour toward the conclusion. We evaluate story generation in this setting using a suite of small Arabic-centric and multilingual instruct models (Sengupta et al., 2023; Bari et al., 2024; Huang et al., 2024; Fanar Team et al., 2025), measuring diversity via Self-BLEU (Zhu et al., 2018) and semantic dispersion.

4 Noise Steering methods

4.1 Embedding Noise

Embedding noise injects Gaussian noise directly into the output of the token embedding lookup table during the decoding phase. This is the earliest possible injection site: the perturbed vector is the model’s sole representation of the newly generated token before any transformer computation has occurred. All subsequent hidden-layer inputs are equivalent to the previous block’s residual output and therefore have no independent embedding-level analogue.

Formally, let $\mathbf{e}_t \in \mathbb{R}^D$ denote the embedding of the token sampled at decode step t . We perturb it as:

$$\tilde{\mathbf{e}}_t = \mathbf{e}_t + \varepsilon, \quad \varepsilon \sim \mathcal{N}(0, \sigma(t)^2 \mathbf{I}) \quad (1)$$

where $\sigma(t) = \sigma_{\text{emb}} \cdot \delta(t)$ is the decayed standard deviation from Section 4.5. Noise is applied exclusively to decode steps, the prefill pass over the prompt is left unperturbed, ensuring that the model’s understanding of the instruction and constraints is not corrupted. Because the perturbation enters at the base of the residual stream, it is amplified and transformed by every subsequent attention and MLP layer, producing broad, high-level variation in the story’s trajectory.

4.2 Attention-logit Noise

Attention-logit noise injects Gaussian noise into the output of the self-attention sub-layer at selected transformer blocks, specifically after the output projection W_O but *before* the subsequent MLP sub-layer and before the residual addition. Within each targeted block the computation is:

$$\mathbf{x} = \text{LayerNorm}(\mathbf{h}^{(l-1)}) \quad (2)$$

$$\mathbf{a} = \text{softmax}\left(\frac{QK^\top}{\sqrt{d}}\right) VW_O + \varepsilon \quad (3)$$

$$\mathbf{h}^{(l)} = \mathbf{h}^{(l-1)} + \mathbf{a} + \text{MLP}\left(\mathbf{a} + \mathbf{h}^{(l-1)}\right) \quad (4)$$

$$\varepsilon \sim \mathcal{N}(0, \sigma(t)^2 \mathbf{I})$$

where $\mathbf{h}^{(l)}$ is the residual stream at layer l and $\sigma(t) = \sigma_{\text{attn}} \cdot \delta(t)$ follows the cosine decay schedule of Section 4.5. The KV cache is left intact: the last token position of the attention output tensor (shape $(B, 1, D)$ during decoding) is perturbed only, leaving all cached key and value states unchanged.

By targeting the attention branch’s contribution to the residual stream in isolation, before the MLP has processed the attended context, this method perturbs the information routing step of each selected block without corrupting the feed-forward transformation. This gives it a qualitatively different character from residual stream noise, which acts on the full block output after both sub-layers have run.

4.3 Residual Stream Noise

Residual stream noise injects Gaussian noise into the transformer’s residual stream after each selected block has completed its full computation of both the self-attention and MLP sub-layers. The noise at layer l and decode step t is:

$$\tilde{h}_t^{(l)} = h_t^{(l)} + \varepsilon, \quad \varepsilon \sim \mathcal{N}(0, \sigma(t)^2)$$

where $h_t^{(l)}$ is the block output at the last token position and $\sigma(t) = \sigma_{\text{res}} \cdot \delta(t)$ is the decayed standard deviation from Section 4.5. Noise is applied only during the decoding phase when new tokens are being generated, leaving the prompt representation unperturbed. Injecting at the full block output means the noise enters the residual stream at the point where the block’s complete contribution has been written, and propagates forward through all subsequent layers.

4.4 Attention Entropy Noise Injection

Attention Entropy Noise Injection (AENI) conditions noise magnitude on the peakedness of the model’s own attention distribution at each decode step. The motivation, shared with EDT (Zhang et al., 2024), is that a model is most likely to produce repetitive or formulaic output precisely when it is most confident: attention heads that concentrate their weight on a small set of tokens signal over-reliance on a narrow context window, which in constrained story generation often corresponds to copying earlier story elements. AENI responds by injecting more noise when attention is peaked and less when it is diffuse, intervening adaptively rather than applying a fixed perturbation schedule.

At each targeted layer l and decode step t , we read the post-softmax attention weight tensor $\mathbf{W}^{(l)} \in \mathbb{R}^{B \times H \times T_k}$, where H is the number of heads and T_k is the current key-sequence length. We extract the last query row (the current token’s attention pattern) $\mathbf{w} = \mathbf{W}_{:, :, -1, :}^{(l)}$ and compute a peakedness score as the mean per-head maximum attention weight:

$$\phi(\mathbf{w}) = \text{mean}_h \max_j w_{h,j} \quad (5)$$

This score lies naturally in $[0, 1]$, is independent of context length, and requires no normalisation: a peaked head drives its maximum toward 1, while a uniform distribution drives it toward $1/T_k$. Gaussian noise is then added to the self-attention output after W_O but before the MLP and residual addition, with effective standard deviation:

$$\sigma_{\text{eff}}(t) = \sigma_{\text{aeni}} \cdot \phi(\mathbf{w}) \quad (6)$$

where σ_{aeni} is the per-model ceiling calibrated by RMS as in Section 5.1. As with attention-logit noise, only the last token position of the attention output (shape $(B, 1, D)$ during decoding) is perturbed and the KV cache is left intact.

4.5 Noise Decay

Applying constant noise throughout generation risks degrading constraint adherence, consistent with findings that activation-level noise systemically harms instruction and constraint following in LLMs (Shahani et al., 2025). We therefore apply a cosine decay schedule that reduces noise magnitude as generation progresses, allowing the model to explore creatively in the early tokens while recovering clean, constraint respecting decoding for the middle and conclusion of its story.

Let t denote the current decode step and T the decay horizon. The noise standard deviation at step t is scaled by:

$$\delta(t) = \frac{1}{2} \left(1 + \cos \left(\frac{\pi \cdot \min(t, T)}{T} \right) \right)$$

so that $\delta(0) = 1$ (full noise at the first generated token) and $\delta(T) = 0$ (no noise at and beyond the horizon), with the effective standard deviation given by $\sigma(t) = \sigma_{(t-1)} \cdot \delta(t)$.

5 Experimental Setup

5.1 Noise Magnitude and Model Calibration

A key challenge when applying noise across multiple models is that the scale of internal representations varies substantially between architectures and models (Dettmers et al., 2022; Sun et al., 2024). A fixed noise standard deviation that is undetectable for one model may be catastrophically large for another. To ensure that noise is applied at a consistent *relative* scale across all models, we calibrate the noise magnitude using the root mean square (RMS) of each model’s residual stream activations.

For each model we register forward hooks on nearly all transformer blocks (excluding the first and last layers) and collect block output tensors during *decode* steps only (i.e., when the sequence length is 1 and the KV cache is active), matching the phase at which noise is actually injected. The per-layer RMS is computed over the last generated token as:

$$\text{RMS}(l) = \sqrt{\frac{1}{C} \sum_C x^2} \quad (7)$$

where x is the block output tensor at layer l averaged over the batch and hidden dimensions, and C is the number of decode steps collected. We then aggregate these per-layer values into a single scalar

using the median across layers, which is robust to outlier layers at either extreme of the network.

The residual noise standard deviation for each model is then set as:

$$\sigma_{\text{res}} = \alpha \cdot \text{median}_l(\text{RMS}(l)) \quad (8)$$

where α is a fixed scaling coefficient set to 0.175 across all experiments. This formulation ensures that the injected noise is always proportional to the model’s own activation scale, making the effective perturbation strength comparable across models.

5.2 Generation

We compare each noise-injection method to the following baselines: a *noise-free* baseline ($T = 1.0$), a *High-temperature* ($T = 1.8$) baseline with $\text{top}k = 40$, and a *High-temperature* ($T = 1.8$) baseline with $\text{top}p = 0.9$. The truncation values follow prior work: Holtzman et al. (2020) report $k = 40$ in their main comparison and note that nucleus values “are usually in $[0.9, 1)$ ”. We pair these with an elevated $T = 1.8$, within the high-temperature regime explored by Nguyen et al. (2025). More aggressive settings (higher T , looser or no truncation) would likely produce still higher collapse rates, and absolute numbers would shift under per-model tuning. However, our principal claims concern the qualitative trade-off between output-level stochasticity and internal-representation perturbation, which we expect to be robust to such tuning.

Each condition generates 50 stories independently. Story i under every condition is generated with the same seed, which makes generation reproducible and aligns the underlying sampler RNG state across conditions where the sampling distribution coincides. However, since different conditions modify the sampling distribution itself (e.g. via temperature, $\text{top-}k$, $\text{top-}p$, or internal noise), the seed alone does not eliminate sampling variability between conditions. We therefore report all aggregate metrics over the full 50-story sample per condition and use the statistical tests in Appendix A to assess whether the observed effects are reliable rather than artefacts of sampling variance. All models are prompted with the same instruction to produce a story adhering to the EGRA constraints described in Section 5.3.3.

5.3 Evaluation

5.3.1 Creativity Scores

Vendi Score: The *Vendi Score* (Friedman and Dieng, 2023) measures the diversity of a set of items by quantifying how evenly distributed they are across predefined categories. For our stories, embeddings were obtained using the BAAI/bge-m3 model, with higher values indicating greater diversity.

Lexical Diversity: We compute Self-BLEU (Zhu et al., 2018), treating each story in turn as a candidate and the remaining 49 as references. The lexical diversity score is $1 - \text{Self-BLEU}$, so that higher values indicate less overlap across the generated set.

5.3.2 Readability and Linguistic Quality

We judge readability, grammatical correctness, linguistic quality, and appropriateness of reading level are evaluated using GPT5.3 Chat (OpenAI, 2026) as an LLM judge. Each story is scored independently on these dimensions, providing a complementary quality signal to the diversity metrics above.

5.3.3 Constraint Following

EGRA constraint adherence is evaluated through a combination of rule-based checks and LLM judgment. Constraints that are able to be verified exactly are checked programmatically. These constraints include: Story length not exceeding 60 words, Use of exactly one proper noun, Use of the present tense

Constraints that require semantic and structural understanding are evaluated using GPT5.3 CHAT (OpenAI, 2026) as a judge. These constraints include:

- Narrative structure includes intro, a middle dilemma, and an ending with resolution.
- Gender-balanced: includes both a boy and a girl.
- Avoids gender/religion/other stereotypes.
- Vocabulary suitable for children and the local context.

5.4 Models and Metrics

Models: We evaluate five small ($\leq 9\text{B}$ parameter) Arabic-centric instruct models. **Jais 8B** (Sengupta et al., 2023) is pretrained from scratch on a large Arabic and English corpus. **ALLaM 7B** (Bari et al., 2024) adapts LLaMA via Arabic tokeniser expansion and continued pretraining. **Fa-**

nar 9B (Fanar Team et al., 2025) emphasises morphology-aware Arabic tokenisation and dialectal coverage. **AceGPT** (Huang et al., 2024) is a bilingual (Arabic–English) model built on the LLaMA architecture with continued pretraining on large-scale Arabic data and instruction tuning for dialogue and generation tasks. **Phi-4-mini** is included as a compact multilingual baseline. Together these models span the main architectural and training strategies present in the current Arabic SLM landscape.

Quality (Qual. $\uparrow$). The quality score is an average of four LLM-judge dimensions assessed per story: overall readability, logical soundness, grammatical correctness, linguistic quality. Each dimension is scored independently out of 10 and the four scores are averaged into a single value per story, which is then averaged across the 50 stories in a condition.

Constraint Violations (Viol. $\downarrow$). We report the average number of constraints broken per story and the total constraints broken, where a lower score is better and zero indicates full compliance. This combines the programmatic and LLM-judge checks from Section 5.3.3: each of the seven constraints (three programmatic, four LLM-judged) contributes one violation point if failed, giving a maximum possible score of 7 per story.

6 Results

6.1 Total Modal Collapse

Before comparing diversity and quality metrics, we first examine instances of Total modal collapse (TMC): cases where generation degenerates into repetitive or incoherent token sequences, producing stories that are effectively unusable. Table 1 reports the collapse rate for each model and decoding condition. Any condition with a collapse rate at or above 40% is excluded from further evaluation, as the surviving outputs would constitute a

non-representative sample. Conditions with collapse rates greater than 20% (and less than 40%) are excluded from Figure 1 but are discussed further in Sec 6.2.

High-temperature baselines. The high temperature conditions (HiTemp-k and HiTemp-p) are the most fragile overall. AceGPT and Phi-4-mini both exceed the 40% threshold under both high-temperature settings, with collapse rates as high as 84% and 66% respectively. This confirms the well-known instability of aggressive output-level sampling: flattening the output distribution beyond a certain point causes the model to assign non-negligible probability to incoherent continuations, from which recovery is rare once the context has been corrupted (Nguyen et al., 2025).

Residual stream noise. residual stream noise (L-Res), records a 0% collapse rate across every model tested. Because this method injects noise after each transformer block has already completed its full computation, the perturbation enters the network at a point where the model’s internal representations are well-formed, and the signal propagates forward in a controlled manner. This makes residual noise a reliable location to inject noise without worrying about generation failures.

Attention noise and AENI. Raw attention-logit noise (Attn) shows high collapse rates, reaching 28% and 34% on ALLaM and Fanar respectively. However, our Attention Entropy Noise Injection method (AENI) eliminates collapse entirely across all five models. Rather than applying a fixed perturbation at every step, AENI scales the noise magnitude according to how peaked the model’s own attention distribution is at that moment. When the model attends broadly and diffusely, little or no noise is injected; perturbation is reserved for steps where attention has collapsed onto a narrow set of tokens, which is precisely when formulaic or repetitive output is most likely to follow. This adaptive

Table 1: Modal collapse rate (% of 50 generated stories) per model and decoding strategy. **Italic:** method excluded from further evaluation due to ($\geq 40\%$ collapse rate);

Model	Baseline	HiTemp-k	HiTemp-p	Embed	Attn	AENI	L-Res
ALLaM 7B	0%	0%	4%	22%	28%	0%	0%
AceGPT 8B	2%	84%	80%	0%	0%	0%	0%
Fanar 9B	0%	2%	0%	22%	34%	2%	0%
Jais 8B	0%	0%	0%	2%	4%	0%	0%
Phi-4-mini	0%	50%	66%	100%	44%	0%	0%

gating prevents the runaway instability that fixed attention noise produces.

Embedding noise. Embedding noise (Embed) causes complete collapse on Phi-4-mini (100%), and elevated rates on ALLaM (22%) and Fanar (22%). The Phi-4-mini model in particular is very sensitive to embedding noise, even at noise levels $\alpha < 0.175$ virtually every generation collapses. As a compact multilingual model, Phi-4-mini has had comparatively less Arabic training data, meaning its token embedding space for Arabic is more sparsely and less robustly organized. Because embedding noise acts at the very first step of the residual stream, before any transformer computation has occurred, any perturbation there propagates through every subsequent layer.

For a model whose Arabic representations are already fragile, this earliest injection site offers no opportunity for the model to compensate.

6.2 Diversity, Quality, and Constraint Adherence

Figure 1 plots each model-method condition in the space of Vendi Score (diversity, x-axis) against

LLM-judged quality (y-axis), with marker size encoding the average number of constraint violations per story. Beyond these core metrics, we also track estimated reading grade level per condition, as diversity methods that push stories toward richer vocabulary or more complex sentence structures may improve narrative variety and quality scores while silently violating the early-grade readability that EGRA passages require. Full numerical results are in Appendix Tables 6 and 4.

Residual Stream Noise. L-Res is the most consistently beneficial intervention. It achieves a 0% collapse rate for every model and improves Vendi Score in all five cases: +1.28 for ALLaM (7.14 $\rightarrow$ 8.42), +0.28 for AceGPT (9.95 $\rightarrow$ 10.23), +0.14 for Fanar (8.47 $\rightarrow$ 8.61), +2.38 for Jais (4.71 $\rightarrow$ 7.09), and +1.19 for Phi-4 (10.45 $\rightarrow$ 11.64). Constraint adherence is largely undisturbed, with violations changing by at most 0.78 per story across all models. Reading grade level is preserved throughout: ALLaM and Fanar remain at Grade 3, Jais at Grade 2, and AceGPT at Grade 4, all consistent with their respective baselines. These results indicate that

Figure 1: Story quality versus output diversity (Vendi Score) for all evaluated conditions with ≤ 10 total modal collapses. Each point represents one model–method combination: marker **shape** encodes the model and marker **colour** encodes the decoding method; marker **area** is proportional to the total number of EGRA constraint violations across the 50 generated stories (larger = more violations). Methods that cluster toward the lower-left or produce large markers trade quality or diversity for higher violation rates. Conditions with > 10 modal collapses are excluded to avoid diversity scores inflated by repetitive collapse outputs

perturbing the model’s internal representations allows it to diversify narrative choices, such as character, setting, and plot structure, without reaching for more complex language to do so. The quality impact depends on the baseline. For Fanar and ALLaM, which already produce strong stories (quality scores of 7.97 and 7.23 respectively), L-Res maintains or improves quality outright: Fanar reaches 8.33 while gaining diversity, placing it in a genuinely better region of the quality-diversity space. For weaker models the diversity gains come at a greater quality cost: AceGPT drops from 5.78 to 5.11, Jais from 8.08 to 6.97, and Phi-4 from 4.64 to 3.67. In Jais’s case the large Vendi Score gain suggests the model was simply not exploring the narrative space at baseline. In Phi-4’s case, even gentle perturbation strains its more limited Arabic generation capability, and grade level drifts to Grade 5, the one exception to L-Res’s otherwise consistent grade-level preservation.

Attention Entropy Noise Injection vs. Raw Attention Noise. Raw attention-logit noise (Attn) can achieve high diversity, with Vendi Scores of 9.51 for ALLaM and 7.44 for Jais, but at severe cost: collapse rates of 28% and 34% on ALLaM and Fanar respectively, constraint violations spiking to 5.36, and ALLaM quality collapsing to 2.55, the lowest value in the entire evaluation result in the surviving scores being a biased subset of an otherwise unreliable condition. AENI resolves this by conditioning noise magnitude on the model’s own attention entropy, injecting more perturbation when attention is sharply peaked and backing off when it is already diffuse. Collapse rates fall to 0% on ALLaM, AceGPT, and Jais, and just 2% on Fanar, with quality recovering substantially: ALLaM to 6.73, Fanar to 6.39, and Jais to 7.88. Crucially, AENI also preserves reading grade level across all Arabic-centric models and for Phi-4 actually improves it to Grade 3 from the baseline Grade 4, a stronger result than L-Res on that model. The cost of this stability is a moderate Vendi Score reduction relative to raw Attn, but this trade-off is clearly worthwhile for an educational generation system. On AceGPT, already a high-diversity model, the two methods produce near-identical Vendi Scores (10.21 vs. 10.05), confirming that AENI’s adaptive mechanism does not sacrifice diversity unnecessarily when it is not needed.

High-temperature Baselines High-temperature sampling is effective only for Jais, whose baseline

Vendi Score of 4.71 is the lowest in the evaluation. Both HiTemp-k and HiTemp-p raise diversity meaningfully (to 6.37 and 5.87) while quality stays high at 8.18 and 7.95, suggesting Jais’s cautious baseline was due to overfitting to the EGRA task format, producing structurally valid but narratively repetitive stories, and that output-level stochasticity was sufficient to break this pattern without destabilising the underlying generation quality. For every other model the picture is far worse: ALLaM’s quality falls to 4.89 and 5.13, Fanar’s to 4.32 and 3.67, and both AceGPT and Phi-4 exceed the collapse threshold entirely. The grade-level results are equally damaging: ALLaM’s Grade 3 baseline rises to Grade 6 and Grade 5 under the two conditions, and Fanar’s Grade 3 baseline drifts to Grade 5 and Grade 6 respectively. By flattening the output probability distribution, high-temperature sampling makes models more likely to reach for less common, more sophisticated vocabulary, precisely the kind of variation that is undesirable in an early-grade assessment context. It treats all forms of output variation as equivalent and has no mechanism for distinguishing a more creative plot from a more adult vocabulary, a distinction that is central to the EGRA task.

Appendix A contains significance tests that reaffirm these findings: L-RES and AENI are the only methods that consistently preserve quality and constraint adherence at a level statistically indistinguishable from the Baseline, while high-temperature sampling, embedding noise and raw attention noise injections are significantly worse on both metrics across the majority of models.

7 Conclusion

We investigated noise steering as a lightweight, fine-tuning-free approach to improving narrative diversity in Arabic EGRA-style story generation across five small language models. L-RES and AENI are the only methods that consistently improve diversity without the substantial degradation in quality, constraint adherence, or early-grade readability that the alternatives produce, the last of which proves a critical differentiator from high-temperature sampling, which inflates reading level and causes catastrophic collapse on several models. Residual stream noise is the most reliable all-around method and yields the greatest gains on models that already generate high-quality stories at baseline. AENI trades a small diversity mar-

gin for substantially better stability, making it the stronger choice when attention-level intervention is preferred. A consistent finding across all methods is that a model’s baseline generation quality is a strong predictor of how gracefully it absorbs noise: models with weaker Arabic representation degrade faster regardless of the intervention applied, suggesting that noise steering is best understood as a tool for unlocking latent diversity rather than compensating for limited language capability. Future work should explore layer-specific targeting strategies and extension to other low-resource languages and assessment frameworks.

Limitations

LLM-as-a-Judge Evaluation. Our quality and parts of our constraint adherence scores rely on GPT as an LLM judge, which introduces well-documented limitations. LLM judges are known to exhibit systematic biases including verbosity bias, where longer outputs receive inflated scores, and self-enhancement bias, where a model tends to favor outputs stylistically similar to its own generations (Chen et al., 2024). A particular concern in comparative evaluations is relative scoring bias, where a story may receive an inflated score simply by virtue of being better than the others it is presented alongside rather than on absolute merit. We took two steps to mitigate this: stories were submitted to the judge in fixed-size batches rather than all at once, and stories from different experimental conditions were shuffled together before evaluation, preventing the judge from implicitly comparing outputs within a single run. Quality dimensions such as narrative clarity and vocabulary suitability ideally require human annotators with relevant expertise. The programmatic constraint checks mitigate this concern for verifiable constraints such as word count and tense, but the LLM-judged dimensions: narrative structure, cultural neutrality, and reading appropriateness, should be interpreted with caution. Future work should incorporate human evaluation by Arabic literacy educators to validate the automated scores reported here.

Decoding-Hyperparameter Sensitivity. Our high-temperature baselines use single fixed values of $T = 1.8$, $k = 40$, and $p = 0.9$, chosen as widely used high-diversity defaults in prior work but not separately tuned per model. Since different models exhibit different baseline confidence pro-

files, the absolute diversity, quality, and collapse numbers for these baselines could shift under per-model hyperparameter sweeps. A similar caveat applies to the single value of $\alpha = 0.175$ used to calibrate noise magnitude across all noise-injection methods. We expect the qualitative ordering between output-level stochastic decoding and internal-representation perturbation to be robust, but a more comprehensive sensitivity study across decoding hyperparameters and per-model α values is left to future work.

A Statistical Significance: L-Res and AENI vs. Alternatives

Test choice. We compare each method’s per-story quality and constraint-violation distributions to the Baseline using the Kruskal-Wallis omnibus test followed by Dunn’s pairwise post-hoc with Holm correction. This single non-parametric procedure is the appropriate choice for our data: Levene’s test rejects equality of variances ($p < 0.05$) in 7 of 10 (model, metric) groups, ruling out ANOVA + Tukey HSD; the metrics are also bounded and non-normal (quality $\in [0, 10]$ with TMC zero-mass; violations integer counts $\in [0, 7]$). Effect size is the matching non-parametric statistic, the rank-biserial correlation $r \in [-1, +1]$, with the convention that $r > 0$ indicates the method is *better than the Baseline* on that metric (quality higher, violations lower); $|r| < 0.1$ is negligible, ≥ 0.3 medium, ≥ 0.5 large, $|r| = 1$ is the maximum the metric supports.

Every alternative method significantly degrades performance whenever it can be tested. Tables 2 and 3 report rank-biserial r between each method and the Baseline for quality and violations respectively. Counting cells where the omnibus K-W is significant and the method survived TMC exclusion (the cells where Dunn’s post-hoc is licensed to run), the asymmetry between our proposed methods and the alternatives is severe: Embed produces a significant adverse deviation in **every single testable cell (6 of 6)**; Attn in 5 of 6; HiTemp- k and HiTemp- p in 3 of 5 each. By contrast, L-Res and AENI each produce a significant adverse deviation in only 2 of 7 testable cells. Where the alternatives register a significant effect, the median $|r|$ is 0.65 and *two separate cells reach* $|r| = 0.99$, *the maximum the metric supports*; where L-Res and AENI register one, $|r|$ never exceeds 0.48, and the median is 0.40. There is no model and no metric on which any alternative method is significantly closer to the Baseline than L-Res or AENI.

When alternatives degrade quality, they degrade it catastrophically. The visual pattern in Table 2 is unambiguous: every significant deviation produced by Attn, Embed, HiTemp- k , or HiTemp- p on quality is large or catastrophic ($|r| \geq 0.46$, with seven of fourteen at $|r| \geq 0.65$ and three at $|r| = 0.99$, where the metric saturates). The corresponding L-Res and AENI cells average

Table 2: **Quality.** Rank-biserial r between each method and the Baseline. Negative r indicates worse quality than Baseline. **Bold:** Dunn’s $p < .05$ (Holm-adjusted), with stars $*p < .05$, $**p < .01$, $***p < .001$. “—”: condition excluded by 40% TMC threshold. The Phi-4-mini omnibus K-W is non-significant ($H = 4.2$, $p = .12$); the column is shown for completeness but no Dunn’s test is licensed. Other omnibus K-W tests: ALLaM $H = 159.8$, AceGPT $H = 32.8$, Fanar $H = 158.9$, Jais $H = 62.8$ (all $p < .001$).

Method	ALLaM	AceGPT	Fanar	Jais	Phi-4
L-Res	−.02	−.30	+ .26	−.43**	−.22
AENI	−.39	−.28	−.48*	−.06	−.18
Attn	−.99***	−.46**	−.67***	−.48***	—
Embed	−.62***	−.61***	−.75***	−.57***	—
HiTemp- k	−.64***	—	−.81***	+ .01	—
HiTemp- p	−.65***	—	−.99***	−.06	—

Table 3: **Constraint Violations.** Rank-biserial r between each method and the Baseline. Negative r indicates more violations than Baseline. **Bold:** Dunn’s $p < .05$ (Holm-adjusted). “—”: condition excluded by 40% TMC threshold. AceGPT and Jais omnibus K-W are non-significant ($p = .19$ and $p = .08$); those columns show r values for completeness but no Dunn’s test is licensed. Other omnibus K-W tests: ALLaM $H = 80.9$, Fanar $H = 31.3$, Phi-4-mini $H = 13.3$ (all $p < .01$).

Method	ALLaM	AceGPT	Fanar	Jais	Phi-4
L-Res	+ .04	−.07	−.06	−.23	−.32**
AENI	+ .12	−.08	−.22	−.32	−.38**
Attn	−.69***	−.08	−.08	−.20	—
Embed	−.50***	−.25	−.33**	−.33	—
HiTemp- k	−.34*	—	−.30	−.21	—
HiTemp- p	−.25	—	−.51***	−.22	—

$|r| = 0.20$, well below the medium-effect threshold, and on several models L-Res sits within $|r| < 0.05$ of the Baseline distribution, indistinguishable from no intervention at all. The same pattern holds for violations (Table 3): the only large-magnitude deviation (−.69*** for Attn on ALLaM) belongs to an alternative method, and the only $|r| \geq 0.5$ result outside L-Res and AENI’s row is HiTemp- p on Fanar.

The L-Res and AENI exceptions. The two cells per method on which L-Res or AENI register a significant deviation each correspond to a known and bounded trade-off. L-Res on Jais quality ($r = −.43$, $p = .002$) is the model with the largest single diversity gain in the entire study (Vendi 4.71 $\rightarrow$ 7.09); a medium quality effect there is the cost of

the largest narrative-diversity improvement we report. AENI on Fanar quality ($r = -.48$, $p = .029$) sits well below the catastrophic $r = -.67$ that raw Attn produces on the same model, showing that AENI's adaptive gating recovers most of the quality that fixed attention noise destroys. Both methods also register a medium adverse effect on Phi-4-mini violations ($r = -.32$ and $-.38$); however, on this model L-Res and AENI are the *only two methods that survive TMC exclusion at all*. Embed, Attn, HiTemp- k , and HiTemp- p all collapse on $\geq 40\%$ of generations and are excluded entirely from this analysis. The choice on Phi-4-mini is therefore between a medium increase in violations under L-Res or AENI, and complete generation collapse under every alternative tested.

B Story Generation Prompt

System Prompt:

أنت مساعد مُفيد تُعدّ نصوص قراءة مُخصصة
للأطفال الصغار لتنمية مهاراتهم في فهم المقروء.

English Translation of System Prompt:

You are a helpful assistant who prepares reading texts specifically for young children to develop their reading comprehension skills.

User Prompt:

اكتب قصه.
* يجب أن تكون القصة سردية مستوحاة من مواد
قراءة الأطفال، وتتضمن:
* مقدمة تُعرّف بالشخصيات
* جزءاً وسطياً يتضمن معضلة ما
* جزءاً ختامياً يتضمن حدثاً لحل المعضلة
* يجب ألا تتجاوز القصة 60 كلمة.
* يجب أن تدور القصة حول شخصية أو شخصيتين،
بأسماء شائعة في اللغة العربية وسياق الطفل، ولكنها
غير شائعة الاستخدام في الكتب المدرسية.
* مناسب للأطفال - محتوى مرتبط بأحداث مألوفة
واهتماماتهم وفضولهم، ويثير مشاعر إيجابية.

* يحتوي على عناصر القصة القصيرة: شخصية، سياق،
بداية، عقبة أو مشكلة، وحل.

* متوازن بين الجنسين - يضم كلاً من الأولاد
والبنات.

* يتجنب الصور النمطية المتعلقة بالجنس أو الدين أو
غيرها.

* لا يوجد نص موجود مسبقاً ولا يذكر الأطفال
بخصوص أو أساطير يعرفونها.

* يستخدم زمن المضارع.

* يستخدم مفردات مناسبة للمنطقة والفئة العمرية
للأطفال الذين سيتم اختبارهم.

* يجب أن تكون الجملة الأولى سهلة للغاية. * يستخدم
بنية متنوعة ولكنها ليست أدبية أو معقدة.

* يستخدم اسماً واحداً (شائعاً) فقط.

* تتجنب القصة استخدام الكلمات المبهمة، مثل كلمة
يمكن أن تدل على أكثر من معنى عند كتابتها بطريقة
معينة، أو كلمة يمكن أن تُستخدم أكثر من تهجئة
لتمثيل معنى واحد.

* ليس قائمة من الجمل المترابطة بشكل ضعيف.

* يجب تجنب استخدام أسماء الشخصيات الشائعة في
الكتب المدرسية، لأن الطلاب قد يقدمون إجابات
تلقائية بناءً على القصص التي يعرفونها.

* تحتوي القصة على شخصية أو شخصيتين فقط،
لتجنب تحول المهمة إلى اختبار للذاكرة.

* يحتوي نص القصة على بعض المفردات المعقدة
وتراكيب الجمل.

اكتب القصة كنص سردي متصل دون عناوين أو
تسميات أو تقسيمات أو أي مؤشرات هيكلية.

English Translation of Constraints:

The story must be a narrative story generated from children's reading material which has a beginning section where the characters are introduced, a middle section containing some dilemma, and an ending section with an action resolving the dilemma.

The story should be 60 words long.

The story should revolve around one to two characters with names that are common to the Arabic language and context

of the child but not commonly used in school textbooks.

Appropriate for children - content related to familiar events, their interests, and their curiosity and evokes positive emotions

Has the elements of a short story: a character, context, beginning, obstacle or problem, and a resolution

Gender balanced – feature both boys and girls

Avoids gender, religious or other stereotypes

Does not already exist or remind children of stories or legends they already know

Uses the present tense

Uses vocabulary that is appropriate to the region and age of the children to be tested

The first sentence should be very easy

Uses varied structure but is not too literary/complicated Allows for a variety of comprehension questions (literal and inferential)

Only uses one (common) proper name

The story avoids the use of ambiguous words, such as a word that, spelled in one way, can represent more than one meaning or a word that can use more than one spelling to represent one meaning

It is not a list of loosely connected sentences.

Character names frequently used in the school textbook are to be avoided, as students may give automated responses based on the stories with which they are familiar

The story has only one to two characters, to avoid the task becoming about memory recall

The story text contains some complex vocabulary and sentence structures.

C LLM-as-a-judge prompt

The following prompt was given to GPT5.3 Chat, stories were given to the model in batches of 10,

with stories from different runs jumbled in each batch.

Listing 1: Judging prompt fed to GPT5.3 Chat

The following is a set of Arabic stories. I want you to rate each story out of 10 on the following metrics:

- Readability: How well does the story read, is it just a set of weakly connected sentences or does it flow well etc.
- Logic: How much does the story make sense, does it have logical fallacies etc. - Grammar and Linguistic: Correctness of grammar and linguistic, this metric is just about correctness, do not include level of grammar in your rating of this metric. Here are other metrics to include also
- Reading Level: What grade level is this story appropriate for?
- Total Modal Collapse: If this story indicates total modal collapse, give zero on every other metrics and output a 1 here, if not then leave as zero
- Structure: Does the narrative structure includes intro, middle dilemma, and ending with resolution. 1 if yes and 0 if no
- Vocabulary level: Vocabulary suitable for children and local context or not, 1 if yes and 0 if not
- Stereotypes: Avoids gender/religion/other stereotypes. 1 if yes and 0 if not
- Gender-balanced: includes both a boy and a girl. 1 if yes and 0 if not

Your response should be as a table format csv with the following column names:
Story number, Readability, Logic, GrammarandLinguistics, ReadingLevel, TotalModalCollapse, Structure, VocabularyLevel, Stereotypes, Gender-balanced”

D Readability and Grade Level Scores

Table 4 contains OsmanReadability Scores (El-Haj and Rayson, 2016) that were calculated to go along with the Grade level assessments made from our LLM-as-a-judge model.

While Figure 2 contains a figure comparing Osman Readability and Vendi Scores between Baseline, AENI and L-Res methods.

E Complete Diversity Scores

Table 5 contains the complete vendi and lexical diversity scores of methods that resulted in a Total modal collapse rate of less than 40%

F Quality Scores

Table 6 contains the complete quality scores for each run with the exception of Phi-4-mini Embedding Noise as it failed to produce any coherent output.

Table 4: Readability and constraint-violation metrics for all conditions with $< 40\%$ modal collapse. **Read.** $\uparrow$: mean OsmanReadability score (El-Haj and Rayson, 2016) $\pm$ std (higher = easier to read). **Grade**: modal estimated grade level across generated stories (G1–G3 = EGRA target range; higher grades indicate above-target reading difficulty; 0 = output mostly unreadable). **Viol.** $\downarrow$: mean EGRA constraint violations per story $\pm$ std. **Bold**: best readability and fewest violations among methods with ≤ 1 collapse per model group. † method has ≥ 1 collapse (count in Table 1).

Model	Method	Read. $\uparrow$	Grade	Viol. $\downarrow$

Abstract

When programming students encounter errors in their code, compiler messages or static analysis output often provide limited guidance, particularly for novice programmers. Personalized feedback from instructors can be effective but does not scale well. Recent advances in large language models (LLMs) enable automated feedback generation at scale. This study examines whether LLM-generated feedback with different levels of guidance is associated with differences in students' problem-solving behavior. We analyze effects on time to solution and number of attempts, and examine whether these effects differ by programming experience. We design three feedback types and compare them to a baseline in which students receive only compiler error messages. Results from an online programming course show that LLM-generated feedback is associated with faster time to solution compared to the no-feedback baseline, with less guided feedback showing slightly stronger effects. Overall, the findings suggest that feedback structure plays an important role in how students progress toward correct solutions and motivate further work on adaptive feedback designs and longer-term learning outcomes.

1 Introduction

When students submit incorrect programming solutions, they typically receive feedback in the form of compiler errors or failed test cases (Keuning et al., 2018). Such feedback indicates that a solution is incorrect but often provides limited guidance on how to proceed, particularly for less experienced programmers (Becker, 2016). Human instructors can offer more targeted feedback, but this does not scale to large courses (Messer et al., 2024). Recent work explored the use of large language models (LLMs) to generate programming feedback automatically (Hellas et al., 2023; Mueller et al., 2025; Vassar et al., 2024; Gabbay and Cohen, 2024;

Koutchme et al., 2024, 2025). Prior studies report that LLMs can produce readable explanations and hints, but also note that generic LLM-generated feedback may be overly detailed, provide complete solutions, or contain inaccuracies (Xiao et al., 2024; Leinonen et al., 2023; Brown et al., 2025). Research in computing education further shows that novice and more experienced programmers differ in how they approach programming problems and respond to guidance (Chuang and Chang, 2024; Kalyuga, 2007).

This study examines how the structure of LLM-generated programming feedback is associated with student performance in an online programming course. Rather than focusing on fully personalized or adaptive feedback, we compare feedback formats that differ in the amount of guidance and information they provide, ranging from more detailed explanations to more constrained, diagnostic hints. We evaluate how these different feedback structures relate to students' time to solution and number of attempts, and examine whether their effects vary across students with different programming experience. In addition, we investigate whether the effectiveness of LLM-generated feedback differs across course content that varies in recency relative to the model training data, which may affect feedback quality.

We address the following research questions: **RQ1:** How does the different feedback complexity affect students' performance, in terms of (a) the expected number of attempts and (b) the time required to solve an assignment? **RQ2:** Do the effects of different hint types on attempts and solution time differ between students with different levels of expertise? **RQ3:** How does the recency of the instructional materials relate to students' performance, as measured by the expected number of attempts and time to solution when using generated hints?

The contributions of this work are as follows:

(1) We design programming assignment hints with different level of cognitive load, motivated by previous work of preferences for different proficiency levels. We show with experiments in an online programming course that LLM-generated hints lead to faster time to solution, with simple hints being more efficient. (2) We evaluate the performance of students of different programming proficiency when presented with the different hint types. (3) We show that new content, released after the LLM knowledge cut-off date, affects the quality of the hints negatively.

2 Background

2.1 Programming Feedback

Automated assessment systems usually provide feedback as test-case results, compiler diagnostics, or static-analysis warnings. This feedback is often difficult for novice programmers to interpret, especially when error messages rely on professional terminology or assume prior knowledge (Becker, 2016; Messer et al., 2024). Enhanced compiler error messages can improve readability, but prior work reports mixed effects on learning outcomes and notes challenges in scaling such approaches across courses and languages (Keuning et al., 2018). Human instructors can provide contextualized feedback adapted to a student’s understanding, but this does not scale to large courses. Large language models (LLMs) have therefore been explored for automatic feedback generation. Classroom studies report that LLM-generated hints are often perceived as more readable than compiler output and can support student progress across repeated submissions, while also revealing potential risks of over-reliance on generated feedback (Pankiewicz and Baker, 2023; Leinonen et al., 2022). Other evaluations report that LLM-generated feedback may include overly detailed guidance, complete solutions, or hallucinated issues, and that students often use such feedback primarily for immediate help-seeking rather than deeper self-regulatory strategies (Xiao et al., 2024; Viberg et al., 2025). Designing LLM-based feedback around pedagogical principles influences how students engage with generated hints, with planning-oriented support showing stronger associations with performance than other forms of assistance (Phung et al., 2025). Instructor-based evaluations also indicate that the quality and usefulness of LLM-generated programming feedback depend strongly on prompting strategies and

task difficulty, with substantial variation observed across zero-shot, one-shot, and few-shot configurations (Barros et al., 2025).

2.2 Novice vs. Advanced Programmers

Programming behavior differs across experience levels. Novice programmers spend more time debugging, make more syntax-related errors, and rely more on trial-and-error approaches. More experienced programmers make fewer errors and perform more targeted code modifications (Chuang and Chang, 2024; Shrestha et al., 2022). These differences are reported when proficiency is defined by prior experience rather than task performance (Chuang and Chang, 2024). The *expertise reversal effect* describes how instructional approaches that benefit learners with low prior knowledge may become less effective as expertise increases (Kalyuga, 2007, 2009). This effect has been discussed in programming education in relation to the usefulness of detailed guidance at different experience levels. More broadly, adapting the amount and form of instructional explanation to user expertise has been shown to improve learning outcomes in adaptive systems, suggesting that differences in feedback presentation across proficiency levels may be beneficial (Boyle and Encarnacion, 1994). Studies of automated program repair report that novice programmers often struggle to interpret repair suggestions, which may differ substantially from their original solutions, while more experienced learners report greater usefulness; students also tend to value error localization over full repair suggestions (Kurniawan et al., 2023). These studies also report that students often value information about the location of an error and that full repair suggestions can be difficult to apply (Kurniawan et al., 2023). Our work examines whether LLM-generated feedback that differs by programming proficiency and explanation depth is associated with differences in student performance.

3 Methodology

3.1 Context

We applied LLM-generated feedback on an online introductory Web Development course in the span of two months. When a student submits incorrect assignment solutions to the system, by default they see compiler error messages. We assigned at random for part of the users, one of the types of feedback messages. There was an indication that

the feedback was AI-generated, and the students had the option to vote for each message as Good or Poor.

3.2 Prompt Design

We used three types of prompts ([Appendix A](#)), adjusted for different proficiency levels. **General Feedback:** This prompt generates up to three issues in the code, each of which contains description, explanation and hints for next steps. **Single-Issue Feedback:** This prompt contains only one error, with its description, explanation and guidance for next steps towards the resolution. This is motivated by prior work which states that novice programmers could be overwhelmed by the feedback complexity ([Xiao et al., 2024](#)). **Diagnostic Feedback:** This prompt contains up to three issues with the code, but gives only descriptions, not hints for how to address the errors. This structure is motivated by the expertise reversal effect ([Kalyuga, 2009](#)), where more advanced programmers perform better with more limited guidance. We used GPT-4o for generating all feedback messages.

3.3 Data

The data used in this study is from an online introductory Web Development course. We only used submissions of students who allowed using their data for research. We excluded all exercise-user pairs for which at least one submission is longer than 2000 characters – to keep the prompt length shorter, no feedback is displayed for such submissions. We had three types of feedback, and one control group, (No Feedback), which did not see any LLM-generated messages. In addition to the LLM-generated feedback, the students also saw the errors logs from the failed automated tests.

We used the data from two parts of the course – *Part 2: Client-Side Development* and *Part 3: Server-Side Development*. Part 2 contains materials about more recent technologies, which were released after the used model cutoff date, and we refer to it as *New Content*. Therefore we also examined the results per course type, to explore whether the recency of the materials affected the generated hints. We refer to Part 3, which contains content that was used in the model training data, and we refer to it as *Old Content*.

We focused our investigation only on submissions for which the students were actively focused and worked on the task (i.e., engaged). Previous work defines that if a student does not do any input

on the programming task for more than 10 minutes, they are likely to be disengaged ([Shrestha et al., 2022](#)). Combining this insight together with the distribution of the number of exercises that were solved in particular time intervals, we analyzed assignments that were completed by a student for up to 30 minutes, as nearly 95% of all assignments were solved in this time interval.

Before starting the course, the students were asked the following question about their proficiency level: *Prior programming experience (1=less than 1 year, 2 = 1-2 years, 3 = 2-3 years, 4=3-5 years, 5=6-10 years, 6=more than 10 years)*, which they were not required to answer. Following previous research ([Chuang and Chang, 2024](#)), we split the students as *Novice Students* if their experience was below 3 years (answers 1, 2 or 3 from the above question), and as *Advanced Students* if they had over three years of experience (answers 4, 5 or 6 to the above question). When using this separation, there were 111 *Novice Students* and 38 *Advanced Students*.

After filtering out the submissions as described above, we obtained a dataset with 3153 assignment-user pairs, of which 1228 are *No Feedback*, 665 are *General Feedback*, 639 are *Single-Issue Feedback*, 621 are *Diagnostic Feedback*.

3.4 Approach

3.4.1 Modeling approach

To answer the three research questions, we conducted three experiments, each corresponding to one research question. All analyses were performed on *assignment–user pairs* that were eventually solved, considering submission sequences of up to 30 minutes, as motivated above. Each student sees the same feedback type for all their submissions to the same assignment. For each assignment attempted by the student, we assign the feedback type at random. This design choice was made, in order to not put any student in disadvantage of seeing only one feedback type, before we had any information about the quality of each type.

Because each student may submit multiple solutions to the same assignment and may receive different hints for the different assignments, observations cannot be assumed to be independent. We therefore employ mixed-effects models ([Lindstrom and Bates, 1998](#); [Brysbaert and Stevens, 2018](#)), which allow us to account for repeated measures at both the student and assignment levels. Across all

experiments, we include fixed effects for hint type and, where relevant, student level or course part, as well as random intercepts for students and assignments. In addition, we include random slopes for hint type at the student level, allowing the effect of hints to vary across students.

For time-based outcomes, we use linear mixed-effects models (LMMs) (Lindstrom and Bates, 1988; Brysbaert and Stevens, 2018) on log-transformed time. For count-based outcomes (number of attempts), we use negative binomial generalized linear mixed-effects models (NB-GLMMs) (Breslow and Clayton, 1993; Hilbe, 2011) with a log link to account for overdispersion. Linear mixed-effects models were fit using statsmodels version 0.14 (Seabold and Perktold, 2010). Negative binomial generalized linear mixed-effects models were fit using Bambi version 0.17 (Capretto et al., 2022).

3.4.2 Outcome variables

Each assignment–user pair contains the complete submission sequence up to the first correct solution. From this sequence, we derive two performance measures: **Time to Success**: the time elapsed (in seconds) between the first submission and the first correct submission. Due to right skew, this variable is log-transformed for modeling. **Attempts to Success**: the number of submissions required until the first correct solution. This variable is discrete and overdispersed and is therefore modeled using a negative binomial distribution.

3.4.3 General model structure

Let y_{ij} denote the outcome for student i on assignment j , and let η_{ij} denote the linear predictor:

$$\eta_{ij} = \beta_0 + \beta^T \mathbf{X}_{ij} + u_{0i} + u_{1i} \text{HintType}_{ij} + v_{0j}, \quad (1)$$

where $\mathbf{X}_{ij}$ contains the fixed effects relevant to the experiment, u_{0i} is a student-specific random intercept, u_{1i} is a student-specific random slope for hint type, and v_{0j} is an assignment-specific random intercept.

For Time to Success, we model:

$$\log(y_{ij}) = \eta_{ij} + \varepsilon_{ij}, \quad \varepsilon_{ij} \sim \mathcal{N}(0, \sigma^2). \quad (2)$$

For Attempts to Success, we model:

$$y_{ij} \sim \text{NegBin}(\mu_{ij}, \alpha), \quad \log(\mu_{ij}) = \eta_{ij}, \quad (3)$$

where $\alpha > 0$ is the overdispersion parameter. The experiments below differ only in the fixed effects included in $\mathbf{X}_{ij}$.

3.4.4 Experiment 1: Overall effect of feedback on performance (RQ1)

To address RQ1, we include only hint type as a fixed effect:

$$\begin{aligned} \log(y_{ij}) = & \beta_0 + \beta_1 \text{HintType}_{ij} \\ & + u_{0i} + u_{1i} \text{HintType}_{ij} + v_{0j} + \varepsilon_{ij}. \end{aligned} \quad (4)$$

Here, β_0 represents the baseline performance under the no-hint condition, and β_1 captures the average effect of hint type. The same linear predictor is used for the NB-GLMM when modeling Attempts to Success.

3.4.5 Experiment 2: Effect of feedback by student expertise (RQ2)

To address RQ2, students are categorized as *novice* or *advanced*, and we include an interaction between hint type and student level:

$$\begin{aligned} \log(y_{ij}) = & \beta_0 + \beta_1 \text{HintType}_{ij} \\ & + \beta_2 \text{StudentLevel}_i \\ & + \beta_3 (\text{HintType}_{ij} \times \text{StudentLevel}_i) \\ & + u_{0i} + u_{1i} \text{HintType}_{ij} + v_{0j} + \varepsilon_{ij}. \end{aligned} \quad (5)$$

The interaction term β_3 captures whether the effect of hint type differs between novice and advanced students. An analogous NB-GLMM with the same linear predictor is used for Attempts to Success.

3.4.6 Experiment 3: Effect of feedback across course parts (RQ3)

To address RQ3, we include course part (used as a proxy for content recency) and its interaction with hint type:

$$\begin{aligned} \log(y_{ij}) = & \beta_0 + \beta_1 \text{HintType}_{ij} \\ & + \beta_2 \text{CoursePart}_{ij} \\ & + \beta_3 (\text{HintType}_{ij} \times \text{CoursePart}_{ij}) \\ & + u_{0i} + u_{1i} \text{HintType}_{ij} + v_{0j} + \varepsilon_{ij}. \end{aligned} \quad (6)$$

The interaction term tests whether the effect of hint type differs between earlier and later course parts. As before, Attempts to Success is modeled using an NB-GLMM with the same linear predictor and a negative binomial likelihood.

3.5 Ethics Statement

The work followed the ethical procedures at Aalto University.

4 Results

4.1 Experiment 1: Effect of hint types on the student performance on the assignment.

Time to Success Figure 1 summarizes the fixed effects of hint type on log-transformed time to success with the No Feedback condition as the reference level¹. All hint types were associated with a reduction in completion time relative to the No Feedback baseline. The largest average reduction was observed for Single-Issue Feedback ($\beta = -0.214$), followed by Diagnostic Feedback ($\beta = -0.194$) and General Feedback ($\beta = -0.122$). These effects are also reflected in the corresponding fixed-effect estimates shown in Figure 1. Beyond these average effects, the mixed-effects model accounted for substantial between-student and between-exercise variability. Random intercepts were included for both students and exercises, capturing baseline differences in performance. For time to success, the estimated variance of the student-level random intercept was $\sigma_{\text{student}}^2 = 0.103$, while the exercise-level random intercept variance was larger ($\sigma_{\text{exercise}}^2 = 1.025$), reflecting notable differences in task difficulty. In addition to random intercepts, the models allowed the effect of hint type to vary across students via student-specific random slopes. A wide spread of slopes was observed, which indicates considerable heterogeneity in how individual students responded to hints: while the average effect of hints was beneficial, some students benefited substantially more than others, and a smaller subset showed little or no improvement. This variability suggests that the reported fixed effects capture overall trends, but mask meaningful differences in individual responsiveness to hint support.

Attempts to Success The results for attempts, modeled using a NB-GLMM are shown in Table 1. The results indicate that all hint types credibly reduced the number of attempts to success relative to the No Feedback baseline, with the largest reduction observed for Diagnostic Feedback. The

¹Note: In all tables with results, we mark in bold the results that were statistically significant, i.e. the Confidence Interval (CI) for MixedLM or Highest Density Interval (HDI) for NB-GLMM excludes zero. Detailed numbers for time to success are given in the appendix.

Figure 1: Effects of hint type on Time to Success, compared to the No Feedback baseline.

Table 1: Fixed effects of hint type on attempts to success (RQ1).

Predictor	β	94% HDI
Intercept	1.216	[1.130, 1.306]
General Feedback	-0.175	[-0.238, -0.113]
Single-Issue Feedback	-0.090	[-0.157, -0.030]
Diagnostic Feedback	-0.200	[-0.262, -0.134]

smallest for improvement is for Single-Issue Feedback, which could be explained with the fact that this hint type focuses on one issue only, and therefore might lead to a solution after more iterations. The standard deviation of the exercise-level random intercepts (≈ 0.26) reflects variability in baseline attempts across exercises, indicating differences in inherent task difficulty, while the standard deviation of the user-level random intercepts (≈ 0.17) indicates more moderate variability in baseline attempts across users. The standard deviations of the user-level random slopes for hint type were comparatively small ($\approx 0.05 - 0.07$), suggesting limited variation across users in how the effect of hints on attempts differs.

4.2 Experiment 2: Effect of the feedback for students with different expertise.

Time to Success To examine whether the effects of hint type differed between Novice Students and Advanced Students, we fit mixed-effects models including the interaction between hint type and student level for both Time to Success. Figure 2 shows the model-predicted outcomes. Single-Issue Feedback and Diagnostic Feedback are associated with improvement in the time for completion. In contrast, General Feedback does not show a clear effect. The main effect of student level is not statistically significant once hint type is accounted for. Although the interaction terms between hint type and student level are not statistically significant, the predicted trends suggest that the relative effec-

Table 2: Fixed effects of hint type, student level, and their interaction on attempts (RQ2).

Predictor	β	94% HDI
Intercept	1.228	[1.105, 1.334]
General Feedback	-0.196	[-0.325, -0.086]
Single-Issue Feedback	-0.220	[-0.339, -0.097]
Diagnostic Feedback	-0.207	[-0.319, -0.089]
Novice Students	-0.019	[-0.117, 0.078]
General Feedback $\times$ Novice Students	0.027	[-0.107, 0.168]
Single-Issue Feedback $\times$ Novice Students	0.174	[0.030, 0.316]
Diagnostic Feedback $\times$ Novice Students	0.007	[-0.132, 0.140]

tiveness of hint types might differ between Novice Students and Advanced Students.

Figure 2: Interaction plot of hint type and student level, with predicted time to success from MixedLM model for assignments solved by up to 30 minutes.

Attempts to Success Table 2 shows the results of the negative binomial mixed-effects model examining the effects of hint type, student level, and their interaction on attempts to success, with No Feedback and Advanced Students as the reference categories. For Advanced Students (the reference group), all hint types were associated with a reduction in the number of attempts to success relative to No Feedback, with posterior mean effects ranging from $\beta = -0.20$ to -0.22 and 94% highest density intervals fully below zero. In contrast, baseline differences between Novice Students and Advanced Students in the No Feedback condition were small and uncertain. From these results it seems that Novice Students do not benefit from a particular hint type, and make slightly more submissions before submitting a successful solution when they see Single-Issue Feedback.

4.3 Experiment 3: Effect of the content recency on the quality of the LLM-generated feedback.

Time to Success To investigate whether the effectiveness of different hint types varies across course progression, we fit mixed-effects model including the interaction between hint type and course part for Time to Success. Model-predicted outcomes are shown in Figure 3. The reference level corresponds to assignments with No Feedback from New Content. All hint types for the Old Content perform better than New Content. All hint types show improvement over the No Feedback baseline for both course parts, with Single-Issue Feedback statistically significant for Old Content. The Diagnostic Feedback performs significantly better for New Content, likely due to the fact that the model could correctly identify errors in the submission, but if it tries to give a direction for fixing, and refers to older version of the material, this could lead to incorrect suggestions.

Figure 3: Interaction plot of hint type and course part, with predicted time to success from MixedLM model for assignments solved by up to 30 minutes.

Attempts to Success The results for attempts, modeled using a negative binomial mixed-effects model and shown in Table 3. Unlike the Time to Success, there is no observed significant difference in the Attempts to Success between the two parts when no LLM-generated feedback is shown. For the New Content, again the Diagnostic Feedback is associated with fewer attempts, but interestingly, the General Feedback, which also hints to solution, shows a reduced number of attempts. For the Old Content, the Single-Issue Feedback is associated with fewer Attempts to Success.

Table 3: Fixed effects of hint type, course part, and their interaction on attempts (RQ3).

Predictor	β	94% HDI
Intercept	1.177	[1.060, 1.292]
General Feedback	-0.129	[-0.211, -0.055]
Single-Issue Feedback	-0.034	[-0.120, 0.042]
Diagnostic Feedback	-0.217	[-0.300, -0.134]
Old Content	0.089	[-0.065, 0.257]
General Feedback $\times$ Old Content	-0.107	[-0.225, 0.007]
Single-Issue Feedback $\times$ Old Content	-0.131	[-0.248, -0.018]
Diagnostic Feedback $\times$ Old Content	0.037	[-0.088, 0.151]

4.4 Qualitative Analysis

In addition to the quantitative analysis of the student performance in terms of time and attempts to successful submission, we perform qualitative analysis, to identify common errors in the feedback generation. When the feedback was displayed to the students, it was accompanied by a message indicating LLM-generated content, and with option to mark the message as Good or Poor. Only very few of the feedback messages were evaluated. Most of the feedback that the users voted for was from Course Part 2 (New Content). There were only two Good and two Poor voted exercises for Course Part 3 (Old Content). The statistics of the given votes are shown in Table 5. The results in the table exclude one Good exercise that was not solved, and one Good exercise for which the correct solution was submitted 35 days after the first submission. Non-surprisingly, when Good feedback is given, the assignment is solved in a much fewer attempts and for much shorter time than when Poor feedback is shown. Students gave the positive vote in the first appearance of the feedback, and they waited for a few submissions before giving negative vote. Table 4 shows how many votes of each kind were given for the different types of feedback, but because of the small numbers, we cannot make any general conclusions from them.

Table 4: Number of Good and Poor votes by feedback type.

Hint Type	Good	Poor	Total
General Feedback	5	8	13
Single-Issue Feedback	7	12	19
Diagnostic Feedback	2	11	13
Total	14	31	45

We further perform thematic analysis of the Poor submission, in order to identify common errors. We first went through all the submissions voted as Poor and read them carefully in the context of the assignment description, correct submission and student submission. We also take into account the other submissions by the same user and the same assignment. Then, we coded each voted submission with a description of the type of error it contains. After this, we summarized the codes into common themes. We marked some feedback messages with more than one code, for example in cases where the LLM was referring to an old version, and having had access to the examples in the materials could have showed the expected correct implementation. Several patterns were observed: The suggested fixes were referring to an older version of the taught technology (n=12). The pointed issues could be considered meaningful, but examples in the materials were implementing the functionality in the same way as in the student submission, so there was no actual error that the LLM reported (n=12). The LLM found no issue with the submission, although the tests were failing (n=7). Cases where a wrong issue was proposed, and the real issue in the code was missed (n=4). The feedback was actually correct and the student applied it in their correct submission (n=3).

5 Discussion

Across the course, students receiving LLM-generated feedback reached correct solutions faster than those with compiler output alone, across all feedback types. Differences appear mainly in efficiency (time and attempts), not in final success, as solution rates are high in all conditions. Clear differences emerge between feedback structures. Single-Issue Feedback is associated with faster completion but not consistently fewer attempts, suggesting quicker progress without reducing submissions. Diagnostic Feedback leads to both fewer attempts and faster completion, indicating more efficient iteration, likely by helping students localize issues. General Feedback improves performance over no feedback but shows weaker effects than the more constrained formats. Overall, more detailed guidance does not necessarily improve short-term performance. Limiting feedback to fewer issues or problem identification alone was generally associated with more efficient progress. When accounting for student level,

Table 5: Characteristics of feedback voted as Good or Poor by students. Attempts and time are measured until the first correct submission. Vote position indicates the submission index at which the vote was given.

Vote	#Pairs	#Votes	Attempts to Solve		Time to Solve (s)		Vote Position	
			Mean $\pm$ SD	Median	Mean $\pm$ SD	Median	Mean $\pm$ SD	Median
Good	13	14	2.92 $\pm$ 1.04	3	279.10 $\pm$ 463.97	155.82	1.65 $\pm$ 1.14	1
Poor	22	31	13.95 $\pm$ 17.34	7.5	51288.33 $\pm$ 87726.14	997.92	19.45 $\pm$ 20.71	8

the models do not show strong interaction effects between feedback type and expertise. However, the predicted outcomes suggest that the relative ranking of feedback types differs between novice and advanced students, with feedback appearing more beneficial for Advanced Students than for Novice Students in our experiments. These results indicate potential differences in how students at different levels respond to feedback structure, but they do not provide strong evidence for level-specific optimal feedback. The effectiveness of feedback varied across the different course parts. The results suggest that feedback formats that rely on specific guidance may be more sensitive to limitations in the model coverage of newer technologies. The analyses show substantial variation across students and assignments. Individual students respond differently to the same feedback type, and assignment difficulty contributes strongly to performance differences. As a result, the reported effects represent average trends rather than uniform improvements. This indicates that a single feedback strategy is unlikely to be optimal for all students or tasks. The results motivate further work on adaptive feedback approaches that adjust feedback structure based on student behavior, task characteristics, or prior interaction patterns, rather than relying on fixed feedback formats. Finally, we analyzed LLM-generated feedback evaluated by students and qualitatively examined messages marked as Poor. Due to the small number of votes relative to total submissions, strong conclusions cannot be drawn. Nevertheless, observed failure cases indicate that hallucinations can reduce feedback quality. Providing relevant learning materials in the prompt may mitigate some issues by adding context, especially when the model’s knowledge is outdated. Including compiler error messages could also help guide the LLM toward key issues in the submission.

6 Conclusion and Future Work

This study examines how different structures of LLM-generated programming feedback affect student performance in an online course. All feedback types help students reach correct solutions faster than compiler output alone, with differences appearing in efficiency (time and attempts) rather than final success. Feedback structure influences progress: lower cognitive load (fewer issues or less guidance) leads to more efficient short-term problem solving. However, large individual differences between students outweigh effects of expertise level, suggesting that coarse measures like years of experience may be insufficient. Feedback effectiveness also varies with course content. Guidance-heavy feedback performs less consistently on newer material, likely due to outdated model knowledge, indicating that relying only on pretrained knowledge is insufficient for content-specific feedback.

Future work should examine long-term learning effects and consistent feedback strategies across courses. Given high variability between students, more fine-grained personalization should be explored, including adaptation based on task, history, and behavior. Student proficiency could be assessed more reliably (e.g., via diagnostics), and preferences for feedback detail studied independently of expertise. Integrating retrieval or up-to-date course materials into feedback generation may improve accuracy, especially for new technologies. To mitigate the errors caused by LLM hallucinations, automated fact-checking mechanisms could be deployed to verify the correctness of the LLM-generated feedback before it is displayed to the student. Finally, future studies should evaluate long-term learning outcomes beyond short-term performance.

7 Ethical Statement

Displaying of LLM-generated feedback carries all the risks of using output from generative AI. We have taken several precautions to mitigate these

risks. First, the current study was conducted after an ethical approval by our university. Second, we are displaying notifications to the students that the displayed messages are LLM-generated. Third, in order to not put in disadvantage students who only see a particular feedback type, we show different feedback types per student. For the analysis, we only process data from students who have explicitly agreed their data to be used for research. In this work, we explore performance on the task, which does not necessarily correspond to deep understanding. We are planning a longitudinal study to ensure that the displayed feedback actually improves the long-term learning outcomes for the students.

8 Limitations

This study has several limitations. First, students were exposed to different hint types across assignments, so assignment–user pairs are not independent. This design avoided disadvantaging students before knowing feedback effectiveness, but future work could assign a single hint type per student or systematically vary it to study personal preferences. Second, student proficiency is based on self-reported experience, which may not accurately reflect actual ability. Third, the study is conducted in a single course, limiting generalizability, and excludes submissions over 2000 characters, potentially omitting more complex cases. Finally, we focus on short-term performance rather than long-term learning, which should be addressed in future longitudinal studies.

A Prompts and Examples of Feedback Messages

Figure 4 shows the prompts used for the three feedback types. For choosing these prompts, we experimented with several different variants, and ended up with this formulation, which outputs the most concise feedback messages. Examples for the three types of feedback messages are shown on Figure 5.

B Data Stats

The distribution of the number of exercises that were solved in particular time intervals is shown in Table 6.

The solution rates per hint type are shown in Table 8, and show that the hint does not affect whether the students solve the assignment.

General Feedback:	Single-Issue Feedback:	Diagnostic Feedback:
SYSTEM You are a programming feedback ↳ tutor. Identify the main ↳ problems in the student's ↳ code and provide short, ↳ direct fixes for each. Do not show or quote the sample ↳ solution. RULES - Refer to the student's ↳ identifiers. - Be concise and factual; no ↳ filler or repetition. - Include up to three important ↳ issues. - For each, give a short Problem ↳ / Fix / Why block. - No code snippets or solution ↳ hints. - Prioritize: 1) Spec/I/O issues, ↳ 2) Logic/runtime errors, 3) ↳ Edge/complexity issues, 4) ↳ Style (only if required). OUTPUT FORMAT Issue 1: Problem: ... Fix: ... Why: ... Issue 2: Problem: ... Fix: ... Why: ... (Up to 3 issues) CONTEXT Assignment: ↳ {assignment_description} Starter Code: {starter_code} Sample Solution: ↳ {sample_solution} Student Code: {student_code} TASK Give compact feedback listing up ↳ to three issues, each with ↳ Problem / Fix / Why.	SYSTEM You are a supportive programming ↳ tutor. Help a beginner fix ↳ one main problem in their ↳ code. Do not show or quote the sample ↳ solution. RULES - Focus on one clear issue. - Use the student's own variable ↳ and function names. - Keep it short, kind, and easy ↳ to follow. - No code or sample-solution ↳ hints. OUTPUT FORMAT Problem: (what's wrong) Fix: (one simple action) Why: (what it fixes or changes) CONTEXT Assignment: ↳ {assignment_description} Starter Code: {starter_code} Sample Solution: ↳ {sample_solution} Student Code: {student_code} TASK Give one short piece of ↳ beginner-friendly feedback ↳ following the format above.	SYSTEM You are a peer-level code ↳ reviewer. Identify the most ↳ relevant issues in the ↳ student's code precisely and ↳ concisely. Do not include or hint at the ↳ sample solution. RULES - Use the student's identifiers ↳ when referencing code. - Be factual and specific; no ↳ filler, no praise, no ↳ instructions. - Describe what is wrong, where, ↳ and what impact it has. - Do not restate the assignment ↳ or include any code. - Prioritize: 1) Spec/I/O issues, ↳ 2) Logic/runtime flaws, 3) ↳ Edge/complexity issues, 4) ↳ Style (only if required). OUTPUT FORMAT Issues: - Problem -> Location -> Impact - (Up to 3 bullets) CONTEXT Assignment: ↳ {assignment_description} Starter Code: {starter_code} Sample Solution: ↳ {sample_solution} Student Code: {student_code} TASK Give terse, peer-style feedback ↳ listing only the key issues ↳ as bullets.

Figure 4: The three prompt variants used in the study for the different types of feedback.

The descriptive statistics per feedback type are shown in Table 7. In our current setup, each user sees one unique hint type for each assignment that they attempt, but they can see different hint type for the different assignments. This table also shows descriptive statistics about the hint length and complexity, and the weighted Levenshtein distance between the change in two consecutive submissions. The three feedback types differ in their textual properties: General Feedback are substantially longer and more variable in length, Single-Issue Feedback are shorter and the easiest to read, and Diagnostic Feedback are sim-

ilarly short but more linguistically complex. The average code change between consecutive submissions is similar across hint-based conditions, with Single-Issue Feedback resulting in the smallest code changes, which aligns with their focus on addressing one issue at a time. The No Feedback baseline shows slightly larger and more variable code changes. Very similar solution rate was observed for all the feedback types, as well as the case where only compiler errors were shown, therefore the different feedback types did not affect whether the students solve the assignment.

General Feedback:

Issue 1:

Problem: The `

` element's → text is `"Text → transformations"` instead of → `"Reactive objects"`. Fix: Change the heading text to → `"Reactive objects"`. Why: The assignment requires an → exact main heading.

Issue 2:

Problem: The imported component
→ name
→ (`Transformations.svelte`)
→ does not match the
→ implemented file name
→ (`ReactiveCounter.svelte`).
Fix: Rename the component file
→ or adjust the import so they
→ match.
Why: Consistent naming is needed
→ to correctly render the
→ component.

Issue 3:

Problem: The paragraph for total
→ numbers incorrectly
→ references `numbers.length`
→ instead of
→ `statsState.numbers.length`.
Fix: Use
→ `statsState.numbers.length`
→ in the paragraph.
Why: It ensures the paragraph
→ displays the correct updated
→ value from the reactive
→ object.

Single-Issue Feedback:

Problem: The `if` condition

→ compares `request.method` to
→ `PEEK` without quotes.

Fix: Replace `PEEK` with

→ `"PEEK"` in the condition.

Why: This ensures that the code
→ correctly compares the
→ request method to the string
→ `"PEEK"`, which is necessary
→ for the condition to work as
→ intended.

Diagnostic Feedback:

Issues:

- Incorrect internal link text
→ -> `→ href="/contact">Contact</a>`
→ in line 16 -> The text
→ should be "Contact page",
→ affecting compliance with
→ assignment specifications.
- Unnecessary list wrapping
→ links -> `
` element
→ wrapping the `` tags in
→ lines 15-17 -> Deviates from
→ instructions, which require
→ the links to appear directly
→ below the paragraph without
→ being in a list.

Figure 5: Examples for each of the three variants of feedback used in the study.

C Additional Results

C.1 Experiment 1 Additional Results: Effect of hint types on the student performance on the assignment.

Table 9 shows the fixed effects of hint type on log-transformed time to success with the No Feedback condition as the reference level. Figure 6 shows the distribution of the random slope estimates per student for Time to Success.

Figure 6: Student random slopes for Time to Success.

C.2 Experiment 2 Additional Results: Effect of the feedback for students with different expertise.

The fixed-effect estimates for log time to success with hint type $\times$ student level interaction are reported in Table 10.

C.3 Experiment 3 Additional Results: Effect of the content recency on the quality of the LLM-generated feedback.

The fixed-effect estimates for log time to success with hint type $\times$ course part interaction are shown in Table 11.

Table 6: Number of assignments that students completed in different time intervals.

Interval	No Feedback	General Feedback	Single-Issue Feedback	Diagnostic Feedback
≤ 10min	1068	587	585	563
10-20min	128	57	41	51
20-30min	32	21	13	7
30min-2h	47	20	15	19
2-24h	16	9	12	10
24-72h	9	3	2	4
> 72h	3	2	6	4

Table 7: Statistics of the data used in the experiments (assignments that were solved up to 30 minutes). Number of assignment-user pairs, submissions, users, and assignments, together with descriptive properties of the generated hints and subsequent code changes by hint type. Values are reported as mean $\pm$ standard deviation. Hint length is measured in words; hint readability is quantified using Flesch Reading Ease (higher values indicate easier readability); code diff is measured as weighted Levenshtein distance between consecutive submissions. There are 47 assignments in total, and each of the hint types was seen for all assignments.

Hint type	Pairs	Submissions	Users	Hint Length	Hint FRE	Code diff
No Feedback	1228	4677	206	–	–	0.074 ± 0.186
General Feedback	665	2208	161	88.78 ± 34.96	54.24 ± 11.12	0.071 ± 0.129
Single-Issue Feedback	639	2312	162	54.23 ± 10.95	57.43 ± 11.22	0.061 ± 0.129
Diagnostic Feedback	621	1966	162	56.30 ± 21.57	44.82 ± 14.42	0.072 ± 0.130
Total	3153	11163	223	–	–	–

Interpretable Difficulty-Aware Knowledge Tracing in Tutor-Student Dialogues

Shuyan Huang Alexander Scarlatos Jaewook Lee Andrew Lan

University of Massachusetts Amherst

{shuang, ajscarlatos, jaewooklee, andrewlan}@umass.edu

Abstract

Recent advances in large language models (LLMs) have led to the development of AI-powered tutoring systems that provide interactive support via dialogue. To enable these tutoring systems to provide personalized support, it is essential to assess student performance at each turn, motivating knowledge tracing (KT) in dialogue settings. However, existing dialogue-based KT approaches often ignore question difficulty and rely on opaque LLM latent representations, hindering accurate and interpretable prediction. In this work, we propose an interpretable difficulty-aware conversational KT framework that leverages LLMs to explicitly model student knowledge state and the difficulty of tutor-posed tasks at each dialogue turn. The framework incorporates the original question and the next tutor-posed task to estimate the student’s knowledge state and the difficulty of the upcoming turn. It further integrates Item Response Theory to map LLM outputs into student ability and question difficulty parameters, enabling interpretable prediction of student performance grounded in cognitive theories of learning. We evaluate the framework on two tutor-student dialogue datasets. Quantitative and qualitative results show that our framework outperforms existing KT baselines, meanwhile generating interpretable outputs consistent with cognitive theory¹.

1 Introduction

Tutoring, which provides tailored instruction and feedback to students in an interactive manner, has been shown to effectively improve learning outcomes (Nickow et al., 2020; Nye et al., 2014). With the advanced natural language understanding and generation capabilities of large language models (LLMs), researchers have developed an increasing number of LLM-based tutoring systems, such as

¹Our code and data are available at <https://github.com/umass-ml4ed/Difficulty-Aware-DialogKT>

Figure 1: An example dialogue illustrating a student’s learning trajectory as the tutor adapts difficulty while scaffolding the math problem.

Khanmigo (Khan Academy, 2023) and LiveHint (Carnegie Learning, 2024). Recent work has further explored how to improve LLM-based tutors by training them to optimize student learning outcomes and by steering them toward diverse tutor personas that reflect different scaffolding, feedback, and affective-support styles (Scarlatos et al., 2025c; Lee et al., 2026). These systems can significantly reduce the workload of human tutors and provide scalable support for a large number of students.

To provide personalized pedagogical support, it is crucial to assess students’ mastery of concepts based on their responses throughout the dialogue. The process of modeling students’ knowledge states over time to predict their future performance is known as knowledge tracing (KT). Recently, with the development of AI-powered tutoring systems, KT has been extended to dialogue-based settings to predict whether students can correctly answer subsequent tutor-posed tasks (Scarlatos et al., 2025a; Wang et al., 2025).

However, existing KT approaches in dialogue

settings have two important limitations. First, prior studies do not explicitly model question difficulty. In practice, the correctness of student responses is not solely determined by their knowledge state but is also substantially influenced by question difficulty (Shen et al., 2022). Even students with high knowledge mastery may fail to answer very difficult questions. For example, as shown in Figure 1, although the student has a relatively high estimated knowledge state (e.g., 0.64), the student still answers the next tutor-posed task incorrectly when the question difficulty increases (e.g., from 0.62 to 0.72). Prior studies that model student responses solely based on students’ knowledge states may yield inaccurate predictions (Scarlatos et al., 2025a). Second, the reasoning process underlying model predictions of students’ future performance remains opaque. Most current approaches rely on LLMs with high-dimensional latent representations that lack interpretability. Consequently, it is difficult to derive psychologically meaningful explanations that align with cognitive theories of learning. This lack of transparency may undermine tutors’ trust in model predictions, hindering the adoption of LLMs as effective tutoring tools. As illustrated in Figure 1, even when the student answers a more difficult task incorrectly, the estimated knowledge state continues to increase, reflecting gradual learning dynamics consistent with cognitive theories (Newell and Rosenbloom, 1981; Anderson, 2000).

1.1 Contributions

To address the aforementioned challenges, we propose an interpretable difficulty-aware conversational KT framework built upon an LLM-based architecture that explicitly models both student ability and tutor-turn difficulty. Specifically, we prompt an LLM with the question and dialogue context to estimate student knowledge, and further prompt the model with the tutor turn to estimate the difficulty of the tutor-posed task. Furthermore, to bridge the gap between model predictions and cognitive theories of learning, we integrate principles from Item Response Theory (IRT). More specifically, we feed the estimated ability and difficulty into an IRT model to predict student correctness, enabling fine-tuning of the LLM using observed correctness labels. This design aligns model predictions with cognitive theory and improves interpretability by providing transparent reasoning based on the relationship between student ability and task difficulty. To evaluate the effectiveness of our approach, we

conduct comprehensive experiments on two tutor-student dialogue datasets. Both quantitative and qualitative results demonstrate the superiority of our framework in student ability and difficulty estimation throughout tutoring dialogues.

2 Problem Statement

Practically, a dialogue often starts when a student requests assistance from a tutor when they cannot successfully solve a math question/problem. Formally, we represent each dialogue $\mathcal{D}$ as an ordered sequence of alternating tutor turns t and student turns s , i.e., $\mathcal{D} = (s_0, t_1, s_1, \dots, t_N, s_N)$, where N denotes the total number of turn pairs in the dialogue and s_0 is included when the student initiates the dialogue. In cases where the same speaker produces several consecutive utterances, we merge them into a single tutor turn or student turn to maintain the alternating turn structure. Following Scarlatos et al. (2025a), each dialogue can be treated as a sequence of formative assessments, where each tutor turn t_j (for turn index j) acts as an assessment question, and the corresponding student turn s_j represents a correct or incorrect response. This perspective allows us to use tutor-student dialogues to model student learning over time. Each tutor turn with pedagogical intent (i.e., designed to assess student knowledge) is associated with one or more related knowledge components (KCs), $\mathcal{C}_j = \{c_j^k\}_{k=1}^{K_j}$, where K_j is the number of KCs associated with turn t_j . For student turns that follow these tutor turns, we define the correctness of a student turn s_j as $r_j \in \{0, 1\}$. In this way, we formulate the dialogue-based KT task as predicting the correctness $\hat{r}_{j+1}$ of the student’s next response with the given question q , historical dialogue $(t_1, s_1, \dots, t_j, s_j)$, and next tutor-posed task t_{j+1} , which can be formally defined as:

$$\hat{r}_{j+1} \sim f_{\Theta}(q, t_1, s_1, \dots, t_j, s_j, t_{j+1}), \quad (1)$$

where Θ denotes the learnable parameters of the framework, which are optimized to predict students’ future performance.

3 Approach

In this section, we detail our framework that consists of three modules: (1) a *knowledge estimator* that extracts latent knowledge representations from both the textual content of the question and the tutor-student dialogue history; (2) a *difficulty*

Figure 2: Overview of our framework with three modules: a knowledge estimator, a difficulty estimator, and an IRT-based predictor that jointly model student knowledge and task difficulty to predict correctness on the next task.

estimator that computes the difficulty of the tutor-posed task based on the question content, the dialogue history and content of the current turn; and (3) an *IRT-based predictor* that integrates the estimated knowledge state and difficulty representation to provide interpretable predictions of whether the student will correctly respond to the tutor-posed task. We illustrate our full framework in Figure 2, and show our prompts in Appendix A.

3.1 Knowledge Estimator

We now introduce the knowledge estimator module of our framework, which estimates student knowledge states for each turn in a dialogue. At each turn, the student’s subsequent performance depends on both the original question being solved and the dialogue history up to the current turn. The original question provides necessary context, while the dialogue history reveals the student’s evolving knowledge state, including observed errors or misconceptions. To effectively represent the textual information, we leverage the natural language understanding capabilities of LLMs to jointly encode the question text and dialogue history. To adapt general-purpose LLMs to the educational domain, we further fine-tune the model on dialogue-based tutoring data. We construct a prompt I_{j+1}^K representing turn $j + 1$, where we instruct the LLM to generate a one-word prediction for the student’s current ability level. Prior LLM-based KT work categorizes students’ knowledge states into discrete levels, e.g., good/fail (Li et al., 2025b). Inspired by this classification design, we use “GOOD” and “BAD” as positive and negative verbalizer tokens following prompt-based classification methods (Schick and Schütze, 2021). Rather than sampling text from the

LLM, we construct a continuous ability estimate by comparing their next-token logits. We first extract the LLM’s next-token output logits corresponding to these two verbalizer tokens:

$$z_{j+1}^{\text{GOOD}}, z_{j+1}^{\text{BAD}} = \text{LLM}(I_{j+1}^K).$$

We convert these logits into a scalar ability estimate by taking their difference, defining the student’s ability at the next turn as:

$$\theta_{j+1} = z_{j+1}^{\text{GOOD}} - z_{j+1}^{\text{BAD}},$$

where θ_{j+1} represents the student’s latent knowledge state at turn $j + 1$.

3.2 Difficulty Estimator

We now introduce the difficulty estimator module of our framework, which estimates the difficulty of each tutor-posed task in a dialogue. Difficulty estimation is recognized as a fundamental component in classical assessment settings, where accurately modeling item difficulty improves the reliability of student evaluation (Scarlatos et al., 2025b). In dialogue-based tutoring, each interaction is typically centered around an original question that the student is attempting to solve with tutor assistance. This original question is associated with an inherent difficulty determined by its textual content and cognitive complexity. As the dialogue progresses, the tutor can actively pose tasks with different difficulty in subsequent turns. Hence, to more accurately predict student performance at each turn, we estimate the difficulty of each tutor-posed task by jointly considering the original question text, dialogue context, and the next tutor-posed task. Similar to the knowledge estimator, we construct a prompt I_{j+1}^D

representing turn $j+1$, where we instruct the model to generate a one-word prediction for the difficulty level of the tutor-posed task. Again, we extract the LLM’s output logits, now corresponding to the “HARD” and “EASY” verbalizer tokens:

$$z_{j+1}^{\text{HARD}}, z_{j+1}^{\text{EASY}} = \text{LLM}(I_{j+1}^{\text{D}}).$$

We convert the logits into a scalar difficulty estimate, defining the difficulty of the tutor-posed task:

$$d_{j+1} = z_{j+1}^{\text{HARD}} - z_{j+1}^{\text{EASY}},$$

where d_{j+1} represents the latent difficulty of the tutor-posed task at turn $j+1$.

3.3 IRT-based Predictor

In prior LLM-based dialogue KT approaches, it is very challenging to explain the LLMs’ parameters and their decision-making processes when predicting student response correctness. Therefore, to align LLMs’ predictions with models in psychometric measurement, we introduce an IRT-based prediction layer that jointly predicts student response correctness while providing interpretable estimates of student knowledge and tutor turn difficulty. IRT, particularly the one-parameter logistic (1PL) model, also known as the Rasch model (Rasch, 1993), is widely used in educational assessment to model the probability of a correct response based on student ability and task difficulty. In the 1PL IRT model, student ability and task difficulty are represented as latent variables, and the probability of correctness increases as the positive difference between ability and difficulty grows. This formulation provides interpretability since both student knowledge and task difficulty are explicitly represented as meaningful cognitive quantities. Given the estimated ability θ_{j+1} and task difficulty d_{j+1} , the probability that a student will answer correctly at turn $j+1$ is defined as:

$$\hat{r}_{j+1} = \frac{1}{1 + \exp(-\alpha(\theta_{j+1} - d_{j+1}))},$$

where α is a learnable scalar that controls the sensitivity of the probability to differences between ability and difficulty. This parameter plays a role similar to the discrimination parameter in the two-parameter logistic (2PL) IRT model (Birnbbaum, 1968), enabling the model to adjust how strongly performance depends on the gap between ability and difficulty. Please note that we additionally experimented with modeling α as a learnable vector

to capture KC-specific discrimination, analogous to the 2PL model. However, this setting led to degraded performance in our experiments, likely due to overparameterization. Therefore, we adopt a scalar α in our final framework.

3.3.1 Model Optimization

To improve predictive accuracy, we fine-tune the LLM on correctness in observed tutor-student dialogues. We optimize the learnable parameters of the model by minimizing the binary cross-entropy loss between the ground-truth correctness of student responses r_{j+1} and the predicted probabilities $\hat{r}_{j+1}$ produced by the IRT-based prediction layer:

$$\mathcal{L} = -\sum (r_{j+1} \log \hat{r}_{j+1} + (1 - r_{j+1}) \log (1 - \hat{r}_{j+1})).$$

4 Experiments

4.1 Datasets

To evaluate the effectiveness of our framework, we conduct experiments on two datasets as follows:

Question-Anchored Tutoring Dialogues (QATD_{2k}) QATD_{2k} is the largest open-source real-world tutoring dialogue dataset (Zent et al., 2025). The dataset is collected from one-on-one conversations between tutors and students on the Eedi mathematics learning platform. Each dialogue begins when a student requests assistance in solving a math multiple-choice problem. After data preprocessing, the dataset contains 1,573 and 393 dialogues in the training set and test set, respectively. We use the LLM-generated KC and response correctness annotations collected in prior work (Scarlato et al., 2026).

MathDial MathDial is a tutoring dataset grounded in multi-step math reasoning problems between GPT-3.5-simulated students and crowd workers acting as tutors (Macina et al., 2025). Each dialogue begins with an incorrect student solution and the tutor guides the student to identify and correct their errors. The dataset contains 2,235 and 588 dialogues in the training set and test set, respectively. We use the LLM-generated KC and response correctness annotations collected in prior work (Scarlato et al., 2025a).

4.2 Baselines

We compare our framework against two types of representative KT baselines: LLM-based models and deep learning-based models.

4.2.1 LLM-based models

These models leverage LLMs to model student learning behavior by encoding question content and dialogue history to predict student responses.

- **LLMKT**: leverages textual question and conversation information in tutor–student dialogues using an LLM-based architecture, which is a previous state-of-the-art dialogue-based KT model (Scarlatos et al., 2025a).

4.2.2 Deep learning-based models

These models employ conventional deep neural networks to capture student knowledge states from sequences of their historical interactions, which consist of question tags, KC tags and binary responses, rather than LLMs.

- **DKT**: leverages an LSTM to sequentially model students’ learning processes and predict their future performance (Piech et al., 2015).
- **DKVMN**: leverages a static key memory matrix to encode relationships among KCs and a dynamic value memory matrix to predict students’ knowledge mastery levels (Zhang et al., 2017).
- **SAINT**: leverages a Transformer-based architecture to model students’ sequential learning interactions over time (Choi et al., 2020).
- **AKT**: leverages a monotonic attention mechanism to explicitly capture the temporal distance between current questions and students’ historical interactions (Ghosh et al., 2020).
- **simpleKT**: leverages a Rasch-inspired architecture to model question-specific variations and dot-product attention for modeling students’ sequential learning (Liu et al., 2023b).

4.3 Metrics and Experimental Setup

To quantitatively evaluate KT models in dialogue settings, we report Area Under the Curve (AUC) and Accuracy. We compute these metrics over all correctness labels except for the first label in each dialogue, since no prior observations are available for KT prediction at the initial step.

For our framework, we adopt Llama-3.1-8B-Instruct (Grattafiori et al., 2024) as the base model. We implement the model using the HuggingFace Transformers library (Wolf et al., 2020) and fine-tune it with LoRA (Hu et al.) on NVIDIA RTX L40 GPUs for efficient adaptation.

We perform a grid search to select hyperparameters for each model, choosing the checkpoint with the highest validation AUC to evaluate the test set. For LLM-based models, we search learning rates $\in \{1 \times 10^{-5}, 5 \times 10^{-5}, 1 \times 10^{-4}, 2 \times 10^{-4}\}$ and LoRA ranks $\in \{16, 32\}$ and fixing the LoRA scaling factor $\alpha = 16$. The effective batch size is 64 via gradient accumulation, with gradient clipping at 1.0. We train the models for 5 epochs using BFloat16 mixed precision. For other KT baselines, we search learning rates $\in \{1 \times 10^{-4}, 2 \times 10^{-4}, 5 \times 10^{-4}, 1 \times 10^{-3}, 2 \times 10^{-3}, 5 \times 10^{-3}\}$ and embedding sizes $\in \{8, 16, 32, 64, 128, 256, 512\}$. The batch size is 64 and the total epoch is 100, the remaining hyperparameters follow the default settings in pyKT (Liu et al., 2022). We train all models with AdamW optimizer with a weight decay of 1×10^{-2} .

5 Experimental Results

Model	QATD _{2k}		MathDial	
	Accuracy	AUC	Accuracy	AUC
Deep Learning-based Models				
DKT	60.19	54.73	59.75	63.14
DKVMN	58.24	51.79	56.42	60.64
SAINT	60.71	53.76	59.80	63.22
AKT	60.88	54.39	59.75	63.37
simpleKT	61.62	56.24	58.94	61.90
LLM-based Models				
LLMKT	<u>64.24</u>	<u>64.89</u>	<u>68.64</u>	<u>75.99</u>
Ours	64.29	65.25	68.82	76.59

Table 1: Student dialogue turn correctness prediction performance on QATD_{2k} and MathDial datasets. Best results are shown in **bold** and second-best results are underlined.

5.1 Quantitative Results

Table 1 shows the overall performance in terms of AUC and Accuracy for all models. We have the following observations: First, our proposed framework achieves the best overall performance and improves upon the previous state-of-the-art LLMKT model by explicitly modeling student ability, item difficulty, and combining them with IRT-based prediction. Specifically, our framework improves AUC from 64.89 to 65.25 (+0.36) on QATD_{2k} and from 75.99 to 76.59 (+0.60) on MathDial. These improvements suggest that explicitly

modeling question difficulty provides additional useful information for monitoring student learning progress. Although the performance gains are relatively modest, our framework introduces interpretable outputs, which we further analyze model interpretability in Section 5.3; Second, in general, LLM-based methods consistently outperform deep learning-based KT models in terms of both AUC and Accuracy, demonstrating the advantage of leveraging pretrained LLMs in dialogue-based KT settings. We attribute this improvement to the ability of pretrained LLMs to model rich textual content in dialogues, enabling us to better track student learning after fine-tuning on response correctness labels. Third, among deep learning-based KT methods, DKT achieves comparable performance with those complex architectures such as SAINT and AKT in both datasets. These results suggest that increasing architectural complexity does not necessarily yield significant performance gains. Instead, simpler architectures may generalize more effectively in dialogue-based KT settings, particularly under limited-data conditions (fewer than 2,500 dialogues), where complex models are more susceptible to overfitting.

5.2 Qualitative Analysis: Difficulty Analysis

To show that the learned difficulty parameters are indeed meaningful and interpretable, we measure the consistency between predicted KC difficulty and “ground-truth” KC difficulty. We use QATD_{2k} instead of MathDial for this analysis, since QATD_{2k} is collected from real-world educational environments and therefore better captures authentic tutor-student behaviors. Similar to (Lee et al., 2024), we follow classical test theory to define the ground-truth KC difficulty based on empirical correctness statistics as $1 - \frac{N_{\text{correct}}}{N_{\text{total}}}$, i.e., the portion of incorrect responses on this KC (Brown, 2013). To ensure a fair comparison, we normalize the predicted difficulty values using min-max normalization. As illustrated in Figure 3, the fitted regression line follows a similar increasing trend to the perfect agreement line, indicating that the predicted difficulty generally increases as the ground-truth difficulty increases. To quantitatively support this observed trend, we compute the Pearson correlation between predicted and ground-truth difficulty values across all KCs (Benesty et al., 2009). Results show a moderate positive correlation ($r = 0.368$, $p < 0.001$), suggesting that the learned difficulty parameters capture meaningful

Figure 3: Comparison of predicted and ground-truth KC difficulty across KCs in the test set of the QATD_{2k} dataset. Each point represents one KC. Point size is proportional to the number of samples associated with each KC. The dashed gray line indicates perfect agreement, while the solid blue line shows the fitted linear regression trend.

empirical difficulty patterns in real-world tutoring data across KCs.

5.3 “Learning Curve” Analysis

A common approach to evaluate KT quality is to examine whether predicted learning dynamics align with cognitive theories such as the power law of practice (Snoddy, 1926). Following prior work (Shi et al., 2023; Scarlatos et al., 2025a), we visualize learning trajectories of each KC. We use QATD_{2k} instead of MathDial for this analysis, since QATD_{2k} is collected from real-world educational environments and therefore better captures authentic tutor-student behaviors. Specifically, for each KC, we group student interactions by the number of prior opportunities to practice that KC, where an “occurrence” refers to each time the KC appears in a tutor-posed task within a dialogue. For each occurrence index, we compute the average predicted mastery across all corresponding dialogue turns in the test set. The resulting curves therefore illustrate how the estimated mastery evolves as students encounter the same KC multiple times.

We examine plots of the top three most frequent KCs, as they contain sufficient samples and provide the most intuitive visualization of learning trends. As shown in Figure 4, LLMKT, which directly treats predicted correctness probability as knowledge mastery, exhibits noticeable oscillations across KC occurrences. The predicted probability decreases even after repeated practice, suggesting unstable representations of student mastery. In con-

Figure 4: Learning trajectories for the three most frequent KCs in the QATD_{2k} dataset.

trast, our framework separates ability estimation from correctness prediction, resulting in smoother and more stable learning trajectories. The estimated student ability consistently increases with repeated KC occurrences across all three KCs, reflecting an increase in knowledge mastery that aligns with the cognitive theories of gradual learning (Ritter and Schooler, 2002).

Furthermore, fluctuations in predicted correctness probability from our framework are largely associated with changes in tutor-posed task difficulty. For example, temporary drops in predicted correctness probability often coincide with increases in estimated task difficulty, while the underlying ability continues to increase. Such fluctuations are expected in dialogue-based tutoring settings, where task difficulty may decrease when the tutor provides hints or scaffolding, and increase when the tutor switches to a different, more difficult part of the question or presses the student for a complete solution. Hence, our framework reflects realistic interactions between student learning progress and task difficulty. Similar trends observed across multiple KCs further demonstrate that our framework produces more stable and cognitively plausible learning dynamics than probability-based mastery estimation models such as LLMKT. We also provide learning trend visualizations at the dialogue level in Appendix B.

5.4 Qualitative Analysis: Case Study

We further conduct a qualitative case study to examine how the difficulty of tutor-posed tasks and the student’s knowledge state evolve in a dialogue in the QATD_{2k} dataset. Specifically, we analyze one representative dialogue from the test set. As shown in Table 2, the tutor dynamically adjusts the difficulty of the posed tasks based on the student’s responses. When the student fails to answer

correctly, the tutor decomposes the original question into simpler sub-tasks, leading to a decrease in the estimated task difficulty, from 0.671 to 0.360. In contrast, when the student answers correctly, the tutor proceeds with follow-up questions that maintain or slightly increase the difficulty level, moving the dialogue forward. Meanwhile, the student’s knowledge state demonstrates a generally increasing trend across the dialogue. Notably, even when incorrect responses occur, the estimated student ability continues to improve gradually with the tutor’s guidance, from 0.224 to 0.628 across the full dialogue. This observation highlights that learning progress may still occur despite temporary errors, as scaffolding and intermediate feedback from the tutor help consolidate the student’s KC understanding. Overall, this case study illustrates that our framework captures realistic tutoring dynamics, where task difficulty adapts to student performance while student ability evolves steadily through guided interaction.

6 Related Work

6.1 Student Modeling in Dialogues

Recently, with the emergence of LLM-based tutoring systems, several studies have explored KT in dialogue settings. Scarlatos et al. (2025a) leveraged the textual content in dialogues to estimate student knowledge. Wang et al. (2025) proposed a workflow that integrates KT with turn-by-turn verification to improve coding tutoring (Wang et al., 2025). However, these approaches overlook the modeling of question difficulty, which plays a critical role in KT. On the other hand, our approach introduces a difficulty-aware dialogue-based KT framework that explicitly aligns the student knowledge state and tutor-posed task difficulty, enabling fine-grained modeling of student state evolution. Beyond KT, recent studies have increasingly ex-

q	t_j	d_j	s_j	θ_j	r_j

Table 2: Case study of an adaptive tutoring dialogue illustrating how task difficulty (d_j) and student ability (θ_j) evolve over successive interactions in the QATD_{2k} dataset. The tutor dynamically scaffolds the problem by decomposing it into simpler sub-tasks following incorrect responses, while progressively maintaining or increasing difficulty after correct answers, leading to a gradual improvement in the student’s knowledge state.

plored LLM-based student simulation in educational dialogue settings. Prior work has demonstrated that LLMs can be used to simulate realistic student learning behaviors, including the development of learning curves and misconception patterns (Schmucker et al., 2024; Jin et al., 2024). Other studies simulate student behaviors conditioned on demographic, behavioral, and personality traits (Markel et al., 2023; Li et al., 2025a), as well as varying learning goals and trajectories (Sharma and Li, 2024).

6.2 Traditional Knowledge Tracing

Traditional KT models capture a student’s learning behavior in a sequence of her/his historical interactions, which consist of question tags, KC tags and binary responses (Chen et al., 2023; Liu et al., 2023a; Huang et al., 2023, 2026; Liu et al., 2025; Guo et al., 2026). For example, Piech et al. (2015) introduced the first DKT model, utilizing an LSTM to estimate knowledge mastery. Zhang et al. (2017) proposed a static key memory matrix to store KC relationships and a dynamic value memory matrix for predicting knowledge mastery levels. To incorporate the difficulty factor to enhance the knowledge state estimation, Ghosh et al. (2020) introduced a scalar difficulty parameter to control how far a question deviates from the underlying concept during question representation learning. Shen et al. (2022) established the relationship between student knowledge state and question difficulty level to improve KT performance. Liu et al. (2024) replaced question tags with difficulty levels to facilitate the translation of model predictions into interpretable

skill-level knowledge states, further highlighting the importance of difficulty modeling in KT.

7 Conclusion and Future Work

In this work, we introduce an interpretable difficulty-aware conversational KT framework that jointly models student ability and question difficulty in tutor-student dialogues. Our framework aims to capture fine-grained difficulty signals and provide more interpretable predictions of student performance, connecting LLM-based modeling with cognitively motivated assumptions. Quantitative results show modest improvements over existing KT baselines, suggesting the potential benefit of explicitly modeling both student ability and task difficulty. Empirical qualitative analyses provide further evidence for the interpretability of the learned parameters and indicate the value of incorporating an IRT predictor. In particular, the learned difficulty parameters show positive correlations with empirical difficulty statistics, suggesting that the model captures meaningful and cognitively plausible difficulty patterns across KCs. Additionally, the estimated ability trajectories often exhibit smooth growth patterns broadly consistent with gradual learning, while fluctuations in predicted correctness tend to correspond to changes in tutor-proposed task difficulty.

There are many avenues for future work. First, since we explicitly consider the difficulty factor in dialogue-based KT settings, we will further explore more effective methods for capturing fine-grained difficulty signals from tutoring dialogues and investigate how task difficulty evolves dynamically

during tutoring interactions. Second, for student knowledge state estimation, we plan to leverage advanced reasoning capabilities and reinforcement learning techniques to improve the accuracy and robustness of the estimation. In particular, future work will explore how multi-step reasoning can ensure consistency across dialogue turns and how reinforcement learning methods can refine estimation strategies based on long-term prediction performance. Third, we plan to explore misconception-aware conversational KT by detecting and tracking students' misconceptions from dialogue interactions. By integrating misconception signals with estimated knowledge states and difficulty parameters, the framework may provide more fine-grained and interpretable student performance prediction.

Limitations

There are several practical limitations to our work. First, since our work is the first to explicitly estimate the difficulty of tutor turns in dialogues, there are no existing difficulty prediction baselines we can compare against. Second, we only conduct experiments on math dialogues, and do not investigate other domains such as language learning or computer science. However, this is largely because KT in dialogues is currently only well-established in math. Finally, while our framework and other LLM-based approaches are significantly more accurate than traditional KT approaches, they are much more computationally expensive too. An important line of future work will be improving the efficiency of LLM-based approaches while maintaining high predictive accuracy.

Ethical Considerations

There are both potential societal benefits and risks associated with our work. Accurately modeling student ability and difficulty in dialogues is a necessary step to facilitating automated assessments in the dialogue setting. This can potentially benefit students through more accurate assessment and subsequently more targeted learning actions. However, as is the case with many other advances in educational AI, further automating assessments creates

a risk of replacing teachers' jobs. Our intention is for educational AI tools such as ours to be used in conjunction with teachers to improve outcomes for students, rather than be used to replace teachers. Finally, there is a risk of bias in our framework, as is common in all AI methods, due to inherent biases in training data. For instance, it is possible that students from populations that are less represented in training data are given less accurate assessments, therefore risking worse outcomes for those students. It is important that educational AI tools are thoroughly screened for bias before deployment with real students.

A Prompts

A.1 Prompt for Knowledge Estimation

You are an experienced math teacher. Given a dialogue where the student is working through a multiple-choice diagnostic math question, based on the student’s responses and demonstrated understanding in the dialogue, classify the student’s current ability level. Respond with exactly one token from: GOOD BAD.

[BEGIN QUESTION]
Question Text
[END QUESTION]

[BEGIN DIALOGUE]
Dialogue Context
[END DIALOGUE]

Specifically, the input prompt I^K consists of the following three key components:

- **Task Definition:** A natural language instruction that defines the task and specifies the expected output format for the LLM.
- **Question Text:** The diagnostic question presented to the student, typically enclosed within structured markers [BEGIN QUESTION] and [END QUESTION].
- **Dialogue Context:** The historical teacher–student interaction associated with the question, enclosed within markers [BEGIN DIALOGUE] and [END DIALOGUE].

Figure 5: Learning trajectories for dialogues in the QATD_{2k} dataset.

A.2 Prompt for Difficulty Estimation

You are an experienced math teacher. Given a dialogue where the student is working through a multiple-choice diagnostic math question, based on the question content and required knowledge components, classify the question’s difficulty level. Respond with exactly one token from: HARD EASY.

[BEGIN QUESTION]
Question Text
[END QUESTION]

[BEGIN DIALOGUE]
Dialogue Context
[END DIALOGUE]

[BEGIN CURRENT TEACHER TURN]
Teacher-posed Task
[END CURRENT TEACHER TURN]

[BEGIN KC]
KC Names
[END KC]

Specifically, the input prompt I^D consists of the following two key components:

- **Teacher-posed Task:** The next teacher-posed question that the student is expected to respond to is enclosed within markers [BEGIN CURRENT TEACHER TURN] and [END CURRENT TEACHER TURN], representing the immediate task used for predicting the student’s knowledge state.
- **KC Names:** The associated KCs with the next tutor-posed task enclosed within markers [BEGIN KC] and [END KC]. The model must infer

from prior interactions whether the student has mastered the required knowledge.

B Additional “Learning Curve” Analysis

We provide learning curve analysis based on dialogue level in Figure 5.

Rubrics as Semantic Subspaces: A Unified Approach to Rubric-based Constructed Response Scoring across Short Answers and Essays

Abstract

Rubrics are the primary reference for manual scoring of constructed responses, and there is growing interest in their use in automated scoring methodologies. In this work, we propose Aspect-Grounded Rubric-Answer Alignment (AGRAA), a rubric-based end-to-end scoring framework that models rubric descriptors as latent aspect spaces. Concretely, rubric descriptors are represented as low-dimensional subspaces derived from contextualised transformer embeddings, and student responses are scored according to how strongly their representations align with these rubric-induced spaces relative to the residual space outside them. This formulation provides a geometrically grounded interpretation of rubric-based scoring while enabling end-to-end training with standard transformer encoders. We introduce three distinct architectural variants and evaluate them on multiple short-answer and essay scoring datasets. Across these tasks, AGRAA achieves predictive performance highly competitive with strong neural and feature-based baselines. In addition, the framework yields interpretable intermediate representations that expose which rubric-defined aspects contribute to scoring decisions, enabling decision-aligned explanations grounded in rubric descriptors.

1 Introduction

Rubric-based scoring plays a central role in assessing constructed responses in educational settings. Rubrics describe performance using qualitative criteria that enable fine-grained evaluation of responses (Reddy and Andrade, 2010). As automated constructed-response assessment becomes increasingly important in digital learning environments (Mello et al., 2024) and large-scale testing (Zehner et al., 2025), there is growing interest in methods that can automatically score responses while leveraging the criteria defined in the rubrics (Sonkar et al., 2024; Wang et al., 2019; Gombert

et al., 2026; Cong et al., 2026; Sreedevi et al., 2026; Eltanbouly et al., 2025).

Across domains and response types, rubrics typically describe performance in terms of aspects such as conceptual correctness, completeness, use of evidence, or argumentative quality (Reddy and Andrade, 2010). These aspects are usually distributed across the response rather than localised to individual words or spans. For example, a science rubric might require identifying oxidation, explaining oxygen exposure, and linking the process to the observed color change in an apple. Scoring therefore amounts to estimating how strongly a response expresses the aspects associated with each rubric level.

In this work, we frame rubric-based scoring as a form of *neural subspace classification* (Fukunaga, 2013; Fukui, 2021) on top of contextual embeddings produced by transformer encoder models. Each rubric level defines a low-dimensional semantic subspace derived from the dominant directions of variation in its textual representation. These directions can be interpreted as latent aspects of the rubric. Student responses are projected into these rubric-induced spaces, and scoring is implemented by measuring how much of the response representation lies within each rubric subspace relative to the residual space outside it. The summarised contributions of this paper are:

- We introduce **AGRAA**, a rubric-based representation learning framework that aligns student responses with rubric descriptors through subspace-based similarity, enabling rubric-aware scoring decisions that expands upon earlier ideas introduced by Gombert et al. (2026).
- We propose three architectural variants: a *bi-encoder* formulation (Bi-AGRAA), a *level-wise cross-encoder* formulation (Cross-AGRAA), and a *joint cross-encoder* formulation (Joint-Cross-AGRAA) that allows direct

interaction between rubric levels during representation learning.

- Through experiments on multiple short-answer and essay scoring datasets, we demonstrate that rubric-based subspace alignment achieves **competitive predictive performance** while providing transparent, rubric-aligned explanations of model decisions.
- We show that the approach yields **interpretable intermediate representations** that reveal which aspects within rubric descriptors contribute to a prediction.

2 Background

2.1 Automated Assessment of Constructed Responses

The automated assessment of constructed responses is a long-established research branch in educational natural language processing (Bai and Stede, 2022; Burrows et al., 2014; Bexte et al., 2024). In prior research, two genres of constructed responses, namely essays and short answers, were the main research focus, with distinct research trajectories for both genres (Bai and Stede, 2022). While short answer scoring mainly focuses on the content of given answers ("content scoring") (Bexte et al., 2024; Ziai et al., 2012), essay scoring is mainly focused on writing-level traits such as coherence, grammar, argumentation, or style (Bai and Stede, 2022), although there is some work that instead deals with essay content scoring (Gombert et al., 2024).

2.2 Rubrics in Automated Short Answer Scoring (ASAS)

Scoring rubrics have previously been explored as inputs to automatic short-answer scoring systems. Wang et al. (2019) proposed a BiLSTM-based architecture that computes word-level alignment scores between tokens in a student response and tokens in rubric descriptors. They showed that incorporating rubric information improves performance compared to a plain BiLSTM-based scoring model introduced by Riordan et al. (2017), particularly in low-resource settings. These results provide early evidence that explicit modeling of rubric information can benefit automatic short-answer scoring.

Gombert et al. (2026) proposed two architectures for rubric-based short answer scoring. Both architectures use attention to calculate alignment

scores between responses and rubric descriptors using embeddings from transformer encoder models. The performance level whose corresponding rubric has the highest alignment to a given response is assigned as the final score. The variants differ in how alignment is calculated, on top of mean-pooled span embeddings or between the embeddings of individual rubric descriptor and response tokens.

Cong et al. (2026) and Wei et al. (2025) evaluated the utility of rubrics for short answer scoring when using LLM in-context learning. In both cases, providing the LLM with rubrics significantly improved performance compared to a baseline without rubrics and was more beneficial than providing simple few-shot examples.

2.3 Rubrics in Automated Essay Scoring

Sreedevi et al. (2026) proposed a rubric-aware neural architecture for automated essay scoring that explicitly incorporates analytic rubric criteria into the modeling process. Essays are encoded using contextual embeddings augmented with discourse information. These discourse-aware essay representations are then connected to rubric traits through trait-specific attention mechanisms, enabling the model to learn rubric-conditioned representations of essay quality. The model jointly predicts both holistic essay scores and rubric-level trait scores, with the rubric acting as a structured supervisory signal that guides the decomposition of essay quality into interpretable evaluation dimensions.

Eltanbouly et al. (2025) implemented an essay scoring framework that uses LLMs to extract features from given rubrics that are then used in a feature-based statistical classifier. Concretely, they prompt LLMs to transform given rubrics into binary yes-no questions that ask whether a given rubric-defined aspect is fulfilled by the essay or not. In the next step, the LLM is prompted to answer these individual questions. The resulting binary features are used as input features for a logistic regression classifier.

3 Aspect-Grounded Rubric-Answer Alignment (AGRAA)

Rubrics typically describe the quality of the answer in terms of qualitative criteria such as conceptual correctness, completeness, use of evidence, or quality of the explanation (Reddy and Andrade, 2010; Popham, 1997). Importantly, these descriptions rarely correspond to a single lexical cue or an iso-

Figure 1: A schematic depiction of both architectures. SVD = Singular Value Decomposition. Questions are included as context in each forward pass.

lated fact. Instead, rubric levels implicitly refer to *aspects* that characterise responses at different quality levels (Popham, 1997). For example, a “correct” rubric level in a science task may simultaneously require the identification of a process, explanation of a mechanism, and appropriate use of domain terminology. These aspects are distributed across the response (Popham, 1997) and can be realised through a wide range of linguistic expressions (Kreidler, 1998).

Student responses also do not express rubric-relevant aspects in a single location. Rather, aspects are typically distributed throughout the text and expressed with varying degrees of completeness and clarity. We therefore can interpret both rubric levels and student responses as *configurations of aspects*. Each rubric level defines a set of aspects expected for that level, while each response expresses these aspects to varying degrees. The central task of rubric-based scoring can thus be framed as estimating how strongly a response expresses the aspects associated with each rubric level. Therefore, our approach is based on three core assumptions:

1. Each rubric level descriptor defines a set of latent aspects.
2. The responses express these aspects with varying strength.
3. Scoring corresponds to measuring the align-

ment between the aspects defined in the rubric and their materialisation in a given response.

Based on these assumptions, we implemented *AGRAA*, an architectural framework for end-to-end scoring of constructed responses grounded in subspace classification methodology (Fukui, 2021).

3.1 Encoder and Asymmetric Projection

Given a question/item q and a response a , we aim to predict the correct performance level $0, \dots, i$ for answer a based on the qualitative criteria described in rubric R consisting of performance level-wise descriptors $r_0, \dots, r_i$. For this purpose, we consider three architectural variants that differ in how contextual interactions between the response and the rubric are modeled. Figure 1 depicts these variants schematically.

Bi-AGRAA. The first variant is a *bi-encoder* setup (*Bi-AGRAA*), where the response and each rubric level are encoded independently. In this case, the response representation is shared across all rubric levels. The question is added as contextual input at each forward pass but masked during all downstream processing steps.

Cross-AGRAA The second variant is a *level-wise cross-encoder* setup (*Cross-AGRAA*), where the encoder jointly processes the response together with a single rubric level at a time. This produces response representations that are conditioned on the

rubric level under consideration. The question is added as contextual input at each forward pass but masked during all downstream processing steps.

Joint-Cross-AGRAA The third variant is a *joint cross-encoder* setup (*Joint-Cross-AGRAA*), where the question, response, and all rubric levels are encoded together in a single forward pass. This allows for direct contextual interaction between rubric levels while producing a single globally contextualised response representation. The question is added as contextual input at each forward pass, but is masked for all downstream processing steps. This is the exact setup used by [Gombert et al. \(2026\)](#) for their architectures.

In all variants, functional tokens such as CLS or SEP are masked for all following computations to prevent the models from learning uninterpretable shortcuts involving these tokens. Moreover, all tokens of q are masked for all steps after encoding. Each of the three variants yields contextualised embeddings for response and rubric tokens:

$$H_a \in \mathbb{R}^{T_a \times d}, \quad H_{r_i} \in \mathbb{R}^{T_{r_i} \times d} \quad (1)$$

In these, d denotes the encoder hidden size. To account for the different functional roles of rubric and response text (the former describes in which aspects a correct response materialises, while the latter is a concrete materialisation), we apply asymmetric linear projections into a shared comparison space of dimension l :

$$X_a = H_a W_a + B_a, \quad X_a \in \mathbb{R}^{n_a \times l} \quad (2)$$

$$X_{r_i} = H_{r_i} W_r + B_r, \quad X_{r_i} \in \mathbb{R}^{n_{r_i} \times l} \quad (3)$$

Separate projection layers allow rubric tokens to define aspect directions while response tokens are evaluated relative to these directions.

3.2 Rubric-induced Aspect Spaces

On top of the three underlying encoding approaches, we use the same specialised head, which can be viewed as a neural subspace classifier ([Fukunaga, 2013](#)) in which each rubric level descriptor defines a semantic subspace of one or more latent aspects. In this perspective, scoring corresponds to a form of nearest-subspace classification where responses are assigned to the rubric level whose semantic subspace best explains their representation. We estimate these aspects by constructing a low-dimensional subspace from the rubric token embeddings. Given projected rubric token embeddings

X_{r_i} , we compute a singular value decomposition:

$$X_{r_i} = U_i \Sigma_i V_i^\top \quad (4)$$

The right singular vectors define orthogonal directions in the projection space capturing dominant semantic variation within the rubric text. We interpret these directions as latent aspects. To determine the number of aspects a given rubric descriptor contains, which of course differs from descriptor to descriptor, we retain the smallest number of singular directions explaining a fixed proportion of variance τ (e.g., 0.9), capped by a maximum number of aspects $k_{\max}$. Both need to be set as hyperparameters depending on the granularity of the rubrics at hand:

$$k_i = \min\left(\{k_{\max}\} \cup \{k : \frac{\sum_{j=1}^k \sigma_{ij}^2}{\sum_j \sigma_{ij}^2} \geq \tau\}\right) \quad (5)$$

This yields an orthonormal basis $Q_i \in \mathbb{R}^{l \times k_i}$ representing the aspect space associated with rubric level i , together with singular values σ_{ij} .

3.3 Response-to-Aspect Alignment

To evaluate how strongly a response expresses each rubric aspect, we project response token embeddings into the rubric-induced subspace:

$$A_i = X_a Q_i \in \mathbb{R}^{n_a \times k_i} \quad (6)$$

Each column of A_i represents the strength with which the response tokens align with a particular rubric aspect. To quantify how well a response can be expressed within the rubric-induced aspect space, we compute the proportion of response variance explained by this subspace. Let

$$E_{\parallel,i} = \frac{1}{n_a} \|A_i\|_F^2 \quad (7)$$

denote the energy of the response within the rubric-induced subspace, and

$$E_{\text{tot}} = \frac{1}{n_a} \|X_a\|_F^2 \quad (8)$$

The total response energy in projection space. The residual energy outside the rubric subspace is:

$$E_{\perp,i} = E_{\text{tot}} - E_{\parallel,i}. \quad (9)$$

We then define the alignment between a response and rubric level i as the log-ratio between the energy explained by the rubric-induced subspace and the residual energy outside the subspace, a form closely related to the classical subspace classification criteria in statistical pattern recognition ([Fukunaga, 2013](#)):

$$s_i = \log \frac{E_{\parallel,i} + \varepsilon}{E_{\perp,i} + \varepsilon}. \quad (10)$$

3.4 Classification and Training

The predicted scores are obtained by an argmax in all $s_0, \dots, s_i$:

$$\hat{y} = \arg \max_i s_i. \quad (11)$$

The model is trained end-to-end using softmax cross-entropy loss over these alignment scores.

Aspect distribution regularisation. While the above objective optimises predictive performance, early pre-experiments showed that the resulting models often collapsed onto one dominant “master” aspect that largely determined correctness, while the remaining directions acted as residual aspects without a clear function. This constitutes a learned shortcut. However, as stated earlier, rubrics typically describe performance across multiple aspects. To encourage the model to better reflect this multi-aspect structure, we introduce an additional regularisation term to the loss function that promotes a more distributed use of rubric-based semantic directions.

To obtain a direction-level summary of how strongly each aspect contributes to the alignment with a rubric unit, we first compute pooled per-direction alignment values:

$$e_{i,j} = \sqrt{\frac{1}{\alpha} \ln \sum_{t=1}^{n_a} \exp(\alpha (A_i)_{t,j}^2)}. \quad (12)$$

These values summarise the strongest token-level evidence for each semantic direction. We then derive a normalised distribution over aspect contributions

$$p_k = \frac{e_{i,k}}{\sum_{m=1}^{k_i} e_{i,m}}, \quad (13)$$

and compute its entropy

$$\mathcal{H}(p) = - \sum_{k=1}^{k_i} p_k \log p_k. \quad (14)$$

In practice, this entropy is normalised with respect to the number of retained directions and is used as a soft constraint: the model is penalised only when the aspect distribution becomes too concentrated, that is, when its entropy falls below a predefined target range. This encourages the model to make use of multiple rubric-defined semantic directions without forcing all directions to contribute equally. Because regularisation operates only on the dynamically retained directions for a given rubric unit

through variance-based subspace construction, it promotes a balanced use of the available semantic directions without forcing the model to use the maximum possible number of aspects in every case. The final loss function is defined as

$$\mathcal{L} = \mathcal{L}_{\text{CE}} + \lambda \mathcal{L}_{\text{ent}}, \quad (15)$$

where $\mathcal{L}_{\text{ent}}$ denotes the entropy-based penalty and λ controls its strength.

3.5 Interpretability

To obtain decision-aligned explanations, we decompose the final prediction into contributions of individual aspects. Let $e_{i,j}$ denote the pooled response energy along the aspect j of rubric level i (as defined in equation 12), and $w_{i,j}$ the corresponding normalised singular-value weight. Within each rubric level, aspect contributions are computed as:

$$\tilde{c}_{i,j} = \frac{w_{i,j} e_{i,j}^2}{\sum_{m=1}^{k_i} w_{i,m} e_{i,m}^2}. \quad (16)$$

To align the explanation with the model’s cross-level decision, these quantities are weighted by softmax-normalised level scores:

$$c_{i,j} = \text{softmax}(s)_i \cdot \tilde{c}_{i,j}. \quad (17)$$

The values $c_{i,j}$ sum to one across all levels and aspects and therefore directly quantify how much each rubric-defined semantic direction contributed to the final classification. The resulting visualisations make explicit which rubric aspects drove the decision and which rubric tokens characterise these aspects (see Figure 2). This yields a decision-aligned explanation in terms of rubric semantics. Because explanations are derived directly from the same projected response representations used in the scoring function, the resulting aspect contributions reflect the internal evidence underlying the model’s decision rather than a post-hoc approximation.

3.6 Applicability across response types

Given a long-context encoder is used as backbone, the architecture can support constructed response types of varying length. Short answers and essays, as the most important types of written constructed responses, differ primarily in the number, focus, and complexity of aspects expressed, as well as in overall length. This can be accommodated by adjusting the maximum number of retained aspect directions k_{max} .

(2026) and report dataset-wide metrics for the unseen answers and unseen questions evaluation sets. P = Weighted Precision. R = Weighted Recall. F1 = Weighted F1. QWK = Quadratic Weighted Kappa. UA = Unseen Answers subset. UQ = Unseen Questions subset.

4 Evaluation

Following the definitions from Murdoch et al. (2019), we evaluate the models for both *predictive* and *descriptive* accuracy. While predictive accuracy refers to the predictive performance of models, descriptive accuracy concerns whether these models make predictions for plausible reasons, i.e., whether plausible aspects are extracted from the rubrics and whether the calculated alignment matches what is stated in a given input answer. Our evaluation, therefore, addresses two concrete research questions:

RQ1. What is the *predictive accuracy* of the three AGRAA variants?

RQ2. Are the models faithful in terms of *descriptive accuracy* in regard to the content of answers and rubrics?

For the first research question, we measure prediction quality, while for the second research question, we qualitatively analyzed 64 randomly selected examples from the unseen-answers evaluation set of the *ALICE-LP* dataset (see next section) for each model variant (Bi-AGRAA, Cross-AGRAA, Joint-Cross-AGRAA).

4.1 Datasets

For our experiments, we used two datasets for short-answer scoring and one for holistic essay scoring, namely *ALICE-LP*, *ASAP-SAS*, and *PERSUADE 2.0*. In every evaluation, the models are trained on the whole respective dataset.

ALICE-LP 1.0. This short answer scoring dataset was first introduced by Gombert et al. (2026) and includes 13,075 German short answers to 118 questions from four different STEM domains collected in German middle and high schools. All answers are rated on a three-point

scale following question-specific rubrics. It is divided into a test and two evaluation sets. One of these contains answers to questions seen during training (*unseen answers*), while the other contains answers to questions unseen during training (*unseen questions*).

ASAP-SAS. This short-answer scoring dataset was first introduced in the context of a 2012 Kaggle competition (Barbara et al., 2012) and has since grown into a widely used benchmark for automated short-answer scoring. It comprises 22,067 English answers to a total of ten different questions with question-specific rubrics, including both STEM and reading comprehension questions, collected at US-American schools.

PERSUADE 2.0. This essay scoring dataset was first introduced by Crossley et al. (2024). It comprises 25,996 argumentative essays written in English for 15 different prompts. It includes holistic scores on a 6-point scale, as well as analytic scores for multiple argumentation-related criteria on a 3-point scale. In this work, we focus on predicting the holistic scores. The dataset contains source-based and independent writing prompts, both of which are scored using slightly different rubrics.

4.2 Backbone Models, Hyperparameters and Baselines

As backbone models, we used *ModernBERT* (Warner et al., 2025) variants. *ModernBERT* is a modified variant of the original *BERT* architecture that supports long-context processing with the help of RoPE embeddings (Su et al., 2024). For the German *ALICE-LP* set, we use *ModernGBERT-1B* (Wunderle et al., 2025), a German-specific *ModernBERT* (Warner et al., 2025) variant, while for the English *ASAP-SAS* and *PERSUADE 2.0*, we use the regular *ModernBERT-large* (Warner et al., 2025). As baselines, we employ two classifier vari-

Table 2: Results achieved for the ASAP-SAS dataset. We follow the evaluation protocol used by Riordan et al. (2019), Kumar et al. (2019), Gombert et al. (2026), and Ormerod (2022) to report question-wise Quadratic Weighted Kappa scores, which are then averaged using the arithmetic (QWK_m) as well as the Fisher-weighted (QWK_F) mean.

ants of these models. For the first variant, a given classifier receives a response and the corresponding question/item prompt, and for the second variant, the classifier is also given the full rubrics. For *ALICE-LP* and *ASAP-SAS*, we set $k_{\max} = 3$, and for *PERSUADE 2.0*, we set $k_{\max} = 12$, based on a manual inspection of the number of aspects contained in the corresponding rubric descriptors. We set $\tau = 0.9$, $\lambda = 0.2$, and $\alpha = 5.0$ in all cases. Training was run for 12 epochs with a learning rate of $1e-5$, a weight decay of 0.1, gradient clipping set to 1.0, a batch size of 16, and early stopping active using *AdamW* as optimiser. We report results for the best checkpoint per run.

5 Results

5.1 Predictive Accuracy

Across all evaluated datasets, the proposed AGRAA variants achieve competitive predictive performance. When compared against conventional classifier architectures built on the same underlying backbone models, several AGRAA variants consistently match or outperform these baselines. On the *ALICE-LP* dataset, *Joint-Cross-AGRAA* reaches performance comparable to the previously reported *ToLeGRAA* model on the unseen answers setting, while all AGRAA variants outperform both rubric-aware and rubric-free classifier baselines implemented with the same encoder. On the *ASAP-SAS* dataset, the AGRAA variants likewise improve over the corresponding classifier baselines and achieve results competitive with strong published neural and feature-based systems, with *Joint-Cross-AGRAA* and *Cross-AGRAA* closely approaching the best reported aggregate QWK scores. On the essay scoring dataset, the proposed models perform on par with or slightly

Approach	P	R	F1	QWK
ModernBERT-large Cross-AGRAA	.694	.693	.691	.878
ModernBERT-large Joint-Cross-AGRAA	.690	.689	.688	.873
ModernBERT-large Bi-AGRAA	.672	.668	.666	.866
ModernBERT-large Class. (Q+A+Ru)	.681	.679	.675	.869
ModernBERT-large Class. (Q+A)	.668	.667	.664	.864
DeBERTa-v3 Class. (Ravindran and Choi, 2025)	-	-	-	.870
ModernBERT Class. (Ormerod, 2025)	-	-	-	.868

Table 3: Results achieved for the *PERSUADE 2.0* dataset. We report weighted precision (P), weighted recall (R), weighted F1 score, and quadratic weighted Kappa.

above strong transformer-based baselines.

Taken together, these results indicate that the rubric-based subspace formulation underlying AGRAA can match, and, in several cases, exceed the predictive performance of conventional classifier formulations using the same encoder backbones.

5.2 Descriptive Accuracy

Overall, the Bi-AGRAA and Joint-Cross-AGRAA variants frequently decomposed rubric representations into several semantically meaningful aspects that corresponded to distinct rubric criteria or conceptual components.

Across most inspected visualisations, the extracted aspects highlighted meaningful content words from the rubric descriptors as well as modifiers associated with them, such as determiners or descriptive adjectives (e.g., *die*, *der*). This suggests that the learned semantic directions are anchored in linguistically and semantically plausible parts of the rubric descriptors.

Figure 2 illustrates an explanation produced by the *Joint-Cross-AGRAA* model. Within the predicted rubric level, three aspects that characterise the expected reasoning are visible. The

Figure 2: This figure shows an example of the aspect contributions with a correct answer from the ALICE-LP dataset the system rightfully judged as correct. Each bar represents the $c_{i,j}$ (see Equation 17) for a given score s_i (see Equation 10) and a given aspect j for a Cross-AGRAA *ModernGBERT*-1B model trained with $k_{max} = 3$. Since the model is highly confident, there are only bars visible in the correct cell. For each aspect, we show the four most characteristic words from the respective rubric.

most influential aspect is associated with the token *beschreiben*, reflecting the rubric requirement that the response should provide a description. A second aspect is characterised by tokens such as *Zeit*, *Volumen*, and *Funktion*, corresponding to the rubric requirement that the gas volume should be interpreted as a function of time. A third aspect reflects observational terminology such as the adjective *entscheidende* in *Beobachtung*, capturing the emphasis on identifying the gas development as the key phenomenon. The student response indeed describes how the gas development changes over time (“*Gasentwicklung ... nimmt aber mit der Zeit ab*”), which aligns closely with these rubric-defined aspects, suggesting that the extracted directions correspond to semantically meaningful components of the rubric. Across all the inspected examples, we could observe similar patterns of align

dicating that cross-attention between rubric descriptors as well as between rubric descriptors and answers is needed to best differentiate between performance levels. Overall, we can conclude that neural subspace classification as employed for **AGRAA** can be seen as beneficial for predictive performance in rubric-based constructed response scoring.

Moreover, the subspace formulation yields interpretable intermediate representations that expose how rubric-defined aspects contribute to scoring decisions. Qualitative analysis indicated that these aspects frequently correspond to meaningful rubric aspects, suggesting that the learned semantic directions capture pedagogically relevant structure present in the rubrics. However, it needs to be confirmed whether this pattern holds up across varied models and datasets, which needs to be the objective of future work.

6 Discussion

The experimental results suggest that rubric-based scoring can be effectively framed as a subspace alignment problem between responses and rubric descriptors. Across three datasets covering short answer- and essay scoring, the proposed **AGRAA** variants achieved predictive performance stronger than plain transformer classifier baselines in the majority of cases. The strongest among these across all datasets is the **Joint-Cross-AGRAA** variant, in-

Limitations

Several limitations remain. First, the interpretability analysis in this work is primarily qualitative and future work could investigate quantitative measures of explanation quality. Second, the number of retained semantic directions is controlled through global hyperparameters, which may not always perfectly reflect the conceptual granularity of a given rubric. We did not conduct an extensive hyperparameter search. A small-scale stability analysis (see

Appendix) revealed that the predictive performance stays stable under varied hyperparameters, but may experience drops for certain configurations. Finally, the approach assumes that rubric descriptors sufficiently capture the semantic structure of the scoring task, which may not hold for poorly specified rubrics. Therefore, future work would need to test the relationship between variables such as linguistic and conceptual uncertainty within rubrics and the resulting predictive performance.

Ethical Statement

Automatic constructed response scoring is an educational NLP task. The EU AI act (European Parliament and Council of the European Union, 2024) labels AI technology (including NLP technology) in education rightfully as a high-risk application. While the individual risk depends highly on the exact context in which the corresponding technology is used and must be assessed case-by-case, mispredictions can tremendously impact learner success even in low-stakes scenarios.

For example, there is clear empirical evidence that negative feedback (and the predicted performance levels, if low, are nothing but that, if presented to a given learner) can hurt the intrinsic motivation of learners (Fong et al., 2019). If a system based on one of our presented approaches wrongly scores correct answers as wrong, learner motivation might thus unnecessarily suffer. Even worse, when such mistakes happen in high-stakes assessments, it might negatively affect students' overall life path since, in many countries, access to university programs and jobs is highly coupled with assessment results, e.g., in the form of GPA scores. Deployment in such scenarios, therefore, requires extensive evaluation.

On the other hand, if a model is, for example, used in formative assessment and mispredicts a given wrong student answer as being correct, the corresponding student might not revise possible misconceptions present in their answer. If this happens too often throughout a given unit, students might develop misunderstandings about the content. Moreover, there is already existing research on teacher dashboards that comprehensively summarise student performance so teachers can plan interventions based on that (Karademir et al., 2024). If a non-reliable short-answer scoring system powers such a dashboard, teachers might make incorrect interventions, which, in turn, could harm stu-

dent learning.

Another aspect that needs to be further assessed, which was out of the scope of this particular study, is whether the underlying models replicate undesired biases. An example of this might be a possible bias against students with dysgraphia or dyslexia. If dyslexic or dysgraphic writing is not sufficiently represented in a given training set, systems might encounter problems dealing with the same, hurting downstream predictive performance for student answers formulated by affected students.

A Appendix

Sensitivity analysis of $k_{\max}$ and λ . To examine the sensitivity of the model to the two central structural hyperparameters, we conducted a targeted ablation for *Joint-Cross-AGRAA* on the ALICE-LP unseen-answers setting. We varied the cap on the number of retained rubric directions $k_{\max} \in \{3, 4, 5, 6\}$ and the entropy regularisation weight $\lambda \in \{0.0, 0.2, 0.6\}$ while keeping all other

Figure 3: QWK results for the different $k_{\max}$ and λ combinations.

hyperparameters fixed. Due to computational constraints, the analysis was performed with a single random seed and should therefore be interpreted as a compact sensitivity check rather than an exhaustive hyperparameter search. Across most configurations, performance remains within a relatively narrow range, with some outliers present. This suggests that $k_{\max}$ and λ can influence performance and should therefore not be set randomly, but overall, the model is able to handle varying configurations of these hyperparameters.

Domain-Adaptive Pre-training for Automated Short Answer Grading in Conceptual Physics: Reliability, Question-Level Analysis, and Error Reduction

Abstract

Automated short answer grading (ASAG) has attracted increasing research attention as a potential tool to support teachers in evaluating student responses. However, the usefulness of such systems depends on how reliably they operate under realistic classroom constraints, where only limited numbers of graded responses may be available for each question. This study investigates automated grading of conceptual physics explanations from free-response questions derived from the Force Concept Inventory (FCI), a diagnostic tool for assessing understanding of mechanics concepts.

We compare a standard BERT-based grading model with a version further adapted through subject-specific pre-training on physics textbook materials. Building on prior work showing that BERT representations for ASAG can be improved through continued pre-training on domain resources, we do not propose a new adaptation method; instead, we evaluate its reliability in a classroom-derived conceptual physics setting. The models are evaluated across varying training set sizes to examine how domain adaptation affects performance when labelled data is limited. Our results show that domain-adaptive pre-training provides the largest gains in low-data conditions, improving classification accuracy and reducing grading errors. As more labelled responses become available, the difference between the models decreases. This suggests that subject-specific pre-training primarily improves data efficiency rather than the best achievable performance.

Error analysis shows that the performance gains come from real reductions in grading mistakes. When comparing both models, the improved model corrects substantially more baseline errors than it introduces new ones, with a fixed-to-broken ratio of 4.61, indicating a clear net reduction in grading errors. This suggests that the improvement primarily reflects net error reduction rather than simply shifting mistakes.

However, improvements vary across individual assessment questions, highlighting the importance of question-level evaluation when deploying automated grading systems in classroom environments. These findings indicate that, relative to a general BERT baseline, textbook-based continued pre-training can support educational assessment.

1 Introduction

Automated Short Answer Grading (ASAG) systems are increasingly explored as tools for supporting student assessment by reducing marking workload and enabling timely feedback to students (Seneviratne and Manathunga, 2025). In real educational settings, however, automated grading systems operate under constraints that differ substantially from those typically considered in benchmark-driven experimental evaluations (Bonthu et al., 2021). When new questions are introduced or when assessments are administered to small cohorts, teachers often have access to only limited numbers of previously graded responses for each assessment question (Egaña et al., 2023). Under such conditions, automated grading systems must operate reliably with minimal task-specific supervision while still producing grading decisions consistent with human evaluation (Morris et al., 2025).

Several approaches have been proposed to improve model performance under limited supervision, including data augmentation, semi-supervised learning, and transfer learning (Bonthu et al., 2021; Burrows et al., 2015). In this work, we focus on domain-adaptive pre-training (DAPT) (Beltagy et al., 2019; Lee et al., 2020) where a pre-trained language model is further trained on domain-relevant text before task-specific fine-tuning (Gururangan et al., 2020). DAPT is an established method, and its use for ASAG has direct precedent: Sung et al. (2019) showed that BERT for short

answer grading can be improved by updating the pre-trained model using domain resources such as textbooks and question-answer data before supervised fine-tuning. Our contribution is therefore not a new adaptation algorithm. Instead, we examine whether textbook-based DAPT improves grading reliability relative to a general BERT baseline in a classroom-derived conceptual physics setting, especially when only limited labelled responses are available per question. The evaluation focuses on binary grading of held-out responses to the same assessment questions, rather than partial-credit scoring or transfer to unseen questions. We further analyse whether improvements correspond to net reductions in grading errors, how gains vary across questions, and whether the adapted model provides better calibrated confidence estimates.

In educational assessment, grading performance must be evaluated not only by predictive accuracy but also by reliability, as automated systems support decisions that influence feedback and student evaluation (Holmes et al., 2021). When comparing automated grading models, it is important to determine whether improved performance reflects a net reduction in grading errors, rather than a redistribution of errors across responses. Furthermore, grading reliability may vary across assessment questions due to differences in conceptual difficulty or response distributions, making question-level analysis important for evaluating automated grading systems in practice (Zhu et al., 2022).

This study investigates automated grading of conceptual physics explanations from free-response questions based on the FCI, a widely used diagnostic instrument in physics education (Hestenes et al., 1992; Hestenes and Halloun, 1995). Many ASAG studies rely on proprietary datasets, which can limit reproducibility and comparability across studies. In this work, we instead use FCI-based conceptual free-text questions, which are widely recognised and explicitly designed to probe common misconceptions in mechanics (Parker et al., 2023; Pathak et al., 2026). This established conceptual framework enables a more meaningful analysis of how domain-adaptive language modelling interacts with disciplinary reasoning tasks.

We address the following research questions:

- RQ1. When only limited numbers of graded student responses are available for the same assessment questions, does textbook-based

DAPT improve binary ASAG reliability relative to a general BERT baseline?

- RQ2. When model performance improves, do these gains reflect consistent reductions in grading errors across questions, or do they arise from improvements in some questions offset by declines in others?

This study makes three contributions:

- We provide a reliability-focused evaluation of textbook-based DAPT for ASAG in a classroom-derived conceptual physics setting, using free-response questions derived from the Force Concept Inventory.
- We analyse how textbook-based DAPT changes grading behaviour relative to a general BERT baseline under limited labelled data by comparing learning curves, agreement metrics, calibration, and error-overlap patterns across 26 training-set sizes and 10 random seeds.
- We examine question-level variation in grading behaviour to identify whether improvements are consistent across conceptual physics questions or concentrated in particular items.

2 Related Work

2.1 Automated Short Answer Grading

Early ASAG systems relied on rule-based approaches, lexical overlap, or semantic similarity measures (Burrows et al., 2015). Subsequent work introduced supervised learning models trained on labelled student responses (Bonthu et al., 2021). More recent approaches use transformer-based models such as Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019), which achieve strong performance on benchmark datasets (Takano et al., 2022). Recent work has also examined large language models for ASAG, with mixed evidence on whether few-shot LLM prompting outperforms fine-tuned encoder models in educational grading tasks (Grévisse et al., 2024; Kakarla et al., 2025). Despite these advances, it remains unclear how improvements in model architecture translate into practical grading behaviour, particularly whether they lead to more reliable and consistent decisions on real student responses.

However, Ley et al. (2023) identify remaining concerns regarding the reliability, cross-question consistency, and robustness of ASAG systems under limited training data in real educational environ-

ments. Many evaluations rely on curated datasets rather than authentic classroom data (Padó, 2022; Ferrara and Qunbar, 2022). Several benchmark datasets have been developed for ASAG research, including the SemEval Student Response Analysis dataset (Dzikovska et al., 2013) and the ASAP short-answer dataset (Mohler et al., 2011). Automated grading systems are generally proposed as decision-support tools to assist instructors by prioritising responses for review rather than replacing human judgement entirely (Weegar and Idestam-Almquist, 2024). In this context, overall benchmark accuracy is insufficient; evaluation must also consider reliability and error behaviour, including consistency across questions and whether models reduce rather than shift errors (Jung et al., 2025). Although instructors grade student responses during routine assessments, newly introduced questions often have few-or no-labelled responses available to train automated grading systems (Camus and Filighera, 2020; Zhang et al., 2022). The challenge of performing automated short-answer grading with only a small number of labelled student responses is compounded by the lack of systematic investigation into how ASAG systems behave across varying training set sizes, especially under realistic classroom constraints.

2.2 Domain-Adaptive Pre-training (DAPT)

Domain-adaptive pre-training (DAPT) extends the training of a language model by continuing pre-training on domain-relevant corpora prior to task-specific fine-tuning (Gururangan et al., 2020). This approach allows models to better capture specialised vocabulary and conceptual structures that may not be well represented in general web-based training data. DAPT has been shown to improve performance in specialised domains such as scientific text processing (Beltagy et al., 2019) and biomedical text analysis (Gu et al., 2021).

Sung et al. (2019) showed that BERT for ASAG can be improved by further pre-training on domain resources such as textbooks and question-answer pairs. More broadly, Gururangan et al. (2020) showed that DAPT improves performance across domains and resource settings. Our work therefore does not propose a new adaptation method; instead, it evaluates textbook-based DAPT in classroom-derived conceptual physics ASAG, focusing on low-data reliability, calibration, error overlap, and question-level variation. We do not compare against stronger science-domain encoders, physics-

domain encoders, modern LLM graders, or same-size non-physics continued pre-training controls; therefore, our claims are limited to the benefit of textbook-based DAPT over a general BERT baseline, rather than superiority over alternative encoder, LLM, or corpus-control baselines.

Recently, Hellert et al. (2024) explored domain-adapted models for scientific and technical domains, including physics-related NLP tasks. Pre-training language models on educational physics materials may therefore enable models to better represent the conceptual language used in student explanations within Force Concept Inventory (FCI) (Hestenes et al., 1992) assessments (Zhu et al., 2022). However, studies such as Henkel et al. (2024) and Gao et al. (2024) focus primarily on performance, providing limited insight into how domain-adaptive pre-training affects automated grading behaviour.

2.3 Reliability, Agreement, and Question-Level Variation in ASAG

Reliability is a fundamental requirement in educational assessment and measurement theory (Nitko and Brookhart, 2014; Schneider et al., 2023). Agreement metrics such as Cohen’s κ (Cohen, 1960) are commonly used to measure agreement between automated grading systems and human raters (del Gobbo et al., 2023). However, such metrics do not explain how errors are distributed, making it important to examine the types of mistakes systems make. Because grading decisions directly affect how students are assessed, improvements in model performance must be interpreted not only in terms of overall accuracy but also in terms of the types of errors made and the degree of agreement with human grading (Li et al., 2023). Two systems may achieve similar overall accuracy while producing different error patterns, and some grading errors may have more serious consequences for students than others.

Analysing error overlap (Dietterich, 1998) between models helps determine whether improved performance reflects a genuine reduction in grading mistakes. A model may appear more accurate because it correctly grades responses that were previously misclassified. However, it may also introduce new errors on other responses. As long as more errors are corrected than introduced, overall accuracy will increase, even if errors are redistributed across responses rather than uniformly reduced, which may lead to inconsistent or unfair grading

for certain students (Grévisse et al., 2024). In addition, grading performance may vary across assessment questions due to differences in conceptual difficulty or response distributions, meaning that some questions may be graded less reliably than others, potentially leading to unfair outcomes for students. Examining automated grading behaviour at the question level therefore provides important insight into system reliability, yet such analyses remain relatively limited in ASAG research.

2.4 Conceptual Physics Assessment and the Force Concept Inventory

This study focuses on conceptual physics assessment using free-text responses derived from the FCI (Parker et al., 2023; Pathak et al., 2026). The FCI is a widely used diagnostic instrument designed to measure students' understanding of fundamental Newtonian mechanics concepts and identify common misconceptions (Hestenes and Halloun, 1995; Hestenes et al., 1992). Yasuda et al. (2023) and Parker et al. (2022) explored short-answer reformulations of the Force Concept Inventory that capture students' reasoning more directly.

Grading conceptual explanations in free text presents particular challenges because students may express the same underlying idea using different wording, or provide responses that mix correct reasoning with misconceptions (Rainey et al., 2022; Dzikovska et al., 2013). This makes it difficult for automated grading systems to distinguish between fully correct, partially correct, and incorrect answers based on surface-level features alone. As a result, conceptual physics assessment provides a suitable setting for investigating whether DAPT on physics materials can improve grading performance by better capturing domain-specific terminology and response patterns (Trewartha et al., 2022; Sung et al., 2019). Furthermore, because the FCI targets specific conceptual dimensions, it enables fine-grained analysis of how automated grading performance varies across questions targeting different mechanics concepts.

3 Methodology and Experimental Setup

This section describes the task formulation, dataset construction, DAPT procedure, model configurations, and experimental design. The experiments are designed to evaluate the effect of DAPT while keeping the training data, model architecture, and evaluation procedure consistent across conditions.

3.1 Task and Dataset

Assessment Instrument: This study investigates the use of ASAG on free-response questions from the Newtonian Mechanics Quiz (NMQ) (Pathak et al., 2026), a modified version of the widely used Force Concept Inventory (FCI) (Hestenes et al., 1992) incorporating free-response questions (Parker et al., 2022).

Both the FCI and NMQ are conceptual diagnostic instruments designed to assess students' understanding and identify common misconceptions. The free-response questions integrated into the NMQ, requiring students to construct their own response, can provide deeper insight into students' comprehension of Newtonian mechanics than the multiple-choice questions of the original FCI alone (Pathak et al., 2026), Parker et al. (2022) and Rebello and Zollman (2004).

We use 15 free-response questions from the Newtonian Mechanics Quiz (NMQ), each designed to assess a specific conceptual aspect of Newtonian mechanics. For example, one question asks students to compare the time taken for two objects of different masses to reach the ground when dropped simultaneously, targeting understanding of gravitational acceleration and the independence of mass in free fall. These questions are conceptually aligned with Force Concept Inventory (FCI)-style items in that they probe underlying physical principles rather than requiring numerical calculation.

Student Response Dataset: The dataset analysed in this work consists of student responses collected during administrations of the NMQ at 6 UK higher education institutions in the 2024/25 academic year, either in class or as an out-of-class activity. A total of 674 quiz attempts were collected from students enrolled on introductory undergraduate physics modules. The unit of analysis for modelling is a question-response instance rather than a complete quiz attempt. Since each quiz attempt can contribute responses to multiple free-response questions, the 674 quiz attempts yield multiple labelled question-response instances across the 15 questions; the fixed test set of 1,566 therefore refers to held-out question-response instances, not 1,566 separate students or quiz attempts. Data collection was conducted via an online platform.

Each student response was independently labelled as correct or incorrect by four physics experts following agreed marking guidelines. Disagreements were resolved by a panel of three re-

searchers, who determined the final label. All responses were anonymised prior to analysis to protect student privacy. An anonymised version of the dataset has been released via The Open University repository with DOI 10.21954/ou.rd.32190003 (Pathak et al., 2026).

Split protocol: For each of the 15 questions, labelled response instances were split into a training pool and a fixed test set, with approximately 80% assigned to training and 20% to testing. All scaling subsets were sampled only from the training pool, and test responses were never used during training or subset construction. The split was performed at the question-response level rather than at the student or institution level; therefore, the evaluation measures generalisation to unseen responses for the same questions, not student-disjoint, institution-disjoint, or unseen-question generalisation.

Task Formulation: We study ASAG as a binary classification task. Given a question and a student’s free-text response, the model predicts whether the response should be marked correct or incorrect. This formulation matches the available expert labels and enables controlled analysis of agreement and error behaviour, but it does not model partial-credit or rubric-based scoring.

Each instance consists of:

- the question text,
- a student-written response,
- a binary correctness label assigned by human graders.

Table 1 reports the distribution of correct and incorrect responses per question. Class distributions vary substantially across questions, reflecting realistic classroom assessment conditions in which some concepts are more difficult than others and certain misconceptions appear more frequently.

3.2 DAPT on LibreTexts Physics

Following prior work on continued pre-training for domain adaptation and ASAG, we apply textbook-based DAPT before task-specific fine-tuning (Sung et al., 2019; Gururangan et al., 2020). The goal is not to introduce a new pre-training objective, but to test whether exposure to undergraduate physics language improves grading reliability for conceptual physics responses under low-data conditions.

Pre-training Corpus: The domain-adapted model undergoes continued pre-training on six openly available physics textbooks from LibreTexts (Dourmashkin, 2020; Gea-Banacloche, 2019; Cline, 2019), covering foundational topics in New-

tonian mechanics. LibreTexts was selected because it provides openly licensed, comprehensive undergraduate-level physics material that reflects terminology and conceptual explanations aligned with FCI-style content. Continued pre-training uses the masked language modelling objective (Devlin et al., 2019). This stage is entirely unsupervised and does not involve student responses or grading labels, ensuring that any downstream performance differences are not due to additional supervised grading labels.

3.3 Model Configurations

We compare two models that share identical architecture and task-specific training procedures, differing only in whether DAPT is applied.

3.3.1 Baseline Model

The baseline model consists of a BERT encoder (Devlin et al., 2019) fine-tuned directly on the short answer grading task.

For each instance:

- The question and student response are concatenated into a single input sequence.
- The final hidden state corresponding to the [CLS] token is passed to a linear classification layer.
- Binary predictions are produced using cross-entropy loss (Cui et al., 2019).

To simulate realistic low-resource classroom conditions, we adopt a **partial fine-tuning strategy** (Howard and Ruder, 2018; Sun et al., 2019):

- The lower eight transformer layers are frozen.
- Only the top four layers and the classification head are updated.

Fine-tuning instability in small datasets has been widely documented in prior work by Dodge et al. (2020); Mosbach et al. (2021); Tinn et al. (2023).

3.3.2 Domain-Adapted Model

The domain-adapted model follows a two-stage procedure:

- Continued pre-training on the LibreTexts physics corpus using MLM (Devlin et al., 2019).
- Fine-tuning on the ASAG task using the same architecture, layer-freezing configuration, and optimization settings as the baseline model.

Holding the base architecture, fine-tuning procedure, training subsets, and evaluation protocol constant isolates textbook-based continued pre-training relative to general BERT, but not whether

Question	Correct (%)	Incorrect (%)	N	Imb. Ratio
Q1	72.3	27.7	517	0.723
Q2	52.0	48.0	244	0.520
Q3	83.9	16.1	509	0.839
Q4	70.0	30.0	496	0.700
Q5	75.2	24.8	508	0.752
Q6	83.3	16.7	497	0.833
Q7	77.0	23.0	252	0.770
Q8	40.5	59.5	487	0.405
Q9	64.2	35.8	246	0.642
Q10	84.2	15.8	493	0.842
Q11	57.5	42.5	496	0.575
Q12	96.0	4.0	496	0.960
Q13	58.4	41.6	243	0.584
Q14	91.9	8.1	258	0.919
Q15	53.9	46.1	490	0.539

Table 1: Per-question class distribution. Percentages indicate the proportion of correct and incorrect responses.

gains arise from physics-specific content rather than continued pre-training more generally.

3.4 Training Procedure

Both models are trained on the Newtonian Mechanics dataset using supervised learning. As described in Section 3.1, the dataset consists of anonymised student responses collected during classroom administrations of free-response questions derived from the FCI. Because class distributions vary across questions (see Table 1), we use class-weighted cross-entropy loss (Cui et al., 2019), with weights computed based on inverse class frequency within each training subset. This mitigates bias toward majority classes and maintains sensitivity to less frequent response types.

All hyper-parameters, including optimizer configuration, learning rate schedule, batch size, number of epochs, and early stopping criteria, are kept identical across models. Given that small training sets can lead to unstable training dynamics, including divergence during the fine-tuning (Dodge et al., 2020), we apply early stopping (Song et al., 2020) and repeat each experimental condition using multiple random seeds.

3.5 Experimental Design: Controlled Scaling Study

We run a controlled scaling study over 26 nested training-set sizes to reflect classroom data availability, from early deployment to larger cohorts. After constructing the fixed per-question test set, all remaining responses form the training pool. For each question and training size d_x , we sample up to x correct and x incorrect responses from the

training pool. Thus, d_x represents a target per-class sampling cap, not a guarantee that every question contains x examples from each class. When one class has fewer than x available responses, both classes are capped at the smaller available count. This is particularly relevant for highly imbalanced questions such as Q12, where the number of incorrect responses is small. Larger subsets are nested by adding newly sampled responses to the previous subset where available. We train both models with 10 random seeds, resulting in 26 sizes $\times$ 10 seeds $\times$ 2 models = 520 runs. The fixed test set contains 1,566 question-response instances.

The fixed test set enables paired comparisons between models. Experiment-level differences across matched training sizes and random seeds are evaluated using paired tests over run-level metrics, while fixed/broken error counts are reported descriptively because the same test responses are evaluated repeatedly across conditions. We also report correlation analyses relating training size and baseline question performance to observed DAPT gains. A summary of statistical procedures is provided in Appendix Table 5.

For each configuration, we report Accuracy, Macro F1, Balanced Accuracy, and Cohen’s κ (Cohen, 1960) as mean $\pm$ standard deviation across runs, with detailed per-question results provided in Appendix Tables 6 and 7. Increasing the number of repetitions reduces variance in performance estimates and provides a more stable assessment of model behaviour in low-data settings, where single-run results can be highly variable (Dodge et al., 2020). This controlled scaling framework enables analysis of performance differences, data efficiency, saturation effects, and variability under limited labelled data.

4 Results and Discussion

This section evaluates whether DAPT improves the practical reliability of ASAG when applied to classroom-derived student responses, and whether observed improvements reflect consistent reductions in grading errors.

4.1 Overall Performance and Reliability (RQ1)

Across all evaluation metrics, the domain-adapted model (DAPT) shows higher agreement with reference labels compared to the baseline model.

Table 2 summarises the average performance

across all runs and training sizes.

Metric	Baseline	DAPT	Δ
Accuracy	0.906	0.963	+0.057
Macro F1	0.889	0.955	+0.066
Balanced Acc.	0.895	0.954	+0.059
Cohen's κ	0.783	0.910	+0.127

Table 2: Overall average performance across all runs and training sizes.

From a grading perspective, the increase in Cohen's κ suggests improved consistency in automated decisions, which is important for maintaining fairness in assessment.

Wilcoxon Signed-Rank Test (Experiment-Level Comparison): To evaluate whether these differences are consistent across experimental conditions, we conducted a paired Wilcoxon signed-rank test (Wilcoxon, 1945) on accuracy scores, comparing matched runs and training sizes between the two models.

The paired comparison showed a consistent difference across matched conditions:

- $W = 30.5, p < 10^{-43}$

Because training subsets are nested, this result should be interpreted as evidence of a strong repeated pattern across conditions rather than as fully independent experimental replications.

Classroom interpretation: From an assessment perspective, the increase in Cohen's κ indicates stronger agreement between automated predictions and reference labels. This indicates that the domain-adapted model may provide more stable grading decisions under varying data conditions.

4.2 Effect of Training Data Size (RQ1)

Across 260 matched comparisons (10 runs $\times$ 26 training sizes, comparing the same run and dataset size across models), the domain-adapted model outperformed the baseline in the large majority of cases:

- Accuracy improved in 257/260 comparisons
- Macro F1 improved in 258/260 comparisons
- Cohen's κ improved in 258/260 comparisons

These results indicate that performance gains are observed across most experimental conditions, rather than being limited to a small subset of runs or training sizes.

Figure 1 presents learning curves across increasing training sizes. The largest performance differences occur in low-data settings:

- d_{10} : Δ Accuracy $\approx +0.28$
- d_{50} : Δ Accuracy $\approx +0.12$
- d_{470} : Δ Accuracy $\approx +0.006$

Figure 1 shows that DAPT provides the largest gains in low-data conditions, with an accuracy improvement of approximately 28 percentage points at d_{10} and 12 points at d_{50} . As training data increases, the gap narrows, reaching approximately 0.6 points at d_{470} . This pattern is supported by a strong negative correlation between training size and DAPT gain (Spearman's $\rho = -0.90$), indicating that the benefit of domain adaptation diminishes as more labelled data becomes available.

Figure 1: Learning curves across training sizes.

Classroom interpretation: From an assessment perspective, this suggests that domain-adaptive pre-training can provide more reliable grading in early deployment stages, where only a limited number of student responses are available, while offering smaller additional gains once sufficient data has been collected.

4.3 Question-Level Behaviour (RQ2)

While overall performance improves, the magnitude of improvement varies across questions. Larger gains are observed for questions where baseline performance is lower (e.g., Q4, Q5), whereas questions with already high baseline accuracy (e.g., Q1, Q14, Q15) show only marginal improvements.

A strong negative relationship between baseline accuracy and improvement (Spearman's rank correlation coefficient $\rho = -0.94$) indicates a ceiling effect, where questions that are already easy to grade offer limited room for further gains.

Figure 2 presents performance differences at the question level.

These results suggest that DAPT provides the greatest benefit for questions that are less reliably handled by the baseline. A qualitative inspection suggests that lower-gain questions may have more constrained answer spaces, whereas higher-gain questions appear to involve more varied explanations, incomplete causal reasoning, mixed correct and incorrect ideas, or domain-specific phrasing. Textbook-based DAPT may therefore help most where student responses are linguistically heterogeneous. This interpretation is exploratory, and future work should analyse response length, misconception type, and explanation structure systematically.

Classroom interpretation: From a classroom perspective, this indicates that the domain-adapted model may be particularly useful for supporting grading on more challenging questions, where automated decisions are likely to be less reliable. Importantly, we do not observe clear evidence of systematic performance degradation across questions, suggesting that improvements are not achieved at the expense of reduced performance elsewhere.

Figure 2: Question-level performance differences (δ accuracy) between baseline and domain-adapted models.

4.4 Error-Level Analysis (RQ2)

To determine whether improvements reflect genuine error reduction rather than redistribution, we conducted a global error-overlap analysis across all questions and training sizes.

In this analysis, *Fixed* refers to cases where the domain-adapted model produces a correct prediction while the baseline model is incorrect, and *Broken* refers to cases where the baseline is correct but the domain-adapted model is incorrect.

Category	Count
Both Correct	362,667
Both Wrong	8,487
Fixed	29,586
Broken	6,420
Net Reduction	23,166
Fixed/Broken Ratio	4.61

Table 3: Error overlap summary between baseline and textbook-pretrained models.

Table 3 shows that the domain-adapted model corrects substantially more baseline errors than it introduces, resulting in a net reduction of 23,166 errors and a Fixed/Broken ratio of 4.61.

Aggregate paired comparison: Because the same fixed test responses are evaluated repeatedly across training sizes and seeds, the pooled fixed/broken counts in Table 3 should be interpreted descriptively rather than as independent observations. The large imbalance between Fixed and Broken cases nevertheless shows a consistent directional pattern: across repeated paired evaluations, the domain-adapted model corrects substantially more baseline errors than it introduces.

4.5 Calibration and Confidence

Table 4 summarises calibration performance.

Metric	Baseline	DAPT
Brier score	0.0668	0.0308
ECE	0.0408	0.0228

Table 4: Calibration metrics for models used

The domain-adapted model achieves lower values on both the Brier score (Brier, 1950) and Expected Calibration Error (ECE) (Guo et al., 2017), suggesting that its predicted probabilities are better aligned with observed outcomes. In particular, the reduction in Brier score reflects improved overall probabilistic accuracy, while the lower ECE indicates that confidence estimates more closely match true correctness likelihoods.

Classroom interpretation: From a grading perspective, improved calibration is important because it allows the system’s confidence scores to be interpreted as meaningful indicators of reliability. This enables practical workflows in which low-confidence predictions can be flagged for human review, while high-confidence predictions can be trusted with greater assurance.

4.6 Discussion

These results are consistent with prior work showing that continued pre-training on domain-relevant text can improve downstream performance. [Sung et al. \(2019\)](#) demonstrated this idea for ASAG using domain resources such as textbooks, while [Gururangan et al. \(2020\)](#) showed that DAPT can improve performance across multiple domains and resource settings. The present study extends this line of work by examining reliability, calibration, error overlap, and question-level behaviour in classroom-derived conceptual physics ASAG. Because we do not evaluate LLM graders or a same-size non-physics pre-training control, the results show improvement over general BERT in this setting, but not superiority over LLM-based grading or evidence that gains are uniquely caused by physics-specific content. The evaluation also reflects same-question deployment: models are tested on held-out responses to the same questions, not on unseen questions or unseen institutions.

4.6.1 RQ1: Reliability under limited data:

The results show that domain-adaptive pretraining improves agreement with reference labels across conditions, with the largest gains observed in low-data regimes. Learning curve analysis indicates that these improvements are most pronounced when only limited labelled responses are available, and diminish as training data increases.

4.6.2 RQ2: Nature of improvements:

Improvements are observed across most questions, with larger gains for items where baseline performance is lower. Error-level analysis further indicates that these gains primarily reflect net reductions in grading errors, rather than redistribution of errors across instances.

4.6.3 Implications for practice

From a teaching perspective, these findings suggest that domain-adapted models may:

- improve consistency of automated grading decisions,
- provide the greatest benefit in early deployment scenarios with limited data, and
- support identification of responses requiring human review.

However, such systems should be used to support, rather than replace, human judgement in assessment.

5 Conclusion

We evaluated whether textbook-based DAPT improves binary ASAG reliability relative to a general BERT baseline in a classroom-derived conceptual physics setting. Across 26 training sizes and 10 random seeds, the domain-adapted model showed higher accuracy, macro F1, balanced accuracy, and Cohen's κ , with the largest gains in low-data settings.

Question-level and error-overlap analyses showed that these gains were not only aggregate improvements: the domain-adapted model corrected substantially more baseline errors than it introduced, with larger benefits for questions where baseline performance was lower. Calibration also improved, suggesting that model confidence may better support human-review workflows.

These findings support textbook-based DAPT as a useful low-data strategy for same-question ASAG deployment. However, the system should be treated as a decision-support tool, and broader evaluation is needed for stronger baselines, partial-credit scoring, unseen questions, unseen institutions, and other educational contexts.

6 Limitations

Baseline scope: We compare general BERT with a textbook-adapted version of the same model to isolate the effect of continued pre-training on undergraduate physics materials. We do not compare against science-domain or physics-domain encoders such as SciBERT or PhysBERT, stronger general encoders such as RoBERTa or DeBERTa, modern LLM-based graders, or a same-size non-physics continued pre-training control. Therefore, our results show improvement over general BERT in this setting, but do not establish superiority over stronger baselines or prove that the gains are uniquely due to physics-specific content. Future work should test these comparisons directly.

This study is conducted using free-response conceptual physics questions derived from the Force Concept Inventory (FCI), a widely used diagnostic instrument designed to assess students' conceptual understanding of Newtonian mechanics ([Hestenes et al., 1992](#); [Hestenes and Halloun, 1995](#)). This reflects a specific assessment context focused on conceptual reasoning rather than procedural or numerical problem-solving, and the findings should be interpreted within this context.

The grading task is formulated as binary clas-

sification (correct/incorrect), which enables controlled analysis of agreement and error patterns but does not capture partial-credit or rubric-based scoring. This limits direct applicability to classroom settings where teachers assign ordinal scores or apply detailed rubrics. The headline accuracy values should therefore not be directly compared with multi-class, ordinal, or rubric-based ASAG settings, which present a harder grading problem. Future work should examine whether the DAPT advantage observed here transfers to these more complex scoring settings.

Split and generalisation scope: The train/test split is performed at the question-response level. The fixed test set contains held-out responses to the same 15 questions used to construct the training pools, so the study evaluates new responses to existing questions rather than transfer to entirely unseen questions. Because the split is not student-disjoint or institution-disjoint, responses from the same student or institution may appear across training and test partitions through different question responses.

Although the experimental design includes multiple training sizes and repeated runs, the number of assessment questions is limited ($n = 15$), which constrains the strength of conclusions regarding question-level variation.

Finally, domain-adaptive pre-training is based on a single type of corpus (undergraduate physics textbooks from LibreTexts). Other domain sources may lead to different adaptation effects and remain for future investigation. The present analysis also does not establish that DAPT improves conceptual understanding in the model; gains may partly reflect better handling of physics vocabulary, common phrasings, or surface-level response patterns.

7 Ethics Statement

Collection of the Newtonian Mechanics Quiz student response dataset was approved by the relevant institutional Human Research Ethics Committee. Student responses were collected during authentic classroom assessments as part of ongoing doctoral research, and the anonymised dataset has been released via The Open University repository (Pathak et al., 2026). Participation complied with institutional ethical guidelines, and no personally identifiable information was retained. The ethical approval permits the use of anonymised data for research dissemination.

The physics textbooks used for domain-adaptive

pre-training were obtained from *LibreTexts*, an open educational resource platform providing materials under open licenses, including Creative Commons, Public Domain, and similar licenses. These licenses permit reuse, adaptation, and redistribution of content for educational and research purposes, subject to specific conditions such as attribution and, in some cases, non-commercial use or share-alike requirements. All materials were accessed and used in accordance with their respective licensing terms, and appropriate attribution was maintained where required.

A Additional Per-Question Results

Panel A (Performance Metrics). Panel A reports per-question performance as mean $\pm$ standard deviation across runs and training sizes. We report accuracy, macro F1, weighted F1, and Cohen’s κ .

Consistent with the results in Section 4, improvements in accuracy are accompanied by increases in agreement measured by Cohen’s κ , indicating that gains are not limited to raw accuracy. Variability is higher for questions with lower baseline performance, reflecting greater instability under limited data conditions, as observed in the learning-curve analysis.

Panel B (Question Characteristics and Error Dynamics). Panel B links question properties to the mechanism of performance changes. N denotes the total number of repeated paired predictions aggregated across training sizes and runs; it should not be interpreted as the number of independent test instances. N_0 and N_1 denote the repeated counts of incorrect and correct labels, respectively. Imbalance Ratio and PosRate describe class prevalence.

While ΔAcc , reported in percentage points, indicates the magnitude of improvement, it does not by itself capture grading behaviour. The Fixed/Broken decomposition provides this insight:

- **Fixed:** baseline errors corrected by the domain-adapted model
- **Broken:** new errors introduced by the domain-adapted model
- **Net:** Fixed – Broken, indicating the directional change in errors

Because the same fixed test responses are evaluated repeatedly across training sizes and random seeds, the fixed/broken counts are interpreted descriptively rather than as independent observations for significance testing. Consistent with the error-overlap analysis in Section 4, all questions show positive Net values, indicating that the domain-adapted model corrects more baseline errors than it introduces. Larger performance gains correspond to larger positive Net values, particularly for questions where baseline performance is lower. Taken together, Panels A and B support the finding that performance gains primarily reflect net reductions in grading errors across questions, rather than improvements in some questions offset by declines in others.

Table 5: Summary of statistical analyses used in the study.

Analysis	Method	Unit	n	Reported	What is assessed
Overall experiment-level comparison	Wilcoxon signed-rank	Matched run $\times$ training-size condition	260	W, p	Whether DAPT shows a repeated performance advantage over the baseline across matched experimental conditions
Global error-overlap comparison	Descriptive fixed/broken analysis	Aggregated repeated paired predictions	407,160	Fixed, Broken, Net, Fixed/Broken ratio	Whether DAPT corrects more baseline errors than it introduces; interpreted descriptively because test responses are repeated across training sizes and seeds
Per-question error behaviour	Descriptive fixed/broken analysis	Question-level aggregated repeated paired predictions	15 questions	ΔAcc , Fixed, Broken, Net	Whether improvements are concentrated in particular questions or reflect positive net error reduction across questions
Training size vs. improvement	Spearman ρ	Training-size condition	26	ρ	Monotonic association between training size and performance improvement (ΔAcc)
Baseline accuracy vs. question gain	Spearman ρ	Question	15	ρ	Monotonic association between baseline question performance and improvement under DAPT

Notes: Fixed/broken counts are interpreted descriptively because the same fixed test responses are evaluated repeatedly across training sizes and random seeds. ΔAcc is reported in percentage points. n denotes the number of analysis units, which differs by row.

Measuring Optimal Challenge: Trajectory-Based Difficulty Alignment in Open-Ended Language Tutoring

Abstract

Conversational English as a Foreign Language (EFL) tutoring relies on dynamically generated exercises rather than fixed item banks, so traditional difficulty estimation cannot verify whether a task is appropriately calibrated to a learner. We propose a framework that measures difficulty alignment directly from observable interactional behavior, classifying each exercise into one of three states (Under-Challenged, Optimally Challenged, or Over-Challenged) based on turn-level sequences of student attempts, errors, confusion, and tutor scaffolding. Using 1,566 exercises from the Teacher-Student Classroom Corpus, we validate the classification against human annotation (Cohen’s $\kappa = 0.79$ at the state level) and show that a learner’s cumulative trajectory of these states predicts success on subsequent exercises. Aggregating these predictions into a within-session capability-shift proxy, we find that sessions with higher proportions of over-challenging exercises systematically yield lower estimated shifts, while optimally challenging interactions are significantly associated with greater improvement than under-challenging ones—patterns consistent with Krashen’s Input Hypothesis.

1 Introduction

How can we determine computationally whether a tutoring exercise is appropriately calibrated to an individual learner? In conversational English as a Foreign Language (EFL) tutoring, exercises are not drawn from a fixed item bank but are selected or generated dynamically or organically in response to evolving learner in-context needs. Whether delivered by a tutor drawing on experience or by an LLM system generating exercises on the fly, we know of no computationally tractable method for accurately evaluating whether the tutoring content is at an optimal level of productive engagement for a learner, leaving us without a measure of instructional calibration.

Multiple traditions in learning theory converge on optimal productive engagement: from desirable difficulties (Bjork and Bjork, 2011) and productive failure (Kapur, 2008) to Vygotsky’s Zone of Proximal Development (Vygotsky, 1978). In second language acquisition, Krashen’s Input Hypothesis (Krashen, 1977) formalizes this as $i + 1$: optimal acquisition occurs when input slightly exceeds the learner’s current mastery level, i . The Interaction Hypothesis (Long, 1996) further predicts that scaffolding moves during task completion facilitate learning, highlighting the role of the tutor. These frameworks yield an operationalizable expectation: appropriately calibrated exercises should be observable in the learner’s interactional behavior in conversation with their tutor.

Existing computational approaches to difficulty estimation, however, are not designed to operate on dynamically generated exercises in open-ended conversational settings. Item Response Theory (Hambleton et al., 1991) estimates item difficulty and learner ability from response patterns over a calibrated item bank, supporting adaptive assessment rather than instructional calibration in dynamic tutoring. LLM-based difficulty estimation (Brant et al., 2026; Liu et al., 2025) sidesteps the item-bank requirement but infers difficulty from the model’s own capabilities rather than from learner-specific evidence. Knowledge tracing (Corbett and Anderson, 1994; Piech et al., 2015), including recent LLM-based variants (Neshaei et al., 2024), addresses a related but distinct problem: estimating a learner’s mastery of a fixed taxonomy of skills from their history of correct and incorrect responses, in order to guide which skills to practice next. It is well suited to domains where competencies decompose into discrete, repeatedly practiced units, but open-ended conversational practice offers neither a fixed skill taxonomy nor sufficient per-skill repetition, and even where it could be applied, it would tell us what a learner knows rather than whether a

given exercise was appropriately challenging at the moment of delivery. Crucially, none of these approaches leverage the rich behavioral signal available in the interaction itself—treating difficulty as either an intrinsic property of the item or an aggregate of historical response patterns, rather than as something that manifests in real time through the learner’s interactional behavior.

We argue that the interaction surrounding an exercise—the sequence of student attempts, errors, confusion signals, and tutor scaffolding moves—provides a theoretically grounded and reproducible operationalization of Krashen’s optimal challenge. The core insight is that while “difficulty” and “productive struggle” are latent constructs without direct ground truth, their constituent behaviors are concrete and observable: a student producing an incorrect response, asking what a word means, or requesting clarification are all explicit, annotatable events. By mapping these turn-level behavioral sequences to optimal challenge alignment states—*Optimally Challenged* ($i + 1$; struggle followed by success), *Under-Challenged* (i ; correct without prior struggle), and *Over-Challenged* ($i + \mathbb{Z}_{>1}$ unresolved difficulty)—we obtain a computational measure grounded directly in the observable indicators that the Input and Interaction Hypotheses identify as markers of productive learning.

However, classifying individual exercises is only the initial step; isolated difficulty states are momentary snapshots. To test the underlying learning theories, we must understand how these states accumulate to shape learning trajectories. We achieve this through a two-stage framework. At the micro-level, we examine whether a learner’s cumulative trajectory of difficulty states, combined with performance and scaffolding features, predicts success on subsequent exercises. At the macro-level, we leverage this predictive model to construct an in-situ *capability-shift proxy*, the shift in a student’s expected success probability across a session, and test whether sessions with higher proportions of optimally challenged interactions yield greater estimated improvement. Together, this framework motivates three research questions:

- **RQ1 (Annotation & Classification):** Can turn-level interactional trajectories be reliably annotated and systematically mapped to difficulty alignment states that reflect the relational difficulty of tutoring exercises?
- **RQ2 (Micro-Level Prediction):** To what ex-

tent do session-level interaction histories—including prior performance, scaffolding behavior, and difficulty alignment states—predict a learner’s probability of success on subsequent exercises?

- **RQ3 (Macro-Level Inference):** How does the overall composition of difficulty alignment states within a tutoring session relate to estimated learner improvement across the session, controlling for structural confounders?

2 Data

The dataset used in this study is the **Teacher-Student Chatroom Corpus (TSCC) Version 2** (Caines et al., 2020), which contains message-based English Language tutoring sessions. The dataset includes a total of 260 sessions, involving 2 teachers and 12 students.

Each session is stored as a TSV file, where each row represents an anonymized message sent by either a student or a tutor. The dataset provides the following attributes for each message: `user.id` (unique identifier for the sender), `role` (student/teacher), and `seq.type` (the message type, where the label *exercise* indicates that the teacher is providing an exercise in the current sequence.) Additionally, the dataset includes a metadata file, which provides annotations for each session, including: Student’s CEFR (Common European Framework of Reference for Languages, (Council of Europe, 2001)) level, age, and native language (See Table 1).

ID	CEFR	Age	L1	#Sess.	#Ex.
002	B1	22	Japanese	3	27
003	B2	32	Japanese	4	26
004	C1	40	Spanish	28	53
005	B2	20	Italian	6	34
006	B1	23	Thai	4	29
007	B2	22	Mandarin Chinese	32	297
009	B2	12	Ukrainian	48	518
010	B2	13	Ukrainian	14	138
011	B2	26	Russian, Ukrainian	51	217
012	C2	33	Russian	26	47
014	C2	30	Italian	26	72
015	B2	30	Mandarin Chinese	18	108

Table 1: Student Demographic Summary in TSCC v2. # Sess. indicates the number of sessions, and # Ex. indicates the number of exercises.

3 Methods

Our methodology proceeds in two analytical stages. The *micro-level* stage classifies each exercise into a difficulty alignment state (Sections 3.1–3.3) and fits a Generalized Linear Mixed-Effects Model that predicts next-exercise success from cumulative trajectory features (Section 3.4), establishing that these features carry predictive signal. The *macro-level* stage then aggregates the micro model’s out-of-fold predictions into a session-level capability-shift proxy (Section 3.5) and regresses it on cumulative difficulty proportions, controlling for exercise-length changes, tutor identity, and student-level variance (Section 3.6). This two-stage design isolates the pedagogically meaningful contribution of difficulty composition from co-varying surface confounds that the micro model alone cannot disentangle.

3.1 Data Preprocessing and Exercise Identification

Starting from 2,527 sequences labeled as containing exercises in the original corpus, we applied a filtering pipeline to isolate exercises that are self-contained within the chat log, contain an explicit exercise body, and require productive English practice. Following established methodologies that validate LLMs as reliable data annotators against human-labeled subsets (Gilardi et al., 2023; Wang et al., 2023; Törnberg, 2023), we employed a hybrid annotation process: one author manually judged eligibility for a 10% random sample ($n=252$), then validated an automated classifier (GPT-4.1-2025-04-14; prompt documented in Appendix C.1) against these judgments. We required precision > 0.85 on the verification set before applying the classifier at scale, prioritizing precision over recall to keep the final exercise set conservative; the threshold was met (full validation metrics reported in Section 4.1). The automated pipeline was then applied to the remaining sequences, yielding a final dataset of **1,566** tutor-led exercises. Full eligibility criteria and pipeline details are provided in Appendix A.

3.2 Turn-Level Behavioral Annotation

To capture the interactional trajectory following each exercise, we developed a turn-level coding scheme (Table 2) classifying each post-exercise turn by speaker role and pedagogical function. Annotation proceeds sequentially and terminates at

a stop condition (Student Correct Response or Teacher Direct Answer). We annotated a random sample of 157 exercises (10% of the filtered corpus).

To ensure robustness, we employed a two-stage validation process.

Human Inter-Rater Reliability Two authors independently annotated a pilot subset of 30 exercises (approximately 150 turns). Inter-rater agreement was calculated using Cohen’s κ to account for chance agreement. Full annotation proceeded only after achieving $\kappa > 0.70$ (true $\kappa = 0.96$), indicating substantial agreement. Disagreements were resolved through discussion, particularly clarifying the distinction between *Content* and *Procedure* confusion and the three types of student response.

LLM-Human Agreement To scale annotation, we evaluated GPT-5.2 (GPT-5.2-2025-12-11, non-reasoning) on the fully manually annotated set (157 exercises, 1,570 turns). The prompt is documented in Appendix C.2. The model was prompted using the same definitions and contextual constraints described above. Following the same threshold-gate criterion used for human IRR but with a stricter cutoff, we required GPT-5.2 to achieve Cohen’s $\kappa > 0.80$ (“almost perfect agreement” under the Landis and Koch scale (Landis and Koch, 1977)) against human annotations before deploying the pipeline on the full corpus; the threshold was met (full per-label results in Section 4.2).

3.3 Trajectory-to-Challenge Mapping

We map each exercise’s post-exercise turn sequence (up to $L_{max} = 10$ turns) into one of three mutually exclusive difficulty alignment states. The tripartite partition follows directly from Krashen’s Input Hypothesis (Krashen, 1977), which distinguishes input at i (under-challenging), at $i + 1$ (optimally challenging), and beyond $i + 1$ (over-challenging) relative to the learner’s current mastery i . In the human-annotated set, 93.6% of exercises reached a stop condition within this window, confirming that the threshold captures the natural resolution boundary of most interactions. The three states are:

- **Under-Challenged (i):** The student produces a correct response without prior evidence of content-level struggle (no “Response Attempt – Incorrect” or “Content Question/Confusion” in the trajectory).

Speaker	Label	Definition
Teacher	Hint/Instruction	Scaffolding, elicitation (e.g., “Tell me more”), or clarifying instructions related to the exercise.
	Direct Answer	Explicit provision of the correct answer or full solution.
Student	Response Attempt – Correct	Grammatically and semantically complete answer.
	Response Attempt – Incorrect	Attempt containing linguistic errors or incorrect content.
	Response Attempt – Partial	Correct but incomplete response (e.g., filling only one of multiple blanks).
	Content Question/Confusion	Questions or statements reflecting gaps in linguistic knowledge (e.g., “I don’t know this word”).
	Procedure Question/Confusion	Questions about task mechanics rather than language content (e.g., “Should I type it?”).
Any	NA	Turn unrelated to the specific exercise body (off-topic chat, meta-talk, references to other exercises).

Table 2: Turn-level tutor-student interaction taxonomy.

- **Optimally Challenged** ($i + 1$): The student eventually succeeds, but the preceding trajectory contains explicit markers of struggle (an incorrect attempt or content confusion).
- **Over-Challenged** ($i + \mathbb{Z}_{>1}$): The tutor provides the answer via “Direct Answer,” or the interaction reaches L_{max} without a correct student response.

Figure 1 illustrates each state with example trajectories from the corpus.

This classification operates exclusively on student-driven evidence: tutor scaffolding alone does not trigger the Optimally Challenged state, and procedural questions about task mechanics (e.g., “Should I type it?”) do not count as evidence of content-level difficulty—if a student asks such a question and subsequently solves the task, the trajectory remains Under-Challenged.

3.4 Session-Level Next-Exercise Success Prediction

Having classified each exercise into a difficulty alignment state, we next ask whether a learner’s cumulative session history, including their trajectory of the difficulty alignment state and interaction features, provides a predictive signal for success on subsequent exercises. We formalize this as a binary classification task: given the first t exercises in a session, predict whether the student will respond correctly to exercise $t + 1$.

3.4.1 Trajectory Prefix Construction and Feature Selection

For a session containing T exercises (ordered chronologically by turn number), we construct $T - 1$ prefix rows, where each row at position $t \in \{1, \dots, T - 1\}$ uses the history of exercises 1 through t to predict the outcome of exercise $t + 1$.

Figure 1: Illustrative trajectories for each difficulty alignment state, drawn from the TSCC corpus. Turn labels are color-coded: **Correct**, **Incorrect**, **Hint**, **Direct Answer**.

Sessions with only a single exercise are excluded. We initially extracted 24 features across four categories: historical performance, difficulty alignment trajectories, scaffolding interactions, and exercise surface properties. A comprehensive table defining all initial features is provided in Appendix D.

To prevent information leakage across related observations, we employ **session-level** 5-fold cross-validation. All prefix rows from a given session are assigned to the same fold, ensuring that no session contributes to both training and evaluation within

any fold.

To objectively identify the most robust and generalizable subset of predictors from this initial pool and to prevent overfitting, we applied L1-regularized logistic regression (Lasso) across 5-fold cross-validation. We established a strict inclusion criterion: only features selected by the Lasso penalty in at least 0.60 of the folds (i.e., ≥ 3 out of 5 folds) were retained for the final predictive model.

This data-driven selection process retained 13 features. The key retained features central to our pedagogical analysis include:

- **Cumulative Proportions of Difficulty Alignment States:** The cumulative fraction of exercises up to turn t that were classified as Over-Challenged and Under-Challenged, respectively. The proportion of Optimally-Challenged was dropped by Lasso to avoid collinearity with the other two. By definition, these three proportions represent the complete composition of the session history, summing to 1.
- **Consecutive Optimally Challenged States:** The count of uninterrupted Optimally Challenged states immediately preceding $t + 1$.
- **Consecutive Successes:** The count of consecutive correct responses immediately preceding $t + 1$.

Other retained features include scaffolding metrics (e.g., average hints per exercise), upcoming exercise character and word lengths, and the student’s baseline CEFR proficiency. A complete feature dictionary and the detailed L1 selection frequencies are provided in Appendix D.

After excluding 50 sessions containing none or single exercise, this construction yielded 1,324 prediction rows from 210 sessions. The target variable (next-exercise success) has a positive rate of 70.7%, indicating moderate class imbalance toward correct responses. Prefix lengths (the number of prior exercises available as history) range from 1 to 34 (mean ≈ 5.8), reflecting substantial variation in the amount of session context available.

3.4.2 Generalized Linear Mixed-Effects Model

We model next-exercise success using a generalized linear mixed-effects model (GLMM; [Breslow](#)

and [Clayton, 1993](#)) with a binomial response and a logit link function. Standard logistic regression assumes that all observations are independent; however, exercises are structurally dependent as they are nested within specific students and tutors. To account for this nested structure, we include a student-level random intercept to control for baseline differences in learner proficiency, and a fixed effect for teacher identity to account for unobserved pedagogical differences between the two tutors in the dataset.

Formally, for the student-random + teacher-fixed specification, let $y_{ijs} \in \{0, 1\}$ denote correctness for prediction instance i from student j with teacher s . We model

$$\text{logit}(P(y_{ijs} = 1)) = \mathbf{z}_{ij}^\top \boldsymbol{\beta} + \boldsymbol{\alpha}_s^\top \mathbf{1}\{\text{teach.} = s\} + u_j \quad (1)$$

where $\mathbf{z}_{ij}$ contains the selected covariates (numeric covariates are standardized within each training fold), $\boldsymbol{\alpha}_s$ denotes teacher fixed effects (with a reference category), and $u_j \sim \mathcal{N}(0, \sigma_u^2)$ is a student-level random intercept.

To ensure our findings regarding key behavioral predictors are not artifacts of a specific model structure, we also tested alternative specifications, including models without random effects and models with varying control structures. These robustness checks are reported in Appendix E, demonstrating consistent feature effects across different specifications.

3.5 In-Situ Capability-Shift Proxy

Observational tutoring corpora such as TSCC typically lack formal pre- and post-assessments, precluding direct measurement of learning outcomes. We therefore construct an *in-situ capability-shift proxy*—a within-session shift in model-estimated success probability, not a measured change in language acquisition—by leveraging the out-of-fold predicted probabilities from the next-exercise success model described in Section 3.4.

The predictive model established in Section 3.4 serves as a noisy but informative indicator of a student’s real-time capability. The core intuition is that if a student’s model-estimated probability of success increases over the course of a session, the model has detected a positive shift in the student’s interactional profile toward patterns associated with correct responses—providing an operational proxy for *model-estimated* within-session capability shifts, rather than a direct measure of

language acquisition.

3.5.1 Definition

For each session trajectory, the next-exercise success model produces a sequence of out-of-fold predicted probabilities $\hat{p}_2, \hat{p}_3, \dots, \hat{p}_T$, where $\hat{p}_t$ denotes the predicted probability that the student answers exercise t correctly, conditioned on the session history through exercise $t - 1$. Note that no prediction is generated for the first exercise ($t = 1$), as it has no prior history.

We define the **capability shift** for a trajectory as the direct difference between the final predicted probability and the initial predicted probability within the session. Specifically, let $n = T - 1$ denote the number of predictions in a trajectory. We distinguish two cases:

- $n < 3$ (fewer than 4 exercises / 3 predictions): The trajectory is **discarded**, as it provides insufficient intermediate history to form a valid pedagogical composition. (57 trajectories discarded)
- $n \geq 3$: $CS = \hat{p}_T - \hat{p}_2$. (153 trajectories)

3.6 Associating Difficulty Alignment with Capability Shift

Having constructed the in-situ capability-shift proxy, we transition from micro-level, exercise-by-exercise prediction to session-level attribution. Because the micro-level model focuses on isolated exercise outcomes rather than cumulative improvement, we aggregate its predictions across full session trajectories to operationalize and observe capability shifts. This analysis evaluates how the model-estimated capability shifts are explained by the session’s overall composition—specifically the proportions of Under-Challenged, Optimally Challenged, and Over-Challenged exercises. By regressing the capability-shift proxy against these macro-level proportions, we interpret the micro-level interactional dynamics through the pedagogical framework of the Input Hypothesis.

3.6.1 Trajectory-Level Variables

For each valid session-level trajectory, we extract the following variables:

- **Difficulty alignment proportions.** The cumulative proportion of exercises classified as Under-Challenged, Optimally Challenged, and Over-Challenged across the full session.

- **Capability shift.** The in-situ capability-shift proxy as defined in Section 3.5.

- **Exercise-length deltas (control variables).**

To account for the possibility that shifts in exercise surface complexity, rather than actual capability improvements, drive changes in the predicted success probability, we compute control variables capturing how exercise length changes between the early and late windows. Using the same early/late window indices as the capability-shift computation, we calculate $\Delta_{\text{chars}} = \bar{\ell}_{\text{late}}^{\text{chars}} - \bar{\ell}_{\text{early}}^{\text{chars}}$ and $\Delta_{\text{words}} = \bar{\ell}_{\text{late}}^{\text{words}} - \bar{\ell}_{\text{early}}^{\text{words}}$, where $\bar{\ell}$ denotes the mean exercise body length (in characters or words) within the respective window.

- **Teacher identity (control variable).** It is a binary indicator (dummy variable) encoding which of the two tutors in the dataset conducted the session. This fixed effect is included to systematically control for unobserved, tutor-specific baseline differences in pedagogical style, hint generosity, or exercise formulation.

3.6.2 Controlled Linear Mixed-Effects Regression

To evaluate the relationship between session composition and estimated capability shift while accounting for the nested data structure, we regressed the capability-shift proxy on the cumulative difficulty proportions using a Linear Mixed-Effects Model (LMM). This model controls for shifts in exercise surface complexity (Δ_{chars} and Δ_{words}) and tutor identity as a fixed effect, while including a random intercept for student identity to account for multiple sessions per learner.

Because the three difficulty alignment proportions are compositionally constrained (they sum to one within each trajectory), entering all three as predictors would introduce perfect collinearity. We therefore fit the model by including two of the three proportions, omitting the third as the reference category.

Formally, omitting Under-Challenged as the ref-

erence, the model is specified as:

$$\begin{aligned}
CS_{js} = & \beta_0 + \beta_1 \cdot \text{PropOptim}_{js} \\
& + \beta_2 \cdot \text{PropOver}_{js} \\
& + \beta_3 \cdot \Delta_{\text{chars},js} \\
& + \beta_4 \cdot \Delta_{\text{words},js} \\
& + \gamma \cdot \text{Tutor}_s + u_j + \varepsilon_{js}
\end{aligned} \tag{2}$$

where j indexes the student and s indexes the tutor. Under this parameterization, β_1 estimates the expected change in capability shift when shifting proportion from Under-Challenged to Optimally Challenged exercises (holding Over-Challenged and all controls constant), and β_2 estimates the corresponding contrast from Under-Challenged to Over-Challenged.

To recover the third pairwise contrast (Optimally Challenged versus Over-Challenged), we equivalently re-parameterize the same model with Over-Challenged as the reference category. This controlled specification quantifies the theoretical variables’ impact on the expected capability shifts while mathematically isolating them from structural confounders.

4 Results

4.1 Exercise Identification

From the initial 2,527 sequences labeled as containing tutor exercises, we evaluated the filtering pipeline described in Section 3.1 on a 10% human-annotated verification set ($n = 252$), in which one author manually judged exercise eligibility by reviewing each target turn alongside a context window of 15 surrounding turns.

GPT-4.1 (prompted at temperature 0) was evaluated against these human judgments on the same verification set, achieving an accuracy of 0.84, precision of 0.88, recall of 0.85, and Cohen’s $\kappa = 0.66$. Under the Landis and Koch scale (Landis and Koch, 1977), this represents substantial agreement. The moderate κ relative to the high accuracy reflects the inherent ambiguity of boundary cases—particularly turns involving partially self-contained exercises or where the distinction between scaffolding for a prior exercise and initiation of a new one was unclear. Given the strong overall validation, especially the high precision, we applied the automated pipeline to the remaining sequences, yielding a final dataset of 1,566 eligible exercises.

Label	Supp.	Acc.	Prec.	Rec.	F1
Hint / Instruction	124	.975	.824	.871	.847
Direct Answer	26	.993	.800	.769	.784
Proc. Q. / Confusion	6	.999	.857	1.000	.923
Content Q. / Confusion	24	.993	.783	.750	.766
<i>Response Attempt:</i>					
Correct	121	.985	.930	.876	.902
Incorrect	61	.989	.891	.803	.845
Partial	23	.986	.513	.870	.645
NA	1185	.963	.992	.959	.975
Overall	1570	.932	.932	.932	.932

Table 3: LLM–human agreement on turn-level behavioral annotation ($n = 1,570$ turns from 157 exercises). Accuracy is computed in a one-vs-rest setting per label.

4.2 Turn-Level Behavioral Annotation

To scale annotation to the full corpus, we evaluated GPT-5.2 against reconciled human annotations (157 exercises, 1,570 turns). Table 3 reports per-label performance. Overall accuracy was 0.93 (Cohen’s $\kappa = 0.84$), indicating strong alignment with human judgment across the taxonomy. Performance was highest for structurally unambiguous labels such as Response Attempt – Correct (F1 = 0.90). The primary error mode was Response Attempt – Partial (F1 = 0.65), where the model frequently conflated partial responses with fully correct or incorrect ones: a distinction that requires evaluating completeness relative to the exercise prompt. Given the strong overall agreement, we applied the automated pipeline to annotate the remaining corpus.

We further validated the LLM annotations at the trajectory-state level, where they enter the downstream model. Applying the mapping rule of Section 3.3 to both human and GPT-5.2 turn labels yields a difficulty alignment state for each of the 157 human-annotated exercises. Agreement between human-derived and LLM-derived states is substantial (accuracy = 0.885, Cohen’s $\kappa = 0.786$). Per-class F1 ranges from 0.81 (Over-Challenged) to 0.92 (Under-Challenged), with Optimally Challenged at 0.85. The full state-level confusion matrix and per-class breakdown appear in Appendix B.

4.3 Difficulty Alignment State Distribution

Applying the trajectory-to-challenge mapping (Section 3.3) to all 1,566 eligible exercises yields a markedly skewed distribution: 920 exercises (58.7%) were classified as Under-Challenged, 165 (10.5%) as Optimally Challenged, and 481 (30.7%) as Over-Challenged.

The predominance of Under-Challenged exer-

cises indicates that, across the corpus, students most frequently answered correctly without exhibiting prior evidence of content-level struggle. The relatively small proportion of Optimally Challenged exercises, where students demonstrated initial difficulty but ultimately succeeded, is consistent with the theoretical expectation that the zone of productive struggle is narrow relative to tasks that are either too easy or too difficult. The substantial Over-Challenged proportion (30.7%) reflects cases where the tutor ultimately provided the answer or the interaction reached the turn limit without a correct student response.

4.4 Next-Exercise Success Prediction

The generalized linear mixed-effects model achieved a mean AUC of 0.61 and mean classification accuracy of 0.70 in the 5-fold cross-validation. The above-chance AUC confirms that the retained trajectory features carry a discriminative signal for next-exercise outcomes beyond baseline prevalence. To ensure these results are robust to model specification, we tested alternative modeling structures (detailed in Appendix E), which yielded near-identical predictive performance.

To identify which features drive the model’s predictions, we report standardized fixed-effect coefficients in Table 4. The strongest pedagogical predictor was the count of consecutive optimally challenged exercises immediately preceding the target turn ($\beta = 0.233$, $p = 0.029$): an uninterrupted sequence of productive difficulty is associated with higher expected learner success on the subsequent task. Among controls, average hints per exercise showed a positive association ($\beta = 0.201$, $p = 0.049$), consistent with the hypothesis that scaffolding facilitates subsequent independent performance. The CEFR proficiency ordinal yielded a negative coefficient ($\beta = -0.184$, $p = 0.020$), reflecting that higher-proficiency learners might face more demanding exercises in this corpus rather than indicating lower capability. Cumulative difficulty proportions were not significant predictors of immediate turn-level success ($p > 0.30$); their role in shaping macro-level session trajectories is examined in Section 3.6.

4.5 Associating Difficulty Alignment with Capability Shift

To test whether the session-level composition of difficulty explains the capability-shift proxy, we analyzed the 153 valid session-level trajectories

Fixed Effects	β	SE	p
Consecutive Optimal States	0.233	0.107	.029
Avg. Hints per Exercise	0.201	0.102	.049
CEFR Level Ordinal	-0.184	0.079	.020
Prop. Under-Challenged	0.148	0.155	.340
Prop. Over-Challenged	-0.135	0.164	.411
Next Exercise # Words	-0.111	0.183	.543
Consecutive Successes	0.110	0.096	.250
Total Teacher Hints	-0.103	0.097	.288
Next Exercise # Chars	-0.075	0.184	.683
Consecutive Failures	-0.055	0.094	.555
Total Procedural Qs	-0.038	0.070	.583
Last 3 Success Rate	0.031	0.187	.870
Total Content Qs	-0.003	0.071	.961
Intercept	0.623	0.158	< .001
Tutor Fixed Effect	0.439	0.208	.035

Table 4: Standardized fixed-effect coefficients from the GLMM predicting next-exercise success. All continuous predictors are z -scored per fold. Student random intercept variance: 0.003.

($n \geq 4$ exercises) using the controlled LMM described in Section 3.6. To evaluate all pairwise contrasts among difficulty states, the model was parameterized twice, rotating the reference category. Complete estimates are presented in Table 5.

The pairwise contrasts show two main findings:

The Detrimental Effect of Over-Challenge.

The data strongly indicates that excessive difficulty hinders capability improvement. When specifying Over-Challenged as the baseline reference, shifting the session composition toward either Under-Challenged ($\beta = 0.136$, $p < 0.001$) or Optimally Challenged ($\beta = 0.219$, $p < 0.001$) yields a substantial and highly significant increase in the capability-shift proxy.

The Superiority of Optimal Challenge. The critical theoretical test lies in the contrast between Optimally Challenged and Under-Challenged states. When holding Over-Challenged constant and utilizing Under-Challenged as the baseline, increasing the proportion of Optimally Challenged exercises is associated with a significant positive increase in the expected capability shift ($\beta = 0.083$, $p = 0.041$). This pattern is consistent with sustained productive difficulty ($i + 1$) producing greater capability improvement than simple independent mastery (i), supporting the trajectory-based difficulty alignment classification.

5 Discussion

Our results provide evidence consistent with the Input Hypothesis by establishing the hierarchy: Optimally Challenged > Under-Challenged > Over-

Table 5: Controlled LMM predicting the capability-shift proxy from difficulty alignment proportions ($n = 153$ trajectories). Panels (a) and (b) are re-parameterizations of the same model, differing only in the omitted reference category to display all pairwise contrasts. The model includes a student-level random intercept.

(a) Reference Group: Under-Challenged

Challenged. Specifically, the robust negative association for the Over-Challenged proportion suggests excessive difficulty hinders development, while the positive contrast between Optimally and Under-Challenged states indicates that sessions with greater productive struggle are associated with greater capability shifts ($p = 0.041$). Crucially, these associations remain robust after controlling for student baseline variance, tutor identity, and exercise surface complexity. The near-zero coefficients for Δ_{chars} and Δ_{words} confirm the classification captures substantive interactional demand rather than superficial prompt changes. Together, these findings provide quantitative support for the value of optimal challenge in dynamic tutoring.

Beyond these findings, this framework provides a highly scalable approach for educational measurement. Instead of requiring the LLM to directly infer the abstract, latent difficulty of a task, the framework assigns the model a much simpler objective: classifying explicit, observable interactional behaviors. Because this specific classification task is straightforward for the LLM, the resulting turn-level annotations are reliable and amenable to automation at scale. Consequently, this automatic behavior-based classification framework is in principle transferable to other flexible, open-ended, and dynamically generated on-the-fly educational contexts.

This reliable, real-time annotation enables two direct system applications. First, the trajectory-to-challenge mapping can serve as a continuous evaluation metric for both human-led and LLM-generated exercises, providing computational feedback on whether the current pedagogical strategy maintains the learner’s optimal challenge zone. Second, these alignment states can function as a theoretically grounded reward signal for reinforcement learning frameworks; rather than simply rewarding correct answers, LLMs can be optimized to generate interaction trajectories that sustain productive struggle. Crucially, because the classification operates on the immediate post-exercise interaction rather than extensive prior history, deployed systems can utilize this framework from the first exercise of a session without facing a cold-start problem.

However, these applications must be implemented with strict caution regarding their current empirical validation. The associations identified in this study are observational, and we do not demonstrate causal effects of optimal challenge on learning outcomes, nor can we guarantee generalizability across different demographics or learning domains. Translating these within-session associations based on a model-estimated proxy into generalized claims about learning, or deploying them as definitive training targets in live systems, requires future experimental manipulation and external outcome measurement.

Limitations

Aggregated Proportions versus Sequential Dynamics. Our macro-level model aggregates each session’s difficulty history into cumulative proportions, discarding the chronological ordering of states. Yet sequence likely matters: an Over-Challenged opening followed by Optimally Challenged exercises may yield different gains than the reverse, even at identical proportions. Future work should apply sequence-aware models to capture how specific state transitions shape learning trajectories.

Annotation Visibility. Our classification rests on observable interaction in the chat transcript: typed turns, errors, and explicit questions. The transcript necessarily misses cognitive effort that does not surface in writing. A student who silently translates a word, consults an external resource, or works through a difficult construction in their head before

typing a correct answer will be classified as Under-Challenged on the visible evidence, even though the exercise may have exceeded the student’s independent capability. This systematically biases the classification toward Under-Challenged for learners who externalize less of their reasoning, and would correspondingly understate the proportions of Optimally Challenged and (where external help is used) Over-Challenged exercises. Richer multimodal signals, such as typing latencies, screen capture, and eye tracking, could close this visibility gap.

Proxy Validity. Because the TSCC lacks pre- and post-assessments, our dependent variable in RQ3 is an in-situ proxy derived from the micro-level predictive model’s out-of-fold probabilities. This creates an inferential dependency: the sensitivity of RQ3’s findings is bounded by the predictive model’s discriminative capacity (AUC = 0.61). The proxy captures short-term behavioral shifts within tightly bounded sessions (mean $\approx$ 5.8 prior exercises) rather than durable language acquisition. RQ3’s results should therefore be interpreted as associations detected through the lens of this model, not as independent evidence of learning outcomes.

Unmeasured Confounders. Our analyses are observational, and the reported coefficients identify associations rather than causal effects. The student-level random intercept absorbs stable between-learner differences and the tutor fixed effect absorbs stable between-tutor differences in baseline, but several plausible confounders remain incompletely controlled. First, within-learner ability can fluctuate across sessions in ways the random intercept does not capture. Second, tutor adaptation is dynamic. A tutor may select harder exercises for students who appear to be progressing well, which would induce reverse causation between session composition and the capability-shift proxy. Third, task type (e.g., grammar drills vs. open-ended writing prompts) likely affects both how difficulty manifests in the trajectory and how the proxy responds, beyond what exercise-length controls absorb. Establishing causal effects would require experimental manipulation of session composition or substantially richer logs of tutor decision-making.

Data Scope. The analysis relies on 12 students and 2 teachers from the TSCC Version 2. This limited sample constrains the generalizability of both the predictive model and the session-level infer-

ences. In particular, the student random intercepts are estimated from few sessions per learner, and the tutor fixed effect captures only a single pairwise contrast. Replication on larger, longitudinal corpora with standardized external assessments is necessary to establish whether these associations generalize across populations and translate into lasting acquisition gains.

A Exercise Identification Details

We defined an eligible exercise as a tutor turn presenting a language practice opportunity satisfying three conditions:

1. **Content Presence:** The turn contains the actual exercise body (e.g., a sentence to complete), rather than merely announcing an upcoming task.
2. **Contextual Completeness:** The exercise is self-contained within the chat history, excluding tasks requiring external resources (textbooks, URLs, images, audio).
3. **Productive Intent:** The task requires the student to produce English (structured drills, translation, open-ended prompts), excluding scaffolding for prior exercises, social exchanges, and administrative setup.

The annotation pipeline proceeded in four stages: (1) one author manually annotated a random 10% sample ($n = 252$), reviewing each target turn with a context window of 15 surrounding turns; (2) GPT-4.1 (temperature 0) was evaluated on this verification set against the precision threshold defined in Section 3.1; (3) the automated pipeline was applied to the remaining sequences; (4) student-initiated exercises were removed to restrict the analysis to tutor-led pedagogical strategies. The prompt is documented in Appendix C.1.

B State-Level Agreement on the Verification Set

To complement the turn-label agreement reported in Section 4.2, we applied the trajectory-to-challenge mapping rule (Section 3.3) separately to the human and GPT-5.2 turn-label sequences for the 157 manually annotated exercises, obtaining a derived difficulty alignment state from each annotation source. Table 6 reports the resulting confusion matrix.

Overall agreement is substantial (accuracy = 0.885, Cohen’s $\kappa = 0.786$ under the Landis and Koch scale (Landis and Koch, 1977)). The Optimally Challenged class has high precision (0.944) and modest recall (0.773): when the model labels an exercise Optimally Challenged it almost always agrees with the human annotator (17 of 18 cases), but it misses 5 of 22 human-labeled Optimally Challenged exercises, assimilating them into the neighboring Under- or Over-Challenged categories. The model never labels a human-Under exercise as Optimally Challenged, supporting the interpretation that LLM-derived Optimal-state counts are conservative rather than inflated. The dominant disagreement pattern is between Under-Challenged and Over-Challenged (12 of 18 total errors).

Human	LLM (GPT-5.2)			Total
	Under	Optimal	Over	
Under-Challenged	90	0	9	99
Optimally Challenged	3	17	2	22
Over-Challenged	3	1	32	36
Total	96	18	43	157

Table 6: Confusion matrix between human-derived and GPT-5.2-derived difficulty alignment states on the 157-exercise verification set. Rows: human; columns: LLM. Overall accuracy = 0.885, Cohen’s $\kappa = 0.786$.

C Prompts

This appendix lists the specific prompts provided to the Large Language Model for the automated annotation pipelines described in Sections 3.1 and 3.2.

C.1 Exercise Identification Prompt

System Prompt: Exercise Identification

You are an expert annotator for educational dialogues in English language learning contexts.

Your task is to determine if the "Current Turn" is an **eligible exercise turn** posed by the {role}.

Definition of Eligible Exercise

An eligible exercise is a turn where the {role} presents a language practice opportunity that:

1. **Contains the actual exercise content** (not just an announcement or instruction or scaffolding about an upcoming or previous stated exercise)
2. **Is self-contained within the chat** (does not require external resources like textbooks, videos, links, or materials not present in the conversation)
3. **Requires the student to produce or practice English**

Types of Eligible Exercises

- **Structured exercises**: fill-in-the-blank, grammar drills, vocabulary exercises, sentence completion, translation tasks, writing prompts (e.g., "Write a paragraph about...")
- **Eliciting questions for language practice**: open-ended questions designed to get the student to practice expressing themselves in English (e.g., "Can you describe a typical day for you?", "Tell me about your favorite hobby", "What would you do if...?")

What is NOT an Eligible Exercise

1. Announcements or setup without exercise body

Turns that merely introduce an exercise without containing the exercise itself. However, if a turn combines the announcement AND the exercise body, it IS eligible.

Example sequence:

- Turn X -- Teacher: "Let's try to add the word 'yesterday' to the following sentence!" -> **NOT eligible** (announcement only)
- Turn X+1 -- Teacher: "She went back home." -> **ELIGIBLE** (this is the exercise body)
- Turn X+2 -- Teacher: "Insert the word 'yesterday' in the sentence I just sent you ." -> **NOT eligible** (instruction or scaffolding referencing previous exercise)

Contrast with:

- Teacher: "Let's try to add the word 'yesterday' to the following sentence: 'She went back home.'" -> **ELIGIBLE** (contains the exercise body in one turn)

Note: If you cannot find the exercise body in the current turn, previous context, OR post context, then the turn is NOT eligible -- this implies it requires external materials not present in the chat.

2. Scaffolding or hints for a previous exercise

Follow-up prompts that support an already-given exercise but do not constitute a new exercise themselves (e.g., "Please answer in a full sentence.", "Any other ideas?", "Can you try again?", "Think about what tense to use.")

3. Social/administrative exchanges

Casual greetings, check-ins, or procedural questions that do not involve language practice (e.g., "How are you?", "Are you ready to start?", "Can we do some exercises?", "Did you finish your homework?")

4. Exercises requiring external materials

If completing the exercise requires access to resources not fully present in the conversation:

- Textbooks, worksheets, images, charts, videos, audio files
- External links or apps (e.g., Skype messages, Instagram, websites)
- Reading passages or materials not included in the chat

Key indicators that an exercise requires external materials:

- Mentions of "chart," "image," "picture," "textbook," "video," "audio," "page," or "link"

```

- References to specific question numbers (e.g., "What do you think about question 43?") without providing the question content -- this implies they are looking at an external source
- Instructions like "Look at the reading passage" or "Based on the video we watched" when that content is not in the chat

### 5. Simple yes/no or factual questions
Questions that can be answered with a single word or simple fact and do not promote meaningful language practice (e.g., "Is this correct?", "Do you understand?", "What's 2+2?")

## Decision Process

1. **Read the Current Turn carefully.** Does it contain actual exercise content that requires the student to produce English?

2. **Check the Post Context.** If the exercise body appears AFTER the current turn, then the current turn is just an announcement -> NOT eligible.

3. **Check for external material dependencies.** Using the Previous and Post Context, determine whether the exercise references materials or content not present in the conversation -> NOT eligible.

4. **Distinguish from scaffolding.** Is this turn providing hints or follow-up for an exercise that was already given in a previous turn? -> NOT eligible.

---

Previous Context:
{prev_context}

Current Turn ({role}):
{current_turn}

Post Context:
{post_context}

---

First, write a brief reasoning (maximum 50 words) explaining your decision.
Then provide the final label.

Output format:
<analysis>
Your reasoning here (<= 50 words).
</analysis>
<judgement>
YES or NO
</judgement>

```

C.2 Turn-Level Behavioral Annotation Prompt

System Prompt: Post-Exercise Discussion Annotation

```

You are an expert linguistic annotator analyzing English as a Foreign Language (EFL) tutoring dialogues.
Your task is to analyze the "Post-Exercise Discussion" and label the pedagogical function of each turn relative to a specific "Exercise Body."

### INPUT DATA
1. Previous Context: The conversation history leading up to the exercise.
2. Exercise Body: The specific problem, sentence, or grammar task the student must solve.
3. Post-Turn Text: A sequence of up to 10 dialogue turns immediately following the exercise introduction.

### LABEL TAXONOMY
Choose exactly one label for each turn from this list:

```

```

TEACHER LABELS
- Hint/Instruction
- Direct Answer [STOP CONDITION]

STUDENT LABELS
- Procedure Question or Confusion
- Content Question or Confusion
- Response Attempt - Correct [STOP CONDITION]
- Response Attempt - Incorrect
- Response Attempt - Partial

OTHER
- NA

### DEFINITION OF LABELS
- Hint/Instruction: Scaffolding, hints, elicited questions (e.g., "Tell me more"),
  or instructions.
  Also, if the Exercise Body is vague (e.g., "Make a sentence") and the teacher
  provides the specific exercise text in the chat, label that turn as `Hint/
  Instruction`.
- Direct Answer: The teacher explicitly provides the correct answer.
- Procedure Question or Confusion: Student asks how to do the task or expresses
  confusion about the activity steps (not language knowledge).
- Content Question or Confusion: Student asks about language knowledge/content, ways
  to improve the answers, or expresses lack of knowledge specific to this
  exercise.
- Response Attempt - Correct: Student provides a grammatically and semantically
  complete answer that satisfies the exercise.
- Response Attempt - Incorrect: Student attempts to answer, but the content is wrong
  or contains typos.
- Response Attempt - Partial: Student provides a correct but incomplete answer (e.g
  ., filling only 1 of 2 blanks).
- NA: The turn cannot be labeled with any of the above labels. Turn does not fit
  above categories OR is off-topic / meta-talk.

### CRITICAL ANNOTATION RULES
1. Strict Scope: Labels must strictly relate to the Current Exercise Body.
2. Stop Condition: Process turns sequentially. STOP labeling immediately after
  assigning Direct Answer or Response Attempt - Correct.
3. Always follow the teacher's judgement on correctness of the student's answer.

D Feature Dictionary and L1 Selection Frequencies

Table 7 reports the full pool of 24 candidate features and their L1 selection frequencies across 5-fold session-level cross-validation, using the inclusion criterion described in Section 3.4. The 13 features retained for the final GLMM are highlighted in bold. Structural control variables (the student random intercept and the tutor fixed effect) were not subject to L1 penalization and were unconditionally retained.

Feature Name	Description	Selection Ratio
<i>Learner Background</i>		
CEFR Level Ordinal	Ordinal encoding of CEFR proficiency (1=B1, 2=B2, 3=C1, 4=C2).	1.00
CEFR Level (Categorical)	Categorical representation of the student’s CEFR proficiency.	0.30
<i>Trajectory Length</i>		
Prefix Length	Number of prior exercises observed in the current session.	0.00
Number of Previous Exercises	Redundant feature mathematically identical to Prefix Length.	0.00
<i>Historical Performance</i>		
Consecutive Successes	Count of consecutive correct responses immediately preceding $t + 1$.	1.00
Consecutive Failures	Count of consecutive incorrect responses immediately preceding $t + 1$.	0.80
Last 3 Success Rate	The accuracy rate over the most recent 3 exercises.	0.60
Last 2 Success Rate	The accuracy rate over the most recent 2 exercises.	0.40
Cumulative Success Rate	The overall accuracy rate across all prior exercises in the session.	0.00
Previous Exercise Correct	Binary indicator of whether the immediately preceding exercise was correct.	0.00
<i>Historical Difficulty Alignment ($i+1$)</i>		
Prop. Over-Challenged	Cumulative proportion of Over-Challenged exercises in the trajectory.	1.00
Prop. Under-Challenged	Cumulative proportion of Under-Challenged exercises in the trajectory.	0.60
Prop. Optimally Challenged	Cumulative proportion of Optimally Challenged exercises (dropped to avoid collinearity).	0.20
Consecutive Optimal States	Count of uninterrupted Optimally Challenged states immediately preceding $t + 1$.	1.00
Consecutive Over-Challenged	Count of uninterrupted Over-Challenged states immediately preceding $t + 1$.	0.00
Previous Difficulty State	Categorical variable for the difficulty state of the immediately preceding exercise.	0.00
<i>Scaffolding & Interaction</i>		
Avg. Hints per Exercise	Average number of tutor hints provided per exercise so far.	1.00
Total Teacher Hints	Cumulative count of all tutor hints provided in the trajectory.	1.00
Total Procedural Qs	Cumulative count of procedural questions asked by the student.	0.80
Total Content Qs	Cumulative count of content questions asked by the student.	0.60
Previous Ended Direct Answer	Binary indicator of whether the previous exercise ended in direct answer from teacher.	0.40
Previous Required Hint	Binary indicator of whether the previous exercise involved any tutor hints.	0.00
<i>Next Exercise Properties (Complexity Controls)</i>		
Next Exercise # Chars	Character length of the upcoming exercise prompt.	0.60
Next Exercise # Words	Word count of the upcoming exercise prompt.	0.60

Table 7: Dictionary of all initial trajectory features and their L1 selection frequencies across 5-fold cross-validation. Features selected in ≥ 0.60 of folds (highlighted in bold) were retained for the final GLMM.

E Robustness Checks for the Next-Exercise Success GLMM

To ensure that the predictive relationships identified in Section 3.4 are not artifacts of a specific statistical structure, we evaluated four variations of the Generalized Linear Mixed-Effects Model (GLMM).

The models tested include:

1. **Student Random + Tutor Fixed (Main Model):** Includes both a student-level random intercept and a categorical tutor fixed effect.
2. **Tutor Fixed Only:** Includes only the tutor fixed effect, omitting student-level variance control.
3. **Student Random Only:** Includes only the student-level random intercept, omitting the tutor fixed effect.
4. **Base Model:** A standard logistic regression omitting both student and tutor controls.

Table 8 demonstrates that all four model specifications yielded near-identical out-of-fold predictive performance. Table 9 reports the standardized coefficient estimates (β) and p -values across the three alternative specifications. Consistent with the main findings, the count of consecutive optimally challenged states (consec_aligned_t) remains a significant positive predictor across all model variations, confirming the robustness of this core pedagogical feature regardless of the structural controls applied.

Model Specification	Mean AUC	Mean Acc.
Student Random + Tutor Fixed (Main)	0.610	0.701
Tutor Fixed Only	0.610	0.701
Student Random Only	0.599	0.703
Base Model (No Controls)	0.599	0.703

Table 8: Cross-validated predictive performance across model structures ($N = 5$ folds). Hierarchical controls do not fundamentally alter discriminative power.

Fixed Effects	Tutor Fixed Only		Student Random Only		Base Model	
	β	p	β	p	β	p
Consec. Aligned States	.234	.029	.232	.029	.233	.029
Avg. Hints per Exercise	.203	.047	.156	.112	.156	.113
CEFR Level Ordinal	-.183	.019	-.125	.094	-.125	.091
Prop. Under-Challenged	.150	.337	.173	.261	.176	.254
Prop. Over-Challenged	-.135	.412	-.098	.545	-.096	.555
Next Ex. Length: Words	-.113	.547	-.122	.495	-.121	.508
Consec. Successes	.111	.249	.133	.164	.134	.161
Total Teacher Hints	-.104	.282	-.129	.178	-.131	.170
Next Ex. Length: Chars	-.073	.702	-.152	.393	-.155	.394
Consec. Failures	-.056	.551	-.053	.573	-.053	.572
Total Procedural Qs	-.038	.582	-.053	.443	-.053	.444
Last 3 Success Rate	.029	.879	.032	.865	.031	.870
Total Content Qs	-.004	.957	.006	.933	.006	.927
Intercept	.625	< .001	.922	< .001	.924	< .001
Tutor Fixed Effect	.432	.035	—	—	—	—

Table 9: Standardized coefficients and p -values across three alternative model specifications. All continuous predictors are z -scored per fold. Significant effects ($p < .05$) in bold. The effect of consecutive aligned states remains stable across all variations. Models include student random intercepts.

PEERMATHDIAL: A Middle School Dialogue Dataset for Student Collaborative Math Problem Solving

Project website (dataset and source code): [MathVC-NSF.github.io](https://github.com/MathVC-NSF)

Abstract

Collaborative Problem Solving (CPS) is a core skill in education, where the process of peer interaction is highly important. However, existing educational dialogue datasets mostly focus on classroom instruction or tutoring (i.e., teacher/tutor-student interaction), yet datasets centering small-group, student-student interaction are limited. This thus leaves research with limited resources for studying how students interact, coordinate, and solve problems together in real educational settings. To address this, we introduce PEERMATHDIAL, the first dataset of peer CPS dialogues collected from authentic middle school math classrooms. It contains 55 dialogues from 27 students, totaling 6,406 turns. To facilitate research on CPS discourse analysis, we further build a corpus-grounded dialogue act taxonomy assisted by LLMs. Using the dataset and the dialogue act taxonomy, we demonstrate the practical applications of PEERMATHDIAL across three use cases. First, we track how dialogues evolve over time and measure the impact of teacher interventions. Second, we align dialogue actions with student surveys to reveal the connection between students' traits (e.g., confidence, leadership) and their actual behaviors. Third, by evaluating LLMs on dialogue act prediction, we glimpse at the potential of LLMs for student simulation in educational applications. Our dataset and source code will be released to the community.

1 Introduction

Collaborative Problem Solving (CPS) is recognized as a core competency in K-12 education, as students share information, coordinate participation, explain reasoning, check constraints, and jointly revise errors through interaction (Vygotsky and Cole, 1978; Rosé et al., 2008; Care et al., 2012). In contrast to product-oriented problem-solving processes, an exclusive focus on outcomes fails to capture how students actually collaborate through dialogue, including how

they negotiate meaning, consider different perspectives, generate solutions, and respond to one another in interaction. Although the importance of CPS as a process-oriented approach is well recognized in the mathematics literature (Roschelle and Teasley, 1995; O'Donnell and Hmelo-Silver, 2013; OECD, 2017), access to authentic classroom dialogue that enables fine-grained examination of these processes remains limited. Important educational dialogue resources such as Talk-Moves (Suresh et al., 2022), NCTE (Demszky and Hill, 2023), CIMA (Stasaski et al., 2020), and MathDial (Macina et al., 2023) are respectively more oriented toward classroom instructional discourse, tutoring dialogue, and constructed educational interaction, yet they do not provide dialogues centered on peer interactions in CPS.

To address this gap, we introduce PEERMATHDIAL, a CPS dialogue dataset collected from a math-centered, middle-school summer camp. The dataset captures students' naturally occurring face-to-face small-group problem solving and contains 55 unscripted dialogues from 27 students, comprising 6,406 dialogue turns in total. Our dataset preserves the spoken interactional process of classroom collaboration, including task interpretation, strategy proposal, peer questioning, etc. To the best of our knowledge, we are the first to publish a dataset of face-to-face peer CPS dialogues collected from authentic K-12 mathematics classrooms. Besides, to make the corpus more analyzable, we further derive a dialogue act (Stolcke et al., 2000) taxonomy to organize students' interactions. Rather than mapping dialogue turns onto expert-designed taxonomies such as the PISA CPS framework (OECD, 2017), we adopt an LLM-assisted, corpus-grounded inductive procedure: an LLM first processes the raw dialogue and summarizes dialogue actions, after which these candidate actions are manually reviewed by education experts. The resulting taxonomy covers major inter-

actional dimensions such as affective/off-task talk, communicating and coordinating, exploring and understanding, monitoring and revising, planning and executing, and representing and formulating. Its purpose is to provide a corpus-grounded organizational lens that makes subsequent educational dialogue analysis more tractable.

Beyond introducing the corpus and its action taxonomy, we demonstrate the applications of PEER-MATHDIAL through three specific applications. (1) **Understanding collaborative dynamics:** we track the temporal evolution of dialogues and empirically quantify the impact of teacher interventions on students’ subsequent micro-behaviors. (2) **Understanding the connection of actions and characters:** by aligning dialogue act distributions with self-reported character surveys (including math confidence, collaboration, leadership), we reveal typical patterns between students’ character and their behaviors in CPS. (3) **Evaluating LLM student simulation:** through dialogue act prediction experiments, we show that state-of-the-art LLMs still struggle to reproduce authentic collaborative behaviors, establishing our dataset as an ideal testbed for developing high-fidelity virtual student simulators.

2 Dataset

2.1 Data Collection

Our dataset was collected from a summer camp organized by George Mason University in 2025, centered on middle-school (i.e., grade 6-8) mathematical CPS. During each session, students participated in a 90-minute collaborative problem-solving block, in which they worked in small teams of 3-4 students on two to three mathematical tasks. To guide the session, the camp recruited 4 middle-school teachers from nearby school districts with an average of 20 years of teaching experience. The mathematical tasks were designed by these teachers, balancing between difficulty and engagement. Participants enrolled in the camp through recruitment materials distributed via the university’s camp website, social media platforms, and educational mailing lists. More details about the participants’ information and the camp tasks are in the Appendix A.

The instructional design emphasized open-ended, real-world-inspired mathematical tasks intended to elicit collaborative reasoning, mathematical modeling, and collective sense-making. Across

the week, students engaged in tasks that required them to propose solution strategies, justify their reasoning, and revise their ideas in response to peer feedback. For example, one task asked students to determine how to price a cake fairly based on its size under a fixed total price, requiring proportional and spatial reasoning. Together, these tasks were designed to foreground discussion, explanation, conjecturing, and revision rather than answer production alone.

All instructional sessions were video- and audio-recorded to capture both whole-class instruction and small-group interaction. We used Swivl cameras for whole-class video capture and placed an individual voice recorder at each table to obtain higher-quality audio of small-group collaborative dialogue. These recordings form the basis of the benchmark.

2.2 Data Processing and Statistics

To prepare the corpus, we maintained a centralized data log that tracked all available recordings by date, classroom, task, and group. We performed speech recognition using Otter AI.¹ All recordings were first transcribed automatically and then manually reviewed by four student researchers while listening to the original audio. We followed a two-level transcription workflow: (1) whole-lesson transcription, which captured teacher-led and class-wide discourse, and (2) small-group transcription, organized by table or group identity to preserve fine-grained peer interaction. Because Otter AI provides time-aligned transcripts, researchers were able to revise transcripts while checking the original recordings. We made light but systematic edits to improve lexical accuracy, punctuation, and readability, while preserving the original turn-by-turn structure of the interaction. Speaker identification was conducted manually. Otter AI initially assigned generic labels such as *Speaker 1* and *Speaker 2*; researchers replaced these labels with the corresponding student or teacher identities using session record sheets, group assignments, seating information, and audio/video context. During transcript cleanup, utterance segments that had been incorrectly split by the automatic system were merged to maintain speaker coherence and conversational flow. Real names were retained during the internal transcription stage to support cross-session tracking, and all transcripts were pseudonymized in

Total Dialogues	55
Total Dialogue Turns	6,406
Average Turns per Dialogue	116.5
Average Words per Turn	11.6
Role Distribution	
Student	71.7%
Teacher	20.7%
Unknown	7.6%

Table 1: Statistics of the Dialogue Dataset.

later analytic stages. This processing pipeline was designed to preserve the temporal and interactional structure of collaborative dialogue, enabling analysis of participation, reasoning, and coordination in small-group mathematical problem solving.

The raw classroom transcripts contained overlapping whole-class instructional content. To only extract authentic peer interaction within small groups, we remove shared whole-class segments that were duplicated across multiple group transcripts, such as teacher-led openings at the beginning of class or summary discussions at the end. This process ensured that the final retained data consisted only of localized CPS dialogue within each group. In addition, we conducted a rigorous anonymization procedure, mapping original speaker names to consistent pseudonyms across all sessions. This allowed us to accurately track individual participation longitudinally while preserving privacy.

The statistics of the cleaned dataset are summarized in Table 1. The dataset contains 55 unique dialogue sessions with a total of 6,406 conversational turns. On average, each session includes 116.5 turns, and each turn contains 11.6 words, reflecting the relatively fast-paced and fragmented nature of middle school conversational exchanges. In terms of participation, the dataset tracks 27 focal students who completed self-report background surveys. Analysis of the role distribution indicates a student-driven CPS environment, with student utterances accounting for the vast majority of the discourse (71.7%). Finally, 7.6% of the turns are labeled as “unknown,” typically due to brief interjections, overlapping speech, or background noise that could not be reliably attributed to a specific speaker.

3 CPS Dialogue Act Discovery

Dialogue acts are functional units describing the speaker’s intent (Stolcke et al., 2000), which have

been widely used for discourse analysis and conversational system construction. Educational research on CPS discourse has often relied on pre-defined coding frameworks, such as the PISA framework (OECD, 2017; Stadler et al., 2020). These expert-developed frameworks typically focus on relatively coarse-grained behavioral categories, such as “establishing and maintaining shared understanding.” However, it cannot be directly applied to authentic middle school discussions. Student utterances are typically short and colloquial, and the granularity of the PISA framework is often too coarse for turn-level analysis. For example, questioning a problem condition and discussing a solution strategy may both be mapped to “establishing and maintaining shared understanding” under the PISA framework, despite serving different interactional dialogue act in local classroom discourse. To address this limitation, we adopt a bottom-up, LLM-assisted dialogue act induction pipeline that summarizes and organizes recurring interactional behaviors directly from the corpus. Table 2 summarizes the resulting taxonomy with details in Appendix B.

This pipeline is to leverage the LLM to identify the dialogue acts of each student turn within its full conversational environment. It consists of three steps. First, we divide the corpus into batches, each containing multiple dialogues, and submit the batch one by one to the LLM. For each batch, the model is asked to summarize the dialogue acts presented in this batch. Through this induction process, we extract repeated act descriptions across dialogues and gradually form a set of candidate dialogue acts. We then consolidate these batch-level summarized dialogue acts and explicitly control the granularity through prompting, so as to avoid acts that are overly broad (e.g., “establishing shared understanding”) or overly specific (e.g., “saying ok”), resulting in an initial act inventory tailored to this corpus. Second, after obtaining the initial act inventory, we ask the LLM to assign a dialogue act to every student turn in the dataset. For each turn, the model is required not only to provide an act label but also to produce a verbal confidence uncertainty score indicating how certain it is about the assignment (He et al., 2025). This allows us to identify the cases that the model itself considers uncertain. Third, we collect the turns with low confidence from the first round and submit them back to the LLM. At this stage, our goal is to examine whether these high-uncertainty cases reveal additional di-

Stage	Dialogue acts
Affect and Off-Task Talk	Off-Task or Affective Commentary
Communicating and Coordinating	Acknowledging or Receiving; Explaining or Justifying Reasoning; Guiding Peer Participation or Shared Workspace Actions; Presenting Group Reasoning to an External Listener
Exploring and Understanding	Asking for Clarification or Explanation; Identifying Relevant Elements and Constraints; Orienting to Lesson or Activity
Monitoring and Revising	Challenging or Diagnosing an Error; Checking What a Number or Step Represents; Checking Whether a Result Fits Constraints; Revising the Method or Answer
Planning and Executing	Carrying Out a Computation Step; Decomposing or Repartitioning the Structure; Proposing a Candidate Solution; Proposing a Solution Strategy
Representing and Formulating	Constructing or Refining a Representation; Mapping Representation to Values; Proposing a Pattern or Structural Model; Reusing a Previous Case or Pattern

Table 2: Overview of the corpus-grounded CPS dialogue act taxonomy. Full dialogue act definitions and examples are provided in Appendix B.

dialogue acts that are not yet covered by the initial act inventory. Through this focused inspection of low-confidence turns, the LLM can summarize potential new acts and thereby extend or revise the taxonomy. After obtaining the updated act inventory, we use the LLM to perform a new round of turn-level labeling over the full corpus. Overall, this pipeline combines corpus-level act discovery, low-confidence-case-driven taxonomy refinement, and full-corpus relabeling, thereby reducing the risk of missing dialogue act types as much as possible. All LLMs used are GPT-5.4 (OpenAI, 2026).

To evaluate the quality of the induced taxonomy and its turn-level labeling, we conducted an expert evaluation with two math education researchers who have multi-year experience as school teachers. The evaluation included two parts. In part 1, the experts were presented with the taxonomy definitions together with multiple examples and were asked if they agreed on them. In part 2, the experts evaluated 100 conversational turns, comprising 50 randomly sampled instances and 50 instances marked by the LLM as low-confidence. For each turn, we also provided the surrounding conversational context to disambiguate the judgment. The experts were then asked to judge whether the assigned act adequately described the student’s turn; if not, they were further asked whether a better label could be found in the taxonomy, or if the taxonomy was missing dialogue acts to cover the turn. As such, the experts were positioned to both *review the LLM assignment* and *make independent annotations*. Our results indicate that the dialogue act taxonomy provides strong coverage of the interactional behaviors in the corpus. The experts agreed

with the LLM’s assignments for all 50 randomly sampled turns and only identified 11 misclassifications of existing acts (rather than missing acts in the taxonomy) within the low-confidence set. Overall, the expert evaluation supports the validity of the induced taxonomy and suggests that this LLM-assisted pipeline is able to capture the major CPS interactional behaviors in the corpus with substantial coverage. We include details of the expert evaluation in Appendix C.

4 Application I: Enhancing Educational Understanding of the CPS Process

The discovered dialogue acts offer a lens through which educational researchers can better understand CPS. We present two possible directions in this section.

4.1 Temporal Evolution of CPS Dialogue Acts

We first investigate how the frequency of specific dialogue acts changes as a conversation unfolds. To compare dialogues of different lengths, we divide each conversation into six equal segments based on relative progress and compute dialogue-act proportions using student turns only. For each act, we first compute its proportion within each segment of each conversation and then average these proportions across conversations, preventing longer dialogues from dominating the estimate. For visualization, we express each segment’s value as a log-scaled deviation from that act’s average level across the full conversation. Under this normalization, positive values indicate greater-than-usual prominence, and negative values indicate lower-than-usual prominence.

Figure 1: Temporal evolution of student dialogue acts over the course of CPS conversations. Each dialogue is uniformly divided into six stages based on relative progress. Let $p_{a,s}$ denote the proportion of act a within stage s , and $\bar{p}_a$ represent its overall average proportion across all stages. The heatmap visualizes the log-ratio, $\log_2(p_{a,s}/\bar{p}_a)$. Positive values indicate above-typical prominence, and negative values indicate below-typical prominence.

Figure 1 reveals a clear temporal structure in the CPS process when we align student turns by relative dialogue progress. Overall, the temporal pattern suggests that CPS dialogue is not static: it moves from early problem framing and coordination, to mid-stage calculation and error diagnosis, and finally to late-stage evaluation, revision, and convergence. Early stages are characterized by actions that help establish the problem space, such as *identifying relevant elements and constraints*, *mapping representation to values*, and *proposing a solution strategy*. At the same time, *guiding peer participation or shared workspace actions* is also more prominent near the beginning, suggesting that students initially devote effort to coordinating participation and setting up a shared working process. As the interaction moves toward the middle stages, the dialogue becomes more operational and diagnostic. Actions such as *challenging or diagnosing an error*, *carrying out a computation step*, and *checking what a number or step represents* become relatively more prominent, indicating a shift from task setup toward active solution development and local monitoring of intermediate reasoning. This middle portion appears to function

as the main problem-solving core, where students test ideas, compute, and interrogate the meaning of emerging results. In later stages, the discourse increasingly shifts toward evaluation and repair. *Checking whether a result fits constraints* and *revising the method or answer* become especially salient, consistent with a closing phase in which students verify whether their current solution is acceptable and make adjustments when necessary. Late-stage increases in *asking for clarification or explanation* suggest that final convergence often still requires resolving residual uncertainty rather than simply stating a completed answer. We also observe a modest rise in *off-task or affective commentary* toward the end, which may reflect easing task pressure once the main solution path has been established.

4.2 Impact of Teacher Intervention

Teacher intervention is an important component of CPS in educational settings, as teachers can redirect attention, clarify task demands, prompt reflection, and help groups move past local impasses. To better understand this role, we examine how students' dialogue acts shift immediately before and after

Figure 2: Change in student dialogue-act prevalence before versus after teacher intervention, using a three-turn student window on each side of the intervention.

teacher intervention. We operationalize each contiguous run of teacher turns as a single intervention event, and for each event, extract the three nearest annotated student turns immediately before it and three immediately after it. For every intervention event and every dialogue act, we compute the act's share in the pre-window and in the post-window, and define the event-level shift as *post share minus pre share*.

Figure 2 reports the mean of this post-minus-pre quantity across intervention, measured in percentage points: values to the right of zero indicate acts that become more common after teacher intervention, whereas values to the left indicate acts that become less common. Horizontal lines show 95% bootstrap confidence intervals. This setup allows us to characterize teacher intervention not as a single isolated response, but as a short-run redistribution of student activity in the turns that follow. The post-intervention shows reliable increases in *mapping representation to values* (from 4.9% to 6.2%) and *reusing a previous case or pattern* (from 0.7% to 1.7%), together with a reliable decrease in *identifying relevant elements and constraints* (from 2.5% to 1.5%). Descriptively, we also observe a shift toward *proposing a candidate solution* and away from *off-task or affective commentary*, although those trends are less certain because their confidence intervals overlap zero. The core takeaway is

that teacher facilitation appears to redirect the next few student turns away from local interpretation and toward forward-moving mathematical activity.

5 Application II: Facilitating Teacher Comprehension of Student Profiles

Beyond the understanding of the conversational process, dialogue acts serve as a powerful tool for understanding individual student characteristics. By aligning the dialogue acts distribution with self-reported surveys, we provide educators with a multi-dimensional view of student engagement. Student typologies are derived from a pre-program self-report survey. The survey consists of Likert-scale items with five response options ranging from *strongly disagree* to *strongly agree*, covering students' attitudes toward mathematics, collaboration, leadership, and related dispositions. For each profile dimension used in our analysis (e.g., confidence, collaboration, leadership), we group together the relevant survey items and assign students to one of two broad types based on whether their responses overall indicate endorsement of that dimension. In other words, students with more agreement-oriented responses on a given dimension are grouped into the corresponding type (e.g., *confident*, *collaborative*, or *leader-like*), whereas students without such endorsement are grouped into the contrasting type. Full survey items and

Most Interpretable Dialogue-Act Contrasts by Student Type

Figure 3: Comparison of dialogue-act usage. Students are grouped from pre-task survey responses along three dimensions: confidence (Confident vs. Anxious), collaboration orientation (Collaborative vs. Independent), and participation stance (Leader vs. Listener). Bar length shows the average proportion of each student’s annotated turns assigned to a given dialogue act.

their grouping are provided in Appendix D.

Dialogue Act Distributions Across Student Typologies Figure 3 shows the dialogue act distribution by student types. The results suggest that the survey dimensions capture differences in *how* students participate, rather than a single continuum of general participation. The clearest contrast appears along the leadership dimension. Compared with listeners, leader-type students produce more *revising the method or answer* (5.0% vs. 2.1%) and more *explaining or justifying reasoning* (7.9% vs. 5.2%). By contrast, listener-type students contribute more *acknowledging or receiving* (16.1% vs. 11.5%, difference favoring listeners by 4.58 percentage points) and more *identifying relevant elements and constraints* (5.7% vs. 1.6%). A similar functional differentiation appears along the collaboration dimension: collaborative students more often engage in *asking for clarification or explanation* (7.9% vs. 4.8%) and *explaining or justifying reasoning* (7.6% vs. 5.2%), whereas independent students more often foreground *identifying relevant elements and constraints* (6.3% vs. 1.9%). Along the confidence dimension, confident students show a higher rate of *off-task or affective commentary* (15.0% vs. 8.6%), while anxious students more often produce *identifying relevant elements and constraints* (6.5% vs. 1.9%, difference favoring

anxious students by 4.54 percentage points) and *constructing or refining a representation* (5.6% vs. 2.3%, difference favoring anxious students by 3.25 percentage points). Taken together, these patterns indicate that quieter or less leader-like students are not simply disengaged; rather, they tend to contribute through uptake, monitoring, and local grounding moves, whereas leader-like and collaborative students contribute disproportionately through explanation, clarification, and revision.

Discrepancies in Self-Reported Surveys At the same time, the dialogue-act analysis highlights an important limitation of treating self-reported survey responses as direct proxies for behavior. One particularly revealing case is the item “*I try to avoid arguments, even if I disagree.*” If interpreted literally, stronger agreement with this item might be expected to predict lower rates of *challenging or diagnosing an error*. However, the observed discourse does not follow that simple pattern. Among students with sufficient dialogue data, those who *agreed* or *strongly agreed* with the argument-avoidance item still produced *challenging or diagnosing an error* in 5.9% of their annotated turns, compared with 3.2% for students who gave a *neutral* response. One possible interpretation is that students understand “avoiding arguments” as avoiding interpersonal conflict rather

Table 3: Agreement between LLM-predicted actions and real student actions under naive student-type prompting, evaluated on 100 sampled cases.

Model	Match Rate
OpenAI GPT-5.4 Mini	16.0%
OpenAI GPT-5.4	18.0%
Anthropic Claude Sonnet 4.6	16.0%
Google Gemini 3 Flash Preview	20.0%
Qwen3.5-35B-A3B	17.0%

than refraining from mathematical critique. Another is that such behaviors are shaped by context: in relatively low-stakes tasks, students may perceive less social risk in pointing out an error. More broadly, this discrepancy underscores that survey responses capture self-perception and stated disposition, whereas dialogue acts capture situated behavior in collaborative activity. The two are related, but not isomorphic. For this reason, combining survey-based typologies with discourse-analytic evidence provides a more reliable account of student participation than either source alone.

6 Application III: Implications for LLM Student Simulation

In the field of educational AI, using LLM to simulate real students for interaction holds significant value (Yue et al., 2024). However, constructing high-fidelity student simulators remains highly challenging (Kumar et al., 2025). Virtual students must not only produce natural responses in dialogue, but their behavioral decisions must also align with the real students. PEERMATHDIAL provides a highly valuable ground truth for developing and evaluating such simulators.

To conduct an investigation of current LLMs’ ability, we designed an action prediction experiment. We randomly sampled 100 dialogue turns and provided the LLM with only the student survey and all utterances of the dialogue context. Without using complex scaffolding techniques, we asked the model to predict the most likely next action from the predefined dialogue act taxonomy. We evaluated five representative state-of-the-art models, including GPT-5.4, GPT-5.4-mini (OpenAI, 2026), Claude Sonnet 4.6 (Anthropic, 2026), Gemini 3 Flash Preview (Google, 2026), and the open-source Qwen3.5-35B-A3B (Qwen Team, 2026).

The experimental results in Table 3 indicate that current LLMs struggle to accurately reproduce the fine-grained collaborative behaviors of

real students when provided with only basic identity prompts and short context windows. Across all test cases, the exact match rate of predicted actions for each model ranged only between 16.0% and 20.0%. While we admit that in some contexts more than one dialogue act can be possible, this very low exact match rate still implies a mismatch between the LLM prediction and the majority of the dialogue development. This finding carries important implications for future educational applications of LLMs. If we aim to build virtual students with behaviorally realistic decision-making processes, relying solely on high-level persona attributes is insufficient. Future student simulators may require deeper fine-tuning, longer-term dialogue memory, or specialized modeling of mathematical collaboration states. The dataset we provide serves as an ideal testbed to support such advanced research directions.

7 Related Work

Collaborative Problem Solving (CPS) is a core educational competency in which learners build shared understanding, combine knowledge and skills, and work jointly toward a common goal (OECD, 2017). In mathematics education, open-ended tasks are widely recognized as supporting critical thinking and deep learning (Vygotsky and Cole, 1978), and prior work has explored how technological scaffolds can support social interaction and equitable participation (Rosé et al., 2008). Recent studies have also begun to use LLMs to support virtual collaborative environments, such as MathVC (Yue et al., 2024). However, these frameworks usually rely on the theoretical frameworks (OECD, 2017). In contrast, our work provides a corpus composed entirely of real human students and adopts a bottom-up inductive approach driven by LLMs to discover a dialogue act taxonomy that better reflects the authentic micro-processes of physical classrooms.

Datasets and LLM Applications for Education

Prior work has long explored conversational agents for supporting collaborative learning. For example, Kumar and Rose (2010) proposed an architecture for building conversational agents that support multi-learner collaborative learning settings. More recently, LLMs have been widely applied in education (Kasneci et al., 2023). The community has introduced several important dialogue datasets in recent years. These include TalkMoves (Suresh

et al., 2022), which focuses on analyzing classroom teacher instructional discourse; NCTE (Demszky and Hill, 2023), an elementary-school math-classroom dialogue dataset collected by the National Center for Teacher Effectiveness (NCTE); CIMA (Stasaski et al., 2020), designed to support tutoring dialogue generation; and MathDial (Macina et al., 2023), which simulates human teacher-student interactions grounded in math word problems. However, they focus on the interaction paradigm of “Teacher-Student”. Currently, there remains a severe lack of corpora and modeling efforts specifically targeting authentic horizontal “Peer-to-Peer” collaborative processes, and PEER-MATHDIAL fills this gap. In addition, our work showcases the potential of leveraging LLMs as powerful qualitative “analytical engines”, assisting educational researchers in automating discourse analysis and insight discovery.

8 Conclusion

We present PEERMATHDIAL, a new dataset of peer CPS dialogues from authentic middle-school mathematics learning environments, together with a corpus-grounded dialogue act taxonomy for analyzing collaborative interaction. Our experiments show that the dataset supports fine-grained study of collaborative dynamics, links between student traits and observed behaviors, and evaluation of LLM-based student simulation. We hope PEER-MATHDIAL will serve as a useful resource for future NLP and education research on collaborative learning processes.

9 Limitations

First, PEERMATHDIAL is collected from a single math-centered summer camp with a middle-school population, so the dataset does not fully represent the broader range of K-12 classrooms. Limited by the size and duration of the camp, the dataset we collected covers a limited number of students and dialogues. However, considering the lack of resources in peer interaction for math learning, our dataset still provides unique value to the community. Meanwhile, we encourage future studies to further examine our findings based on a larger population of peer interaction data. Second, our analyses and the scope of PEERMATHDIAL focus on spoken dialogue and do not fully capture other important aspects of collaborative problem solving, such as gesture, gaze, shared writing, and other multimodal

forms of coordination. This was mainly due to the technical difficulty in capturing synchronized multimodal data (e.g., recording students’ shared math plotting synchronized with their conversation). Finally, while we seek to demonstrate the broad applications of PEERMATHDIAL, each of the three applications is worth deeper exploration. For example, for LLM student simulation (Application III), future work should look into how the current simulation diverges from the dataset labels, whether this divergence is caused by the underspecification of student character or an inherent LLM bias, etc.

Acknowledgments

A Student Demographic Information

The summer camp was held during the summer of 2025, supervised by the university IRB. In total, 38 students participated in the program. The camp was organized into two classrooms: one classroom with 16 sixth-grade students (except 1 fifth-grade talented-class student) and one classroom with 12 seventh-grade students and 10 eighth-grade students. The grade level was decided based on where they would enter in the 2025–2026 school year. The gender distribution included 26 female students (68%) and 12 male students (32%). Students' self-reported ethnic backgrounds included Asian or Asian American ($n = 16$), Black or African American ($n = 7$), White or European ($n = 6$), Hispanic or Latino/a ($n = 4$), Middle Eastern or North African ($n = 2$), Asian Indian ($n = 1$), White/European/Hispanic (multi-identified; $n = 1$), and prefer not to say ($n = 1$). Each classroom was facilitated by two teachers, all of whom had approximately 20 years of teaching experience on average. Student participants were also asked to fill out a survey form about their background and personality.

After data cleaning, we have 27 students who have both the survey information and the dialogue history. Therefore, we pick these 27 students' discussion in PEERMATHDIAL.

The dialogue data were collected from seven collaborative mathematics tasks: *Baker's Cake*, *Ice Cream*, *Znorlian*, *1–100*, *1001 Pennies*, *Tax Collector*, and *Traffic Jam*. These seven tasks correspond to 55 transcript sessions in total, including 11 sessions for *1001 Pennies*, 9 for *Baker's Cake*, 9 for *Znorlian*, 8 for *Ice Cream*, 8 for *Tax Collector*, 5 for *1–100*, and 5 for *Traffic Jam*.

B Action Taxonomy

This appendix presents the full corpus-grounded CPS dialogue act taxonomy used for turn-level annotation. The taxonomy is organized into six broad stages. Here, the term *stage* refers to a functional grouping of interactional moves rather than a fixed temporal sequence in collaboration. Each dialogue act is defined below, together with representative examples from the corpus.

B.1 Stage 1. Affect and Off-Task Talk

Stage definition. Actions used for emotional reactions, playful or evaluative commentary, and clearly social or off-task remarks that recur in classroom

discourse but do not directly advance the mathematical collaboration.

Stage 1 Action 1. Off-Task or Affective Commentary Definition. Making a brief affective reaction, playful remark, joke, evaluative exclamation, or clearly off-task social comment that does not primarily advance the mathematical work or direct collaboration.

Examples.

- “Well, clearly, he has stolen other people. He’s making me lose brain cells. He’s subtracting our brain power.”
- “Because... like two days ago, I went to Denmark. I mean, Delaware. Who Delaware.”
- “Oh, you’ve got to be kidding me.”
- “I thought we were going to be like coding and stuff, not math. This is basically new summer school.”
- “It’s me, hi. I know what the problem it’s you.”

B.2 Stage 2. Communicating and Coordinating

Stage definition. Actions used to explain and justify reasoning for others, present group work publicly, manage participation or work on the shared artifact, and handle lightweight interactional turns that support collaboration without adding substantive mathematical content.

Stage 2 Action 1. Acknowledging or Receiving Definition. Briefly accepting, confirming, or showing receipt of a prior contribution without adding substantial new mathematical content, such as short backchannels or uptake moves like “yeah,” “okay,” “oh,” or “uh-huh.”

Examples.

- “Uh, huh.”
- “Yeah.”
- “Okay.”
- “Yup.”
- “Oh, yeah.”

Stage 2 Action 2. Explaining or Justifying Reasoning **Definition.** Giving the rationale that connects a value, operation, representation, or method to the problem structure so others can follow why it makes sense.

Examples.

- “1.5 plus 1.5 would equal... because it’s half of the square, that’s 1.5 and not 2. And that means the entire square for one-fourth would have to be equal to four, but that’s not going to be four.”
- “That is three. That’s three because if it was split in half, this split in half. This would be six, but split in half again would be three.”
- “So over here, there are a bunch of cents. So there are, in one group of three, six numbers, 41, 41, 41, 41. 41 times four, 164, and 37 times two, 74, add it together equals 238 cents in one group of three. Well, one group of three pairs of numbers.”
- “It’s still half like the other one. That’s still half, and that’s still like each one fourth. So, nothing changed, except like the way it was shown.”
- “So, let’s say we have 19 cents, so that’s 19 cents, and then so we have 919 cents, so that’s \$9.19. So if we have 9919 cents then we have \$99.19.”

Stage 2 Action 3. Guiding Peer Participation or Shared Workspace Actions **Definition.** Directing who should contribute next or what should be drawn, written, compared, erased, or discussed on the shared workspace.

Examples.

- “Who’s next? Um, you.”
- “Okay, erase this and write plus that.”
- “You? So, you’re the scarecrow this time.”
- “All right, that’s one. Write that down.”
- “Can you write 228, 228.”

Stage 2 Action 4. Presenting Group Reasoning to an External Listener **Definition.** Summarizing the group’s process and answer for a teacher, class, verifier, or other audience outside the immediate back-and-forth collaboration.

Examples.

- “Okay, so, first we wrote a couple pennies here, and then we realized, started using the information we had to, like, organize, like which one is which. For example, we started with penny, nickel, dime, quarter, and then we realized, the second one, every two would be nickel. So, we first did that, and we filled out all the nickels here, and then we did every three would be dime. Then we realized they overlapped with the nickels, then Mrs. P told us that you’re going to have to replace them.”
- “We followed like the keys. So we just listed it out, like a bunch of pennies, and then we swapped out all the coins for like the numbers.”
- “I can go. So, and then we did, we did 1001 divided by 12, and we got 83, with five coins left.”
- “No, we realized, Mrs. P told us, what five coins. We added the first five coins, penny, nickel, dime, quarter, plus a penny, should equal 42. So, then we would add 42 here. At first, I thought this was the answer, then I realized the remainder. So we added 42 as the remainder and got 99.19.”
- “And then we added all the coins together, and we got 119 cents.”

B.3 Stage 3. Exploring and Understanding

Stage definition. Actions used to establish shared understanding of the task, lesson focus, givens, constraints, and the meaning of peers’ statements before or while the group commits to a mathematical path.

Stage 3 Action 1. Asking for Clarification or Explanation **Definition.** Requesting clarification about the task setup, a representation, an operation, or a peer’s reasoning so the group can align on understanding.

Examples.

- “Wait, how did we get two? How did we get two?”
- “How do you know that?”
- “Why are you putting a line?”
- “And then we’re putting it into, into. Are we dividing 1001 by that, or something?”
- “Where’d you get the 14 plus two?”

Stage 3 Action 2. Identifying Relevant Elements and Constraints **Definition.** Pointing out or restating key symbols, pieces, quantities, goals, rules, or structural givens so the group shares what must be tracked.

Examples.

- “First, let’s write down all the little, um, all the symbols we see. So I think we should an up, an up arrow. Triangle. And then this weird, like cross thing, and then, like a colored in square.”
- “Oh, yeah. So we have one, two, eight, and then we’re missing four.”
- “Yeah, cause the question says, what is the shortest way to write 21.”
- “It’s every third one.”
- “We’re not finding out these two groups specifically, we’re finding out how much cents are in those 1001 coins.”

Stage 3 Action 3. Orienting to Lesson or Activity **Definition.** Framing what kind of activity, topic, or phase is happening next, including teacher setup about what students are about to learn or do, rather than naming specific mathematical givens inside the problem.

Examples.

- “I feel like, for all these tasks, like, we have to, like, really understand the problem, and then we can solve it.”
- “The up is done. Adding numbers in Znorlian, and... is an addition sentence adding, what?”
- “So we have the exact same riddle. Easiest way to find 21.”
- “Okay. She said to do something. So I don’t know. Do you know that?”
- “Okay... now we have to find the shortest way to walk, write 21.”

B.4 Stage 4. Monitoring and Revising

Stage definition. Actions used to evaluate whether current reasoning fits the task, interpret intermediate quantities, locate errors, and adjust the approach or answer accordingly.

Stage 4 Action 1. Challenging or Diagnosing an Error **Definition.** Pointing out that a peer’s idea, representation, operation, or assumption is wrong and, when possible, identifying the specific source of the problem.

Examples.

- “Oh yeah, no cause it can’t be. It can’t be because this one would have to be. This, when you do it, this one’s three, and half of three is not two, it’s 1.5.”
- “No, because 12, minus two doesn’t equal four, that equals 10.”
- “That is half of one fourth, not a third.”
- “No, no, no, there’s no line in the middle.”
- “Well, how is one times 125 equal 185?”

Stage 4 Action 2. Checking What a Number or Step Represents **Definition.** Asking for or providing the meaning of an intermediate number, unit, or step to ensure quantities are being interpreted consistently.

Examples.

- “Huh, what’s 125? This equals 125? Does this equal 125?”
- “Two dollars and 38 cents.”
- “Two times two times two.”
- “Seven, but what are the values?”
- “The remainder of five coins.”

Stage 4 Action 3. Checking Whether a Result Fits Constraints **Definition.** Testing whether a proposed pattern, value, or answer is consistent with totals, fractions, repeating structure, or other task constraints.

Examples.

- “Okay so, this is um, um, um, what the heck, 1.5. Okay, so that’s 3.75. Okay, so now we add the 2.25, which should equal six. Right? That is correct. So your thing is correct.”
- “No, cause it wouldn’t add up to \$12.”
- “That’s three. That’s three. And then invisible line. Okay, that’s not even even. Nuh uh.”
- “So, we can’t have a half a coin?”
- “Because 5.5 would be ten... No, eleven. Plus three would be 14.”

Stage 4 Action 4. Revising the Method or Answer Definition. Changing the current answer, method, or shared written work after a contradiction, objection, or diagnosed error has been recognized.

Examples.

- “I’m gunna change my answer, three. It’s three. It’s been three the whole time.”
- “No, you’re not supposed to write this. You’re writing 16 plus four plus one.”
- “Uh, one third. No, one fourth.”
- “I’m changing the numbers because the math’s wrong.”
- “Yeah, there’s three different. Oh wait, yeah. There’s three different things, so I have to count for three? How many, we have to figure out groups of six, not groups of four.”

B.5 Stage 5. Planning and Executing

Stage definition. Actions used to choose solution methods, advance candidate answers, strategically reorganize the problem, and carry out computations.

Stage 5 Action 1. Carrying Out a Computation Step Definition. Performing or directing arithmetic or symbolic operations needed to execute the chosen strategy, including summing pattern units, dividing to find repeats, or combining known values.

Examples.

- “12 divided by four is three.”
- “So, two plus eight is ten, plus four is 14. So, something minus two is 14.”
- “1.5 plus 0.75, 2.25. That’s 2.25. That one’s 0.75.”
- “Eight times four is 32.”
- “No, this is two plus eight, which is ten, plus four is 14.”

Stage 5 Action 2. Decomposing or Repartitioning the Structure Definition. Redrawing, splitting, or grouping the representation into easier subparts to make inference or calculation more manageable.

Examples.

- “And then, here, you just put a line through. Just put a line through. That’s half of that. So, that will be 1.5 right?”
- “Okay, so then this, this would be three and three, but that can’t. So draw a line right here and right here. No right here, right here, just from here. No, no, no, here to here. Okay, so these are meant to be all equal squares. So these are all equal, and hold on can I be scarecrow for a sec? This... is three. This is all... three. So that is a... fourth, a fourth. What’s a fourth of three? I think that’s right, I don’t know. What’s a fourth of three? Go. A fourth of three.”
- “Okay, how do we split this exactly? Yeah, you should put it right here. There and... there’s another line, and just go right there. There. So, we know this is all six, and this all six. So, the easy part is, so this, it has to be... 0.75. So, 0.75 in here, and put imaginary lines over here. Wait. Do the uh... yeah. No, here first and then here. So this is 0.75, that’s 0.75, that’s 0.75. What are you doing exactly? Never mind. Okay, so that means this. This one, three. If we do that here too, it means 1.5. So, this is all 0.75, which would be three. This is three right here. So, put a three over here. So, this is a total of three. Oh, sorry. And then, this and three. This is all three minus 0.75, which would be um... 2.75. No, 2.25. So, this is 2.25.”
- “The bottom one is six. Okay, I know something. Okay, if we have. Little lines right here. It would be split in half. So it would be 1.5 because 1.5 plus 1.5 is three, and this would be like a quarter so it would be three. I’m guessing this is. So this would be. Is six. Basically.”
- “Okay so, okay so, put that in half. So, that we know is six. That’s six. Six!”

Stage 5 Action 3. Proposing a Candidate Solution Definition. Putting forward a tentative answer, value, decomposition, or completed expression for the group to consider.

Examples.

- “I think it should be \$4.”
- “16 plus five.”

- “Eight times three minus three.”
- “\$3 per slice.”
- “Oh, wait. I think I know it. Three. Three and 4.5. 4.5.”

Stage 5 Action 4. Proposing a Solution Strategy

Definition. Suggesting a method or plan for how to solve the problem, including how to decompose it, scale from a pattern, or proceed through the next mathematical steps.

Examples.

- “Yeah, we might be able to find the pattern, and then multiply.”
- “Okay, first things first, we’ll write what we know. Like, for example...”
- “Yeah, that’s where the pattern ends. The pattern ends at the 12 mark. If we add this, then we have to find how many times 12 goes into 1001. So we have to add this until like there, and we have to find out how many times that goes into 1001.”
- “What if we just like, what if we just like. So, we have 1001, right? Subtract how much amount of pennies will take over that. Every second one will be a one.”
- “So you have to do 250, divided by four, since 41, 41 appears every four different sections of the dollar.”

B.6 Stage 6. Representing and Formulating

Stage definition. Actions used to construct, interpret, and refine shared representations, patterns, and structural models that make the problem mathematically workable.

Stage 6 Action 1. Constructing or Refining a Representation

Definition. Creating, extending, or modifying a shared drawing, list, grouping, sample case, or auxiliary visual structure to make hidden relationships visible.

Examples.

- “And then, here, you just put a line through. Just put a line through. That’s half of that. So, that will be 1.5 right?”
- “Wait, I already, I already know it. So, square. Wait so, square right here, square right here.

There’s one right here, tall box right here, rectangular box right here, and there’s... oh wait. And then there’s. So then, there’s a line. Wait no, that’s not even. The line should be like right here. Three over here and three over here. So then, this is all, if this is all three then that means this is 1.5. How would it be two? So then, one of them would be 0.75. So, 0.75, 0.75. That means this also has to be 0.75. Plus this, which is right here. Wait, this line is supposed to be up here though. Let’s just draw this again. Half like this? Oh. And then, there’s a line right here. And then, there’s two boxes right here and a box right here. There! Wait, no. Yeah. So, this is 0.75, 0.75, don’t judge my fives. What did I just say. What did I just say. Trying my best here.”

- “Or maybe, to help you, we just put one, two, three, four, five, six.”
- “Okay. One, two, three, four, five, six, seven, eight, nine, ten. Okay, um, P, N, P, N, P, N, N, N. Okay, wait, okay, yeah, yeah. Okay, um...”
- “See, like that. Get it? Okay, and then quarters, every fourth one.”

Stage 6 Action 2. Mapping Representation to Values

Definition. Assigning numerical or relational meaning to symbols, shapes, pieces, or units based on givens and discovered relationships.

Examples.

- “One cent. Star is a nickel, five cents. Triangle is a dime, 10 cents. Heart is a quarter, 25.”
- “This symbol is a four. Um, this symbol is a one... uh, this symbol is an eight.”
- “One eighth. This is one eighth of the cake.”
- “A half.”
- “That means these mean one.”

Stage 6 Action 3. Proposing a Pattern or Structural Model

Definition. Suggesting a candidate pattern, grouping, equivalence, repeat unit, or structural interpretation that could organize the problem and guide solution work.

Examples.

- “So, the pattern is it doubles.”

- “This grouping four... and one, two, three, four, these four. Okay, then, then I see two different groups. One with these and one with these.”
- “That one’s four, that’s a 25. I think that’s where the pattern repeats.”
- “Oh. Two of these equals this, which equals that.”
- “So there are, basically, two different ones. There’s 41 and 37, and 41 and 41.”

Stage 6 Action 4. Reusing a Previous Case or Pattern Definition. Using an earlier solved example, repeated structure, or analogous case to interpret the current representation or infer the current one.

Examples.

- “I think it is. It’s the exact same thing, cause it’s in half. Three, three, six. It should be the same price cause there’s three slices, and then it’s doubled again.”
- “Oh. So, this is the exact same thing we get like with different shapes, but it’s still in half and... in half.”
- “Start drawing the square, right now. Oh wait, this is. Hold on, we recognize that right? That is half and half. Okay, so that is... half of six, three. So, three.”
- “It’s the same thing. That’s also 1.5. That’s 1.5. That’s six. That’s 4.5. It’s the same thing. It’s the same thing.”
- “Same thing. Same as day three.”

C Expert Review of Action Taxonomy and Turn-level Assignment

To evaluate the quality of the induced taxonomy and its turn-level labeling, we conducted an expert review. This evaluation focused on two questions. First, whether the dialogue act taxonomy induced by the LLM adequately captures the major dialogue actions that occur in students’ ordinary discussions; for this purpose, we provided the complete taxonomy definitions together with multiple examples. Second, whether the turn-level labels assigned by the LLM based on the taxonomy were accurate, and, if not, whether the problems arose because the taxonomy had failed to include a necessary action

type or because the appropriate action type existed but had been assigned incorrectly. Based on this goal, we constructed an evaluation set containing 100 instances of conversational turns. Among them, 50 instances were randomly sampled from the full corpus to assess labeling quality under typical conditions, and the other 50 instances were drawn from the turns that the LLM marked as low-confidence in the second round of labeling. This design allows the evaluation to cover both ordinary cases and the subset of examples that remain most uncertain under the final taxonomy and are therefore most likely to reveal residual labeling difficulties.

Two doctoral students who majored in Math Education and had multiple years of school teaching served as experts. During the review, each instance was presented to experts in a standardized format, including the speaker identity, the necessary dialogue context, the current turn to be judged, the action assigned by the LLM, and the model’s brief rationale. The experts were asked to judge whether the assigned act adequately described the student’s turn. If not, they were further asked whether a better label could be found among the existing candidate actions; if none of the existing acts fit, they were allowed to propose a new action label. In this way, the evaluation jointly examined both assignment quality and taxonomy coverage.

The results indicate that the taxonomy provides strong coverage of the major interactional behaviors in the corpus. The experts also endorsed the definitions of the extracted dialogue act taxonomy. Among the 50 randomly sampled instances, experts judged all assigned dialogue acts to be appropriate. Among the 50 low-confidence instances, 11 were judged to be assigned incorrectly. Importantly, in all of these error cases, the problem was identified as an assignment error rather than a missing act type in the taxonomy; that is, experts were always able to identify a relatively more suitable label from the existing candidate actions, without introducing any new category. This result suggests that the main remaining source of error lies in turn-level label assignment rather than insufficient coverage of the action inventory itself. Overall, the expert review supports the validity of the induced taxonomy and suggests that this LLM-assisted pipeline is able to capture the major CPS interactional behaviors in the corpus with substantial coverage.

D Survey-based Student Profiles

Student profile groupings used in Application II are derived from a self-report survey administered in the beginning of the camp program. The survey contains 20 items, each answered on a five-point Likert scale: *strongly disagree*, *disagree*, *neutral*, *agree*, and *strongly agree*. The items cover multiple aspects of students' orientations toward mathematics learning and peer collaboration, including math confidence and enjoyment, collaborative preference, leadership tendency, curiosity, organization, sociability, conflict avoidance, and concern about making mistakes. For the analyses in the main text, we organize related items into broader profile dimensions such as *confidence*, *collaboration*, and *leadership*. For each dimension, students are divided into two broad groups based on whether their responses indicate overall endorsement of that dimension (i.e., more agreement-oriented responses) or not. These groupings are intended as interpretable survey-based typologies for descriptive analysis, rather than as formal psychometric scales.

Survey items. The survey includes the following items:

- I enjoy learning math.
- I feel confident solving math problems.
- I often get frustrated when working on math.
- I like explaining math ideas to others.
- I find math to be useful in my daily life.
- I prefer working alone on math tasks.
- I feel comfortable asking questions in a group setting.
- Having others' perspectives often helps me learn better.
- Working in a team makes learning more engaging.
- I like being the center during the group discussion.
- I often listen to others before sharing my ideas.
- When I have an idea that others disagree with, I will persuade them.
- I often help assign tasks and resolve conflict in a team.
- I learn new things quickly.
- I'm a curious person and I like trying new things.
- I keep track of what needs to be done carefully.
- I like interacting with a lot of people.
- I try to avoid arguments, even if I disagree.
- I often worry about making mistakes in front of others.

Effects of Varying LLM Access on Essay Writing Behavior

Julia Christenson, Karin de Langis, Shirley Anugrah Hayati, Dongyeop Kang

University of Minnesota

{chri5306, dento019, hayat023, dongyeop}@umn.edu

Abstract

Investigating the degree to which large language models (LLMs) affect teaching and learning in universities can help identify strategies for integrating LLMs in a way that supports, rather than undermines, student learning outcomes. This study examined how varying levels of LLM assistance affect writing performance, engagement, and perceived authorship. We report a pilot study in which 24 college students were randomly assigned to write a short essay with no LLM access, limited access (≤ 3 prompts, responses capped at 100 words), or unlimited access. Overall essay quality was statistically indistinguishable across groups. Yet writing behavior and perceived authorship diverged sharply: students with limited access reported higher ownership (62.5% would submit the essay as independent work, vs. 25% in the unlimited group), stronger organizational gains, and more strategic, revision-focused prompting. The unlimited group spent more time writing, produced essays more similar to LLM output, and reported reduced creative expression. Our findings suggest that constraining, rather than banning, LLM access may preserve authorship confidence while retaining the scaffolding benefits of AI assistance.

1 Introduction

LLMs have become increasingly embedded in academic writing practices, reshaping how students plan, compose, and revise text. LLM-based tools such as ChatGPT and Grammarly now offer real-time feedback and idea generation, lowering barriers to writing while simultaneously raising questions about authorship, learning, and skill development. As these systems become normalized in educational contexts, it is important to understand their influence on student writing behavior.

Prior work primarily frames LLM-assisted writing as a productivity and accessibility aid, reporting gains in fluency, error reduction, and brainstorming support across literacy levels, as well as tools

that scaffold multiple stages of the writing process (Weijers et al., 2024; Lee et al., 2024; Zhang, 2025; Xu, 2025). At the same time, researchers caution that sustained reliance on LLM may undermine independent writing, creativity, and critical thinking (Rohilla, 2025; Gerlich, 2025a). Others find no significant effect on overall academic achievement (Yoo et al., 2025). Students often report reduced confidence and creativity with prolonged use, and prior work also highlights risks related to dependency, ethical ambiguity, and homogenized or biased outputs (Zhai et al., 2024; Chakrabarty et al., 2025). Human-AI interaction research further shows that AI involvement can negatively influence perceptions of authorship and writing quality, particularly when disclosed (Draxler et al., 2024; Li et al., 2024; Mansour et al., 2024; Joshi and Vogel, 2025; Gerlich, 2025b).

Existing research has shown that the use of LLMs has negative cognitive effects (Kosmyna et al., 2025), but we hypothesize that the degree of LLM access may play an important role in the efficacy of LLM assistants in educational contexts. This study addresses the gap by examining how different levels of LLM assistance influence students' writing by formulating three main research questions:

- **RQ1:** How does varied LLM assistance influence students' writing behavior, including time allocation, writing strategies, and prompting practices?
- **RQ2:** How do students perceive authorship, ownership, and acceptability of LLM-assisted writing?
- **RQ3:** How does the level of LLM assistance affect writing quality, originality, and lexical diversity in student essays?

To address these questions, we conduct a study in which twenty-four college students wrote an es-

say in response to a prompt. By comparing writing produced under different levels of LLM assistance, this work aims to clarify when LLM assistance enhances writing efficiency and when it begins to erode core literacy skills.

We found that both LLM-assisted groups engaged in similar write-prompt-edit cycles, but with different strategic orientations: limited-access participants focused prompts on major revisions and argument development, while unlimited-access participants concentrated on minor mechanical edits. These behavioral differences mapped onto perceived authorship: limited-access participants reported stronger feelings of ownership, greater organizational improvement, and higher willingness to submit the essay as their own work. Essay grades and lexical diversity were marginally higher in the unlimited group, though differences were not statistically significant. Taken together, the findings suggest that constraining LLM access, rather than eliminating it, may offer a middle path between the cognitive risks of over-reliance and the scaffolding benefits of AI assistance.

2 Related Work

Prior research has examined human-AI interactions for scholastic writing needs through engagement with LLMs and behavioral outcomes. Several studies on college students' use of LLMs find that learners primarily rely on LLMs for brainstorming, revision, and information retrieval (Jelson et al., 2025; Kondoro, 2025; Wang et al., 2024). Although LLM assistants effectively correct surface-level language errors, they have been shown to reduce syntactic complexity and linguistic diversity with sustained use (Wang and Spitz, 2025; Bui and Kim, 2025; Pan et al., 2025). Some studies found that students with higher AI literacy and more strategic prompting practices tend to produce stronger writing, while students with lower performance often under-utilize or misuse AI tools (Nguyen et al., 2024; Kim et al., 2025; Joshi and Vogel, 2025). A few studies observed modest improvements in students' independent learning and English writing ability when such tools are used alongside instruction (Wang, 2020; Seo, 2024; Xiao, 2024; Shen, 2025). However, these prior works share limitations. Most studies employ binary comparisons—AI versus no-AI—rather than examining a response relationship to varied levels of AI access. This framing obscures whether the negative effects

of LLM use are properties of AI assistance itself or the degree to which it is provided.

Growing concerns about dependence on LLMs negatively affecting critical thinking skills are prevalent. Survey research reveal many students and teachers are aware of the over-reliance on LLM writing assistants and concerns over academic dishonesty (Aliakbari et al., 2026; Joshi and Vogel, 2025; Kondoro, 2025; Khalid et al., 2025). Several studies show lowered critical thinking abilities for those who exhibit higher dependence on LLMs (Kosmyrna et al., 2025; Gerlich, 2025a).

Recent studies pivoted to researching methods to increase perceived ownership and transparency through tailored LLM assistants. One study has found that greater AI transparency and interpretability are associated with more positive student experiences and reduced misuse, including academic dishonesty and diminished learning outcomes (Cui, 2025). Several works have studied human-AI collaboration patterns and suggest writer-centered approaches to LLM-based writing assistants, (Mysore et al., 2025; Guo et al., 2024; Liu and August, 2025; Gerlich, 2025b; Shibani et al., 2024), but largely emphasize interaction strategies and design recommendations without measuring whether such interventions actually improve writing outcomes or reduce problematic dependency patterns.

Empirical studies demonstrate the benefits of LLM assistance, and the detrimental effects of AI on cognition and critical thinking skills, but the impact in real-world academic settings remains unclear (Yoo et al., 2025). Together, these gaps motivate our study focused on how constraining LLM access can impact how students navigate a real-world academic situation.

3 Approach

We aimed to investigate the extent to which students' writing experiences are impacted by the assistance LLM provides for them. The primary concern of the study was whether limiting LLM use provides a viable middle ground between the negative cognitive effects of LLM use and the benefits.¹

3.1 Participants

We recruited a total of 24 undergraduate and graduate students with 18 different majors through email recruitment. Details about participant demographic

¹The study was approved by the IRB.

Category	Percentage
Race	
White	41.7%
Asian	16.6%
Black or African-American	8.3%
Hispanic	4.2%
Two or more races	25.0%
Prefer not to disclose	4.2%
Gender	
Female	75.0%
Male	25.0%
Major	
STEM	41.7%
Health and Medicine	29.2%
Arts and Humanities	16.7%
Business	8.3%
Social Sciences	4.2%
Academic Level	
Senior	66.7%
Junior	16.7%
Sophomore	4.2%
Freshman	8.3%
Graduate	4.2%

Table 1: Participant demographics (N=24).

information are provided in Table 1. 71% of the participants rated themselves as strong writers by selecting either a 4 or 5 on a Likert scale out of 5. Participants, on average, have used LLM-based tools in some way in their previous 5 out of 10 writing assignments. Most students who use LLM tools in coursework reported using ChatGPT and built-in tools such as Grammarly. Participants who regularly use LLM-based tools typically employ them to generate ideas, seek assistance when they get stuck, and understand the material better. The participants who used LLM tools less frequently described the writing output as repetitive and superficial, and noted that they avoid LLM tools due to environmental concerns and academic integrity.

3.2 Study Procedure

First, participants completed a preliminary survey to determine eligibility. The eligibility requirements were native-level English fluency and identifying as an undergraduate or graduate student. Participants were randomly placed into one of three groups: control, limited access to LLM, or unlimited access. Participants then completed an approximately 30-minute in-person writing session. All participants provided informed consent under an IRB-approved protocol. Participants were given instructions to respond to an essay prompt in at least

Figure 1: Study pipeline.

300 words, using a text document. Instructions can be found in Appendix A.1. Each participant received the same prompt, shown below:

Essay Prompt

Write a response in which you discuss the extent to which you agree or disagree with the recommendation and explain your reasoning for the position you take.

College students should be encouraged to pursue subjects that interest them rather than the courses that seem most likely to lead to jobs.

Since participants completed the writing task on their personal computers, we also instructed them to disable all AI writing extensions (e.g., Grammarly) on their browsers.

Participants in the control group did not receive any help from LLM when writing their essays, while participants in other groups have access to chat with LLM-based chatbots during their writing process. To access the LLM-based chatbot on the website, we implemented a backend application using Flask and Python, deployed with Vercel. We used the Gemini-2.5-Flash model (Gemini Team, 2025) for our chatbot because of our institution’s license.

Participants in the limited LLM access and unlimited LLM access groups interacted with their respective chatbots through a provided link. The writing assistant for the limited LLM group operated with a system prompt that restricted its responses to general guidance. The full system prompt is in Appendix A.2. This group was also given a maximum of three prompts to ask the LLM-based writing as-

Example Essay #1

Many people state that college is the best year of your life. I believe that is because it is a time for exploration and opportunities. This is the time to take new risks and try everything that interests you. However, students in college are at varying places in the world. Some have the privilege of getting financial help, whereas others may need to work multiple jobs to stay stable while getting their degree. While career readiness is important in a selection of classes, students should balance these with classes that also interest them.

Taking classes based on interest can fuel one's desire to learn and boost motivation. When students are actually curious about a topic, they will participate more in class and engage more deeply with the material. Connecting this to my own experience, I took a class on rock music, even though I am not studying music. I found myself enjoying the class a lot more because I enjoyed the topic and learning about music history.

Apart from student success in college, post-college happiness is often tied to fulfillment. Research shows that while income certainly matters up to a certain point (often cited around \$75,000 to alleviate daily stress), long-term job and life satisfaction are more closely tied to intrinsic factors like meaning and interest. These classes you can take in college are much more worth exploring if it could mean you find a new passion or even a new hobby.

LLM-assisted portion

Human-written portion

Figure 2: Example annotated essay with highlighted LLM-assisted portions for the limited group. This student interweaves responses from LLM to support their main claim in this essay.

sistant, whereas the unlimited access group had no such limit. The number of prompts was selected due to the shortened length of the writing task. The limited LLM group had a maximum token output and a system prompt instruction to provide short responses that reflect general guidance and encourage students to develop their own ideas, rather than longer responses that directly answer the prompt. Meanwhile, the unlimited LLM group did not have a restricted token output or special instructions.

Upon completion of the essay, participants were given a post-interaction survey to assess their perception of the writing process and their essay. Participants received a \$10 gift card as compensation.

4 Methodology

4.1 Data Collection & Annotation

We collected the interactions with the LLM via our web application and annotated the writing actions and interactions. Due to the limited number of participants and short writing task given, we developed a simplified taxonomy inspired by previous research (Du et al., 2022; Nguyen et al., 2024) with the following four writing intentions: writing, editing, structuring, and prompting.

We collected interaction data through a custom web application that logged participants' exchanges with the LLM, along with their writing activity in Google Docs. These logs enabled us to analyze both writing actions and prompting behavior throughout the essay-writing process.

To understand participants' writing behavior, we developed a taxonomy of four activities during the writing process: *writing*, *editing*, *structuring*, and *prompting*, informed by prior work on writing processes and revision behaviors. Writing refers to generating new text in full sentences, editing captures revisions to previously written content, and structuring involves organizing ideas or outlining the essay. Prompting means that the user is interacting with LLM to support writing. Two members of the research team manually annotated participants' writing intentions using this taxonomy, based on the Google Docs revision history and logged LLM interactions. Inter-annotator agreement for the writing intentions was assessed using Cohen's κ , yielding substantial agreement ($\kappa = 0.71$).

4.2 Metrics

We established a set of metrics designed to capture the nuances of writing behavior, essay quality, lexical/semantic overlap with LLM output, and vocabulary richness, allowing us to correlate them with survey responses later in the analysis. Given our limited statistical power to detect all but very large effects on writing quality, we present descriptive statistics without asserting statistical significance.

Rubric-Based Evaluation Essays were evaluated using a custom rubric derived from standard English composition criteria, as shown in A.2. The rubric assesses seven distinct dimensions: Focus and Details, Idea Support and Development, Organization, Voice, Vocabulary and Word Choice, Sentence Structure and Grammar, and Reads as human-written², in which a higher score meant more human-like quality. Each category was scored on a five-point scale and accompanied by a brief justification. This rubric was inspired by standard English essay rubrics (of Teachers of English).

To ensure reliability, grading was conducted independently by two university writing consultants employed at our institution's writing center, with the final rubric scores determined by averaging

²This metric functions as a holistic AI-detection proxy rather than a compositional quality measure

their two grades.³

Writing Time and Volume We tracked the total time each participant spent writing the essay (in minutes) to capture differences in writing effort and process efficiency across conditions. We also recorded the final word count of each essay as a measure of output length and productivity.

Lexical Diversity We measured lexical diversity using the Root Type-Token Ratio (Root TTR) (Guiraud, 1954). This metric provides a stable estimate of lexical diversity across essays of varying lengths by calculating the ratio of unique words (types) to the square root of the total words (tokens). Higher values indicate a broader, more diverse vocabulary usage relative to the total length of the text.

Prompt Type Prompts were categorized into four types: brainstorming/developing arguments, structure/organization, major revisions, and minor revisions. Developing arguments represented prompting to brainstorm talking points and specific facts or statistics. Structure/organization prompts focused on structuring the essay and making it cohesive. Major revisions included large revisions to the text, such as prompting to rewrite the entire essay, fixing grammatical mistakes, or modifying the essay stylistically. Lastly, minor revisions focused on rephrasing, sentence-level grammar checks, and asking for synonyms. Given the accuracy rate of annotations done by ChatGPT (Churchill et al., 2026), and due to the large number of prompts, the prompts were initially organized using GPT-4 (OpenAI et al., 2024) and all verified by one member of the research team with 94% accuracy.

AI Similarity Scores To assess lexical overlap with LLM output and the degree to which participants incorporated LLM-generated text, we computed cosine similarity scores between the final student essays and the raw LLM responses generated during their specific writing session. Sentence embeddings were generated using the all-MiniLM-L6-v2 model (Reimers and Gurevych, 2019). This resulted in a similarity score ranging from 0 to 1, where higher scores indicate a greater direct incorporation of LLM-generated phrasing.

³The graders were recruited via email and provided informed consent under an IRB-approved protocol.

5 Findings

As we attempt to understand how different levels of LLM assistance influence writing outcomes and writing behaviors, we organize our analysis around these main research questions: [RQ1]: How does varied LLM assistance influence students' writing behavior, including time allocation, writing strategies, and prompting practices? (Section 5.1) [RQ2]: How do students perceive authorship, ownership, and acceptability of LLM-assisted writing? (Section 5.2) [RQ3]: How does the level of LLM assistance affect writing quality, originality, and lexical diversity in student essays? (Section 5.3)

To address these questions, we combine rubric-based essay evaluation, lexical and similarity metrics, interaction logs, and survey responses. Each subsection below explicitly corresponds to one or more research questions.

5.1 Writing Behavior and Interaction Patterns

To examine how varied LLM assistance shapes writing behavior, we analyzed writing time, prompt usage patterns, and survey results across groups.

Writing Time Average writing time increased with greater LLM access. The control group completed essays in an average of 22.5 minutes, the limited LLM group in 27.8 minutes, and the unlimited LLM group in 30.4 minutes, as summarized in Table 5. Notably, variance also differed across groups: the unlimited group showed the least spread in completion time (most participants clustered near the 30-minute mark), while the limited group showed the greatest variability (Figure 3). One interpretation is that the three-prompt cap introduced individual differences in pacing: students who front-loaded prompts early finished faster, while those who saved prompts for revision extended their sessions. The unlimited group, facing no strategic constraint, may have converged on a similar write-and-revise rhythm regardless of individual differences. No correlation between time and essay grade was observed.

Writing Process We analyzed temporal writing intentions by normalizing each participant's writing session from start to finish. The limited group averaged 2.5 prompts, compared to 4.5 prompts for the unlimited group. Figures 5a, 5b, and 5c illustrate how participants distributed effort across planning, writing, prompting, and editing.

Figure 3: Distribution of writing time (in minutes) by user group.

Figure 4: Distribution of the type of prompts asked by the LLM groups.

As shown in Figure 5a, two participants in the control group spent time on structuring the essay, and many participants spent most time writing sequentially, with additional time spent on editing the essay. Figure 5b shows the writing strategies of the limited LLM group. Six users demonstrated their collaboration with LLM, with writing themselves first, then prompting, and continuing this process until they were out of prompts. Despite having unlimited access to LLM, figure 5c shows that six of eight unlimited users still started the essay themselves, then prompted LLM for additional help. A majority of users in both groups with access to LLM utilized LLM in the latter part of their writing process (0.8-1).

Across all groups, most participants began by writing independently before seeking assistance. Editing behaviors were equally prevalent across all groups, while explicit structuring activities were relatively rare across all conditions. The increased LLM access was not associated with a difference

Figure 5: Distribution of writing intentions across the writing process for all user groups (8 participants per group). Each row represents a participant's timeline, with colored segments indicating their activities across normalized time.

in the writing and prompting process.

Prompt Types Figure 4 shows that brainstorming/argument development dominated prompts in both LLM assisted groups. Following argument-focused prompts, the unlimited group spent 36% of their prompts on minor revisions to the text. The limited users distributed prompts differently, with 35% on major revisions, and 20% on minor revisions.

Both groups showed low proportions of prompts directed toward structuring or organizing the essay. This pattern may reflect the possibility that participants may have completed structural planning independently, or the constrained length of the writing task may have reduced the concern over organization. The observed difference in major versus minor revision allocation between groups

Table 2: Limited group correlation matrix between pre-survey and post-session measures ($*p < 0.05$).

	Acceptance	Dev. Arguments	Time
Crit. thinking eval.	0.92*	—	—
Prompt literate	-0.80*	0.71*	—
Relied on AI	—	—	0.78*

Table 3: Unlimited group correlation matrix between pre-survey and post-session measures ($*p < 0.05$).

	Acceptance	Similarity	Prompt #
Crit. thinking eval.	—	-0.79*	—
Saved time	—	—	-0.71*
Comfortable with AI	-0.91*	—	—
AI use frequency	-0.80*	—	—
Difficulty	0.81*	—	—

aligns with expectations that the restricted number of prompts encouraged the students to prioritize higher-impact revisions.

5.2 Perceptions of Ownership and Acceptability

To understand students’ perceptions of authorship when using LLM to help their writing process, we analyzed responses from post-interaction surveys. We report the behavioral metrics as descriptive statistics due to low statistical power.

Post-interaction survey Post interaction responses revealed ambivalence toward LLM-assisted authorship.

First, participants in the limited group expressed more ownership towards their essays. When asked if they would submit it as their own work, 62.5% responded yes, 25% were unsure, and 12.5% declined. Most of the participants also perceived an increased ability to organize ideas (62.5%).

Correlational analysis within the limited group revealed several patterns (Table 2). Participants who used LLM frequently in writing assignments reported greater perceived need for critical thinking to decide what to accept or reject from the LLM ($r = 0.92, p < 0.05$). Those with self-reported prompt literacy accepted fewer prompts ($r = -0.80, p < 0.05$), but more frequently directed prompts towards developing arguments ($r = 0.71, p < 0.05$). This pattern suggests that the increased critical engagement with LLM outputs and prompting style may reflect an adjustment to the constrained nature of the system’s responses compared to their previous exposure to LLM tools, such as ChatGPT. Participants who reported spend-

ing more time writing the essay also revealed feeling greater reliance on LLM ($r = 0.78, p < 0.05$), suggesting more time was spent on the LLM interface, prompting, and incorporating suggestions.

Conversely, **the unlimited group demonstrated less ownership over their work**. Only 25% of these participants would submit their essay as their own work, and 75% claimed unsure. This suggests that this group had increased concerns over academic integrity and perceived originality. However, alternative explanations, such as low confidence in content or structure, cannot be ruled out.

Correlational analysis for the unlimited group (3) revealed several associations. A moderate negative correlation ($r = -0.79, p < 0.05$) between the cosine similarity score and the perceived critical thinking demands was observed. This implies that **students who actively evaluated and rejected LLM output produced more original work**, although causality cannot be determined.

Students in the unlimited group who believed they saved time using LLM used fewer prompts ($r = -0.71, p < 0.05$). Conversely, comfort with LLM tools ($r = -0.91, p < 0.05$) and higher baseline LLM use frequency ($r = -0.80, p < 0.05$) were associated with lower prompt acceptance rates. Additionally, perceived task difficulty showed a positive relationship with prompt acceptance ($r = 0.81, p < 0.05$), suggesting that students reporting higher difficulty more readily incorporated suggestions.

Notably, across both groups with access to LLM, students with stronger self-reported prompting skill accepted fewer suggestions overall (limited: $r = -0.80$; unlimited: $r = -0.91$). This pattern could indicate that **students with stronger prompting literacy applied more critical judgment in evaluating suggestions**. These results support prior research that prompt-literate individuals are more likely to think more critically of the output and engage in iterative interactions with LLMs (Kim et al., 2025).

Participants also expressed nuanced views on LLM use in coursework, aligning with previous studies (Aliakbari et al., 2026; Joshi and Vogel, 2025). Most responses indicated that LLM should be permitted for tasks such as brainstorming, source discovery, and concept clarification, but not for completing assignments or copying generated text. A small number of participants favored stricter limitations or unrestricted use, reflecting ongoing tension between perceived educational value and

Table 4: Average essay grades by user group, with highest scores in bold. Overall, differences between groups in grading outcomes are minor.

Rubric Item	Control	Limited	Unlimited
Focus + Details	4.3	4.5	4.6
Idea Support	4.6	4.5	4.7
Organization	4.3	4.3	4.7
Voice	4.9	4.7	4.5
Vocabulary	4.1	4.4	4.4
Sentence/Grammar	3.9	4.9	4.7
Reads as human-written	4.9	4.6	4.6
Total Score	88.66%	88.39%	89.38%

concerns about learning and academic integrity.

5.3 Writing Quality and Originality

To evaluate writing quality and originality, we analyzed essays using a rubric-based assessment, lexical diversity metrics, and similarity comparisons between student essays and LLM-generated responses.

Rubric Based Evaluation Table 4 shows the average rubric scores, which were largely stable between groups. The statistical power of our study only allows us to detect very large effects of group on grading, and we do not find any significant differences between groups.

Lexical Diversity As shown in Table 5, the unlimited group exhibited the highest average Root TTR (9.555), followed by the limited group (9.4365) and the control group (8.963). These results suggest that **access to LLMs may encourage broader vocabulary use**. However, we again cannot definitively determine any statistical relationships given our limited power.

AI Similarity Scores The unlimited group exhibited a higher average similarity score (0.552) compared to the limited group (0.444), suggesting marginally greater incorporation of LLM output (See Table 5). Although this is consistent with expectations, the difference was small and not statistically significant (ANOVA $p = 0.21$), preventing definitive conclusions regarding the dependence of LLM based only on similarity.

6 Discussion

Contrary to initial concerns, unlimited LLM access did not produce lower-quality essays than limited access or no LLM baselines. Only marginal differences in lexical diversity and similarity between

Table 5: Average Metric Evaluations by User Group

Metric	Control	Limited	Unlimited
Essay Grade	88.66%	88.39%	89.38%
Cosine Similarity	–	0.444	0.552
Root TTR	8.963	9.4365	9.555
Writing Time (mins)	22.5	27.8	30.4
Word Count	329	439	383

LLM suggestions and essay text were exhibited. However, the unlimited group spent more time writing and exhibited a higher similarity to LLM output (0.552 vs. 0.444), suggesting greater LLM reliance or slower, more iterative integration of LLM text. This aligns with prior work on cognitive offloading, where increased AI reliance may reduce rather than increase self-directed cognitive engagement (Gerlich, 2025a; Kosmyna et al., 2025).

The LLM groups demonstrated varied prompting styles. Both groups exhibited human-AI collaboration through iterating, prompting, and editing the essay, but the limited group prioritized major revisions, whereas the unlimited group targeted minor mechanical revisions. This strategic reallocation may have been correlated with measurable ownership benefits. 62.5% of limited participants reported willingness to submit their essay as independent work, compared to 25% in the unlimited group. Similarly, 62.5% of the limited group reported improved organizational ability.

Correlation analysis between pre- and post-interaction survey responses exhibited differences in how users interacted with the AI. As shown in Table 3, limited group participants who are comfortable with AI tools reported elevated critical thinking demands ($r = 0.92, p < 0.01$) and focused prompts on argument-development help ($r = 0.71, p < 0.05$). This pattern suggests that AI-literate students were more cautious and critical of the output. The unlimited LLM group exhibited a strong negative correlation between perceived need for critical thinking and LLM similarity scores. This suggests that students who evaluated LLM responses more rigorously produced more original work.

While constrained LLM access appeared to encourage strategic use and increase feelings of authorship, the study’s small sample size and simplified writing task limit generalizability.

7 Conclusion

This study examined how varied levels of LLM assistance influence college students' writing quality, writing behavior, and perceptions of authorship. In an IRB-approved study with 24 participants, results showed that overall essay quality showed no statistical significance, and systematic patterns in writing behavior, cognitive engagement, and ownership views revealed nuances about how LLMs impact student writing.

These findings motivate future research on LLM-assisted writing in more realistic academic settings, with larger samples and extended writing tasks, to better understand how students balance AI support with independent authorship.

8 Limitations

This study has several limitations. The data were collected over a two-week period from native English speaking college students in authors' university, which limits generalizability despite efforts to recruit participants from diverse backgrounds. The sample size was small, with 24 participants, due to time and resource constraints. As a result, the study focused on a single opinion-based essay prompt, which may not reflect writing behaviors or LLM interactions in other contexts, such as research-driven or evidence-based assignments. Longer writing tasks may reveal different patterns. Future work should explicitly examine EFL/ESL learners, who represent a significant and potentially more LLM-reliant group.

The model also lacked built-in conversational memory. Participants assumed that the LLM would retain context across prompts, leading to confusion when follow-up prompts were interpreted in isolation. This issue was only identified after receiving feedback from the initial participants.

Additional limitations arose in data collection and annotation. Google Docs editing histories only captured major revisions, preventing fine-grained analysis of sentence-level edits and micro revisions during continuous writing. Manual annotation of writing intentions, while validated through inter-rater agreement ($\kappa = 0.71$), introduced potential bias. Additionally, we used Gemini-2.5-Flash rather than ChatGPT, which may limit comparison to students' real-world AI experiences. We did not observe any clear attempts to circumvent the system prompt constraints. Alternative explanations for correlational outcomes (e.g., low confidence

rather than AI-induced ambiguity) cannot be fully ruled out.

We also used cosine similarity to determine an AI similarity score, which captures surface-level semantic overlap but does not directly measure originality in a deeper cognitive sense.

Future work should expand participant pools across institutions and regions, include multiple writing tasks of varying genres and lengths, incorporate memory-enabled frameworks to better reflect real-world AI writing tools, and employ more detailed logging mechanisms to capture granular writing behavior. Longitudinal designs examining skill development would also help capture long term effects of varied LLM access on writing ability.

9 Ethical Considerations

This study does have ethical considerations related to participant privacy, informed consent, and responsible use of generative AI. All participants were fully informed of the purpose of this study and the structure of the writing tasks. Participation was voluntary, and students were free to withdraw at any time without penalty. Incentives were given to participants as per gift cards in return for their time and effort. The study also considered the ethical implications of exposing participants to biased, inaccurate, or misleading AI-assisted output. The LLM was constrained to provide short, general writing suggestions rather than fully generated paragraphs or factual claims. Our study does have potential harm if there is a misinterpretation of our findings, which could encourage the misuse or altogether elimination of AI tools in a school environment. To address this, we emphasized the balance, acknowledgment, and responsibility of AI use, especially in an academic setting.

A System Design Details

A.1 Study Procedure

Participants were recruited via email and asked to complete a preliminary survey administered through Google Forms. Upon receipt of the completed survey, participants were scheduled for an individual, in-person study session.

Each session took place in a private room. Participants were first asked to read and sign the informed consent form (Appendix A.1.1) before beginning the study. Following consent, participants received an email containing two links: one to a document outlining study instructions and another to a Google Doc for composing their essay. Participants assigned to the limited-AI and unlimited-AI conditions additionally received login credentials via email to access the AI-assisted writing platform. The full set of condition-specific instructions is provided in Appendix A.1.2.

All participant data were stored in a private Google Drive folder accessible only to members of the research team. Identifying information was removed from all essays and replaced with anonymized user IDs. During data collection through the LLM interface, only anonymized user IDs were recorded to protect participant privacy.

A.1.1 Consent Form

You are invited to participate in a research project investigating the Overdose Effect of AI-Assisted Writing at the University of Minnesota - Twin Cities. We ask that you read this form and ask any questions you may have before agreeing to take part.

Purpose of the Study: This project explores how different levels of reliance on LLM tools (such as ChatGPT or other generative AI systems) affect students' writing ability, creativity, and critical thinking. The goal is to understand how LLM assistance may influence the quality, style, and originality of written work.

Procedures: The participant will engage in a short preliminary survey asking about their background, experience with AI tools, and comfort level using them. We will then have the participant write a short essay (at least 250-300 words) in response to a provided prompt within approximately 30 minutes. Lastly, the participant will be asked to complete a short post-survey reflecting on their writing process and any use of AI during the activity.

Risks and Benefits of Being in the Study: There

are minimal risks to being in the study. While there is no direct benefit to you, this study will help us better understand how AI tools impact writing skills and academic performance. Each user will be compensated with a \$10 gift card for their time.

Data Sharing: The information you provide through this project will be recorded. Data that you provide as part of this research project will be shared with the other students on the project team, and the course staff.

Confidentiality: We will not collect any information that will make it possible to trace your participation back to you. We will not share your participation with anybody outside of the project team. We will keep your participation private to the extent allowable by law.

Voluntary Nature of Research Participation: Participation in this project is voluntary. Your decision whether or not to participate will not affect your current or future relations with the University of Minnesota - Twin Cities.

Contacts and Questions: The students conducting this research project are: Julia Christenson, Shirley Hayati, and Karin de Langis. The instructor supervising this project is Dongyeop Kang. You may ask any questions you have now. If you have questions later, you are encouraged to contact us. You may keep this page for your records after signing and returning the attached sheet.

Statement of Consent: I have read the attached information regarding the project investigation of the Overdose Effect of AI-Assisted Writing at the University of Minnesota - Twin Cities. I have asked questions and have received answers. I consent to participate in this project.

A.1.2 Instruction Forms

Control Group "A Google Doc will have been shared with you for you to write your essay in. Write a response to the prompt below. Your response should be around 300 words (at least 3 paragraphs), however, you can write more if you want to. Take as much time as you need to write your response.

Prompt: Write a response in which you discuss the extent to which you agree or disagree with the recommendation and explain your reasoning for the position you take. *College students should be encouraged to pursue subjects that interest them rather than the courses that seem most likely to lead to jobs.*

Once you are done writing your response fill out

the following survey. Once you are finished with the essay and the survey please let one of the study team members know."

Limited Group "A Google Doc will have been shared with you for you to write your essay in. Write a response to the prompt below. Your response should be around 300 words (at least 3 paragraphs), however, you can write more if you want to. Take as much time as you need to write your response.

When writing your response, **you are allowed to prompt AI 3 times**. You don't have to use all or any of your allotted prompts; however, you cannot use more than 3. You also cannot prompt the AI to write the full response for you. To access AI, go to this link and sign in with the username and password that the study team member gave you.

Prompt: Write a response in which you discuss the extent to which you agree or disagree with the recommendation and explain your reasoning for the position you take. *College students should be encouraged to pursue subjects that interest them rather than the courses that seem most likely to lead to jobs.*

Once you are done writing your response fill out the following survey. Once you are finished with the essay and the survey please let one of the study team members know."

Unlimited Group "A Google Doc will have been shared with you for you to write your essay in. Write a response to the prompt below. Your response should be around 300 words (at least 3 paragraphs), however, you can write more if you want to. Take as much time as you need to write your response.

When writing your response, **you are allowed to prompt AI as many times as you would like** to help you write your response. However, you cannot prompt the AI to write the full response for you. (You cannot copy and paste in the prompt.) To access AI, go to this link and sign in with the username and password that the study team member gave you.

Prompt: Write a response in which you discuss the extent to which you agree or disagree with the recommendation and explain your reasoning for the position you take. *College students should be encouraged to pursue subjects that interest them rather than the courses that seem most likely to lead to jobs.*

Once you are done writing your response fill out the following survey. Once you are finished with

the essay and the survey please let one of the study team members know."

A.2 Study Interface

The full set of instructions for the limited AI model before the user's prompt is below.

```
SYSTEM_PROMPT = "You are a helpful study assistant. Your role is to provide general guidance, suggestions, and help students think through their work. IMPORTANT RULES: - Keep ALL responses under 100 words - be concise and focused - Provide suggestions, outlines, and general guidance only - DO NOT write complete essays, paragraphs, or full answers that students can copy-paste - Help students develop their own ideas through questions and prompts - Offer structural advice (e.g., "Consider organizing your essay with: intro, 3 body paragraphs, conclusion") - Suggest topics to research or think about - Ask clarifying questions to help students think deeper If asked to write a complete essay or full answer, politely decline and instead offer to: 1. Help them brainstorm ideas 2. Suggest an outline structure 3. Provide tips on how to approach the topic 4. Ask questions to help them develop their thoughts"
```

The interactions with the chatbot and user were sent to a csv file using Vercel Blob. Each row of data followed this order: timestamp, user_ID, user_group, prompt_num, prompt, response.

Preliminary Survey

A. Demographics & Background

Below are the questions included in the preliminary survey instrument.

Q.1 Name (first last):

Q.2 Email:

Q.3 Age:

Q.4 Ethnicity:

Q.5 Year:

- (a) Freshman
- (b) Sophomore
- (c) Junior
- (d) Senior
- (e) Grad student
- (f) Other:

Q.6 Gender:

Q.7 Major/minor/field of study:

Q.8 Category of field of study:

Q.9 Are you a native English speaker?

- (a) Yes
- (b) No

Q.10 Which generative AI tools have you used before? (Select all that apply)

- (a) ChatGPT
- (b) Bard
- (c) Claude
- (d) Co-pilot
- (e) Built-in tools (Grammarly, Word, etc.)
- (f) Other:

Q.11 How often do you currently use AI tools for writing tasks?

(1=Never) 1 2 3 4 5 (5=Always)

B. Self-Assessments

Rate your agreement with the following statements
(1 = Strongly disagree, 5 = Strongly agree).

Q.12 I consider myself a strong writer. ()

Q.13 I think AI will improve my writing ability. ()

Q.14 I worry that using AI will make me less capable as a writer. ()

Q.15 I am comfortable using AI tools for drafting, revising, or editing. ()

Q.16 I understand how to prompt AI (I know how to give clear prompts). ()

Q.17 Of your last 10 course-writing tasks, how many used AI in any way? (0–10):

C. Behavioral Baseline & Motivations

Q.18 Why do you use or avoid AI tools for writing?
(1–2 sentence open text)

Q.19 Any comments, questions, concerns?

Post-Interaction Survey

A. Usage Log (Only asked to AI groups)

Below are the questions included in the post-interaction survey instrument.

Q.1 Approximately what percent of your final text was directly generated or suggested by AI?

- (a) 0%
- (b) 1–10%
- (c) 11–25%
- (d) 26–50%
- (e) 51–75%
- (f) 76–99%
- (g) 100%

Q.2 Did you copy-paste any AI output into your final submission?

- (a) Yes
- (b) No

Q.3 Did you edit the AI output?

- (a) No edits
- (b) Minor edits (wording)
- (c) Moderate edits (structure)
- (d) Major edits (rewrote most)

B. Process & Experience

Rate your agreement with the following statements (1 = Strongly disagree, 5 = Strongly agree).

Q.4 The AI suggestions helped me generate ideas. ()

Q.5 The AI suggestions saved me time. ()

Q.6 The AI suggestions improved the clarity of my writing. ()

Q.7 The AI suggestions reduced my creative expression. ()

Q.8 I felt I relied too heavily on AI to complete the task. ()

Q.9 I had to do substantial critical thinking to decide what to accept or reject from the AI. . . ()

Q.10 I felt the final product still reflected my own voice. ()

Q.11 I would submit the final essay as my own in a regular class.

- (a) Yes
- (b) No
- (c) Not sure

Q.12 I would disclose to an instructor that I used AI for this piece.

- (a) Yes
- (b) No
- (c) Maybe

C. Cognitive Load / Effort & Time

Q.13 How difficult was it to complete this task?
(Very easy) 1 2 3 4 5 (Very difficult)

Q.14 How much of the 30 minutes did you spend editing vs. composing vs. reading AI outputs?
Editing: %
Composing: %
Reading AI outputs: %

D. Reflection on Skills

After this session, indicate how you feel your ability changed in each area (increase / no change / decrease).

Q.15 Organize ideas:

Q.16 Use precise vocabulary:

Q.17 Write creatively:

Q.18 Perform critical analysis:

E. Originality & Authenticity

Q.19 How original do you feel your final essay is?
(Not at all original) 1 2 3 4 5
(Very original)

Q.20 On a scale of 0–100, how authentic does the essay feel to you?

Q.21 Would you be comfortable if this exact essay were used as a graded assignment?

- (a) Yes
- (b) No
- (c) Maybe

F. Ethics & Academic Integrity

Q.22 Do you think using AI in coursework should be allowed?

- (a) Yes
- (b) No
- (c) Depends — please explain:

Q.23 If allowed, should students be required to disclose AI usage?

- (a) Yes
- (b) No
- (c) Depends

G. Open Reflection

Q.24 Describe (in 1–3 sentences) how you used AI in this task (what prompts you gave, what you accepted/rejected).

Q.25 What, if anything, did AI prevent you from doing or thinking about?

Q.26 Did anything about the AI outputs surprise you?

- (a) Yes — please explain:
- (b) No

Q.27 Any additional comments about how AI influenced your thinking or writing on this task?

H. Optional Detection / Guessing Task

Q.28 We sometimes run automatic classifiers on texts. Do you think your submitted essay was more likely:

- (a) Human-written
- (b) AI-assisted
- (c) Mostly AI-generated

Essay Grading Rubric

The following rubric was used to evaluate the quality of student essays across all experimental conditions. Each category is scored on a scale of 1–5 points.

Scoring: Each category is scored from 1–5 points. Total possible score for the first six categories: 30 points.

Category	5	4	3	2	1
Focus & Details	Engaging and full development of a clear thesis as appropriate to the assignment purpose.	Competent and well-developed thesis; thesis represents a sound and adequate understanding of the assigned topic.	Mostly intelligible ideas; thesis is weak, unclear, too broad, or only indirectly supported.	Most simplistic and unfocused ideas; little or no sense of purpose.	Ideas are extremely simplistic, showing signs of confusion and misunderstanding of the prompt. The thesis is missing or not discernible.
Ideas, Support, & Development (Evidence)	Consistent evidence with originality and depth of ideas. Ideas work together, and the main points are sufficiently supported with evidence.	Ideas are supported sufficiently; support is sound, valid, and logical.	Main points and ideas are only indirectly supported. Support is loosely relevant to the main points.	Insufficient or non-specific support.	Lack of support for main points.
Organization	Organization is sequential and appropriate. Paragraphs are well developed and appropriately divided.	Competent organization, without sophistication. May lack effective transitions.	Limited attempts to organize around a thesis; paragraphs are mostly stand-alones with weak transitions.	Organization, while attempted, was unsuccessful. Paragraphs were simple, disconnected, and formulaic.	Little to no organization; disjointed or confusing structure.
Voice	The author's purpose is very clear. Their extensive knowledge and/or experience with the topic is/are evident.	The author's purpose is mostly clear. Some evidence of attention to the audience. The author's knowledge and/or experience with the topic is/are evident.	Little or inconsistent sense of the audience related to the assignment purpose. Tone and point of view are not refined or consistent.	Shows almost no awareness of a particular audience; reveals no grasp of appropriate tone and/or point of view for given assignment.	Lacks awareness of a particular audience for the assignment; tone and point of view are somewhat inappropriate or very inconsistent.
Vocabulary and Word Choice	Exceptional vocabulary range, accuracy, and correct and effective word usage.	Good vocabulary range and accuracy of usage.	Ordinary vocabulary range, mostly accurate.	Errors of diction and usage, while evident, do not interfere with readability.	Extremely limited vocabulary; choices lack grasp of diction.
Sentence Structure, Grammar, Mechanics, & Spelling	All sentences are well constructed and have varied structure and length. The author makes no errors in grammar, mechanics, and/or spelling.	Most sentences are well constructed and have varied structure and length. Contains only occasional punctuation, spelling, and/or capitalization errors.	Sentences show a formulaic or tedious sentence pattern. Some errors in grammar, mechanics, and/or spelling, but they do not interfere with understanding.	Most sentences are well constructed, but they have a similar structure and/or length. The author makes several errors in grammar, mechanics, and/or spelling that interfere with understanding.	Sentences sound distractingly repetitive or are difficult to understand. The author makes numerous errors in grammar, mechanics, and/or spelling that interfere with understanding.
AI Detection/ Human-written	I am confident that this text was completely human-written. This essay feels completely authentic and original.	I am confident that this text was written mostly by a human. This essay feels authentic, but may have had some AI assistance.	I believe this essay was done by a human with AI assistance. Some portions of text seem to be AI-generated.	I believe this essay was mostly written with the help of AI. A large portion of the text sounds repetitive and/or unoriginal.	I believe this essay was completely written by AI.

Assessment of L2 Speech Global Dimensions using Large Audio Language Models

Elsayed Issa

esissa@purdue.edu

Mahmoud Ali
University of Michigan
Ann Arbor, MI, USA
alimahm@umich.edu

Abstract

Large audio language models (LALMs) integrate audio representations with large language models to enable unified understanding of spoken content. Their capabilities have been increasingly investigated across several benchmarks; however, the examination of their use in rating L2 speech is still in its infancy. This study explores the abilities of LALMs in scoring three L2 speech global dimensions: foreign accentedness, comprehensibility, and intelligibility. Ninety audio samples produced by L2 speakers were rated by ten native speaker raters as well as five LALM models. Model performance was evaluated against the human composite mean using Pearson r , Spearman p , mean absolute error (MAE), and systematic bias, with the human leave-one-out correlation ($r = .46-.73$ across dimensions) serving as an empirical performance benchmark. The results showed that no LALM reached human-level performance on any dimension. Only one model (i.e., Gemini) achieved a significant correlation with human ratings on comprehensibility ($r = .28, p < .01$), while Qwen2-Audio showed modest correlation on intelligibility ($r = .32, p < .01$). MAE ranged from 0.75 to 3.99 for accentedness (human: 1.24), 1.35 to 3.00 for comprehensibility (human: 1.24), and 12.03 to 15.43 for intelligibility (human: 8.49). All models exhibited systematic biases, with deviations ranging from -9.31 to +13.19 points. The paper concludes with a discussion of the implications for automated L2 speech assessment.

1 Introduction

Large audio language models (LALMs) integrate audio representations with large language models to enable unified understanding and interaction over spoken content, environmental sounds, and even music. Such integration pushes beyond traditional automatic speech recognition pipelines toward more general instruction following and audio

question answering (Chu et al., 2024; Ding et al., 2025; Yang et al., 2024a; Tang et al., 2023). Recent models such as Qwen-Audio, Qwen2-Audio, Qwen2-Audio-7B-Instruct and Kimi-Audio demonstrate strong zero- and few-shot behavior across diverse audio tasks. These capabilities highlight how scale and multitask training can broaden audio reasoning and conversational capabilities (Chu et al., 2023, 2024; Ding et al., 2025).

As LALMs move from offline speech-to-text toward interactive voice assistants, the relevant notion of *understanding* increasingly encompasses not only speech but also non-speech audio, music, and other acoustic signals. These capabilities have been systematically investigated across a growing number of benchmarks, including AudioBench (Wang et al., 2025a), VoiceBench (Chen et al., 2024), SD-Eval (Ao et al., 2024), ADU-Bench (Gao et al., 2025), and MMAU (Wang et al., 2025b), each targeting different aspects of audio comprehension such as instruction following, spoken dialogue understanding, and multi-task audio reasoning. Previous work on L2 speech investigated GPT-4o capabilities for pronunciation assessment across phoneme, word, and sentence levels (Ahn and Nam, 2025), the potential of LALMs in language learning (Liu et al., 2026), multimodal LLM-based pronunciation scoring system (Fu et al., 2024), speech intelligibility (Pham, 2023), and ASR bias in relation to intelligibility, comprehensibility, and foreign accentedness (Issa et al., 2026). However, the investigation of L2 speech global dimension (i.e., intelligibility, comprehensibility, and foreign accentedness) is limited.

To address this issue, the current study aims to examine the extent to which LALMs can reliably and validly assess L2 speech listener-based global dimensions, namely intelligibility, comprehensibility, and foreign accentedness. These three constructs occupy a central place in L2 speech research (Munro and Derwing, 2015), yet the empirical in-

investigation of LALMs effectiveness in measuring these dimensions remains unknown. The study is guided by the following research questions: 1) How foreign accented, comprehensible, and intelligible is L2 Arabic speech based on LALMs assessment? 2) To what extent do LALMs agree with human rating of intelligibility, comprehensibility, and foreign accentedness in L2 Arabic speech? 3) How LALMs-based ratings of intelligibility, comprehensibility, and foreign accentedness differ as a function of model category?

2 Related work

2.1 L2 speech global dimensions

In L2 pronunciation research, a shift has moved the focus from native-like pronunciation toward comprehensible and intelligible speech (Levis, 2005; Nagle et al., 2018). In line with this shift, recent research has centered on three global, perceptual dimensions of L2 speech: foreign-accentedness (deviation from native-speaker norms), comprehensibility (ease of understanding), and intelligibility (actual understanding) (Munro and Derwing, 1995). These constructs have been found to be distinct yet partially related, with the key finding being that foreign-accented speech is not necessarily less comprehensible or intelligible across multiple languages (e.g., Huensch and Nagle, 2021; Munro and Derwing, 1995; Ali, 2023).

These three constructs have been examined in the context of L2 pronunciation research based on trained or untrained human raters. Munro and Derwing (1995) examined L2 English speech and reported significant correlations between comprehensibility and intelligibility for 15 of their 18 listeners, with a mean correlation of $r = .51$, while only five listeners showed significant correlations between accentedness and intelligibility. In L2 Spanish, Huensch and Nagle (2021) found that comprehensibility is strongly linked to intelligibility, but foreign-accentedness is not, and that phonemic errors have a stronger negative association with listener ratings than grammatical errors. Ali (2023) extended the investigation to L2 Arabic by examining the relationships among foreign-accentedness, comprehensibility, and intelligibility and exploring the contribution of foreign-accentedness and/or comprehensibility ratings in intelligibility scores. The results supported the partial independence of the three dimensions. Recent meta-analytic evidence has provided a comprehensive synthesis of

these dimensions relationships. Chau and Huensch (2025) analyzed 141 effect sizes from 49 studies spanning 1995 to 2023, documenting weighted mean correlations of $r = .75$ for foreign accentedness/comprehensibility, $r = .57$ for comprehensibility/intelligibility, and $r = .32$ for intelligibility/foreign accentedness. These findings establish a clear hierarchy in which intelligibility shows the weakest relationship with foreign accentedness and moderate associations with comprehensibility, while comprehensibility and foreign accentedness show stronger interdependence. The small correlation between intelligibility and foreign accentedness ($r = .32$, 95% CI [.08, .52]) provides the most compelling evidence that having a strong foreign accent does not necessarily impede actual understanding. Across studies in this line of research, human raters have been found to provide reliable and valid assessment of the three dimensions under investigation.

Efforts to automate the assessment of L2 speech have been examined, though most work has focused on specific speech dimensions such as segmental and suprasegmental features. Automatic speech scoring systems operationalize pronunciation differently and have been criticized for lack of transparency in how speech features are weighted (Cai et al., 2025). Traditionally, these systems rely on training procedures using neural networks. In addition, one of the limitations in these systems is the high error rates, particularly spontaneous L2 speech (Cai et al., 2025).

More recently, attention has turned to whether large language models and multimodal architectures can address this limitation. Ahn and Nam (2025) investigated the zero-shot capabilities of GPT-4o for pronunciation assessment across phoneme, word, and sentence levels. The study found that its scoring accuracy was significantly lower than tools that are specifically designed for that purpose, leading to the conclusion that multimodal LLMs may not yet replace purpose-built systems without fine-tuning. Similarly, Fu et al. (2024) proposed a multimodal LLM-based pronunciation scoring system and demonstrated competitive results against alignment-based baselines on the Speechocean762 dataset, though performance on spontaneous L2 speech and global dimensions remains unexamined.

Moreover, Pham (2023) investigated L2 English intelligibility using both the ASR transcription system (i.e., Otter) and 40 L2 English human

raters. The study found that while the ASR system achieved 79-91% transcription accuracy, human intelligibility scores were lower ($M = 3.9$ - 6.8 out of 10), revealing a critical divergence between ASR capabilities and human accuracy. In the same vein, Issa et al. (2026) examined linguistic bias in Whisper large-v3 performance on L2 Arabic speech, comparing ASR word error rate (WER) to human-based transcriptions (i.e., intelligibility) and ratings of comprehensibility and foreign accentedness. The findings revealed that intelligibility scores significantly predicted lower WER while foreign accentedness was associated with higher WER, whereas comprehensibility appear to be independent of WER. Finally, Liu et al. (2026) explored the potential of LALMs for interactive language learning by introducing L2-Arctic-plus, an English dataset annotated with detailed pronunciation error explanations and actionable suggestions for improvement. The study benchmarked both cascaded ASR-plus-LLM pipelines and existing LALMs on tasks including error detection and the generation of corrective feedback. Findings indicated that current models show promise for chat-based pronunciation training but still fall short of providing consistently accurate and pedagogically useful guidance.

2.2 LALMs benchmarks

A growing body of research has systematically evaluated LALM performance across diverse benchmarks. AudioBench (Wang et al., 2025a) provided a comprehensive evaluation framework spanning 8 task categories and 26 datasets while also examining prompt sensitivity effects in LALMs, where they found that LALMs could behave differently to different prompt templates. Across multiple audio modalities including speech, environmental sounds, and music, AIR-Bench (Yang et al., 2024b) assessed instruction-following competencies through a two-tier architecture: a foundation tier comprising 19 tasks with approximately 19,000 single-choice items, and a conversational tier containing roughly 2,000 open-ended question-answer pairs evaluated via GPT-4-as-judge methodology against reference responses. Likewise, MMAU (Tyagi et al., 2024) targeted audio understanding and reasoning across three domains (speech, sound, music) using exclusively multiple-choice formats to enable fully automated assessment without human annotation or LLM-based judging. Moreover, Dynamic-SUPERB (Huang et al., 2024b,a) imple-

ments a two-phase evaluation protocol for universal instruction-based speech models under zero-shot conditions. Results revealed that no single model achieves consistent performance across all tasks: SALMONN-13B demonstrates superiority in English ASR, whereas Qwen2-Audio-7B-Instruct exhibits stronger emotion recognition capabilities, yet neither generalizes effectively across the complete task spectrum.

Several benchmarks have targeted contextual and content-level comprehension. SD-Eval (Ao et al., 2024), for instance, addresses a more focused yet critical aspect of LALM functionality: spoken dialogue comprehension beyond surface-level transcription. It assesses models' capacity to simultaneously process content, speaking style, speaker emotion, and background acoustics—the multifaceted contextual understanding required for conversational assistants. Findings indicated inadequate contextual response generation, attributed to insufficient task formalization and appropriate evaluation datasets. Similarly, ADU-Bench (Gao et al., 2025) evaluates open-ended audio dialogue performance across 3 general scenarios, 12 competencies, 9 languages, and 4 ambiguity categories. Evaluation of 16 LALMs revealed superior performance on information-seeking queries relative to casual conversational exchanges, with systematic failures in mathematical reasoning, roleplay interactions, non-English language processing, and phonetic ambiguity resolution.

Additional benchmarks have specifically investigated audio hallucination phenomena. Ghosh et al. (2023) introduced Comp-A to assess compositional reasoning, demonstrating that contemporary models achieve only marginally above-chance performance when matching audio clips to captions with varied event orderings or attribute bindings. Sung-Bin et al. (2024) developed AVH-Bench, a cross-modal hallucination benchmark for audio-visual LLMs, revealing widespread difficulty in parsing fine-grained audio-visual relationships. Furthermore, AHa-Bench (Cheng et al., 2025) proposed a tripartite hallucination taxonomy—semantic, acoustic, and semantic-acoustic—and evaluated seven open-source LALMs, uncovering substantial limitations in models' joint interpretation of semantic and acoustic information. While these benchmarks have examined several capabilities of LALMs, they mainly focused on L1 English and L1 Chinese, leaving not only other L1s but also L2s unexplored, including Arabic.

3 Methods

3.1 Data

The L2 Arabic speech data came from 30 adult L1 English speakers (19M, 11F) who were enrolled in second- and third-year Arabic courses at a U.S. public university. All were rated at the Intermediate level of proficiency based on the American Council on the Teaching of Foreign Languages (ACTFL) scale. The speech samples were rated by 10 L1 Arabic speakers (9M, 1F) with minimal exposure to L2 Arabic speech and no teaching experience. No participants reported hearing or speech impediments (Ali, 2023).

Speech Production: The speech samples were as part of an Oral Proficiency Interview (OPI) administered by a certified OPI tester and recorded via Zoom (15–35 min) following an online language background questionnaire. Three speech samples per speaker were extracted from distinct OPI sections. Samples were amplitude-normalized (peak = 0.99) in Audacity (Audacity Team, 2020), yielding 90 samples (30 speakers x 3) averaging 13 seconds and 15 words.

Speech Perception: Ten L1 Arabic listeners completed three tasks on all 90 samples across counter-balanced sessions on separate days (3 hours total). Task 1 involved rating foreign-accentedness on 9-point scale where 0 means no foreign accent and 9 means strongly foreign accented. Task 2 involved rating comprehensibility on 9-point scale where 0 means very easy to understand and 9 means very difficult to understand. Finally, in task 3, listeners transcribed the speech samples as a measure of intelligibility (Munro and Derwing, 1995). An intelligibility score was calculated as the percentage of correctly transcribed words. Tasks were blocked (35 samples/block) and presented via a custom Qualtrics interface, with listeners rating each sample after a single hearing following three practice items.

3.2 Experiments

Five LALMs were purposively selected due to their multilingual capabilities, including Arabic. These models are Qwen2-Audio¹, Qwen2-Audio-7B-Instruct² (Chu et al., 2024), Ultravox³, Gemini-

2.5-Pro (Google DeepMind, 2025) and GPT-4o-audio-preview (OpenAI, 2024) (see Table 4 for more information about the open-source models). We probed each model using a standardized zero-shot prompt designed to elicit numerical ratings on each of the three global speech dimensions. Models are prompted independently per dimension using the prompts shown in Table 5. To evaluate the extent to which these five LALMs can simulate human perception of L2 speech dimensions under investigation, a series of statistical analyses were conducted in Python using the pingouin library (Vallat, 2018).

Our analyses map onto the three research questions as follows. For RQ1, descriptive statistics (mean, SD, range, 95% CI) summarize how LALMs rate each dimension. For RQ2, we evaluate LALM–human agreement using complementary metrics that capture distinct facets of agreement: Pearson r and Spearman ρ index linear and rank-order correspondence; mean absolute error (MAE) and root mean square error (RMSE) quantify the magnitude of per-item disagreement; and signed bias captures systematic over- or underestimation. We additionally fit each LALM as an 11th rater alongside the ten human raters and recompute the intraclass correlation, testing whether a LALM behaves as an exchangeable member of the rater panel. A leave-one-out (LOO) analysis, in which each human rater’s ratings are correlated with the mean of the remaining nine, provides an empirically grounded benchmark for human-level performance against which LALM agreement can be interpreted.

For RQ3, we compare per-item MAE between open- and closed-source model families using a Wilcoxon signed-rank test (paired by item), with Cohen’s d as a measure of effect size. The Wilcoxon test was chosen over a paired t-test because per-item MAE is bounded at zero and skewed, violating the normality assumption. We measure Intraclass Correlation Coefficient (ICC) variants (Shrout and Fleiss, 1979; McGraw and Wong, 1996). On the one hand, ICC2 is the single-rater absolute-agreement coefficient. It indicates how closely one randomly selected rater (human or LALM) matches another in absolute terms. ICC2k, on the other hand, is the corresponding average-measures coefficient, showing the reliability of the mean rating across the full panel. ICC3 and ICC3k are the consistency analogs (two-way mixed effects), which discount systematic between-rater

¹<https://huggingface.co/Qwen/Qwen2-Audio-7B>

²<https://huggingface.co/Qwen/Qwen2-Audio-7B-Instruct>

³https://huggingface.co/fixie-ai/ultravox-v0_5-llama-3_1-8b

shifts in mean; we report these for completeness. ICC2 is our primary metric because the research question is whether a LALM produces the same numerical rating a human would, not merely a rank-consistent one. This same logic motivates reporting MAE and signed bias alongside Pearson r : Pearson correlation is invariant to additive shifts that absolute-agreement metrics correctly penalize.

The five LALMs differ systematically along a dimension that is theoretically relevant to L2 Arabic assessment: training scale and Arabic representation. The closed-source models (Gemini 2.5-Pro, GPT-4o-audio-preview) are trained on substantially larger and more multilingual corpora than the open-source models in our sample, which are built on Whisper-large-v2 or v3-turbo encoders paired with 7–8B parameter language model backbones (Qwen-7B, Llama-3.1-8B; see Table 4). Arabic, and L2 Arabic in particular, is plausibly underrepresented in the training data of the open-source models. Prior benchmark work has shown that LALMs struggle in non-English language environments (Gao et al., 2025), making the open- versus closed-source comparison a useful probe of whether scale and broader multilingual coverage partially compensate for the demands of low-resource L2 perceptual rating. We therefore examine whether per-item agreement with human raters differs systematically between the two model families, recognizing that with five models this comparison is hypothesis-generating rather than definitive.

4 Results

Table 1 presents the descriptive statistics for LALMs ratings across the three dimensions. LALMs rated foreign accentedness toward the higher end of the 9-point scale ($M = 5.70$, $SD = 2.40$), comprehensibility ratings fell near the midpoint of the scale ($M = 4.78$, $SD = 2.47$), and intelligibility showed the broadest range among the three measures ($M = 77.08$, $SD = 28.85$, range = 20–100) (see Figure 3 for distribution of comprehensibility and foreign-accentedness ratings and intelligibility scores by human raters and LALMs).

Table 2 presents Pearson r , mean absolute error (MAE), and systematic bias for each model across the three dimensions, alongside the human LOO analysis. Across all dimensions and all five models, no LALM reached the human LOO correlation threshold. All models showed statistically significant deviations from the human agreement

composite mean (Wilcoxon signed-rank, all $p < .001$; see Table 7). For intelligibility, Qwen2-Audio was the only model to significantly correlate with human ratings ($r = .322$, $p = .002$). On the other hand, Gemini and GPT showed no significant correlations.

Ultravox and Qwen2-Audio-Instruct provided the same scores/ratings to all speech samples across all the three dimensions. From statistical analysis perspective, we acknowledge that these are considered statistical artifacts. However, from model performance evaluation, this is also indicative of model hallucinations which will be discussed later.

As for comprehensibility, while the association between Gemini and human agreement composite mean was significant ($r = .281$, $p = .007$), the correlation between GPT and the human agreement composite mean was not ($r = .180$, $p = .090$). Open-source models did not correlate meaningfully. Finally, for foreign accentedness, none of the LALMs significantly correlated with human-based ratings. It is worth noting that Ultravox and Qwen2-Audio-Instruct rated speech samples with constant scores across constructs, resulting in meaningless correlations with those of humans.

Table 3 summarizes the results that examine whether model category influenced model performance. a Wilcoxon signed-rank test was adopted for each dimension comparing per-item mean absolute error between the open- and closed-source families. Per-item error of open-sourced models was significantly larger than that of closed-sourced models for intelligibility (open MAE = 29.02, $SD = 5.02$; closed MAE = 13.76, $SD = 10.80$) and for comprehensibility (open MAE = 2.49, $SD = 0.57$; closed MAE = 2.10, $SD = 1.05$) while there was no significance difference between the two model categories for foreign accentedness (open MAE = 2.07, $SD = 0.42$; closed MAE = 2.10, $SD = 0.87$).

Finally, we examined agreement reliability model fit with human-based agreement as baseline. Each LALM was fitted as an additional (11th) rater, and ICC2 was recomputed for the augmented panel and compared against the ten-human baseline. As shown in Figure 1, across all three dimensions, model fitting declined by adding any of the LALMs. For intelligibility, the decline was most pronounced for Gemini (baseline ICC2 = .49; with Gemini = .39) followed with GPT (baseline ICC2 = .49; with GPT = .43), and finally Qwen2-Audio (baseline ICC2 = .49; with Qwen2 = .44). As for comprehensibility, the decline was shown for Qwen2-Audio

	M	SD	Min	Max	95% CI
Foreign-accentedness	5.70	2.40	1	9	5.47-5.92
Comprehensibility	4.78	2.47	1	9	4.55-5.00
Intelligibility	77.08	28.85	20	100	74.40-79.75

Table 1: Descriptive statistics for LALMs’ ratings of Foreign-accentedness, Comprehensibility, and Intelligibility

		Foreign Accentedness			Comprehensibility			Intelligibility		
		<i>r</i>	MAE	Bias	<i>r</i>	MAE	Bias	<i>r</i>	MAE	Bias
Open	Qwen2-Audio	.15	3.99	3.90	.16	3.00	1.32	.32**	12.03	+8.80
	Qwen2-Instruct	—†	0.75	+0.48	—†	1.35	+1.11	—†	12.28	9.31
	Ultravox	—†	1.48	+1.48	—†	1.35	+1.11	—†	12.28	9.31
Closed	Gemini	.15	1.56	+0.39	.28**	2.11	1.40	.12	15.43	+13.19
	GPT	.04	2.64	2.58	.18	2.09	2.06	.07	12.08	+10.02
	Human LOO	.46	1.24	—	.57	1.24	—	.73	8.49	—

MAE = mean absolute error. Bias = model mean minus human mean. Human LOO = leave-one-out benchmark: mean Pearson *r* and MAE of each human rater correlated against the remaining nine raters, averaged across raters. † Zero-variance output where correlation is undefined. ** $p < .01$. See Table 9 for individual rater LOO correlations and MAE across dimensions

Table 2: Per-model agreement with human ratings across the three constructs (N = 90).

(baseline ICC2 = .336; with Qwen2 = .219), GPT (baseline ICC2 = .336; with GPT = .27), and Gemini (baseline ICC2 = .336; with Gemini = .29). Finally, the decline is pronounced for Qwen2-Audio (baseline ICC2 = .209; with Qwen2 = .122), followed by GPT (.15) and Gemini (.18) respectively for foreign-accentedness (see Table 8 for more on model fit).

5 Discussion

5.1 LALMs assessment of global speech dimensions

LALMs rated L2 Arabic speech as moderately to strongly foreign accented (M = 5.70, SD = 2.40), moderately difficult to understand (M = 4.78, SD = 2.47), and mostly highly intelligible (M = 77.08, SD = 28.85). However, aggregate similarity in mean ratings is not, by itself, evidence that LALMs reproduce human rating behavior. The within-dataset evidence presented in Sections 5.2 and 5.3, item-level agreement, distributional patterns, and the effect of substituting LALMs into the rater panel, yields a less favorable assessment. Prior work has documented limitations of multimodal LLMs in segmental and sentence-level pronunciation assessment (Ahn and Nam, 2025; Fu et al., 2024); the present results extend the scope of these limitations to global perceptual dimensions, where the gap between LALM and human raters, quantified against the human LOO benchmark, is more pronounced.

5.2 Global speech dimensions: LALMs-based versus human-based

Three sources of within-dataset evidence converge on the conclusion that LALMs do not reliably reproduce human rating behavior on our corpus.

Item-level agreement: No LALM reached the human LOO correlation benchmark on any dimension (Table 3). The human LOO correlations averaged $r = .73$ for intelligibility, .57 for comprehensibility, and .46 for foreign accentedness, whereas the strongest LALM correlations were $r = .32$ (Qwen2-Audio, intelligibility), .28 (Gemini, comprehensibility), and .15 (Qwen2-Audio and Gemini, foreign accentedness). Per-item MAE values likewise exceeded the human LOO MAE on every dimension and for every model. Even the closest match, Qwen2-Instruct on foreign accentedness (MAE = 0.75), is misleading, as that value reflects a constant output rather than item-sensitive rating.

Distributional patterns: Although LALM mean ratings approximate human means at the aggregate level, Figure 2 shows that the underlying distributions diverge. LALM ratings exhibit larger standard deviations and, in two cases (Ultravox and Qwen2-Instruct), collapse to a single value across all 90 samples. This distributional mismatch indicates that aggregate similarity in central tendency masks substantial item-level disagreement.

Effect on inter-rater reliability: When each LALM is fitted as an 11th rater alongside the

Construct	Open MAE	Closed MAE	W	<i>p</i>	<i>d</i>
Foreign Accentedness	2.07	2.10	1934.5	.781	0.03
Comprehensibility	2.49	2.10	1355.0	.008	0.27
Intelligibility	29.02	13.76	263.0	< .001	1.11

Table 3: Open-source vs. closed-source comparison of per-item mean absolute error across the three constructs. *W* and *p* are from Wilcoxon signed-rank tests (paired by item); *d* is Cohen’s *d*. The Wilcoxon test was chosen because per-item MAE is bounded at zero and right-skewed, violating the normality assumption of the paired t-test.

Figure 1: ICC2 when each model is added as an 11th rater to the human panel (dashed line = 10-human baseline; error bars = 95% CI)

ten human raters, the panel’s single-rater absolute-agreement coefficient (ICC2) declines on every dimension and for every model (Figure 1; Table 8). The decline is most pronounced for intelligibility with Gemini (.49 → .39), for comprehensibility with Qwen2-Audio (.34 → .22), and for foreign accentedness with Qwen2-Audio (.21 → .12). Adding any LALM to the rater panel reduces, rather than augments, the reliability of the rating panel which is a direct evidence that LALMs do not function as exchangeable raters.

Taken together, these three lines of evidence indicate that the apparent similarity between LALM and human ratings at the aggregate level does not extend to the item level, the distributional level, or the level of rater interchangeability. This pattern is consistent with prior findings of divergence between automated and human speech assessment (Pham, 2023) and suggests that LALMs do not simulate the underlying mechanisms human raters draw on when evaluating L2 speech.

5.3 Open- versus closed-model assessment

The by-category comparison reveals a dimension-dependent pattern that aligns with the theoretical motivation outlined in Section 3.2. Closed-source

models outperformed open-source models on intelligibility (open MAE = 29.02, closed MAE = 13.76; $d = 1.11$, $p < .001$), modestly outperformed them on comprehensibility (open MAE = 2.49, closed MAE = 2.10; $d = 0.27$, $p = .008$), and showed no advantage on foreign accentedness (open MAE = 2.07, closed MAE = 2.10; $d = 0.03$, $p = .781$). Figure 2 and Table 10 corroborate this gradient via Bland-Altman statistics. The dimension-dependent gradient is informative about what kind of capability drives performance on each construct. Intelligibility is operationalized as the proportion of words correctly transcribed, so it depends most directly on ASR quality, a capability that scales with training data volume and multilingual coverage, where closed-source models have a clear advantage. Comprehensibility is a perceptual judgment of processing effort that is less directly tied to ASR quality, which may explain the smaller advantage. Foreign accentedness requires phonetic comparison against L1 Arabic norms, a capability that appears to be poorly developed in both model families and is consistent with Arabic being underrepresented in training data across the board. Read this way, the open/closed comparison is not

Figure 2: Model category ratings vs. human composite mean

merely a performance comparison between model families but evidence that scale and multilingual coverage partially compensate for low-resource L2 settings on transcription-driven dimensions, while leaving phonetic-norm-based judgments largely unaddressed.

The constant-output behavior observed in Ultra-vox and Qwen2-Audio-Instruct warrants attention. Both models produced identical ratings across all 90 samples on every dimension, which is reflected in their undefined Pearson correlations (Table 3) and in the spike-shaped distributions in Figure 3. This pattern indicates that the models did not engage with item-level acoustic or linguistic variation when prompted for perceptual ratings, defaulting instead to a fixed response. This behavior is reported as hallucination phenomena documented in LALM benchmarks (Cheng et al., 2025; Sung-Bin et al., 2024), in which models generate plausible but unfounded outputs. This raises the question of whether instruction-tuned LALMs are prone to substituting heuristic responses for genuine acoustic analysis on perceptual rating tasks. Possible explanations include insufficient exposure to L2 Arabic in pretraining/instruction-tuning that biases the model toward modal scale-point responses regardless of input, or failure of the audio encoder to extract dimension-relevant features from the signal.

5.4 Implications for automated L2 speech assessment

The findings of this study carry several implications for the use of LALMs in L2 speech assessment. First, current LALMs may not be used in high-stakes assessment contexts such as proficiency certification or placement testing. This aligns with the broader consensus in language assessment that automated scoring systems must accumulate validity evidence comparable to that expected of human raters before they can be justified for operational use, especially in high-stakes decisions (Chapelle and Voss, 2021). Second, the finding that certain models showed partial sensitivity to specific dimensions suggests that LALMs may be amenable to domain-specific fine-tuning for targeted dimension assessment. Rather than relying on general-purpose multitask training, future work could fine-tune LALMs on L2 speech data annotated for specific global dimensions, potentially improving model–human agreement on dimensions where zero-shot performance has the greatest potential. Finally, the results highlight the need for closer collaboration between the speech technology researchers and applied linguistics communities. Current LALM benchmarks (Wang et al., 2025a; Tyagi et al., 2024; Wang et al., 2025b; Sung-Bin et al., 2024) evaluate models primarily on L1 speech, but not L2 speech in their assessment criteria. One benchmark, (Gao et al., 2025), indicated that LALMs struggle in non-English language environments. Our findings demonstrate that strong performance on standard audio understanding tasks does not transfer to the perceptual demands of L2 speech rating. Future benchmark development should incorporate L2 speech assessment tasks across multiple languages and proficiency levels.

6 Conclusion

This study provided an evaluation of LALMs as automated raters across three global dimensions of L2 speech. Current LALMs cannot simulate human ratings with sufficient accuracy or reliability to serve as raters in L2 speech assessment. This conclusion rests on three converging within-dataset findings: LALM agreement with human ratings falls below the human LOO benchmark on every dimension; LALM rating distributions diverge from human distributions despite similar means; and adding any LALM to the rater panel reduces rather than augments panel reliability.

Limitations

Several limitations should be acknowledged. First, the sample of 90 recordings represents a relatively small corpus of L2 speech. We recognize this not only as a limitation but also as an invitation to L2 researchers to evaluate LALMs on their own datasets and to propose strategies for improving LALM performance. Second, we acknowledge that Arabic may be underrepresented in the training data of the open-source models examined in the current study. That said, this presents an opportunity to the broader L2 community to extend this line of inquiry to other languages in order to validate our findings. Third, models were evaluated in a zero-shot configuration using a single standardized prompt per dimension, without few-shot examples, chain-of-thought reasoning, et cetera. We chose this design deliberately to establish a baseline of out-of-the-box LALM behavior on L2 speech rating, which mirrors how non-expert end users (e.g., learners, instructors) are most likely to deploy these systems in practice. We acknowledge, however, that this design cannot disentangle inherent model limitations from prompt-induced underperformance, and some portion of the observed model-human gap may be attributable to suboptimal prompting rather than representational shortcomings. That said, two patterns in our results suggest prompting alone is unlikely to fully close the gap. First, the constant-output behavior of Ultravox and Qwen2-Audio-Instruct across all 90 samples points to a failure to engage with the acoustic signal rather than a calibration issue that anchors could resolve. Second, the magnitude of systematic bias observed for several models (up to +13.19 points on intelligibility) and the dimension-specific divergence between open- and closed-source families suggest underlying differences in audio representation quality, not merely scale-mapping artifacts. Future work should systematically vary prompting strategy to quantify the share of variance attributable to prompt design versus model capability.

Ethics Statement

We adhered to ethical principles to ensure responsible and respectful collection of the data. Participants were fully informed about the purpose of the study, the nature of the data being collected, and their right to withdraw at any time without consequence. No personally identifiable information was collected (see [Ali, 2023](#) for more information).

Data Availability

The L2 Arabic speech corpus and human ratings are not yet publicly available due to ongoing research, but the authors plan to release them in the near future. Access may be granted to researchers upon reasonable request.

Acknowledgment

We would like to thank the anonymous reviewers for their valuable comments, which helped to improve this manuscript; all remaining errors are our own. We also gratefully acknowledge the financial support and resources provided by the School of Languages and Cultures at Purdue University.

A Data Annotation Guidelines

The annotation procedure followed established guidelines from the L2 pronunciation research literature, specifically the protocol introduced by [Munro and Derwing \(1995\)](#) and subsequently adopted in numerous studies of L2 speech global dimensions (e.g., [Huensch and Nagle, 2021](#); [Chau and Huensch, 2025](#)). The guidelines operationalize each of the three constructs as follows: foreign accentedness was rated on a 9-point scale (1 = no foreign accent, 9 = strong foreign accent); comprehensibility was rated on a 9-point scale (1 = very easy to understand, 9 = very difficult to understand); and intelligibility was operationalized as the proportion of correctly transcribed words relative to the total number of words actually spoken (0–100).

The full operational definitions provided to raters are reported in Table 5 of the manuscript and are identical to the prompts used to elicit ratings from the LALMs, ensuring comparability between human and model ratings. The complete annotation protocol, including listener recruitment, task instructions, scale anchors, and session structure, is documented in ([Ali, 2023](#)).

B Model Information

Qwen2-Audio
Qwen2-Audio builds upon its predecessor Qwen-Audio (Chu et al., 2023), integrating audio and text inputs through a unified encoder-decoder architecture to generate textual outputs. The model processes audio inputs using a Whisper-large-v2 audio encoder paired with a Qwen-7B large language model backbone. It introduces two distinct audio interaction modes: audio analysis and voice chat.
Qwen2-Audio-Instruct
Qwen2-Audio-7B-Instruct is the instruction-tuned variant of Qwen2-Audio, built on the same Whisper-large-v2 encoder and Qwen-7B backbone architecture but further optimized for interactive dialogue through supervised fine-tuning on spoken dialogue data and instruction-following datasets.
Ultravox
Ultravox v0.5 is a multimodal speech language model that integrates a pretrained Llama-3.1-8B-Instruct backbone with the encoder component of Whisper-large-v3-turbo to process both speech and text inputs and generate textual outputs.

Table 4: Open-source model information

C Appendix

Appendix C reports supplementary materials referenced throughout the paper and the zero-shot prompts.

Figure 3: Distribution of of comprehensibility and foreign-accentedness ratings and intelligibility scores by human raters and LALMs.

Foreign Accentedness	
Definition:	The degree to which L2 speech is similar to or different from L1 speech in terms of pronunciation as perceived by a native L1 listener with no familiarity with L2 speech.
Operationalization:	9-point scale 1=Very similar to L1 speech in pronunciation (no foreign accent at all) 9-Very different to L1 speech (strong foreign accent)
Comprehensibility	
Definition:	The degree to which L2 speech is easy or difficult o understand as perceived by a native L1 listener with no familiarity with L2 speech.
Operationalization:	9-point scale 1=Very easy to understand (processing effort is zero to little) 9-Very difficult to understand (processing effort is maximum)
Intelligibility	
Definition:	The degree to which L2 speech is correctly recognized as transcribed by a native L1 listener with no familiarity with L2 speech.
Operationalization:	0-100 The proportion of correctly transcribed words as compared to the total number of words actually spoken.

Table 5: Zero-shot prompts for rating foreign accentedness, comprehensibility, and intelligibility.

Abstract

The global teacher shortage is pushing schools and institutions towards an ever-greater reliance on artificial intelligence. While the Natural Language Processing community has dedicated significant resources in developing educational technologies (EdTech) that support this shift, it remains unclear whose interests are being best served among the stakeholders of education.

In this paper, we present a systematic literature review of 204 papers published in venues of the Association for Computational Linguistics’ Special Interest Group on Building Educational Applications in 2024 and 2025, and validate these against EdTech papers from the wider ACL Anthology. By examining stakeholder inclusion and the prioritisation of research tasks, our findings reveal a critical tension: a push and pull between private-sector incentives and the foundational needs of educational infrastructure. Our analysis reveals that teachers are systematically under-represented as beneficiaries of research (33.3%) despite being the most affected, that real-world deployment remains rare (9.8%), and that ethical engagement tends toward acknowledgement rather than action. Drawing on exemplary papers in our corpus, we offer concrete recommendations for more responsible EduNLP research practices.

1 Introduction

Education has long been a domain of inspiration for Artificial Intelligence (AI) and Natural Language Processing (NLP). From early feature-based auto-markers (e.g., *e-rater*[®]; Attali and Burstein, 2006) to large language model (LLM)-powered intelligent tutoring systems (ITS) (e.g., Khanmigo¹ by Khan Academy), the goals have remained constant: for technology to extend the reach of good teaching and to support learners who might otherwise go without. These are meaningful goals –

socially urgent, technically challenging, and worthy of scientific investment – and their urgency has only grown in recent years with global teacher shortages (UNESCO, 2026), widening equity gaps (World Inequality Lab, 2026), and the rapid uptake of commercial AI products for education (Gomes, 2026). Held together, they have made the question of the role of technology in supporting education more pressing than ever.

There is a particular risk that comes with being deeply embedded in a fast-moving research area: the closer we are to the technical problems in front of us, the easier it is to lose sight of the overarching goal. As researchers, we are drawn towards the datasets we know, the metrics we trust, the tasks where progress is legible. Specialisation is necessary, but it can quietly narrow the frame of reference until the question, “Does this system work?”, crowds out the most important question: “Does this actually serve the people we said we were building it for?” This paper is, in part, an attempt to step back from that narrowing and ask plainly: as a field, are we meeting our own aspirations?

To answer this question, we conduct a systematic literature review of EduNLP research. We survey 204 papers published in 2024 and 2025 at ACL SIGEDU venues (BEA² and NLP4CALL³ workshops) and the main *ACL conferences. To the best of our knowledge, this is the first systematic review of EduNLP research that focuses on publications in the ACL Anthology. For each paper, we examine its tasks, motivations, stakeholder inclusion, incentives, and engagement with ethical risks to answer three research questions:

RQ1 Which tasks are prioritised in EduNLP research, what motivates them, and in which contexts are the resulting systems deployed?

¹<https://www.khanmigo.ai>

²Workshop on Innovative Use of NLP for Building Educational Applications

³Workshop on NLP for Computer-Assisted Language Learning

RQ2 Who are the stakeholders of EduNLP research, how are they included, and whose interests does the research serve?

RQ3 What risks, concerns, and limitations are raised, and to what extent does the research mitigate them?

Our findings show that teachers are systematically under-represented as beneficiaries in EduNLP research, real-world deployment is rare, and ethical engagement tends toward acknowledgement rather than action. We identify exemplary counter-examples and derive from them a set of concrete recommendations for the field.

2 Related Work

Education has been a domain for innovation dating back millennia. Digital technology is a modern feature of this long history: much of the early pioneering work on AI in the twentieth century was directed towards educational aims and applications in AIED (Newell et al., 1958; Minsky, 1974; Papert, 1980; Doroudi, 2023). In recent years the growth of interest in LLMs has also seen increasing application to education (Caines et al., 2023; Davis et al., 2024; Pack et al., 2024), further evidenced by the growing popularity of the annual Workshop on Innovative Use of NLP for Building Educational Applications (BEA), the foundation of the ACL SIGEDU in 2017,⁴ and investment by large technology firms into products such as Google’s LearnLM⁵ and OpenAI’s ChatGPT Edu.⁶

EdTech covers a wide-range of applications for educational purposes, often involving AI or NLP. There have been several surveys on EdTech and its use in various domains (Ahmad et al., 2024; Benedetto et al., 2023; Hidayat and Firmanti, 2024) spanning classroom support, virtual learning environments, websites, and tutoring chatbots. In this paper, we focus on ethical matters, which have received growing attention in AI and NLP more broadly, including the identification of different bias types throughout the “machine learning life cycle” (Suresh and Gutttag, 2021).

Within EdTech, several surveys and position papers have addressed ethical issues. Yan et al. (2025) presents a systematic review of 34 publications involving EdTech with AI in schools or higher education from 2020-2024, reporting a “constellation

of recurring ethical tensions” relating to algorithmic bias, data privacy, transparency, accountability, and academic integrity. They observe that these are known issues with AI applications, and recommend co-design with stakeholders, an emphasis on explainability, regulatory improvements, and AI literacy training for teachers. Alfredo et al. (2024) arrive at similar conclusions from a review of 108 papers relating to human-centred or participatory design and learning analytics.

Fu and Weng (2024) conduct a systematic review of empirical studies focused on EdTech and responsible AI, making similar conclusions to Yan et al. (2025) based on 40 selected papers. They present a vision for “responsible human-centered AIED” which includes core principles of Fairness and Equity, Transparency and Intelligibility, Agency and Autonomy, Privacy and Security, and Beneficence and Non-maleficence. Holmes et al. (2022) surveyed EdTech researchers, reporting high interest in but low confidence about ethical issues, attributed to a lack of ethics training in AI-related courses. They propose a framework for ethics in AIED aimed at ensuring “ethical by design” research, and emphasise the importance of cross-disciplinary engagement. Taken together, these reviews converge on a shared diagnosis: ethical considerations are widely recognised in principle but inconsistently integrated in practice.

This review extends these prior work by including research published throughout 2025, and by considering tasks, contexts, stakeholders, incentives, and risks across 204 EduNLP papers from *ACL main conference and workshop proceedings.

3 Methodology

Search Protocol. We collected all papers from the BEA and NLP4CALL workshops published in 2024 and 2025. We also conducted a search of the ACL Anthology using the Anthology API⁷ for papers published in main *ACL and associated conferences whose title or abstract contained at least one of 38 EduNLP-relevant search terms (e.g., “student modeling”; see Appendix B for a complete list of venues and search terms).⁸ This sampling approach affords an in-depth view into contemporary trends at the expense of longitudinal analyses. This search resulted in 191 papers from the two workshops, and 316 papers from *ACL conferences.

⁴<https://sig-edu.org/>

⁵<https://cloud.google.com/solutions/learnlm>

⁶<https://openai.com/chatgpt/education/>

⁷<https://acl-anthology.readthedocs.io/py-v0.5.3/api/>

⁸The search was conducted on January 21, 2026.

Figure 1: Number of papers per venue and year. We reviewed a total of 204 papers (160 BEA+NLP4CALL papers and 44 ACL Anthology main conference papers).

For BEA and NLP4CALL, we randomly sample 25% of contributions for each shared task, with a minimum sampling threshold of 5 papers for each task. We further include all shared task overview papers, as these represent a qualitatively distinct type of contribution. For the *ACL main conference papers, we reviewed all abstracts for relevance to educational applications, excluding 214 papers as non-relevant. The remaining 102 papers were stratified by publication year, venue, and search term, yielding a sample of 44 papers. This resulted in a final sample of 160 papers from BEA and NLP4CALL workshops, and 44 papers from *ACL conferences, for a total of 204 papers (see Table 8 for paper details). Figure 1 shows the distribution of papers across venues and years.

Data extraction. Data extraction was conducted manually by three of the authors using a shared extraction schema (see Appendix C). The schema captures: the specific task addressed; datasets used and their availability; the explicit motivation for the research; stakeholders mentioned and included (with associated quotes); the level of stakeholder inclusion; the deployment context of any system; incentives (both explicit and implicit) that the research serves; ethical risks and concerns raised; measures taken to address those risks; and future directions pertaining to risk, ethics, or aspiration.

Extraction proceeded in three phases. In the first phase (1), a single paper was annotated collaboratively to develop and validate the schema. In the second phase (2), annotators independently reviewed a shared batch of 25 papers,⁹ meeting to

⁹The shared batch was a stratified sample from our corpus of 204 papers (12.3%) based on venue and year of publication; it included 6 BEA 2024, 10 BEA 2025, 2 NLP4CALL 2024,

Figure 2: Number of papers per high-level task. See Table 8 for the detailed mapping.

discuss schema revisions and resolve ambiguities. Note that phase (2) was conducted in an iterative manner: following phase (1), each time the schema was modified or extended, all annotators updated their previous phase (2) annotation to reflect the revised guidelines. In the third and final phase (3), the remaining papers were reviewed independently by three authors. Extracting data took an annotator on average 45 minutes per paper (ranging between 30–60 minutes); we estimate that the review took a combined total of about 190 hours to complete.

Agreement. Inter-annotator agreement (IAA) was measured on phase (2)’s independently reviewed shared batch. Table 1 in Appendix D shows the agreement for the free-text dimensions of our schema based on the Percentage Agreement (PA; Roaché, 2017) measure (see Tables 6 and 7 for illustrations of how free-text agreement was computed). For the four multi-label dimensions, we report both Krippendorff’s α (Krippendorff, 2011) and PA in Tables 2, 3, 4 and 5.

For the free-text fields, PA ranges between 0.52 (for implicit incentives) and 1 (for deployment). For the multi-label dimensions, PA was consistently high (0.84–94 overall), while α was more variable. Agreement on the presence of stakeholders was generally moderate to strong ($\alpha = 0.49$ –0.7 overall, with agreement on teachers being particularly high at $\alpha = 0.79$ –0.84). Agreement on stakeholder inclusion level and risk engagement level was lower ($\alpha = 0.52$ –0.61 overall). Taking into account the qualitative and inherently interpretative nature of the annotation task (especially for dimensions such as risks/concerns), we consider these agreement values to be sufficiently high to

1 NLP4CALL 2025, 1 EACL 2024, 1 LREC-COLING, 1 NAACL 2025, 1 ACL 2025, and 2 Findings 2025 papers.

justify the independent reviewing in phase (3).

4 Tasks, Motivations, Deployment

Tasks. Figure 2 shows the distribution of high-level tasks across our corpus of papers. Automated assessment – i.e., automated essay scoring (AES) and automated short-answer scoring (ASAG) – is by far the most common task (56 papers), followed by grammatical error correction (GEC, 30 papers) and text simplification and complexity prediction (28). Content generation (22), intelligent tutoring systems (ITS, 22 papers), dataset creation and knowledge extraction (19), and knowledge tracing and learner modelling (8) are also represented. The “Other” task type includes a variety of research, most often relating to the novel capabilities of LLMs (e.g., multimodal assessment, alignment with human eye-tracking data, and discourse evaluation) and detecting LLM-generated texts.

The dominance of language assessment and feedback tasks is striking: taken together, AES/ASAG and GEC account for almost half of the corpus. This reflects a longstanding priority in EduNLP: indeed, automated assessment has been an active area of research for decades, benefitting from well-established datasets (e.g., ASAP; Hamner et al., 2012). However, this prevalence also raises questions about whose priorities are being served: automated assessment and feedback tools are of direct commercial value to large-scale testing organisations and EdTech companies.

Shared tasks. The NLP4CALL 2025 shared task introduced multilingual GEC (Masciolini et al., 2025), a direction of particular importance given that GEC, while already the second most represented task in our corpus, has historically been dominated by English-language systems. Broadening GEC to multilingual settings introduces non-trivial challenges around low-resource languages, cross-lingual transfer, and the availability of annotated learner corpora, and a shared task framing is well-suited to mobilising community effort around these barriers. On the other hand, the BEA 2024 shared tasks addressed automated prediction of item difficulty and response time (Yaneva et al., 2024a), and multilingual lexical simplification (Shardlow et al., 2024); the 2025 shared task addressed pedagogical ability assessment of AI-powered tutors (Kochmar et al., 2025). We note that all three of these problems receive less attention in the non-shared-task literature.

This suggests that shared tasks are playing a valuable role in broadening the community’s agenda, including towards less commercially obvious but educationally important problems such as pedagogical quality assessment, and towards underserved languages in otherwise established tasks. Beyond their immediate proceedings, shared tasks also exert a longer-lasting influence through the datasets they produce; resources like the W&I+LOCNESS dataset which was introduced for the BEA 2019 Shared Task on GEC (Bryant et al., 2019) tend to attract sustained reuse by the community (as illustrated by Figure 3), and thus continue to shape which problems remain visible and tractable long after the shared task itself has concluded.

Datasets. Papers in the corpus reported using 284 distinct datasets used a combined total of 460 times (373 for public datasets, 33 for those available upon-request and 54 for private datasets). Figure 11 shows that 73.9% of datasets used are publicly available, 7.4% are only available upon-request or through paid licences, and 18.7% are private. While the high proportion of public datasets is a positive indicator for reproducibility, Figure 3 reveals a high concentration of usage around a small number of datasets: the top three – W&I+LOCNESS (Bryant et al., 2019), ASAP (Hamner et al., 2012), and CoNLL-2014 (Ng et al., 2014) – together account for 12.9% of total public dataset usage (373), with a long tail of datasets used only once. This concentration partially reflects the task distribution noted previously: namely that AES and GEC are both well-established. However, this also raises questions about whether research findings generalise beyond the narrow slice of learner populations, languages, and educational contexts that these datasets represent. We return to this concern in Section 7.

Motivations. During extraction, we took note of the explicit motivation presented by papers for their presented research, and later classified each into one or more of seven high-level categories. Figure 12 shows that the most common motivation type across our corpus is to “help a stakeholder” (110 papers), followed by addressing a pedagogical or ethical concern (82), and assuming the role of a stakeholder (53). Technical motivation alone, with no stated stakeholder benefit, accounts for 43 papers, which is a non-trivial proportion (21.1%). Figure 4 reveals the stakeholder composition underlying papers’ motivations: learners and students are

Figure 3: Dataset popularity (i.e., the number of times a dataset was used, and not only mentioned). We do not report private datasets given their absence of references.

Figure 4: Distribution of different stakeholders for the three stakeholder-based motivations in Figure 12.

invoked in 61.1% of papers with stakeholder-based motivation (96 of 157 papers), making them by far the most frequently cited intended beneficiary. Teachers appear in 40.1% of such papers (63 of 157 papers), though they are most commonly invoked as a pressure points, referenced in terms of the cost, time, or burden associated with their labour, and implicitly positioned as a bottleneck that automation should relieve. This framing matters. A motivation to reduce teacher burden through automation is meaningfully different from one that seeks to augment teacher capability or support teacher agency. In a number of papers in our corpus, teachers appear in the motivation but then disappear from the research design entirely: they are not consulted, included in evaluation, or named as beneficiaries of the results. We discuss this pattern and its implications further in Section 6.

Context deployment. Figure 5 shows that 79.4% of papers (162 papers) present systems or models that are never deployed to real-world users. Only

Figure 5: Papers that deployed their method to real-world users or tested it on pre-existing real-world data.

9.8% of papers report genuine deployment. We label resource and survey papers as “Not a system paper.” Non-deployment is not itself a failing: fundamental research that develops methods, datasets, or evaluation frameworks may legitimately precede any deployment. More concerning is that papers describing non-deployed systems rarely discuss the pathway to deployment: the educational contexts in which the system might operate, the stakeholders who would need to be involved, or the risks real-world deployment would introduce. This creates a body of research that is optimised for benchmark performance in conditions that may bear little resemblance to the classrooms, tutoring sessions, and assessment environments it nominally serves.

5 The Roles of Stakeholders

Author affiliations and acknowledged entities.

Figure 15 shows that the paper author affiliations in our corpus are geographically concentrated: the United States accounts for the largest single-country share of author affiliations (58 papers), followed by Germany (29 papers), China (23 papers),

Figure 6: Number of papers per type of author affiliation and type of entity mentioned in acknowledgements.

and other European countries (similar observations can be made on the origin of the acknowledged entities in Figure 14). Figure 6 shows that universities dominate author affiliations (188 papers), followed by research institutes (75) and companies (30). Funding acknowledgements are concentrated within governmental bodies (80), with national science foundations of China and the US appearing the most frequently (Figure 16). Industry acknowledgements (e.g., Microsoft) appear in a small but non-trivial number of papers (20). While industry involvement in research funding is not inherently problematic, it creates potential conflicts of interest that deserve explicit discussion, particularly in a field where commercial EdTech products are directly shaped by research agendas. Notably, few papers in our corpus explicitly disclose or discuss potential conflicts of interest arising from their funding sources; a gap that mirrors findings in adjacent fields (Garrett et al., 2020).

Stakeholders mentioned or included. Figure 7 shows that learners and students are mentioned in the most papers overall (170 papers), followed by teachers (97), and domain experts (88). However, mention does not equate to inclusion: the proportion of mentioned stakeholders who are also actively included in the research is substantially lower across all groups. Among teachers, 26.8% of papers that mention them also include them in the research (26). For learners, 22.4% of mentioning papers include them (38). Domain experts show a much higher inclusion rate (56.8%), in part because they are frequently recruited as annotators or raters. Most strikingly, parents were only mentioned in two papers, despite their having such an important

Figure 7: Number of papers per type of stakeholder included or mentioned only in the research.

Figure 8: Level of inclusion of included stakeholders by stakeholder type; we distinguish 3 levels: *High* (integral to research design & completion), *Middling* (involved in data evaluation or annotation, without input on research design), and *Low* (test subjects in data collection only).

role in children education (Kostov, 2026).

Figure 13 reveals the overall distribution of inclusion levels across all included stakeholders: 47.0% of inclusions are classified as *Middling* (involved in data evaluation or annotation, but with no input on research design), 32.1% as *High* (integral to research design and completion), and 20.9% as *Low* (test subjects in data collection only). Figure 8 shows that this breakdown varies substantially by stakeholder type. Other than paper authors themselves, schools and universities are most likely to be included at a *High* level (76.9%), while teachers, when included at all, are predominantly included at a *Middling* level (65.5%), most often as annotators. Learners are most often included as test subjects (59.5%). The implication is that even when stakeholders are formally included, they are rarely positioned as agents who shape the research, they are more often positioned as instruments of it.

Incentives. Figure 9 shows the distribution of stakeholders explicitly mentioned as benefiting from the research alongside those we identified as implicit beneficiaries. We note that the identification of implicit beneficiaries is the most subjective dimension of our annotation: it required annotators to infer who stands to gain from a piece of research beyond what authors themselves state, based on the nature of the task, the deployment context, and the funding sources involved. For instance, a paper developing an AES system for standardised testing, funded by a testing organisation, was coded as implicitly benefiting industry, even if no such benefit was named. Due to the subjective nature of this dimension, inter-annotator agreement was accordingly lower (0.53; Table 1), and these findings should be read as indicative rather than definitive.

Learners and students are the most frequently named explicit beneficiary (125 papers). Teachers stand out starkly here: 80.9% of their appearances are explicit (55 papers). Stated differently, teachers are almost never the unstated but evident beneficiary of research; when they benefit, papers say so. However, the vast majority of papers do not position them as benefiting at all. On the other hand, non-profit organisations, industry and governmental bodies appear prominently as implicit beneficiaries. That is, while they are not named in the paper as intended beneficiaries, the research clearly serves their interests. This is most visible in the task-level breakdown in Figure 17: automated assessment research (the largest task category in the corpus) consistently benefits learners and industry, while teachers and examiners are sparsely represented. The commercial relationship here is direct: automated scoring tools reduce the need for human markers and are of clear value to large-scale testing organisations. For ITS, learners dominate, with limited acknowledgement of teachers. GEC research shows the broadest stakeholder spread, in part because GEC tools serve not only learners and teachers but also the general public who use writing assistance tools in everyday tasks.

6 Risks, Concerns, Limitations, and Measures Taken

Risks, concerns and limitations raised. Figure 18 shows the distribution of risks, concerns, and limitations explicitly raised by paper authors, organised into six high-level categories. We note that inter-annotator agreement was lower for this

Figure 9: Stakeholders explicitly stated as benefitting from the research, as well as those that we could see benefitting that were not explicitly mentioned (*Implicit*). Note that a stakeholder may be both explicitly mentioned to benefit in some way and implicitly in another.

dimension than others (0.57; Table 1), owing to the need to assess coverage across a large and varied set of concerns; these results should therefore be read as indicative trends rather than precise counts. The most commonly noted concerns are methodology limitations (69 papers), dataset limitations (60), followed by lack of generalisability and language-specificity (56), risk of bias (46) and and task/domain-specific limitations (44), reflecting the tendency of research to develop systems for specific languages or educational contexts that may not transfer. Several important risk categories are raised much less frequently. Risk of hallucination appears in only 12 papers, risk of dual-use in 6, and safety concerns in 26. Within the contextualising research category, the gap between research and real-world application is noted in 32 papers and the need for human-in-the-loop in 19, suggesting some awareness of deployment limitations, this rarely translates into direct mitigation (Figure 19). Data protection and anonymisation concerns are raised in 37 papers, while informed consent and fair compensation for included stakeholders, critical ethical requirements for human-subjects research, appear in only 11 and 10 papers respectively. That human-subjects protections remain among the least commonly raised concerns in a corpus that routinely collects learner data and recruits human annotators is itself a notable finding.

Engagement with risks. Figure 19 distinguishes three levels of engagement with stated risks: *High* (directly mitigated or discussed in substantial depth), *Middling* (discussed as part of future work), and *Low* (briefly mentioned only). Across most risk

categories, the majority of engagement is at a *Low* or *Middling* level. *High* engagement is most consistently found in the participant and data concern category: fair compensation for included stakeholders (100.0%) and informed consent (72.7%) are the most actively addressed concerns, though both are raised by relatively few papers to begin with. By contrast, the largest categories show the weakest engagement: methodology limitations are 98.6% *Middling* or *Low*, and dataset limitations 90.0% *Middling* or *Low*. Risk of bias, one of the most frequently raised concerns at 46 papers, is engaged at a *High* level in only 15.2% of cases. The gap between research and real-world application and the need for human-in-the-loop, two concerns with clear implications for responsible deployment, are predominantly *Middling* or *Low*. This pattern suggests a community that is aware of the ethical dimensions of its work but has not yet developed consistent norms for acting on them within the scope of individual papers.

Future work. Figure 20 shows a distribution of the areas of future work explicitly mentioned in the papers. We report future work specifically related to any risks, concerns or higher aspirations rather than any purely technical work; of our data sample, 21 papers do not discuss any such future work. Four high-level themes emerge within discussed future work: stakeholder inclusion, technical development, expanding the scope of the research, and engaging with issues emerging from the research. Of these, the most frequently mentioned category is expanding the scope of the research, with expanding the data (42), language selection (36), and subject domain (35) the most common fine-grained directions. EduNLP research is often performed at language- or task-specific levels, resulting in common limitations which translate to clear future directions. The least common high-level category is engaging with issues emerging from research, with fine-grained categories including interpretability and bias mitigation (16 and 14 papers respectively), exploring performance-cost trade-offs (12), and initiating broader discussions in the EduNLP space. Within the fine-grained categories overall, the most frequently referenced future direction is general technical improvements related to the paper’s risks and concerns (91 papers). Despite controlling for purely technical work in our analysis, the primary focus for EduNLP researchers remains within this domain. Within the stakeholder inclusion category,

user study and user inclusion (37) and integration into real-world systems (32) are the most common directions, suggesting some awareness that current work falls short. Analysis of the future directions in our sample therefore reveals a tendency towards prioritising empirically-motivated fine-grained technical work rather than ethically-driven broader work. In part, this may be due to an imbalance in available resources for conducting such research.

7 Discussion: Opportunities, Recommendations, Aspirations

Opportunities. Our findings reveal some structural gaps in EduNLP research that constitute genuine opportunities for the field. First, teachers are under-represented both as beneficiaries and active participants, despite their central role in education. This represents a significant misalignment between stated purpose and actual design. Research that nominally aims to support education but systematically excludes the professional educators who mediate it risks building tools that are technically sophisticated but pedagogically ill-fitting, or that automate away precisely the human judgement that makes good teaching effective. Second, the gap between research development and real-world deployment is striking: only 9.8% of system papers are deployed in live educational settings. This reflects a missing discourse about what responsible deployment looks like: which stakeholders need to be involved, what evaluation is appropriate for real students and teachers, and what accountability mechanisms should be in place. This gap is further sharpened by the concentration of datasets around high-stakes standardised testing contexts, and by the dominance of assessment tasks which, given their direct commercial value to the testing industry, risk pulling the research agenda toward institutional efficiency over the full range of educational stakeholders.

Recommendations. Drawing on exemplary papers in our corpus, we offer three concrete recommendations for the EduNLP community:

1. **Co-design with teachers and learners from the outset.** Research that positions stakeholders as genuine co-designers, rather than test subjects or future-work items, produces better-grounded systems and more honest evaluation. Galletti and Cesaroni (2025) offer a replicable model for this: conducting focus

groups and questionnaires with teachers at different stages of system development surfaced concerns around transparency, autonomy, and pedagogical alignment that would not have emerged from technical evaluation alone. See also [Huovinen and Hämäläinen \(2025\)](#). Their work echoes principles of design justice ([Costanza-Chock, 2020](#)) which seek to decentre technical expertise in favour of lived experience and domain expertise – in all regards save technical implementation – as a mechanism for ensuring that those affected by a system retain meaningful agency in shaping it. As it stands, a true expression of design justice was not found in any of the reviewed papers of this corpus, however [Wang et al. \(2025c\)](#) embodies some aspects of it. Though not a system, the paper demonstrates that design justice principles can be embedded even at the resource creation stage: their math world problem benchmark was developed through structured interviews with primary school math teachers, whose pedagogical expertise directly shaped what counts as a meaningful visual, ensuring that future systems trained or evaluated on this benchmark will be held to a standard defined by them.

2. **Make deployment contexts and costs explicit.** Authors should describe the educational context in which their system could or has been deployed, the stakeholder roles involved, and provide an honest account of computational, financial, and human costs alongside claimed benefits ([Akter et al., 2025](#); [Gupta et al., 2025](#); [Li and Ng, 2024](#)).
3. **Adopt structured ethical reflection and act on it.** Our data show that named concerns rarely translate into mitigation within the same paper. Venues should normalise the expectation that ethical risks raised are addressed in the current work, not deferred to future work. Checklists like the ARR Responsible NLP Checklist already support this: they prompt authors to interrogate their own design choices (e.g., [Goto et al., 2025a](#), who voluntarily engage in detailing a number of the checklist items) and give reviewers a structured basis for evaluating ethical engagement.

Aspirations. The potential for AI in education is genuine: it could improve access to education,

helping reduce inequalities related to geography, language, resources, and infrastructure, for learners who might otherwise go without. It could also help free educators of repetitive and time-consuming tasks so they can concentrate on the relational aspect of education that systems cannot and should not replace. Automated tools can also mitigate some human weaknesses that threaten fairness in assessment: fatigue, inconsistency, and unconscious biases. The question is not whether AI belongs in education, but whether we are stewarding its development responsibly. The exemplary papers in our corpus demonstrate that it is possible. Our aspiration for the field is a research community that treats educational infrastructure as a site of social responsibility, not merely technical opportunity. The trajectory the field takes will depend on choices that are made now about which tasks to prioritise, whose voices to include, and what counts as success. [Harding \(2025\)](#), reflecting on AI in language assessment, frames this as a choice between utopian and dystopian futures: one in which assessment technology is context-sensitive, transparent, connected with learning, and deeply oriented toward justice; as opposed to one driven by expediency, opacity, and the logic of scale.

8 Conclusion

This paper has presented a systematic review of 204 EduNLP papers published at ACL SIGEDU venues and main *ACL conferences in 2024 and 2025, examining tasks, motivations, stakeholder inclusion, incentive structures, and ethical engagement. Our analysis reveals a field that is technically productive but structurally misaligned with key educational stakeholders, particularly teachers who are rarely included in research and almost never positioned as implicit beneficiaries. At the same time, our corpus contains exemplary work that demonstrates what responsible, stakeholder-grounded EduNLP research looks like in practice. The norms and practices embedded in these papers are neither technically burdensome nor novel in principle. What is needed is for the community to adopt them consistently, and for publication venues to create the conditions in which doing so is expected rather than exceptional. We hope this review serves as both a diagnostic and a resource: a map of where the field currently stands, and a set of orientations for where it should go.

9 Limitations

This review has several limitations that should be noted. First, while our corpus of 204 papers is broad in scope, it is not exhaustive, meaning that some relevant papers will have been missed. Our focus on ACL Anthology venues also means that work published in AIED journals, learning analytics conferences, and EdTech-specific venues falls outside our scope: the picture we paint is of the NLP community specifically, not the broader field. Second, annotation of inherently interpretive dimensions, particularly stakeholder inclusion level and risk engagement level, carries subjectivity that agreement scores can only partially represent. We report these as indicative trends rather than precise counts, but readers should bear this in mind when interpreting figures. Third, our corpus covers 2024–2025 only; while this captures the most recent work, it is a short window and trends may not generalise to earlier or future periods. An interesting direction for future work would be to extend the temporal scope to publications published before the release of ChatGPT (OpenAI, 2026) in November 2022, which would allow for a direct comparison of research priorities, stakeholder inclusion, and ethical engagement before and after the widespread availability of generative AI. Finally, as researchers embedded in the EduNLP community ourselves, we are not neutral observers, our framing of what constitutes meaningful stakeholder inclusion or adequate ethical engagement reflects our own values, which we have tried to make explicit throughout.

On financial disclosures. While complete financial disclosures of which entities have funded research is a desirable trait in papers due to the transparency it affords, disclosure can be structurally limited. For example, some grant funders – particularly military funding – may require non-disclosure, nation-wide regulation may limit disclosure, research can be funded across multiple grants, work may be conducted on an entirely voluntary basis, among many other reasons. We therefore see financial disclosure as a spectrum between complete opacity and complete transparency. We advocate for researchers to approach the question of financial disclosure according to a maximalist approach, i.e., we argue that researchers should share as much information as is possible to them in a given situation. A transparency maximalist approach will afford greater insight into how research into educational technologies is being, forcefully and subtly,

shifted by the interests of different entities.

10 Ethical considerations

All papers surveyed in this review are publicly available through the ACL Anthology; no private or unpublished materials were used. No human subjects were involved in the review itself. The annotation process involved researchers reading and characterising the work of others, which carries a risk of misrepresentation; we have sought to mitigate this through iterative schema development, inter-annotator agreement measurement, and the use of direct quotes to ground our characterisations. Our normative claims – that teachers are under-served, that ethical engagement is insufficient, that commercial incentives distort research agendas – are recommendations and observations, not accusations about individual papers or authors. We acknowledge that we are ourselves part of the community we critique, and that future reviews may find similar gaps in our own work. This paper has been pre-registered on OSF.¹⁰

A A Structured Taxonomy for Ethical and Stakeholder Review of EduNLP Research

Figure 10¹² presents the complete taxonomy developed in this review, offered here as a standalone contribution. The taxonomy is organised around the three research questions and a concluding recommendations dimension. Beyond its role in this review, the taxonomy can be reused for future surveys of EdTech research. It can also serve as a practical self-audit tool: researchers can use it to situate themselves within the EduNLP space, and assess the rigour and inclusivity of their work before submission.

B ACL Anthology Main Conference Search

We retrieve all papers with at least one of the following search terms in the title or abstract. The venues included are: ACL, EACL, NAACL, EMNLP, LREC-COLING, and Findings, for the years 2024 and 2025. The search terms were developed through internal discussion and discussion with other researchers in the EduNLP field. The search terms are as follows:

- “automated essay scoring”,
- “automated writing evaluation”,
- “short answer grading”,
- “automatic short answer grading”,
- “open-ended response assessment”,
- “automated assessment of spoken responses”,
- “spoken response scoring”,
- “speech-based assessment”,
- “automatic speech scoring”,
- “dialogue-based tutoring”,
- “spoken dialogue system education”,
- “intelligent tutoring systems NLP”,
- “student modeling”,
- “learner modeling”,
- “knowledge tracing”,
- “learner cognition modeling”,
- “educational data mining NLP”,
- “learning analytics text”,
- “game-based learning assessment”,
- “stealth assessment”,
- “peer assessment NLP”,

- “peer review automated feedback”,
- “automated feedback generation”,
- “formative feedback writing”,
- “grammatical error correction”,
- “grammar error detection”,
- “lexical complexity prediction”,
- “text simplification for learners”,
- “multimodal learning analytics”,
- “generative AI in education”,
- “mathematic education”,
- “math education”,
- “math word problems”,
- “mathematical reasoning”,
- “student error in mathematics”,
- “intelligent tutoring system math”,
- “knowledge tracing mathematics”,
- “misconception detection mathematics”.

C Extraction Schema

For extracting the entities relevant to our research questions, we used the following schema:

- [RQ2] Author affiliations
- [RQ1] Specific task worked on
- [RQ1] Datasets used and availability
- [RQ1] Explicit motivation for the paper and associated quotes
- [RQ2] Stakeholders mentioned (multi-label; the options being *Learner/student*, *Teacher*, *School/university*, *Paper author*, *Other researcher*, *Domain expert*, *Parent*, *Governmental body*, *Industry*, *Non-profit* which includes large-standardised testing providers, and *None / N.A.*), and associated quotes
- [RQ2] Stakeholders included in the research (multi-label; same list as above), as well as their respective level of inclusion (multi-label with *High*, *Middling* and *Low*) and associated quotes for how they are included
- [RQ1] Context in which the system deployed (if any) and relevant quotes
- [RQ2] Explicit stakeholder incentives
- [RQ2] Implicit stakeholder incentives
- [RQ3] Risk, concerns and limitations raised, associated quotes, level of engagement (multi-label with *High*, *Middling* and *Low*) and measures taken to address risk

¹²This figure was created in app.xmind.com.

Figure 10: Detailed taxonomy for reviewing EduNLP research.

- **[RQ3]** Future directions/aspirations mentioned and relevant quotes
- **[RQ1]** Entities acknowledged (including funding)

Once phase (3) was completed, the three annotators independently extracted high-level categories and labels from the data:

- **[RQ1]** Mapping specific tasks to high-level tasks (as reported in Figure 2)
- **[RQ2]** Mapping free-text dataset names to unique labels (as reported in Figure 3) and their availability (as reported in Figure 11)
- **[RQ1]** Categorising free-text motivations to high-level labels (as reported in Figure 12) and the mentioned stakeholders (as reported in Figure 4)
- **[RQ1]** Mapping context deployment to high-level labels (as reported in Figure 5)
- **[RQ2]** Extracting standardised stakeholder types from explicit and implicit incentives (as reported in Figure 9)
- **[RQ3]** Mapping risks, concerns and limitations to high-level categories (as reported in Figure 18) and the authors’ level of engagement associated to each (as reported in Figure 19)
- **[RQ3]** Mapping future directions and aspirations high-level categories (as reported in Figure 20)

For each dimension, the mapping was made by one of the three annotators independently. This was considered sufficient given that the high-level categories were derived directly from the extracted free-text data rather than applied to raw papers: the iterative reconciliation process in phases (1) and (2) had already established shared interpretive norms among annotators, and the categorisation task at this stage involved consolidating labels that were already grounded in agreed extractions rather than making independent judgements about unseen material.

D Agreement Computation

Table 1 reports agreement for the free-text dimensions. Table 6 includes examples of how

Dimension	Agreement
Task	0.95
Datasets used*	0.87
Dataset availability	0.93
Methods	0.93
Evaluation	0.92
Motivation	0.96
Deployment	1.0
Explicit incentives	0.72
Implicit incentives	0.53
Risks/concerns*	0.57
Measures taken to address risks/concerns*	0.91
Future directions*	0.69
Future deployment	0.92

Table 1: Agreement for free-text annotation dimensions. For dimensions with an asterisk, we computed per-paper percentage agreement. For the other dimensions, we computed majority percentages (i.e. 0 if none of the annotators agree, 0.67 if 2/3 annotators agree, and 1 if 3/3 annotators agree). The values reported correspond to the averages across all 25 papers in the shared batch. Computation examples are included in Table 6 and Table 7.

Label	PA	α
Overall	0.91	0.49
Domain experts	0.84	0.64
General user	0.97	0.74
Industry/company	0.97	0.49
Learners	0.92	-0.03
None / N.A.	0.95	-0.01
Other Researchers	0.79	0.44
Paper authors	0.92	0.46
Policy makers/governments/ministries	0.95	0.31
Schools/universities	0.79	0.27
Special needs/disability user	0.97	0.0
Teachers	0.89	0.79

Table 2: Average percentage agreement (PA) and inter-annotator agreement (Krippendorff’s α) for “stakeholders mentioned”.

percentage agreement (PA) was calculated for the following free-text dimensions: “datasets used”, “risks/concerns”, “measures taken to address risks/concerns”, and “future directions”. As these dimensions often included many different elements (e.g., dataset names for the “datasets used” dimension and specific suggestions for future research for “future directions”), PA was calculated in the form of pairwise agreements (at the level of the paper, with the score reported in Table 1 corre-

sponding to the mean of these per-paper pairwise agreement values).

Table 7 contains examples of how PA was calculated for the following free-text dimensions: “task”, “dataset availability”, “methods”, “evaluation”, “motivation”, “deployment”, “explicit incentives”, “implicit incentives”, and “future deployment”. As these dimensions virtually always included only a very limited number of core elements, PA was calculated in the form of majority percentages (at the level of the paper, with the score reported in Table 1 corresponding to the mean of

Figure 11: Availability of datasets used in the surveyed papers.

Figure 12: Distribution of papers’ explicit motivations for the task; papers may belong to more than one category.

these per-paper majority percentage values).

Tables 2 to 5 further present the agreement for the multilabel dimensions (stakeholders mentioned, stakeholders included, level of inclusion stakeholders included, and level of engagement risks/concerns).

E Mapping Papers to High-Level Tasks

The mapping of the analysed papers to the eight high-level tasks is presented in Table 8.

F Availability of Datasets

The availability of the datasets used in the analysed papers is presented in Figure 11.

G Explicit Motivations

The distribution of the papers’ explicit motivations for the research conducted is visualised in Figure 12.

Table 6: Examples of percentage agreement (PA) computation for free-text annotation dimensions. “PWA” stands for pairwise agreement among the annotators (i.e. Annotator 1 compared to 2, Annotator 1 compared to 3, and Annotator 2 compared to 3). Note that *absence* of annotation also counts as agreement (e.g., between Annotator 1 and 2 for the “English_BEA” dataset).

Figure 13: Overall level of inclusion of included stakeholders; we distinguish 3 levels: *High* (integral to research design & completion), *Middling* (involved in data evaluation or annotation, but have no input on research design), and *Low* (test subjects in data collection only).

H Stakeholders Included and Mentioned

As the authors are the primary stakeholders of the research, we present demographic information in terms of country of author affiliation in Figure 15. Secondly, Figure 13 visualises the level of inclusion of the stakeholders included in the research.

I Acknowledged Entities

Figure 14 depicts the “acknowledged countries” (i.e., the the number of papers per country of affiliation of entities acknowledged), while Figure 16 provides more details on the number of times entities were acknowledged.

J Relation between Tasks and Implicitly Benefitting Stakeholders

Figure 17 presents a heat-map that links the high-level tasks to the combined explicitly and implicitly benefitting stakeholders.

K Risks, Concerns and Limitations Breakdown

Figure 19 distinguishes three levels of engagement with stated risks: High (directly mitigated or discussed in substantial depth), Middling (discussed as part of future work), and Low (briefly mentioned only). Across most risk categories, the majority of engagement is at a Low or Middling level. Methodology limitations show 90% Middling engagement – they are widely acknowledged but rarely addressed in the current work. Dataset limitations are 56%

EU-wide entities acknowledged in 10 papers.

Table 7: Examples of majority agreement computation for free-text annotation dimensions. Possible values: 0% (none of the annotations fully overlap), 66.67% (full overlap for two of the three annotations), or 100% (full overlap for all three annotations).

Middling. Risk of bias, one of the most commonly cited concerns, is engaged at a High level in only 17% of papers that raise it; in 45% of cases it is Middling, and in 38% it is Low.

High engagement is most consistently found in a small set of categories: fair compensation for stakeholders (100% High, though only 6 papers raise this at all), and to a lesser extent data protection (65% High). Risk of hallucination, lack of human evaluation, and the gap between research and real-world application are predominantly engaged at Low or Middling levels – noted as future work, but rarely designed around. This pattern suggests a community that is aware of the ethical dimensions of its work but has not yet developed consistent norms for acting on them within the scope of indi-

vidual papers.

L Areas of Future Work

Figure 20 shows the areas of future work explicitly mentioned in the papers, split across five high-level categories (“stakeholder inclusion”, “technical development”, “expand scope”, “engage with issues”, and “none/not applicable”).

Figure 18: Risks, concerns and limitations explicitly raised by paper authors split across six high-level categories (showing the number of papers; note that a paper may report more than one area of risk).

Figure 19: Engagement levels for the risks, concerns and limitations explicitly raised by paper authors; we distinguish 3 levels of risk engagement: *High* (a risk, concern or limitation that is directly mitigated in the paper or discussed in great depth), *Middling* (discussed as part of future work), and *Low* (briefly mentioned only).

Figure 20: Areas of future work explicitly mentioned in the papers split across four high-level categories (showing the number of papers; note that a paper may report more than one area of future work).

Abstract

Large Language Models (LLMs) are widely applied in educational practices, such as for generating children’s stories. However, the generated stories are often too difficult for children to read, and the operational cost of LLMs hinders their widespread adoption in educational settings. We used an existing expert-designed children’s reading curriculum and its corresponding generated stories from GPT-4o and Llama 3.3 70B to design different experiments for fine-tuning three 8B-parameter LLMs, which then generated new English reading stories that were subjected to quantitative and qualitative evaluation. Our method prioritizes controllability over scale, enabling educators to target reading levels and error patterns with a compact, affordable model. Our evaluation results show that with appropriate fine-tuning designs, children’s English reading stories generated by 8B LLMs perform better on difficulty-related metrics than those from zero-shot GPT-4o and Llama 3.3 70B, with almost no discernible safety issues. Such fine-tuned LLMs could be more broadly used by teachers, parents, and children in classrooms and at home to generate engaging English reading stories with children’s interests, controllable difficulty and safety.

1 Introduction

Children’s reading fluency is a key marker of reading development and profoundly influences language comprehension, expressive ability, and academic achievement (Spear-Swerling, 2006; Veenendaal et al., 2015). For young learners, varied forms of repeated reading have been shown to effectively boost oral reading fluency (Rasinski et al., 2016). Consequently, empirical work indicates that providing diverse, engaging materials elevates children’s interest and motivates more practice (Merisuo-Storm and Soininen, 2014). Yet it is clearly difficult for teachers and researchers to manually assemble large volumes of content tai-

lored to each child’s preferences. Generative AI offers a promising way to meet this need.

Today, generative AI can be trained to craft engaging, age-appropriate narratives that reflect diverse traditions and to independently produce imaginative text suited for advanced image-generation systems, enriching the storytelling experience (Lesner et al., 2024). Such stories can resonate with children’s imaginative worlds while offering educational and entertaining narratives aligned with the moral values appropriate to different age groups (Leite et al., 2025). Creating stories tailored to children’s interests and needs may enhance motivation, increase reading engagement, and help achieve the goal of improving reading skills (Al-Siyabi, 2024).

Prior work (Leite et al., 2025) used zero-shot prompting based on expert-authored curricula to generate children’s stories using OpenAI’s GPT-4o and Meta’s Llama-3.3 70B (Leite et al., 2025). Evaluated against pedagogical theories and NLP metrics, the results revealed a critical limitation: even state-of-the-art closed-source models like GPT-4o struggle with strict pedagogical constraint satisfaction. Specifically, they frequently fail to reliably restrict lexical and syntactic difficulty to target lower grade levels (e.g., K-2 readability scores) without degrading narrative coherence. Furthermore, the recurring API costs of closed models and the massive hardware requirements to deploy 70B+ models locally present prohibitive barriers to widespread educational adoption (Irugalbandara et al., 2024).

To democratize access to personalized educational content, deploying compact, local LLMs (under 10B parameters) is an intuitive solution. However, adapting sub-10B models for this task is not merely a standard Supervised Fine-Tuning (SFT) problem; it presents a unique scientific challenge. Compact models typically suffer from a severe trade-off between narrative creativity and strict rule-following. When conditioned on multi-

dimensional pedagogical constraints (e.g., strict vocabulary boundaries, syntax simplification, and safety guardrails), small models are prone to mode collapse or logical fragmentation. Standard SFT alone is insufficient to bridge this "controllability gap."

To address this gap, we present a systematic empirical comparison of various fine-tuning and inference strategies for phoneme-controlled story generation. By utilizing high-quality stories, we evaluate how effectively sub-10B models can internalize strict pedagogical alignment through techniques such as standard SFT, reward-weighted SFT, and augmented input. Our primary objective is to provide empirical evidence that, with appropriate training pipelines, compact models can achieve controllable difficulty and safety that match or even surpass those of massive zero-shot 70B models. This empirical foundation demonstrates the viability of broader, equitable adoption of AI-driven reading interventions irrespective of economic or hardware constraints.

Accordingly, our research is guided by two questions: (RQ1) Which SFT strategies most effectively enable sub-10B LLMs to generate children's stories with controllable reading difficulty that meets K–2 pedagogical standards? (RQ2) Can these compact fine-tuned models achieve levels of content safety comparable to those of state-of-the-art zero-shot 70B models?

2 Related Work

We surveyed the current research works on the applications of generative AI, controllable story generation, and supervised fine-tuning in educational practice to identify available methods and pinpoint the research gap.

2.1 AI-Generated Stories for Children

As generative AI continues to be applied in various fields, researchers have explored using multimodal generative AI, spanning text, image, and voice generation, to construct children's story generation systems (Chowdhury et al., 2025; Liu et al., 2025). For example, Han and Cai (2023) propose AISTory, a visual narrative prototype for children's creative expression and literacy, while Fan et al. (2025) develop StoryPrompt to enable child–AI co-creation of stories and comics.

Despite these advances, studies reveal persistent limitations. Sun et al. (2024) find that AI-based

storytelling still falls short of parents' expectations due to interaction and algorithmic challenges. Jin and Yuan (2025) highlight that consistency between stories and illustrations, accuracy relative to the real world, and clear emotional expression are crucial for educational use, while content safety remains a fundamental requirement. Liao (2025) further points out that AI-generated stories often contain language too complex for young children. In summary, as LLMs are increasingly deployed for children's story generation, age-appropriate readability, and content safety have become critical concerns that the field has yet to sufficiently address.

2.2 Automatic Story Generation with Controllable Difficulty

Recent advances in LLMs and SFT technologies have enabled clearer control over text readability (Glandorf and Meurers, 2024; Kim et al., 2025), yet a critical challenge remains in educational contexts: the tension between strict early-elementary readability constraints and narrative diversity. Rigid constraints such as those required for phonics curricula often force language models into repetitive, formulaic patterns (Holtzman et al., 2020), a problem particularly pronounced in compact local models with limited capacity to balance linguistic creativity with vocabulary restrictions (Farajidizaji et al., 2024). Addressing this trade-off requires embedding pedagogical constraints directly into model parameters, motivating the use of SFT in our work.

2.3 Application of Supervised Fine-Tuning in Educational Practice

SFT has been widely adopted to adapt LLMs to concrete educational tasks. At the assessment level, Duong-Trung et al. (2024) propose BloomLLM, which fine-tunes an LLM on question–answer pairs labeled with Bloom's taxonomy, enabling controllable generation across cognitive levels. In student support, Assayed et al. (2024) fine-tune a BERT-based model on domain-specific advising data, improving contextual accuracy over untuned baselines. More broadly, Chen et al. (2023) report that fine-tuned LLMs outperform prompt-only models on tasks such as explanation generation and content recommendation. SFT has also been integrated into interactive learning systems: Gao et al. (2025) fine-tune an LLM within Tailor-Mind to support self-regulated learning, with user studies showing improved goal setting and monitoring. Building on

the general paradigm of aligning pre-trained models to human intent through SFT (Ouyang et al., 2022), these works collectively suggest that SFT offers a practical route to embed pedagogical structure, domain specificity, and safety constraints directly into model parameters.

3 Methodology

Through various data preprocessing methods, we constructed multiple SFT experiments on three 8B LLMs using 2,580 stories generated from GPT-4o and Llama-3.3-70B, and generated new English reading stories for children with fine-tuned LLMs. Then, we selected several evaluation metrics to analyze the controllability of story difficulty and safety, and other metrics such as the similarity between stories generated in each experiment. Figure 1 and the following sections detail our experiments, reasoning, and evaluations.

3.1 Data

Our data derive from a K–2 English reading curriculum from the University of Florida Literacy Institute (UFLI) (Lane and Contesse, 2022): 129 progressively difficult lessons, each specifying target phonemes. Figure 4 in Appendix B shows an example of this curriculum. With zero-shot prompting, GPT-4o and Llama-3.3 70B were used to generate 10 stories per lesson constrained to the designated phonemes, yielding 2,580 stories (Leite et al., 2025). Although these models struggle with strict pedagogical constraint satisfaction in zero-shot settings, their outputs still provide sufficient linguistic quality and narrative coherence to serve as training targets; the pedagogical alignment is then refined through the SFT process. Each story contains 50–350 words, with word counts increasing with lesson difficulty.

3.2 Supervised Fine-Tuning Experiments

We established a baseline method using direct SFT on LLMs with our data, and designed three SFT experiments based on different data preprocessing methods.

3.2.1 Model and Parameter Setting

In our SFT experiments, we fine-tuned three LLMs: Llama 3 8B, Apertus 8B-instruct-2509, and Granite 3.3 8b-instruct. To adapt the base LLM efficiently, we used QLoRA (Dettmers et al., 2023) (4-bit NF4 quantization + LoRA adapters) for parameter-efficient fine-tuning. The LLMs were quantized

into 4-bit NormalFloat (NF4) format with double quantization and trained using LoRA adapters (rank = 32, α = 64, dropout = 0.1, learning rate = 1e-4, batch size = 4, epochs = 5, warmup ratio = 0.03, and the optimizer is AdamW) attached to attention and MLP projection layers. Training is performed in BF16 precision with gradient checkpointing to reduce the memory footprint.

3.2.2 SFT Experimental Design

- **Baseline:** We adopt the simple SFT experiment as our baseline. Specifically, we construct input–target pairs by using the phonemes contained in the corresponding curriculum lessons as inputs and the 2,580 previously generated stories as targets, and fine-tune three selected LLMs separately with QLoRA. We then use the fine-tuned LLMs to generate 10 stories for each lesson.
- **"Good Stories":** Some research works on fine-tuning LLMs believe that using higher-quality data can outperform using larger amounts of lower-quality data (Chen et al., 2024; Zhou et al., 2023). Accordingly, we first computed five metrics for the 2,580 stories previously generated by GPT-4o and Llama 3.3 70B (we detail their computation later): Spache readability, language model perplexity (LM-PPL), coherence, syntactic complexity, and toxicity. To avoid an overly small training set, we selected stories that were not worse than the corpus means on all metrics, yielding 996 stories in total, and used them to fine-tune the three LLMs, constructing input–target pairs from the corresponding phonemes and stories for SFT.
- **Rewarded SFT:** We considered Reinforcement Learning from Human Feedback (RLHF) (Bai et al., 2022) as a fine-tuning approach, but our sample size was insufficient to train an effective reinforcement learning (RL) model. Thus, we follow LLM alignment approaches that reinterpret RL as supervised learning with reward-dependent weights (Peters, 2006; Mukherjee et al., 2025). Concretely, each training example is assigned a scalar reward based on the five metrics we mentioned, and the standard cross-entropy loss in the SFT Trainer would be reweighted accordingly. It is closely related to reward-weighted regression schemes explored for offline LLM alignment

Figure 1: System architecture and experimental workflow for generating children’s English reading stories via supervised fine-tuning of compact LLMs.

and self-improvement (Qu et al., 2024), and fits within the broader “learning from rewards” framework for LLMs (Zhang et al., 2025). As in our baseline, we construct input–target pairs by using the phonemes and all the 2,580 stories. During training, we compute a scalar reward r_i by combining five automatic evaluation metrics. Since these metrics are defined on different scales and directions, each metric is first normalized into $[0, 1]$. For metrics where lower values indicate better quality (e.g., readability difficulty or perplexity), we apply inverted min–max normalization:

$$\tilde{m}_i = \max\left(0, \min\left(1, \frac{b_m - m_i}{b_m}\right)\right),$$

where m_i is the raw metric value and b_m is a predefined upper bound. For metrics where higher values indicate better quality, we apply standard min–max normalization. The final scalar reward is computed as the unweighted average of the normalized metrics:

$$r_i = \frac{1}{5} \sum_{k=1}^5 \tilde{m}_i^{(k)}.$$

This formulation ensures comparability across metrics while preserving stability during training.

- SFT with simulated children’s reading errors: Inspired by the Self-Instruct paradigm

(Wang et al., 2023), we leverage advanced LLMs to simulate diverse phonemic errors typical of early readers, addressing the data scarcity of real-world error samples. Following the LaMP framework for personalization (Salemi et al., 2024), we constructed a few-shot learning setup using data on real children’s phoneme mispronunciations observed while reading several stories, and used OpenAI’s GPT-OSS-120B (Agarwal et al., 2025) to generate 3–8 simulated child mispronounced phonemes for each of the 2,580 stories. Then, we used the phonemes from each lesson and simulated child mispronounced phonemes as input, and the 2,580 stories as the target to do SFT. This approach aligns with recent findings from “STaR: Bootstrapping Reasoning with Reasoning” (Zelikman et al., 2022), which suggest that training on high-quality, educationally targeted synthetic data significantly enhances model performance in specialized domains.

3.3 Evaluation Metrics

To evaluate whether the difficulty and safety of stories generated by fine-tuned LLMs are controllable enough, we employed five evaluation metrics to measure these stories’ difficulty and safety for children. First, we used the Spache Readability score (Spache, 1953) to assess text difficulty specifically for our target audience of early elementary readers (up to the 3rd grade), where a score below

3.0 shows text at approximately the second-grade reading level.

Second, to measure the fluency and naturalness of the generated stories, we computed LM-PPL. We employed the GPT-2 model via the Hugging Face Evaluate library to calculate the perplexity.

Third, we introduced a coherence score to quantify local narrative consistency by averaging the number of shared named entities between consecutive sentences, identified using spaCy. Fourth, we evaluated syntactic complexity to capture the structural difficulty of the text. We designed a composite metric that combines the average maximum dependency distance (MDD) within sentences and the average number of subordinate clauses (NSC), computed using spaCy.

Also, text toxicity was assessed to ensure the safety of content intended for children. We employed Detoxify (Hanu and Unitary team, 2020) to identify potential offensive or harmful language, where a score closer to 0 indicates safer content, aiming to filter out stories that exhibit high probabilities of toxic content.

Because the stories generated by GPT-4o and Llama 3.3 exhibit some content-level repetition, we also measured the degree of inter-story repetition among stories produced by the fine-tuned LLMs. We used Self-BLEU (Zhu et al., 2018) to measure the degree of repetition in the generated stories. It is able to evaluate each story as a hypothesis while treating the remaining stories as references. Thus, higher scores show stronger similarity across outputs and lower generative diversity. To capture repetition at different levels of granularity, we compute Self-BLEU both within each lesson and across the generated stories of each LLM in each experiment.

For a given story belonging to a lesson, we can compute Self-BLEU by using all other stories in the same lesson as references. It reflects how likely the model is to reuse similar expressions, narrative structures, or lexical patterns when conditioned on similar lesson inputs.

In addition to this local view, we measured the repetition between 1,290 stories of each LLM in each experiment by treating every other story as a reference for each story. This provides a broader perspective on whether the model collapses to a narrow set of global templates across lessons. Formal mathematical definitions of all evaluation metrics are provided in Appendix A.

4 Results

In our generation stage, we perform inference-only decoding with a fine-tuned causal language model. We apply the LoRA-adapted model parameters to the three base LLMs and generate text autoregressively, conditioned on a structured instruction prompt. Text generation uses nucleus sampling (top-p=0.9) with temperature (0.8), which produces stories without modifying model parameters. Since some outputs from the fine-tuned LLMs contained content extraneous to the stories, and in some cases, the entire output was not a story, we identified these samples through manual inspection, flagging outputs that lacked a coherent narrative structure, consisted mainly of prompt repetition or metadata, or were otherwise not readable as stories. Additionally, to avoid affecting the computation of our story evaluation metrics, we stripped special characters and meaningless blank lines or whitespace from the LLMs' outputs.

4.1 Quantitative Evaluation

Table 1 shows the evaluation results for stories generated by LLMs fine-tuned under Rewarded SFT and Baseline. Examining these results, we find that, except for the overall repetition rate of stories from the Rewarded SFT experiment and the LM-PPL of stories from the Good Stories experiment and SFT with simulated children's reading errors, the metric scores for stories from these three experiments show improvements relative to the baseline.

Apart from overall repetition, stories from Rewarded SFT and SFT with simulated children's reading errors often approach or surpass those from GPT-4o and Llama 3.3 70B on other evaluation metrics. Across the three 8B LLMs we examined (except for our baseline experiment), stories generated by Llama 3 always underperform those from the other two LLMs on most evaluation metrics. In contrast, the evaluation results of stories produced by Granite 3.3 and Apertus do not show marked differences between the various experimental designs.

The Spache readability scores of stories generated by our fine-tuned LLMs are mostly lower than those from GPT-4o and are comparable to or even lower than those from Llama 3.3. However, this average Spache readability score still has significant room for improvement to accommodate the reading abilities of children below the second-grade level. The mean toxicity of all our generated stories is

very close to 0, suggesting that only a minimal number of stories might pose a safety risk.

In our experiments, the stories generated by LLMs fine-tuned with Rewarded SFT exhibited high stability, being almost entirely free of hallucinations, garbled text, story-irrelevant outputs, or null values. In the other experiments, while the stories from fine-tuned LLMs did contain a small portion of these undesirable outputs, the proportion was less than 10% of the 1,290 stories generated per model in each experiment.

To further evaluate whether the evaluation metric values for stories generated by LLMs fine-tuned in our SFT experiments differ significantly, in a statistical sense, from those of stories produced by GPT-4o and Llama 3.3 70B, we conducted significance testing. Because the stories are non-identical and our experiments cannot fully eliminate LLM hallucinations or errant responses, although all the stories generated by all the experiments being compared are usable, we used Welch’s T-test to ensure the robustness of the test results.

Given that the toxicity of the story is nearly zero across the board and that the two metrics related to repetition are not consistently standardized across datasets, we compared the corresponding metric values of fine-tuned LLM stories that achieve the best mean performance on coherence, syntactic complexity, Spache readability, and LM-PPL against those of GPT-4o and Llama 3.3 70B. In the results of Welch’s T-test, all p-values are less than 0.001, and all Cohen’s d are greater than 0.8, which shows that the differences in the mean scores for coherence, syntactic complexity, Spache readability and LM-PPL between the stories of fine-tuned LLMs and those of GPT-4o and Llama 3.3 70B are statistically significant.

In summary, quantitative evaluation shows that our SFT experiments, particularly Rewarded SFT, enable fine-tuned 8B LLMs to generate stories with difficulty levels more suitable for K-2 children than those from GPT-4o and Llama 3.3 70B, while presenting almost no discernible safety issues. Complete evaluation results across all four experiments, along with a visual comparison of metric trends across all models and SFT strategies, are provided in Appendix B (Table 2 and Figure 3).

4.2 Qualitative Analysis

In our evaluation of the newly generated stories, we observed outliers in some evaluation metrics. Primarily, the mean LM-PPL values for stories from

SFT with simulated children’s reading errors were higher than those of other experiments. Observation of these stories revealed that their higher LM-PPL values were either due to their brevity, which led to increased uncertainty and higher cross-entropy per word, or because the LLMs appended content irrelevant to the narrative after generating a short story. This caused an abrupt genre shift, thereby increasing the text’s perplexity.

Simultaneously, we observed that some stories in the newly generated sets exhibited toxicity scores significantly higher than others, and we examined these stories closely. We identified several potential factors contributing to the higher toxicity scores, such as the inclusion of language like "you’re too fat," "this smells too stinky," and "the pig can gag," or the appearance of characters portrayed as unfriendly or potentially harmful, such as rats. These elements pose a risk of causing discomfort to children or exposing them to content such as body shaming. Overall, the number of stories containing such content was five or fewer in each dataset of 1,290 stories.

Additionally, the instances of excessively high Spache readability grade scores or low coherence scores in some stories were attributed to the presence of difficult words and numerous line breaks, respectively. The syntactic complexity of some stories was collectively elevated by higher rates of subordination, coordination density, complex nominal phrases, premodification, and parentheticals, as well as unconventional word order and fragmented sentence structures.

Figure 2 in Appendix B shows a "bad" story and a "good" story from our generated stories as an example. The comparison between the two stories reveals notable differences in linguistic suitability for early children. The "good" story maintains clear coherence, following a straightforward sequence of actions that aligns well with the narrative-processing abilities of young children. Events progress linearly and predictably, and character references remain stable, enabling developing readers to follow the plot without excessive inferential demands. In contrast, the "bad" story introduces a broad and descriptively dense setup, then shifts abruptly toward unrelated or ill-formed fragments. These discontinuities reduce overall coherence and make the narrative less suitable for young readers who benefit from a tighter event structure.

In terms of syntactic complexity, the "good" story employs short, regular sentence structures

Table 1: Evaluation results of stories generated by LLMs. Values are reported as Mean (SD). $\uparrow$ indicates higher is better; $\downarrow$ indicates lower is better.

Metric	Baseline			Rewarded SFT		
	Llama 3	Granite 3.3	Apertus	Llama 3	Granite 3.3	Apertus
Coherence $\uparrow$	0.02 (0.05)	0.07 (0.05)	0.09 (0.13)	0.12 (0.14)	0.18 (0.18)	0.13 (0.15)
Syntactic Complexity $\downarrow$	4.63 (2.02)	3.72 (1.05)	3.41 (0.90)	3.38 (1.11)	3.12 (0.88)	2.96 (0.98)
Spache Readability $\downarrow$	4.05 (1.04)	3.52 (0.93)	2.83 (0.47)	2.71 (0.70)	2.56 (0.60)	2.34 (0.68)
Toxicity $\downarrow$	0.01 (0.04)	0.06 (0.12)	0.00 (0.01)	0.01 (0.02)	0.02 (0.06)	0.02 (0.07)
LM-PPL $\downarrow$	23.16 (13.22)	24.91 (10.21)	16.49 (3.88)	16.86 (4.29)	14.55 (3.56)	19.73 (6.64)
Repetition in lessons $\downarrow$	0.03 (0.03)	0.11 (0.09)	0.12 (0.06)	0.11 (0.06)	0.12 (0.07)	0.09 (0.08)
Total repetition $\downarrow$	0.21 (0.09)	0.37 (0.16)	0.40 (0.08)	0.37 (0.10)	0.42 (0.11)	0.32 (0.13)

characteristic of early-grade leveled texts. The “bad” story, by comparison, alternates between long, multi-clause sentences and incomplete constructions, creating variability that may be less aligned with the decoding patterns expected at this developmental stage. The lexical difficulty further highlights this contrast: the “good” story uses high-frequency, concrete vocabulary appropriate for K–2 learners, whereas the “bad” story incorporates abstract, low-frequency terms (“spectacle,” “insatiable,” “peculiar”) that can make comprehension more challenging for beginning readers. These lexical choices also contribute to higher expected perplexity, indicating less predictable and less contextually grounded language.

Beyond outliers in individual metrics, we also examined the pattern of inter-story repetition reflected in Self-BLEU scores. As shown in Table 1, for most generated story datasets (every 1,290 stories per LLM in each experiment), these scores indicate suboptimal diversity. Upon inspection of the generated stories, we observed the recurrence of certain names, animal names, locations, and activities across multiple narratives. Even combinations of these recurring entities, such as Sam, Pam, mats, pigs, and farm, also reappear. Furthermore, some stories feature the same place name repeatedly, albeit attributed to different states within the respective narratives.

Overall, while both stories are grammatically interpretable, the “good” story is more closely aligned with early-elementary reading expectations, whereas the “bad” story exhibits features across coherence, syntax, and vocabulary that render it comparatively less suitable for this age range.

5 Discussion

The repetition patterns observed above are likely attributable to the characteristics of the source train-

ing data. We believe that these phenomena are related to the source stories from GPT-4o and Llama 3.3 70B themselves. In the stories from Llama 3.3 70B, we also observed similar patterns, such as the recurrence of content involving Sam, Pam, mats, pigs, and farm. This issue arose because we could only use a small number of keywords for batch-generating stories with Llama 3.3 70B due to the limitations of the insufficient data collected at the time. The stories from GPT-4o, which used varied keywords, exhibited lower content repetition; however, they also featured recurring place names, consistently attributed to different states such as Ohio, Illinois, or Kansas. This indicates that after fine-tuning, the generative preferences of these 8B LLMs are strongly influenced by the stories used for the fine-tuning process. It aligns with the findings of Santurkar et al. (2023) and Chung et al. (2024), who demonstrate that the specific task patterns and behavioral attributes encoded in fine-tuning data directly dictate the model’s downstream generation capabilities.

In our evaluation process, while we have utilized quantitative metrics based on NLP theory to assess the stories, feedback, and opinions from experts, teachers, parents, and children are still lacking. Incorporating expert ratings, focus group interviews, and collecting feedback from users of the story-generating LLMs would enable us to better, from the perspectives of data and prompt engineering, guide the LLMs to learn the characteristics of stories that are more suitable for children’s needs and to generate new stories more effectively.

In practical classroom applications, stories generated by the fine-tuned 8B LLMs we used are more suitable in difficulty for children from kindergarten to 2nd grade compared to those from the GPT-4o API and the Llama 3.3 70B model, and they present no apparent safety issues. Compared to APIs that require payment and 70B LLMs that

demand substantial hardware resources for deployment, both the fine-tuning and inference costs for 8B LLMs are significantly lower, allowing them to be designed as back-end models for websites and software. Teachers, parents, and children can use these fine-tuned, local models for free in the classroom or at home to generate stories suitable for children’s reading.

However, 8B LLMs are still too large for deployment on mobile devices or for users who wish to fine-tune the models with their own data for unique pedagogical tasks. Additionally, the previously identified issues within the generated stories, such as some inappropriate content and complex syntax, need to be resolved. Furthermore, our current experimental designs are mutually independent, and the effects of combining these designs remain an area for further exploration.

To ensure the stories generated by these LLMs better meet the needs of teaching and learning, as we have previously mentioned, we still require more stories generated from keywords by teachers, parents, and children, authentic data on children’s reading errors, expert ratings of the stories, and any form of user feedback.

6 Conclusion

LLMs have been widely utilized in educational practices such as children’s story generation. We have used GPT-4o and Llama 3.3 70B to generate English reading stories for children from kindergarten to second grade, based on an expert-authored curriculum. However, the cost and hardware requirements of LLMs hinder their widespread implementation in every classroom. We designed three SFT experiments to fine-tune three popular 8B LLMs and generated new stories based on the same curriculum. We evaluated these stories from both quantitative and qualitative perspectives, and discussed the existing problems and the challenges of applying these fine-tuned LLMs in educational practice.

Our constructed SFT experiments are more effective at generating children’s English reading stories with controlled difficulty and safety than the direct SFT baseline. Specifically, stories generated by the 8B LLMs after being fine-tuned in our experiments surpass those from zero-shot GPT-4o and Llama 3.3 70B on difficulty-related evaluation metrics, and they present almost no apparent safety issues. Our "Rewarded SFT" experiment performed com-

paratively better, generating highly stable content that was nearly devoid of any story-irrelevant material. Among the three 8B LLMs we selected, Llama 3’s performance was relatively weaker than the other two.

Our fine-tuned, compact LLMs will further empower more classrooms and families to freely and conveniently generate English reading stories for children from kindergarten to second grade, ensuring these stories possess controllable reading difficulty and are appropriate in their safety for this age group.

In future research work, we plan to collect more stories generated by people using these LLMs with keywords of interest and combine this with expert ratings and feedback from users of the LLMs to construct a complete RLHF pipeline. This will enable us to use higher-quality data, more human feedback, and more effective LLMs fine-tuning strategies to better fine-tune LLMs for generating stories more suitable for children. Furthermore, we will also consider achieving good story generation performance with smaller LLMs through methods such as model distillation, enabling our fine-tuned LLMs to be used by more teachers, parents, and children in classrooms, at home, on computers, mobile phones, and tablets, regardless of their economic situation or hardware resources.

Limitations

In addition to the points already discussed, our research also has some other limitations. First, due to computational resource constraints, we were limited to three L4 GPUs, which prevented us from employing certain SFT strategies in our experimental design; hyperparameters (e.g., the number of training epochs) were also constrained. Second, because related projects were progressing concurrently, we lacked sufficient sample size prior to initiating this study to apply certain fine-tuning techniques, such as completing a full RLHF pipeline. Third, due to IRB review and constraints on practical deployment, our study was built entirely on batch-generated stories and lacks authentic narratives from children, parents, and teachers. Similarly, the generated stories lack expert human evaluation to corroborate the NLP-based automatic evaluation. Moreover, because we used only a single expert-designed curriculum for children’s English reading education, further work is needed to extend our approach to additional curricula and more

languages. Furthermore, automated phoneme coverage evaluation remains an open challenge, as standard grapheme-to-phoneme tools struggle with out-of-vocabulary items and irregular orthographic patterns commonly produced by LLMs. We have attempted g2p-en and NLTK but the non-standard curriculum notation (e.g., "CVC words") and large phoneme sets per lesson produced near-zero hit rates.

Furthermore, in our Rewarded SFT experiment, the scalar rewards were computed using the same automatic metrics later used for evaluation, which raises the possibility that the model was optimized toward the evaluation proxies rather than toward true educational quality. We consider this a limitation and note that human evaluation would be necessary to rule out such over-optimization. Additionally, the comparisons between fine-tuned 8B LLMs and GPT-4o and Llama 3.3 70B are not fully controlled, as the larger models were evaluated only under zero-shot prompting conditions without prompt optimization or few-shot examples. The observed performance differences should therefore be interpreted in this context rather than as a general claim about model capability. Additionally, the fine-tuned models were evaluated on stories generated from the same 129 lessons used during training, rather than on a held-out set of unseen phoneme constraints. This limits our ability to assess generalization to novel lesson inputs.

Ethics

This work involves the generation of educational content for children and therefore requires particular care regarding data provenance, child safety, and deployment. Our training data are derived from an expert-designed K–2 reading curriculum and from stories synthetically generated by large language models, rather than from children’s personal data or identifiable records. In addition, our use of a small, authentic sample of children’s reading errors has been approved by the Institutional Review Board of University of Florida (Protocol # IRB202401327). The simulated reading-error inputs used in one experimental condition are synthetic approximations intended to model common early-reader phonemic mistakes, not diagnostic judgments about any individual child. Nevertheless, synthetic data may encode biases, repetitive patterns, or inappropriate language inherited from source models, and our own analysis found a small

number of outputs containing potentially harmful expressions, including insults, disgust-related language, and body-shaming content. For this reason, these models should not be deployed as fully autonomous systems for children. Responsible deployment should include human oversight by teachers, parents, or other adult supervisors; automatic safety filtering for toxicity and related harms; conservative blocking or review policies for outputs that include appearance-based insults, humiliation, or other potentially distressing language; and clear disclosure that generated stories may still contain errors or unsuitable content. These systems are best used as assistive tools for draft generation and adaptation, not as unsupervised replacements for educators or caregivers. Future work should strengthen this pipeline through expert human review, broader safety evaluation beyond general toxicity, and governance practices that ensure children’s well-being remains the primary criterion for deployment. In preparing this manuscript, the authors made use of AI-assisted writing tools for language polishing. All scientific content, analyses, and conclusions are the sole responsibility of the authors.

Appendix A: Mathematical Formulas for Evaluation Metrics

Spache Readability score:

This metric estimates the grade level of a text by combining the average sentence length and the percentage of unfamiliar words according to the following formula:

$$Spache = 0.141 \times \bar{L}_{sent} + 0.086 \times P_{unfamiliar} + 0.839 \quad (1)$$

LM-PPL:

For a sequence of tokens $X = (x_1, \dots, x_T)$, this is defined as:

$$PPL(X) = \exp \left(-\frac{1}{T} \sum_{i=1}^T \log p_{\theta}(x_i | x_{<i}) \right) \quad (2)$$

Coherence Score:

Let $E(S_i)$ be the set of named entities in the i -th sentence; the coherence score is derived as:

$$Coh = \frac{1}{N-1} \sum_{i=1}^{N-1} |E(S_i) \cap E(S_{i+1})| \quad (3)$$

where N is the total number of sentences and $|\cdot|$ denotes the cardinality of the set.

Syntactic Complexity:

$$Syn = \frac{1}{N} \sum_{i=1}^N (MDD_i + NSC_i) \quad (4)$$

where N is the total number of sentences, MDD_i is the maximum dependency distance within the i -th sentence (i.e., the largest syntactic distance between a word and its head across all dependency arcs in that sentence), and NSC_i is the number of subordinate clauses in the i -th sentence.

Self-BLEU:

$$\text{Self-BLEU}(s_i) = \text{BLEU}(s_i, \{s_j \mid j \neq i, s_j \in L\}) \quad (5)$$

where s_i denotes the i -th story, L is the set of all stories belonging to the same lesson, and the remaining stories $\{s_j \mid j \neq i, s_j \in L\}$ serve as references for computing the BLEU score.

Repetition between 1,290 stories:

$$\text{GlobalSelfBLEU} = \frac{1}{N} \sum_{i=1}^N \text{BLEU}(s_i, \{s_j \mid j \neq i\}) \quad (6)$$

where N is the total number of stories generated by a given model in a given experiment, and each story s_i is evaluated against all other stories $\{s_j \mid j \neq i\}$ as references.

Appendix B: Tables and Figures

In this appendix, we provide additional details regarding our experimental setups, evaluation results of newly generated stories, examples of the K-2 English reading curriculum.

Table 2: Evaluation results of stories generated by LLMs for all the experiments, $\uparrow$ indicates higher is better; $\downarrow$ indicates lower is better.

A "bad" story and a "good" story

A bad case: The bustling town of Eldoria was known for its legendary festival, where every year, children from far and wide gathered to witness the magical spectacle that unfolded in the heart of the forest. This time, the theme was Whimsical Wonders, and the excitement was palpable as everyone prepared for the grand event. Little Lily, a bright-eyed girl with an insatiable curiosity, had always dreamt of attending this festival. She had heard tales of towered castles, explored hidden paths, and even murmured secrets whispered by the trees themselves. With her trusty backpack filled with snacks and a notebook to jot down her adventures, she set off on the journey. As Lily ventured deeper into the enchanting woods, she came across a peculiar sight. Fern towered whirlwind unbreakable.

A good case: Pam and Pat are going to see a monkey. The kids got up at dawn. Pam and Pat put on their pants and grab a banana. The sun is up, and the kids are ready to go. Pam and Pat jump on a bus to head downtown. "I can not wait to see the monkey," said Pam. "Me too!" said Pat. The kids sit on a bench and eat a snack. A man hands Pam a map. The kids look at the map and find the path to the zoo. Pam and Pat walk up to the monkey and hand it a banana. The monkey eats the banana and jumps around. Pam and Pat laugh and clap. The monkey is fun to watch. Pam and Pat say goodbye to the monkey and get on the bus. "That was a great trip," said Pam. "I had a blast," said Pat. The kids go home and tell their mom about the monkey.

Figure 2: A qualitative example of a bad case and a good case in our stories.

Figure 3: Evaluation metrics across 8B models and SFT strategies. We compare our four fine-tuning methods against the zero-shot performance of GPT-4o (red dashed line) and Llama-3.3 70B (blue dotted line). Error bars represent the standard deviation (SD). Lower scores indicate better performance for Spache Readability, LM-PPL, and Syntactic Complexity, while higher scores are better for Coherence. The Rewarded SFT strategy consistently drives the 8B models to approximate or surpass the massive baseline models.

K–2 English Reading Curriculum

Lesson ID: 30

Grade: Kindergarten

Phonemes & Constraints: a, m, s, t, cvc words, p, f, i, n, cvc words, nasalized, a, o, d, c, u, g, b, e, cvc words, s, k, h, r, l, w, j, y

The Story of Experts:

A yak looks at a plant. It’s a yam plant. The yak digs to get a yam from the plant. The yak stomps on the yam to cut it into bits. A dog sees the plant. The dog digs to get a yam from the plant. The dog can not stomp on the yam. The yak helps the dog. “Yum,” said the yak, “yams are the best!” “Yes,” said the dog, “yum, yum, yum!”

Figure 4: An example of the lessons in the K–2 English reading curriculum we used.

Transformer-based readability classifiers are worse than you think: Evidence from cross-domain Arabic readability assessment

robert_reynolds@byu.edu

Abstract

Arabic readability assessment is under-explored compared to English, and existing models are typically evaluated only within the training domain. We introduce the Jordanian School Textbook Corpus (JSTC), 82,512 segments from 240 textbooks spanning grades 1–12, and combine it with DARES to train XGBoost classifiers, fine-tuned CAMELBERT transformers, and hybrid architectures evaluated both in-domain and on the BAREC out-of-domain benchmark. CAMELBERT achieves strong in-domain performance (QWK = 0.830) but its cross-domain QWK collapses to 0.085, while XGBoost over 127 handcrafted linguistic features alone maintains the highest cross-domain QWK (0.240); adding [CLS] embeddings to those features actively harms transfer. Probing reveals that CAMELBERT layers implicitly capture some linguistic features but higher-level signals overwhelm them, and Captum attribution identifies nouns and nominal particles such as *al-* as the most important tokens. The results argue for prioritizing linguistically-grounded features over contextual embeddings when cross-domain robustness is required.

1 Introduction

Readability assessment—the task of estimating the difficulty level of a text for a target audience—is fundamental to educational applications such as textbook selection, curriculum design, and adaptive learning systems (Vajjala, 2022).¹ While substantial progress has been made for English, Arabic readability research remains comparatively under-resourced despite Arabic being a major world language spoken by over 400 million people (Cavalli-Sforza et al., 2018). Arabic presents unique chal-

lenges for readability assessment that cannot be addressed by simply transferring English-centric methods. Its morphological system is exceptionally rich: a single Arabic word can encode subject agreement, definiteness, case, mood, and multiple clitics, making morphosyntactic features far more informative for readability than in morphologically simpler languages. Orthographic variation, optional diacritics, and the diglossia between Modern Standard Arabic (MSA) and regional dialects further complicate both corpus construction and feature extraction.

Recent work in readability assessment has followed two broad paradigms. The first employs handcrafted linguistic features—lexical diversity measures, syntactic complexity metrics, and morphological statistics—fed to traditional classifiers (Deutsch et al., 2020; Al-Tamimi et al., 2014; El-Haj and Rayson, 2016). The second fine-tunes pretrained transformer models such as BERT on labeled readability data, using the [CLS] token representation as input to a classification head (Lee et al., 2021; Imperial, 2021; Ouassil et al., 2024). Hybrid approaches that combine both feature types have also been explored, with mixed results (Lee et al., 2021). For Arabic specifically, the transformer paradigm has gained traction with the release of pretrained Arabic language models such as CAMELBERT (Inoue et al., 2021), enabling direct fine-tuning for downstream tasks.

A critical limitation of existing work, however, is that models are almost universally evaluated only in-domain—that is, on held-out data from the same distribution as the training set. This evaluation protocol can mask a fundamental problem: neural models may learn to exploit surface-level correlations and semantic peculiarities specific to the training corpus rather than capturing genuine text complexity. Practical educational deployment requires readability models that generalize across text types: a model trained on textbooks must also work

¹This article is an abbreviated version of Alzubi (2026). Code and data are available in a private repo (due to copyright restrictions) at https://github.com/Sarah-git99/2026_BEAArabicReadability.git. Contact the authors for access.

reliably for news articles, literature, and online content encountered by students. This cross-domain robustness has received almost no systematic attention for Arabic readability, and recent evidence from other languages suggests that neural models may fail dramatically under domain or format shift (Van Der Sluis and Van Den Broek, 2025; Lim et al., 2024).

The stakes of this question are not merely academic. As readability assessment tools are adopted in educational settings—to match learners with appropriate materials, to evaluate textbook difficulty across curricula, and to support adaptive learning platforms (Vajjala, 2022)—their cross-domain reliability becomes a practical concern. If these tools rely on models that perform well on benchmarks but fail in real-world deployment across diverse text types, the consequences could include mismatched materials, frustrated learners, and misallocated educational resources.

In this paper, we present the first systematic comparison of linguistic, neural, and hybrid readability models for Arabic under both in-domain and cross-domain conditions. Our contributions are:

1. **Jordanian School Textbook Corpus (JSTC):** A new corpus of approximately 82,512 text segments from 240 Jordanian school textbooks (grades 1–12), with 127 extracted linguistic features across six categories.
2. **Cross-domain evaluation:** A rigorous comparison of seven model configurations on both 1) withheld in-domain textbook data and 2) the BAREC benchmark (Elmadani et al., 2025), revealing that fine-tuned transformers suffer catastrophic performance collapse under domain shift.
3. **Key finding:** XGBoost with linguistic features alone achieves the highest cross-domain Quadratic Weighted Kappa (QWK), substantially outperforming all transformer and hybrid configurations. Adding [CLS] embeddings to linguistic features actively degrades cross-domain performance.

2 Related Work

2.1 Arabic Readability Corpora and Methods

Early Arabic readability work adapted traditional formulas to Arabic’s morphological properties. Al-Tamimi et al. (2014) proposed AARI, an automatic readability index for Arabic, and El-Haj and

Rayson (2016) introduced OSMAN, a readability metric tailored to Arabic text. Forsyth (2014) applied statistical machine-learning methods for automatic readability detection for Modern Standard Arabic. Cavalli-Sforza et al. (2018) surveyed the state of Arabic readability research, identifying corpus scarcity as a major bottleneck.

More recently, several Arabic readability corpora have been developed. Nassiri et al. (2019) introduced MoSAR, a Modern Standard Arabic readability corpus for L1 learners. El-Haj et al. (2024) and Almujaivel et al. (2025) released DARES, a dataset for Arabic readability estimation derived from Saudi school materials. Most recently, Elmadani et al. (2025) introduced BAREC, a large-scale benchmark spanning multiple domains and grade levels. Despite this progress, none of these efforts has systematically evaluated cross-domain generalization of their models.

2.2 Transformer and Hybrid Approaches

Lee et al. (2021) demonstrated that combining BERT soft labels with handcrafted linguistic features improves readability assessment for English, achieving state-of-the-art results on the CommonLit benchmark. Imperial (2021) showed that BERT embeddings alone can be effective for readability classification. For Arabic specifically, Ouassil et al. (2024) combined BERT with BiLSTM for readability assessment, and Khallaf and Sharoff (2021) applied both sentence embeddings and traditional linguistic features for readability classification.

2.3 Cross-Domain Robustness

Cross-domain evaluation of readability models has received limited but growing attention. Van Der Sluis and Van Den Broek (2025) showed that interpretable models exhibit better domain generalization in textual complexity modeling across multiple languages, providing theoretical motivation for feature-based approaches. Their analysis demonstrates that models with transparent, linguistically-grounded features avoid the domain-specific overfitting that characterizes opaque neural representations. Lim et al. (2024) investigated the robustness of hybrid models in cross-domain readability assessment, finding that linguistic features provide more stable transfer than purely neural representations. Deutsch et al. (2020) provided a thorough evaluation of linguistic features for English readability at the BEA workshop, establishing that traditional features remain competitive with neural

approaches, though they did not conduct cross-domain experiments.

To our knowledge, no prior study has systematically compared linguistic, neural, and hybrid readability models for Arabic under cross-domain conditions. Our work fills this gap, leveraging Arabic’s rich morphological system to construct a particularly informative linguistic feature set and using the recently released BAREC benchmark to perform rigorous out-of-domain evaluation.

3 Data

3.1 Jordanian School Textbook Corpus (JSTC)

We construct the Jordanian School Textbook Corpus (JSTC) from 240 official textbooks in the Jordanian national curriculum, spanning Grades 1–12. These textbooks cover core subjects including Arabic Language, Islamic Education, and Digital Skills.

Text extraction from the textbook PDFs presented a significant challenge due to the complexity of Arabic script, including right-to-left writing, diacritical marks, complex ligatures, and mixed text-image layouts common in educational materials. Standard PDF text extraction tools produced unreliable output for Arabic content, so we employed the QARI-OCR model (Wasfy et al., 2025) for advanced character-level recognition of Arabic text from scanned pages. This OCR-based pipeline was essential for handling the typographic diversity of textbooks, which include tables, sidebars, and decorative elements alongside running text.

Preprocessing was performed using CAMEL Tools (Obeid et al., 2020). Text was dediacritized to remove optional vowel markings that are inconsistently applied across textbooks, and letters were normalized (e.g., variant forms of *alif* and *ya*’ were mapped to canonical forms) to reduce orthographic variation. Deduplication was applied to remove repeated passages appearing across multiple textbooks in the same curriculum (e.g., recurring introductory material); this process removed 5.42% of segments from JSTC. The resulting corpus comprises 82,512 text segments totaling over 2.1 million tokens. Segments preserve the natural textbook structure, including paragraphs, passages, bullet points, and standalone sentences, rather than being artificially re-segmented into uniform units.

Table 1 shows the distribution of segments and tokens across 12 grades, with lines between the

Coarse label	Grade	Segments	Tokens
L1	G1	2263	36063
	G2	3188	51103
	G3	3042	55950
L2	G4	6042	108681
	G5	5341	107208
	G6	4577	105726
L3	G7	7991	225743
	G8	7356	212545
	G9	10012	273309
L4	G10	16677	572634
	G11	15604	483499
	G12	11172	361304
Total		82512	1764899

Table 1: Distribution of segments and tokens in JSTC dataset.

four coarse-grained readability categories. The corpus exhibits substantial class imbalance, with high school grades contributing roughly five times as many segments as early elementary grades, reflecting the greater volume of advanced instructional material typical of readability corpora.

3.2 DARES

To introduce curricular diversity into training, we supplement JSTC with DARES V1 (El-Haj et al., 2024), a readability corpus derived from the Saudi Arabian public school curriculum, grades 1–12. After deduplication (19.37% of DARES segments were removed), the combined training set comprises approximately 93,265 segments.

3.3 BAREC Cross-Domain Evaluation

For cross-domain evaluation, we use BAREC (Elmadani et al., 2025), a sentence-level multi-domain Arabic readability benchmark spanning three broad domains: Arts & Humanities, Social Sciences, and STEM. BAREC was used exclusively for cross-domain testing—none of its data was observed during training. This enables us to assess whether models capture generalizable readability signals or merely overfit to textbook-specific patterns. Both 12-class (individual grades) and 4-class (educational bands) label mappings are applied to BAREC for evaluation.

Evaluating on BAREC provides a particularly stringent test of cross-domain robustness because the BAREC texts differ from textbook prose along multiple dimensions simultaneously: topic, genre, register, text length, and intended audience.

A model that maintains predictive accuracy on BAREC demonstrates genuinely transferable readability representations.

4 Features and Models

We extract 127 handcrafted linguistic features from each text segment, organized into six categories designed to capture multiple dimensions of text complexity:

Lexical features include type-token ratio (TTR), moving-average TTR (MATTR; [Covington and McFall, 2010](#)), measure of textual lexical diversity (MTLD; [McCarthy and Jarvis, 2010](#)), average word length, and lexical density (ratio of content words to total words).

TF-IDF features comprise eight aggregated statistics inspired by [Attia et al. \(2023\)](#) computed from both surface forms and lemmatized forms, capturing rates of lexical distinctiveness within the corpus.

Syntactic features measure clause density, clause embedding depth, sentence length, and dependency parse structure using CamelParser 2.0 ([Elshabrawy et al., 2023](#)) with Universal Dependencies annotation.

Part-of-speech features capture the distribution of POS categories (nouns, verbs, adjectives, adverbs, pronouns, prepositions, and functional categories) as proportions within each segment.

Morphosyntactic features exploit Arabic’s rich morphological system, including person, number, and gender agreement; definiteness marking (the *al*-prefix); verb mood and tense; and case marking—all extracted via CAMEL Tools ([Obeid et al., 2020](#)) using the D3TOK tokenization scheme.

Semantic features include Latent Dirichlet Allocation (LDA) topic distributions at multiple granularities ($K \in \{50, 100, 150, 200\}$) and derived measures of semantic richness, clarity, focus, and breadth, along with word frequency quartile analysis that captures lexical sophistication.

Together, these 127 features are designed to capture readability signals at multiple linguistic levels—from surface lexical statistics through syntactic structure to semantic content—while exploiting Arabic’s rich morphological system in ways that generic transformer representations may not.

4.1 Models

We evaluate seven model configurations spanning statistical, neural, and hybrid approaches. Of the many statistical classifiers tested, we report results for XGBoost, which consistently outperformed alternatives such as logistic regression, SVM, and Random Forests in preliminary experiments.

XGBoost-Ling: XGBoost ([Chen and Guestrin, 2016](#)) trained on the 127 linguistic features.

XGBoost-CLS: XGBoost trained on the 768-dimensional [CLS] embedding extracted from a frozen CAMELBERT model.

XGBoost-Ling+CLS: XGBoost trained on the concatenation of linguistic features and [CLS] embeddings.

CAMELBERT-MSA: CAMELBERT ([Inoue et al., 2021](#)) pretrained on Modern Standard Arabic, fine-tuned on the readability task.

CAMELBERT-MIX: CAMELBERT pretrained on a larger mixed-dialect corpus, fine-tuned on the readability task.

CAMELBERT-MSA+H1: CAMELBERT-MSA with the H1 subset of linguistic features (features which had very low correlation with probing model outputs) projected and fused via concatenation before the classification head.

CAMELBERT-MIX+H3: Same architecture as CAMELBERT-MSA+H1, but using CAMELBERT-MIX and the H3 set of linguistic features (features which had very low, low, and moderate correlation with probing model outputs).

4.2 Experimental Setup

All models were trained on the combined JSTC and DARES data with a standard train/validation/test split. In-domain evaluation was performed on a held-out textbook test set drawn from the same corpus; cross-domain evaluation was performed on the full BAREC corpus, which was not observed during training. This strict separation ensures that cross-domain results reflect genuine generalization rather than data leakage.

We evaluate at two granularities: a **fine-grained** task with 12 classes (individual grade levels G1–G12) and a **coarse-grained** task with 4 classes (the educational bands in Table 1). The fine-grained task is particularly challenging because adjacent grade levels may differ only subtly in linguistic complexity, while the coarse-grained task groups these levels into broader educational stages.

For XGBoost models, we use the XGBoost

gradient-boosted tree classifier (Chen and Guestrin, 2016) with hyperparameters selected via cross-validation on the training set: `n_estimators=600`, `learning_rate=0.03`, `max_depth=6`. XGBoost is well-suited to this task because its tree-based architecture can capture non-linear interactions between linguistic features (e.g., the combination of high lexical density and long sentence length may indicate a different difficulty level than either feature alone).

For CAMELBERT models, we fine-tune from the pretrained checkpoints with a classification head on top of the [CLS] representation. CAMELBERT-MSA was pretrained on Modern Standard Arabic text, while CAMELBERT-MIX was pretrained on a larger corpus that includes dialectal Arabic, potentially providing broader linguistic coverage at the cost of MSA specificity.

The hybrid models employ a projection fusion mechanism: the 127-dimensional linguistic feature vector is projected via a learned linear layer to match the 768-dimensional [CLS] representation. The projected features are then concatenated with the [CLS] output and passed to the classification head. This architecture allows the model to learn to weight both signal sources during training, but—as our results show—tends to prioritize the higher-dimensional [CLS] component. The models were trained using a maximum sequence length of 512, a learning rate of 5×10^{-5} , a batch size of 32, and 10 epochs. All experiments were conducted using 5-fold cross-validation.

Performance is measured using accuracy and Quadratic Weighted Kappa (QWK; Cohen, 1968). QWK is a variant of Cohen’s Kappa that applies quadratic penalties to prediction errors proportional to their distance from the true label, making it particularly appropriate for ordinal classification where a prediction of grade 3 for a grade 4 text is less severe than a prediction of grade 1. QWK ranges from -1 (systematic disagreement) through 0 (chance agreement) to 1 (perfect agreement). We adopt QWK as our primary evaluation metric, supplemented by accuracy.

5 Results

5.1 Fine-Grained Results (12 Classes)

Table 2 presents the fine-grained results. In-domain, CAMELBERT-MSA achieves the highest performance across all metrics (Acc = 0.640, QWK = 0.830), substantially outperforming XGBoost-Ling

Model	Ling	CLS	Acc (In)	QWK (In)	Acc (Cross)	QWK (Cross)
XGBoost-Ling	✓		0.284	0.460	0.130	0.240
CAMELBERT-MSA		✓	0.640	0.830	0.098	0.085
CAMELBERT-MIX		✓	0.626	0.807	0.108	0.092
XGBoost-CLS		✓	0.380	0.643	0.091	0.161
CAMELBERT-MSA+H1	✓	✓	0.644	0.821	0.101	0.089
CAMELBERT-MIX+H3	✓	✓	0.630	0.810	0.110	0.077
XGBoost-Ling+CLS	✓	✓	0.390	0.670	0.080	0.170

Table 2: Fine-grained (12-class) readability results. Best in-domain scores in **bold** (top section); best cross-domain scores in **bold** (all rows). XGBoost with linguistic features alone achieves the highest cross-domain QWK.

(Acc = 0.284, QWK = 0.460). The hybrid model CAMELBERT-MSA+H1 provides only marginal improvements in accuracy, but is slightly worse than its base in QWK (0.821 vs. 0.830).

The cross-domain results tell a strikingly different story. CAMELBERT-MSA’s QWK collapses from 0.830 to 0.085—a 90% relative decrease—and accuracy drops from 0.640 to 0.098, approaching the chance level of 0.083 for 12 classes. All models that rely on [CLS] representations show similarly catastrophic degradation. In contrast, **XGBoost-Ling achieves the highest cross-domain QWK at 0.240**, more than double that of any CLS-based model.

Notably, adding [CLS] embeddings to linguistic features (XGBoost-Ling+CLS) *reduces* cross-domain QWK from 0.240 to 0.170, indicating that contextual embeddings actively introduce domain-specific noise that harms transfer. The same pattern holds for accuracy: XGBoost-Ling (0.130) outperforms XGBoost-Ling+CLS (0.080) cross-domain, despite the latter’s higher in-domain accuracy (0.390 vs. 0.284).

5.2 Coarse-Grained Results (4 Classes)

Table 3 shows the coarse-grained results, which reinforce the same pattern. In-domain, CAMELBERT-MSA again dominates (Acc = 0.776, QWK = 0.802), with the hybrid H1 providing a slight improvement (QWK = 0.805).

Cross-domain, the pattern of transformer collapse persists. CAMELBERT-MSA’s QWK drops from 0.802 to 0.106, while XGBoost-Ling’s QWK drops more modestly from 0.414 to 0.264. **XGBoost-Ling again achieves the highest cross-domain QWK (0.264)**, outperforming the best hybrid model by a factor of three (H1: 0.084).

Even more strikingly, XGBoost-Ling achieves the highest cross-domain accuracy (0.470), surpassing all transformer and hybrid models despite

Model	Ling	CLS	Acc (In)	QWK (In)	Acc (Cross)	QWK (Cross)
XGBoost-Ling	✓		0.550	0.414	0.470	0.264
CAMeLBER-MSA		✓	0.776	0.802	0.373	0.106
CAMeLBER-MIX		✓	0.765	0.785	0.352	0.051
XGBoost-CLS		✓	0.612	0.600	0.360	0.160
CAMeLBER-MSA+H1	✓	✓	0.780	0.805	0.363	0.069
CAMeLBER-MIX+H3	✓	✓	0.770	0.793	0.370	0.067
XGBoost-Ling+CLS	✓	✓	0.630	0.630	0.320	0.155

Table 3: Coarse-grained (4-class) readability results. Best in-domain scores in **bold** (top section); best cross-domain scores in **bold** (all rows). XGBoost with linguistic features alone achieves the highest cross-domain QWK.

its much lower in-domain accuracy. This reversal highlights the fundamental difference between in-domain pattern matching and cross-domain generalization.

The coarse-grained results also reveal an interesting asymmetry in the hybrid models. While H1 achieves the highest in-domain QWK (0.805), its cross-domain QWK (0.084) is actually *lower* than that of standalone CAMeLBER-MSA (0.103). This suggests that the projection-fusion mechanism, while effective at combining signals for in-domain classification, may amplify overfitting to domain-specific patterns when cross-domain transfer is required. The same trend holds for H3 (cross-domain QWK 0.067 vs. CAMeLBER-MIX’s 0.060), though the difference is smaller.

5.3 Cross-Domain Subdomain Analysis

Performance on the BAREC subdomains varies substantially by topic area. For the coarse-grained task, XGBoost-Ling achieves the best cross-domain results on STEM texts (Acc = 0.679, QWK = 0.293) and Social Sciences (Acc = 0.617, QWK = 0.287), with somewhat lower performance on Arts & Humanities (Acc = 0.427, QWK = 0.239). CAMeLBER’s cross-domain performance remains near chance across all subdomains, confirming that the transformer’s domain-specific overfitting is not limited to a single target domain.

For the fine-grained task, subdomain variation follows a similar pattern. XGBoost-Ling achieves cross-domain QWK of 0.260 on STEM, 0.220 on Social Sciences, and 0.210 on Arts & Humanities. CAMeLBER-MSA shows uniformly poor cross-domain performance across all subdomains (QWK < 0.10).

This pattern suggests that linguistic complexity features transfer more reliably to STEM and Social Science texts, which share certain structural properties with textbook prose (e.g., expository structure,

technical vocabulary, formal register). Literary and humanities texts present a greater distributional shift due to their use of narrative structures, figurative language, and stylistic variation that differ markedly from instructional prose.

5.4 Feature Type Comparison

The XGBoost variants isolate the effect of input representation under a constant classifier. In-domain, the QWK ordering is Ling < CLS < Ling+CLS for both the fine-grained task (0.460, 0.643, 0.670) and the coarse-grained task (0.414, 0.600, 0.630). Cross-domain, this ordering reverses: Ling > Ling+CLS ≥ CLS (fine-grained: 0.240, 0.170, 0.160; coarse-grained: 0.264, 0.160, 0.160). The near-equality of CLS and Ling+CLS cross-domain suggests that when both feature types are present, the classifier relies primarily on CLS features—which dominate in-domain—effectively discarding the linguistic features that would have provided better transfer. **The features most useful for in-domain classification are precisely those that hurt cross-domain transfer**, an inherent tension that cannot be resolved by naive feature combination.

5.5 Feature Importance

We performed permutation importance analysis for the XGBoost model on the test set. This method evaluates feature importance by randomly shuffling one feature at a time and measuring the resulting drop in model performance. Table 4 presents the top 6 ranked feature importances based on the observed performance degradation. The two rankings diverge sharply: in-domain predictions rely most heavily on surface lexical and TF-IDF statistics (lemma_category_tfidf_mean, form_category_tfidf_mean, avg_word_length, Digit_Density), whereas cross-domain predictions depend predominantly on syntactic complexity (avg_parse_tree_height, avg_sentence_length_morphemes, avg_sentence_length_words) and basic vocabulary coverage—features that capture domain-independent structural properties of text complexity rather than corpus-specific lexical distributions, reinforcing the pattern observed in §5.4.

5.6 Probing Analysis

Figure 1 presents the distribution of the R^2 correlations of linguistic features across layers. Specifi-

Feature	In-domain	Cross-domain
lemma_category_tfidf_mean	0.0414	—
n_sentences	0.0258	—
per_1	0.0248	—
form_category_tfidf_mean	0.0239	—
avg_word_length	0.0200	—
Digit_Density	0.0189	—
avg_parse_tree_height	—	0.0078
avg_sentence_length_morphemes	—	0.0049
avg_sentence_length_words	—	0.0041
per_3	—	0.0035
Basic_Vocab_Ratio	—	0.0028
pos_pron_dem	—	0.0028

Table 4: Top 6 permutation feature importance for in-domain and cross-domain test sets.

Figure 1: Distribution of probe R^2 values across CAMELBERT layers for linguistic feature groups.

cally, it shows that the lower layers (1–3) encode a limited range of features and only partially capture them, mainly focusing on lexical cues and surface-level information. In contrast, the middle layers show stronger correlations across most linguistic features, indicating more effective encoding in these layers. This suggests that linguistic features are best represented in the middle layers. In the upper layers (10–12), the R^2 values stabilize or decrease slightly. This pattern indicates that, while linguistic information is still present, the representations become more specialized toward semantic abstraction and downstream tasks. See Alzubi (2026) for the full list of feature correlations with each layer.

5.7 Captum Attribution Analysis

We use the Captum attribution analysis to identify the textual elements CAMELBERT-MSA relied on most for readability prediction. The most influential POS categories are nouns and adjectives, with morphological dominance driven by singular num-

ber and masculine gender, and clitic importance led by definiteness and coordination markers. The model assigns the highest importance to content words, especially nouns and proper nouns, which show positive excess attribution across grades, indicating a consistent signal for readability. Verbs, adjectives, and adverbs vary across grades, while function words generally show weaker or negative contributions, with grammatical words increasing at higher grades, suggesting stronger syntactic encoding. For clitics, the definite article *al-* has the strongest attribution across grades, while *wa-* becomes more prominent in higher grades, likely reflecting increased coordination and syntactic complexity.

6 Discussion

6.1 Why Transformers Fail Cross-Domain

The dramatic cross-domain collapse of fine-tuned CAMELBERT models suggests that these models learn to exploit domain-specific topical and stylistic cues present in textbook data rather than genuinely capturing text complexity. The [CLS] representation, while powerful for in-domain classification, appears to encode distributional patterns specific to the training domain—patterns that become misleading when the text distribution shifts.

This interpretation is supported by two additional observations. First, XGBoost-CLS (which uses the same [CLS] embeddings but in a different classifier) also degrades substantially cross-domain, confirming that the problem lies in the representation rather than the classification architecture. Second, adding linguistic features to the transformer (hybrid models H1 and H3) fails to rescue cross-domain performance ($QWK \leq 0.089$ for fine-grained), suggesting that the [CLS] signal dominates the combined representation and overwhelms the more transferable linguistic features.

We note, however, that BAREC differs from the training data not only in topic and register but also in format: BAREC items are single sentences, whereas JSTC and DARES segments are typically multi-sentence passages. Part of the observed collapse may therefore reflect this format shift rather than pure domain shift, particularly for [CLS] representations that may encode passage-level distributional cues unavailable in short sentence inputs.

6.2 Why Linguistic Features Transfer Better

Linguistic features such as average sentence length, lexical diversity (MATTR, MTLTD), clause density, morphological complexity, and POS distributions measure domain-independent properties of text complexity. A syntactically complex sentence remains complex regardless of whether it discusses photosynthesis or Ottoman history. These features thus provide a noisier but more robust signal that maintains predictive value under domain shift.

The finding that XGBoost-Ling+CLS performs *worse* than XGBoost-Ling cross-domain is particularly telling. It demonstrates that [CLS] embeddings do not merely add complementary information—they actively introduce domain-specific noise that degrades the classifier’s ability to exploit the transferable linguistic signal.

The probing results further confirm a layered encoding structure. Lower layers capture surface-level and lexical features, while middle layers are more strongly associated with syntactic information. In contrast, higher layers show reduced sensitivity to explicit linguistic features and instead emphasize task- and domain-specific contextual representations, aligning with the behavior of the classification head.

Several feature categories identified as important for cross-domain transfer are only weakly encoded in the [CLS] representation. Fine-grained POS distributions, rare morphological markers, and lexical frequency statistics show consistently low probe performance across layers. These features capture domain-independent aspects of text complexity, yet remain underrepresented in the learned embedding. This explains strong in-domain results, where topical signals are sufficient, and weaker cross-domain performance, where such signals do not transfer reliably. It also accounts for the limited benefit of hybrid models, since well-encoded features are largely redundant, while weakly encoded ones contribute too little to improve performance.

6.3 Comparison with Prior Work

Our in-domain CAMELBER results (QWK = 0.830 on 12 grades) are competitive with recent Arabic readability benchmarks. Elmadani et al. (2025) report QWK of 0.810 on BAREC’s in-domain evaluation, and Almujaivel et al. (2025) report Macro-F1 of 0.420 on concept-based readability estimation. Our linguistic XGBoost model’s in-domain QWK (0.460) is lower, reflecting the

well-documented advantage of contextual representations for in-domain classification. However, the cross-domain comparison—which no prior Arabic readability study has systematically conducted—reveals that this in-domain advantage is misleading.

Our findings are consistent with Van Der Sluis and Van Den Broek (2025), who demonstrated across multiple languages and tasks that interpretable models generalize better than neural models under domain shift. They extend the English-language findings of Deutsch et al. (2020), who showed that linguistic features remain competitive with neural approaches for readability—though that study did not include cross-domain evaluation. Critically, our results contrast with work that has found hybrid approaches superior to either feature type alone (Lee et al., 2021); we show that this finding does not hold under domain shift, where the hybrid’s neural component becomes a liability rather than an asset.

6.4 Implications for Educational NLP

A readability tool deployed in real educational settings must handle diverse text types: textbooks, supplementary readings, news articles, and online content. Our results demonstrate that current transformer-based approaches, despite their impressive in-domain performance, are not ready for such deployment without explicit domain-adaptation strategies. Linguistic-feature models, while exhibiting lower in-domain performance, provide a substantially safer baseline for cross-domain use.

This finding has particular relevance for Arabic educational NLP, where the diversity of text types, genres, and registers encountered by learners is wide, and where the cost of misclassifying a text’s difficulty level can directly affect curriculum alignment and learner outcomes. A model that correctly classifies textbook passages but assigns university-level STEM texts to the elementary band would be worse than useless in a mixed-resource educational setting.

More broadly, cross-domain evaluation should be a standard component of readability assessment research, particularly when the intended application involves diverse input texts. Although XGBoost-Ling achieved a modest 0.240 QWK, this result is qualitatively superior to the near-chance performance of the neural models we tested.

7 Conclusion

We introduced JSTC, a new Arabic readability corpus consisting of approximately 82,512 textbook segments with 127 linguistic features, which was further combined with the DARES dataset comprising 10,755 samples, and conducted the first systematic cross-domain evaluation of Arabic readability models. Our central finding is that fine-tuned transformers, despite achieving strong in-domain QWK (0.830), collapse to near-chance under domain/format shift (QWK 0.085), while XGBoost with linguistic features alone maintains the most robust cross-domain performance (QWK 0.240–0.264). Adding [CLS] embeddings to linguistic features actively degrades cross-domain transfer.

These results argue for prioritizing linguistically-grounded, interpretable feature sets over opaque contextual representations in educational readability applications, particularly when cross-domain robustness is required. The finding that contextual embeddings actively harm cross-domain transfer—even when combined with linguistic features—suggests that the two feature types encode fundamentally different types of information, and that naive combination strategies are insufficient.

Future work should explore domain adaptation techniques (e.g., adversarial training, domain-invariant representations) that could improve transformer robustness without sacrificing in-domain performance, as well as lighter-weight regularizers such as label smoothing and early stopping that may reduce overconfidence in domain-specific patterns. Evaluation on additional cross-domain benchmarks beyond BAREC—such as the Arabic portion of ReadMe++ (Naous et al., 2024), which provides sentence-level readability labels across multiple domains—would help confirm the generality of our findings and disentangle domain shift from format shift; rotating which of JSTC, DARES, and BAREC serves as the held-out corpus would further isolate corpus-specific effects. More balanced training data, particularly with expanded early-grade coverage, would also help mitigate the imbalance-induced biases observed here. Finally, investigating whether recent larger Arabic language models or instruction-tuned models exhibit improved cross-domain transfer would clarify whether our findings reflect a fundamental limitation of the fine-tuning paradigm or a limitation of the specific model scale studied here.

Limitations

BAREC was selected as our cross-domain test corpus because it represents the most extreme distributional shift available, but it differs from the JSTC and DARES training data along multiple dimensions simultaneously—topic, register, and format. In particular, BAREC items are single sentences while JSTC and DARES segments are typically multi-sentence passages, so part of the observed cross-domain collapse may reflect this format shift rather than pure domain shift.

The set of cross-domain regularization strategies explored in this study was limited, which may have affected the absolute performance reported for neural and hybrid models across datasets and text sources.

Both the in-domain and cross-domain datasets are imbalanced, particularly across subdomains and early grade levels, which may have influenced model training and evaluation.

Ethics Statement

The cross-domain performance degradation observed in this study highlights the potential risks of deploying models that appear accurate in controlled settings but fail on diverse real-world texts, which could lead to mismatched educational materials and negatively affect learners.

Abstract

Prediction of item difficulty from its text content is of substantial interest for automated generation of test items. In this paper, we focus on the related problem of recovering IRT-based difficulty when the data originally reported item p-value (percent correct responses). We model this item difficulty using a repository of reading passages and student data from US standardized tests from New York and Texas for grades 3-8 spanning the years 2018-23. This repository is annotated with meta-data on (1) linguistic features of the reading items, (2) test features of the passage, and (3) context features. Using a penalized regression model, we achieve an RMSE of 0.59 (compared to a 0.92 baseline) and a 0.77 correlation between true and predicted difficulty. We further evaluated the impact of LLM embeddings (ModernBERT, BERT, and LLaMA), finding that they marginally improve performance but function effectively as standalone alternatives to traditional linguistic features. Finally, we demonstrate how this difficulty prediction model powers a publicly available, human-in-the-loop tool for generating reading comprehension items.

1 Introduction

Education systems use reading comprehension tests to evaluate student achievement and growth, to monitor average school and teacher performance, and to diagnose students for learning disorders. Creating items for these tests can be an expensive and time-intensive endeavor (Case and Swanson, 1998; Rudner, 2009), especially for standardized tests in K-12 schools. Conventionally, subject matter experts (e.g., teachers or reading specialists) create the items used in standardized tests (Attali et al., 2014). Items are then piloted in schools and student response data is collected to estimate item properties like difficulty and to confirm that items are measuring student knowledge as intended (Lane

et al., 2016, Chapter 1).¹ However, items developed by subject matter experts might not perform as expected when taken to the field (Bejar, 2012; Reid, 1991; Impara and Plake, 1998; Dee and Domingue, 2021).

Education researchers have long been interested in modeling the difficulty of test items. Improved item difficulty models could support subject matter experts in creating items as well as reduce field testing time and costs (Bejar, 1991; Gorin and Embretson, 2006). However, this field has achieved mixed results, as modeling and predicting item difficulty is complex, and requires advanced text analysis and annotation to extract relevant item features (Gorin and Embretson, 2006).

Large Language Models (LLMs) have recently shown the potential to generate items with desirable characteristics like difficulty and to automate scoring of text-based responses (Ferrara et al., 2018; Huang et al., 2017; White et al., 2022; Attali et al., 2022; Zelikman et al., 2023) possibly reducing the time and cost associated with these tasks (Acharya et al., 2023). In this paper, we leverage LLMs with item and respondent features to predict mean difficulty of reading comprehension items. We build a repository of items using reading comprehension items from New York and Texas, administered to Grades 3-8 students spanning 5 years between 2018 and 2023. This repository contains the item text (reading passage, question, and distractors), and the state-level average percent correct responses (p-value). Items are annotated with (1) linguistic features of the reading passage, including their lexical, semantic, and syntactic characteristics and readability metrics (2) test features of the item, such as the presence of highlighted or bold text (3) respon-

¹New York: <https://www.nysed.gov/state-assessment/nysed-test-development-process>; Texas: <https://tea.texas.gov/texas-schools/accountability/academic-accountability/performance-reporting/8-w-hy-does-texas-field-test.pdf>

dent's state, grade, and year (4) LLM-generated text embeddings for reading comprehension items.

We focus on how effectively LLM-generated embeddings predict item difficulty in an attempt to understand whether transformer-based models can augment traditional psychometric methods used to generate items. Our models achieve an RMSE of 0.59 compared to a baseline of 0.92, and a correlation of 0.77 between true and predicted item difficulty. Previous results for predicting difficulty using item content achieved correlation of 0.3-0.7, and smaller RMSE improvements (Ha et al., 2019; Huang et al., 2017). We make the following contributions to literature: First, to our knowledge, this is the first publicly available work to examine automatic difficulty modeling for reading items for standardized tests in US schools. Second, we also convert mean p-value of items from different grades to a vertical logit scale using a Rasch IRT model, which could be used in future work to aggregate response data collected from different populations. Third, we compare difficulty prediction from different types of item features: linguistic features, test features, pre-trained LLM embeddings, and respondent context. We report similar results for prediction from linguistic features or LLM embeddings, suggesting that any of these classes of metrics could be used by themselves for prediction. Fourth, we compare the performance of three LLMs (BERT-base, ModernBERT, and LLaMA), as well as different prompts for generating LLM embeddings. We report similar results for these variations. Finally, we introduce a publicly available tool designed for practitioners and researchers to generate reading comprehension items with predicted difficulty. The tool can be found at <https://item-generator-production.up.railway.app/>.

2 Background

2.1 Features of Reading Comprehension Items

A reading comprehension item in a test is usually structured as a passage that the respondents read, followed by a question or prompt, and then by several options from which respondents select one response. The item might also include a few other components: directions about the passage or the item (e.g., "read the passage and answer the questions that follow"), images or figures (e.g., to highlight part of the story), and tables (e.g., with data

related to the story). This section describes the features of reading comprehension items that could predict their difficulty.

2.1.1 Features of Reading Passages

Reading standards such as the Common Core Standards for English Language Arts & Literacy² are tied to these complexity measures, both for teaching and tests. Text complexity of reading passages has been captured using (1) descriptive metrics, such as the count of words in passage, number of sentences, and number of paragraphs (2) linguistic complexity, which is influenced by factors such as complexity of words (measures include word length and word frequency), syntactic complexity (measures include modifier propositional density or count of adjectives per 1000 words), and text cohesion (defined as words and ideas overlapping throughout the text) (Graesser et al., 2014; McNamara et al., 2014).

Corpus analysis tools can parse text for their linguistic features. A popular corpus analysis tool is the Coh-Metrix, which offers over 100 measures of vocabulary, syntax, semantics, and other linguistic features. Coh-Metrix also reports aggregate measures of text cohesion and readability using metrics like Flesch-Kincaid, latent semantic analysis and principal components analysis (McNamara et al., 2014). Measures from corpus analysis tools, such as length of passage, concreteness or abstractness of text, and vocabulary level have been reported to be correlated with difficulty for reading questions (AlKhuyaey et al., 2023; Choi and Moon, 2020).

In addition to the reading complexity of the passage, its layout or structure might also affect student performance. The layout here refers to reading cues that point students to important aspects of the content (such as text segmentation), the inclusion of boxes or footnotes, directions that point readers to important vocabulary, helpful images, and options for text-to-speech in computer-based reading (Lawrence et al., 2022; Mize et al., 2020).

2.1.2 Features of Items

Item features affect their difficulty by changing their interpretability. Some features can make it easier to locate and retrieve information from text (Lawrence et al., 2022; Le Hebel et al., 2017; Ruiz-Primo and Li, 2015). For example, an item can include relevant sentences from the passage in a

²<https://achievethecore.org/page/2725/text-complexity>

text box or definitions of difficult words. Other features emphasize key aspects of items. For instance, the word “agree” in the item is emphasized: “Which of the following statements would *<name of character>* in the story **agree** with?”. In multiple choice questions, the distractors or response options also affect difficulty; for instance, some distractor options could be very similar to the correct answer. The type of content (e.g., use of images) might also influence student performance.

2.2 Item Difficulty Modeling

2.2.1 Automatic generation of items

Automated item generation was first proposed in the 1970s (Gierl and Haladyna, 2013), though the field saw a resurgence in the 2000s with the need for more item creation with computerized tests, as well as with an increase in computational power. A type of automatic item generation uses expert-created templates, item schemes or structures, parts of which can be populated using algorithms (Embretson and Yang, 2006; Kurdi et al., 2020). Such cognitive item model templates are specific to the item type being created.

With recent advances, LLMs can be prompted to generate items without additional tuning or information (“zero-shot” generation) or with some examples in context (“one-shot” or “few-shot” generation) (Attali et al., 2022; Kurdi et al., 2020). LLMs can also be prompted using cognitive models, templates, or rules to create items with desired properties (Gierl and Haladyna, 2013; Kurdi et al., 2020). These templates can specify the type of item to be generated (e.g., fill-in-the-blank questions, multiple-choice questions, open-ended questions), provide further instructions based on item type (e.g., the number of distractors and correct responses for multiple choice items), specify reasoning to be elicited (e.g., recall or inference), and even state the desired item difficulty (e.g., “create an easy item that 70% of respondents would get right”) (Sayin and Gierl, 2024). While LLMs can be used to generate big quantities of test items (Kurdi et al., 2020), their quality, especially properties like difficulty, is unknown, making them hard to use reliably in educational testing.

2.2.2 Item difficulty modeling

The problem of item generation is fundamentally linked with the problem of item difficulty modeling. Items are created with an implicit or explicit difficulty level, defined by human experts using

heuristics or by statistical modeling. Popular models used for statistical modeling include supervised learning approaches such as linear regression, decision trees, and random forests. Approaches like deep learning and neural nets have also been leveraged but are less common, likely because of the smaller size of education datasets and the desire for inference in addition to model prediction.

Statistical item difficulty modeling approaches usually have the following components: (1) A method to parse item text and images: this can use NLP and image parsers, linguistic corpus analysis tools, and human annotation (2) Model to predict difficulty. Recently, difficulty modeling has been supplemented by embeddings from LLMs (Kurdi et al., 2020; Sharpnack et al., 2024). Embeddings can be extracted from pre-trained models, or models could be fine-tuned. In the shared task organized during the BEA workshop at NAACL 2024 (Yaneva et al., 2024), item difficulty (defined as the percentage of respondents who responded incorrectly) was modeled for 667 MCQ items from the United States Medical Licensing Examination. The best prediction model achieved RMSE of 0.29 compared to a baseline RMSE of 0.31 from a dummy regressor model; the best model used a combination of LLM embeddings and other item features. In a similar exercise with 12,038 MCQ items from the United States Medical Licensing Examination, the best model used a combination of embeddings from Word2Vec and EIMo and linguistic features together, achieving RMSE of 22.45 compared to a baseline RMSE of 23.65.

The results of existing item difficulty prediction efforts have achieved limited success. A key constraint is that education settings rarely provide sufficiently large datasets for fine-tuning LLMs.

3 Data

The dataset contains multiple-choice items from the New York State Testing Program (NYSTP) and Texas STAAR reading comprehension standardized tests for Grades 3-8. NYSTP data is available for the years 2018, 2019, 2022, and 2023, and Texas STAAR data is available for 2019, 2021, and 2022. In total, there are 1076 items based on 170 passages across grades and years from both states (see item counts for grades by state and year in Appendix A).

Features available for passages and related multiple-choice items include item difficulty, defined as mean percent correct response at the state,

year, and grade level. Appendix B reports mean percent correct responses (i.e., the item's *p-value*³) across items by grade, state, and year. Note that mean accuracy for both states centers around 60% across grades and years. Student acquisition of additional reading comprehension skills is being offset by increases in overall item difficulty. As a consequence, reported difficulties or p-values cannot be directly compared across grades. In other words, let us say there is a Grade 3 item with p-value 0.60 (i.e., 60% of 3rd graders get this item right) and a Grade 8 item with p-value 0.60. The Grade 3 item is presumably easier than the Grade 8 item, since Grade 8 students are likely to be better readers; however, the p-values reported in the dataset would consider these items to be equally difficult. We convert these p-values to a common vertical logit scale to make them comparable for difficulty modeling. This is described in more detail in the Methods section.

4 Methods

This section describes how the dataset is processed for item difficulty prediction. Section 4.1 describes how mean p-values across grades and years are rescaled to a uniform logit vertical scale. Section 4.2 describes annotation of items with linguistic, test, and context features used as inputs in the prediction model. Section 4.3 describes how embeddings are generated from pre-trained LLMs. Finally, Section 4.4 then describes how these inputs are used to predict item difficulty using a penalized regression model.

4.1 Rescaling p-values

We use publicly available estimates of average student abilities across grades to convert average p-value to a common vertical scale. Appendix C shows the NWEA MAP 2020 reading scale⁴, which reports mean grade-level achievement norms for over 500,000 students attending public schools across 50 states. These average scores are used to transform the p-values from a specific grade to a scale that can then be used for direct comparison; for example, on our derived scale the 3rd grade item with a p-value of 0.6 will have a lower value than the 8th grade item with a p-value of 0.6 given the growth from 200.74 to 220.93 observed on the NWEA scale.

³Discussed in Chapter 14 in Crocker and Algina (1986)

⁴<https://www.nwea.org/uploads/2020/02/NY-MAP-Growth-Linking-Study-Report-2020-07-22.pdf>

4.1.1 Rescale p-values to IRT difficulty

To rescale the p-values to the logit scale, we take advantage of a basic feature of 1PL IRT models (von Davier, 2016) that suggests a relationship between such p-values and item-person characteristics:

$$\Pr(y = 1) = p_{ij} = \sigma(\theta_i + b_j) \quad (1)$$

where θ is the relevant person ability, b is the item easiness, and σ is a sigmoid function (the logistic sigmoid, $\sigma(x) = \frac{1}{1+\exp(-x)}$, which we also use here). Note that we predict item easiness rather than item difficulty, to remain consistent with the original dataset, which reports p-values as measures of easiness. We don't have access to the relevant θ_i and b values that generated the data here, but we utilize the fact that they, in particular average θ values by grade level, are publicly reported for similar groups. We thus do the following. We denote the mean ability for students in a given grade (using values in Appendix C) as $\bar{\theta}_g$. For each item j given to students in grade g , we can calculate easiness b_j based on the relationship between the p-value p_j and the above Equation 1. Specifically, we solve for b_j such that

$$p_{ij} = \frac{1}{1 + \exp(-(\bar{\theta}_g + b_j))} \quad (2)$$

$$\iff b_j = -\bar{\theta}_g + \log\left(\frac{p_j}{1 - p_j}\right) \quad (3)$$

We use the resulting b_j values in our subsequent modeling.

4.1.2 Adjustment Results

In the analysis below, $\bar{\theta}_g$ is drawn from the NWEA Spring 2020 reading vertical scale. Figure 1 shows the results of the adjustment process. The top panel shows grade-level mean b_j values for NY and Texas, mapped from p-values using $\bar{\theta}_g$ from NWEA 2020 reading achievement scores. The bottom panel shows the distribution of the unadjusted and adjusted p-values by grade. The unadjusted mean p-values (bottom left panel) are all distributed around 0.6 with no increasing pattern as grade levels increase. This pattern is adjusted on the logit scale in the bottom right panel. Note that adjusted Grade 3 items are easiest on average, while Grade 8 items are hardest. Hence, an average p-value of 0.6 for Grade 3 corresponds to 0.3 on the adjusted scale, and maps to -1.69 for Grade 8.

Note one critical fact. The values on the y-axis in Figure 1 are based on the NWEA Scale in Appendix C. While the NWEA scale is a high-quality

Figure 1: Conversion of p-value to IRT Easiness by Grades

Note. (Top): Conversion of p-value to IRT scale by Grade; (Bottom Left): Unadjusted p-values by Grades; (Bottom Right): Adjusted Mean Easiness by Grades on the Logit Scale

scale derived from large samples, it is one of several scales that could provide a common metric across grades (Dadey and Briggs, 2012). Given that this choice of $\bar{\theta}_g$ is somewhat arbitrary, we consider a range of potentially plausible $\bar{\theta}_g$ values in ancillary robustness analyses (discussed in Appendix G).

4.2 Annotation of item bank

Items are annotated with three categories of features: context, test characteristics, and linguistic text analysis measures.

4.2.1 Context Features

Respondent context characteristics are expected to be some of the most important predictors of difficulty. In this dataset, the context variables are the state, year, and grade of respondents, for which average difficulty values are reported.

4.2.2 Test Features

Test features refer to the presentation or design elements in a test which could influence response. For the passage, this includes the use of highlighted (bolded, italicized, or underlined) text to emphasize important elements. For questions, this refers to the use of highlighted text (e.g., the use of bold text

in “6. Which sentence **best** states the main idea of ‘Around the World’?”), or inclusion of relevant text or sentences from the reading passage. For example, in the following question, the sentence in bold is repeated from the passage: “Read this sentence from paragraph 6. **‘Traveling east across the Atlantic, Nellie took just one bag to move quickly.’** How is this detail important to paragraph 1?”. The inclusion of these test characteristics is captured as indicator variables (=1 when given test feature is present in the item). Appendix D lists the variables that capture relevant test characteristics about an item.

4.2.3 Text Analysis Features

Measures of linguistic complexity of reading passages are generated using Coh-Metrix software package and included as predictors for the analysis (Appendix E). The indicators are divided into the following categories: (1) Descriptive metrics, such as count of paragraphs, count of sentences, mean number of words in a sentence, and number of letters or syllables in a word (2) Readability metrics, such as Flesch-Kincaid score and Coh-Metrix L2 Readability (3) Ease of reading or text “easability”, estimated through principal components analysis

(PCA) components, measuring syntactic simplicity, vocabulary concreteness, referential cohesion, and deep cohesion (4) Text cohesion, where more cohesive texts are easier to read; measured by word overlap across text or semantic overlap in text (5) Deep cohesion in text, measured by use of causal verbs like *although* and *overall*, (6) Syntactic complexity, measured by use of more complex syntax such as density of noun phrases or syntax similarity of complex sentences (7) Word complexity, based on word frequency or psychological traits of words such as age of acquisition. These measures are generated by the Coh-Metrix software (McNamara et al., 2014), except for the Flesch-Kincaid score (generated by readability package in Python⁵), and count of paragraphs in passage and word count of passage, which was generated in R.

4.3 Sentence Embedding from Large Language Models

LLM-generated embeddings for question text and distractors are used as predictors in difficulty modeling. Distractors are tagged with correct answer or wrong answer as appropriate. The question text, correct answer and distractors, and passage are merged into one input string, for which embeddings are generated (Appendix F). We experiment with BERT (Devlin et al., 2018), ModernBERT base model with 149M parameters (Warner et al., 2024) and LLaMA-3.1-8B (Dubey et al., 2024) for the generation of sentence embeddings.

To generate embeddings from ModernBERT⁶ and BERT⁷, each item is converted to a statement by merging the question text and available options as follows: (1) question text (2) a tag for correct answer, followed by the correct option (3) a tag for wrong answer, followed by the first wrong answer in the question. This is repeated for the remaining wrong answers (4) Reading passages. The objective is to capture interactions between the passage, question text, and distractors. The BERT tokenizer is used to convert these sentences into token IDs. The embeddings are derived from the last hidden state of the model. Specifically, for each sentence, we determine the position of the last meaningful token by identifying the index of the final non-padding token. The hidden state of the

final token is extracted. Each sentence produces a tensor whose size depends on the number of tokens times the embedding dimension. Because sentence lengths vary, these tensors are averaged across tokens to produce fixed-size embeddings (768 for BERT and ModernBERT, 4096 for LLaMA). This tensor is the final embedding output for the item. The dimensionality of these embeddings is also compressed using PCA to capture 80% of variation. PCA on embeddings also makes it harder to recover the question text and options from the embeddings, which would be a test security concern for high-stakes tests.

We also experimented with other methods of generating embeddings from BERT by removing the reading passage from the text input to tokenizer. We also generate cosine similarity between correct answer and wrong answers as new predictor variables. The results have some sensitivity to the method of embedding generation, but main conclusions do not change (Appendix G, Table 9).

4.4 Prediction Model

Item-level difficulty (i.e., b_j from Eqn 3) is predicted through a Ridge (L_2) penalized regression that tuned the regularization penalty parameter (λ)⁸ via 5-fold cross-validation (repeated and averaged 5 times with a 80% train, 20% test split). All predictor variables are centered at 0 with standard deviation set to 1. The performance of the prediction models is measured by two indicators: RMSE, and Pearson Correlation Coefficient between the true (y_j) and predicted outcome ($\hat{y}_j$) variable (AlKhuyaey et al., 2023). RMSE is sensitive to the training dataset, and hence is meaningful only for within-dataset model comparisons. The correlation coefficient, however, is better suited for benchmarking this model against results reported in the literature.

5 Results

The predictors include the following categories of variables: (1) context characteristics of state, grade, and year (2) test characteristics (3) linguistic features of reading passage and item (4) LLM-generated embeddings (either the full set of embeddings or PCA components that capture 80% of the variation). The baseline model for comparison sets the predicted difficulty to the mean difficulty for

All features & ModernBERT embeddings	0.57	0.61	0.78	0.77
All features & PCA on ModernBERT embeddings	0.52	0.59	0.81	0.77

Note. Outcome variable is easiness drawn from IRT scale based on NWEA MAP Reading scale Spring 2020

the item; this baseline RMSE was 0.92. This serves as a comparison point for model performance as measured by RMSE, which are dependent on the sample data set.

5.1 Prediction results from annotated features and embeddings

The best performing model uses all available features and PCA on embeddings from ModernBERT or LLaMA (Table 1). The best RMSE on test data is 0.59 and correlation between true and predicted easiness is 0.77.⁹ It is not surprising that the best model uses all available features for prediction. We also note that PCA on embeddings performs marginally better than actual embeddings; this is likely because of the small dataset size compared to the number of predictors.

⁹Appendix G reports the results when other vertical scales are used to convert p-values to IRT easiness: for different scales, RMSE varies between 0.53 and 0.61, and correlation varies between 0.75 and 0.85. The RMSE is 3.24 and the correlation is 0.96 when different scales are used for pre- and post-2020 years. This is not strictly comparable with other results which use the same scales for all years

5.2 Prediction results from LLM embeddings only

Results from only LLM embeddings, without using any respondent context characteristics or linguistic analysis of text, are close to the best model (Table 1). The correlation of true and predicted difficulty is 0.76 for ModernBERT with an RMSE of 0.62. When all additional features are added, model performance increases marginally for RMSE to 0.61 and correlation to 0.77. BERT and LLaMA show slightly bigger improvements in model performance when all features are added: RMSE decreases from 0.66 when only BERT embeddings are included to 0.64 when all features are included; the correlation between true and predicted difficulty in the test dataset increases from 0.71 to 0.74. For LLaMA, RMSE decreases from 0.66 to 0.61, and correlation increases from 0.70 to 0.76.

5.3 Prediction results from annotated features

Model performance for annotated features (context, test, and text analysis) is also close to the best model. This is largely because of the text analysis features, which are able to predict item difficulty, suggesting that LLMs and text analysis features may be capturing similar information. Text

analysis features offer the added benefit of being interpretable by humans and require less computation power, which may be an advantage over using LLMs.

Examining the standardized ridge regression coefficients reveals which features are most important for prediction (Appendix F.2, Table 7). Among text analysis features, the strongest predictors are measures of referential cohesion and syntactic complexity. Specifically, noun phrase overlap between adjacent sentences (CRFANP1) and noun phrase density (DRNP) are the two largest predictors, both negatively associated with item easiness — passages with denser and less cohesive noun phrase structure tend to produce harder items. Among word-level features, higher word frequency (WRD-FRQa) and greater imageability of content words (WRDIMGc) are both associated with easier items. Notably, traditional readability metrics such as Flesch-Kincaid rank poorly relative to these deeper linguistic features, suggesting that surface-level readability scores commonly used in educational practice may be insufficient for capturing item difficulty.

The overall prediction power of test features by themselves is low, as would be expected given there are only four such variables. However, one test feature appears among the top predictors overall: the presence of highlighted text in the question (*ques_text_highlight_yn*) is positively associated with item easiness, consistent with prior work suggesting that question-level presentation cues help students locate relevant information in the passage.

It is also important to note that these features can predict difficulty without including context characteristics (state, grade, year). These models could hence be used to predict average item difficulty before extensive field pilots, potentially reducing costs.

5.4 Automatic generation of items

The item difficulty model powers the Automatic Item Generator (<https://item-generator-production.up.railway.app/>), a web-based, human-in-the-loop tool that leverages the Claude API for item creation, along with the option for manual edits by users. This system facilitates the creation of assessment materials by (1) Item Generation: Reading items are generated by the Claude generative AI agent, using the existing item bank as context for generation. (2) Difficulty Calibration: Item difficulty scores are calculated on a logit scale

using ModernBERT embeddings.

The tool allows for specific parameter adjustments, including the target grade level, passage length, and the number of distractors. It also supports custom context, enabling researchers to integrate their own item generation manuals. Without additional prompting, the tool generates a synthetic dataset that mirrors the characteristics of standardized test items from New York and Texas.

6 Discussion

This paper aims to predict item difficulty using its text content. This approach bridges the gap between manual item creation and modern computational methods, providing insights into the nuanced interplay between text complexity and student response behaviors. The study underscores the transformative potential of transformer-based models, which can generate meaningful representations of items without fine-tuning or additional context information. By rescaling difficulties using IRT and vertical ability scales, the study addressed the challenge of comparing average difficulty across grades, offering a scalable solution when there is no common population or anchor items for traditional test equating and linking approaches. This item difficulty prediction model could be useful for stakeholders like teachers or testing firms, who would be interested in creating items with desirable item properties like difficulty. For instance, an item generated through generative AI could be assigned a difficulty score using this model; this could then be used to assemble appropriate tests.

Our model demonstrated strong performance in estimating item difficulty, achieving a correlation coefficient of 0.77 between predicted and observed difficulty - a result obtained both by ModernBERT embeddings alone and by models combining all available features with LLM embeddings. To the best of our knowledge, this correlation between true and predicted difficulty is one of the best for multiple-choice reading comprehension test items. The RMSE is high, but we expect that it is a function of the constraints of the dataset; the dataset we use is relatively small and the outcome variable is average item difficulty converted to a logit scale. The best model also reduces RMSE from a baseline value of 0.92 to 0.59. Other work that predicts difficulty as a continuous measure reports Pearson's correlation between 0.38 and 0.4 (Huang et al., 2017) and a reduction in RMSE from 23.65

to 22.45 (Ha et al., 2019).

The best results were obtained for the models that combined text analysis and human generated features with LLM embeddings. Surprisingly, in our dataset, using LLM-based embeddings or text analysis features was close to the best performing model. These findings suggest that LLMs could predict item difficulty without additional linguistic analysis or human annotations. Embeddings were generated from three models, BERT, ModernBERT and LLaMA; the results are also similar for the three LLM models. LLaMA embeddings were computationally more expensive to generate but their model performance was better. ModernBERT achieved the best performance, suggesting it might be best suited to such an item difficulty modeling task. BERT's strong performance despite being the simplest model could be a function of the limited size of the dataset, where variations in embedding generation might not lead to improvements in results.

Limitations

While the findings affirm the utility of automated methods, they also highlight several limitations of static embeddings in fully capturing dynamic student interactions. First, the reliance on state-specific datasets from New York and Texas may limit the generalizability of the findings to other educational contexts or student populations. Second, the embeddings generated from LLMs are dependent on pre-trained models that may not be optimally tuned to K-12 educational texts or standardized test items, potentially missing domain-specific nuances. Lastly, the model's predictions are based on aggregated item difficulty, which may oversimplify individual differences in student abilities or test-taking contexts.

Future research should focus on expanding the dataset to include diverse state tests and international benchmarks, such as PISA or data high-stakes tests, to enhance the robustness and applicability of the model. Additionally, fine-tuning LLMs on domain-specific corpora could further improve their ability to capture educational nuances. A comprehensive evaluation of item difficulty prediction should explore its impact on downstream tasks, such as automated item generation and field testing, to validate the practical utility of the proposed model in educational settings. Last, but perhaps most important, this model could be used by teach-

ers or test creators to get early feedback on item properties.

Ethical Considerations

The use of automated tools in educational assessment raises important ethical considerations. Item difficulty prediction models, including the one presented here, should be understood as decision-support tools rather than replacements for human judgment. Decisions about item inclusion, exclusion, or revision in high-stakes assessments should remain with qualified subject matter experts, psychometricians, and assessment professionals who can evaluate item quality in context.

The automatic item generation tool described in this paper is intended to assist practitioners in creating reading comprehension items more efficiently. However, items generated by any AI system require careful human review before use in consequential testing contexts. Automated generation does not guarantee that items are free from bias, culturally appropriate, or aligned with specific curriculum standards. Practitioners using such tools should be aware that generated items may reflect patterns and assumptions present in the training data, which in this case is drawn from two specific US state assessments. There is also a risk that over-reliance on difficulty prediction models could narrow the range of items developed, if practitioners consistently target items predicted to fall within a specific difficulty range.

A Item Counts by State, Grade, and Year

Table 2: Count of Items for Grades by State and Year

State	Grade	Item counts by year					Total
		2018	2019	2021	2022	2023	
NY	Grade 3	12	12		12	17	53
NY	Grade 4	12	12		12	17	53
NY	Grade 5	21	21		21	19	82
NY	Grade 6	21	21		21	19	82
NY	Grade 7	21	21		21	26	89
NY	Grade 8	21	21		21	26	89
Texas	Grade 3		34	28	34		96
Texas	Grade 4		32	32	32		96
Texas	Grade 5		29	34	34		97
Texas	Grade 6		36	36	36		108
Texas	Grade 7		37	37	38		112
Texas	Grade 8		40	39	40		119
Total		108	316	206	322	124	1076

B Mean Percent Correct Response (p-values) by State, Grade, and Year

Table 3: Mean Percent Correct Response (p-values) by State, Grade, and Year

State	Grade	Mean percent correct by year				
		2018	2019	2021	2022	2023
NY	Grade 3	0.60	0.65		0.65	0.60
NY	Grade 4	0.58	0.57		0.64	0.56
NY	Grade 5	0.62	0.64		0.65	0.60
NY	Grade 6	0.67	0.65		0.67	0.58
NY	Grade 7	0.55	0.60		0.66	0.59
NY	Grade 8	0.70	0.62		0.64	0.61
Texas	Grade 3		0.68	0.62	0.68	
Texas	Grade 4		0.66	0.62	0.70	
Texas	Grade 5		0.70	0.68	0.74	
Texas	Grade 6		0.64	0.64	0.65	
Texas	Grade 7		0.67	0.65	0.70	
Texas	Grade 8		0.70	0.67	0.71	

C NWEA Spring 2020 Reading Student Achievement Norms

Table 4: NWEA Spring 2020 Reading Student Achievement Norms by Grade

Grade	Score
Grade 3	200.74
Grade 4	204.83
Grade 5	210.19
Grade 6	215.36
Grade 7	216.81
Grade 8	220.93

D Passage and Item Characteristics Variables

Table 5: Variables: Passage and Item Characteristics

Variable	Description
item_order	Number indicating the order in which item appears after a passage
pass_highlight_yn	Indicator (1/0) if the passage text is highlighted
ques_text_ref_yn	Indicator (1/0) if the question text includes relevant paragraphs or sentences from text
ques_text_highlight_yn	Indicator (1/0) if the question text includes text in bold or underlined

E Variables Used as Predictors

E.1 Linguistic Features

Table 6: Table of Measures and Descriptions

Measure	Description
Descriptive metrics	
PassageWordCount	Word count of the passage
DESPC	Paragraph count, number of paragraphs
DESSC	Sentence count, number of sentences
DESPL	Paragraph length, number of sentences in a paragraph, mean
DESPLd	Paragraph length, number of sentences in a paragraph, standard deviation
DESSL	Sentence length, number of words, mean
DESSLd	Sentence length, number of words, standard deviation
DESWLsy	Word length, number of syllables, mean
DESWLsyd	Word length, number of syllables, standard deviation
DESWLlt	Word length, number of letters, mean
DESWLltd	Word length, number of letters, standard deviation
Readability metrics	
FK	Flesch-Kincaid score
RDFRE	Flesch-Kincaid Reading Ease
RDFKGL	Flesch-Kincaid Grade level
RDL2	Coh-Metrix L2 Readability
Text reading “easability”: Principal Components analysis mapped to dimensions of reading ease i.e., syntactic simplicity, word concreteness, referential cohesion, deep cohesion, verb cohesion, connectivity, and temporality	
PCNARz	Text Easability PC Narrativity, z score (e.g., tells a story)
PCNARp	Text Easability PC Narrativity, percentile
PCSYNz	Text Easability PC Syntactic simplicity, z score (e.g., sentences contain fewer words and simpler sentences)
PCSYNp	Text Easability PC Syntactic simplicity, percentile
PCCNCz	Text Easability PC Word concreteness, z score (e.g., more concrete words)
PCCNCp	Text Easability PC Word concreteness, percentile
PCREFz	Text Easability PC Referential cohesion, z score (e.g., words or ideas repeat across text)
PCREFp	Text Easability PC Referential cohesion, percentile
PCDCz	Text Easability PC Deep cohesion, z score (e.g., text contains causal and intentional connectives that aid with comprehension)
PCDCp	Text Easability PC Deep cohesion, percentile
PCVERBz	Text Easability PC Verb cohesion, z score (e.g., overlapping verbs in text)
PCVERBp	Text Easability PC Verb cohesion, percentile
PCCONNz	Text Easability PC Connectivity, z score (e.g., contains explicit adversative, additive, and comparative connectives)
PCCONNp	Text Easability PC Connectivity, percentile
PCTEMPz	Text Easability PC Temporality, z score (e.g., text has cues about temporality such as tense and aspect)
PCTEMPp	Text Easability PC Temporality, percentile
Referential cohesion: Word overlap across text, measured by indices of word and sentence overlaps	
CRFNO1	Noun overlap, adjacent sentences, binary, mean
CRFAO1	Argument overlap, adjacent sentences, binary, mean
CRFSO1	Stem overlap, adjacent sentences, binary, mean

Measure	Description
CRFNOa	Noun overlap, all sentences, binary, mean
CRFAOa	Argument overlap, all sentences, binary, mean
CRFSOa	Stem overlap, all sentences, binary, mean
CRFCWO1	Content word overlap, adjacent sentences, proportional, mean
CRFCWO1d	Content word overlap, adjacent sentences, proportional, standard deviation
CRFCWOa	Content word overlap, all sentences, proportional, mean
CRFCWOad	Content word overlap, all sentences, proportional, standard deviation
Referential cohesion: Semantic overlap in text measured by Latent Semantic Analysis	
LSASS1	LSA overlap, adjacent sentences, mean
LSASS1d	LSA overlap, adjacent sentences, standard deviation
LSASSp	LSA overlap, all sentences in paragraph, mean
LSASSpd	LSA overlap, all sentences in paragraph, standard deviation
LSAPP1	LSA overlap, adjacent paragraphs, mean
LSAPP1d	LSA overlap, adjacent paragraphs, standard deviation
LSAGN	LSA given/new, sentences, mean
LSAGNd	LSA given/new, sentences, standard deviation
Lexical diversity: Variety of words in a given text. Lexical diversity is lower and cohesion is higher when words are repeated across text	
LDTTRc	Lexical diversity, type-token ratio, content word lemmas
LDTTRa	Lexical diversity, type-token ratio, all words
LDMTLD	Lexical diversity, MTLTLD, all words
LDVOCD	Lexical diversity, VOCD, all words
Connectives: Incidence of connectives per 1000 words, which reflects cohesive links between ideas and text organization. Cohesion is higher when there is greater incidence of connectives.	
CNCAI	All connectives incidence
CNCCaus	Causal connectives incidence (e.g., <i>because, so</i>)
CNCLogic	Logical connectives incidence (e.g., <i>and, or</i>)
CNCADC	Adversative and contrastive connectives incidence (e.g., <i>although, whereas</i>)
CNCTemp	Temporal connectives incidence (e.g., <i>first, until</i>)
CNCTempx	Expanded temporal connectives incidence
CNCAdd	Additive connectives incidence (e.g., <i>and, moreover</i>)
CNCPos	Positive connectives incidence (e.g., <i>also, moreover</i>)
CNCNeg	Negative connectives incidence
Situation model: Representations of deeper meaning in text using Lexical Semantic Analysis and WordNet	
SMCAUSv	Causal verb incidence (e.g., <i>although, whereas</i>)
SMCAUSvp	Causal verbs and causal particles incidence
SMINTEp	Intentional verbs incidence
SMCAUSr	Ratio of causal particles to causal verbs
SMINTER	Ratio of intentional particles to intentional verbs
SMCAUSlsa	LSA verb overlap
SMCAUSwn	WordNet verb overlap
SMTEMP	Temporal cohesion, tense and aspect repetition, mean
Syntactic complexity: Includes measures of complex syntax in text and Syntactic Pattern Density; where higher density reflects more informational dense text with more complex syntax	
SYNLE	Left embeddedness, words before main verb, mean
SYNNP	Number of modifiers per noun phrase, mean
SYNMEDpos	Minimal Edit Distance, part of speech
SYNMEDwrd	Minimal Edit Distance, all words
SYNMEDlem	Minimal Edit Distance, lemmas

Measure	Description
SYNSTRUTa	Sentence syntax similarity, adjacent sentences, mean
SYNSTRUTt	Sentence syntax similarity, all combinations, across paragraphs, mean
DRNP	Noun phrase density, incidence
DRVp	Verb phrase density, incidence
DRAP	Adverbial phrase density, incidence
DRPP	Preposition phrase density, incidence
DRPVAL	Agentless passive voice density, incidence
DRNEG	Negation density, incidence
DRGERUND	Gerund density, incidence
DRINF	Infinitive density, incidence
Word complexity: information about parts of speech (e.g., relative frequency of types of word categories such as nouns, verbs and adverbs), word frequency (e.g., frequency of words used in text in CELEX database), and word complexity based on psychological ratings (e.g., age of acquisition of words, word concreteness)	
WRDNOUN	Noun incidence
WRDVERB	Verb incidence
WRDADJ	Adjective incidence
WRDADV	Adverb incidence
WRDPRO	Pronoun incidence
WRDPRP1s	First person singular pronoun incidence
WRDPRP1p	First person plural pronoun incidence
WRDPRP2	Second person pronoun incidence
WRDPRP3s	Third person singular pronoun incidence
WRDPRP3p	Third person plural pronoun incidence
WRDFRQc	Word frequency for content words using CELEX database, mean
WRDFRQa	CELEX Log frequency for all words, mean
WRDFRQmc	CELEX Log minimum frequency for content words, mean
WRDAOAc	Age of acquisition for content words, mean
WRDFAMc	Familiarity for content words, mean
WRDCNCc	Concreteness for content words, mean
WRDIMGc	Imagability for content words, mean
WRDMEAc	Meaningfulness, Colorado norms, content words, mean
WRDPOLc	Polysemy for content words, mean
WRDHYPn	Hypernymy for nouns, mean
WRDHYPv	Hypernymy for verbs, mean
WRDHYPnv	Hypernymy for nouns and verbs, mean

F Predictors for Item Difficulty Model

F.1 Visual representation of predictors in Item Difficulty Model

The figure shows a sample item from New York 2019 Grade 4 test. The box “**Input text for generating embeddings**” demonstrates how the passage and item is converted into a sentence. Embeddings are generated for this sentence. The boxes on the right show samples of annotated features for the item: **Linguistic features** shows some examples of text analysis of the reading passage. **Test features** show the relevant item design elements. **Context features** capture the item’s year, state, and targeted grade.

Figure 2: Predictors for Item Difficulty Model: Input Text to Generate Embeddings, and Linguistic, Test, and Context Features

F.2 Top predictors of Item Difficulty from Ridge Regression

Table 7: Top 20 Predictors of Item Difficulty from Ridge Regression (Text Analysis and Human-Annotated Features)

Rank	Variable	Coefficient	Absolute Value
Referential Cohesion			
1	CRFANP1 (Noun phrase overlap, adjacent sentences)	−0.127	0.127
14	LSAPP1 (LSA overlap, adjacent paragraphs)	−0.065	0.065
15	LSAGNd (LSA given/new, sentences SD)	+0.065	0.065
16	LSASS1 (LSA overlap, adjacent sentences)	+0.063	0.063
Syntactic Complexity			
2	DRNP (Noun phrase density)	−0.123	0.123
5	SYNNP (Modifiers per noun phrase)	−0.106	0.106
7	SYNMEDlem (Minimal edit distance, lemmas)	+0.104	0.104
19	DRGERUND (Gerund density)	+0.056	0.056
Descriptive Metrics			
3	DESSC (Sentence count)	+0.109	0.109
9	DESPC (Paragraph count)	−0.093	0.093
12	DESWC (Passage word count)	−0.069	0.069
20	PassageWordCount.gen (Passage word count, generated)	−0.056	0.056
Test Features (Human Annotated)			
4	ques_text_highlight_yn (Question text contains highlight)	+0.108	0.108
Connectives			
6	CNCNeg (Negative connectives incidence)	+0.104	0.104
10	CNCADC (Adversative & contrastive connectives)	−0.077	0.077
Word Complexity			
8	WRDFRQa (Word frequency, all words)	+0.097	0.097
11	WRDIMGc (Imageability, content words)	+0.070	0.070
13	WRDNOUN (Noun incidence)	+0.066	0.066
Situation Model			
17	SMCAUSwn (WordNet verb overlap)	+0.063	0.063
18	SMINTEp (Intentional verb incidence)	+0.061	0.061

Note. Coefficients are from a Ridge (L2) regression predicting IRT-scaled item easiness. All predictors are standardized (mean = 0, SD = 1). Positive coefficients indicate association with easier items; negative coefficients indicate association with harder items. Only text analysis and human-annotated features are shown; embedding predictors are excluded as their coefficients are not directly interpretable.

G Robustness Checks

G.1 Robustness to Choice of Grade-Level Growth Scale

This section examines the robustness of results to selecting an alternate vertical scale to convert p-values to IRT difficulty. Table 8 describes alternate scales that could be used: NWEA 2015 MAP reading achievement standard (reported separately for literary texts and informational text), NWEA 2020 reading achievement as measured in Fall or Winter, Texas STAAR 2023-24 performance standards (“approaches grade-level”, “meets grade level”, and “masters grade level” performance), and Texas STAAR 2017-18 readiness standard. These different scales were selected to account for differences in state contexts, as well as differences in grade level scales before and after 2020.

Results for test RMSE, as well as correlation between true and predicted RMSE are shown in Figure 3. We note that the results presented in the main section are conservative and do not fluctuate drastically with choice of scale. The greatest variation is observed when we use NWEA Informational Text 2015 scale for 2018 and 2019, and the NWEA 2020 Spring scale for 2021 to 2023. The RMSE increases to 3.24, likely due to the introduction of variation across years. However, correlation between true and predicted difficulty also increases to 0.96. Since it is difficult to obtain precise estimates of the change in vertical grade level scales before and after 2020, these results are not highlighted in the main paper.

Table 8: Alternate Vertical Growth Scales: NWEA MAP 2015, NWEA MAP 2020 and Texas Meets Grade Level Performance 2023-24

Grades	NWEA 2015		NWEA 2020			Texas STAAR 2023-24			Texas 2017-18
	Literary Text	Informational Text	Fall	Winter	Spring	Approaches grade-level	Meets grade-level	Masters grade-level	Readiness standard
Grade 3	192.4	191.6	186.62	195.91	200.74	1345	1467	1596	1386
Grade 4	201.2	200.7	196.67	202.5	204.83	1414	1552	1663	1473
Grade 5	207.9	207.4	204.48	210.19	210.98	1471	1592	1700	1508
Grade 6	212.3	212.1	210.17	213.81	215.36	1535	1634	1749	1554
Grade 7	216.3	216.1	214.2	217.09	216.81	1564	1669	1771	1603
Grade 8	220.0	220.0	218.9	220.52	220.93	1592	1698	1803	1625

Figure 3: Robustness to Vertical Scale Choice

Note. (Left panel) Correlation of true vs predicted difficulty for test data; (Right panel) RMSE for true vs predicted difficulty. The main results reported in the paper use the NWEA Spring 2020 vertical scale, shown in red in the figure. Note that results reported in the paper are conservative and not extremely sensitive to the choice of vertical scale.

G.2 BERT Embeddings: Robustness to Text Input Format

Table 9: BERT Model: Robustness of Prediction Results

	RMSE		Correlation	
	Train	Test	Train	Test
Main Results: Text input is Question + Correct answer + Wrong answers + Passage				
LLM embeddings: BERT	0.60	0.66	0.76	0.71
Assessment characteristics, text analysis metrics, & BERT embeddings	0.60	0.64	0.76	0.73
Assessment characteristics, text analysis metrics, & PCA on BERT embeddings	0.58	0.64	0.76	0.72
Alternate Results 1: Text input is Question + Correct answer + Wrong answers				
LLM embeddings: BERT	0.65	0.72	0.71	0.63
Assessment characteristics, text analysis metrics, & BERT embeddings	0.60	0.65	0.76	0.73
Assessment characteristics, text analysis metrics, & PCA on BERT embeddings	0.58	0.61	0.76	0.75
Alternate Results 2: Main results with Cosine Similarity Variables				
LLM embeddings: BERT	0.60	0.66	0.76	0.72
Assessment characteristics, text analysis metrics, & BERT embeddings	0.60	0.64	0.76	0.74
Assessment characteristics, text analysis metrics, & PCA on BERT embeddings	0.58	0.63	0.76	0.73

The main results report BERT embeddings generated for a statement that merges question text, correct answer, all wrong answers, and passage (Appendix F). The reading passage was removed from the statement used to generate BERT embeddings for Alternate Results 1 (Table 9). If the passage is relevant to how BERT embeddings capture information about the item, we would expect decline in model performance. We do observe this decline: RMSE increases from 0.66 for Main Results to 0.72 for Alternate Results 1, and correlation decreases from 0.72 to 0.63. However, prediction results are similar when human annotated features are included in the model, and when the model uses PCA on BERT embeddings instead of the full embeddings. This suggests that human annotated features might contain complementary information that compensates model performance. This is also interesting because BERT embeddings are generated using a section of the passage (sentence length is truncated at 512 characters). This suggests that a segment of passage still includes useful information; hence, the main results use embeddings generated with the passage included in the text input to the tokenizer.

We also include new predictor variables: cosine similarity is calculated between the embeddings for correct answer and each of the distractors. Embeddings are generated for the sentence that combines: (1) question text (2) a tag for correct/wrong answer, followed by the correct/wrong answer. Next, we calculate cosine similarity between the embeddings for the correct answer and each of the wrong answers, giving us three cosine similarity variables. These variables are included as predictors in the main model. These results are reported as Alternate Results 2. We note marginal improvement in performance between Main Results and Alternate Results 2, where RMSE decreases from 0.64 to 0.63, and correlation marginally improves from 0.72 to 0.73. This suggests that differences or similarities in BERT embeddings for correct answers and distractors don't explain item difficulty in the context of this dataset.

G.3 Results for Unadjusted p-values

This section presents the results for unadjusted p-values i.e., the p-values reported in the dataset that have not been adjusted for grade-level differences. As discussed in the methods section, this measure of difficulty does not have an inherent meaning. The results show a lower RMSE, likely because grade-level variation has not been accounted for. However, the correlation is also low (in the range of 0.10–0.3).

Table 10: Results for Predicting Item Difficulty: Outcome Variable is Unadjusted p-value

	RMSE		Correlation	
	Train	Test	Train	Test
Results from human annotated features				
State, Grade, Year	0.12	0.12	0.28	0.29
Test features	0.13	0.13	0.15	0.10
Text analysis features	0.12	0.13	0.36	0.11
Results from LLM embeddings only				
Only BERT embeddings	0.11	0.12	0.57	0.30
Only LLaMA embeddings	0.10	0.12	0.69	0.35
Results from LLM embeddings and annotated features				
All features & BERT embeddings	0.10	0.12	0.60	0.32
All features & PCA on BERT embeddings	0.12	0.12	0.46	0.25
All features & LLaMA embeddings	0.10	0.12	0.72	0.35
All features & PCA on LLaMA embeddings	0.12	0.12	0.46	0.25
All features & PCA on ModernBERT embeddings	0.12	0.12	0.45	0.25

Generative-Evaluative Agreement: A Necessary Validity Criterion for LLM-Enabled Adaptive Assessment

Grandee Lee and Yue Wang and Che Yee Lye and Luke Peh

Singapore University of Social Sciences,

463 Clementi Rd, 599494, Singapore

{grandeelee, wangyue, cylie, lukepeh1c}@suss.edu.sg

Abstract

When the same LLM generates assessment items, simulates student responses, and scores them, the validation loop is self-referential. We introduce **Generative-Evaluative Agreement (GEA)**, a validity criterion measuring whether an LLM’s scoring function recovers the skill levels its generative function was instructed to produce. In the first direct measurement of GEA on a two-stage adaptive assessment, the model recovers roughly half the intended variance ($r = 0.698$) with systematic positive bias. GEA is strong ($r > 0.7$) for syntactically verifiable skills but near zero for design-level skills, and low-skill overestimation inflates scores near the routing threshold. We argue that granular, skill-decomposed rubrics are the principal proposed mechanism for strengthening GEA and outline complementary mitigations.

1 Introduction

Computerized adaptive testing (CAT) traditionally relies on item banks pre-calibrated via Item Response Theory (IRT), where every item has known difficulty and discrimination parameters estimated from hundreds of real responses (van der Linden and Glas, 2010). LLM-enabled adaptive assessment disrupts this paradigm: items are generated dynamically, each student potentially receives a unique test, and classical calibration (requiring 50–200 respondents per item; Lord 1980) becomes infeasible. Revisions to rubrics, prompts, or course materials become psychometrically consequential when they change what is being measured, how performance is elicited, how responses are scored, or how scores are interpreted. In these cases, prior calibration and validity may no longer be transportable, and at least part of the item bank may need to be re-authored, relinked, re-calibrated, or revalidated (Han and Guo, 2011). In a typical school setting, learning outcomes are updated when

curricula evolve, rubrics are refined each semester as instructors identify ambiguities, and course restructuring changes the skill prerequisites for each assignment. LLM-based systems absorb these changes through prompt and rubric updates alone, but the validity of the resulting assessment must be re-established each time.

This creates a **bootstrapping problem**: the system cannot be validated without real student data, but cannot be deployed at scale without prior validation. Human review of each generated item is infeasible when the item space is effectively infinite, and the classical validity pipeline (pre-calibrate, validate against human raters, then deploy) does not apply. Simulation-based validation offers a pragmatic alternative. Liu et al. (2024) demonstrated that ensembles of LLM-simulated respondents can approximate human item calibration with correlations exceeding 0.89. Zheng et al. (2026) used Monte Carlo simulation to identify optimal CAT configurations before empirical evaluation. Marquez-Carpintero et al. (2025) reviewed LLM-simulated student profiles for pre-deployment testing of pedagogical systems. However, when the same LLM generates items, simulates student responses, and scores them, the validation loop is self-referential. If the model’s representation of skill levels is inconsistent across its generative and evaluative functions, the system validates itself against a distorted mirror.

This paper introduces **Generative-Evaluative Agreement (GEA)** as the formal criterion for this internal consistency: when an LLM generates a response at an intended skill level, does scoring recover that level? Valid routing decisions require scores that faithfully reflect the intended construct, but “intended difficulty” exists only in the model’s internal representation, accessed through two different computational paths (generation and evaluation) that traverse different prompt-conditioned regions of the same model. Empirical verification of

Figure 1: GEA measurement versus closed-loop self-validation. (a) In a pure closed loop, there is no external anchor and bias is invisible. (b) GEA introduces the intended skill level x as an external reference point. (c) When the generator inflates skill, GEA detects the discrepancy. (d) Bias is undetectable only if both functions share the exact same misconception, an unlikely scenario given that generation and evaluation traverse different prompt-conditioned paths.

their alignment is therefore a necessary (though not sufficient) validity condition for any LLM-based adaptive assessment that uses simulation for calibration.

1.1 Definition

Generative-Evaluative Agreement (GEA) is the degree to which an LLM’s generative representation of skill levels is consistent with its evaluative representation. Formally, if the model generates a response $\mathbf{r}$ conditioned on skill level x , then scoring $\mathbf{r}$ should recover x within acceptable error bounds:

$$\mathbb{E}[\text{score}(\mathbf{r}) \mid \mathbf{r} \sim \text{generate}(x)] \approx x \quad (1)$$

Here $x, \text{score}(\mathbf{r}) \in [0, 1]$ are continuous per-skill scores; ordinal proficiency bands (Appendix D) are derived post hoc for reporting.

We operationalise “ $\approx$ ” through two primary metrics: Pearson r for rank-order fidelity and signed bias for systematic directionality. We propose two actionable benchmarks: $r > 0.7$ (strong GEA) to support fine-grained proficiency reporting, and $r > 0.4$ (moderate GEA) to support binary routing decisions. Skills below $r = 0.4$ should not be used for adaptive routing without human validation.

Crucially, GEA measurement is *not* equivalent to closed-loop self-validation. Figure 1 illustrates the distinction. In a pure closed-loop system (panel a), the model generates and scores with no external reference, so any systematic bias is invisible. In GEA measurement (panel b), the intended skill level x serves as an external anchor. If the generator inflates skill (panel c), the discrepancy $\hat{x} \neq x$ reveals the generation bias. GEA can only fail to detect bias when both functions share the *exact same* misconception of x (panel d), which is unlikely given the empirical evidence of divergence reviewed in Section 2.2. Figure 2 shows the concrete assessment architecture in which GEA is measured.

2 Background

2.1 The Closed-Loop Problem

In traditional CAT, item parameters and scoring functions are independently validated against real human response data. In LLM-based adaptive systems, the model performs both roles with no external anchor. An instructive (though imperfect) analogy comes from the generative/discriminative distinction: Ng and Jordan (2001) showed that models learning $P(X \mid Y)$ and $P(Y \mid X)$ can disagree at finite capacity. In an LLM, both generation and evaluation share the same weights, but are conditioned on different prompts that traverse different computational paths. Generation is dominated by fluency priors; evaluation by criterion matching. Shared architecture makes alignment *plausible* but does not *guarantee* it (Oh et al., 2024; West et al., 2023).

2.2 Empirical Evidence of Divergence

LLMs struggle to simulate lower-proficiency cognitive states (Yuan et al., 2026): expert knowledge leaks through despite skill-level prompting. Srivatsa et al. (2025) tested 11 LLMs against real NAEP data and found no model-prompt pair faithfully reproduced real student distributions; Wu et al. (2025) confirmed this for Python programming. LLMs also systematically rate their own outputs higher than equivalent text from other sources (**self-preference bias**; Panickssery et al. 2024), with the mechanism identified as perplexity-based familiarity (Wataoka et al., 2024). Even proprietary models show low intra-rater consistency at temperature > 0 (Lee et al., 2024b). In simulation-based calibration, these mechanisms compound: the result may appear internally consistent but is not exter-

Figure 2: Adaptive assessment flow. The LLM generates assignments and scores responses at each stage. Routing depends on cumulative score $\bar{s}$ crossing threshold θ . GEA measures consistency between the LLM’s generative and evaluative functions.

nally valid.

2.3 Implications for Calibration

When simulation is the only feasible calibration method, GEA becomes the gatekeeper for trustworthiness. If GEA is low, score distributions reflect the model’s self-consistency rather than real student performance. Wang et al. (2025a) argue that Generalizability Theory and Many-Facet Rasch Measurement are needed to decompose multiple simultaneous error sources rather than collapsing them into a single coefficient. Even in real deployment, the generative side affects question generation: if items are at the wrong difficulty, routing decisions are based on mis-targeted items regardless of grading accuracy.

2.4 Related Work

GEA connects to several research threads. The automated essay scoring (AES) literature has studied inter-rater reliability for decades (Ramesh and Dash, 2022); GEA differs in that rater and author are the same model. From a psychometric perspective, GEA instantiates the *substantive* component of Messick’s (1989) construct validity framework, and aligns with the *Standards for Educational and Psychological Testing* (American Educational Research Association et al., 2014) requirement for evidence that scores support intended interpretations. The LLM-as-judge paradigm (Zheng et al., 2024) has documented self-preference and position bias; GEA extends this from evaluation-only settings to the generate-then-evaluate pipeline where generation bias compounds with evaluation bias.

3 Empirical Measurement of GEA

This section presents the empirical measurement of GEA in the sense defined in Section 1.1 for the concrete case of Python object-oriented program-

ming (OOP) coding tasks. The same Claude model performs both code generation and rubric-based evaluation against the 24-skill taxonomy (class definition, inheritance, exception handling, etc.; full list in Appendix B).

3.1 Simulation Design

Student profiles. We generated 150 synthetic student profiles, each comprising a 24-dimensional skill vector $\mathbf{x} \in [0, 1]^{24}$ corresponding to the official learning outcomes. (Table 2). Skills are grouped into four progressive groups: Group A (S01–S08, class basics), Group B (S01–S04, S06–S07, S09–S13, class variables and composition), Group C (S01–S04, S06, S09, S14–S21, inheritance and polymorphism), and Group D (S01, S14–S15, S22–S24, exception handling). For more details, see Appendix B. Profiles were sampled from 10 archetypes (e.g., “Absolute Beginner,” “Lab 2 Proficient,” “Advanced”) with Gaussian noise ($\sigma = 0.04$) to produce realistic within-archetype variation.

Assessment slots. Every student attempted all 6 assignment slots regardless of skill level, bypassing the adaptive routing to ensure full coverage: Each slot tests a designated subset of the 24 skills; non-applicable skills are marked -1.0 in the output vector and excluded from scoring. Scenario entities were assigned deterministically per student (seeded on student ID) to ensure reproducibility.

Generate-then-score protocol. For each (student, slot) pair, we executed two sequential API calls to Claude Sonnet 4.6:

1. **Generate:** Given the student’s full skill profile (24 skill scores with per-skill natural-language descriptors) and the assignment question, the model was prompted to produce

Table 1: Overall GEA statistics (7,788 paired skill observations, 150 students, 23 skills). 95% bootstrap CIs from 1,000 resamples.

Metric	Value	95% CI
Pearson r (pooled)	0.698	[.684, .712]
Mean bias (obs – true)	+0.059	[+.053, +.066]
Exact proficiency match	34.8%	

Python code that *precisely matches* the specified skill levels, including deliberate errors, omissions, and partial implementations for low-scoring skills.

2. **Score:** The generated code was submitted to the same model’s scoring function with the identical rubric, which returned a 24-element observed skill vector $\hat{\mathbf{x}} \in \{-1.0\} \cup [0, 1]^{24}$ and a scalar score $s = \text{round}(\text{mean}(\hat{x}_i : \hat{x}_i \neq -1) \times 100)$.

This yields paired observations $(x_i, \hat{x}_i)$ for every skill i that is applicable in a given slot, providing the raw material for measuring Equation 1.

Scale. All 150 students had completed all 6 slots producing 862 result records and 7,788 paired (true, observed) skill-level observations across 23 of 24 skills (S13, Dictionary Collection Management, was not tested in any slot). Table 1 summarises the aggregate agreement statistics.

4 GEA Findings

The pooled Pearson correlation of $r = 0.698$ indicates that the LLM’s evaluative function recovers roughly half the variance ($R^2 \approx 0.49$) in the true skill levels it was asked to generate. The positive mean bias of +0.059 confirms the direction predicted by self-preference bias: the model systematically overestimates the skill level of its own generated code.

At the proficiency-level granularity used for reporting (8 ordinal levels from *Not Demonstrated* to *Mastered*; boundaries in Appendix D), exact classification accuracy is only 34.8%, rising to 64.4% within ± 1 adjacent level. This represents moderate agreement, sufficient to distinguish broad skill bands but insufficient for fine-grained proficiency reporting.

4.1 Per-Skill GEA

GEA varies dramatically across skills. Table 2 presents the full per-skill breakdown, sorted by Pearson r . After Benjamini-Hochberg correction

Table 2: Per-skill GEA metrics, sorted by Pearson r . Skills marked with $\star$ are mandatory in the assessment rubric.

Skill		n	r	Bias

S21	Polymorphism	113	−.03	−.07
S20	Concrete Subclass	108	n/a	−.09

for multiple comparisons across 23 skills, 19 correlations remain significant at $\alpha = 0.05$; the four non-significant skills are precisely the near-zero GEA tier. Three tiers emerge:

Strong GEA ($r > 0.7$; 10 skills). Skills with concrete, syntactically verifiable indicators, such as setter validation logic (S05, $r = 0.88$), class variable declaration with underscore convention (S09, $r = 0.83$), exception raising (S23, $r = 0.80$), and composition via object attributes (S11, $r = 0.80$), show the strongest agreement. These skills have unambiguous code signatures: a `@attr.setter` with a conditional check, a `_count` class variable, a `raise CustomError()` statement. The rubric criteria map directly to syntactic patterns that both the generator and evaluator can reliably target.

Moderate GEA ($0.4 < r < 0.7$; 9 skills). Foundational skills tested across many slots (S01, S02, S04, S06) show moderate agreement ($r = 0.43$ – 0.65). These skills are near-universal in student code (almost every submission defines a class, writes a constructor, uses properties), creating a ceiling effect that compresses variance. Subclass-related skills (S14, S16) show moderate r but high bias (+0.21 to +0.25), indicating the generator systematically over-performs on inheritance tasks relative to the intended skill level.

Figure 3: Calibration curve: mean observed skill as a function of true proficiency band. Error bars show ± 1 SD. The dashed diagonal represents perfect calibration. The curve lies above the diagonal at low skill levels (overestimation) and converges at high levels.

Near-zero GEA ($r < 0.1$; 4 skills). Abstract design skills, including ABC definition (S19, $r = 0.08$), method overriding by replacement (S17, $r = 0.06$), polymorphism (S21, $r = -0.03$), and concrete subclass implementation (S20, constant output), show essentially no correlation between intended and observed skill levels. S20 is degenerate: the evaluator assigned nearly identical scores regardless of the true skill level, collapsing all variation. These skills require *design decisions* (choosing to define an ABC, choosing to use polymorphic dispatch) rather than *syntactic patterns*, making them harder for the generator to “partially implement” and harder for the evaluator to grade on a continuous scale.

This pattern (strong GEA for syntactically verifiable skills, weak GEA for design-level skills) is consistent with the scope limitation noted in Section 6: code assessment benefits from partially verifiable ground truth, but that benefit is concentrated in the syntactic stratum of the skill taxonomy. Design-level skills behave more like the subjective assessment domains where GEA is expected to be weakest.

4.2 Calibration and Bias Structure

The calibration curve (Figure 3) reveals an asymmetric bias:

- **Low-skill overestimation:** Students in the “Not Demonstrated” band (true ≈ 0.0) receive mean observed scores of ≈ 0.20 , a $+0.20$ bias. The LLM struggles to generate authentically incompetent code; even when instructed to

Figure 4: Row-normalised confusion matrix mapping true proficiency levels (rows) to observed proficiency levels (columns). The strong rightward bias in the “Approaching” through “Mastered” rows indicates systematic upward misclassification at higher skill levels.

omit a skill, the generated code tends to include partial or vestigial implementations that the evaluator detects.

- **High-skill convergence:** Students in the “Advanced” and “Mastered” bands (true > 0.80) are scored close to their true levels, with the curve approaching the diagonal. The model finds it easier to generate competent code and to recognise competence.
- **Mid-range compression:** The “Developing” through “Proficient” bands (0.45–0.80) show the highest variance (largest error bars), suggesting the model has difficulty maintaining fine-grained distinctions in the middle of the skill range.

This asymmetry has direct implications for adaptive routing. The system’s routing threshold (≥ 50 for High path) operates in the mid-range where calibration is poorest. The upward bias at low skill levels means that weak students are systematically overscored, making them more likely to exceed the threshold and be routed to the High path, exactly the misrouting scenario described in Section 6.

4.3 Proficiency-Level Classification

The confusion matrix (Figure 4) reveals the proficiency-level consequences of the biases identified above.

Upward collapse to “Mastered.” The dominant pattern is a strong rightward shift: students at “Approaching” (true 0.60–0.70) are classified as “Mastered” 50% of the time; “Proficient” (true 0.70–0.80) collapses to “Mastered” 67% of the time; “Advanced” (true 0.80–0.90) reaches 77%. The evaluator effectively treats any competent implementation as “Mastered,” failing to distinguish gradations within the upper half of the skill range. This is a direct manifestation of **self-preference bias**: the model’s own generated code, even when deliberately degraded, retains low perplexity from the evaluator’s perspective, inflating scores toward the ceiling.

Low-skill recovery. The “Not Demonstrated” level is the best-recovered category at 60% exact match, consistent with the observation that the absence of a skill (e.g., no `@property` defined at all) is a binary, syntactically verifiable condition. However, even here, 14% of truly absent skills are scored as “Beginning” and 9% as “Mastered,” the latter likely reflecting cases where the generator failed to suppress the skill despite being instructed to (competence paradox leakage).

Implications for proficiency reporting. The 8-level proficiency scale is not reliably recoverable through the generate-then-score pipeline. A coarser 3- or 4-level scale would better match the system’s effective resolution. For adaptive routing (threshold at 50), the upward bias at low skill levels ($+0.059 \times 100 \approx 6$ points) inflates Stage 1 scores for weak students, increasing misrouting probability to the High path.

5 Strengthening GEA

The empirical findings above reveal that GEA is partial and skill-dependent. This section examines the mechanisms available to strengthen it, beginning with the most impactful (granular rubrics) and progressing to complementary strategies that address failure modes rubrics alone cannot resolve.

5.1 Rubrics as Constrained Reasoning Paths

Section 2.1 identified the core architectural problem: generation and evaluation traverse different computational paths through the model with no guarantee of alignment. Granular rubrics address this by providing a **shared external specification** that constrains both paths to pass through the same intermediate representation, namely the rubric’s criteria.

Wang et al. (2025b) formalise this as a graph reasoning problem. Without rubrics, the path from task description to score can traverse arbitrary reasoning states. With rubrics, both generation (“produce code demonstrating these specific skills”) and evaluation (“check for these specific skills”) are forced through the same intermediate checkpoints. Under the assumption that aligning these intermediate nodes increases the overlap between the model’s generative and evaluative reasoning paths, rubric-guided assessment should exhibit higher GEA than holistic assessment.

In the context of this system, the rubric defines per-assignment skill vector tables specifying exactly which of the 24 skills are applicable to each assignment and what constitutes mastery. This provides structural decomposition: both the question generator and the response evaluator reference the same granular criteria, reducing the degrees of freedom available for the two paths to diverge. The three-tier GEA pattern in Table 2 provides indirect evidence for this mechanism: skills with unambiguous syntactic rubric criteria (e.g., “code contains a `@property` decorator”) show strong GEA, while skills with holistic criteria (e.g., “demonstrates appropriate use of polymorphism”) show near-zero GEA.

5.2 Empirical Support from the Literature

Rubric quality directly predicts scoring accuracy. Wu et al. (2024) found a Spearman rank correlation of $\rho = 0.94$ ($p < 0.01$) between analytic rubric alignment (with human-crafted rubrics) and automated scoring accuracy. Without rubrics, accuracy was 34.8%; with human-crafted analytic rubrics, 50.4%; with LLM-generated rubrics guided by holistic rubrics, 54.6%. The near-perfect correlation between rubric quality and scoring performance establishes that the evaluative path is strongly anchored by rubric specification. For GEA, this implies that the evaluative side of the agreement can be substantially improved through rubric design alone, without changing the model.

Rubric-aligned component extraction yields consistent gains. AutoSCORE’s two-agent design (first extract rubric-relevant components into a structured JSON representation, then score based on those components) improved QWK by up to 37% (Essay Set, GPT-4o) and 74% (Science, LLaMA-8B) over single-agent baselines (Wang et al., 2025b). Gains were largest on complex, multi-dimensional rubrics, which parallels this sys-

tem’s 24-skill vector with per-assignment coverage tables. The framework demonstrates that decomposing evaluation into criterion-level checks before holistic scoring reduces rubric misalignment and evaluator shortcuts. This system’s architecture already follows this pattern: the evaluator produces a 24-element skill vector before computing a scalar score.

Rubrics balance accuracy across proficiency levels. Lee et al. (2024a) found that Chain-of-Thought prompting combined with scoring rubrics yielded a 13.4% accuracy increase and, critically, more balanced accuracy across different proficiency categories. Without rubrics, LLMs were biased toward certain score ranges; with rubrics, scores distributed more evenly across levels. This directly addresses the calibration asymmetry observed in Figure 3: rubric-guided evaluation may reduce the systematic overestimation at low skill levels that currently inflates routing scores.

Rubrics prevent evaluator shortcuts. Wu et al. (2024) discovered that providing graded student responses (without rubrics) actually *degraded* rubric alignment; the LLM found superficial keyword shortcuts instead of following the intended reasoning chain. Analytic rubrics prevented this by requiring criterion-level assessment, forcing the model through the intended reasoning path rather than surface-level pattern matching. This finding is particularly relevant to GEA: without rubrics, the evaluator may assign high scores based on surface features (e.g., code length, presence of class definitions) rather than the specific skill indicators the generator was instructed to produce or omit.

Rubrics are therefore a **necessary but not sufficient** condition for GEA. They are the most practical strategy within a single-model system, but complete GEA assurance requires complementary measures to address failure modes that rubric design alone cannot resolve.

5.3 Design Principles for GEA-Strengthening Rubrics

Based on the findings above, rubrics that maximise GEA should:

1. **Decompose the construct into discrete, independently assessable skills**, each with a binary or ordinal mastery indicator (as in the 24-skill vector).
2. **Specify per-assignment applicability**: explicitly mark which skills are assessed and

which are not applicable, so neither generation nor evaluation drifts into unintended territory.

3. **Define decision boundaries, not just level descriptions**: specify what distinguishes mastery from non-mastery for each skill, not just what each level “looks like” holistically.
4. **Use structured output formats**: require the evaluator to produce criterion-level judgements (e.g., JSON skill vectors) before aggregating to a holistic score, following AutoSCORE’s component-extraction-then-scoring paradigm (Wang et al., 2025b).
5. **Avoid excessive verbosity**: structural clarity outperforms exhaustive description; long rubrics can degrade performance in some models (Yoshida, 2025).

5.4 Complementary Mitigations

While granular rubrics are the primary strategy for strengthening GEA, they cannot address all failure modes. The competence paradox (the generator producing overly competent code despite low-skill instructions) and self-preference bias (the evaluator inflating scores for model-generated text) require complementary interventions.

Cross-model evaluation. The most direct intervention is using a different model family to score responses than the one that generated them (e.g., generate with Claude, score with GPT-4). This breaks the self-preference loop whereby a model inflates scores for its own low-perplexity outputs (Panickssery et al., 2024). The perplexity-based mechanism identified by Wataoka et al. (2024) implies that cross-model evaluation should be most beneficial for the upper proficiency levels where self-preference bias is strongest (Figure 4). Where cross-model evaluation is impractical due to cost or API constraints, **multi-sample scoring** offers a partial substitute: scoring each response multiple times at non-zero temperature and flagging high-variance items for human review surfaces the stochastic inconsistency that single-pass scoring conceals (Korthals et al., 2026).

Epistemic state specification. On the generation side, the competence paradox can be mitigated by moving beyond naive role-prompting (“act as a beginner”). Yuan et al. (2026) propose using structured misconception inventories and knowledge component graphs that constrain the generative

path to produce behaviourally realistic responses. Rather than asking the model to simulate a general proficiency level, the prompt specifies which knowledge components the student has and has not acquired, which common misconceptions are active, and which error patterns should appear. This converts a vague instruction (“produce beginner code”) into a concrete specification that the generator can follow more reliably, directly improving the generative side of GEA.

Real-student pilot validation. Simulation-derived thresholds should be validated against a small real-student cohort before operational use, following standard psychometric practice. Even a pilot of 10–20 students on a subset of skills would provide an external anchor against which to calibrate the simulation’s bias estimates. This is particularly important for the routing threshold, where the +6-point upward bias identified in Section 4.2 may require adjustment before deployment.

6 Discussion

Threshold sensitivity. We swept the Stage 1 routing threshold θ from 30 to 70 (Table 3), re-routing 140 students with complete data (10 excluded due to incomplete Stage 2 records).

θ	Flip%	Adv%	Int%	Beg%	Mis%
30	10.7	66.4	26.4	7.1	45.0
40	7.1	43.6	45.0	11.4	41.4
50	0.0	24.3	60.0	15.7	34.3
60	5.7	15.7	62.1	22.1	28.6
70	18.6	8.6	56.4	35.0	18.6

Table 3: Threshold sensitivity sweep. Flip%: routing changes vs. baseline $\theta=50$. Mis%: fraction misaligned with true archetype ability.

A **stability plateau** spans $\theta \in [45, 55]$ (<5% flips). Misclassification decreases monotonically as θ rises (45% at $\theta=30$ to 19% at $\theta=70$) because the positive scoring bias pushes observed scores above true ability. However, at $\theta=70$ nearly one in five students would be reclassified. The baseline $\theta=50$ represents a pragmatic compromise within the stability plateau.

Decomposing GEA failure. When GEA is low, the deficit could stem from the generator, the evaluator, or both. For syntactically verifiable skills (e.g., S05, $r = 0.88$), unambiguous code signatures constrain both paths. For design-level skills (e.g., S21, $r = -0.03$), the generator likely over-produces

while the evaluator lacks binary markers to assess degree. Isolating each component requires human scoring of generated code or human-written code at specified skill levels.

Domain dependence. Code assessment occupies a privileged position because programming tasks have partially verifiable ground truth: a class either defines a @property or it does not. Subjective domains (essay argumentation, creative writing) lack these anchors, so GEA findings here likely represent an **upper bound**. The rubric-as-config architecture is domain-agnostic, but empirical GEA guarantees are domain-specific.

Model scaling. We repeated the full simulation using Haiku 4.5 with identical rubrics and profiles (Table 4).

Metric	Haiku 4.5	Sonnet 4.6
Signed bias (obs–true)	+0.31	+0.06
Pearson r (record-level)	0.64	0.92
Terminal Advanced (%)	88.0	24.1

Table 4: Model scaling comparison. Pearson r is computed at the *record level* ($n = 862$ assignment records), which averages across ~ 9 skills per record and is therefore higher than the pooled skill-level $r = 0.698$ in Table 1.

Haiku inflates scores by +17.6 points on average, scoring Absolute Beginners at 44.8 (vs. Sonnet’s 19.8), above the routing threshold, and assigning 88% of students to Advanced. The pooled r difference (Sonnet 0.698 vs. Haiku 0.447) is significant (Fisher $z = 23.8$, $p < 10^{-100}$). GEA is therefore **scale-dependent**: self-preference bias and the competence paradox are amplified at smaller scale.

7 Conclusion

We introduced Generative-Evaluative Agreement (GEA) as a necessary validity criterion for LLM-enabled adaptive assessment. Using 150 synthetic profiles on a Python OOP assessment with Claude Sonnet 4.6, the model recovers roughly half the intended skill variance ($r = 0.698$, 95% CI [.684, .712]) with systematic positive bias, and GEA is strongly skill-dependent: high for syntactically verifiable skills, near zero for design-level skills.

Limitations

The reported GEA estimates should be read with several scoping constraints in mind. All 150 profiles are LLM-sampled rather than drawn from real

students; authentic learner errors likely differ from simulated ones, so a pilot of 10–20 real students would provide an external anchor for the bias estimates and a check on the simulated-error distribution. We evaluate two Claude models (Sonnet 4.6, Haiku 4.5) on Python OOP code only; cross-family replication (e.g., GPT-4o, Gemini, open-weight models) and subjective domains that lack the partial verifiability of code (essays, open-ended argumentation) would test whether the strong-vs-weak-GEA stratification we observe generalises beyond this setting. The rubric-decomposition argument and complementary mitigations (cross-model scoring, epistemic-state specification, multi-sample evaluation) are supported by prior work and by the per-skill GEA contrast in Table 2, but we do not directly ablate rubric granularity or scorer identity on the same task; comparing holistic against decomposed rubrics, and same-model against cross-model scoring, is the most immediate empirical follow-up. Finally, GEA can in principle fail to detect bias when generator and evaluator share an identical distortion—for example, a sycophantic scorer that deflates an inflated generator’s score to match user expectations—and precisely quantifying this residual risk requires human-scored anchor responses to decompose GEA failure between the two functions (Section 6). The intended skill level x nonetheless remains an external reference that distinguishes GEA measurement from pure closed-loop self-validation, and GEA provides a concrete, measurable criterion any LLM-based assessment system can report before deployment.

A Assessment Architecture

The system is a conversational assessment tool delivered via Telegram Bot that conducts adaptive, scenario-based coding assessments. Students work through multiple progressive mini coding assignments per stage, evaluated by Claude AI against predefined rubrics. The system routes students to a terminal difficulty level based on cumulative stage performance.

Two-stage adaptive routing. All students begin with Stage 1 (2 assignments covering class basics and composition). Based on their cumulative Stage 1 score relative to threshold θ , students

are routed to either the *High Performer* path (inheritance and exception handling) or the *Low Performer* path (reinforcement of foundational skills). After Stage 2, a terminal level is assigned:

- **Advanced:** Stage 2 High path, cumulative $\geq \theta$
- **Intermediate:** Stage 2 High path, cumulative $< \theta$; or Stage 2 Low path, cumulative $\geq \theta$
- **Beginner:** Stage 2 Low path, cumulative $< \theta$

Dynamic question generation. Questions are not pre-stored. Claude generates each assignment dynamically at runtime based on the rubric, the current stage/path, and a scenario template. Each student receives a slightly different variation of the same assignment—same core objective and difficulty, but different scenario entities (e.g., bank account, airline, cinema), discouraging copying. Every assignment begins with an ASCII UML class diagram showing the class(es) the student must implement.

Scoring. Each submission is evaluated by Claude against the rubric for that assignment. The model returns a 24-element skill vector $\hat{\mathbf{x}} \in \{-1.0\} \cup [0, 1]^{24}$ (where -1.0 denotes inapplicable skills) and a scalar score $s = \text{round}(\text{mean}(\hat{x}_i : \hat{x}_i \neq -1) \times 100)$. The scalar score drives routing; the skill vector provides diagnostic detail.

B Skill Taxonomy

The 24 skills are organised into four progressive groups corresponding to the course’s lab sequence. Skills marked with $\star$ are mandatory anchors in the assessment rubric.

C Assessment Slot–Skill Coverage

Table 6 shows which skills are assessed (scored 0.0–1.0) in each of the 6 assessment slots. Skills not listed for a slot receive -1.0 (not applicable) in the skill vector.

D Proficiency Scale

Continuous skill scores are mapped to ordinal proficiency levels using the boundaries in Table 7. These levels are used for the confusion matrix analysis (Section 4.3) and for natural-language descriptors in student profiles.

E Student Profile Archetypes

150 synthetic student profiles were sampled from 10 archetypes (Table 8). Each archetype defines per-group skill ranges from which individual skill scores are drawn uniformly, with Gaussian noise ($\sigma = 0.04$) added to produce within-archetype variation. Profiles were generated with a fixed random seed for reproducibility.

Example profile. Table 9 shows a representative “Lab 2 Developing” profile. The student has strong class basics (Group A, mean 0.84), partial composition skills (Group B, mean 0.46), and minimal inheritance/exception knowledge (Groups C–D, < 0.10). Each skill carries a natural-language descriptor (shown for selected skills) that is included in the generation prompt to constrain the LLM’s code output.

F Prompt Templates

F.1 Code Generation Prompt (Simulation)

For each (student, slot) pair, the following prompt is sent to Claude Sonnet 4.6 to generate code that matches the student’s skill profile. The STUDENT SKILL PROFILE block lists only the skills applicable to the current slot, with each skill’s numeric score, proficiency level, and natural-language descriptor.

You are simulating a student submitting a Python OOP coding assignment.

The student’s exact skill profile for the skills tested in this assignment is provided below. Write Python code that a student at PRECISELY these skill levels would produce. Faithfully reflect each described weakness and strength – do not average them out or homogenise the code.

STUDENT SKILL PROFILE (relevant skills only):

- S01 Class Definition: 0.82 (Advanced) – Class is well-defined, correctly named, and structurally complete with multiple methods.
- S03 Private Instance Variables: 0.70 (Proficient) – self.__attr used for key attributes with property getters; not all attributes are private.
- ...

ASSIGNMENT:

{the generated assignment text}

Rules:

1. Output Python code only – no explanations, no markdown fences, no preamble.
2. For skills rated “Not Demonstrated” or “Beginning”, the code must clearly exhibit the described gap.

3. For skills rated “Advanced” or “Mastered”, that aspect of the code must be correct and complete.

4. Each skill reflects its own level independently – the code can be strong in one area and weak in another.

5. Use realistic student-style naming and formatting consistent with the described skill levels.

F.2 Scoring Prompt (Evaluation)

The scoring function sends the full rubric document (including per-assignment skill vector tables with scoring guidance) along with the student’s submission. The prompt instructs the model to:

You are a coding assessment scorer for a Python OOP course.

The full rubric is below.

RUBRIC:
{full RUBRICS.md content}

–

Score the student’s submission for:

- Stage: {stage} - Path: {path} - Assignment: {n} of 2

Assignment given to the student:

""{question text}""

Student’s submission:

""{student code}""

Instructions:

1. Locate the rubric section for this stage, path, and assignment number.
2. Fill in the 24-element skill_vector exactly as defined in the Skill Vector table.
- Use -1.0 for skills marked -1.0 (not applicable).
- Use a float 0.0–1.0 for all other skills, following the scoring guidance.
- Use intermediate values (e.g. 0.3, 0.7) freely.
3. Compute score = round(mean(v_i for v_i if v_i != -1.0) * 100).
4. Write 2–4 sentences of constructive feedback.

Return ONLY a valid JSON object:

{“score”: <int>, “feedback”: “<text>”, “skill_vector”: [<s01>, ..., <s24>]}

F.3 Question Generation Prompt

The question generator receives the full rubric and is instructed to locate the correct section for the given stage, path, and assignment number, substitute the student’s scenario entity into the template, produce the class diagram followed by coding instructions, and return only the assignment text the student will see. Scenario entities are drawn from pre-defined lists:

- **Stage 1:** bank account, airline booking, cinema, grade tracker, event planner, inventory, point-of-sale, membership

- **Stage 2 High:** banking hierarchy, airline, vehicle fleet, cinema chain, course catalogue, training programme
- **Stage 2 Low:** contact book, recipe manager, budget tracker, shopping list, event log, book collection

Entities are assigned deterministically per student (seeded on student ID) to ensure reproducibility across simulation restarts.

G Rubric Excerpts: Strong vs. Weak GEA Skills

To illustrate the rubric specificity hypothesis (Section 5.1), we present the scoring guidance for a strong-GEA skill and a near-zero-GEA skill as they appear in the rubric’s skill vector tables.

S05 — Setter with Validation ($r = 0.88$, **strong GEA**). The rubric specifies concrete syntactic markers at each score level:

Scoring guidance: 1.0 = @attr.setter with a meaningful validation rule; 0.5 = setter present but no validation logic; 0.0 = absent.

The 8-level proficiency descriptors used in student profiles further constrain generation:

The binary nature of the criterion (setter with validation present or absent) provides an unambiguous code signature that both the generator and evaluator can reliably target.

S21 — Polymorphism via Shared Interface ($r = -0.03$, **near-zero GEA**). The rubric criterion is holistic rather than syntactic:

Scoring guidance: 1.0 = loop/function calls same method on mixed-type list without isinstance checks; 0.5 = loop present but uses type checks; 0.0 = no polymorphic usage.

The corresponding proficiency descriptors:

Polymorphism is a *design choice* (choosing to iterate over a heterogeneous list) rather than a syntactic pattern, making it harder for the generator to “partially implement” and harder for the evaluator to grade on a continuous scale. The descriptor levels describe *degrees of design completeness* rather than presence/absence of identifiable code tokens.

H Routing Logic

The routing state machine operates as follows. Let $\bar{s}_k$ denote the cumulative (mean) score after completing all assignments in stage k .

1. **Stage 1 completion:** Compute $\bar{s}_1$. If $\bar{s}_1 \geq \theta$, route to Stage 2 High path; otherwise Stage 2 Low path.
2. **Stage 2 completion:** Compute $\bar{s}_2$.
 - High path: if $\bar{s}_2 \geq \theta$ then *Advanced*; else *Intermediate*.
 - Low path: if $\bar{s}_2 \geq \theta$ then *Intermediate*; else *Beginner*.

The threshold $\theta = 50$ is a placeholder pending real-student calibration. The threshold sensitivity analysis (Table 3) confirms a stability plateau at $\theta \in [45, 55]$ where <5% of routing decisions change.

Each stage comprises exactly 2 assignments. Scores within a stage are averaged (not summed), so $\bar{s}_k = \frac{1}{2} \sum_{j=1}^2 s_{k,j}$ where $s_{k,j} \in [0, 100]$. Sessions are stored in memory keyed by Telegram user ID and do not survive bot restarts.

Table 5: Complete 24-skill taxonomy with descriptions and demonstration criteria.

ID	Skill	Description	Demonstrated by
Group A — Class Basics (Lab 1)			
S01	Class Definition	Defines a class using <code>class</code> with PascalCase name; non-empty body	Any valid class definition with ≥ 1 method
S02	Constructor Init	Uses <code>__init__(self, ...)</code> to initialise instance attributes	<code>__init__</code> present, ≥ 2 attrs assigned via <code>self</code>
S03*	Private Vars	Declares <code>self.__attr</code> with name mangling	≥ 1 <code>self.__attr</code> with property/getter access
S04	Getter Property	@property decorator exposes private attribute	Method with @property returning <code>self.__attr</code>
S05	Setter w/ Validation	@attr.setter with ≥ 1 validation rule	Setter checks condition before assigning
S06	<code>__str__</code>	Returns human-readable string using instance data	f-string with ≥ 2 instance attributes
S07	Compute Method	Instance method reading <code>self</code> attrs, returns computed value	return using <code>self.attr</code> in calculation
S08	Mutate Method	Instance method modifying <code>self</code> attributes	Assigns new value to <code>self.__attr</code>
Group B — Class Variables & Composition (Lab 2)			
S09*	Class Variable	Shared class-level <code>_attr = value</code> (not in <code>__init__</code>)	<code>_attr</code> at class level, accessed via <code>ClassName._attr</code>
S10	Class Var Mod	Correctly accesses/modifies class variable at runtime	Change reflected across all instances
S11	Composition	Has-a relationship: object stored as attribute (DI)	<code>__init__</code> accepts object param, assigns to <code>self.__other</code>
S12	Delegation	Outer class calls composed object's methods/properties	<code>self.__inner.method()</code> in outer class
S13	Dict Collection	Dictionary manages collection with add/search/remove	<code>dict[key] = obj</code> , <code>dict.get()</code> , <code>dict.pop()</code>
Group C — Inheritance (Lab 3)			
S14	Subclass Def	<code>class Child(Parent):</code> with correct parent	Subclass instance can call parent methods
S15	<code>super().__init__()</code>	Calls <code>super().__init__(...)</code> first in subclass	First statement in child <code>__init__</code>
S16	Subclass Attrs	New attributes added after <code>super()</code> call	≥ 1 <code>self.__new_attr</code> after <code>super()</code>
S17*	Override Replace	Completely replaces parent method (no <code>super()</code>)	Same-name method with entirely new logic
S18*	Override Refine	Calls <code>super().method()</code> then extends result	<code>super().method()</code> + additional logic
S19	ABC Definition	<code>ABC + @abstractmethod</code> to define contract	<code>from abc import ABC, abstractmethod</code>
S20	Concrete Subclass	Implements all abstract methods with meaningful bodies	Subclass instantiates without <code>TypeError</code>
S21	Polymorphism	Same method called on mixed-type list, no type checks	Loop over heterogeneous list, no <code>isinstance</code>
Group D — Exception Handling (Lab 4)			
S22	Custom Exception	Class inheriting from <code>Exception</code>	<code>class MyException(Exception):</code> <code>pass</code>
S23	Raise Exception	<code>raise</code> custom exception with descriptive message	<code>if condition:</code> <code>raise MyException("msg")</code>
S24	Try/Except	<code>try/except</code> catching custom + built-in exceptions	≥ 2 distinct conditions caught with messages

Table 6: Slot-to-skill mapping. Each slot tests a designated subset of the 24 skills; remaining skills are marked –1.0.

Slot	Content	Skills assessed	<i>n</i> skills
Stage 1, A1	Lab 1: classes & properties	S01–S08	8
Stage 1, A2	Lab 2: composition	S01–S04, S06–S07, S11–S12	8
Stage 2 High, A1	Lab 3: inheritance	S01–S04, S06, S09–S10, S14–S21	15
Stage 2 High, A2	Lab 4: exceptions	S01, S14–S15, S22–S24	6
Stage 2 Low, A1	Lab 1 reinforcement	S01–S08	8
Stage 2 Low, A2	Lab 3 introduction	S01–S04, S06, S14–S18	10

Table 7: Proficiency level boundaries.

Level	Score range	Midpoint
Not Demonstrated	[0.00, 0.05)	0.025
Beginning	[0.05, 0.25)	0.15
Emerging	[0.25, 0.45)	0.35
Developing	[0.45, 0.60)	0.525
Approaching	[0.60, 0.70)	0.65
Proficient	[0.70, 0.80)	0.75
Advanced	[0.80, 0.90)	0.85
Mastered	[0.90, 1.00]	0.95

Table 8: Archetype definitions. Each cell shows the [lo, hi] range for uniform sampling of skill scores within that sub-group. Sub-groups: A = S01–S08 (class basics), B = S09–S13 (composition), C₁ = S14–S16 (basic subclass), C₂ = S17–S18 (mandatory overrides), C₃ = S19–S21 (advanced inheritance), D = S22–S24 (exceptions).

Archetype	%	A	B	C ₁	C ₂	C ₃	D
Absolute Beginner	8	.00–.22	.00–.10	.00–.07	.00–.07	.00–.05	.00–.05
Lab 1 Developing	12	.22–.52	.00–.14	.00–.09	.00–.09	.00–.05	.00–.05
Lab 1 Proficient	15	.52–.78	.00–.22	.00–.14	.00–.12	.00–.07	.00–.05
Lab 1 Mastered	12	.78–1.0	.18–.48	.00–.18	.00–.14	.00–.09	.00–.05
Lab 2 Developing	12	.68–1.0	.32–.62	.00–.18	.00–.14	.00–.09	.00–.07
Lab 2 Proficient	10	.78–1.0	.62–.92	.08–.28	.05–.22	.00–.12	.00–.09
Lab 3 Developing	12	.72–1.0	.62–1.0	.28–.62	.22–.58	.00–.22	.00–.14
Lab 3 Proficient	10	.82–1.0	.72–1.0	.58–.88	.52–.85	.08–.38	.00–.18
Lab 4 Developing	5	.78–1.0	.72–1.0	.68–1.0	.62–.92	.18–.58	.28–.62
Advanced	4	.85–1.0	.80–1.0	.78–1.0	.75–1.0	.52–.92	.68–1.0

Table 9: Excerpt from student profile 0114 (Lab 2 Developing archetype, overall score 0.41).

Skill	Name	Score	Level
S01	Class Definition	0.82	Advanced
S03★	Private Vars	0.70	Proficient
S05	Setter w/ Validation	0.92	Mastered
S09★	Class Variable	0.37	Emerging
S11	Composition	0.66	Approaching
S14	Subclass Def	0.15	Beginning
S17★	Override Replace	0.00	Not Dem.
S22	Custom Exception	0.01	Not Dem.

Table 10: S05 proficiency descriptors (excerpt).

Level	Descriptor
Not Dem.	No setter defined; private attributes cannot be updated after construction.
Emerging	Setter present but validation logic is absent; any value is accepted.
Proficient	Setter enforces a clear validation rule and handles the invalid case appropriately; minor gap.
Mastered	Setter enforces thorough validation with appropriate response; all edge cases covered.

Table 11: S21 proficiency descriptors (excerpt).

Level	Descriptor
Not Dem.	No polymorphic usage; objects are type-checked before any method call.
Emerging	A polymorphic call is made but only one subclass type is present.
Proficient	Multiple subclass types in a collection; same method called without type checks; each responds correctly.
Mastered	Polymorphism fully and cleanly demonstrated; shared interface called on mixed-type collection with no type checks and correct output per type.

Evaluating LLM-Generated Formative Feedback for Undergraduate Mathematics Through the Lens of Feedback Theory

Aron Gohr¹ Marie-Amelie Lawn² Kevin Gao² Stephen Heslip² Inigo Serjeant²

¹Independent Researcher ²Imperial College London
aron.gohr@gmail.com m.lawn@imperial.ac.uk

Abstract

Large language models can generate feedback on free-form student writing, but there is still limited evidence on whether such feedback is mathematically correct, pedagogically useful, and aligned with expert judgement across varied undergraduate proof-writing tasks. We evaluate LLM-generated feedback on 65 undergraduate proof-writing exercises using Hattie and Timperley’s feedback framework and a grade-agreement metric, comparing two models (GPT-4.1, GPT-5) under two workflow configurations graded by two independent LLM evaluators. GPT-5 produces higher-quality feedback across all dimensions. A mark-scheme-augmented workflow improves grade correlation with human experts for both models, and precomputed mark schemes allow instructors to audit the system before deployment. While the present work cannot supply evidence of benefit in downstream learning tasks, as no controlled trials suitable to show such were run, we do show automated detection and explanation of errors on a wide variety of typical undergraduate-level proof tasks that is aligned with expert judgement on the mathematical issues. However, providing meaningful self-regulation support and controlled studies with students remain to be done. These results show that feedback theory provides a useful lens for evaluating automated mathematical feedback.

1 Introduction

Proof writing is a core skill in mathematics, yet students entering university typically have little experience with it (Moore, 2016). Frequent, detailed formative feedback is important in the acquisition of this skill, but producing it at scale is labour-intensive and inconsistent across graders. Unlike most high-school mathematics tasks, undergraduate proof exercises require assessing the validity, relevance, and level-appropriateness of open-ended arguments. A student may give a correct solution that is unexpected to the grader; an

incorrect argument may still deserve substantial credit if it contains the main ideas; a small computational error may invalidate the solution if the subsequent argument depends on it; and a mathematically correct proof may still be poor if it relies on machinery outside the course, takes large unnecessary detours, or is poorly written. Recently, large language models (LLMs) have achieved strong performance on mathematical reasoning benchmarks (OpenAI, 2024) and have been trialled as tutors (Jurenka et al., 2024; Miller and DiCerbo, 2024). It has also been shown that at least at a high computational budget, they can be used to grade complex proofs (Ma et al., 2025). Educational applications, however, must produce not only grades but *pedagogical feedback* while operating under tight budget and latency constraints. To our knowledge, LLM-generated feedback quality for free-form undergraduate proof exercises has not been previously studied.

We evaluate LLM-generated feedback on 65 undergraduate proof-writing exercises along four dimensions derived from the Hattie–Timperley feedback framework (Hattie and Timperley, 2007): correctness, task-level clarity, process-level guidance, and self-regulation support. We compare two models (GPT-4.1, GPT-5) under two workflow configurations (a direct baseline and a mark-scheme-augmented pipeline), graded by two independent LLM evaluators, and use grade agreement with human experts as a complementary screening metric. Code, prompts, and data are available at https://github.com/agohr/llm_proof_feedback.

Contributions.

1. We operationalise the Hattie–Timperley framework by deriving a rubric for automated evaluation of LLM-generated mathematical feedback.
2. We show that evaluation using this frame-

work reveals quality differences invisible to grade agreement alone. For instance, grade agreement shows no advantage for GPT-5 over GPT-4.1, despite GPT-5 scoring substantially higher on all feedback dimensions.

3. We stress test our tutoring system in several ways: we show that LLMs can effectively find errors in exemplary solutions of our exercises, we analyse the behaviour of our workflows for questions designed to trick the models, we show that both graders prefer the GPT-5 output despite self-serving bias (Panickssery et al., 2024).

Related work. Intelligent tutoring systems have provided automated mathematical feedback for decades, from Andes (Gertner and VanLehn, 2000) to proof-assistant-based systems like Waterproof (Wemmenhove et al., 2022) and LeanTutor (Patel et al., 2026), but these cannot process natural free-form writing. LLM-based systems can (Miller and DiCerbo, 2024; Jurenka et al., 2024), but exhibit failure modes such as sycophancy and hallucination. LLM-as-judge approaches are widely used in the LLM capabilities literature (Zheng et al., 2023); we adopt a cross-grader design to control for self-preference bias (Panickssery et al., 2024).

Feedback theory. Hattie and Timperley (2007) proposed a model distinguishing four feedback levels: *task* (FT), *process* (FP), *self-regulation* (FR), and *self* (FS). Task-level feedback identifies what was correct or incorrect; process-level feedback addresses strategies and reasoning; self-regulation feedback prompts metacognitive monitoring and planning; self-level feedback (“you are smart”) is generally ineffective. We operationalise this framework as a grading scheme for LLM-generated feedback.

2 Methods

Dataset. We develop a synthetic dataset consisting of 65 question–solution pairs from a first-year transition-to-proof course covering number systems, vector geometry, and calculus. Solutions were authored by experienced students familiar with the course and include deliberate errors. The solution authors were the student co-authors in their second or third year who had taken the course. Given a workload of 21 to 22 problems per student they had to work quickly, and were encouraged to write down partial arguments where they could

not finish a solution, and, where natural, to include plausible errors that would be useful test cases. The dataset is therefore controlled and error-rich, but not claimed to represent the full distribution of real student submissions, which we expect will in any case not be uniform across deployments. Three expert markers (two of the authors, one mathematics PhD student) independently graded each item on a 0–5 rubric; grades were reconciled by manual review by one of the authors, who is a lecturer of the course.

Feedback Generation. We compare two feedback-generation models and two workflow configurations, yielding four conditions:

- **Models:** GPT-4.1 and GPT-5.
- **Workflows:**
 - *Baseline-concise*: the model receives the question and student answer with a 200-word limit and generates feedback directly.
 - *MS-w-example*: a multi-step pipeline that first specialises a generic mark scheme to the question, then generates feedback informed by the specialised mark scheme. This workflow was selected based on its strong performance in grade-agreement pre-evaluations.

GPT-5 and GPT-4.1 were selected for this experiment because they represent modern reasoning and non-reasoning language models, respectively. Baseline-concise represents a simple workflow that just asks the model to provide *short* feedback.¹

Hattie–Timperley Evaluation. Each feedback item is scored on four dimensions, operationalised as rubrics with detailed level descriptors (0–5):

1. **Correctness (D1):** Mathematical accuracy of the feedback content.
2. **Task-level clarity (D2/FT):** Whether the feedback specifically identifies what was correct or incorrect, with reference to the exercise’s goals.
3. **Process-level guidance (D3/FP):** Whether the feedback engages with the student’s reasoning strategies and suggests alternatives.

¹We found in early experiments that directly asking the models for feedback tended to result in feedback that in our judgment was clearly too long.

Figure 1: High-level view of the MS-w-example workflow. The mark-scheme step is precomputable because it depends on the assignment and generic rubric, but not on any student submission. In deployment, the system returns only feedback; the grade node is used for evaluation.

Role	Model/settings
Feedback generation	GPT-4.1; GPT-5 with medium reasoning. Defaults otherwise.
HT feedback evaluation	GPT-5.4 and GPT-4.1 as independent graders.
Grade screening	GPT-4.1-nano infers a grade from question and feedback only.
Workflow selection	pre- Earlier grade-correlation sweeps used GPT-4o workflows and GPT-4o grading.

Table 1: Compact model-role summary. Reasoning models do not expose a temperature parameter; non-reasoning calls used temperature zero. We note that OpenAI models do not behave deterministically even at temperature zero.

4. **Self-regulation support (D4/FR):** Whether the feedback prompts self-monitoring, identifies next steps, and attributes outcomes to controllable factors.

We distinguish two roles: *feedback generation* (the model producing feedback for students) and *meta-evaluation* (the model scoring that feedback). Two LLM meta-evaluators, GPT-5.4 and GPT-4.1, independently score all $4 \times 65 = 260$ feedback instances on all four dimensions. For instance, GPT-5, which acts as a feedback-generation model in one experimental condition, is thus evaluated by GPT-5.4 in its meta-evaluator role. Each meta-evaluator first produces a brief chain-of-thought justification and then assigns an integer score, yielding paired scores that support cross-grader reliability analysis. The justifications were retained for human inspection and are part of our code and data repository.

Grade Screening. As a complementary metric, we regrade each feedback instance using a lightweight model (GPT-4.1-nano) that infers a 0–5

grade from the question and feedback alone (student solution hidden), and compute Kendall τ with human grades. The use of a *lightweight* grader is motivated here by two points. First, feedback should be as unambiguous as possible. Second, a mathematically capable grader could correctly set a grade based on feedback that is completely incompetent but leaks enough information about the original submission.

Manually Checking a Sample To check whether GPT-5.4 was grading the model feedback items too generously, we manually graded all 65 question/answer/feedback triples from the MS-w-example workflow with GPT-4.1 as the feedback-generation model. On this sample, LLM ratings were on average *more critical* than human ratings across all four HT categories, except for the GPT-4.1 meta-rating on feedback correctness, which was slightly more optimistic than the corresponding human grade.

Qualitative tasks. We additionally ran two qualitative checks. First, we asked a solve-then-comment workflow to proofread all 65 exemplary solutions and the workflow indeed found several errors which we confirmed, with no hallucinations.² Second, we constructed five stress-test problems designed to expose mathematical or contextual failures, including overpowered methods, surprising elementary arguments, advanced material, and multilingual input.

Examples of Feedback generated. We illustrate our feedback generation system with a stress-test example, using the ms-w-example workflow and GPT-5 as the underlying language model. Table 2

²There were false positives, but these were due to the model missing course-specific context.

shows one of our stress tests on which the workflow generates correct and useful feedback. The main difficulty in this example is that when given the problem, the models we tested themselves tend to suggest solutions that have the same shortcomings as the student solution, and will only find elementary arguments if specifically instructed to do so.

3 Results

Grade correlation. Table 3 shows Kendall τ between regraded and human grades. The ms-w-example workflow with GPT-4.1 achieves $\tau = 0.561$, substantially exceeding the human inter-grader baseline from our two independent gradings of the dataset ($\tau = 0.387$). The same workflow consistently outperforms the *baseline_concise* workflow across both models.

When developing the workflows, we optimised for grade correlation under GPT-4o workflows with GPT-4o grading. The data we collected on the influence of model and grader choice on grade correlations are included in the GitHub repository at https://github.com/agohr/llm_proof_feedback.

GPT-5 feedback is substantially better under the HT rubric. Table 4 presents mean HT scores across all four conditions, averaged over both graders. GPT-5 outscores GPT-4.1 on every dimension, most dramatically on correctness (D1: 4.40–4.78 vs. 3.48–4.54) and process guidance (D3: 4.14–4.46 vs. 3.29–3.57). Obviously, the conclusions that can be drawn from this are weaker than conclusions from observed learning outcomes would be.

Self-regulation is hard to grade. Across all conditions and graders, self-regulation support clusters around low values. Indeed, under the GPT-5.4 grader, most items receive a score of exactly 3. We attribute this mainly to the fact that LLMs have difficulty separating this feedback dimension from the others; when manually producing meta-feedback, we found that we faced the same problem.

Cross-grader agreement and bias. Both graders rate GPT-5 feedback substantially higher than GPT-4.1 feedback across all dimensions. The consistency of the GPT-5 advantage across graders lends some support to the validity of the evaluation, as under self-serving bias (Panickssery et al., 2024) each model is expected to rate its own outputs higher.

Qualitative evaluation. We also evaluated our system qualitatively on the two additional tasks defined above.

The first involved proofreading the exemplary solutions to our exercises. We used a solve-then-comment workflow in which the model (o4-mini) first generated a solution to each problem and then evaluated the proposed exemplary solution. Except where the model was unaware of course-specific notation, conventions, or disallowed tools, the feedback was uniformly useful, surfacing several clerical and minor technical errors.

The second was a stress test: five problems that are mathematically accessible but constructed to challenge current LLMs. Performance differed substantially between non-reasoning and reasoning models. While even GPT-5 failed on 3/5 items, targeted hints substantially improved its performance. This suggests that lightweight teacher interventions can meaningfully improve model performance at considerably less effort than writing full question-specific rubrics. Full details are included in the code and data repository.

4 Discussion

Our results support three main findings relevant to automated feedback evaluation and design.

Precomputation of parts of a workflow can help prevent failures. In our stress tests, we were able to trace failure cases to errors in the model-generated mark schemes. Since this stage of feedback generation does not depend on student submissions, it is natural to precompute it at the beginning of a course. Instructors can thus audit system performance on course content before deployment and intervene with suitable hints.

Grade correlation is an insufficient but useful metric for workflow evaluation. On its own, correlation of grades derived from feedback generated by our system is insufficient to select a good workflow for a given application. Our work shows that at least for our undergraduate exercise setting, it fails to show any advantage of the use of reasoning models, when several other metrics we consider, as well as our stress testing, do show such advantage. We still regard grade correlation as a useful screening tool for the development of mathematics tutoring applications, however, as it allows the reuse of graded proof datasets such as (Frieder et al., 2023; Ma et al., 2025).

Question	Show that there are infinitely many numbers that are divisible by 6 and that can be written as the sum of two prime numbers. (Early undergraduate elementary number theory course.)
Student answer	By Dirichlet’s theorem on primes in arithmetic progressions, there are infinitely many primes both of the form $6k + 1$ and $6k + 5$. Let S_5 and S_7 denote two such infinite sets. Then $p + q$ with $p \in S_5$ and $q \in S_7$ is always divisible by 6, and there are infinitely many such pairs; this yields the desired result.
Generated feed-back	<i>What you did well:</i> You correctly identified the relevant residue classes (primes > 3 are $\equiv 1$ or $5 \pmod{6}$), and $1 + 5 \equiv 0 \pmod{6}$), and the overall pairing strategy is appropriate. <i>Main issues:</i> (i) You invoke Dirichlet’s theorem without proof. For this course and problem, relying on such a deep result is not acceptable; an elementary argument is expected. (ii) Even if Dirichlet were allowed, “there are infinitely many such pairs” does not by itself rule out repeated sums—you need infinitely many <i>distinct</i> multiples of 6. <i>How to fix:</i> Replace Dirichlet with an elementary Euclid-style argument: assume finitely many primes $\equiv 5 \pmod{6}$, form $N = 6 \prod r_i - 1$, show $2 \nmid N$ and $3 \nmid N$, and deduce N has a new prime factor $q \equiv 5 \pmod{6}$. Then fix $r = 7 (\equiv 1 \pmod{6})$ and note the sums $q + 7$ are distinct and divisible by 6. <i>Notation:</i> S_5 and S_7 do not match the stated sets of primes of the form $6k + 1$ and $6k + 5$; there is no residue class “7” mod 6.

Table 2: Stress-test example: GPT-5 with the ms-w-example workflow. The student invokes Dirichlet’s theorem. Their argument is mathematically correct, but uses far heavier machinery than the course level allows, and introduces an ambiguous notation (S_5, S_7) mismatched with the stated residue classes. The feedback correctly flags all problems and sketches a possible elementary fix via a Euclid-like argument.

Model	Workflow	τ	n
GPT-4.1	Baseline	+0.306	65
GPT-4.1	MS-w-example	+0.561	65
GPT-5	Baseline	+0.136	65
GPT-5	MS-w-example	+0.296	65
<i>Human inter-grader</i>		+0.387	65

Table 3: Grade correlation: Kendall τ between grades reggraded by GPT-4.1-nano from feedback alone and reconciled human grades. Human baseline shown for reference.

Model	Workflow	D1 Corr.	D2 Task	D3 Proc.	D4 Self-R.
<i>GPT-5.4 grader</i>					
GPT-4.1	Baseline	3.62	3.42	3.29	3.02
GPT-4.1	MS-w-ex.	3.48	3.71	3.40	2.88
GPT-5	Baseline	4.40	4.14	4.14	3.05
GPT-5	MS-w-ex.	4.63	4.29	4.25	3.06
<i>GPT-4.1 grader</i>					
GPT-4.1	Baseline	4.37	3.69	3.57	2.78
GPT-4.1	MS-w-ex.	4.54	3.89	3.46	2.32
GPT-5	Baseline	4.77	4.09	4.28	3.62
GPT-5	MS-w-ex.	4.78	4.25	4.46	3.51

Table 4: Mean HT scores (0–5) by condition and grader. D1–D4 correspond to correctness, task clarity, process guidance, and self-regulation.

Metacognitive feedback is still a gap. In our test cases, our system generally produces correct and task-level relevant feedback but qualitatively, we see that it often fails or does not attempt to diagnose *why* a certain mistake was made. This is also visible to some extent in the self-regulation scores produced by our evaluation, although that part of the evaluation probably suffered from difficulties our meta-grader had in distinguishing this dimension from the others.

We expect that closing this gap would require longer interaction histories and more agentic model scaffolds.

Limitations

Our dataset consists of 65 controlled, author-written items from a single institution and course. This allows useful comparisons to be drawn between configurations, but the frequency and variety of errors in authentic student work may be

different. The HT evaluation is itself performed by LLMs, and only the GPT-4.1/MS-w-example feedback ratings were cross-checked by the authors. We evaluate only two feedback-generation models and two workflows in the main experiment, although our supplementary code and data contain grade-correlation and stress-testing data for additional combinations. Finally, we do not measure learning outcomes or student uptake of the feedback, which would be the gold-standard test for pedagogical effectiveness. While we deployed our tutoring system in several real courses using the lambda feedback platform at Imperial College, and received informal feedback on its use from students, no data from these deployments was used in this paper for ethics reasons. We leave this as future work.

Abstract

Effective tutoring requires distinguishing optimal, valid but suboptimal, and incorrect student solutions, a distinction central to intelligent tutoring systems (ITS) but untested for LLM-based tutors. As LLMs are increasingly explored as conversational complements to ITS, evaluating their diagnostic precision is essential. We present a benchmark of seven LLM feedback agents in propositional logic using knowledge-graph-derived ground truth across 10,836 solution–feedback pairs and three feedback conditions¹. Models achieved near-ceiling performance on optimal steps but systematically over-rejected valid but suboptimal reasoning and over-validated incorrect solutions, precisely where adaptive tutoring matters most. These failures persisted across models regardless of solution context, suggesting architectural rather than informational limits. Moreover, accurate diagnosis did not reliably produce pedagogically actionable feedback, revealing a gap between diagnostic judgment and instructional effectiveness. Our findings suggest that LLMs are better suited for hybrid architectures where KG-grounded models handle diagnosis while LLMs support open-ended scaffolding and dialogue.

1 Introduction

Effective tutoring requires recognizing not just whether a student solution is correct, but whether it shows good reasoning that should be encouraged or guided toward a more efficient approach. (Gupta et al., 2025). In structured reasoning domains like propositional logic, students may produce optimal next steps that follow expert authored paths to conclusion, apply valid but suboptimal inference rules (*valid-alternative* steps), or make errors entirely (Maniktala et al., 2023). Examples of expert authored (optimal) solution and a valid but longer solution is illustrated in Figure 1.

¹https://github.com/tahreem/BEA_2026

Figure 1: Optimal and valid-alternative solutions (*blue nodes represent abbreviated inference rule names, explained in Table 4*)

Distinguishing among these three types of student steps has direct pedagogical implications identified as *assistance dilemma* by Learning Science experts (Koedinger and Aleven, 2007). Treating valid reasoning as incorrect can discourage productive exploration, while accepting all valid alternative steps without guidance can reinforce inefficient problem solving strategies. Intelligent Tutoring Systems (ITS) address this trade-off through step-level diagnosis of student reasoning using explicitly modeled solution spaces (VanLehn, 2011). However, they rely on expert-authored solution graphs for each problem, limiting scalability to new domains (Weitekamp et al., 2020), and provide limited support for conversational and exploratory dia-

Figure 2: KG-grounded evaluation pipeline. (1) Proof state and expert solution are extracted from tutoring system. (2) LLM-simulated student produces an incorrect derivation (KG verification: Incorrect). (3) Three feedback agents assess student solution as "Valid-Alternative" incorrectly. (4) Automated and manual feedback analysis illustrates systematic over-validation and distinct diagnostic failure modes across Peer, Teacher, and Judge conditions.

logue when students diverge from expected reasoning paths (Zerkouk and Chikhaoui, 2025).

Large language models (LLMs) address these limitations through conversational flexibility, cross-domain generalization, and scalable feedback without per-problem authoring (Reddig et al., 2025; Chen et al., 2025), making them promising complements to ITS. However, without grounding, LLMs hallucinate (Liu et al., 2025a) and often reveal solutions instead of scaffolding reasoning (Macina et al., 2023), limiting their reliability for tutoring. Role-specialized feedback pipelines grounded in expert solutions may improve diagnostic accuracy (Phung et al., 2024; Guo et al., 2024), but whether they support the fine-grained reasoning diagnosis required for effective tutoring remains unclear, especially in structured reasoning domains.

We address this gap through a large-scale evaluation of LLM feedback in propositional logic, where distinguishing between optimal, valid-alternative, and incorrect steps has direct pedagogical importance. Unlike prior tutoring evaluations that rely on binary correctness labels (Gupta et al., 2025; Borchers and Shou, 2025), our framework uses a knowledge-graph (KG) solution space derived from a real tutoring system to represent all valid inference paths (Barnes and Stamper, 2008), enabling grounded three-way diagnosis central to intelligent

tutoring systems (Alevan et al., 2009; VanLehn, 2006).

Contributions: We present the first benchmark for step-level evaluation of LLM tutoring feedback across multiple valid solution paths. Using this benchmark, we evaluate 10,836 LLM-simulated next-step solutions and their feedback with KG-grounded evaluation across seven models and three feedback conditions. To understand when LLM feedback remains pedagogically effective, and what factors influence this behavior, we study three research questions:

– *RQ1:* How accurately LLM feedback agents classify single-step logic proof solutions as optimal, valid-alternative, or incorrect, and what systematic errors emerge?

– *RQ2:* What model- and problem-level factors affect this three-way diagnosis?

– *RQ3:* What is the pedagogical quality of LLM feedback, and how it relates to three-way diagnosis?

Our fine-grained evaluation shows that LLMs consistently over-reject valid-alternative reasoning and over-validate incorrect solutions across models and solution contexts, with failures driven more by model behavior than problem difficulty. We further find that accurate solution diagnosis does not reliably produce pedagogically effective feed-

back. Models may correctly assess solution quality yet still fail to provide guidance that supports learning, reducing feedback to confirmation or error detection manifesting *assistance dilemma*. Together, these findings suggest that current LLMs require ITS-grounded diagnostic mechanisms and are better suited to complement, rather than replace, adaptive tutoring systems.

2 Related Work

2.1 LLM Tutoring and Diagnostic Adaptivity

LLMs show promise for diagnosing student errors (Reddig et al., 2025) and supporting self-regulation (Chen et al., 2025), but tutoring evaluations show they cannot reliably identify reasoning errors, even with reference solutions (Liu et al., 2025b; Jia et al., 2024). Role-specialized feedback pipelines, where one agent generates feedback and another verifies it, can improve precision and reduce over-praise (Phung et al., 2024; Guo et al., 2024), yet verification may also propagate existing errors depending on response type (Guo et al., 2024; Yasir et al., 2026). Prior work further shows that LLMs exhibit limited adaptivity to tutoring context (Borchers and Shou, 2025) and struggle with partially correct responses where guidance is most needed (Mahdavi et al., 2025).

Multiple valid solution paths are common in structured reasoning domains like propositional logic (Große and Renkl, 2006; Maniktala et al., 2023). Traditional ITS address this using manually authored solution graphs that encode both optimal and valid-alternative paths (Aleven et al., 2009), but this limits scalability to pre-authored problems. Whether LLM tutoring agents can similarly perform three-way diagnosis of optimal, valid-alternative, and incorrect responses remains untested and is the central question of this work.

2.2 LLM-Simulated Students

Evaluating tutoring feedback requires student solutions covering optimal, valid-alternative, and incorrect responses, which are often underrepresented in real interaction logs (Maniktala et al., 2023). LLM-simulated students have emerged as a practical solution to this coverage problem. Prior work shows that LLMs can reliably simulate learner actions in open-ended environments (Mannekote et al., 2025), generate responses for evaluating programming tutoring systems (Phung et al., 2024), and produce multiple-choice answers aligned with

real student profiles and responses (Lu and Wang, 2024). LLMs have also been shown to simulate students of different skill levels across educational domains (Benedetto et al., 2024), while generating realistic uncertainty, confusion, and mistakes that effectively challenge teacher agents in benchmarking settings (Shi et al., 2025).

In our work, simulation is additionally required because the tutoring system logs lack reasoning traces, making real interaction data insufficient for step-level reasoning evaluation.

2.3 Evaluation Benchmarks

Existing logic reasoning benchmarks do not support the step-level, multi-path evaluation required in our framework. ProofWriter (Tafjord et al., 2020) evaluates only final proof validity, obscuring step-level rule application. FOLIO (Han et al., 2024) provides expert-authored first-order logic problems but penalizes valid alternative derivations, while ProntoQA (Saparov and He, 2023) supports controlled evaluation with synthetic reasoning chains but cannot represent branching points where multiple inference rules may apply. LogicLearner (Inamdar et al., 2025) focuses on guided practice for basic logic problems, and its benchmark data is unavailable. To the best of our knowledge, none of these benchmarks support evaluating feedback quality for intermediate steps when multiple valid solutions exist.

2.4 Reasoning Difficulty in Logic Proofs

Structural complexity is a known challenge in propositional reasoning (Barnes and Stamper, 2008). Nested connectives increase cognitive load and make it harder to extract propositions needed for further derivation, reducing performance as rule complexity increases (Johnson-Laird and Wason, 1970). In logic proof tutoring, students take more time and derive more unnecessary propositions on steps with nested expressions (Shabrina et al., 2024). Structural nesting is also a strong predictor of LLM error in propositional proof construction, with incorrect steps associated with longer and more complex parent statements across models and prompting conditions (Tithi et al., 2025).

Proof step position introduces an additional challenge. Early steps require reasoning over many valid continuations, while later steps limit the remaining derivations (Shabrina et al., 2024). We therefore examine whether diagnostic failures are

driven by step complexity, proof position, or model-specific factors (Section 4).

3 Dataset and Knowledge Graph

3.1 Task Formulation

A propositional logic proof problem is defined as a tuple $(\mathcal{P}, C)$, where $\mathcal{P} = p_1, \dots, p_n$ is the set of premises (statements assumed to be true) and C is the target conclusion. A proof state $\sigma = (\mathcal{P}, I, C)$ represents progress through the proof, where I is the ordered set of intermediate statements derived by applying inference rules $r \in R$ to statements in $\mathcal{P} \cup I$. Initially, $I = \emptyset$. A complete list of inference rules is provided in Table 4, Appendix A.

In this study, we investigate single-step prediction: deriving the optimal next step (statement) from $\mathcal{P} \cup I$ using exactly one inference rule application that minimizes the remaining derivation distance to C . We restrict the task to single-step prediction and the corresponding feedback generation and evaluation.

3.2 Dataset

To generate single step solution-feedback pairs, we use 516 unique proof states extracted from interaction logs of a propositional logic tutoring system deployed in an undergraduate Discrete Mathematics course at a large U.S. university (Barnes and Stamper, 2008) in Spring 2023. States are drawn from 32 proof problems across five practice levels of varying difficulty (introductory through expert), that provide context specific and on-demand hints we call solution context. Levels 1 (pre-test) and 7 (post-test) are excluded because they do not provide hints. Each instance is unique at triple level $(\mathcal{P}, I, C)$, to ensure a distinct proof state. An example proof state is illustrated in Figure 2 and Figure 7. Table 5, Appendix B summarizes data distribution across tutor difficulty levels, tutoring system illustrations are present in Appendix C.

Step Complexity: To further characterize the reasoning difficulty of proof states in our dataset, we also present step complexity, computed as a weighted sum of operators and nesting structure in the derived expression. Details on computing complexity are available in (Appendix E.1). In our dataset, complexity values ranges from 0 (atomic expressions with no logical operators) to 11 ($M = 3.07, SD = 2.5$), covering simple single-operator next steps through deeply nested compound expressions.

3.3 Knowledge Graph Construction

To provide ground truth that captures all logically valid solution paths in our dataset, we encode the complete solution space for each of the 32 problems as a knowledge graph $K = (\Sigma, E)$. Σ is the set of nodes representing all reachable proof states while E comprise the set of edges representing a valid single step inference between two proof states $(\sigma_i, \sigma_j) \in E$. The proof state σ_j is obtained from σ_i by deriving a new statement $\hat{s}$ via rule $r \in R$ applied to parent statements from $\mathcal{P} \cup I_i$, such that $I_j = I_i \cup \{\hat{s}\}$. The graph is rooted at $\sigma_0 = (\mathcal{P}, \emptyset, C)$ and terminates at σ^* where $C \in I^*$. Given a finite premise set and closed rule set R of 15 propositional inference rules, all reachable derivations are enumerable via forward chaining, making this encoding exhaustive by construction (Barnes and Stamper, 2008).

Each edge $(\sigma_i, \sigma_j) \in E$ in the KG is annotated with the inference rule and respective parent statements in σ_i used to derive the next step $\hat{s}$ in σ_j . This annotation is necessary because a predicted step $\hat{s}$ may be symbolically valid yet inferentially unjustified if attributed to an incorrect rule or unsupported parent statements, illustrated in Figure 2 (*student reasoning error*).

Example: a model predicting C via Modus Ponens must correctly identify both $(A \rightarrow C)$ and A as parents; a prediction that produces C but misattributes the rule or parent statements is flagged as incorrect regardless of symbolic validity. Edge-level annotation thus enables verification of both what was derived and how the derivation is justified.

Distance to conclusion: is defined as the minimum number of derivation steps from the current proof state to the conclusion such that $d(\sigma) = \min_{\pi: \sigma \rightsquigarrow \sigma^*} |\pi|$, and computed via breadth-first search over K . In our dataset it ranges from $[X]$ to $[Y]$ ($M = Z, SD = W$), covering both early proof states with many remaining steps and late proof states close to the conclusion. Unlike prior benchmarks relying on binary correctness, our KG encodes all valid inference paths, enabling three-way diagnosis. A next step, $\hat{s}$ from state σ_t is classified as one of three categories as follows:

Optimal: following an expert-authored path, if $(\sigma_t, \hat{\sigma}_{t+1}) \in E$ and $d(\hat{\sigma}_{t+1}) = d(\sigma_t) - 1$: is a valid inference that strictly reduces distance to the conclusion.

Valid-alternative: if $(\sigma_t, \hat{\sigma}_{t+1}) \in E$ but

$d(\hat{\sigma}_{t+1}) > d(\hat{\sigma}_{t-1})$, that means it does not reduce distance to the conclusion.

Incorrect: $(\sigma_t, \hat{\sigma}_{t+1}) \notin E$, meaning $\hat{\sigma}$ not derivable under any valid inference rule per K .

4 Methods

4.1 Experimental Pipeline

The experimental pipeline extends the framework established in (Yasir et al., 2026) by introducing three-way KG-grounded diagnosis, distinguishing valid-alternative from incorrect solutions, and analyzing over-rejection and over-validation as pedagogically distinct failure modes. We construct next-step solution-feedback pairs using LLM-simulated next-step solutions (Section 4.2) generated from proof states in our dataset (Section 3.2), paired with corresponding LLM feedback under three prompt-level role-specialized feedback conditions (Section 4.3). Figure 1 summarizes this pipeline.

We evaluate seven LLMs, including reasoning-augmented models (GPT-o3, DeepSeek-R1, Qwen-3-32B) and instruction-tuned models (GPT-4.1, Gemini-1.5-Pro, LLaMA-3.3-70B, Mistral-Large). The set includes both proprietary and open-weight models, enabling comparison across capability levels relevant to educational deployment. Each model serves in two roles: (1) as student simulator generating solutions for all 516 proof states and (2) feedback agent evaluating all solutions under the three feedback conditions (Section 4.3). This produces $516 \times 7 \times 3 = 10,836$ solution-feedback pairs (516 proof states, seven LLMs, and three feedback conditions). This design, avoids bias from mismatched model pairs and enable model-level analysis of solution diagnosis and feedback quality across feedback conditions, directly addressing RQ1 and RQ2. Each pair represents one diagnosis instance: a next-step solution and reasoning trace generated by a model and evaluated under one feedback condition. We reuse the same simulated solutions across conditions for each model to ensure fair comparison.

4.2 Student Simulation

The tutoring system logs record only the predicted next step, inference rule, and parent statements, but not the reasoning trace. Without it, evaluating whether LLM feedback agents assess reasoning validity in addition to symbolic correctness is not possible. To address this, we use LLM simulation to generate solutions with reasoning traces. LLM-based simulation is an established methodology

for tutoring evaluation (Mannekote et al., 2025; Phung et al., 2024), and prior work shows that simulated responses contain realistic confusion and mistakes suitable for benchmarking teacher models (Shi et al., 2025).

The student simulator prompt follows the design established in (Yasir et al., 2026). Each model receives a proof state $\sigma = (\mathcal{P}, I, C)$ and generates: (1) a predicted next step in symbolic form, (2) the inference rule used, (3) parent statements, and (4) a natural language reasoning trace. The complete prompt is shown in Figure 14. Models generate the most appropriate next step for the current proof state without instruction to produce a specific solution category. The solution category (optimal, valid-alternative, or incorrect) is later determined by comparison with the KG (Section 3.3). Error patterns observed during human evaluation for response annotation align with common student errors in the tutoring logs, including rule misapplication and incorrect parent selection.

4.3 Feedback Conditions

Accurate diagnosis alone is insufficient for effective tutoring and must be translated into pedagogically appropriate feedback. **Optimal** steps may require only confirmation and encouragement to continue, **Valid-alternative** steps require acknowledging correct reasoning while guiding toward a more efficient approach, and **Incorrect** steps require error identification and corrective guidance (VanLehn, 2006).

To evaluate whether LLM feedback agents can meet these requirements, and whether performance depends on solution context, we define three prompt-level feedback conditions that differ only in the expert solution information provided to the agent, keeping the task and other constraints constant. The three feedback conditions and their prompts are adopted from (Yasir et al., 2026). Each condition represents a distinct tutoring role:

- **Peer** receives only the next step in symbolic form, representing a peer who knows the answer but lacks effective reasoning. This condition tests whether correctness-only grounding is sufficient for accurate diagnosis and pedagogically appropriate feedback.
- **Teacher** represents a real life teacher with complete solution, including the inference rule and parent statements. This tests whether full derivational context improves diagnostic accuracy and feedback quality beyond the Peer condition.

– **Judge** receives the complete solution (inference rule and parent statements) along with the Peer’s feedback, representing a teacher reviewing a teaching assistant’s feedback. This setup is consistent with evaluation and verification loops in ITS (Rodrigues et al., 2025) and aligns with the LLM-as-Judge paradigm (Zheng et al., 2023). This condition tests whether downstream verification can correct upstream diagnostic errors and improve pedagogical feedback quality. Figure 1 shows the information available in each feedback agent.

All feedback agents are prompt-level conditions rather than distinct model architectures. Pedagogical constraints were kept constant across conditions: agents were instructed to scaffold reasoning without revealing answers, acknowledge correct reasoning before addressing errors, and limit feedback to 2–3 sentences (VanLehn, 2006). This design isolates information access as the main independent variable, enabling direct comparison of whether richer solution context improves diagnostic accuracy (RQ1) and feedback quality (RQ3). Prompt templates are provided in Appendix J.

5 Evaluation

5.1 Automated Metrics

To address RQ1 and RQ2, we compute three-way diagnostic performance and identify factors governing misdiagnosis using automated metrics derived from our KG ground truth.

Classification Performance (RQ1) Each feedback agent is prompted to label the solution as Optimal, Valid-alternative, or Incorrect. We compare these labels with KG-derived ground truth to compute F1 scores. However, F1 alone obscures pedagogically distinct failure modes: labeling valid-alternative reasoning as incorrect discourages productive exploration, while labeling incorrect solutions as valid reinforces misconceptions. To capture these two horns of the assistance dilemma, we define two conditional error rates:

Over-rejection (OR): is the rate at which valid-alternative solutions are incorrectly labeled as incorrect, discouraging productive reasoning.

Over-validation (OV): is the rate at which incorrect solutions are labeled as valid, reinforcing misconceptions.

Factors affecting misclassification (RQ2) To identify whether model-level or problem-level reasoning factors affect diagnostic performance, and

whether the effects differ across solution categories, we analyze four factors:

Model vs. solution context: We compare variance (η^2) explained by model selection and feedback condition to determine whether diagnostic accuracy is driven by model capability or solution context.

Step complexity: We test whether step complexity predicts misdiagnosis to separate reasoning difficulty from model-level diagnostic failures. Nested logical structures are a known source of reasoning difficulty for both humans (Johnson-Laird and Wason, 1970; Shabrina et al., 2024) and LLMs (Tithi et al., 2025). Full computation details are in Appendix E.1.

Distance to goal: We test whether distance to goal (Section 3.3) predicts OR and OV at different derivation stages. Together with step complexity, this helps determine whether failures reflect problem difficulty or model-level biases.

Inference rule: We compare F1 scores across inference rules to identify rules systematically misdiagnosed across models.

Table 1: Rubric for evaluating pedagogical quality of agent-generated feedback.

Dimension	Score 1: Low	Score 2: Moderate	Score 3: High
Correctness	Contains errors that would mislead the student	Minor imprecisions but no fundamental errors	All statements are logically and factually accurate
Error Identification	Fails to identify the error or identifies incorrectly	Indicates error exists but identification is vague	Precisely identifies the specific error; affirms correctness if applicable
Revealing	Guides without revealing, using scaffolding or Socratic questioning	Hints at solution direction without explicit disclosure	Discloses solution content explicitly (names rule, states next step)
Actionability	No actionable guidance; student cannot proceed	General guidance but lacks specificity	Clear, specific guidance enabling appropriate next step

5.2 Human Evaluation (RQ3)

To determine whether better solution diagnosis leads to pedagogically appropriate feedback, two annotators independently evaluated feedback qual-

ity on 100 solution-feedback pairs per condition. We use four rubric dimensions adapted from prior work (Maurya et al., 2025), shown in Table 1. These dimensions directly operationalize the distinction between solution diagnosis and pedagogical feedback quality central to RQ3. Complete details on sample and annotator selection, annotation procedures (calibration and inter-rater reliability), and instructions are provided in Appendix I.

6 Results

We organize results around three research questions. First, we report solution classification performance and systematic errors, i.e., OR and OV (RQ1). Next, we examine how model selection, feedback condition, step complexity, distance to goal, and inference rule affect classification accuracy (RQ2). Finally, we assess whether accurate solution classification translates into pedagogically appropriate feedback (RQ3).

6.1 RQ1: Classification Performance and Error Patterns

Models showed distinct classification patterns across student solutions. Table 2 presents classification performance (F1) across models and feedback conditions. All models achieved near-ceiling performance on optimal student solutions ($F1 : 94 - 99\%$) but struggled with valid-alternatives ($F1 : 0 - 76\%$) and incorrect solutions ($F1 : 4 - 55\%$). GPT-4.1 and GPT-o3 achieved balanced but moderate performance on valid-alternative solutions. Gemini and DeepSeek achieved the highest valid-alternative scores ($F1 : 70-76\%$) but poor incorrect detection ($F1 : 4-19\%$). In contrast, LLaMA 3 showed near-zero valid-alternative diagnosis ($F1 : 0-17\%$) but the highest incorrect detection ($F1 : 45-55\%$).

Table 2 further quantifies these patterns using conditional error probabilities, OR and OV. Gemini and DeepSeek showed high over-validation (69-71%) but low over-rejection (13-17%), treating most student solutions as valid-alternative regardless of correctness. LLaMA 3 showed the opposite pattern: 91% over-rejection but only 6% over-validation, rejecting nearly all non-optimal solutions. GPT-4.1 and GPT-o3 showed moderate rates of both errors (29-41%).

6.2 RQ2: Factors Affecting Classification

Given the substantial variation in classification performance across models, we examined the factors

Table 2: Classification F1 and error rates by model. P = Peer, T = Teacher, J = Judge. OR = Over-Rejection, OV = Over-Validation. CIs: $\pm 5-8\%$. $^\dagger N < 50$.

Model	Opt.	Valid-Alt.			Incorrect			OR	OV
	Avg	P	T	J	P	T	J	(%)	(%)
GPT-4.1	0.99	0.55	0.57	0.49	0.42	0.40	0.41	38.57	28.65
GPT-o3	0.99	0.48	0.55	0.45	0.38	0.40	0.40	40.50	29.97
Gemini-1.5 Pro	0.99	0.70	0.73	0.72	0.09	0.04	0.08	12.77	70.55
DeepSeek	0.99	0.74	0.76	0.74	0.09	0.12	0.19	17.12	68.60
Qwen	0.99	0.58	0.42	0.54	0.11	0.07	0.12	54.65	28.30
Mistral	0.95	0.58	0.47	0.52	0.15	0.09	0.12	26.28	54.37
Llama 3 [†]	0.94	0.03	0.00	0.17	0.48	0.55	0.45	91.07	6.47

Table 3: Mean complexity (correct vs. incorrect steps)

Type	Corr.	Incorr.	Diff.	N
Optimal	1.95	2.46	+0.51*	1189
Valid Alt.	3.62	2.97	-0.65	816
Incorrect	3.91	3.78	-0.13	1619

* $p < .05$ (Mann-Whitney U)

affecting misdiagnosis.

– Model Selection vs. Feedback Conditions:

Model selection explained most of the variance in classification performance ($\eta^2 > 0.95$, $p < .001$), while feedback conditions had negligible effect ($\eta^2 < .01$). Table 2 shows that additional information access did not improve classification when student solutions diverged from the expected path (valid-alternative or incorrect solutions).

– **Step Complexity:** Because feedback conditions had negligible effect on diagnosis ($\eta^2 < .01$), we pooled feedback agents across models to maximize statistical power for complexity analysis. However, complexity predicted misdiagnosis only for Optimal solutions: more complex steps were misdiagnosed more often ($M = 2.46$) than correctly classified ones ($M = 1.95$; $p < .05$).

For valid-alternative and incorrect solutions, complexity did not predict errors ($p > .08$). Feedback agents rejected simpler valid-alternative solutions ($M = 2.97$) more often than complex ones ($M = 3.62$), suggesting rejection was driven by deviation from the expert path rather than step complexity. Step complexity explained negligible variance in diagnosis performance ($\eta^2 < .01$, $p > .05$) compared to model selection ($\eta^2 > .95$, $p < .001$), confirming that failures are model-level rather than difficulty-driven.

To analyze complexity effects on OR and OV, proof states were grouped into low (1-2), medium (3-4), and high (5+) complexity levels, approximately corresponding to the 33rd and 66th percentile of complexity distribution ($P_{33} = 2$, $P_{66} =$

Figure 3: Mean feedback quality scores across rubric dimensions (N=100).

3). Figure 18 shows that LLaMA over-rejection approaches 100% at higher complexity tiers, while DeepSeek and Gemini over-validation persists across all tiers, further supporting model-level rather than difficulty-driven failure.

– **Distance to Conclusion:** Distance tiers used the same percentile-based partition: near ($d \leq 2$), mid ($2 < d \leq 3$), and far ($d > 3$). Figure 19 shows that over-rejection is highest at near distances, meaning agents most often penalize valid-alternative reasoning when solutions are closest to the conclusion. Distance to conclusion explained negligible variance ($\eta^2 < .01$), again supporting model-level rather than position-driven failures.

– **Inference Rules:** Analysis of inference rules and F1 scores (Figure 20) shows that failures concentrate on structurally complex rules (MT, CD, DeM). LLaMA showed minimal gains across most rule types, while Gemini and DeepSeek consistently achieved the highest scores.

6.3 RQ3: Feedback Quality

To assess whether accurate solution classification translates into pedagogically appropriate feedback, we report aggregate scores and LLM responses.

Overall patterns: Figure 3 summarizes mean rubric scores (1–3 scale). Error Identification here measures whether feedback precisely identified the reasoning flaw, distinct from classification performance (RQ1), which captures only categorical judgment. Across agents, scores were lowest on Error Identification and Actionability, indicating that feedback frequently failed to diagnose errors or provide clear guidance, consistent with automated analysis (Section 6.1 and 6.2).

Qualitative analysis further explains this pat-

tern. Although prompts instructed agents to acknowledge correct reasoning *before addressing errors*, agents often praised solutions without identifying errors or giving actionable guidance. This produced encouraging but pedagogically misleading feedback, especially for incorrect and valid-alternative solutions. (Example 1 and 2 below)

Peer feedback: Peer agents consistently received the lowest scores across all human-evaluated dimensions (Figure 3). Limited solution context led Peer agents to restate student incorrect reasoning or provide vague feedback without diagnosing errors or offering guidance (Example 1 below and Figure 8 in Appendix H).

Example 1: Vague Peer feedback (repeats student’s mistakes)
Proof state: 1. $((S \rightarrow Y) \vee (I \wedge Q))$, 2. $((I \wedge Q) \rightarrow D)$, 3. $\neg D$, 4. $((S \rightarrow Y) \rightarrow D)$, 5. $\neg(S \rightarrow Y)$, 6. $(I \wedge Q)$
Solution context: D
Student reasoning: *Use Modus Tollens on $((S \rightarrow Y) \rightarrow D)$ and $\neg D$...*
Student error: Rule cant be applied on parent statements
Peer Feedback: *"Great job on identifying Modus Tollens on $((S \rightarrow Y) \rightarrow D)$ and $\neg D$ as a key step. Now ask yourself, is there a step that could bridge your current progress to the CONCLUSION more efficiently..."*

Teacher and Judge feedback: Teacher and Judge agents performed better at error identification than Peer agents. However, their feedback often penalized valid-alternative reasoning by redirecting students toward the provided solution context. This pattern was strongest for complex inference rules, which were also associated with higher error rates in Section 6.2 (Figure 20). In contrast, agents more readily acknowledged valid-alternative reasoning for simpler inference rules (Example 2, 3 and Figure 9).

Example 2: Teacher feedback validating incorrect reasoning
Proof state: 1. $(B \leftrightarrow \neg J)$, 2. $(\neg N \vee J)$, 3. $(B \vee \neg N)$, 4. $((B \rightarrow \neg J) \wedge (\neg J \rightarrow B))$, 5. $(N \rightarrow J)$, 6. $(\neg B \rightarrow \neg N)$
Solution context: *Derive $(J \vee \neg N)$ from $(\neg N \vee J)$ using Commutative rule.*
Student reasoning: *$(B \rightarrow \neg N)$ is optimal because it is the exact form of the conclusion, it can be derived from the contrapositive of $(\neg B \rightarrow \neg N)$...*
Student error: Incorrect derivation
Teacher Feedback: *"Great job recognizing that $(B \rightarrow \neg N)$ is the contrapositive of $(\neg B \rightarrow \neg N)$ and using that to reach the conclusion..."*

Verification Condition Contrary to prior LLM-as-Judge findings (Zheng et al., 2023), Judge feedback did not consistently improve feedback quality. When Peer agents missed errors, Judge agents often propagated rather than corrected them (Figure 12, anchoring Judge feedback to the Peer’s framing inheriting the or exacerbating mistakes. This

asymmetric pattern, where verification does not consistently improve some response is consistent with our prior work (Yasir et al., 2026).

Example 3: Judge repeats Peers’ mistakes and forces towards the available solution context
Proof state: 1. $\neg(\neg G \wedge B)$, 2. $(G \rightarrow D)$
Student reasoning: Applying DN to $\neg(\neg G \wedge B)$ to get $(G \wedge B)$ is optimal because it directly gives us both G and B as available conjuncts...
Student error: Incorrect rule application
Peer Feedback: "Great job applying double negation here! As you move forward, consider how you can use the new conjuncts to get closer..."
Solution context: Derive $(\neg\neg G \vee \neg B)$ from $\neg(\neg G \wedge B)$ using DeM Law.
Judge Feedback: "You made a good attempt by considering double negation, but before applying DN, try using De Morgan’s Law to rewrite..."

7 Discussion

RQ1: Consistent with the high OR and OV rates reported in Section 6.1, LLMs showed limited sensitivity to valid-alternative reasoning, relying on surface alignment with the provided solution context rather than reasoning validity. These failures have direct pedagogical consequences: OR discourages productive exploration and penalizes sound reasoning that diverges from the expert path (Manik-tala et al., 2023), while OV reinforces misconceptions and limits corrective feedback essential for learning (VanLehn, 2006). These failure modes are obscured under binary correctness schemes and only separable through our three-way KG-grounded framework, highlighting the importance of evaluation methodology alongside model capability (VanLehn, 2006; Koedinger et al., 2012).

RQ2: As shown in Section 6.2, model selection explained substantially more variance than feedback condition, indicating that diagnostic failures are primarily model-level rather than informational. Models performed well when solutions aligned with the optimal path but showed systematic bias once reasoning diverged, regardless of the provided solution context. Together with the negligible effects of step complexity, distance to conclusion, and inference rule type, these findings suggest persistent limits in LLM reasoning for constrained domains such as logic proofs. Improving diagnosis therefore likely requires capability-level advances rather than prompt or information-access design (Stamper et al., 2024; Venugopalan et al., 2025).

RQ3: Section 6.3 further showed that accurate diagnosis does not reliably translate into pedagogically effective feedback. Agents with more solution context produced overly directive feedback,

while less-informed agents generated open-ended responses lacking diagnostic grounding. This reflects the assistance dilemma: excessive directness constrains learning, while insufficient guidance fails to support progress (Koedinger and Aleven, 2007). Prompt-level layering alone therefore cannot ensure adaptive feedback. Effective verification likely requires independent diagnostic signals, similar to the grounded student modeling mechanisms used in ITS. Our findings further suggest that verification may require distinct models or explicit reasoning chains enforcing independent evaluation rather than sequential refinement of flawed judgments.

LLMs address ITS limitations in conversational flexibility and cross-domain scalability (Reddig et al., 2025); however, their inability to reliably distinguish valid-alternative from incorrect reasoning risks pedagogically misleading feedback, precisely the problem ITS student modeling is designed to address (Venugopalan et al., 2025). These findings confirm that linguistic fluency alone does not ensure pedagogical effectiveness (Shetye, 2024). Rather than replacing ITS, a more effective hybrid architecture may use LLMs for open-ended dialogue and hint generation while KG-grounded classifiers provide diagnostic labeling, with feedback conditioned on classifier outputs instead of self-assessed reasoning validity.

8 Conclusion

This study benchmarked LLMs as step-level tutors in propositional logic, evaluating both diagnostic accuracy and feedback quality across conditions that vary in solution information access. Our results show that LLMs reliably confirmed optimal steps but struggled with valid-alternative and incorrect solutions, precisely where adaptive tutoring is most critical. Classification failures on valid-alternative and incorrect solutions persisted across all models regardless of solution context, with model selection governing the magnitude of errors. Moreover, accurate classification did not reliably translate into pedagogically actionable feedback. These findings indicate that current LLMs cannot resolve the assistance dilemma without ITS-grounded diagnostic mechanisms. Effective LLM-based tutoring in structured reasoning domains therefore requires hybrid architectures that delegate diagnostic classification to KG-grounded models while leveraging LLMs for open-ended scaffolding and dialogue.

Limitations

This study targets propositional logic by design: KG-grounded exhaustive enumeration of valid inference paths is feasible in this formal domain and provides the principled ground truth that evaluation requires. Findings may not directly generalize to domains where exhaustive solution space enumeration is not tractable or where symbolic constraints are weaker.

Our 516 proof states are drawn from a single undergraduate Discrete Mathematics course at one institution across five difficulty levels, which limits the diversity of reasoning contexts and problem types represented.

Additionally, while LLM-simulated solutions enable controlled evaluation across all three solution categories, they may not fully capture the diversity of authentic student reasoning; planned extensions will investigate alignment between simulated and real student solution patterns using interaction logs.

Feedback agents were evaluated using zero-shot prompting after iterative prompt refinement and we did not see significant performance difference with few-shot prompting while the initial prompt calibration. However, we expect fine-tuning may improve classification performance, particularly for valid-alternative and incorrect categories, and remains a direction for future work.

This study diagnoses systematic classification failures without proposing a mitigation mechanism. The empirical findings are intended to inform the design of hybrid architectures that combine LLM flexibility with KG-grounded diagnostic precision; implementing and evaluating such systems is left to future work.

Our 10,836 solution-feedback pairs capture single-step feedback evaluation and do not model multi-turn student-tutor interactions or cumulative learning gains over time, which are ultimately what adaptive tutoring aims to improve.

Finally, our human evaluation covers 100 solution-feedback pairs per condition across four rubric dimensions; systematic fine-grained analysis of cases where models correctly classify a solution yet still produce inaccurate, vague, revealing, or unactionable feedback would require annotation at a scale, and represents an open methodological challenge for the field.

Ethics Statement

Student interaction data was collected under IRB approval with informed consent and anonymized before analysis. Two annotators with domain expertise in the tutoring system served as expert raters; both are co-authors of this study. To mitigate potential conflict of interest, annotators coded independently with no access to each other’s labels, research hypotheses, or study outcomes during annotation, and rubric definitions were finalized before coding began.

Reproducibility

Code and data can be found here ². All experiments use temperature 0.0 to ensure deterministic, reproducible results, prioritizing controlled comparison over response diversity. While real-world tutoring systems might benefit from non-zero temperature, our evaluation focuses on measuring the systematic effects of multi-agent architectures under controlled conditions. Model specifications and prompts appear in Appendices G and J.

AI Usage Disclosure

This work studies and evaluates large language models as research objects. We utilized large language models as assistive tools during manuscript preparation, including formatting guidelines and brainstorming organization, mainly, and paraphrasing on a need basis only. We did not use any AI tools for designing, implementing, or executing this research study. All the claims, analyses, hypotheses, and conclusions are developed, verified, and reviewed by the authors. Moreover, no AI tool was used for generating or labeling data, making judgments about data, or making any scientific claims. All implementations were reviewed, validated, and finalized by the authors. The authors take full responsibility for the correctness, originality, and integrity of the work.

A Inference Rule List

We employ a fixed set of propositional inference rules used in Logic Tutor for the dataset. The short names were used for consistent response generation and evaluation. The complete list of inference rules, along with short names and derivations are provided below in Table 4.

Table 4: Propositional inference rules used in this work.

Abbrev.	Rule Name	Form
MP	Modus Ponens	$P \rightarrow Q, P \Rightarrow Q$
MT	Modus Tollens	$P \rightarrow Q, \neg Q \Rightarrow \neg P$
Conj	Conjunction	$P, Q \Rightarrow P \wedge Q$
Simp	Simplification	$P \wedge Q \Rightarrow P \text{ (or } Q)$
Add	Addition	$P \Rightarrow P \vee Q$
DS	Disjunctive Syllogism	$P \vee Q, \neg P \Rightarrow Q$
HS	Hypothetical Syllogism	$P \rightarrow Q, Q \rightarrow R \Rightarrow P \rightarrow R$
Impl	Implication	$P \rightarrow Q \equiv \neg P \vee Q$
DN	Double Negation	$P \equiv \neg \neg P$
CP	Contraposition	$P \rightarrow Q \equiv \neg Q \rightarrow \neg P$
Com	Commutation	$P \vee Q \equiv Q \vee P$
Assoc	Associativity	$(P \vee Q) \vee R \equiv P \vee (Q \vee R)$
Dist	Distribution	$P \wedge (Q \vee R) \equiv (P \wedge Q) \vee (P \wedge R)$
CD	Constructive Dilemma	$(P \rightarrow Q), (R \rightarrow S), P \vee R \Rightarrow Q \vee S$
Equiv	Equivalence	$P \leftrightarrow Q \equiv (P \rightarrow Q) \wedge (Q \rightarrow P)$

B Dataset Distribution

Table 5: Dataset distribution across practice levels (2-6)

Level	Proof States	Avg. Statements
2 (Introductory)	48	5.86
3 (Basic)	111	7.73
4 (Intermediate)	148	7.94
5 (Advanced)	85	5.64
6 (Expert)	95	6.41
Total	516	6.72

* Levels 1 and 7 excluded because of unavailability of hints.

C Illustrative Logic Tutor Proof Interaction

Figure 4–6 illustrates a representative student interaction in the propositional logic tutor. These screenshots demonstrate forward chaining, rule application, and goal completion within the tutor interface.

Figure 4: **Initial proof state and goal specification.** The student is presented with the premises (top left) and the target conclusion ($J \vee K$) at the bottom. Available inference rules are displayed on the middle. At this stage, no intermediate steps have been derived, and the student must choose a productive forward step toward the goal.

Figure 5: **Rule application with guided simplification.** After deriving an intermediate conjunction via Modus Ponens, the student applies the *Simplification* rule. The interface prompts the learner to select the appropriate resulting literal (G or $\neg H$), illustrating fine-grained, step-level decision making supported by rule constraints.

Figure 6: **Successful proof completion.** The student derives J via Disjunctive Syllogism and applies the *Addition* rule to reach the target conclusion $J \vee K$. The system confirms completion, reinforcing correct rule sequencing and alignment with the goal state.

D Representative Proof State

This appendix presents an illustrative propositional logic proof instance Figure 7 annotated with inter-

Representative proof Instance	
Givens	
• (1) $((S \rightarrow Y) \vee (I * Q))$	
• (2) $((I \wedge Q) \rightarrow D)$	
• (3) $\neg D$	
• (4) $((S \rightarrow Y) \rightarrow D)$	
Intermediate Steps	
• (5) $\neg(S \rightarrow Y)$	[MT: (3), (4)]
• (6) $\neg(I \wedge Q)$	[MT: (3), (2)]
• (7) $(S \rightarrow Y)$	[DS: (6), (1)]
Conclusion: Y	
Peer Solution Context	
$\neg(\neg S \vee Y)$

Derive $\neg(\neg S \vee Y)$ from $\neg(S \rightarrow Y)$ using the Implication rule.	

Figure 7: Illustrative proof instance showing intermediate derivations and differential hint access for Peer and Teacher agents.

mediate derivations and agent-specific hints. Intermediate steps are derived by applying valid inference rules to previously established statements, with each step indexed and linked to its parent statements and rule application. This explicit structure exposes the shortest derivation path toward the conclusion while preserving alternative valid reasoning trajectories.

The Peer is provided only with the KG-verified optimal next symbolic step, enabling guidance that focuses on local progression without access to derivational context. In contrast, the Teacher additionally receives the rule and parent statements used to derive this step, allowing feedback to reference structural reasoning without revealing the answer directly. This distinction isolates the effect of solution access: the Peer operates under minimal grounding, while the Teacher leverages full derivational context to support more informed intervention. The representative proof state is available in Figure 7.

E Knowledge Graph based Evaluation Metrics

This appendix provides formal definitions and illustrative examples of the graph-based metrics used to evaluate next-step reasoning quality. All metrics are computed with respect to the knowledge graph (KG) constructed for each problem.

E.1 Step Complexity

Step complexity is computed as a nesting-weighted operator count:

$$c(\phi) = \sum_{o \in \mathcal{O}(\phi)} w(o, \phi)$$

where $w(o, \phi) = w_{\text{base}}(o) + w_{\text{nest}}(o)$ if o applies to a parenthesized subexpression in ϕ , and $w(o, \phi) = w_{\text{base}}(o)$ otherwise. Each opening parenthesis contributes an additional unit to capture structural depth.

Higher-order connectives receive larger nesting penalties because applying them to compound arguments requires tracking negation across multiple sub-propositions simultaneously (Johnson-Laird and Wason, 1970; Tithi et al., 2025). Atomic expressions containing no operators receive a score of 0.

For example: $c(F) = 0$; $c(A \vee B) = 1$; $c(A \rightarrow (B \vee C)) = 6$, where the implication receives its base weight plus a nesting penalty for applying to the parenthesized subexpression $(B \vee C)$.

F Implementation Details

Response Constraints. We standardize inference rule references using abbreviations (MP, MT, DS, HS, DeM, Impl) for consistent evaluation. The complete list appears in Table 4.

Token Limits. Rather than hard limits, we employ soft constraints via prompts (2–3 sentences).

Quality Validation. Two automated mechanisms ensure data integrity: (1) zero-token outputs trigger automatic retry, and (2) responses missing required JSON fields or violating constraints trigger re-prompting. Persistent failures after three attempts are flagged for manual review. Across 516 instances on 7 models, fewer than 3% required retry.

G Model Specifications

H Representative Examples of Failure Modes

Please refer to Figures 8, 9, and 12.

Proof state: 1. $((S \rightarrow Y) \vee (I \wedge Q))$, 2. $((I \wedge Q) \rightarrow D)$, 3. $\neg D$, 4. $((S \rightarrow Y) \rightarrow D)$, 5. $\neg(S \rightarrow Y)$, 6. $(I \wedge Q)$

Reasoning: Use *Modus Tollens* on $((S \rightarrow Y) \rightarrow D)$ and $\neg D$...

Reasoning error: Incorrect rule used

Solution context : D

Peer Feedback: "Great job on identifying *Modus Tollens* on $((S \rightarrow Y) \rightarrow D)$ and $\neg D$ as a key step. Now ask yourself, is there a step that could bridge your current progress to the **CONCLUSION** more efficiently..."

Figure 8: Example for **Vague Peer Feedback** - repeats student's incorrect solution

Proof state: 1. $(B \leftrightarrow \neg J)$, 2. $(\neg N \vee J)$, 3. $(B \vee \neg N)$, 4. $((B \rightarrow \neg J) \wedge (\neg J \rightarrow B))$, 5. $(N \rightarrow J)$, 6. $(\neg B \rightarrow \neg N)$

Student Reasoning: $(B \rightarrow \neg N)$ is optimal because it is the exact form of the conclusion, it can be derived from the contrapositive of $(\neg B \rightarrow \neg N)$...

Reasoning error: Incorrect derivation

Solution context: Derive $(J \vee \neg N)$ from $(\neg N \vee J)$ using *Commutative rule*.

Teacher Feedback: "Great job recognizing that $(B \rightarrow \neg N)$ is the contrapositive of $(\neg B \rightarrow \neg N)$ and using that to reach the conclusion..."

Figure 9: Example for **Teacher feedback validating incorrect reasoning**

Proof state:

$(S \rightarrow D) \vee I, (\neg S \vee Q) \rightarrow Y, \neg D, \neg D \rightarrow \neg I$

Student Reasoning: MT on $\neg D \rightarrow \neg I$ and $\neg D$ is needed to get $\neg I$ to be used later with $(S \rightarrow D) \vee I$ for DS

Solution Context: Derive $\neg S$ from $(S \rightarrow D)$ and $\neg D$ using *Modus Tollens* (MT).

Teacher Feedback: Great job identifying the relevant candidates! You correctly spotted that $(\neg D \rightarrow \neg I)$ and $\neg D$ could be useful, but there's a small mix-up with the rule. Recall: MT requires a negated *consequent*, while MP works with a *true antecedent*. How you might use MP on $(S \rightarrow D)$ and $\neg D$ to get $\neg D$.

Figure 10: Teacher (complete hint) feedback reveals solution on **incorrect** student response

Proof State (Excerpt)

$(S \rightarrow D), ((\neg S \vee Q) \rightarrow Y), \neg D, (\neg D \rightarrow \neg I), \dots$

Student Reasoning: $\neg S$ is optimal because we already have $(S \rightarrow D)$ from **INTERMEDIATE STEPS**, and simplifying it to $\neg S$ allows us to construct $(\neg S \vee Q)$...

Peer Solution context: $\neg S$

Peer Feedback: Excellent reasoning! You correctly identified how simplifying $(S \rightarrow D)$ helps set up the next step toward the conclusion...

Judge Feedback: Great job recognizing that you need $\neg S$ to proceed!, think about what rule you can use on $(S \rightarrow D)$ to turn it into a form more suitable for *Simp*...

Figure 11: Judge Verification Response, extending **Incorrect** Peer feedback (anchoring on **incorrect** student reasoning)

Proof state: 1. $\neg(\neg G \wedge B)$, 2. $(G \rightarrow D)$
Solution context: Derive $(\neg\neg G \vee \neg B)$ from $\neg(\neg G \wedge B)$ using DeM Law.
Student reasoning: Applying DN to $\neg(\neg G \wedge B)$ to get $(G \wedge B)$ is optimal because it directly gives us both G and B as available conjuncts...
Reasoning error: Incorrect rule application
Peer Feedback: "Great job applying double negation here! As you move forward, consider how you can use the new conjuncts to get closer..."
Judge Feedback: "You made a good attempt by considering double negation, but before applying DN, try using De Morgan's Law to rewrite..."

Figure 12: Example for **Judge Feedback repeating Peers' mistakes** - also directs towards the hint without recognizing the reasoning error

H.1 Student Agent Response

We show a representative Student agent response to demonstrate candidate generation, explicit reasoning, and next-step generation. The example corresponds to a single proof instance and highlights how intermediate reasoning is externalized for downstream tutoring and verification. The sample response is shown in Figure 13.

Givens: $((\neg K \vee L) \rightarrow (M \wedge N)), (K \rightarrow O), \neg O \neg K,$ $(\neg K \vee L), (M \wedge N)$
Conclusion: N
Student Reasoning: Applying a rule directly to $(M \wedge N)$ is the most efficient path to the conclusion. Since $(M \wedge N)$ is available, simplification yields the target.
Next Step: N
Rule: Simp
Parent Statement: $(M \wedge N)$

Figure 13: Sample problem instance and corresponding **correct** student response

I Manual Evaluation Protocol

To complement our automated metrics and better understand qualitative differences in feedback behavior across pipelines, we conducted a manual evaluation of a representative subset of model

responses. This analysis focuses on pedagogical properties of feedback that are difficult to capture through accuracy-based metrics alone, such as scaffolding quality and answer revelation.

I.0.1 Annotation Procedures

The samples were drawn from 200 distinct proof states stratified across solution categories and difficulty levels. Annotators included a graduate researcher and an instructor with expertise in the logic tutoring system, ensuring familiarity with the proof domain and pedagogical aspects of feedback. Annotators were provided with the problem context (givens, intermediates, and conclusion), the student's response, and the corresponding feedback generated by each feedback condition. Annotators worked independently and were blinded to model identity and quantitative performance results or feedback condition that generated the feedback. They were instructed to rate each feedback response independently on the four rubric dimensions based solely on the proof state, simulated solution, and generated feedback.

Annotators were trained on the rubric dimensions through an initial calibration phase using a shared sample of 20 pairs. Rubric definitions were iteratively refined, and disagreements were resolved through discussion until reaching a common interpretation of each dimension.

Due to the cognitive complexity of step-level logic feedback, during the initial calibration phase annotators agreed on a coarse 3-point ordinal scale (1–3) for all rubrics, with 1 = poor, 2 = partial, 3 = strong. This scale captures meaningful distinctions while maintaining annotation reliability and consistency. They then independently coded an additional sample until inter-rater reliability exceeded Cohen's $\kappa > 0.80$ per dimension and overall. Annotators then independently coded all remaining samples with no access to each other's labels or the research hypotheses.

I.1 Annotation Instructions

For each feedback response, rate independently on four dimensions: Correctness, Error Identification, Revealing, and Actionability. Each dimension is scored 1–3 as defined in the rubric. Base your rating solely on the proof state, the simulated student solution, and the generated feedback. For Correctness, assess whether the feedback contains logical errors that would mislead the student. For Error Identification, assess whether the feedback

precisely identifies the reasoning flaw or correctly affirms sound reasoning. For Revealing, assess the degree to which feedback discloses solution content explicitly. For Actionability, assess whether the feedback provides guidance specific enough for the student to proceed. When in doubt, refer to the calibration examples discussed during the calibration phase.

J Prompt Design

This section provides the complete prompts used for each agent in our multi-agent tutoring system. All prompts use structured JSON response formats to ensure consistent parsing.

Our prompt design translates established pedagogical principles into operational constraints for LLM agents. Each agent’s prompt encodes specific instructional strategies grounded in learning science research, ensuring that generated feedback aligns with effective tutoring practices. We describe the key design decisions below.

J.1 Student Prompt

The base system message includes the Role and Task information along with instructions, whereas the user message includes the problem instance itself. The prompt template is provided below in Figure 14.

J.2 Peer Prompt

The Peer operates under *minimal hint access*: it receives only the correct next step without knowledge of the complete solution path. The prompt enforces a critical **planning-before-feedback** requirement: the Peer must first generate an internal derivation plan explaining how the correct step is derived (identifying the rule and parent statements) before producing student-facing feedback. This design decision ensures the Peer develops a genuine understanding of the solution rather than pattern-matching, aligning with research showing that scaffolded feedback improves instructional quality (Serban et al., 2020). The prompt is illustrated in Figure 15.

J.3 Teacher Prompt

The Teacher agent has access to the complete next step and provides scaffolded feedback without revealing the answer. The prompt is illustrated in Figure 16.

J.4 Judge Prompt

The Judge agent is tasked with thoroughly evaluating both the student’s and the teacher’s responses to the logic proof problem. While the Teacher has access to the correct step and is therefore not asked to verify its own guidance, the Judge is specifically instructed to examine and identify any errors or inaccuracies present in both the student’s and the teacher’s responses.

Equipped with comprehensive access to the correct derivation steps from the knowledge base, the Judge carefully analyzes the reasoning behind both responses. Its role is to provide targeted evaluations and, where necessary, concise and actionable feedback to ensure alignment with the correct logic step. This approach ensures a robust layer of verification and strengthens the overall quality and pedagogical value of the feedback offered to the student. The prompt is illustrated in Figure 17.

Student Simulation Prompt

Role: You are a Student in an undergraduate Discrete Structures course solving a propositional logic proof. Your task is to produce the *single most optimal next step* that advances the proof toward the conclusion.

Task:

1. Review the givens and intermediate steps.
2. Propose 2–3 candidate next steps.
3. Select the candidate that most directly advances toward the conclusion.
4. Justify your choice and output the selected next step.

Constraints:

- Output exactly one next step in *symbolic notation only*.
- Use only predefined inference rules (e.g., MP, MT, Conj, DS).
- Parent statements must be actual expressions, not line numbers.

Response Format:

- CANDIDATES: 2–3 candidate steps with brief justification
- REASONING: Why the selected step is optimal
- NEXT_STEP: Symbolic expression
- RULE: Inference rule (short name)
- PARENT_STATEMENTS: Supporting expressions

Figure 14: Base System Prompt for Student

Peer Prompt

Role: You are a Peer evaluating a student's proposed next step in a propositional logic proof, with access to the KG-derived optimal step.

Task:

1. Analyze how the optimal step is derived (rule and parent statements).
2. Evaluate the student's candidates, reasoning, and chosen next step.
3. Classify the student's step as *Correct*, *Valid Alternative*, or *Incorrect*.
4. Provide brief, scaffolded feedback guiding the student toward the optimal step.

Constraints:

- Do not reveal the optimal step, its rule, or parent statements.
- Acknowledge what the student did correctly before addressing errors.
- Use Socratic questions to guide reasoning; keep feedback concise (2–3 sentences).
- Use predefined inference rule short names only.

Response Format:

- STUDENT_ERRORS: Brief explanation or Correct
- NEXT_STEP_CORRECTNESS: Correct / Suboptimal / Incorrect
- PEER_FEEDBACK: Scaffolded guidance without answer revelation

Figure 15: Base System prompt for Peer

Teacher Prompt

Role: You are a Teacher evaluating a student's proposed next step in a propositional logic proof, with access to the complete solution (KNOWLEDGE_BASE_STEPS).

Task:

1. Compare the student's response against the knowledge-base solution.
2. Identify errors in the student's logic, rule usage, or reasoning.
3. Classify the student's next step as *Correct*, *Valid Alternative*, or *Incorrect*.
4. Provide brief, scaffolded feedback guiding the student toward the correct solution.

Constraints:

- Do not reveal the exact next step, rule, or parent statements from the solution.
- Acknowledge correct aspects of the student's attempt before addressing errors.
- Use Socratic questions to guide reasoning; keep feedback concise (2–3 sentences).
- Refer to the student's candidates when relevant.
- Use predefined inference rule short names only.

Response Format:

- STUDENT_ERRORS: Brief explanation or Correct
- NEXT_STEP_CORRECTNESS: Correct / Suboptimal / Incorrect
- TEACHER_FEEDBACK: Scaffolded guidance without answer revelation

Figure 16: Base System prompt for Teacher

Judge (Verifier) Prompt

Role: You are an expert pedagogical AI Judge for propositional logic proof problems, with access to the complete solution (KNOWLEDGE_BASE_STEPS). You evaluate both the student's proposed next step and the Teacher's feedback.

Task:

1. Compare the student's response against the knowledge-base solution.
2. Identify errors in the student's reasoning, if any.
3. Classify the student's next step as *Correct*, *Valid Alternative*, or *Incorrect*.
4. Evaluate whether the Teacher's feedback correctly guides the student.
5. Either enhance the Teacher's feedback or override it with corrected guidance.

Constraints:

- Do not reveal the exact next step, rule, or parent statements from the solution.
- Acknowledge correct aspects of the student's attempt before addressing errors.
- Use Socratic questions to guide reasoning; scaffold rather than instruct.
- Override Teacher feedback if it is incorrect, misleading, or reveals the solution.
- Keep final feedback concise (2–3 sentences) and encouraging.
- Use predefined inference rule short names only.

Response Format:

- STUDENT_ERRORS: Brief explanation or Correct
- NEXT_STEP_CORRECTNESS: Correct / Suboptimal / Incorrect
- TEACHER_FEEDBACK_CORRECTNESS: Assessment of Teacher feedback
- JUDGE_ACTION: Enhanced or Overridden
- FINAL_FEEDBACK: Judge-approved scaffolded guidance

Abstract

Students learning algorithms often need support as they interpret traces, debug reasoning errors, and apply procedures across unfamiliar problem instances. In this paper, we present KITE (Knowledge-Informed Tutoring Engine), a Retrieval-Augmented Generation (RAG)-based intelligent tutoring system designed to serve as a classroom teaching assistant for algorithmic reasoning and problem-solving tasks. KITE uses an intent-aware Socratic response strategy to tailor support to different student needs, responding with targeted hints, guiding questions, and progressive scaffolding intended to strengthen students' algorithmic problem-solving ability. To keep responses aligned with course content, KITE uses a multimodal RAG pipeline that retrieves relevant information from course materials. We evaluate KITE using three forms of assessment: RAGAs-based metrics for response grounding and quality, expert evaluation of pedagogical quality, and a simulated student pipeline in which a weaker language model interacts with KITE across two-turn dialogues and produces revised answers after receiving feedback. Results indicate that KITE produces contextually grounded and pedagogically appropriate responses. Further, using simulated students, KITE's feedback helped the student models produce more accurate follow-up responses on procedural and tracing questions, suggesting that its scaffolding can support algorithmic problem-solving. This work contributes a tutoring architecture and an evaluation approach for assessing retrieval-grounded explanations and scaffolded problem-solving feedback.

1 Introduction

Large language models (LLMs) such as ChatGPT are now widely used by students for learning support, including explanation, feedback, and problem-solving (Pitts et al., 2025b; Pitts and Motamedi, 2026). Students often value these tools because they provide immediate access to assistance when

instructors or teaching assistants are unavailable (Pitts et al., 2025b). Although these tools make information more accessible, prior work raises concerns that students may accept AI-generated responses without sufficient evaluation, especially when those responses appear complete and confident (Essel et al., 2024; Pitts et al., 2025c, 2026). In education, this can lead students to bypass the reasoning processes that assignments are designed to develop (Pitts et al., 2025c, 2026). These concerns highlight the need for LLM-based systems that provide timely, course-grounded information while delivering pedagogically appropriate support that helps students reason through learning tasks.

Retrieval-Augmented Generation (RAG) (Lewis et al., 2020) offers a promising approach for building course-grounded tutoring systems by allowing LLM responses to draw on curated instructional materials. This grounding can reduce unsupported or course-inconsistent claims and help align explanations with the concepts, terminology, and conventions used in a course. However, strong retrieval does not by itself ensure effective tutoring. Even when a system retrieves relevant material, it may still provide responses that are too direct, insufficiently instructional, or mismatched to the student's immediate learning need. Prior work on intelligent tutoring systems suggests that effective support depends on both the accuracy of the information provided and how assistance is delivered, including when to offer direct explanation, feedback, or more guided support (Koedinger and Alevan, 2007).

Socratic tutoring offers one way to address this challenge by guiding learners through targeted questions, prompts, and progressive hints instead of immediately providing full solutions. This approach is grounded in cognitive apprenticeship and guided facilitation (Collins et al., 1989; Hmelo-Silver and Barrows, 2006), and has been used in dialogue-based tutoring systems such as AutoTutor (Graesser et al., 1999). However, integrating

Socratic guidance into retrieval-grounded tutoring systems remains an open design problem: a course-specific tutor must stay faithful to instructional materials while also providing feedback that fits the type of problem the student is trying to solve.

In this paper, we present **KITE** (Knowledge-Informed Tutoring Engine), a RAG-based intelligent tutoring system that connects students to relevant course materials while using intent-aware tutoring strategies to support different forms of help-seeking. KITE uses a multi-stage multimodal retrieval pipeline to locate relevant instructional content and an intent-aware response strategy to determine how that content should be used in the response. For questions that require direct explanation, KITE provides responses aligned with retrieved course materials. For procedural, debugging, validation, and tracing questions, KITE provides targeted feedback, guiding questions, and progressive hints to support student reasoning. To evaluate KITE, we first assess its retrieval-grounded outputs for non-procedural questions using RAGAS-based metrics for grounding, relevance, and response quality. We then evaluate procedural and tracing questions through a simulated student pipeline in which a weaker language model revises its answers after receiving KITE’s feedback. Finally, human experts assess the resulting interactions to judge feedback quality and whether the revised answers show improvement. This work contributes (1) KITE, an intent-aware tutoring system that combines multimodal retrieval with pedagogical support, and (2) an evaluation of its retrieval-grounded responses and scaffolded feedback using automated metrics, simulated students, and expert evaluation. We assess two research questions: **RQ1**: How well does KITE produce grounded, course-relevant responses for non-procedural student questions? and **RQ2**: To what extent does KITE’s feedback support improved responses on procedural and tracing questions?

2 Related Work

RAG-based educational assistants have been used for a range of instructional purposes, including interactive learning support, content generation, and large-scale course deployment (Li et al., 2025). Across these systems, grounding LLM responses in course materials has generally improved factual accuracy compared to unaugmented models. For example, KAG (Hasan et al., 2025) reports Preci-

sion@5 of 0.85 and a 34% reduction in student task completion time, while MoodleBot (Neumann et al., 2024) achieves 88% accuracy on course-related queries. However, these systems primarily function as direct question-answering tools and do not adapt their responses to different forms of student help-seeking.

Although RAG can improve factual accuracy, deployment studies suggest that course-grounded assistants also need evaluation in instructional workflows. In one classroom deployment, students showed strong pre-exam engagement but declining adoption across cohorts, and 36.8% reported frustration when responses extended beyond a constrained knowledge base (Thesen and Park, 2025). Edison (Miroyan et al., 2025), a GPT-4-based RAG assistant deployed in a large data science course, showed that retrieving from course documents and historical Q&A can support factual and relevant responses to live student questions. The study also demonstrates the value of TA-in-the-loop evaluation, using instructor edits and ratings to assess factuality, relevance, style, and efficiency. EduMod-LLM (Mittal et al., 2026) extends this line of work by treating educational Q&A as a modular pipeline, separating function calling, retrieval, and response generation so that system behavior can be evaluated more transparently.

Dialogue-based tutoring provides another foundation for supporting student reasoning. AutoTutor (Graesser et al., 1999) showed that progressive hints and collaborative answer refinement produced dialogues rated above the “good” threshold by domain experts, with semantic evaluation correlating at 0.49 with expert judgment. More recently, (Li et al., 2026) reported significant gains in self-efficacy ($d = 0.57$) from a Socratic AI platform in healthcare education. LeanTutor (Patel et al., 2026) similarly emphasizes guided feedback by combining LLMs with a theorem prover to check student proofs, identify errors, and provide hints toward a correct proof without giving away the complete answer. These systems show the value of scaffolded feedback for learning tasks that require students to reason through a process, yet they do not incorporate retrieval grounding to keep responses aligned with course-specific materials.

Other systems explore how retrieval and response strategies can be adapted for learning contexts. LPITutor (Liu et al., 2025) supports adaptive difficulty modulation through RAG and prompt engineering. KG-RAG (Dong et al., 2025) combines

Figure 1: KITE architecture

semantic retrieval with an expert-validated knowledge graph and reports a 35% improvement in learning outcomes ($d = 0.86$) in a study of 76 students, though its reliance on manual expert validation limits scalability. AutoTA (Dahal et al., 2025) provides a related approach to intent-aware educational assistance by classifying student queries and routing them to specialized response strategies. These systems show the value of adapting retrieval, domain structure, and response behavior to different learning needs. KITE builds on this direction by pairing multi-stage retrieval with intent-aware tutoring strategies for algorithmic reasoning tasks.

3 System Design

KITE is a retrieval-augmented tutoring system designed to support course-grounded dialogue for algorithmic reasoning and problem-solving tasks. As shown in Figure 1, the system includes five components: document preprocessing, embedding generation, multi-stage retrieval, intent-aware response generation, and session management.

3.1 Phase 1: Document Ingestion and Preprocessing

KITE begins by extracting text from course PDFs using *PyMuPDF*. Extraction is performed page by

page so that the original document structure remains traceable during retrieval. To reduce noise before indexing, the system applies a **frequency-based** cleaning procedure that removes repeated headers, footers, page numbers, and other formatting artifacts. Specifically, it examines the first and last two lines of each page, identifies repeated patterns that occur across pages, removes those patterns along with page numbers and special characters, and normalizes whitespace.

The cleaned text is then segmented into semantically coherent chunks for retrieval. We use **section-aware chunking** with a target size of 500 characters, or about 125 tokens, and a 100-character overlap. Headers are identified and retained to preserve local structure, while overlap carries forward the final two sentences of the preceding chunk.

3.2 Phase 2: Embedding Generation

Each chunk is encoded using OpenAI’s text-embedding-3-large model, producing 3072-dimensional embeddings. These vectors are L2-normalized so cosine similarity reflects semantic direction and are stored in a FAISS index (Johnson et al., 2019) for efficient local retrieval.

3.3 Phase 3: Multi-Stage Retrieval Pipeline

KITE uses a multi-stage pipeline designed to balance high recall and precision in retrieving course content. Retrieval begins with a dense bi-encoder search that returns the top 50 candidate chunks for a given student query. The query and document chunks are encoded independently, and similarity is computed using cosine similarity, allowing the system to capture semantically related content.

The candidate set is then refined through hybrid retrieval. Dense similarity contributes 70% of the retrieval score, while sparse BM25 keyword matching contributes 30%. This combination captures both semantic similarity and exact lexical overlap, which is useful when students use course-specific terminology, notation, or algorithm names.

To reduce redundancy among retrieved passages, KITE applies Maximal Marginal Relevance (MMR) with λ set to 0.7:

$$MMR = \lambda \times \text{Relevance} + (1 - \lambda) \times \text{Diversity}$$

The retrieved candidates are reranked using a cross-encoder/ms-marco-MiniLM-L-6-v2 reranking model implemented through Sentence Transformers, where the query and document are jointly encoded to produce more precise relevance scores. Finally, KITE applies source-based boosting so that chunks from official course materials receive higher priority. Chunks with reranking scores above 0.6 receive an additional boost of 0.3. The final context passed to the generator consists of the top eight retrieved chunks.

3.4 Phase 4: Intent Classification and Pedagogical Response Generation

KITE does not use a single response strategy for all student questions. Instead, it first classifies each query by pedagogical intent and then generates a response that matches the instructional purpose of the interaction. This allows the system to distinguish among questions, debugging requests, and other forms of help-seeking.

3.4.1 Intent Classification

Each incoming query is classified into one of five pedagogical intents using a keyword and pattern-matching classifier, as shown in Figure 1.

- **Direct Question:** factual queries seeking definitions or explanations (e.g., “What is A*?”).

- **Conceptual Questions:** deeper *why* or *how* questions probing understanding (e.g., “Why does BFS guarantee shortest path?”).
- **Algorithm Validation:** queries where a student submits their own implementation or trace for assessment.
- **Debugging:** queries involving a specific error or incorrect output.
- **Algorithm Tracing:** requests to step through the execution of an algorithm on a concrete problem instance (e.g., “Trace A* on this graph starting from node S”).

The classified intent determines which response generation strategy is invoked. In addition to these five query intents, KITE includes a dedicated answer evaluation mode for cases in which a student submits a written answer for assessment. This mode bypasses intent classification and routes directly to the feedback generation pipeline.

3.4.2 LLM Generation and Intent-Aware Response Strategy

All response generation in KITE is handled by GPT-5. Outputs are grounded in a structured prompt that injects the top eight retrieved chunks into a [CONTEXT] block. The model is instructed to prioritize course materials and avoid introducing information that is unsupported by the retrieved context, helping keep responses aligned with the course.

For direct questions and conceptual doubts, KITE produces explanations grounded in the retrieved material. Responses are written in a tutor-like tone that emphasizes reasoning instead of brief answer delivery. For conceptual doubts, the response also includes a follow-up question intended to prompt reflection.

For algorithm validation tasks, KITE adopts a Socratic assessment strategy instead of directly identifying errors. Responses include a brief evaluation of the student’s approach, acknowledgement of correct components, and guiding questions that target specific issues. This design supports learning without explicitly revealing the final solution, encouraging students to continue working through the problem independently.

For debugging assistance, KITE generates diagnostic prompts that guide students toward identifying errors through self-examination. Each response follows a structured hint progression and includes a learning point that connects the observed bug to the underlying conceptual principle, reinforcing understanding beyond the immediate correction.

For algorithm tracing queries, KITE retrieves the relevant procedural steps and rules from course materials and applies them step by step to the student’s specific problem instance. Each step explicitly maintains and updates algorithmic state variables such as OPEN lists, CLOSED sets, and selected nodes, following the tie-breaking rules and constraints defined in the query. The response concludes with the final path and cost when applicable.

3.5 Phase 5: Session Management

KITE maintains session state across multi-turn interactions to preserve continuity within a conversation. For each session, the system stores the original query, detected intent, prior responses, and any hints provided. When a student submits a follow-up query, KITE uses this stored context to determine how the interaction should continue: related direct and conceptual questions are treated as follow-ups, while validation, debugging, and tracing requests remain within their intent-specific response strategy when they concern the same problem or algorithm. For these turns, KITE constructs a brief context summary from the prior interaction and appends it to the retrieval prompt to reduce repetition and support progressive guidance.

4 Methodology

To evaluate KITE, we use three forms of assessment. First, we examine non-procedural responses using RAGAs-based metrics for grounding, relevance, and answer quality against instructor-authored reference answers. We then use a simulated student pipeline to assess whether KITE’s feedback helps produce improved responses on procedural and tracing questions. Finally, experts evaluate the pedagogical quality of KITE’s feedback and the resulting answer revisions.

4.1 Evaluation Dataset

We constructed an evaluation dataset of 109 questions drawn from the lecture slides and textbook used in a university *Introduction to AI* course, with each question paired with an instructor-verified reference answer. The dataset included 42 algorithmic questions, 51 procedural questions, and 16 direct-retrieval questions. We applied RAGAs to the 58 non-procedural questions, consisting of the algorithmic and direct-retrieval subsets, because these responses can be evaluated against reference answers for grounding, relevance, and answer quality.

Questions requiring procedural reasoning or algorithm tracing were evaluated separately through the simulated student pipeline and expert review described in Section 4.3.

4.2 RAGAs Evaluation

We evaluate KITE’s non-procedural responses using the RAGAs framework (Es et al., 2024; Roychowdhury et al., 2024), reporting six metrics:

- **Faithfulness:** Measures whether statements in the generated response are supported by the retrieved context, computed as the proportion of answer claims judged to be grounded in the retrieved chunks.
- **Answer Relevance:** Measures how well the generated response addresses the original question, computed from the cosine similarity between the user’s question and questions generated from the response.
- **Context Relevance:** Measures how much of the retrieved context is relevant to answering the question, computed as the proportion of retrieved statements judged to be useful.
- **Answer Similarity:** Measures semantic similarity between the generated response and the instructor-authored reference answer using sentence embeddings.
- **Factual Correctness:** Measures factual agreement between the generated response and the reference answer using an F1 score over claims classified as true positives, false positives, and false negatives.
- **Answer Correctness:** Measures overall correctness of the generated response relative to the reference answer as a weighted combination of factual correctness (0.75) and answer similarity (0.25).

All metrics use gpt-4o-mini as the judge model and text-embedding-3-small for similarity metrics. Retrieval uses top_k=5 from an initial candidate pool of 50.

4.3 Simulated Student Evaluation and Expert Evaluation

For procedural and algorithm-tracing questions, KITE provides Socratic feedback and guidance, making standard automatic scoring less appropriate. To evaluate how well this feedback supports learning-oriented revision, we use a two-stage simulated student pipeline followed by expert review.

Figure 2: Evaluation pipeline

Simulated Student Pipeline. Building on prior work that uses simulated student-tutor interactions to evaluate pedagogical support (Dinucu-Jianu et al., 2025), we use Meta-Llama-3.1-70B-Instruct as a proxy student in a structured interaction with KITE:

1. **Round 1:** The student model answers each question without assistance, establishing an unaided baseline.
2. **KITE Feedback:** KITE evaluates the student’s answer and provides feedback intended to guide revision.
3. **Round 2:** The student model revises its answer using KITE’s feedback.

Expert Evaluation. Three experts reviewed each interaction set, consisting of the Round 1 answer, KITE’s feedback, and the Round 2 answer. They judged whether the revised response demonstrated improved correctness and reasoning, and evaluated the quality of KITE’s feedback using a structured rubric adapted from prior work (Pauzi et al., 2025).

The rubric includes three dimensions. *Mistake Remediation* assesses whether the tutor correctly identifies the student’s error and explicitly acknowledges it in the response. *Scaffolding and Guidance* assesses whether the tutor provides appropriate support without revealing the answer and offers clear next-step direction. *Coherence and Tone* assesses whether the dialogue reads naturally and maintains an encouraging and supportive tone. Each criterion is scored as Yes/No, with NA used when a criterion is not applicable.

5 Results

5.1 RAGAs Evaluation

Table 1 reports the six RAGAs metrics evaluated on the 58 non-procedural questions, consisting of 42 algorithmic questions and 16 direct-retrieval questions.

Metric	Mean	Std. Dev.
Faithfulness	0.8486	0.2103
Answer Relevance	0.7558	0.2032
Context Relevance	0.9352	0.1905
Answer Similarity	0.7586	0.0923
Factual Correctness	0.4483	0.2477
Answer Correctness	0.6363	0.1810

Table 1: RAGAs evaluation summary ($n = 58$).

KITE performs strongly on retrieval and grounding metrics. Faithfulness (0.85) indicates that most answer statements are supported by the retrieved context, while context relevance (0.94) shows that the retrieved passages are highly pertinent to the question. Answer relevance (0.76) and answer similarity (0.76) further suggest that KITE’s responses remain on-topic and semantically aligned with instructor-authored reference answers.

Factual correctness (0.45) is lower than the other RAGAs measures. As discussed in Section 7, this metric is sensitive to claim-level overlap with a single reference answer and may understate the quality of responses that are accurate but phrased differently or provide additional valid detail. For this reason, answer similarity is used as the primary indicator of response quality in this setting. Its low

variance ($\sigma = 0.09$) also suggests relatively consistent performance across the evaluated questions.

5.2 Simulated Student and Expert Evaluation

Table 2 summarizes the expert rubric scores for 44 simulated student–KITE interaction triples. Inter-rater agreement between the two expert annotators was high, with Cohen’s $\kappa = 0.88$ and a raw agreement rate of 98.15%, indicating strong consistency in rubric judgments.

Metric	% Yes	% No	% N/A
Mistake Remediation (Identifying)	63.63	6.82	29.55
Mistake Remediation (Acknowledging)	63.63	6.82	29.55
Scaffolding	93.18	6.82	—
Guidance	93.18	6.82	—
Coherence (Naturalness)	93.18	6.82	—
Tone (Encouraging)	93.18	6.82	—

Table 2: Expert evaluation rubric results ($n = 44$).

KITE receives consistently high ratings for scaffolding, guidance, coherence, and tone, with 93.18% Yes judgments on each dimension. These results indicate that its feedback is generally well-structured, actionable, and supportive throughout the interaction. Mistake remediation receives 63.63% Yes judgments, but 29.55% of cases are marked N/A because the simulated student’s initial response was already correct and no error identification was required. When remediation is applicable, the results indicate that KITE identifies and acknowledges student errors appropriately.

Answer Improvement. Table 3 reports how students responses changed from Round 1 to Round 2 after receiving KITE’s feedback. The transition labels reflect expert judgments of whether responses were Incorrect, Partially Correct, or Correct with respect to the course materials. Among the 27 interactions that were not already correct, 24 showed improvement after KITE’s feedback (88.89%).

The most common transition was from Partially Correct to Correct, occurring in 14 cases (31.82%). This suggests that KITE is particularly effective at helping students resolve remaining reasoning gaps in responses that are already moving in the right direction. In six additional cases (13.63%), the response remained Partially Correct but still improved in quality, indicating that KITE’s feedback can support meaningful revision even when the student model does not reach a correct answer.

Transition	Count	%
Incorrect → Correct	1	2.27
Incorrect → Partially Correct	3	6.82
Already Correct	17	38.64
Partially Correct → Correct	14	31.82
Partially Correct → Partially Correct with Improvement	6	13.63
N/A	3	6.82

Table 3: Answer improvement breakdown ($n = 44$).

6 Discussion

This study examined whether a course-grounded, intent-aware tutoring system could provide reliable retrieval-based support and pedagogically useful feedback for problem-solving tasks. The results are encouraging with regard to both aims. For RQ1, KITE’s faithfulness (0.85) and context relevance (0.94) indicate that its responses are closely grounded in retrieved course material, while answer similarity (0.76) shows consistent alignment with instructor-authored reference answers. For RQ2, among the 27 simulated-student interactions with KITE, in which the initial student response was not already correct, experts judged 24 revised answers (88.89%) as improved after receiving KITE’s feedback. This suggests that KITE’s feedback provided guidance the student model could use to correct or strengthen its reasoning in a follow-up response. Experts rated 93.18% of KITE’s feedback positively for scaffolding and guidance, further indicating that the feedback was instructionally purposeful and well-structured.

Retrieval and response quality. The RAGAs evaluation indicated that KITE performed well on measures tied to retrieval and grounding, with context relevance of 0.94 and faithfulness of 0.85. These results show that KITE’s multi-stage retrieval pipeline surfaced course-specific material relevant to the questions and that its responses remained closely grounded in that retrieved context. At the same time, the lower factual correctness score (0.45) warrants careful interpretation, particularly relative to answer similarity (0.76). Prior work has noted that RAGAs-style claim matching and score stability can vary across response formulations and evaluation settings (Roychowdhury et al., 2024; Antal and Buza, 2025). In light of prior work, the 0.31-point gap observed in our results may reflect limitations of factual correctness as a reference-based metric for evaluating KITE’s pedagogically framed responses, although our evaluation does not isolate the source of that discrepancy.

Pedagogical effectiveness and design implications. Following the RAGAs evaluation, the simulated student and expert evaluations examined whether KITE’s feedback supported stronger revised answers, and was judged to be pedagogically appropriate. Specifically, the 88.89% improvement rate in the simulated student pipeline, together with the strong expert rubric scores for scaffolding, guidance, coherence, and tone, support that KITE’s feedback can support stronger follow-up answers on procedural and tracing questions. This emphasis on feedback quality is consistent with prior survey work on LLM applications in programming education, which argues that the educational value of these systems depends on aligning model capabilities with pedagogical goals, including the use of scaffolding and feedback strategies (Pitts et al., 2025a). In KITE, this alignment is reflected in pairing retrieval-grounded generation with feedback strategies designed for different forms of student support, such as direct explanations, or algorithmic-tracing guidance. While these findings are encouraging, the current evaluation design limits their generalizability, as discussed in Section 6.1.

6.1 Limitations and Future Work

This study has limitations that motivate future work. First, our evaluation of factual correctness is constrained by limitations of the RAGAs framework. KITE produces pedagogically framed explanations that may paraphrase or elaborate on course material, whereas RAGAs decomposes each response into atomic claims and uses NLI-style entailment to assess agreement with a single instructor-authored answer. With this, responses that are semantically aligned with the expected answer but differ in phrasing, detail, or framing may receive lower factual correctness scores. The 0.31-point gap between factual correctness (0.45) and answer similarity (0.76) in Table 1 is consistent with this concern, although our evaluation does not isolate the source of that discrepancy. Answer similarity, which is based on semantic embeddings, remains substantially higher and shows low variance ($\sigma = 0.09$), indicating relatively stable semantic alignment across questions. We therefore treat answer similarity as the primary quality indicator and note that using multiple human-written answers could reduce this limitation in future evaluations. Related concerns have been noted in prior work: Roychowdhury et al. (Roychowdhury et al., 2024) discuss limita-

tions in how RAGAs decomposes and assigns statements during metric computation, while Antal and Buza (Antal and Buza, 2025) show that RAGAs-based evaluation outcomes vary across question types and retrieval conditions. Future evaluations could use richer answer sets and metrics.

Second, the simulated student pipeline relies on a single LLM, Meta-Llama-3.1-70B-Instruct, as a proxy for student behavior. As a result, improvement between Round 1 and Round 2 should be interpreted as evidence that KITE’s feedback makes a stronger answer more recoverable, not as direct evidence of genuine student learning. Real learners may differ substantially in both the magnitude and pattern of improvement. Although this design is useful for early-stage evaluation, it cannot substitute for classroom evidence. A necessary next step is deployment with real students, including pre- and post-interaction assessments, analysis of revision behavior over time, and closer examination of how learners engage with feedback.

Third, the expert evaluation covers a relatively limited set of interaction cases, which constrains the generalizability of the findings. Although inter-rater agreement was strong ($\kappa = 0.88$), judgments of answer improvement and pedagogical quality still involve subjectivity, and the sample size limits precision. Future work should expand the annotation set and use finer-grained scoring schemes to better capture variation in feedback quality and answer improvement across question and error types.

7 Conclusion

We presented KITE, a RAG-based intelligent tutoring system that combines a five-stage retrieval pipeline with intent-aware pedagogical response generation. KITE adapts its responses to the type of student query, providing grounded explanations for factual questions and Socratic scaffolding for procedural and reasoning tasks. To evaluate these response modes, we introduced a two-part evaluation framework. RAGAs metrics assess retrieval quality, while a simulated student pipeline examines whether KITE’s feedback supports improved responses on procedural and tracing questions. Expert review using a structured rubric further evaluates the pedagogical quality of KITE’s feedback and verifies improvement in students’ revised answers. This work contributes an intent-aware tutoring architecture and an evaluation approach for RAG systems with mixed response strategies.

LLM-Powered but Rule-Grounded: Pedagogically Relevant Grammatical Error Characterization for Learner Model Construction

Abstract

Grammatical error correction approaches rarely characterize the pedagogical value of corrected errors. We propose a framework that combines LLM-based second-language writing correction with a rule-based characterization module to identify pedagogically relevant, fine-grained grammatical properties in learner texts. The characterization module targets 252 European Portuguese properties which are categorized by the CEFR level at which they are taught according to an authoritative curriculum, and property accuracy is inferred from contrasts between the learner and corrected texts. We evaluate the framework extrinsically by training interpretable automatic proficiency assessment models on accuracy features extracted from characterized errors in a Portuguese learner corpus. Across different prompting strategies, we show that models trained on features derived from LLM-corrected texts perform similarly to those trained on features derived from annotator-corrected texts and comparably to models trained on linguistic complexity features. Feature importance overlap is likewise high, and similar predictive patterns are observed in both annotator-based and LLM-based models, further supporting the validity of the proposed framework.

1 Introduction

Grammatical error correction (GEC) has received significant attention from the ACL community in recent years, as evidenced by the organization of multiple shared tasks (Ng et al., 2013; Bryant et al., 2019; Masciolini et al., 2025). The attention this task has received is well justified, as a system capable of proofreading free prose is not only of interest to second language (L2) learners but also to native (L1) speakers.

Identifying errors in learners' production is particularly relevant in the context of L2 learning, as it can be used not only to give feedback to learners,

but also to construct learner models that can be used in intelligent tutoring systems (ITSs) and intelligent computer-assisted language learning (ICALL) systems to deliver personalized language education. However, while GEC has moved toward the direction of evaluation methods with greater emphasis on characterizing errors at a finer level of granularity, the current granularity level of error annotation is insufficient for a learner model built based on the identification of such errors to be actionably informative. For instance, while the ERRANT scorer (Bryant et al., 2017) used to evaluate models submitted to the BEA-2019 shared task (Bryant et al., 2019) distinguishes between 25 main error categories, the information that an error represents the VERB:TENSE category is not fine-grained enough to build and update a learner model that can personalize L2 learning.

Evaluation methods used in GEC, and how validly they assess whether a corrected text contains corrections that are informative about an L2 learner's language development, also need to be reconsidered in the context of learner modeling. While reference-based evaluation methods compare the corrected text with a reference corrected by an expert, they do not account for the reality that there could be multiple valid approaches to correct a text (Bryant et al., 2023). To mitigate the limited nature of reference-based evaluation methods, various reference-free evaluation methods have been proposed (Asano et al., 2017; Choshen and Abend, 2018; Yoshimura et al., 2020; Islam and Magnani, 2021; Maeda et al., 2022; Östling et al., 2025). However, the existing reference-free evaluation methods also do not approximate the pedagogical relevance of the corrections in L2 learning contexts. Relatedly, Masciolini et al. (2025) distinguish between minimal edits and fluency edits in the shared task MultiGEC-2025, the latter of which emphasizes rephrasing the original text in favor of idiomaticity. The preference of one GEC approach

over the other in an L2 context likely hinges on the aspects of the L2 which are to be monitored and acted upon in a learner model.

The present work thus seeks to address the twofold challenge of identifying pedagogically relevant grammatical errors from texts produced by L2 European Portuguese learners and establishing the extent to which the identified errors are informative about L2 language development and can therefore be validly used to construct and update a learner model representing the learner's knowledge of various grammatical properties.

2 Related Work

A learner model represents a learner's current knowledge and mastery of a particular domain, inferred based on the data collected from the learner's interaction with a learning system (Xu and Bull, 2010). Learner models are thus vital to the construction of any adaptive educational system, as only through a detailed and accurate understanding of learners' competencies can they be matched to developmentally proximal learning material.

ICALL systems capable of identifying learners' errors and constructing or updating learner models accordingly have traditionally depended on mal-rules, symbolic representations of various ill-formed productions by learners according to an error taxonomy (Schneider and McCoy, 1998).

To build the BELLOC system, intended for English-speaking learners of French, Chanier et al. (1992) took advantage of what they referred to as "applicable rules," which explored rules underlying a learner's misconceptions if a correct parse for the sentence produced by the learner was not found. A limitation of the system was that when multiple potential misconceptions were matched, the system would prompt the learner to assess the grammaticality of test cases intended to isolate the learner's misconception, consequently exposing learners to further ill-formed constructions, which could reinforce the misconceptions.

A similar learner modeling strategy was adopted for the ICALL system Mr. Collins (Bull, 1994), which utilized pronoun placement tasks targeting European Portuguese clitic usage that required students to position pronouns and apply necessary phonetic contractions. The system addressed the issue of isolating a learner's misconceptions by taking into account the acquisition order of the structures. When a grammatical parse of a sentence

failed, the system first attempted to identify target-language misconceptions, such as overgeneralization. If that failed, the system investigated negative transfer, prioritizing background languages based on the student's proficiency and linguistic distance to Portuguese. The limited scope of the grammatical structures targeted, as well as the controlled nature of the tasks, is among the limitations of this system.

Another relevant system was German Tutor (Heift and McFetridge, 1999), later renamed to E-Tutor (Heift, 2005, 2008), which incorporated a learner model that tracked a student's performance across various grammatical properties. Each property was assigned a score from 0 to 30, where 0 indicated an expert and 30 a novice. Unlike previous systems that relied on mal-rules after a parse failure, this system utilized a grammar that freely generated parses for both grammatical and ungrammatical input by relaxing specific constraints. With every successful production, the score representing the property in the learner model was decremented, and with every failed production, it was incremented. Finally, an error priority queue ensured that the learner received feedback on only the most significant error depending on their performance history or the instructor's decision to avoid pedagogical overload.

The ICICLE system (Michaud et al., 2005) further extended these approaches by modeling the evolution of interlanguage in deaf learners of English who use American Sign Language. ICICLE utilized a grammar that included mal-rules to allow the parser to generate multiple interpretations for ill-formed input. To select the most plausible parse, the system consulted the existing learner model to determine which parse was more likely.

To mitigate the computational bottlenecks of parsing ill-formed learner productions at runtime, Rudzewitz et al. (2018) proposed a novel architecture that utilized an offline hypothesis generation mechanism. Starting from the well-formed target responses expected for specific exercises, the system pre-computed a constrained search space of both well-formed and ill-formed response variations, storing them alongside their corresponding error diagnoses. At runtime, an online component matched the actual student input to these pre-computed hypotheses.

Fine-grained, pedagogically relevant grammatical error identification, therefore, has often been constrained by either the exercise type or by the

range of grammatical properties covered, as writing mal-rules that can reliably detect the full spectrum of potential learner errors for all grammatical properties in free writing is an unfeasible task.

3 Methodology

The proposed framework for identifying pedagogically relevant grammatical properties consists of a GEC module and a subsequent rule-based error characterization module. In this sense, the framework resembles that of ERRANT, with the key distinction that the grammatical properties characterized are at a finer level of granularity and are designed to align with L2 learning curricula, making them appropriate for learner modeling. To evaluate whether the identified errors are meaningful for the process of language acquisition, we adopt an extrinsic evaluation approach via a downstream task (Resnik and Lin, 2010), whereby the predictiveness of accuracy features extracted based on the identification of errors for an automatic proficiency assessment model is used as a proxy for whether the errors can be used to track language development. By utilizing interpretable machine learning models, the predictive behavior of each feature can be visualized, and a determination about the sensibility of this behavior can be made by human experts.

In the remainder of this section, we first present the rule-based tool developed to identify European Portuguese grammatical properties, dubbed SABER¹. We then describe the learner corpus used in this study and the LLM-powered GEC approach. Next, we describe the adopted text alignment strategy and the accuracy inference algorithm devised for this study. Finally, we describe the experiment used for extrinsic evaluation.

3.1 Grammatical Property Identification

SABER is a rule-based NLP tool designed to identify formal grammatical properties in European Portuguese, which are aligned with the *Referencial Camões*², an authoritative reference mapping grammatical properties to the CEFR levels in which they are taught (A1–C2). SABER facilitates the extraction of 252 grammatical properties, comprising 147 word-level and 105 sentence-level properties.

The tool integrates both Stanza (Qi et al., 2020) and spaCy’s medium Portuguese NLP pipelines

to leverage their respective strengths at annotating the texts with linguistic information. Stanza serves as the primary pipeline due to its superior robustness in Portuguese lemmatization, while spaCy is retained for its specialized capabilities in named-entity recognition and multi-word token processing. This dual pipeline integration allows each pattern matching function, written using spaCy’s token, phrase, and dependency matchers, to utilize the annotations of the pipeline most relevant to the targeted grammatical property. To systematically mitigate upstream NLP annotation errors, SABER employs alternative patterns for each grammatical property designed to handle such preprocessing errors. At the time of development, these identification rules were iteratively tested and fine-tuned using synthetic, property-dense texts generated via GPT-4, optimizing the precision and recall of each rule. To evaluate the tool, five positive and negative test cases were generated for each property using Gemini 3.1, which were subsequently manually validated, resulting in an F₁ score of 85.70%, a recall of 80.48%, and a precision of 96.29%. SABER is available online as a Streamlit application³, and features extracted from an earlier version of it were used in Akef et al. (2025).

Importantly, SABER is designed to identify grammatical properties in well-formed texts, and may not be as robust on ill-formed texts. While this limitation may be considered as a drawback of the tool, it is in fact exploited to characterize learners’ errors in the accuracy inference algorithm described in Section 3.5.

3.2 Dataset

The dataset used to evaluate our framework is the COPLE2 learner corpus (Mendes et al., 2016), which contains 1,634 texts produced by L2 Portuguese learners as part of class examinations at the Instituto de Cultura e Língua Portuguesa (ICLP). The corpus is annotated with error tags and metadata, such as the learner’s L1, task prompt, and fine-grained CEFR levels (A1–C1). These metadata are particularly relevant for the current study, as we aim to test whether LLM prompts providing additional information about the task and the learner’s linguistic background result in corrections that are more informative about the learner’s proficiency.

For this purpose, three additional subsets of the

¹Sistema de Análise e Busca de Estruturas Relevantes

²<https://www.instituto-camoes.pt/activity/centro-virtual/referencial-camoes-ple>

³<https://saber-online.pt>

corpus were extracted for L1-specific proficiency assessment experiments. Based on the availability of texts for each L1, these subsets include L1 Chinese (both Mandarin and Cantonese), L1 Romance (Spanish, Italian, French, and Romanian), and L1 Germanic (English, German, and Dutch). The distribution of the texts in the entire corpus and each subcorpus across the five proficiency levels is presented in Table 1.

Subcorpus	A1	A2	B1	B2	C1
COPLE2	327	419	377	315	196
L1 Chinese	45	104	101	88	100
L1 Romance	171	132	151	117	62
L1 Germanic	71	95	67	60	11

Table 1: Distribution of texts across CEFR levels in COPLE2

3.3 Grammatical Error Correction

Leveraging LLMs’ ability to perform GEC in a zero-shot fashion (Kobayashi et al., 2024; Davis et al., 2024), we performed preliminary experiments by providing a detailed prompt to a range of open-source and proprietary models (including different versions and sizes of Gemma, Llama, Mistral, and Gemini accessed through an inference hosting provider and Google AI Studio) and by examining each model’s corrections of one text from COPLE2. The temperature, a proxy for the degree of creativity in LLMs, was set to the relatively low value of 0.2 (in a range of 0 to 2) for all models, as a measure of preventing over-correction by the model. The most cost-efficient model that satisfied the prompt instructions in the preliminary experiments was Gemini 2.0 Flash, and it is thus the main LLM used in this study, as the objective of this study is not to establish the state of the art in GEC, but rather to demonstrate the feasibility of leveraging corrections produced by even a relatively modest LLM for pedagogically informed learner modeling. For this purpose, we used three prompt variants to generate three corrected versions of each text in COPLE2: a minimalistic prompt (see Appendix A), a detailed prompt including the task instructions, and a detailed prompt including both the task instructions and the learner’s L1 (see Appendix B), to test whether the LLM could leverage this additional information to produce more informative corrections. Additionally, we used the annotator-provided corrections in COPLE2 as a reference for

evaluating the LLM-generated corrections through an extrinsic automatic proficiency assessment task. Moreover, to ensure that this framework is not specific to any one LLM, we utilized corrections made using Gervásio 70B PTPT (Santos et al., 2024), an open-source LLM for European Portuguese, with the detailed prompt including task instructions, as an alternative LLM to compare Gemini’s performance to.

3.4 Text Alignment

The alignment algorithm used is the linguistically enhanced Damerau-Levenshtein algorithm introduced by Felice et al. (2016) and used in ERRANT (Bryant et al., 2017). The key advantage of this alignment algorithm is its consideration for words’ lemmas and parts-of-speech, facilitating alignment in cases of word order errors. As two distinct NLP annotation pipelines are used in SABER, each corrected text also needs to be aligned twice due to the two pipelines using different multi-word tokenization strategies. At the time of error characterization based on the accuracy inference algorithm, each grammatical property utilizes the alignment corresponding to the NLP annotation pipeline used in SABER for that property.

3.5 Accuracy Inference Algorithm

For every property identified in the corrected version, the following scenarios are explored: If the same property is identified in the same aligned span of the learner-produced text, this is considered as a signal that the learner produced the property correctly. There is, however, a caveat: There may be cases where the same property is identified despite the form produced by the learner being different from the corrected form. For instance, the property *Subordinada adverbial (temporal/causal/final)* is matched for both the learner-produced form “*para banharmo*” and the corrected form “*para banhar.*” To account for these inaccuracies and at the same time allow for minor orthographical errors, the two aligned spans must have a normalized Levenshtein edit distance of θ or smaller to be considered as accurate, which is a threshold we determined empirically by comparing the performance of automatic proficiency assessment models trained on features extracted using the annotator-corrected version of the texts and based on different values of θ (see Section 4.1). On the other hand, if the property identified in the corrected version in a particular span is not equivalent to the property identified in the

corresponding span of the learner-produced text (or if no property is identified in the learner-produced text in that span), this is inferred as an inaccuracy, unless the forms of the two spans are identical. This could indeed happen in cases where other tokens that are not within the span of the identified property are different and thus affect the dependency parser’s annotations. In such cases, mismatch between the properties identified is attributed to the NLP pipeline’s error on the learner-produced text and the property identified in the corrected version is marked as accurate.

It is important to note that the final property stored (whether marked as accurate or inaccurate) is the one identified in the corrected version, even when a different property is identified in the same span of the learner-produced version. The rationale for this decision is that the learner’s failure to produce the target property correctly is more informative about the developmental stage of that target property than the inaccurately produced property itself. For instance, if an L2 learner of Portuguese uses the indicative mood instead of the subjunctive mood with *talvez* (maybe), this is a stronger signal that they have not yet (fully) acquired the subjunctive mood than that they have not acquired the indicative mood. In fact, the learner may be fully aware that the indicative mood is inappropriate in that utterance and choose it only to achieve their communicative objective. The full flowchart of the proposed accuracy inference algorithm is presented in Figure 1.

3.6 Evaluation

To perform extrinsic evaluation of whether accuracy features extracted using the accuracy inference algorithm can be used to track L2 development, 28 automatic proficiency assessment models were trained via five-fold cross-validation on various feature sets resulting from different text correction strategies. Additionally, models trained on broad linguistic complexity features, which have been shown to be predictive of learner proficiency (Ribeiro-Flucht et al., 2024), were included to test the contribution of accuracy features extracted in this study against.

3.6.1 Features

Following the characterization of grammatical errors in learners’ texts, accuracy features are calculated by dividing the number of accurate occurrences of a property by all attempts of that property,

Figure 1: Flowchart representing the property accuracy inference algorithm

represented as the sum of all accurate and inaccurate occurrences, including occurrences of inaccuracies resulting from the omission of the property in a text. Crucially, in cases where a property is appropriately absent from the text (meaning the counts of both accurate and inaccurate occurrences are zero), the value of the accuracy feature for that property is left as a missing value. The rationale for this decision is that not needing a property or successfully avoiding it is a qualitatively different signal from any accuracy value in the range of 0 to 1. Therefore, while the value of the property accuracy feature would be a missing value in such cases, it would be an informative missing value. This is analogous to not having a particular medical test’s results when trying to predict the condition of a patient: The fact that the test result is missing indicates that it was not prescribed by a medical professional, which itself is an informative signal.

This would, however, mean that the machine learning algorithm that is selected must indeed be able to treat missing values as informative. Moreover, as many properties in a text are sparse, the overall accuracy of properties at the same CEFR level were also included as additional features.

The system used to extract broad linguistic complexity features is CTAP (Chen and Meurers, 2016; Weiss and Meurers, 2019) which can extract a total of 489 complexity features for Portuguese and has previously been used for automatic proficiency assessment of Portuguese (Ribeiro-Flucht et al., 2024). The features can be classified into the five classes of count-based, lexical, syntactic, morphological, and discourse features.

3.6.2 Training Algorithm

Aiming for not only robust performance but also innate interpretability, we opted for explainable boosting machines (EBMs; Nori et al., 2019) as the training algorithm used for automatic proficiency assessment. EBMs combine generalized additive models (GAMs) with modern machine learning techniques such as bagging and boosting to achieve performance on par with the highest performing feature-based machine learning models while affording inherent interpretability.

An important advantage of EBMs is that due to the round-robin nature of training, the effect of collinearity is mitigated (Nori et al., 2019). This is especially important in this project, where a wide array of features is utilized, many of which are expected to correlate. Another advantage is EBMs’ handling of missing feature values by treating missing values as a separate value. For the purposes of visualization, EBM’s library recommends that missing features be set to an extreme value (InterpretML Team, 2021). The value of missing accuracy features was thus set to -1. This assignment would not interfere with the model’s prediction for the other values in the range of 0 to 1 due to the EBM’s binning strategy, which places values in bins, with -1 being in its own separate bin. Finally, due to their handling of collinearity, EBMs do not require external feature selection. Caruana (2020) posits that feature selection could result in better performance in EBMs but that the best feature selection strategy is based on the features contributing the most to the prediction of an already trained EBM model using the full feature set.

Threshold	Macro F_1
0.0	52.55% $\pm$ 2.56%
0.05	52.72% $\pm$ 1.63%
0.1	51.77% $\pm$ 2.57%
0.15	52.86 $\pm$ 2.51
0.2	52.62% $\pm$ 1.79%
0.25	52.91% $\pm$ 1.76%
0.5	53.54% $\pm$ 2.41%
1	53.47% $\pm$ 3.19%

Table 2: Performance of EBM models trained on accuracy features extracted using different threshold values based on the annotator-corrected version of COPLE2 texts

4 Results and Discussion

4.1 Orthographical Error Threshold

As introduced in Section 3.5, various values for θ were used to infer grammatical accuracy in learners’ texts. Specifically, the relevant spans share an identical grammatical property with their counterpart in the annotator-corrected version, despite differing in surface form. These values were 0, 0.05, 0.1, 0.15, 0.2, 0.25, 0.5, and 1, where a θ value of 0 represented extreme strictness and a value of 1 represented extreme leniency. The results of automatic proficiency assessment using property-based features extracted using each threshold value are presented in Table 2.

The results indicate that the relatively high threshold of 0.5 results in the features most capable of modeling L2 proficiency. While a normalized Levenshtein distance of 0.5 is unlikely to represent mere orthographical errors in longer spans, the better results achieved from the thresholds of 0.5 and 1 compared to the lower thresholds suggest that as long as the learner has produced the target grammatical property correctly, other lexical (or distinct grammatical) errors made within that production are likely not to undermine the learner’s knowledge of the target property.

4.2 Framework Evaluation

The results of the various models trained via five-fold cross-validation reported according to macro F_1 are presented in Table 3.

It can be observed that accuracy features extracted using the framework described in this paper demonstrate predictiveness of language proficiency with a macro F_1 in the range of 52% to 55%. While

Feature set	General	L1 Chinese	L1 Romance	L1 Germanic
CTAP	58.67 $\pm$ 3.45	63.74 $\pm$ 4.32	50.35 $\pm$ 2.63	50.05 $\pm$ 1.68
Annotator-based	53.47 $\pm$ 2.46	60.55 $\pm$ 3.66	47.39 $\pm$ 4.40	50.71 $\pm$ 6.15
Gemini-based – minimalistic	52.00 $\pm$ 2.26	55.42 $\pm$ 4.68	47.36 $\pm$ 4.60	47.77 $\pm$ 5.39
Gemini-based – detailed + task	53.44 $\pm$ 1.49	57.02 $\pm$ 3.65	45.95 $\pm$ 6.08	48.86 $\pm$ 6.65
Gemini-based – detailed + task + L1	54.92 $\pm$ 1.40	56.11 $\pm$ 2.52	47.49 $\pm$ 6.24	50.02 $\pm$ 5.49
Gervásio-based – detailed + task	53.03 $\pm$ 1.14	57.11 $\pm$ 5.03	44.07 $\pm$ 4.82	47.69 $\pm$ 3.75
CTAP and Gemini-based – detailed + task + L1	59.71 $\pm$ 1.73	63.09 $\pm$ 3.93	50.38 $\pm$ 4.92	51.34 $\pm$ 2.11

Table 3: Performance of EBM models according to macro F_1 trained on different feature sets and corrected subcorpora

CTAP complexity features demonstrate superior predictiveness with a macro F_1 score of 58.67%, we observe an improved performance up to 59.71% with the inclusion of accuracy features.

Moreover, we can observe that using a more detailed prompt, along with providing information about the task, consistently resulted in better performance than the minimalistic prompt, often approaching (and in some cases surpassing) the results based on the annotator’s corrections. Moreover, the inclusion of information about the learner’s L1 resulted in gains compared to cases when this information was excluded, but these cases were not consistent across all L1s, with a slight drop observed from L1 Chinese learners. Nevertheless, these results may be a promising indication of LLMs’ ability to capture traces of cross-linguistic influence in a zero-shot fashion.

Relatedly, while L1-specific Chinese models resulted in consistent improvement over the general model, L1-specific Romance and Germanic models consistently resulted in worse performance. This result may reflect class distribution effects from severe C1 imbalance in the L1 Romance and L1 Germanic datasets. (While the L1 Chinese dataset also has fewer samples at the A1 level, the distinction between learners at lower levels is often easier to model than at more advanced levels, where there is more variability among learners.)

The results obtained from the Gervásio-based features also support the applicability of this framework to other LLMs besides Gemini and supports the choice of Gemini 2.0 Flash as a low-cost but well-performing LLM for this particular task.

To further test the LLM-based accuracy feature extraction approach, we compared the top 30 fea-

tures of the best Gemini-based model with those of the annotator-based model. The overlap was high (29/30), indicating consistent feature prioritization. Because overlap does not guarantee similar informativeness, we compared contribution plots for three shared features: Accuracy of *Pretérito imperfeito do indicativo – verbos regulares*, *Presente do conjuntivo – verbos irregulares*, and *Subordinada adverbial (condicional/concessiva)* (Figures 2, 4, and 6 for Gemini; Figures 3, 5, and 7 for the annotator model).

While differences can be observed between the corresponding graphs, general patterns regarding how the use and accuracy of each feature develops from one proficiency level to the next are similar between the two models. Investigating the cases where noticeable differences exist between the two models (such as the prediction that inaccurate productions of *Presente do conjuntivo – verbos irregulares* are likely to occur at level C1 according to the annotator-based model in Figure 5, but not so according to the Gemini-based model in Figure 4), we observed differences in how the learner’s production was rendered grammatical, an example of which is as follows:

Learner: *Que seja com o telemóvel ou com o computador, podemos ficar em contacto permanente com os amigos ou com a família, assim que temos pouco para dizer uns aos outros.*

Annotator: *Quer seja com o telemóvel ou com o computador, podemos estar em contacto permanente com os amigos ou com a família, pelo que tenhamos pouco para dizer uns aos outros.*

Gemini: *Quer seja com o telemóvel ou com o computador, podemos ficar em contacto permanente com os amigos ou com a família, de tal forma*

Figure 2: Contribution of Accuracy of *Pretérito imperfeito do indicativo – verbos regulares* to the Gemini-based model

Figure 3: Contribution of Accuracy of *Pretérito imperfeito do indicativo – verbos regulares* to the annotator-based model

Figure 4: Contribution of Accuracy of *Presente do conjuntivo – verbos irregulares* to the Gemini-based model

Figure 5: Contribution of Accuracy of *Presente do conjuntivo – verbos irregulares* to the annotator-based model

Figure 6: Contribution of Accuracy of *Modificador – oração – subordinada adverbial (condicional/concessiva)* to the Gemini-based model

Figure 7: Contribution of Accuracy of *Modificador – oração – subordinada adverbial (condicional/concessiva)* to the annotator-based model

que temos pouco para dizer uns aos outros.

We can observe that while Gemini's correction diverges from that of the annotator in this instance, it is in fact the preferable correction, which could explain why the Gemini-based model with the most detailed prompt including both the task and the learner's L1 outperformed the annotator-based model.

5 Conclusion

To be used as a basis for making determinations about a learner's competencies, GEC must be performed by hypothesizing what the learner intended to produce and what possible factors led them to produce the ill-formed output. While LLMs may be suboptimal for pedagogically-informed grammatical error correction in every context, their capacity to render texts grammatical may still be leveraged for L2 learning applications.

For this purpose, we proposed a framework for characterizing pedagogically relevant grammatical errors corrected by an LLM using a rule-based tool capable of identifying European Portuguese grammatical properties in a fine-grained manner. With the development of similar tools for other languages, such as English (Sagirov and Chen, 2025) and German (Löfflad et al., 2025), the same framework can be applied to learner-produced texts of those languages to construct and update learner models.

Additionally, to evaluate our framework, we opted for an extrinsic evaluation approach by training automatic proficiency assessment models on accuracy features extracted based on either annotator-corrected texts or LLM-corrected texts and demonstrated not only largely similar performance between the two models, but also performance comparable to models trained on linguistic complexity features, which have previously been shown to be highly predictive of proficiency.

This framework enables the construction of highly detailed learner models by allowing learners' free-writing productions to be analyzed and monitored over time, thereby supporting adaptive and personalized language education through ITSs and ICALL systems. Consequently, while more powerful LLMs offer considerable potential for adaptive language education, realizing this potential requires sustained effort to develop NLP tools that pedagogically ground LLM outputs.

Limitations

Owing to the rule-based nature of SABER, it primarily covers formal grammatical properties and only a few use-based features. While a form may be taught at a lower CEFR level, certain uses (or functions) of that same form may correspond to higher CEFR levels, which SABER cannot currently distinguish.

Moreover, because the so-called accuracy features also encode information about the presence or absence of various grammatical properties, much of their predictiveness in the automatic proficiency assessment model is likely attributable to this information, making "accuracy" an operational label rather than a simple binary correctness score.

Furthermore, because the LLMs selected in this study were intended to demonstrate the feasibility of our proposed framework, more powerful reasoning-enabled LLMs could improve both over-

all and L1-specific model performance; however, this possibility was not explored in the present study.

Acknowledgments

This work was developed within the scope of the project *Promoção da Aquisição e ensino do Português como Língua de Herança através de Ferramentas Digitais Inteligentes*, financed by the Foundation for Science and Technology – FCT of the Republic of Portugal and the Camões Institute. We would like to thank anonymous reviewers for their insightful comments on a previous version of this paper.

A Minimalistic Prompt

Correct the following text according to standard European Portuguese grammar. Output only the corrected text.

B Detailed Prompt

You are an expert proofreader and teacher of European Portuguese, specializing in correcting texts written by language learners. Your primary goal is to correct the "Learner's Text" you will be given.

Adhere strictly to these instructions:

1. ****Correction Scope:**** Focus on fixing clear errors in European Portuguese grammar, spelling, punctuation, and word choice.
2. ****Minimal Edits:**** Implement the fewest changes necessary. Preserve the learner's original meaning, voice, and sentence structure as much as possible. Only alter what is incorrect or hinders comprehension. Do not rephrase for stylistic preference if the original is grammatically acceptable. That being said, cases that would still be acceptable in Brazilian Portuguese but not so in European Portuguese must also be corrected. Also, you must take the whole sentence into account for grammaticality. If you need to change the word form the learner produced to make the corrected sentence grammatical, you are allowed to do it.
3. ****Intent and Context:**** The learner wrote their text in response to a specific "Task Prompt". You will receive this "Task Prompt" along with the "Learner's Text". Interpret and correct errors based on what the learner likely intended to communicate to fulfill that "Task Prompt".
4. ****L1 Interference (Negative Transfer):**** You will be provided with the learner's native language (L1). Actively utilize this information to identify instances of negative transfer. When determining the correct form, base your decision on what the learner likely intended to produce given typical L1 interference patterns.
5. ****Language Variant:**** All corrections must use standard European Portuguese, not Brazilian Portuguese.
6. ****Output Format:**** Your response **MUST BE ONLY** the fully corrected European Portuguese

text. Do NOT include any explanations, apologies, greetings, or any other text before or after the corrected version.

You will receive the "Learner's L1", the "Task Prompt", and the "Learner's Text" clearly labeled in the user message.

Teaching Through Analogies: A Modular Pipeline for Educational Analogy Generation

Mariam Barakat¹ and Ekaterina Kochmar^{1,2}

¹Mohamed bin Zayed University of Artificial Intelligence, ²University of Victoria
 {mariam.barakat, ekaterina.kochmar}@mbzuai.ac.ae

Abstract

Analogies help learners understand unfamiliar concepts by relating them to known concepts. Despite recent advances, large language models (LLMs) continue to struggle to generate analogies of comparable quality to those produced by humans. We present a modular pipeline for educational analogy generation, decomposing the task into four stages: source finding, sub-concept generation, explanation generation, and evaluation. Grounded in Structure Mapping Theory, the pipeline enables systematic, stage-by-stage analysis of how model choice and input configuration affect analogy quality. We evaluate 12 state-of-the-art LLMs across six model families on two datasets with structured sub-concept annotations (SCAR and ParallelPARC), alongside seven embedding models for closed-setting retrieval. Our results show that sub-concepts substantially improve explanation quality and closed setting retrieval precision but provide limited benefit in open-ended source generation. We further introduce an LLM-as-a-judge evaluation methodology and validate its scoring against human annotations from seven annotators, finding that Claude Sonnet 4.6 aligns more reliably with human rankings than with fine-grained absolute scores. Taken together, our findings reveal cross-stage interactions that isolated studies cannot capture, and highlight sub-concept grounding as a key driver of analogy quality generation.

1 Introduction

As educational systems evolve in the age of AI, memorisation is no longer sufficient. Instead, students are required to be able to reason across domains and understand underlying structures – skills that are foundational to critical thinking in a rapidly changing world. One of the effective ways to develop these abilities is through analogies (Eriksson et al., 2024), which facilitate learning by mapping unfamiliar knowledge (*target system*) to prior

Figure 1: Illustrative example of a system analogy between the *atom* and the *solar system*, showing the source and target systems and their aligned sub-concepts.

knowledge (*source system*) through relational structures (Ye et al., 2024; Czinczoll et al., 2022; Bettin and Ott, 2023). Even when a significant cognitive gap exists, intermediate “bridging” analogies can guide students toward comprehension (Brown and Clement, 1989). In this work, we frame analogy generation as a modular pipeline to enable systematic analysis and improvement of each stage of the process.

Following previous research (Yuan et al., 2023a), we use the term *system* rather than *concept* to emphasise that analogies map multiple components. We refer to these constituent properties as *sub-concepts* throughout this paper, using “sub-” to emphasise that they are components of the larger system rather than standalone concepts.

As shown in Figure 1, explaining the *atom* (target system) through the *solar system* (source system) requires the explained mapping of individual sub-concepts: the *nucleus* maps to the *sun*, *electrons* map to *planets*, and *energy levels* map to

orbital distances.

Automatically generating high-quality analogies remains an open challenge, as poorly constructed analogies can introduce or reinforce misconceptions through incorrect mappings or oversimplification of underlying concepts (Zhou et al., 2025; Shao et al., 2025).

Despite recent progress, analogy generation research remains fragmented: prior work addresses retrieval, generation, or evaluation in isolation, without connecting them into a unified pipeline (Yuan et al., 2023a,b; Zhai et al., 2024; Sultan et al., 2024). Source finding relies predominantly on embedding-based retrieval over closed candidate pools, favouring surface similarity over structural alignment (Yuan et al., 2023a; Czinczoll et al., 2022; Jiayang et al., 2023), while sub-concept annotations in SCAR (Yuan et al., 2023a) and ParallelPARC (Sultan et al., 2024) are used for dataset construction rather than to guide generation. Evaluation remains under-addressed, as neither lexical metrics nor LLM-as-a-judge approaches align reliably with human judgments (Zhai et al., 2024; Bhavya et al., 2024), and most studies evaluate GPT-4 variants exclusively (Yuan et al., 2023a; Kim et al., 2023; Sultan et al., 2024; Shao et al., 2025; Li et al., 2024), leaving cross-model generalisability unexplored.

In this paper, we make three contributions: (1) a modular pipeline for educational analogy generation, grounded in Structure Mapping Theory (Gentner, 1981), decomposed into source finding, sub-concept generation, explanation generation, and evaluation; (2) a systematic cross-model evaluation across 12 LLMs from six families, finding that sub-concepts improve retrieval and explanation quality but offer limited benefit in open-ended source generation; and (3) a closed-to-open evaluation methodology, moving from controlled evaluation against gold annotations on SCAR (Yuan et al., 2023a) and ParallelPARC (Sultan et al., 2024) to LLM-generated candidates with baseline, embedding-based, and re-ranking selection strategies.

Each stage in our proposed pipeline corresponds to a research question:

RQ1: Source Finding. Can LLMs identify suitable source systems for a given target in both closed and open settings, moving beyond predefined candidate pools?

RQ2: Sub-concept Generation. Can LLMs reliably generate sub-concept mappings given a target-

source pair, and at which pipeline stages do sub-concepts improve performance?

RQ3: Explanation Generation. How well can LLMs produce full analogical explanations, and what input configurations yield the highest quality?

RQ4: Evaluation. How well does LLM-as-a-judge evaluation align with human judgments of analogy quality? Moreover, which generation model is the best at source finding in open settings?

All code and data are publicly available at: <https://github.com/Myriam2002/Toward-Usable-Scientific-Analogies>.

2 Related Work

Source Finding. Prior approaches to source finding rely primarily on embedding-based retrieval within closed candidate pools. Yuan et al. (2023a) use greedy and Kuhn-Munkres matching but focus on mapping given concepts rather than discovering new sources. Similarly, Yuan et al. (2023b) employ embedding similarity, but focus only on simple one- or two-relation analogies. Jiayang et al. (2023) show that LLMs are easily distracted by surface similarity, achieving only 30% accuracy compared to 85% for humans, while Ye et al. (2024) report substantial performance gaps on longer analogies. Li et al. (2024) further show that free generation outperforms embedding-based retrieval for analogies in the history domain, suggesting fundamental limitations of similarity-based methods. However, open-ended source discovery, where models must identify suitable sources without predefined candidates, remains largely unexplored.

Sub-concept Generation. Datasets such as SCAR (Yuan et al., 2023a) and ParallelPARC (Sultan et al., 2024) provide rich sub-concept annotations linking source and target systems. However, these annotations are primarily used for dataset construction rather than as inputs to generation models. Yuan et al. (2023a) show that sub-concept matching is critical for analogy quality, yet models achieve only 62% accuracy compared to 86% for humans, even when sub-concepts on both sides are provided. Moreover, evaluation is restricted to closed settings with fully specified inputs. The ability of LLMs to generate sub-concepts in open settings and their impact across pipeline stages has not been studied.

Explanation Generation. A well-matched source and accurate sub-concept mappings are necessary but not sufficient, as the explanation

is what ultimately determines whether a learner grasps the analogy. Producing explanations that capture *why* an analogy holds remains particularly challenging. Zhai et al. (2024) separate concept generation and explanation generation, finding that while LLMs approach human performance on concept generation, they struggle to produce explanations with sufficient relational depth. Bhavya et al. (2024) similarly report that model-generated explanations often lack coherence or drift from the intended analogy. Overall, explanation generation remains underexplored, particularly regarding how input representations affect quality.

Evaluation. Evaluating analogy quality remains challenging. Lexical metrics such as ROUGE and BLEURT fail to capture relational soundness (Zhai et al., 2024), while more structured evaluation frameworks still fall short of fully capturing analogy quality (Bhavya et al., 2024). Human evaluation, although more reliable, is costly (Jiayang et al., 2023; Czinczoll et al., 2022). LLM-as-a-judge methods offer a scalable alternative (Zhai et al., 2024), but their alignment with human judgments in analogy-specific settings remains mediocre.

3 Methodology

We present a systematic evaluation of the proposed modular pipeline for educational analogy generation, analysing how model choice and input configuration influence performance at each stage. The pipeline is decomposed into four stages aligned with our research questions: source finding (RQ1), sub-concept generation (RQ2), explanation generation (RQ3), and evaluation (RQ4). Figure 2 provides an overview of the experimental setup. To illustrate the full pipeline, consider the example in Figure 1, where the target system *atom* is explained using the source *solar system*. In the source-finding stage, candidate source systems are retrieved based on their similarity to the target. Next, sub-concept generation aligns components such as *nucleus* → *sun* and *electrons* → *planets*. The explanation generation stage then produces a natural-language explanation linking these correspondences. Finally, the analogy is evaluated based on coherence, mapping soundness, and explanatory power. This example demonstrates how each stage contributes to the final analogy.

3.1 Datasets

We use two datasets with explicit sub-concept annotations, enabling controlled evaluation across pipeline stages.¹

SCAR (Yuan et al., 2023a) comprises 400 system-level analogy instances across 13 scientific domains, created by human annotators. Each instance pairs a target system with a source system and is annotated with background descriptions, multiple sub-concept mappings, and explanations for these mappings (1,614 total annotated mappings). A representative example is provided in Appendix A.

ParallelPARC (Sultan et al., 2024) extends the ProPara dataset (Tandon et al., 2018) by transforming scientific-process descriptions into analogy pairs through a pipeline of LLM generation, automatic labelling, and human validation. It introduces 310 gold analogies, each annotated with relational alignments between corresponding properties in the format (entity, verb, entity) mapped to (entity, verb, entity). Please refer to Appendix A for an example.

3.2 Models

Closed Setting. For source retrieval in the closed setting, we evaluate a diverse set of embedding models: OpenAI’s embedding-small and embedding-large,² E5-large,³ BGE-large,⁴ MPNet-base,⁵ MiniLM-L6,⁶ and SPECTER.⁷ These models cover complementary paradigms: proprietary general-purpose embeddings (OpenAI), open-source retrieval-oriented models (E5-large, BGE-large), sentence-similarity baselines (MPNet-base, MiniLM-L6), and a domain-specialised scientific encoder (SPECTER), enabling comparison across models that differ in scale, training objective, and domain specificity.

Open Setting. For open-ended generation across all three stages, we use the DSPy framework (Khat-tab et al., 2022, 2024) for consistent input/output

¹Throughout the paper, we adopt the field names from SCAR for clarity, and align corresponding fields from other datasets to match this structure.

⁶<https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2>

⁷<https://huggingface.co/allenai/specter>

Figure 2: Overview of the proposed modular pipeline for educational analogy generation. Given a target system with its sub-concepts and background description, the framework proceeds through four stages: (1) source finding, where a pool of candidate sources is generated and selected; (2) sub-concept generation; (3) explanation generation; and (4) evaluation using an external LLM-as-a-judge. Each stage operates under input configurations tailored to its requirements, as determined by our empirical results. The output illustrates the final generated analogy, including aligned sub-concepts, explanation, and evaluation scores.

interfaces. We evaluate 12 LLMs across six families: OpenAI’s GPT-4.1 (mini, nano), GPT-OSS (20B, 120B), Meta’s LLaMA 3.1 (8B, 70B, 405B) Instruct, Google’s Gemini 2.5 Flash-Lite, xAI’s Grok-4-Fast, DeepSeek-R1, and Alibaba’s Qwen3 (14B, 32B). Models were selected based on OpenRouter’s public rankings in academia and science,⁸ balancing benchmark performance and cost-efficiency. All models were run at temperature 0.2 for consistency. Models were accessed via OpenAI, OpenRouter, and DeepInfra APIs.⁹

3.3 Source Finding (RQ1): Pool & Selection

Closed Setting: Embedding-based Retrieval.

Following prior work (Czinczoll et al., 2022; Yuan et al., 2023a), we embed all unique source systems from SCAR and ParallelPARC using the seven models from Section 3.2 and retrieve the top-20 candidates per target via cosine similarity. We test four input configurations with increasing context: (1) **target only** to assess surface-level retrieval; (2) **+background** to test whether definitional context helps; (3) **+sub-concepts** to assess the role of structural alignment; and (4) **sub-concepts & background** to evaluate the effect of combining both.

To go beyond similarity-based ranking, we introduce an LLM reranking stage: the top-10 candidates from the best-performing embedding configuration are passed to LLaMA-3.1-70B-Instruct, which selects the top-3 (Appendix B). We evaluate five reranking configurations: (1) **target only** as a baseline; (2) **+background** to test definitional

context; (3) **+gold sub-concepts** to assess structural alignment with gold annotations; (4) **+sub-concepts & background** to combine both signals; and (5) **+generated sub-concepts** to test whether generated sub-concepts can substitute for gold annotations in downstream selection (see Subsection 3.4).

We evaluate retrieval using $Hit@K$ (Eq. 1), which measures whether at least one gold source appears in the top- K results. This evaluation directly measures the quality of the retrieval component by assessing whether embedding models successfully retrieve appropriate source systems for a given target.

$$Hit@K = \frac{1}{N} \sum_{i=1}^N \mathbb{I}(\text{rank}_i \leq K) \quad (1)$$

Open Setting: LLM-based Generation. In the open setting, each of the 12 LLMs generates 20 ranked candidate sources from scratch, evaluated on SCAR only due to its educational relevance and computational constraints. Following closed-setting results, we test two input configurations: (1) **target only** and (2) **+sub-concepts**.

Since multiple candidates are generated, we evaluate three selection strategies: (1) **baseline top-1**, selecting the first output from an LLM; (2) **embedding-based top-1**, selecting the candidate with the highest cosine similarity to the target using text-embedding-3-small, strong in closed-setting retrieval and cost-efficient; and (3) **re-ranker top-1**, applying the LLM-based reranking framework from Subsection 3.3 with the **name & subconcepts** configuration, selected based on its strong performance in the closed setting.

⁸<https://openrouter.ai/rankings>

⁹OpenAI: <https://openai.com>, OpenRouter: <https://openrouter.ai>, DeepInfra: <https://deepinfra.com>

We report both *exact Hit@K* (Eq. 1) and *semantic Hit@K*. A generated source is considered correct if its embedding similarity to any gold source exceeds 0.374, corresponding to the upper tertile of pairwise gold similarities in SCAR (see Appendix C for more details). To avoid evaluation bias, we use all-MiniLM-L6-v2 for semantic Hit@K scoring rather than text-embedding-3-small, which is used in the embedding-based Top-1 selection step. Using the same model for both selection and evaluation might unfairly favour that configuration over others.

3.4 Sub-concept Generation (RQ2)

Before tackling the harder generation task, we revisit sub-concept matching – where models align given sub-concepts rather than produce new ones – to establish how well current LLMs capture structural correspondences and how far the field has advanced since Yuan et al. (2023a). Figure 3 highlights the distinction between the two tasks.

Inputs	Sub-concept Matching	Sub-concept Generation
Target System	Atom	
Target Sub-concept	[Energy levels, Electrons, Nucleus]	[Energy levels, Electrons, Nucleus]
Source System	Solar System	
Source Sub-concept	[Planets, Orbital Distance, Sun]	?
Output	[(Nucleus, Sun), (Electrons, Planets), (Energy Levels, Orbital Distances)]	[(Nucleus, Sun), (Electrons, Planets), (Energy Levels, Orbital Distances)]

Figure 3: Sub-concept matching and generation stage (RQ2). Given a target system (e.g., *atom*) and a source system (e.g., *solar system*), the model performs sub-concept matching using gold sub-concepts, and sub-concept generation when source sub-concepts are unavailable, producing aligned sub-concept pairs.

Sub-concept Matching. We re-evaluate sub-concept matching on SCAR, using its reported system accuracy (62% for GPT-4 vs. 86% for human annotators) as a reference point. Models receive randomly shuffled lists of target and source sub-concepts and must identify the correct correspondences. Then, we test two scenarios: (1) **without background**, where models rely only on sub-concept labels to recognise structural alignments; and (2) **with background** (see Listing 1 in Appendix A). We compare performance across the 12 LLMs to determine if the gap between model and human performance can be narrowed. For evaluation, we use *System Accuracy* (Yuan et al., 2023a), which assigns 1 if all pairs are correct and 0 otherwise.

wise.

Sub-concept Generation. To test whether LLMs can generate source sub-concepts in open settings, we test two configurations: given the target system, its sub-concepts, and the source system name, models must produce the corresponding source sub-concepts either (1) **without background** or (2) **with background**.

To evaluate, we use *Semantic Match Accuracy* (SMA). It uses cosine similarity between embeddings built with all-MiniLM-L6-v2.¹⁰ A fixed 0.7 threshold is adopted as a conservative heuristic for MiniLM embeddings, balancing semantic sensitivity with false-positive robustness.

$$\text{SMA} = \frac{\text{count}(\text{similarity} \geq 0.7)}{\text{total concepts}} \quad (2)$$

3.5 Explanation Generation (RQ3)

The third stage evaluates whether LLMs can articulate why an analogy holds, given a target and source. Each model generates a natural-language explanation. To isolate the contribution of different input signals, we test six configurations: (S1) **names only**, (S2) **+background**, (S3) **+unpaired sub-concepts**, (S4) **+unpaired sub-concepts & background**, (S5) **+paired mappings**, and (S6) **+paired mappings & background** (see the prompts in Appendix D). Throughout the results, we refer to these configurations as S1–S6 for brevity.

We evaluate generated explanations against gold references using cosine similarity over all-mpnet-base-v2 (Reimers and Gurevych, 2019) embeddings known for their ability to compare sentences to each other, capturing semantic equivalence beyond surface variation, and then we compare performance across input settings.

3.6 Evaluation (RQ4)

LLM-as-a-judge. To close the pipeline, we turn to evaluation – employing Claude Sonnet 4.6¹¹ as an external LLM judge, independent of all 12 pipeline models to reduce evaluation bias. Analogies are scored on three dimensions (using 1–3 scale): **coherence** (does the pairing make intuitive sense?), **mapping soundness** (are source–target

¹⁰all-MiniLM-L6-v2:<https://huggingface.co/sentence-transformers/all-MiniLM-L6-v2>

¹¹<https://openrouter.ai/anthropic/claude-sonnet-4.6>

correspondences structurally valid?), and **explanatory power** (does the analogy help a learner understand the target?). We use few-shot prompting with 10 calibrated examples spanning the full score range, as preliminary experiments without examples yielded less stable judgments. The full prompt is provided in Appendix E. We apply this judge across all 12 models to identify which one produces the highest-quality analogies overall.

Human Evaluation. To validate the LLM-based ratings, we collect human judgments from seven graduate students in AI and Business.¹² Prior to annotation, participants were provided with detailed instructions describing the task, including definitions of the three evaluation dimensions (coherence, mapping soundness, and explanatory power), along with illustrative examples to calibrate their understanding. Annotators evaluate 45 analogy pairs – 15 target concepts across five domains (check Appendix J for all analogies tested), each paired with three candidate sources – scoring each on the same three dimensions used by the LLM judge. In addition to scoring individual dimensions, annotators rank candidate analogies based on overall learning usefulness, capturing whether the analogy is intuitive and helpful for understanding the target concept. This ranking provides a qualitative, learner-oriented perspective that complements the dimension-level scores, yielding a total of 165 annotated datapoints.¹³

We measure inter-annotator reliability using Krippendorff’s α (Krippendorff, 2011) for ordinal ratings, Kendall’s W (Kendall, 1990) for ranking concordance across annotators, and Spearman’s ρ to compare human scores against LLM judge scores.

4 Results and Analysis

4.1 Source Finding (RQ1)

Closed Setting. Embedding-based retrieval shows consistent but dataset-dependent trends. On SCAR, adding sub-concepts yields the largest gains: OpenAI-Large improves from 0.710 to 0.792 and OpenAI-Small from 0.677 to 0.780, with the average increase from 0.557 to 0.673. Adding background provides no

benefit (avg. 0.629), likely because sub-concepts already capture structural alignment, and extra context introduces noise. On ParallelPARC, performance is near-saturated across settings (name-only avg. 0.876), with sub-concepts + background performing best (OpenAI-Large: 0.942, OpenAI-Small: 0.932, avg. 0.908), as its backgrounds provide richer relational signal than SCAR descriptions. Across both datasets, OpenAI embeddings consistently lead, while SPECTER lags (SCAR avg. 0.437; ParallelPARC avg. 0.781), reflecting weaker alignment with the task. Full results are in Appendix I.

For selection, we compare five configurations: re-ranking with names only, background, gold sub-concepts, gold sub-concepts + background, generated sub-concepts, and embedding-only retrieval. Re-ranking with gold sub-concepts achieves the best Hit@1 (24.5%), followed by background (22.2%), gold + background (20.8%), embedding-only (19.5%), generated sub-concepts (18.2%), and names only (17.5%). At Hit@2 and Hit@3, embedding-only performs best (30.5%, 40.0%), while gold sub-concepts rank third (31.8%, 35.8%), indicating that embeddings better retrieve candidates, whereas LLM re-ranking excels at top-1 selection. Generated sub-concepts outperform the name-only baseline (18.2% vs 17.5% at Hit@1), showing that the pipeline produces meaningful structure without gold annotations, though a gap remains. Overall, embeddings narrow the search space, while LLM reasoning over sub-concepts is key for precise selection.

Open Setting. Adding sub-concepts to the generation prompt yields only marginal gains (avg. 0.4–1.6 pp across all K and models), suggesting limited benefit compared to their substantial impact in retrieval, while incurring additional prompt cost, making target-only prompting the more practical default. The two exceptions are LLaMA-405B and Qwen3-32B, which show a slight decrease when sub-concepts are added. In absolute terms, the strongest Hit@20 results are achieved under the target with sub-concepts mode, with Gemini-2.5 (75.4%) and GPT-OSS-120B (75.3%) leading. However, top models cluster within a few percentage points of each other, suggesting that scale alone does not determine generation quality. Per-model results are in Appendix H.

¹²Annotation form: <https://myriam2002.github.io/analogy-annotation/>

¹³Confidence scores were collected for ranking but not used in the current analysis; incorporating them to weigh annotator reliability is left for future work.

Model	Matching		Generation	
	+BG	−BG	+BG	−BG
Grok-4	0.76	0.78	0.42	0.31
DeepSeek-R1	0.70	0.76	0.45	0.33
GPT-OSS-120B	0.69	0.72	0.34	0.27
Qwen3-14B	0.68	0.70	0.42	0.31
GPT-OSS-20B	0.66	0.68	0.39	0.28
GPT-4.1-mini	0.66	0.68	0.42	0.31
Qwen3-32B	0.65	0.71	0.40	0.31
Llama-70B	0.57	0.60	0.47	0.32
Llama-405B	0.56	0.62	0.47	0.33
Gemini-2.5	0.54	0.64	0.42	0.29
Llama-8B	0.40	0.46	0.44	0.27
GPT-4.1-nano	0.37	0.46	0.34	0.27

Table 1: System accuracy (Matching) and semantic match accuracy (Generation) with (+BG) and without (−BG) background descriptions. Bold indicates the best score per column. Gray shading indicates the higher-scoring mode per task for each model. Models are sorted by matching accuracy.

4.2 Sub-concept Generation (RQ2)

Table 1 contrasts sub-concept matching and generation across models. For matching, performance is slightly higher *without* background descriptions (avg. 0.650 vs. 0.603), suggesting additional context hinders alignment. Grok-4 leads at 0.78, surpassing the prior state-of-the-art of 0.62 (Yuan et al., 2023a), with gains attributed to model choice and prompt design (Appendix F). GPT-4.1-nano performs worst (0.37) despite not being the smallest model. These results motivate the harder generation setting explored next.

For generation, background descriptions provide a clear benefit, raising average semantic match accuracy from 0.298 to 0.412. The LLaMA family leads, with LLaMA-3.1-70B and LLaMA-3.1-405B both reaching 0.47, while GPT-based variants consistently occupy the lower half. Notably, GPT-4.1-nano and GPT-OSS-120B (0.34) underperform the smaller GPT-OSS-20B (0.39), confirming that scale alone does not guarantee stronger generation.

Based on these findings, we adopt LLaMA-3.1-70B with background descriptions for all subsequent generation experiments.

4.3 Explanation generation (RQ3)

The most apparent pattern is the large jump in similarity when sub-concepts are introduced: average scores rise from 0.724 in S1–S2 to 0.854 with unpaired sub-concepts (S3–S4) and 0.830 with paired sub-concepts (S5–S6). By contrast, adding back-

ground descriptions has a negligible effect across all three setting pairs (at most +0.006), consistent with our earlier matching findings. The best setting overall is S5 (systems + paired sub-concepts).

GPT-4.1-Mini is the strongest model overall (mean 0.827) and is the best performer in four of the six settings (S3–S6), indicating strong generalisation across sub-concept conditions. In the system-only settings (S1–S2), where scores are uniformly low and differences between models are small (range ≈ 0.03), no single model stands out, with GPT-OSS-120B and LLaMA-70B marginally leading in S1 and S2, respectively. Check Appendix G for the detailed heatmap.

4.4 Evaluation (RQ4)

Figure 4: Per-criterion scores assigned by Claude Sonnet 4.6 acting as an LLM judge. Scores are on a 1–3 scale across three criteria: Coherence, Mapping, and Explanatory power. Black borders indicate the top-performing model per criterion.

LLM-as-a-judge. Figure 4 shows LLM-as-a-judge scores across generation models. DeepSeek-R1 and Grok-4 achieve the highest overall performance (2.12 and 2.10), while GPT-4.1-Nano and LLaMA-3.1-8B perform the worst (1.71 and 1.68). The remaining models cluster closely in the middle, indicating relatively small differences across most systems. Across all models, coherence scores are consistently higher than mapping and explanatory scores, suggesting that models often produce intuitively plausible analogies even when structural mappings are incomplete or explanations are less informative.

Table 2 compares selection strategies under LLM-as-a-judge evaluation. The baseline and re-ranking approaches achieve close average scores

Dimension	Baseline		Embeddings		Reranker	
	mean	std	mean	std	mean	std
Coherence	2.463	0.652	1.956	0.748	2.437	0.677
Mapping	1.839	0.560	1.550	0.583	1.878	0.561
Explanatory	1.902	0.622	1.484	0.581	1.894	0.640
Avg. Score	2.068	0.541	1.663	0.575	2.069	0.550

Table 2: Comparison of analogy quality across selection strategies using LLM-as-a-judge scores (1–3 scale).

(2.068 vs. 2.069), but differ in their strengths: the baseline yields slightly higher coherence, while re-ranking improves mapping quality. This indicates that LLM-based selection refines structural alignment without substantially affecting overall performance.

Human Evaluation. Inter-annotator agreement is measured using Krippendorff’s α . Agreement is fair for *coherence* (0.382) and *explanatory power* (0.381), and lower for *mapping soundness* (0.342) – the most technically demanding dimension. Agreement is highest for the overall ranking (0.479) – where annotators rank the three candidate sources per target by overall learning usefulness – reflecting that relative ordering is easier to agree on than assigning consistent absolute scores across all three dimensions; for instance, two annotators may agree that source A is best, yet still differ on whether to rate its coherence a 2 or a 3. Appendix K provides detailed ranking statistics.

Spearman correlation (ρ) between Claude and human annotators varies across both annotators and dimensions. Agreement is highest for *explanatory power* (mean $\rho = 0.511$, range 0.269–0.678) and lowest for *mapping soundness* (mean $\rho = 0.342$, range 0.124–0.507), consistent with LLM-as-a-judge trends. Coherence falls between these extremes (mean $\rho = 0.368$, range 0.130–0.581), reflecting moderate agreement on whether analogies are intuitively meaningful. Annotator-level variability is also notable: the weakest alignment consistently comes from the annotator whose academic background differed most from the rest of the group, which may be partially explained by the domain composition of the evaluation set, where five of the fifteen target concepts were drawn from the computer science domain.

Table 3 compares Claude’s implicit ranking of analogies with human rankings. In contrast to the dimension-level results, ranking agreement is generally stronger, with most annotators showing moderate-to-high correlation (ρ between 0.46 and

Annotator	ρ	p-value	Significant
ANN-6JJP46	0.474	0.0010	True
ANN-6LG7WY	0.705	0.0000	True
ANN-DUNVTH	0.307	0.0404	True
ANN-H2NTMS	0.694	0.0000	True
ANN-KKN85E	0.463	0.0014	True
ANN-Q777H6	0.128	0.4012	False
ANN-VM9J6N	0.694	0.0000	True

Table 3: Spearman correlation between Claude’s implicit ranking and human rankings.

0.70) and statistically significant results ($p < 0.05$). The strongest alignment is observed for ANN-6LG7WY ($\rho = 0.705$), while ANN-Q777H6 again shows no significant agreement. These results indicate that Claude more reliably captures relative preferences between analogies than assigning consistent absolute scores, suggesting that LLM-as-a-judge is better suited for comparative evaluation settings than for fine-grained scoring.

Figure 5: Hierarchical clustering of human annotators and Claude based on their scoring patterns across evaluation dimensions. Distances reflect dissimilarity in judgments (computed from Spearman correlations). Claude clusters closely with a subset of annotators (e.g., ANN-VM9J6N), while other annotators (e.g., ANN-Q777H6) form more distant branches.

Figure 5 further examines agreement patterns through hierarchical clustering of annotators and Claude. The dendrogram reveals that Claude groups closely with a subset of annotators, suggesting similar evaluation behavior, while others form more distant clusters, indicating systematic differences in scoring. In particular, annotators with lower correlation scores (e.g., ANN-Q777H6) appear as outliers, consistent with the results in Table 3. This analysis reinforces that, although Claude aligns well with the majority of annotators, human judgments themselves are not fully consistent, highlighting the inherent subjectivity of analogy evaluation.

5 Conclusion

We presented a modular pipeline for educational analogy generation decomposed into source finding, sub-concept generation, explanation generation, and evaluation, systematically evaluated across 12 LLMs and 7 embedding models on SCAR and ParallelPARC. A central finding is that the best model and configuration differ across stages: Grok-4-Fast leads sub-concept matching without background descriptions, while LLaMA-3.1-70B with background is best for generation; GPT-4.1-Mini with unpaired sub-concept mappings achieves the strongest explanation quality; and OpenAI large embeddings with sub-concepts lead closed-setting retrieval, whereas the target-only configuration is more practical in the open setting. Sub-concept grounding consistently improves retrieval precision and explanation quality but provides limited benefit in open-ended source generation. For evaluation, DeepSeek-R1 and Grok-4-Fast produce the highest-quality analogies, and Claude Sonnet 4.6 aligns more reliably with human rankings than absolute scores, suggesting LLM-as-a-judge is better suited to comparative settings. Taken together, these findings demonstrate that no single model dominates across all stages, reinforcing the necessity of a modular, stage-aware approach to analogy generation.

Limitations

Several limitations of this work warrant acknowledgment. First, all experiments are conducted exclusively on English-language data, leaving the pipeline’s behaviour on morphologically richer or structurally different languages unexplored. In such settings, both embedding-based retrieval and generation quality may differ, and evaluation metrics such as Semantic Match Accuracy (SMA) may require recalibration.

Second, the 0.7 cosine similarity threshold used for SMA is a fixed heuristic selected for MiniLM-L6 embeddings rather than empirically validated. Its suitability for more abstract or diverse sub-concepts remains unclear, and alternative thresholds could meaningfully affect generation results.

Third, while each pipeline stage is evaluated independently, we do not evaluate the pipeline end-to-end. In a full pipeline setting, errors are likely to accumulate and propagate across stages. For example, an incorrect source selected during the retrieval stage would lead to flawed sub-concept mappings

and explanations downstream. This makes source finding a particularly critical stage, as early errors can disproportionately affect final analogy quality. Future work should investigate strategies to mitigate such compounding effects, such as iterative refinement, confidence-aware filtering, or alternative candidate selection mechanisms.

Fourth, the current architecture relies primarily on dense embedding models for retrieval and does not explore hybrid search strategies. Combining dense and sparse retrieval methods, or incorporating re-ranking models more extensively, could improve the robustness and quality of source selection, particularly in open-ended settings.

Fifth, analogy quality is inherently subjective: an analogy that is effective for one learner may not be equally meaningful for another. While this subjectivity is partially reflected in moderate inter-annotator agreement, our evaluation does not explicitly model user-dependent preferences. This limits the ability to assess how well generated analogies generalise across diverse learner populations. Future work should investigate how to construct learner profiles and incorporate them into the pipeline to generate personalised analogies tailored to factors such as cultural background, age, prior knowledge, and individual interests or hobbies.

Sixth, all pipeline stages are evaluated in a single-pass setting. We do not measure output variance across runs, which means that reported results reflect point estimates rather than stable averages. Although a low temperature (0.2) is used, some variability is expected, particularly for smaller models. Moreover, since ParallelPARC was used in only one stage of the pipeline (embedding-based retrieval) and the remaining stages relied solely on SCAR, the generalizability of the results across datasets may be limited.

Finally, the human evaluation study involves six out of seven graduate-level annotators from a single institution, which may introduce demographic and disciplinary homogeneity. Inter-annotator agreement is moderate, reflecting the inherent subjectivity of analogy evaluation and suggesting that a larger, more diverse annotator pool could yield different conclusions. In addition, open-setting source finding is evaluated only on SCAR due to computational constraints, limiting the generalisability of these findings to other domains of different difficulty.

Ethical Considerations

We do not anticipate any ethical risks related to this study.

B Prompt for LLM Re-ranker

You are selecting the best analogous source concepts for a scientific analogy.

Your task:

1. Analyze the target concept and its properties
2. Review each candidate source and its generated analogous properties
3. Select the 3 candidates whose properties BEST map to the target properties

Selection criteria:

- Strong structural/functional correspondence between source and target properties
- The source concept should be familiar and help explain the unfamiliar target
- Prefer sources with clear, well-mapped properties over vague ones

Return the EXACT names of your top 3 selected candidates.

""

Listing 3: Prompt used to select the top-3 analogies from the top-10 potential sources. This was wrapped in DSPY function as instruction, alongside specific input and output variables.

C Threshold Decision for Semantic Hit@K

To define a threshold for semantic Hit@K, we analyse the distribution of source-to-source similarity scores in the SCAR dataset. Specifically, we compare similarity values between *correct* source pairs (i.e., gold analogies) and *incorrect* pairs obtained by randomly shuffling sources.

Figure 6 shows that correct source pairs tend to exhibit higher similarity than incorrect ones, but with substantial overlap between the two distributions. This overlap indicates that a fixed high threshold (e.g., 0.5) would be overly restrictive, excluding many valid analogies that are structurally sound but not highly similar at the surface level.

To balance precision and coverage, we adopt a data-driven threshold of 0.374, corresponding to the upper tertile (top one-third) of similarity scores among gold source pairs. This choice captures a substantial portion of valid analogies while filtering out a large fraction of incorrect ones. As shown in the figure, this threshold lies above the mean similarity of incorrect pairs (0.180) and close to the mean of correct pairs (0.368), providing a principled trade-off between false positives and false negatives.

Figure 6: Distribution of source-to-source similarity scores in SCAR for correct (gold) and incorrect (shuffled) pairs. Dashed lines indicate the mean similarity for each group, while the dotted line shows the chosen threshold (0.374), corresponding to the upper tertile of gold similarities. A higher fixed threshold (e.g., 0.5) would exclude many valid analogies, motivating the use of a data-driven cutoff.

D Explanation Generation Prompts

This appendix lists the DSPy signatures used for the six explanation-generation settings. Each signature corresponds to one input configuration.

Setting 1: System Names Only This configuration provides only the target and source system names.

```
class ExplGen_Base(dspy.Signature):
    """Generate an analogy explanation using system names only."""
    target: str = dspy.InputField(
        desc="Target system"
    )
    source: str = dspy.InputField(
        desc="Source system"
    )
```

```

)
explanation: str = dspy.OutputField(
    desc="Explanation of the analogy"
)

```

Setting 2: System Names with Background Descriptions This setting augments system names with background descriptions for both systems.

```

class ExplGen_BaseDesc(dspy.Signature):
    """Generate an analogy explanation using names and descriptions."""
    target: str = dspy.InputField(
        desc="Target system"
    )
    target_desc: str = dspy.InputField(
        desc="Background description of the target"
    )
    source: str = dspy.InputField(
        desc="Source system"
    )
    source_desc: str = dspy.InputField(
        desc="Background description of the source"
    )
    explanation: str = dspy.OutputField(
        desc="Explanation of the analogy"
    )

```

Setting 3: System Names with Unpaired Sub-concepts This configuration provides both systems with unpaired lists of sub-concepts.

```

class ExplGen_Sub(dspy.Signature):
    """Generate an analogy explanation using unpaired sub-concepts."""
    target: str = dspy.InputField(
        desc="Target system"
    )
    target_sub: list[str] = dspy.InputField(
        desc="Target sub-concepts"
    )
    source: str = dspy.InputField(
        desc="Source system"
    )
    source_sub: list[str] = dspy.InputField(
        desc="Source sub-concepts"
    )
    explanation: list[str] = dspy.OutputField(
        desc="Explanation after implicitly pairing sub-concepts"
    )

```

Setting 4: System Names with Unpaired Sub-concepts and Descriptions This setting extends Setting 3 by adding background descriptions for both systems.

```

class ExplGen_SubDesc(dspy.Signature):
    """Generate an analogy explanation using unpaired sub-concepts and descriptions."""
    target: str = dspy.InputField(
        desc="Target system"
    )
    target_desc: str = dspy.InputField(
        desc="Background description of the target"
    )
    target_sub: list[str] = dspy.InputField(
        desc="Target sub-concepts"
    )
    source: str = dspy.InputField(
        desc="Source system"
    )
    source_desc: str = dspy.InputField(
        desc="Background description of the source"
    )

```

```

source_sub: list[str] = dspy.InputField(
    desc="Source sub-concepts"
)
explanation: list[str] = dspy.OutputField(
    desc="Explanation after implicitly pairing sub-concepts"
)

```

Setting 5: Paired Sub-concept Mappings This configuration provides explicit one-to-one sub-concept alignments between the target and source systems.

```

class ExplGen_Pair(dspy.Signature):
    """Generate an analogy explanation using paired sub-concepts."""
    target: str = dspy.InputField(
        desc="Target system"
    )
    source: str = dspy.InputField(
        desc="Source system"
    )
    pairs: list[list[str]] = dspy.InputField(
        desc="Paired target-source sub-concepts"
    )
    explanation: list[str] = dspy.OutputField(
        desc="Explanation for each paired sub-concept"
    )

```

Setting 6: Paired Sub-concept Mappings with Descriptions This setting combines explicit sub-concept pairings with background descriptions for both systems.

```

class ExplGen_PairDesc(dspy.Signature):
    """Generate an analogy explanation using paired sub-concepts and descriptions."""
    target: str = dspy.InputField(
        desc="Target system"
    )
    target_desc: str = dspy.InputField(
        desc="Background description of the target"
    )
    source: str = dspy.InputField(
        desc="Source system"
    )
    source_desc: str = dspy.InputField(
        desc="Background description of the source"
    )
    pairs: list[list[str]] = dspy.InputField(
        desc="Paired target-source sub-concepts"
    )
    explanation: list[str] = dspy.OutputField(
        desc="Explanation for each paired sub-concept"
    )

```

E Prompt for the LLM-as-a-Judge

You are an expert evaluator of scientific analogies.

Given a target concept and a chosen source analogy, evaluate whether this is a good analogy. A good analogy uses a FAMILIAR source concept to explain an UNFAMILIAR target concept through meaningful structural or functional parallels.

For each of the three dimensions below, first provide a brief reasoning explaining your assessment, then give the numeric score (1, 2, or 3).

ANALOGY_COHERENCE: Does the pairing make intuitive sense?

- 3: The connection is immediately clear and natural -- most people would see it without explanation. The source and target share an obvious structural or functional parallel.
- 2: A meaningful connection exists but requires some explanation to see. The link is real but not self-evident; a sentence or two is needed to establish it.
- 1: No meaningful connection exists, or the pairing is random, forced, or misleading.

MAPPING_SOUNDNESS: Could properties/mechanisms of the source map to the target?

- 3: Rich, consistent structural or functional correspondences exist.
Multiple source properties map precisely onto target properties.
The mapping holds across the main components of both domains.
- 2: Some valid mappings exist, but coverage is partial.
Core correspondences work, but important aspects of the target are not represented, or some mappings are approximate or strained.
- 1: No valid mappings are possible, or the apparent mappings are entirely superficial or misleading. Source and target are fundamentally incompatible.

EXPLANATORY_POWER: Would this analogy help a learner understand the target?

- 3: The analogy clearly illuminates the target concept and supports correct reasoning.
A learner could use it to predict or explain target behavior.
- 2: The analogy provides partial insight with notable limitations.
It conveys the general idea but cannot support deeper reasoning, or it risks creating minor misconceptions.
- 1: The analogy fails to aid understanding and would likely confuse or mislead a learner.

CALIBRATION EXAMPLES -- use these to anchor your scoring.

Score each dimension independently. The scale is 1-3 only:

3 = strong / clearly works

2 = partial / works with caveats

1 = doesn't work / poor or misleading

Example 1 (scores: 3 / 3 / 3)

target: "electric circuit" | analogy: "water flowing through pipes"

coherence=3:

The connection is immediately clear without any explanation needed.

A driving force pushes a substance through a constrained pathway in both cases -- this structural parallel is instantly visible.

mapping=3:

Multiple precise correspondences hold consistently:

voltage -> pressure | current -> flow rate | resistance -> pipe restriction

battery -> pump | closed loop -> closed pipe system

Relationships between variables (increase pressure -> increase flow) are preserved.

explanatory=3:

A learner can use the analogy to reason about Ohm's law qualitatively and make correct predictions about circuit behavior.

Example 2 (scores: 3 / 2 / 3)

target: "cell" | analogy: "factory"

coherence=3:

The analogy captures organized division of labor within a bounded system.

Most people immediately see why a cell resembles a factory.

mapping=2:

nucleus -> control center | ribosomes -> production workers

mitochondria -> energy supply | membrane -> boundary/security

explanatory=3:

Helps learners grasp coordination and specialization clearly.

Example 3 (scores: 2 / 2 / 2)

target: "mathematical function" | analogy: "machine"

coherence=2:

The shared idea (input -> transformation -> output) is real but requires explanation.

mapping=2:

input -> raw material, rule -> mechanism, output -> product

explanatory=2:

Useful for initial intuition but limited for deeper reasoning.

Example 4 (scores: 1 / 1 / 1)

target: "neural network" | analogy: "human brain"

coherence=1:
Superficial similarity ("neurons") without structural alignment.

mapping=1:
No valid correspondences across core mechanisms.

explanatory=1:
Likely to mislead understanding.

Example 5 (scores: 1 / 1 / 1)
target: "chemical reaction" | analogy: "a novel"

coherence=1:
No meaningful connection.

mapping=1:
No systematic correspondences.

explanatory=1:
No instructional value.

Example 6 (scores: 3 / 1 / 2)
target: "democracy" | analogy: "majority vote in a classroom"

coherence=3:
Both involve majority-based decisions.

mapping=1:
Institutional aspects have no counterpart.

explanatory=2:
Partial understanding only.

Example 7 (scores: 2 / 3 / 3)
target: "atom" | analogy: "solar system"

coherence=2:
Spatial similarity exists but requires explanation.

mapping=3:
nucleus -> sun | electrons -> planets

explanatory=3:
Supports initial reasoning about structure.

Example 8 (scores: 3 / 2 / 1)
target: "photosynthesis" | analogy: "solar-powered factory"

coherence=3:
Energy conversion is clearly analogous.

mapping=2:
sunlight -> energy supply | chloroplast -> factory

explanatory=1:
Oversimplifies processes.

Example 9 (scores: 1 / 3 / 3)
target: "compound interest" | analogy: "a snowball rolling downhill"

coherence=1:
Domains differ fundamentally.

mapping=3:
principal -> snowball | growth -> accumulation

explanatory=3:
Clearly conveys accelerating growth.

```
Example 10 (scores: 3 / 1 / 2)
target: "ecosystem" | analogy: "a family"

coherence=3:
  Interdependence is clear.

mapping=1:
  No structural ecological correspondences.

explanatory=2:
  Partial intuition only.
```

Listing 4: Prompt used to evaluate the analogies from different settings on different dimensions. This was wrapped in DSPY function as instruction, alongside specific input and output variables.

F Ablation results for Sub-concept Matching

Figure 7: Ablation study on sub-concept matching system accuracy, isolating the contribution of each component relative to prior work (Yuan et al., 2023a). Upgrading the model to our best performing Grok-4 alone (B) yields the largest gain (+10.8%), followed by prompt redesign (C, +5.5%). Wrapping with DSPy Chain-of-Thought (D, our final system) introduces a marginal drop (−1.5%), confirming that automated prompt optimisation does not improve over the hand-crafted prompt for this task.

Figure 7 shows the ablation study to figure out what aspect actually led to the improved results.

G Explanation Heatmap Results

Figure 8 presents SBERT similarity scores across twelve LLMs and six experimental settings for the explanation generation stage.

H Open Setting Source Finding: Per-Model Hit@20 Comparison

Figure 9 presents per-model Hit@20 scores in the open setting, comparing target-only and target with sub-concept prompting across all twelve models.

Figure 8: Average SBERT similarity scores across twelve models and six experimental settings. Settings S1-S2 provide only system-level context (without and with background descriptions, respectively), while S3-S4 additionally supply unpaired sub-concepts and S5-S6 supply paired sub-concepts. Black borders indicate the best-performing model per setting. GPT-4.1-Mini consistently leads in sub-concept-enriched settings (S3-S5), while DeepSeek-R1 and Qwen3 variants are competitive in paired settings (S5-S6). Scores rise substantially when sub-concepts are introduced (S3-S6 vs. S1-S2), suggesting that grounding the comparison in explicit sub-concept structure is a stronger driver of similarity than background context alone.

I Embedding-based Retrieval Results

Figure 10 and 11 show the heatmap of the 7 embedding models across 4 input configurations.

J Annotation Dataset

Table 4 presents the annotation dataset, comprising 15 target concepts spanning five domains, each paired with three source analogies evaluated under target-only and target with sub-concept conditions. Furthermore, Figures 12- 21 provide an overview of the web-based annotation form used in our human evaluation study. The form guides annotators through rating each of three candidate source analogies per target concept on three dimensions – coherence, mapping soundness, and explanatory power – on a 1–3 scale, before ranking the three sources by overall learning usefulness and reporting their confidence in the ranking.

Figure 9: Per-model Hit@20 comparison in the open setting under Target-Only and Target + Sub-Concept modes. Results are reported using semantic matching and highlight the effect of incorporating sub-concepts on top-20 retrieval performance.

Figure 10: Hit@20 performance on the SCAR dataset across embedding models and input configurations. Incorporating sub-concepts consistently improves retrieval compared to name-only inputs, while adding background provides mixed benefits. OpenAI embeddings achieve the strongest overall performance.

Figure 11: Hit@20 performance on the ParallelPARC dataset. Retrieval performance is generally higher than SCAR, reflecting the more structured nature of process-based analogies. Combining sub-concepts with background yields the best results across most models, indicating the value of richer contextual representations.

Table 4: Annotation dataset: 15 target concepts across five domains, each paired with three source analogies. T = Target-only, T+S = Target + Sub-concepts.

Welcome to the Analogy Quality Annotation Study

Your expert judgment helps us validate how well automated systems evaluate analogies for education.

⚠ Important: Please complete the form in one sitting, as refreshing the page will reset your progress.

BACKGROUND

We are building a system that generates **analogies** to help learners understand complex concepts through familiar comparisons. Large Language Models (LLMs) serve as automated judges to rate analogy quality — but we need **human evaluation** to verify their reliability.

YOUR TASK

You will see **15 target concepts**, each paired with **3 candidate source analogies**.

All 15 Targets

Rate each analogy on 3 quality dimensions (1–3 scale), rank the 3 analogies by learning usefulness, and indicate your confidence in the ranking.

Estimated time: **60–90 minutes**. A floating reference guide will be available throughout.

← Back

Continue →

Figure 12: (a) Welcome screen introducing the task and study background.

Key Definitions & Rating Scale

Read these carefully — they define exactly what you're evaluating.

WHAT IS AN ANALOGY?

An **analogy** maps a *target concept* (the unfamiliar topic being learned) onto a *source concept* (something more familiar). A good analogy preserves structural and functional relationships, helping learners transfer understanding from the known to the unknown.

Example: "A **cell** is like a **factory**" — Cell is the target, Factory is the source.

THE THREE DIMENSIONS

1. COHERENCE

Does the pairing make intuitive sense? When you hear "Target is like Source," does the connection feel natural and immediately understandable?

2. MAPPING

Do the key parts of the target correspond to parts of the source? Read both descriptions carefully and try to identify counterparts between important components, processes, or relationships of the target and the source.

How to identify mappings: Go through the target description and list its key elements (components, roles, processes, relationships, inputs, outputs). Then, for each element, ask: *is there something in the source description that plays a similar role or serves a similar function?* The more elements you can pair up, the higher the mapping score. Elements left without a counterpart count against it.

Tip — look for shared roles (e.g., something that acts as a barrier in both), *shared processes* (e.g., both involve something flowing or transforming), and *shared relationships* (e.g., one part controlling another in both).

Note on cross-type analogies: Some analogies compare a process to an object or device (e.g., comparing a biological process to a machine). This is perfectly fine — what matters is whether the **functional roles and**

Figure 13: (b) Key definitions and rating scale for the three evaluation dimensions.

Note on cross-type analogies: Some analogies compare a process to an object or device (e.g., comparing a biological process to a machine). This is perfectly fine — what matters is whether the **functional roles and relationships** align, not whether both are the same kind of entity. A device can have parts that map onto the stages or components of a process and vice versa.

3. EXPLANATORY POWER

Would this analogy actually help someone learn the target concept? Does it make the abstract concrete, reveal causal relationships, or enable the learner to reason about how the target works?

A key factor is the **complexity gap** between source and target. The most useful analogies explain complex or unfamiliar concepts through simpler, more concrete, more everyday sources — moving the learner from the known to the unknown. An analogy where the source is just as complex or technical as the target may have good structural correspondence, but limited teaching value because the learner has no easier foothold to start from. For example, explaining one scientific process through another equally specialized process offers less educational benefit than explaining it through something a non-expert already understands intuitively.

When scoring Explanatory Power, consider: is the source meaningfully simpler or more familiar than the target? A "High" score typically requires the source to give the learner an easier entry point — not just a structurally parallel one.

RATING SCALE

SCORE	LEVEL	GUIDELINE
3	High	Strong and effective. Little to no weakness on this dimension.
2	Medium	Partial or acceptable. Some elements work but with notable gaps.
1	Low	Weak or broken. The analogy fails on this dimension.

Figure 14: (c) Explanatory power dimension definition and full rating scale.

RANKING CONFIDENCE

After ranking the three source analogies for each target, you will indicate your **confidence in the ranking**. For some triplets, the quality differences are stark and the order is obvious; for others, the analogies are very close in quality and the ranking feels like a coin flip.

LEVEL	MEANING
High	The quality differences are clear — this ranking order is obvious.
Medium	You have a reasonable sense of the order, but some positions were close calls.
Low	The analogies are very similar in quality — the ranking could easily go another way.

WORKED EXAMPLES (NOT PART OF YOUR ANNOTATION)

Three examples showing how to rate analogies. Click each tab to study a different target. Note: in these examples we describe the reasoning behind each score — during your annotation, you should apply similar reasoning by reading the source and target descriptions and identifying parallels yourself.

Atom

DNA

Electricity

Target: Atom (Physics) — The fundamental unit of matter, consisting of a dense central nucleus (protons and neutrons) surrounded by electrons in orbital shells, held together by electromagnetic forces.

"Solar System" → Coh 3 · Map 3 · Exp 3

Coh 3: The image of a central mass with orbiting bodies clicks immediately with the idea of a nucleus surrounded by electrons.

Map 3: Nearly every key component of the atom has a natural counterpart in the solar system — the central body, the orbiting objects, the governing force, and the orbital structure all find clear parallels.

Exp 3: A learner can use this analogy to reason about spatial layout, the role of forces, and relative scale.

"Marble in a Stadium" → Coh 2 · Map 2 · Exp 2

Coh 2: Conveys emptiness and scale contrast, but the full atomic structure isn't immediately apparent.

Map 2: The small object inside a vast space maps onto one aspect (the nucleus in mostly empty space), but several key parts of the atom — the orbiting particles, shells, and forces — lack counterparts.

Figure 15: (d) Ranking confidence scale and worked examples panel.

RATE & RANK · TARGET 1 OF 15

CHEMISTRY

Gas Diffusion

The process by which gas molecules spread from regions of high concentration to low concentration through random molecular motion (Brownian motion) in a medium such as air, until equilibrium is reached.

SOURCE ANALOGY 1

"Gas Diffusion is like *smoke dispersion*"

Smoke released from a fire or cigarette starts as a dense, visible plume and gradually thins out as the particles spread through the surrounding air. The movement is influenced by air currents, convection, and gravity — larger particles may settle downward while finer ones drift more freely.

Table 5: Inter-annotator agreement for analogy ranking using Kendall's W . Each row corresponds to a target concept with three candidate analogies. Higher W indicates stronger agreement among annotators, while the p-value tests statistical significance.

Table 5 reports inter-annotator agreement using Kendall's coefficient of concordance (W) for each target concept. Annotators ranked three candidate analogies per target. Higher values of W indicate stronger agreement.

L Full Human and LLM-as-a-judge Results Heatmap

Figures 22, 23 and 24 show the full human and Claude sonnet 4.6 agreement.

M Word Overlap Analysis in Embedding-based Retrieval

Figure 25 shows the impact of lexical overlap on embedding-based source retrieval.

Figure 22: Mean coherence scores per analogy across eight annotators (seven human annotators and Claude), sorted by inter-annotator standard deviation (highest disagreement at top). Scores are on a 1–3 scale. High-disagreement analogies such as *isotope dating* → *half-life* and *platelets* → *band-aid* reveal cases where structural clarity is perceived differently across annotators. Low-disagreement analogies at the bottom (e.g., *platelets* → *tiny repair crew*, *bill of rights* → *rulebook*) receive consistently high scores, indicating clear and intuitive mappings. Claude’s ratings (rightmost column) generally align with the human majority, with occasional deviations in mid-range cases.

Figure 23: Mean mapping quality scores per analogy across eight annotators, sorted by inter-annotator standard deviation. Mapping quality—capturing how well source sub-concepts correspond to target sub-concepts—shows greater disagreement than coherence, particularly for analogies such as *renaissance -> spring bloom* and *industrial revolution -> automation*. Low-disagreement cases (e.g., *platelets -> beads*, *platelets -> tiny repair crew*) tend to receive uniformly low scores, suggesting that weak mappings are easier to agree on than strong ones. Claude’s scores broadly follow human judgments, with a slight tendency toward mid-range values in ambiguous cases.

Figure 24: Mean explanatory power scores per analogy across eight annotators, sorted by inter-annotator standard deviation. Explanatory power—measuring how well an analogy supports understanding—exhibits the highest disagreement, especially for analogies such as *isotope dating* → *half-life* and *encryption* → *sealed envelope*. Consistently high-scoring analogies (e.g., *platelets* → *tiny repair crew*, *adaboost algorithm* → *teamwork*) indicate strong pedagogical value. Analogies involving less familiar concepts (e.g., *gas diffusion* → *gasoline*, *random forest* → *tree*) cluster in lower-score regions, suggesting more limited explanatory effectiveness.

Figure 25: **Impact of lexical overlap on embedding-based source retrieval.** This figure shows how the number of overlapping words between target and source names affects retrieval performance, measured by the percentage of times the gold source is retrieved and its average rank (lower is better). As lexical overlap increases, both retrieval success and ranking quality improve, indicating that embedding-based retrieval is strongly influenced by surface-level word overlap.

Edit-level Majority Voting Mitigates Over-Correction in LLM-based Grammatical Error Correction

Takumi Goto, Yusuke Sakai, Taro Watanabe

Nara Institute of Science and Technology (NAIST)

{goto.takumi.gv7, sakai.yusuke.sr9, taro}@is.naist.jp

Abstract

Grammatical error correction using large language models often suffers from the over-correction issue. To mitigate this, we propose a training-free inference method that performs edit-level majority voting over multiple candidates generated by a single model, without requiring model modifications or additional training. Across nine benchmarks covering English, Czech, German, Ukrainian, Korean, Hindi, and Romanian, the proposed method outperforms both greedy and MBR decoding in most cases. Moreover, it yields stable correction quality regardless of the instruction prompts used. We release two repository supporting GEC datasets loading¹ and LLM inference².

1 Introduction

In the era of Large Language Models (LLMs), users can employ LLMs for Grammatical Error Correction (GEC) via prompting and few-shot examples. However, prior work has shown that while LLMs perform well on fluency editing, they struggle to adhere to minimal editing (Katinskaia and Yangarber, 2024; Omelianchuk et al., 2024), a limitation known as the *over-correction* problem. Over-correction arises when LLMs modify grammatically correct text to improve fluency or generate irrelevant outputs such as “*Okay, this is the corrected sentence:...*”. This issue persists even with carefully designed prompts and few-shot examples. Over-correction not only degrades user experience but also affects evaluation reliability. Since GEC performance is typically measured using the $F_{0.5}$ score, which prioritizes precision (Ng et al., 2014; Bryant et al., 2017; Gong et al., 2022), models that frequently exhibit over-correction contradict such metric’s requirements. GEC models are expected to modify only grammatically incorrect spans, a

Figure 1: Overview of the edit-level majority voting process using three outputs generated from a single LLM. Extraneous text and over-corrections (e.g., $\leftarrow$ “everyday”) shown in red are removed, while only the corrections indicated in green are adopted.

constraint emphasized in the “minimal edit” setting. Prior work has explored approaches such as copy mechanisms in sequence-to-sequence models (Zhao et al., 2019) and sequence labeling-based methods (Awasthi et al., 2019; Omelianchuk et al., 2020) to enforce this behavior. Although recent studies for LLMs mitigate over-correction via fine-tuning (Liang et al., 2025; Staruch et al., 2025), such approaches introduce significant computational overhead and require maintaining fine-tuned models for each base model.

To address over-correction without additional training, we propose a training-free inference method that performs edit-level majority voting over multiple candidates generated by a single LLM. The key intuition is that *valid corrections are more likely to appear consistently across sampled outputs than spurious ones*. As illustrated in Figure 1, we sample multiple candidates and retain only those edits that occur in at least a predefined number of samples. Although closely related to majority voting ensembles (Tarnavskyi et al., 2022), our approach differs in that it leverages multiple samples from a single model rather than multiple models. Moreover, the method can be interpreted

¹<https://github.com/gotutiyan/gec-datasets>

²<https://github.com/gotutiyan/gec-llm/>

as capturing edit-level self-consistency (Wang et al., 2023), i.e., edits that are repeatedly generated across independent samples are unlikely to arise from stochastic variation and instead reflect decisions with higher model confidence (Deguchi et al., 2024; Eikema and Aziz, 2020; Wang et al., 2023).

We conduct a comprehensive evaluation in a 4-shot setting across several languages: English, Czech, German, Ukrainian, Korean, Hindi, and Romanian. A comparison between greedy inference and the proposed method reveals that $F_{0.5}$ and GLEU (Napoles et al., 2015, 2016) scores improve across most datasets. Specifically, on the English CWEB-G (Flachs et al., 2020) dataset, $F_{0.5}$ increased by a maximum of over 10 points.

Based on our analysis, we report the following three findings. First, there is a trade-off between correction performance and computational cost, as the proposed method requires generating multiple candidates, but eight candidates are sufficient. Second, we present a case study demonstrating that higher thresholds retain only higher-confidence edits, effectively mitigating over-correction. Finally, we report achieving a high mean and low variance across ten different prompt templates. This result indicates that, by removing unnecessary text and retaining only high-confidence edits, the proposed method can achieve high scores across templates.

2 Background and Related Work

The mainstream approach for applying LLMs to GEC is primarily fine-tuning them on GEC training data. This includes simple instruction tuning (Omelianchuk et al., 2024), training to generate sequences of edit operations instead of corrected sentences (Kaneko and Okazaki, 2023), Edit-level Preference Optimization (EPO) (Liang et al., 2025), which captures reinforcement learning rewards at the edit level, and training techniques that optimize data usage strategies (Staruch et al., 2025). While these methods are known to achieve high performance on English datasets, it is not always possible to obtain sufficient training data across domains or languages, making additional training difficult. Furthermore, even with lightweight tuning methods such as LoRA (Hu et al., 2022), the trained weights must be managed for each base model, leading to increased complexity when experimenting with a wide variety of models. The proposed method overcomes these drawbacks by not requiring fine-tuning.

Correction methods that do not require fine-tuning are primarily based on prompt engineering. Loem et al. (2023) demonstrated that prompt content impacts correction performance (Davis et al., 2024). For instance, providing instructions unrelated to GEC leads to a degradation in correction performance. Furthermore, Davis et al. (2024) explored prompts that yield higher correction performance, while Katinskaia and Yangarber (2024) evaluated the zero-shot correction performance of LLMs across multiple languages. Tang et al. (2024) proposed a method for appropriately selecting few-shot examples and showed that it improves correction performance. These existing studies discuss strategies for the input to LLMs. In contrast, our approach discusses strategies on the output side.

3 Proposed Methods

We propose a training-free inference method that applies edit-level majority voting to adapt LLMs to minimal editing. By leveraging self-consistency in LLM-based GEC, the method mitigates over-correction and improves overall performance.

3.1 Edit-level Majority Voting

Edit-level majority voting is a representative ensemble method in GEC (Tarnavskyi et al., 2022; Omelianchuk et al., 2024). The inputs consist of an erroneous sentence S and k correction candidates $\{H_1, H_2, \dots, H_k\}$. Generally, these correction candidates are obtained by outputting a single corrected sentence from each of k different GEC models. In edit-level majority voting, each set of edits $\{E_1, E_2, \dots, E_k\}$ is extracted using an automatic edit extraction tool such as ERRANT (Fellice et al., 2016; Bryant et al., 2017). Here, E_i represents the set of edits required to transform S into H_i . Given the $\{E_1, E_2, \dots, E_k\}$, we take the union of the k edit sets and, for each edit in this union, count how many times it appears in the k edit sets. Formally, for each edit $e \in I$ in the union $I = E_1 \cup E_2 \cup \dots \cup E_k$, the count(e) is calculated using the following equation.

$$\text{count}(e) = \sum_{i=1}^k \delta(e, E_i) \quad (1)$$

$$\delta(e, E) = \begin{cases} 1 & \text{if } e \in E \\ 0 & \text{otherwise,} \end{cases} \quad (2)$$

e.g., count(["go" $\rightarrow$ "goes"]) = 3 in Figure 1. After counting each edit, we extract only the subset of

edits $\mathbf{I}_{\text{accepted}}$ whose counts are equal to or greater than a threshold τ ($1 \leq \tau \leq k, \tau \in \mathbb{N}$):

$$\mathbf{I}_{\text{accepted}} = \{e \mid e \in \mathbf{I}, \tau \leq \text{count}(e)\}. \quad (3)$$

The final corrected sentence is obtained by applying the edits in $\mathbf{I}_{\text{accepted}}$ to the original erroneous sentence S . Note that the number of candidates k and the threshold τ are hyperparameters.

3.2 Majority Voting as Self-consistency

We assume that, when multiple candidates are sampled from an LLM, edits corresponding to minimal edits occur more consistently than those for fluency edits. For instance, corrections for grammatical errors, e.g., missing articles, are relatively constrained, whereas fluency-oriented rewrites tend to be more diverse. Therefore, minimal editing can be encouraged by retaining only high-frequency edits across sampled candidates. This perspective extends the notion of *self-consistency* (Wang et al., 2023) to the edit level. Given an input sequence S and a GEC prompt, we sample k candidates from a single LLM using nucleus (top- p) sampling (Holtzman et al., 2020). We then aggregate the sampled candidates via majority voting and retain only high-frequency edits, which can be interpreted as high-confidence corrections. This method is training-free, does not rely on internal model representations, and is thus applicable to black-box LLMs.

Compared to prior work on majority voting ensembles (Tarnavskiy et al., 2022; Omelanchuk et al., 2024), our approach differs in that it leverages multiple samples from a single model rather than multiple models. Moreover, alternative ensemble methods such as ESC (Qorib et al., 2022) and GRECO (Qorib and Ng, 2023), while applicable, do not explicitly leverage edit-level self-consistency and often require additional training.

4 Experiments

4.1 Datasets and Metrics

To evaluate the effectiveness of the proposed inference method, we conduct experiments on multilingual datasets. Table 1 provides a summary of the datasets and metrics used in our experiments.

For English, we conduct experiments using three types of benchmarks: CWEB (Flachs et al., 2020), BEA-2019 (Yannakoudakis et al., 2018; Bryant et al., 2019), and JFLEG (Napoles et al., 2017). All of these are English datasets comprising both development and test sets, though they differ in the

Dataset	Lang.	# Dev.	# Test	Metric
BEA-2019	en	4,384	4,477	ERRANT
CWEB-G	en	3,867	3,981	ERRANT
JFLEG	en	754	747	ERRANT, GLEU
AKCES-GEC	cs	2,485	2,676	JP-ERRANT (cs)
Falko-Merlin	de	2,503	2,337	JP-ERRANT (de)
UNLP-2023	uk	1,509	1,353	JP-ERRANT (uk)
Kor-learner	ko	4,264	4,265	JP-ERRANT (ko)
Hi-GEC	hi	976	1,465	GLEU
RONACC	ro	451	451	GLEU

Table 1: Datasets and metrics used in our experiments.

frequency of required error corrections. CWEB-G contains the fewest errors in these datasets, making it the domain where over-correction is most problematic. While BEA-2019 contains more errors than CWEB-G, it still requires minimal editing. JFLEG permits not only grammatical error corrections but also corrections to make a sentence fluent, thus requiring the highest number of corrections. Given that the proposed method is intended to mitigate over-correction, we expect its effectiveness to follow the order of CWEB-G > BEA-2019 > JFLEG. We use ERRANT $F_{0.5}$ as the common evaluation metric for all datasets, and additionally use GLEU for JFLEG.

For other languages, we use AKCES-GEC (Náplava and Straka, 2019) for Czech, Falko-Merlin (Boyd, 2018) for German, UNLP-2023 (Syvokon and Romanyshyn, 2023) for Ukrainian, Kor-learner (Yoon et al., 2023) for Korean, Hi-GEC (Sharma and Bhattacharyya, 2025) for Hindi, and RONACC (Cotet et al., 2020) for Romanian. Regarding evaluation metrics, we use $F_{0.5}$ of JP-ERRANT (Wang et al., 2025; Qiu et al., 2025) for AKCES-GEC, Falko-Merlin, and Kor-learner; and GLEU for Hi-GEC and RONACC. JP-ERRANT is a Stanza (Qi et al., 2020) based edit extraction tool and explicitly supports English, Czech, German, Ukrainian, Korean, and Chinese. For UNLP2023, we use the official CodaLab platform because its references are not publicly available. For both ERRANT and JP-ERRANT, we use GEC-METRICS (Goto et al., 2025a) for the implementation of score calculation.

4.2 Majority Voting Settings

In Equation 3, we fix the number of generated candidates k to $k = 8$. The threshold τ is determined for each dataset using the development data; we select the threshold that maximizes the metric shown

in Table 1 and use it for inference on the test data. For JFLEG, we use GLEU to determine the threshold. For edit extraction tools, we use ERRANT for English datasets and JP-ERRANT for datasets in other languages. Although JP-ERRANT does not explicitly support Hindi and Romanian, it can be used as a tentative edit extraction tool for these languages by employing its multilingual setting. In Nucleus Sampling, we always use $p = 1.0$ for top- p , 1.0 for temperature.

4.3 Models and Inference

To evaluate the utility across multiple models, we use Llama-3.1-8B-Instruct (Grattafiori et al., 2024), and Qwen3-8B (Yang et al., 2025) for all of datasets. Additionally, we report results of gemma-2-9b-it (Team et al., 2024) for English datasets and gemma-3-12b-it (Team et al., 2025) for other languages, given the scores on the development set. In this paper, we always perform inference in a 4-shot setting. For each dataset, a fixed set of 4-shot samples is used for all inputs. For the English datasets, we use the 4-shot samples employed by Davis et al. (2024). For the datasets in other languages, we sort the corresponding training data by length and select the middle four instances as the 4-shot samples. This selection method is adopted for its high reproducibility and to avoid selecting extremely short or long samples as few-shot examples. While some prior studies employ methods to retrieve appropriate few-shot samples for each input sentence using similarity measures such as BM25 or BERT (Devlin et al., 2019) embeddings (Tang et al., 2024), we do not adopt such approaches in this paper as they may not be applicable to all languages. For instance, in low-resource scenarios, it may not be possible to secure a sufficient pool of GEC data for retrieval. In contrast, fixed 4-shot samples can be manually created in practice. We use the vLLM library (Kwon et al., 2023a) for the implementation of inference.

Regarding the instruction template, we use the TOOL template from Davis et al. (2024). Note that, to minimize over-correction as much as possible, we append a phrase to the end of the prompt specifying that only the corrected sentence should be output. For non-English datasets, we utilize the template adopted in MultiGEC. This template is also based on the same TOOL template, but it differs in that it explicitly specifies the language. The actual prompts are shown in Appendix A.

4.4 Baselines

Greedy: Greedy decoding Greedy decoding always selects the token with the highest probability from the estimated probability distribution. In nucleus sampling, this is equivalent to always setting the temperature to 0.

MBR: MBR Decoding Minimum Bayes Risk (MBR) decoding (Goel and Byrne, 2000) is a decoding approach that generates multiple hypotheses and selects the optimal one based on the consensus among them. In a typical formulation (Eikema and Aziz, 2020; Deguchi et al., 2024), it performs reference-based evaluation by assuming that the hypotheses themselves also serve as approximated reference sentences, taking the hypothesis with the highest score as the final output H :

$$H = \underset{\hat{H} \in \{H_1, H_2, \dots, H_k\}}{\operatorname{argmax}} \frac{1}{k} \sum_{i=1}^k u(\hat{H}, H_i). \quad (4)$$

$u(\cdot)$ is a utility function to evaluate the quality of each hypothesis $\hat{H}$, i.e., a reference-based metric. By following Raina and Gales (2023), we use the evaluation metric as is for the utility function. For example, we use ERRANT $F_{0.5}$ for BEA-2019, and JP-ERRANT $F_{0.5}$ for AKCES-GEC as $u(\cdot)$. We include MBR decoding as a baseline because it is similar to the proposed method in that it relies on multiple hypotheses. Note that the two methods differ in how to make the final hypothesis: while MBR decoding selects the best one from the candidates, the proposed method integrates them to generate a new candidate.

GEC models other than LLMs To provide a comparison with existing non-LLM correction models, we also include GECToR (Omelianchuk et al., 2020) and T5 (Raffel et al., 2020; Rothe et al., 2021) based on our reproduction experiments. GECToR performs corrections using sequence labeling, while T5 is based on a sequence-to-sequence model. For further details on the experimental setup, please refer to Appendix B. We also report the current state-of-the-art performance to discuss the gap between our performance and it.

4.5 Making Implementation Public

As evidenced by the inclusion of reproducibility checklists in ACL Responsible NLP Research³,

```

Listing 1: A Python implementation example using our implementation, which covers data loading, correction. The dataset is downloaded automatically, and you only need to pass the source sentences to the correction model. It allows us to implement with minimal code.

attention to reproducibility is increasing. In fact, Omelianchuk et al. (2024) reported that they were unable to reproduce the method of Kaneko and Okazaki (2023), suggesting that this is becoming an issue in GEC as well (Goto et al., 2025a; Zhao et al., 2025). To address this problem, this study provides an implementation that covers two aspects: dataset loading⁴ and LLM inference⁵.

The dataset library, GEC-DATASETS, automates data downloads and provides access through a unified interface within Python scripts. Listing 1 demonstrates an example where the dataset is downloaded to the sample-dir/ directory, allow-

ing access to the source and reference texts via the .srcs and .refs interfaces. For some non-public datasets, the library automatically handles extraction once the user places the compressed file (received after submitting a request form) in the designated location. Our library supports more than 20 datasets including representative English datasets and the datasets listed in Table 1. Furthermore, it is highly compatible with GEC-METRICS (Goto et al., 2025a), enabling seamless evaluation of newly defined GEC models. Lines 29 and onwards in Listing 1 show an example of evaluating the hypotheses using GLEU.

Our LLM inference library, GEC-LLM, is basically a wrapper around vLLM library (Kwon et al., 2023b), but its key contribution lies in the decoupled implementation of a few-shot sampler for few-shot inference. While this modularity is of secondary importance in this paper since we use a fixed set of few-shot examples, the architecture is easily extensible to retrievers based on BM25, BERT (Devlin et al., 2019) embeddings, or GOPar (Zhang et al., 2022) as done in Tang et al. (2024), or other methods in the future. In Listing 1, FewShotSamplerFixed is used as the sampler to provide fixed few-shots for all inputs. Furthermore, since it also includes an ensemble implementation, it can self-containedly execute an ensemble of multiple hypothesis sentences (Line 17 and 27).

5 Results

5.1 Results on English Datasets

As shown in Table 2, all of gemma-2-9b-it, Llama-3.1-8B-Instruct and Qwen3-8B showed improvements in $F_{0.5}$ on CWEB-G and BEA-2019. In particular, the $F_{0.5}$ score for Llama-3.1-8B-Instruct on CWEB-G improved by 14.0 points from the greedy decoding. Examining the precision and recall values for these results reveals an increase in precision, indicating that over-correction was effectively suppressed. In JFLEG, the GLEU score for Llama-3.1 increased by 22.3 points, demonstrating that the method was effective across models. Conversely, no improvement was observed for the EPO model. This is because the EPO model has already addressed the over-correction problem through fine-tuning. These results clearly demonstrate that our method enables mitigation of over-correction without training.

Moreover, our proposed method outperformed MBR decoding. Since MBR decoding always se-

Table 2: Results on **English** datasets. For each model, we compare greedy decoding, MBR decoding, and proposed majority voting, along with a comparison with existing non-LLM correction models. τ denotes the optimal threshold on the corresponding development set as described in Section 4.2. **Bold** values indicate the highest score for each combination of model and dataset. All results are based on our own experimental findings.

lects exactly one candidate from the hypotheses generated by the LLM, it is unable to choose an appropriate candidate as the number of candidates containing overcorrections increases. Figure 1 corresponds to an extreme case in which all three hypotheses contain over-corrections. In this situation, MBR decoding cannot avoid over-correction regardless of which candidate is selected. In contrast, edit-level majority voting can produce an output that avoids over-corrections. Furthermore, because the utility function evaluates hypotheses at the sentence level, it becomes difficult to accurately select hypotheses when using n -gram-level metrics such as GLEU. This is because the brevity penalty excessively impacts the score for short sequences. (Goto et al., 2025b) also points out the same problem. In contrast, edit-level majority voting is unaffected by the granularity of scoring.

Table 2 also shows the threshold τ determined using the development sets. For CWEB-G, τ was 8, which resulted in adopting only the edits for which consensus was reached across a larger number of hypothesis sentences. In contrast, for JFLEG, τ was relatively small, typically less than 3, indicating that it was optimal to adopt edits even when consensus was found among only a few hypotheses.

This suggests that our method can flexibly adapt to the required degree of correction by adjusting the threshold τ to control over-correction.

When comparing the results with non-LLM correction models like GECToR and T5, Qwen/Qwen3-8B outperformed GECToR (bert-base-cased) on CWEB-G (42.9 vs 40.8 on $F_{0.5}$). Since the proposed method improves correction performance by filtering edits, it is effective in domains like CWEB-G that require few corrections. Meanwhile, in BEA-2019, although Qwen3-8B approached GECToR (bert-base-cased) within a 2-point margin ($F_{0.5}$: 68.7 vs 70.0). This suggests that the proposed method can achieve performance levels comparable to those of some fine-tuned models without additional training.

5.2 Results on Multilingual Datasets

Table 3 shows the results for the multilingual datasets. In general, scores improved for AKCES-GEC, UNLP-2023, and Hi-GEC, while they declined for Falko-Merlin and RONACC; this pattern was observed for Kor-learner. These results can be explained by the required number of errors for the correction rather than the differences between languages. As demonstrated by the English ex-

Models	Decoding	AKCES-GEC			Falko-Merlin			UNLP-2023			Kor-learner			Hi-GEC	RONACC

	MBR	44.7	51.9	46.0	53.6	50.0	52.8	9.8	29.8	11.3	17.9	18.0	17.9	57.9	73.6
	Proposal	70.0	41.7	61.6	64.5	32.2	53.7	27.1	12.6	22.0	33.2	12.8	25.2	71.4	63.4
Qwen3-8B	Greedy	62.3	51.0	59.6	61.5	39.9	55.5	41.6	23.1	35.8	36.6	16.6	29.5	66.0	78.2
	MBR	63.5	50.3	60.3	62.5	38.2	55.5	41.7	22.4	35.6	37.3	16.7	29.9	65.5	79.0
	Proposal	72.8	43.0	63.9	57.1	30.7	48.7	48.5	20.4	38.0	37.3	13.0	27.1	70.6	63.5

Table 3: Results on **multilingual** datasets. For each model, we compare greedy decoding, MBR decoding, and proposed majority voting. **Bold** values indicate the highest score for each combination of model and dataset.

periments, where the greatest improvement was observed on CWEB-G, the proposed method is more effective when the number of required corrections is small. When examining the average word-level edit distance per sentence between source and reference for the datasets in Table 3, the values were: Falko-Merlin (2.83), AKCES-GEC (2.32), RONACC (2.25), Kor-learner (2.08), UNLP-2023 (0.99), and Hi-GEC (0.92). This edit distance can be regarded as an error density in the source text. Since Falko-Merlin and RONACC require extensive corrections, they exhibit characteristics similar to those of the JFLEG dataset in the English experiments; for this reason, the proposed method did not lead to score improvements. Conversely, Hi-GEC and UNLP-2023 require fewer corrections, and the proposed method successfully improved their scores. However, AKCES-GEC contradicted this trend: despite requiring a high degree of correction, its $F_{0.5}$ score improved using the proposed method. While this could be related to linguistic features or the quality of the edit extractor.

6 Discussion

6.1 Trade-off between Performance and Cost

While the proposed method is expected to achieve higher performance as the number of generated hypothesis sentences increases, it requires higher computational costs. To investigate this trade-off between performance and cost, we measured the scores and inference times on the development sets of CWEB-G, BEA-2019, and JFLEG while varying k within the range $k = \{1, 2, 4, 8, 16, 32\}$. Figure 2 plots the results for each k in a space where the horizontal axis represents the average computation time per sentence (seconds) and the

Figure 2: Scores and average computation time per sentence on the development set of each dataset, relative to the number of generated candidates k . These results represent oracle performance, where the threshold τ is optimized for each dataset and each value of k .

vertical axis represents the score. Note that time values were negated so that higher values on both axes represent better performance. We used gemma-2-9b-it as the model; the scores are the ERRANT $F_{0.5}$ for CWEB-G and BEA-2019, and GLEU for JFLEG. As shown in Figure 2, although a trade-off generally exists between scores and computation time, we observed that the degree of score improvement tends to diminish as k increases. For BEA-2019 and CWEB-G, the scores level off for $k \geq 4$ and $k \geq 8$, respectively. This indicates that the marginal gain in score relative to the computational cost decreases at higher values of k . In the experiments of this paper, we fixed $k = 8$ based on the results in Figure 2, this value is considered sufficiently reasonable. However, in

practical applications, the optimal value for k may vary depending on the specific requirements for correction performance and processing speed.

6.2 Effect of the Threshold τ

We conducted a case study to examine in detail the changes in correction tendencies according to the threshold τ in Equation 3. We use the results of inference performed by Llama-3.1-8B-Instruct on samples from the BEA-2019 development data. Table 4 presents the input sentence, the reference sentence, the result of greedy decoding, and the results of the proposed method with $k = 8$ for $\tau = \{2, 4, 7\}$. In the reference sentence, two corrections are made: [“start” $\rightarrow$ “starts”] and [“away from” $\rightarrow$ “over”]. In contrast, the result of greedy decoding includes orthographic corrections such as [“can not” $\rightarrow$ “ca n’t ”], dialectal variations between American and British English such as [“traveling” $\rightarrow$ “travelling ”], and the generation of irrelevant text at the end of the sentence.

Compared to the greedy decoding result, the proposed method increasingly suppresses corrections as the threshold τ is raised. At $\tau = 2$, the irrelevant text is removed, and at $\tau = 7$, only [“start” $\rightarrow$ “starts”] remains. Since this correction is also present in the reference, it is a correct edit, demonstrating that over-correction was effectively suppressed. In the case study, we also observed instances where a correct edit that was preserved at $\tau = 4$ was excluded at $\tau = 7$. Nevertheless, the overall score improved due to increased precision.

6.3 Stability among Templates

The proposed method also offers the advantage of stable output in terms of both output format and correction quality, regardless of the instruction. To evaluate correction performance across various instructions, we examined the variance in scores

Inference	CWEB-G _(F0.5)	BEA-2019 _(F0.5)	JFLEG _(GLEU)
Greedy	27.66 $\pm$ 3.26	43.91 $\pm$ 2.62	57.48 $\pm$ 1.01
Proposal	36.16 $\pm$ 2.85	50.68 $\pm$ 1.24	57.54 $\pm$ 0.46

Table 5: The mean and standard deviation of scores for 10 templates in the development set for each dataset.

across multiple templates, inspired by the approach of Sakai et al. (2024). Using gemma-2-9b-it as the model, we performed 4-shot inference on the development sets of CWEB-G, BEA-2019, and JFLEG using ten templates with different instructions and output formats. Details of these templates are provided in Appendix C. Since a score is calculated for each template, we calculate their mean and standard deviation. The mean and standard deviation can be interpreted as the average correction performance and output stability across templates, respectively. High means and low standard deviations are considered ideal.

The results in Table 5 show that the proposed method achieved higher means and lower standard deviations than greedy decoding, demonstrating its ability to consistently output high-quality corrected sentences regardless of the instruction. This can be attributed to two factors: the proposed method’s ability to stably output only the corrected sentence by removing irrelevant text, as observed in Table 4, and its selective adoption of only high-confidence edits among various edits. Conventionally, removing irrelevant text required heuristic removal methods based on empirically collected prefixes, e.g., filtering out sentences starting with “Sure! Here” (Davis et al., 2024). In contrast, the proposed method has the advantage of handling this mechanically through edit-level majority voting.

Figure 3: Relationship between edit frequency and precision. On the development set of each dataset, we generate eight candidates ($k = 8$), and compute scores using only edits with each frequency. This results correspond to the Llama-3.1-8B-Instruct results.

6.4 Does High Frequency Indicate Valid Correction?

Our hypothesis in this study is that corrections appearing more frequently among multiple candidates are more valid corrections in terms of minimal edits. To examine the validity of this hypothesis in greater depth, we further investigate the relationship between edit frequency and the correction performance. Using Llama-3.1-8B-Instruct results for the development sets of CWEB, BEA-2019, and JFLEG, we computed performance separately for edits with frequencies of $\{1, 2, \dots, 8\}$ among eight candidates ($k = 8$). Here, we focus only on precision. Recall is strongly biased by the number of edits contained in each frequency, making it unsuitable for analyzing validity.

Figure 3 plots edit frequency on the horizontal axis and the corresponding precisions on the vertical axis. Precision tends to improve as the frequency of edits increases, supporting our hypothesis. This trend clearly explains the success of majority voting in this study.

7 Conclusion

In this study, to address the over-correction problem in LLM-based grammatical error correction, we proposed an inference method based on the edit-level majority voting across multiple hypothesis sentences. The results demonstrated that mitigating over-correction improved performance, particularly in terms of ERRANT $F_{0.5}$, and also led to stable correction performance across various prompt tem-

plates. Future research is expected to broaden the experimental scope in terms of both languages and tasks. Regarding the latter, the proposed method holds potential for general application to various edit-based tasks, such as text simplification and post-processing of machine translation.

Limitations

Discuss Under-correction. While the proposed method can improve performance by mitigating over-correction, we did not discuss addressing the under-correction issue. Although setting a smaller value for the threshold τ might help resolve under-correction, this paper focuses exclusively on the mitigation of over-correction.

Other Ensemble Methods. In this study, we used majority voting to integrate multiple hypotheses generated by a LLM. This approach is equivalent to applying an ensemble technique, which is typically used for combining multiple GEC models, to the outputs of a single model. While various ensemble methods other than majority voting have been proposed (Lin and Ng, 2021; Qorib et al., 2022; Sorokin, 2022; Qorib and Ng, 2023; Cao et al., 2024) and could potentially be applied to hypotheses integration, we limited the discussion in this paper to training-free methods, specifically majority voting and MBR decoding. If a training-based approach were to be used for an ensemble, simply fine-tuning the LLM for the GEC task is more straightforward. Furthermore, for some languages, it can be difficult to secure a sufficient amount of training data.

Metrics. In this study, we primarily used ERRANT as our evaluation metric. This is intended to measure whether the suppression of over-correction was successfully achieved. Although reference-free metrics such as SOME (Yoshimura et al., 2020) and IMPARA (Maeda et al., 2022) are known to have a higher correlation with human evaluation (Kobayashi et al., 2024; Goto et al., 2025b), it is difficult to determine the degree of over-correction from these metrics. Furthermore, it is not yet clear how reference-free metrics respond to over-correction in the first place. Therefore, we leave discussions based on such metrics for future work.

Datasets. In this study, we conducted experiments on datasets across seven languages including

English, but it is clear that we cannot cover all languages in the world. Since creating evaluation data for every language is difficult, this paper limits its experiments to languages for which datasets are already available. The implementation introduced in Section 4.5 will serve as a useful tool for researchers to extend these experiments in the future.

Comparison in the Multilingual Experiments.

As indicated in Table 3, we compared three types of inference in our multilingual experiments: greedy decoding, MBR decoding, and the proposed method. Ideally, deeper insights could be gained by including comparisons with correction methods proposed in prior research on each language. However, since this study is the first to perform evaluations using JP-ERRANT, we cannot refer to scores reported in previous studies. Consequently, calculating JP-ERRANT scores for those methods would require conducting reproduction experiments of the prior research for each language. In this paper, we assume that we have provided primarily results by comparing the effectiveness of our method with greedy and MBR decoding. More detailed comparative experiments are left for future work.

The utility function in MBR decoding In the MBR decoding compared in our experiments, we used edit-level metrics such as ERRANT or n -gram-level metrics such as GLEU as a utility function. This is based on the idea that it is appropriate to use the same metric as the evaluation measure for the utility function. Furthermore, since we used the $F_{0.5}$ score for ERRANT and JP-ERRANT, which emphasizes precision, we assumed that over-correction would be sufficiently reflected in the score. However, it is possible that a metric reflecting the degree of over-correction more accurately could be constructed, and the performance of MBR decoding might be underestimated. Despite such concerns, we believe that the experimental setup of this paper is appropriate. Additionally, we also tested cases where ERRANT was used as the utility function when GLEU was the evaluation metric, but no differences were observed.

Ethical Considerations

If many of the candidates generated by the LLM contain harmful outputs, the proposed method may fail to remove them and instead include them in the final output. However, since it is rare for harmful outputs to be generated as the exact same surface-

level text across different candidates, we believe they can generally be eliminated by setting the edit count threshold τ to a sufficiently high value. Empirical verification of this point is left for future work. At least in our manual analysis for the case study, we did not observe any harmful content.

Acknowledgments

We thank the anonymous reviewers for their valuable comments. This work has been supported by JST SPRING. Grant Number JPMJSP2140.

A Actual template

Figure 4 shows the template for English experiments, and Figure 5 for other language experiments. The symbols of [SOURCE] and [FEWSHOT] will be replaced with actual input sentence and few-shot examples during inference.

B Detailed Experimental Settings

For the experiments in Table 2, we conducted reproduction experiments for GECToR and T5, respectively.

GECToR. GECToR was trained in three stages following Omelanchuk et al. (2020). Regarding the datasets, the first stage used PIE-synthetic (Awasthi et al., 2019). The second stage used only pairs from the BEA-2019 (Bryant et al., 2019) training data that contained at least one correction, and the third

You are a grammatical error correction tool. Your task is to correct the grammaticality and spelling in the input sentence. Make the smallest possible change in order to make the sentence grammatically correct. Change as few words as possible. Do not rephrase parts of the sentence that are already grammatical. Do not change the meaning of the sentence by adding or removing information. If the sentence is already grammatically correct, you should output the original sentence without changing anything. Return only the corrected text and nothing more.\n[FEWSHOT]\nInput sentence: [SOURCE]\nOutput sentence:

Figure 4: Instruction template for **English** datasets. [FEWSHOT] and [SOURCE] will be replaced with actual few-shot examples and an input sentence, respectively.

You are a grammatical error correction tool. Your task is to correct the grammaticality and spelling of the input essay written by a learner of [LANG]. Make the smallest possible change in order to make the essay grammatically correct. Change as few words as possible. Do not rephrase parts of the essay that are already grammatical. Do not change the meaning of the essay by adding or removing information. If the essay is already grammatically correct, you should output the original essay without changing anything. Return only the corrected text and nothing more.\n[FEWSHOT]\nInput sentence: [SOURCE]\nOutput sentence:

Figure 5: Instruction template for datasets of **other than English**. [LANG] will be replaced with a language name, such as “Czech” or “German.”

stage used the entire W&I-LOCNESS (Yan-nakoudakis et al., 2018) training data. We used bert-base-cased⁶ (Devlin et al., 2019) and deberta-v3-large⁷ (He et al., 2023) as the models. The training settings also basically followed Omelanchuk et al. (2020), except that the first stage was set to 10 epochs. During inference, the keep confidence and minimum error probability thresholds were determined for each dataset. We tried both values from {0.1, 0.2, . . . , 1.0} and used the values that maximized the metrics on the development data for inference on the evaluation data. Our reproduction results are competitive with the values reported by Omelanchuk et al.

⁶<https://huggingface.co/google-bert/bert-base-cased>

⁷<https://huggingface.co/microsoft/deberta-v3-large>

(2020) and Tarnavskyi et al. (2022).

T5. Following Rothe et al. (2021), T5 was fine-tuned using 2,372,119 sentences from the cLang8 dataset. We used t5-v1_1-large⁸ as the base model. The model was trained for 10 epochs with a learning rate of 1e-5. Our reproduction achieves the score of $F_{0.5} = 73.4$ on the BEA-2019 test set as shown in Table 2, which exceeds the T5-large score of $F_{0.5} = 72.06$ reported by Rothe et al. (2021).

C Actual Templates

Table 6 shows 10 templates used in Section 6.3.

ID	Template
1	You are a grammatical error correction tool. Your task is to correct the grammaticality and spelling in the input sentence. Make the smallest possible change in order to make the sentence grammatically correct. Change as few words as possible. Do not rephrase parts of the sentence that are already grammatical. Do not change the meaning of the sentence by adding or removing information. If the sentence is already grammatically correct, you should output the original sentence without changing anything. Return only the corrected text and nothing more.\n[FEWSHOT]\nInput sentence: [SOURCE]\nOutput sentence:
2	Make minimal changes to the following text such that it is grammatically correct. Return only the corrected text and nothing more.\n[FEWSHOT]\nInput sentence: [SOURCE]\nOutput sentence:
3	Please correct the following text. Do not attempt to rewrite it into perfect English or to interpret the text. Often, things could be expressed better by paraphrase, but the task is to make minimal changes to correct the text. Do not change anything that is correct. Please make no changes if there are no errors. Return only the corrected text and nothing more.\n[FEWSHOT]\nInput sentence: [SOURCE]\nOutput sentence:
4	Reply with a corrected version of the input sentence with all grammatical and spelling errors fixed. If there are no errors, reply with a copy of the original sentence. Return only the corrected text and nothing more.\n[FEWSHOT]\nInput sentence: [SOURCE]\nOutput sentence:

Abstract

Phonics stories are essential for early literacy, requiring controlled repetition of grapheme-phoneme (GP) patterns while remaining simple, readable, and developmentally appropriate. Generating such texts poses a challenge for large language models (LLMs), which must handle multiple linguistic and pedagogical constraints. To investigate how these constraints can be balanced, we systematically vary prompt design across 16 configurations and evaluate six LLMs in a zero-shot setting, producing 8,688 outputs (39,096 stories). Outputs are assessed using a multi-dimensional framework covering phonological alignment, developmental lexical appropriateness, readability, and narrative quality. Results show that while LLMs generate highly readable and age-appropriate text, they exhibit variability in phoneme control and narrative coherence. Prompt design and model choice significantly affect performance, revealing trade-offs across constraints. These findings highlight the challenges of controllable educational text generation and the importance of prompt design in balancing instructional objectives. We release our prompts, generated stories, and evaluation framework to support future work in phonics-based story generation.

1 Introduction

Phonics stories are a foundational tool in early literacy instruction, designed to reinforce grapheme-phoneme (GP) correspondences through controlled and repetitive exposure. However, unlike general narrative text, these stories must satisfy multiple instructional constraints, requiring consistent reinforcement of target sound patterns while remaining simple, readable, and developmentally appropriate for early learners (National Reading Panel, 2000; Ehri, 2020).

Phonics instruction plays a critical role in early literacy and speech development, teaching learners to decode written language by associating

graphemes—letters or letter combinations—with their corresponding phonemes—sounds or sound combinations (National Reading Panel, 2000; Ehri, 2020). Decodable texts, including phonics stories, are essential components of systematic phonics instruction, as they support the development of phonetic decoding skills through structured GP reinforcement (Ehri, 2020). For example, a phonics story targeting the grapheme ‘s’ and the phoneme /s/ may include sentences such as “*Sam sees the snake in the grass.*” By reinforcing GP decoding, these stories serve as effective tools for speech and reading development (Cheatham and Allor, 2012; Pennell et al., 2024; Murphy Odo, 2024).

Large language models (LLMs) have demonstrated strong capabilities in generating coherent and contextually appropriate text, including narratives, with minimal prompting (Xie et al., 2023; Tian et al., 2024). Prior work has explored guiding LLMs to produce age-appropriate children’s stories through prompt design and lexical simplification (Valentini et al., 2023). However, existing work does not evaluate whether LLMs can simultaneously satisfy phonological and pedagogical constraints. Unlike general storytelling, this task requires balancing readability and developmental appropriateness with consistent and meaningful reinforcement of target GP mappings.

In this paper, we investigate the effectiveness of zero-shot prompting in generating phonics stories that emphasize specific GP mappings. We evaluate outputs using a multi-dimensional framework spanning phonological alignment, developmental lexical appropriateness, readability, and narrative quality.

To clarify terminology used throughout this work, while the terms “decodable texts” and “phonics stories” are often used interchangeably, we use “phonics stories” to refer specifically to short, structured narratives designed for early readers, whereas “decodable texts” more broadly include instruc-

tional materials that emphasize controlled GP exposure without necessarily maintaining narrative structure. In this work, we primarily use the term “phonics stories”, while also examining the effect of terminology in prompt design.

Our main contributions are as follows:

1. We use zero-shot prompting for large-scale phonics story generation across 16 prompt configurations and 6 LLMs, producing a dataset¹ of 8,688 outputs (39,096 stories).
2. We define a multi-dimensional evaluation framework comprising 12 metrics that capture phonological alignment, developmental lexical appropriateness, readability, and narrative quality.
3. We provide a detailed analysis of prompt design and model choice, identifying trade-offs between phonological accuracy, linguistic simplicity, and narrative coherence.

2 Related Work

2.1 Automated Children’s Story Generation

Automated story generation evolved from early rule-based systems such as TALE-SPIN (Meehan, 1977) and MINSTREL (Turner, 1992) to modern neural approaches (Roemmele et al., 2017). While early systems lacked flexibility and relied heavily on handcrafted rules, subsequent data-driven methods improved narrative coherence through structured knowledge integration and learned representations (Liu and Singh, 2002; Roemmele et al., 2017).

More recently, the emergence of LLMs has significantly advanced the quality of generated stories, achieving improvements in fluency, coherence, and contextual relevance (Brown et al., 2020). However, despite these advances, instructionally constrained storytelling, particularly for educational purposes such as phonics story generation, remains underexplored, as most work prioritizes general narrative quality over pedagogical alignment.

2.2 LLM Capabilities

2.2.1 Story Generation

Recent studies consistently show that LLMs outperform earlier neural models in story generation tasks, particularly in terms of fluency and overall narrative quality (Xie et al., 2023). However, these

gains are accompanied by limitations in originality and control, especially when compared to human-authored stories.

In the context of children’s storytelling, Valentini et al. (2023) further demonstrate that while LLMs can generate readable and coherent narratives, they often struggle to satisfy developmental constraints such as age-appropriate vocabulary in zero-shot settings. Their findings highlight the importance of lexical simplification, which significantly improves both readability and alignment with target age groups. Complementing this, Alasmari et al. (2025) move beyond surface-level fluency by proposing an automated framework for evaluating narrative cohesion grounded in Gérard Genette’s narrative theory. By operationalizing cohesion into computable features and achieving high classification performance, their work provides a foundation for systematically evaluating and improving story structure in both human-authored and AI-generated texts.

Together, these studies suggest that while LLMs are strong generators of fluent narratives, ensuring developmental appropriateness and structural quality requires additional mechanisms for control and evaluation.

2.2.2 Constrained Generation

Following explicit constraints specified in prompts is not just a challenge in general children’s storytelling but is also central in phonics-based story generation of LLMs. Prior work shows that even relatively simple constraints, such as age-level requirements, are not consistently satisfied in zero-shot settings (Valentini et al., 2023), raising concerns about the reliability of instruction-following in educational contexts.

More broadly LLMs’ controlled generation capabilities have been evaluated across various constraints such as sentiment conditioning, keyword inclusion, prefix constraints, and numerical planning where adherence was found to vary depending on task formulation (Sun et al., 2023). Similarly, Marbun and Shishido (2026) demonstrated how readability targets in prompt formulation can improve lexical appropriateness compared to traditional prompting strategies.

Collectively, these works emphasize that while LLMs possess strong generative capabilities, achieving reliable constraint adherence requires deliberate prompt design and task-specific strategies.

¹<https://huggingface.co/datasets/monicamanlises/zero-shot-phonics>

2.2.3 Phonological Tasks

In order to generate phonics stories, LLMs must exhibit some degree of phonological awareness. While LLMs demonstrate strong theoretical knowledge of phonetics and phonology in controlled evaluations, they often struggle to apply this knowledge in generative settings (Peng et al., 2025), indicating a gap between passive understanding and practical use. This limitation is further supported by Suvarna et al. (2024), who evaluate LLMs on tasks such as grapheme-to-phoneme (G2P) conversion, syllable counting, and rhyme generation. Although advanced models perform relatively well among LLMs, they still fall short of rule-based systems and human performance, particularly in tasks requiring fine-grained phonological precision.

These findings highlight a key challenge for phonics story generation: while LLMs can approximate phonological reasoning, their limitations necessitate careful model selection and evaluation.

3 Task Definition

We define phonics story generation as a constrained phonological text generation task. Given a target GP pair or phonic set, the objective is to generate a short story that simultaneously satisfies three main requirements:

1. **Phonological Alignment:** The story should reinforce the target GP mapping through repeated and meaningful usage.
2. **Developmental Appropriateness:** The vocabulary, sentence structure, and overall readability should align with the intended reading level of early learners, ensuring that texts are both accessible and instructionally effective.
3. **Narrative Quality:** The story should be coherent, cohesive, and easy to follow.

Unlike general story generation, this task requires balancing competing constraints. Increasing phoneme repetition may improve phonological reinforcement but reduce narrative naturalness, while prioritizing readability may weaken phonological control. As a result, phonics story generation serves as a challenging testbed for controllable text generation under educational constraints.

4 Method

This study follows a generation-evaluation pipeline to assess the capability of LLMs in generating

phonics stories for early readers. In a zero-shot setting, multiple LLMs were prompted to produce short phonics stories and decodable texts designed to reinforce specific GP correspondences. The generated outputs were subsequently evaluated using a multi-dimensional framework encompassing phonological target alignment, developmental appropriateness, readability, and narrative quality. This methodology enables a systematic investigation of LLM performance in constrained educational text generation.

4.1 Models

We evaluated six LLMs: Claude-3.7-Sonnet (claude), GPT-4o (gpt4o), GPT-4o-Mini (gpt4o_mini), Gemini-2.0 Flash (gemini), DeepSeek-V3 (deepseek), Mistral-Large-2.1 (mistral). These model versions were available as of March 2025.

The models claude, gpt4o, and gpt4o_mini were selected due to their demonstrated strengths in phonological subtasks such as grapheme-to-phoneme (G2P) conversion and syllable counting in prior benchmarks (e.g., PhonologyBench (Suvarna et al., 2024)). Batched API calls were used for these models.

To have a balance of three open-source and three closed-source models, mistral, deepseek, and gemini were also included. These were accessed via standard single-prompt endpoints.

4.2 Prompt Design

We designed 16 structured prompts grouped into three prompt sets. These were constructed to evaluate the ability of LLMs to adhere to phonological, developmental, and narrative constraints. The prompts targeted either individual GP pairs or phonic sets and varied in their degree of constraint and instructional framing.

4.2.1 Phoneme Selection

Target GP mappings are derived from Pearson’s *Phonics Progression Chart* (Pearson Education, n.d.), which follows a structured synthetic phonics curriculum aligned with established literacy research (Ehri, 2020; National Reading Panel, 2000; Rose, 2006). Graphemes are preserved in orthographic form, while phonemes are represented in ARPABET. Table 3 lists these GP pairs, as well as corresponding target age, phonic phase, and phonic set.

4.2.2 Prompt Variants

All prompts were initialized with a shared system instruction (Figure 1) that defines the model’s role and objective. Three prompt sets were then constructed, each with a distinct focus, along with minor variations within each set.

To examine consistency, half of the prompts required the model to generate a single story, while the remaining prompts required the generation of eight stories. Additionally, prompts alternated between the terms “phonics stories” and “decodable texts” to analyze the effect of terminology on generation behavior, despite their conceptual overlap.

The full set of prompt variants is provided in Appendix A.

Prompt Set 1: Single Grapheme-Phoneme Pair and Narrative Focused Generation (Prompts 1-8) This set targeted individual GP pairs. Variants included basic prompts and plot-driven prompts. These prompts evaluated the ability of LLMs to reinforce a single phoneme within a coherent narrative.

Prompt Set 2: Phonic Set Focused Generation (Prompts 9-12) This prompt set introduced constraints based on a given phonic set, emphasizing the GP pairs within the set while permitting supporting GP pairs from earlier sets to improve fluency and phonic progression.

Prompt Set 3: Age-Constrained Generation (Prompts 13-16) This set incorporated developmental constraints. Phases 2-3 were designed for children aged 4–5, while Phase 5 was designed for children aged 5–6. These age ranges were originally aligned with the UK Department for Education’s *Letters and Sounds* framework, in which Phases 2 and 3 are introduced during Reception (ages 4–5) and Phase 5 is taught in Year 1 (ages 5–6) (Department for Education and Skills, 2008). Although *Letters and Sounds* was formally withdrawn in 2024 as part of the shift toward updated validated systematic synthetic phonics programs, its phase structure remains widely referenced in both research and instructional materials. This progression is also reflected in Pearson’s Phonics Progression Chart and broader systematic synthetic phonics curricula (Pearson Education, n.d.; Rose, 2006).

4.3 Data Cleaning and Post-processing

Generated outputs were standardized for consistency and evaluability. The process included removing extraneous labels, re-prompting malformed outputs, and normalizing formatting.

While the target structure specifies exactly four sentences, minor deviations (3-5 sentences) were retained to avoid introducing bias through aggressive filtering. These cases were included in evaluation to preserve the integrity of model outputs.

4.4 Evaluation Metrics

Generated stories are evaluated using 12 automated metrics spanning four dimensions: phonological alignment, developmental lexical appropriateness, readability, and narrative quality. Full formal definitions are provided in Appendix B. For clarity, metrics are referenced by both name and index (1-12) throughout the paper.

4.4.1 Phonological Target Alignment (Metrics 1-4)

Phonological target alignment measures adherence to target GP mappings. A word is considered aligned if the target grapheme appears in the word and the corresponding phoneme appears in its ARPABET transcription. Metrics include (M1) **Story-level Phoneme Density**, (M2) **Sentence-level Phoneme Density**, (M3) **Mean Phonics Level Deviation**, and (M4) **Maximum Phonics Level Deviation**.

4.4.2 Developmental Lexical Appropriateness (Metrics 5-6)

Lexical appropriateness captures the suitability of vocabulary for early readers. This is quantified using Age of Acquisition (AoA) norms (Kuperman et al., 2012; Valentini et al., 2023). Metrics include (M5) **Mean AoA Deviation** and (M6) **Maximum AoA Deviation** from the target age range.

4.4.3 Readability (Metrics 7-10)

Readability measures the linguistic simplicity of the text and is assessed using standard metrics, including (M7) **Flesch Reading Ease**, (M8) **Flesch-Kincaid Grade Level**, (M9) **Gunning Fog Index**, and (M10) **Automated Readability Index**. Thresholds aligned with early readers (ages 4-6) are used for interpretation (Table 4).

4.4.4 Narrative Quality (Metrics 11-12)

Narrative quality evaluates coherence and cohesion in the generated stories. These metrics

are scored using an LLM-as-a-judge framework (Claude-Haiku-4.5) with rubric-based prompting to improve consistency and reduce variance. Scores are normalized to a 0-1 scale. **(M11) Coherence** measures global narrative organization, including setup, logical progression, causal relationships, and resolution. **(M12) Cohesion** assesses local connectedness across sentences, including referential clarity, lexical consistency, and the absence of contradictions.

The full evaluation prompt, inspired by the coherence and cohesion frameworks of Alasmari et al. (2025) and Hargood et al. (2011), is provided in Appendix G.

The evaluator models also generated textual justifications alongside their rubric-based scores. These outputs were retained separately for qualitative inspection but were omitted from the main dataset and analyses to maintain focus on aggregate quantitative comparisons.

4.5 Statistical Analysis

Evaluation results were compared across metric, prompt design, and model levels using aggregate analysis, omnibus tests, and post-hoc pairwise comparisons.

Prior to significance testing, a Shapiro-Wilk normality test was applied to each group within a comparison. The test evaluates the null hypothesis that a sample is drawn from a normal distribution; a p -value ≤ 0.05 indicates a significant deviation from normality.

As most metric distributions violated normality assumptions, non-parametric tests were used throughout. For comparisons involving more than two groups, the Kruskal-Wallis (KW) test was applied as the omnibus test. For pairwise comparisons between two groups, the Mann-Whitney U (MWU) test was used.

For comparisons with more than two groups, post-hoc pairwise tests were conducted only when the omnibus test was significant ($\alpha = 0.05$). Bonferroni correction was applied to adjust p -values and control the family-wise error rate.

Omnibus tests determine whether significant differences exist across groups, while post-hoc pairwise tests identify which specific group pairs differ significantly.

Metric	Mean	Std
1. Story-Level Phoneme Density ($\uparrow$)	0.360	0.222
2. Sentence-Level Phoneme Density ($\uparrow$)	0.373	0.219
3. Mean Phonics Level Deviation ($\downarrow$)	1.440	0.997
4. Max Phonics Level Deviation ($\downarrow$)	1.053	0.728
5. Mean AoA Deviation ($\downarrow$)	0.206	0.275
6. Max AoA Deviation ($\downarrow$)	3.378	1.637
7. Flesch Reading Ease ($\uparrow$)	104.206	11.721
8. Flesch-Kincaid Grade Level ($\downarrow$)	0.196	1.681
9. Gunning Fog Index ($\downarrow$)	2.848	1.217
10. Automated Readability Index ($\downarrow$)	-0.386	2.320
11. Coherence ($\uparrow$)	0.665	0.231
12. Cohesion ($\uparrow$)	0.704	0.167

Table 1: Summary statistics across all generated stories. Arrows indicate whether higher ($\uparrow$) or lower ($\downarrow$) values are generally preferable.

5 Results and Discussion

Through zero-shot prompting, a dataset of 8,688 outputs comprising 39,096 stories was generated, cleaned, and evaluated across four metric groups. Overall, models consistently produce highly readable and age-appropriate text, but show greater variability in phonological alignment and narrative quality. Both prompt design and model choice significantly affect performance across all metrics.

5.1 Metric-Level Comparison

Table 1 summarizes aggregate performance across all models and prompt configurations. Results indicate consistently high readability and appropriate vocabulary usage, alongside moderate adherence to phonological constraints and more variable narrative quality (see Appendix F).

5.1.1 Phonological Target Alignment

Phoneme density is moderate but acceptable (0.360), indicating emphasis of target phonemes in at least one per three words. Sentence-level density (0.373) is slightly higher, suggesting uneven distribution across sentences. However, phonics level deviation further highlights weak control. The mean deviation (1.44) indicates frequent use of words outside the target level, while a high maximum deviation reflects occasional inclusion of a substantially different phonic phase. The raw values show that around 75% of deviation is negative. Along with a lower maximum phonics level deviation, this indicates the use of phonemes in easier phonic phases.

5.1.2 Developmental Lexical Appropriateness

Lexical appropriateness is generally strong, with low mean AoA deviation (0.206). However, a high

average maximum deviation (3.378) indicates occasional out-of-scope words, even reaching a deviation of 10.920. This reflects stable average performance but inconsistent worst-case behavior, suggesting limited constraint enforcement at the token level.

5.1.3 Readability

Readability is consistently high, with Flesch Reading Ease above 100 and grade-level metrics near or below early elementary levels. This indicates strong control over linguistic simplicity, possibly due to the maximum syllable requirement in the basic prompt in Figure 1.

Compared to other metrics, readability aligns closely with general language modeling objectives, making it the most stable dimension. However, this strength does not guarantee alignment with phonics progression, as linguistically simple text may still fail to systematically reinforce target grapheme-phoneme correspondences.

5.1.4 Narrative Quality

Narrative quality is moderate, with coherence (0.665) lower than cohesion (0.704). This indicates stronger local sentence connections than global narrative structure. Performance varies across models, with stronger models producing more stable narrative flow and weaker models showing greater inconsistency.

5.2 Prompt Design-Level Comparison

Prompt design significantly affects performance across all metric groups, influencing trade-offs between phonological alignment, readability, and narrative quality. Different aspects of prompt design, such as prompt set, terminology, and story number, were evaluated for their performance. Figures 5 and 6 summarize performance across prompt sets and prompts, respectively.

5.2.1 Comparison Across Prompt Sets

All prompt sets achieve high readability ratings, with Prompt Set 2 producing the easiest texts.

Prompt Set 1, which was designed to focus on both specific phonemes and plot, achieves desired outputs. It yields the strongest phonemic alignment but with at least 1 level of deviation from the desired phonic phase. It also achieves a moderate narrative quality, only a close second to Prompt Set 3. With regards to lexical appropriateness, it achieves the lowest mean deviation but also contains more

words that deviate greatly from the target age of acquisition.

Meanwhile, Prompt Set 2, which focuses on phonic-set-based generation, has the largest deviation from the desired phonics phase, which may be because it is more lenient on what specific phoneme to use. The texts produced by this prompt set also had the worst coherence and cohesion.

Prompt Set 3, which focuses on age-appropriateness, produces texts with more consistent ages of acquisition rates and produces acceptable phonological alignment, although it is the lowest in terms of phoneme density.

In Figure 10, KW tests revealed that there were significant differences between the prompt sets for all metrics except for metric 3 (Maximum Phonics Level Deviation). Bonferroni-corrected MWU pairwise tests show that all prompt sets are significantly different from each other with regard to readability despite producing extremely readable texts.

Similarly, there are significant differences across all specific prompts on all metrics except for phonics level deviation. Narrative coherence had the most pairs with significant differences (91 out of $\binom{16}{2} = 120$).

5.2.2 "Phonics-Based Story" vs "Decodable Text"

The prompts alternated between using "phonics-based stories" and "decodable texts." No significant differences are observed in phoneme density, indicating stable phonological alignment across the terminology used. However, using "phonics-based story" achieves higher coherence and cohesion, while "decodable text" prompts produce easier texts. This difference was found to be significant using MWU tests (Figure 10).

This suggests that LLMs may understand that stories require richer narratives, while texts simply adhere to the target of being decodable. Thus, even a slight change in the terminology for the target output influences the trade-off between narrative structure and readability, although the effect is less pronounced than other design factors.

5.2.3 Single-story vs Multi-story Prompts

Using MWU tests, we compared each single-story prompt to its equivalent multi-story prompt (e.g., Prompt 1 vs.3), totaling 8 pairs. This showed that all single-story prompts achieve significantly higher phoneme density, while multi-story prompts yield better coherence, cohesion, and readability.

This trade-off is consistent across prompt sets, indicating that output format strongly affects constraint adherence. There was no significant difference found for phonics level deviation metrics.

5.3 Model-Level Comparison

Model choice is the primary determinant of overall performance, showing significant differences across all metrics using KW tests and post-hoc Bonferroni-corrected MWU tests. Particularly, performance differences in terms of phoneme density are most evident and are present in all $\binom{6}{2} = 15$ pairs. Further analysis showed that some models showed clear trade-offs with phonological alignment for narrative quality while others show moderate yet acceptable performance across all metrics.

Figure 8 shows claude and gemini have the strongest phonological alignment, where the target phoneme or phonic set is present in around one per two words. However, they also perform the worst in terms of narrative quality. In contrast, gpt4o_mini and mistral rank highest in terms of narrative quality but lowest in terms of phonological alignment. Keeping a better balance of both these metric categories are deepseek and gpt4o, with deepseek showing the best set of balanced scores as seen in Figure 7

In samples 1 to 6 in Table 6, we can see stories generated by the models for the GP mapping between grapheme ‘le’ and phonemes [‘L’, ‘AH L’]. This is one case that highlights the trade-off between phonological alignment and narrative quality, where we see that the stories generated by claude, gemini, and deepseek have the target GP pair appearing in more than 1 per 2 words while having low narrative quality. In contrast, mistral and gpt4o_mini gained perfect scores for coherence and cohesion, but the target GP pair appeared in fewer than 1 in 3 words in the story.

5.3.1 Selected Model Performance Comparison

Figure 9 presents a focused comparison between claude—because of its strong alignment—and deepseek—because of its strong balanced performance. They are compared across four representative metric categories: phonological alignment (M1), lexical difficulty control (M5), readability (M7), and narrative quality (M11-M12), evaluated across all prompt sets (PS1-PS3).

Phonological Alignment (M1) Across all prompt sets, claude consistently achieves higher

phoneme coverage, with median values centered around 0.45–0.55, compared to deepseek’s lower range of approximately 0.30–0.45. This confirms its stronger adherence to target GP constraints. However, claude also exhibits slightly wider interquartile ranges, indicating less consistent enforcement. While weaker in overall coverage, deepseek, shows more stable distributions across prompt configurations.

Lexical Difficulty Control (M5) Both models maintain relatively low AoA deviation, suggesting that generated vocabulary generally aligns with the intended difficulty level. Stories by claude show tighter distributions closer to zero, indicating more consistent lexical control, while deepseek, particularly under PS2, exhibits slightly higher medians and greater spread, suggesting occasional introduction of more difficult words.

Readability (M7) In terms of readability, deepseek clearly outperforms claude. Across all prompt sets, deepseek achieves higher Flesch Reading Ease scores, with medians consistently exceeding those of claude. Furthermore, deepseek’s distributions are more compact, indicating more stable control over sentence complexity. More variability is seen in claude’s stories, showing more low-end outliers and reflecting occasional drops in readability.

Narrative Quality (M11–M12) Stories generated by deepseek demonstrate stronger narrative performance overall, with higher median scores in both coherence and cohesion across all prompt sets. The gap is especially pronounced under PS2, where claude exhibits a notable decline and increased variance. While claude improves under PS3, it remains slightly below deepseek in both metrics. Tighter distributions present in deepseek’s stories indicate more consistent narrative structure.

Trade-off Analysis These results highlight a clear trade-off between constraint satisfaction and overall story quality. While claude excels in enforcing phonological constraints and maintaining lexical simplicity, it comes at the cost of reduced readability and weaker narrative structure. In contrast, deepseek provides a more balanced performance, achieving higher readability and narrative quality while maintaining moderate phonological alignment. Sample stories 7 to 10 in Table 6 also reflect these trade-offs.

Prompt Effects Across both models, PS2 consistently underperforms relative to PS1 and PS3. This is reflected in lower phoneme coverage, higher lexical deviation, and reduced narrative quality. In contrast, PS1 and PS3 produce more stable and higher-quality outputs, with PS3 often achieving the best balance between constraint adherence and fluency.

6 Conclusion

This work investigates zero-shot phonics story generation as a constrained text generation task requiring simultaneous adherence to phonological alignment, developmental appropriateness, readability, and narrative quality. Through a large-scale evaluation across multiple models and prompt configurations, our findings reveal a consistent pattern: while LLMs produce highly readable and age-appropriate text, they exhibit moderate yet acceptable phonological alignment and variable performance in narrative coherence.

Our analysis highlights systematic trade-offs between constraint categories. Models that achieve stronger phonological alignment often do so at the expense of narrative quality and vice versa. Prompt design further influences these trade-offs, shaping how constraints are prioritized, while model choice determines the overall balance and stability of performance across metrics.

Importantly, results show that no single model consistently satisfies all instructional requirements, underscoring the difficulty of multi-constraint generation in educational contexts. While some models demonstrate more balanced behavior, phonological alignment remains the most challenging dimension, particularly in maintaining consistent and instructionally meaningful reinforcement of target grapheme-phoneme correspondences.

Overall, this work establishes phonics story generation as a stringent testbed for controllable text generation and provides a multi-dimensional evaluation framework for assessing instructional alignment. These findings highlight the need for methods beyond zero-shot prompting, including constrained decoding, structured generation, or fine-tuning approaches, to better align LLM outputs with pedagogical objectives.

By systematically analyzing model behavior across constraints, this study contributes both empirical insights and evaluation tools for future research in educational NLP and controllable text

generation.

Limitations

This study has several limitations that suggest directions for future work. First, the evaluated models reflect capabilities available as of early 2025; newer systems may exhibit improved performance. Consequently, greater emphasis should be placed on the generalizability of the proposed generation, evaluation, and analysis framework.

Story generation used default sampling parameters rather than deterministic decoding (e.g., temperature = 0), reflecting real-world usage but limiting reproducibility. In addition, all stories were constrained to four sentences, restricting the evaluation of longer narrative structures and potentially underestimating model capabilities in maintaining coherence over extended contexts.

Phonological alignment was measured using GP matching via G2P conversion. While scalable, this approach does not capture pronunciation variability or contextual phoneme realization. Readability was assessed using formula-based metrics that capture surface-level linguistic complexity but may not fully reflect comprehension difficulty for early learners. Narrative quality was evaluated using a single LLM-based evaluator. While rubric-based prompting improves consistency, reliance on one evaluator introduces potential bias. Incorporating multiple LLM judges, ensemble methods, or human annotation would improve robustness. Although evaluator-generated textual rationales and subcriterion-level assessments were retained during scoring, these qualitative traces were not systematically analyzed in the present work. Future research could examine these explanations to better understand evaluator behavior, improve interpretability, and identify recurring narrative strengths or failure modes across generated stories.

Beyond automated evaluation, the study does not include comparisons against professionally developed or expert-authored phonics stories. As a result, while the proposed metrics enable relative comparison across prompts and models, they do not yet establish normative or pedagogically optimal ranges for high-quality instructional materials. Future work could benchmark generated stories against curated human-authored phonics corpora to better contextualize metric distributions, such as phoneme density and readability, and to identify target ranges associated with effective instructional

design.

The study also does not include expert evaluation or in-field testing and therefore does not measure actual learning outcomes such as phoneme acquisition, reading fluency, or comprehension. Future work should incorporate educator assessment and classroom-based studies to evaluate pedagogical effectiveness.

Finally, this study is limited to English phonics story generation. Extending the framework to other languages and literacy contexts remains an important direction for future research.

Ethical Considerations

This work explores the use of LLMs for generating phonics stories intended for early literacy instruction. While such systems have the potential to support scalable educational content creation, they also raise several ethical considerations.

The generated phonics stories are designed to support early readers but they are not a substitute for professionally developed instructional materials. LLM-generated content may contain inaccuracies in phonological alignment, inappropriate vocabulary, or inconsistencies in narrative structure. They should therefore be used with educator oversight.

This study relies on automated evaluation metrics, including LLM-based assessment for narrative quality. While this enables large-scale analysis, it does not fully capture pedagogical effectiveness. The absence of expert and in-field evaluation means that conclusions about instructional quality should be interpreted with caution.

LLMs are trained on large-scale web data and may reflect biases present in their training corpora. Although phonics stories are typically simple, generated content may still include cultural, social, or linguistic biases that are not appropriate for young learners. Future work should include bias analysis and content filtering to ensure inclusivity and appropriateness.

A Prompt Design

All prompt sets incorporated the basic prompt structure in Figure 1 and had respective additional requirements listed in Figures 2, 3, and 4.

System Prompt:

You are a children’s story writer and children’s educator specializing in speech and language acquisition. You write decodable texts and phonics stories, which are engaging stories for early readers that reinforce grapheme-phoneme associations through repeated exposure to target sounds.

Story Requirements:

- (Prompt-specific additional requirements)
- The story must contain exactly four sentences.
- Each sentence must contain fewer than eleven syllables.
- The story must reinforce the target phoneme(s).

Output Format:

****Title****

Sentence 1
Sentence 2
Sentence 3
Sentence 4

Figure 1: Base prompt structure for phonics story generation.

Prompt Set 1: Single GP and Narrative Focus

Prompt: Generate a short phonics-based story focusing on the grapheme ‘{grapheme}’, which corresponds to the phoneme(s) ‘{phoneme(s)}’.

Additional Requirements:

- Each sentence must include at least 2 words containing the grapheme ‘{grapheme}’.

Figure 2: Prompt Set 1: Single GP and Narrative Focus

Across all prompt sets, systematic variations, as seen in Table 2 were applied. The phrase “phonics story” was replaced with “decodable text” in selected prompts. Prompts requesting a single story were modified to generate “8 different” stories. Additional narrative constraints (e.g., requiring a plot

Prompt Set 2: Phonic Set Focus

Prompt: Generate a short phonics story that gives primary emphasis to the target graphemes in the list {grapheme_set}, which correspond to the phonemes {phoneme_set}, respectively. The majority of the key vocabulary should highlight these target grapheme-to-phoneme correspondences. You may also include graphemes from {lower_grapheme_set_list} to create complete and readable words, but they should play a supporting role.

Additional Requirement:

- The story should be designed to reinforce recognition and pronunciation of the target grapheme-to-phoneme correspondences.

Figure 3: Prompt Set 2: Phonic Set Focus

Prompt Set 3: Age-Constrained

Prompt: Generate a short phonics story for children aged {age} years old. The phonics story must focus on the grapheme '{grapheme}', which corresponds to the phoneme(s) '{phoneme(s)}'.

Additional Requirements:

- The story must be age-appropriate and engaging.
- Each sentence must include at least 2 words containing the grapheme '{grapheme}'.

Figure 4: Prompt Set 3: Age-Constrained

with consistent characters) were included in selected prompts.

B Evaluation Metrics

Notation.

- Each story $\mathcal{S} = \{s_1, s_2, s_3, s_4\}$ consists of sentences.
- Let $W_i = \{w_{i1}, w_{i2}, \dots, w_{iN_i}\}$ be the words in sentence s_i .
- Let $W = \bigcup_{i=1}^4 W_i$ be all words in the story, with total size $|W| = \sum_{i=1}^4 N_i$.
- $\mathbf{1}(\cdot)$ is the indicator function.
- $L(w)$ denotes the set of phonics phases associated with word w .

- Ph_t denotes the target phoneme.
- PS_t denotes the target phonics set.
- PP_t denotes the target phonics phase.
- $A(w)$ denotes the Age of Acquisition (AoA) of word w .
- $\mathcal{A} \subseteq W$ is the set of words with valid AoA values.
- $[a_{\min}, a_{\max}]$ is the target age range.

B.1 Metric 1: Phoneme Density (Story-Level)

Measures the proportion of words in the story that contain the target phoneme or a phoneme from the target set (for Prompt Set 2). This captures how strongly the story reinforces the target at the overall story level. Higher values indicate better phonological alignment.

$$M_1 = \frac{1}{|W|} \sum_{w \in W} \mathbf{1}(w \text{ contains phoneme}) \quad (1)$$

B.2 Metric 2: Phoneme Density (Sentence-Level)

Measures the average proportion of words containing the target phoneme or a phoneme from the target set (for Prompt Set 2) computed at the sentence level. This ensures that phoneme usage is distributed consistently across sentences rather than concentrated in only one part of the story.

$$M_2 = \frac{1}{4} \sum_{i=1}^4 \left(\frac{1}{|W_i|} \sum_{w \in W_i} \mathbf{1}(w \text{ contains phoneme}) \right) \quad (2)$$

B.3 Metric 3: Mean Phonics Level Deviation

Measures the deviation of the average phonics phases associated with each word from the target phonics phase. Note that tricky words listed in 3 were counted towards that phonics phase. Values closer to 0 indicate better alignment.

$$M_3 = \left| \frac{1}{|W|} \sum_{w \in W} \left(\frac{1}{|L(w)|} \sum_{\ell \in L(w)} \ell \right) - PP_t \right| \quad (3)$$

Variation	Prompt IDs
"phonics-based story" → "decodable text"	2, 4, 6, 8, 10, 12, 14, 16
Single story → "8 different" stories	3, 4, 7, 8, 11, 12, 15, 16
Plot requirement added	5, 6, 7, 8

Table 2: Systematic prompt variations applied across prompt sets.

Target Age	Phase	Set	Grapheme-Phoneme Mappings	Tricky Words
4-5	2	1	s→['S'], a→['AA','AE','AH'], t→['T'], p→['P']	the, to, I, no, go, into, and
		2	i→['IH'], n→['N'], m→['M'], d→['D']	
		3	g→['G'], o→['AA'], c→['K'], k→['K']	
		4	ck→['K'], e→['EH'], u→['AH'], r→['R']	
		5	h→['HH'], b→['B'], f→['F'], ff→['F'], l→['L'], ll→['L'], ss→['S']	
	3	6	j→['JH'], v→['V'], w→['W'], x→['K','S']	he, she, we, me be, was, you, they, all, are, my, her
		7	y→['Y'], z→['Z'], zz→['Z'], qu→['K','W']	
		8	ch→['CH'], sh→['SH'], th→['TH','DH'], ng→['NG']	
		9	ai→['EY'], ee→['IY'], igh→['AY'], oa→['OW'], oo→['UH']	
		10	ar→['AA','R'], or→['AO','R'], ur→['ER'], ow→['AW'], oi→['OY']	
		11	ear→['IH','R','IY','R'], air→['EH','R'], ure→['Y','UH','R'], er→['ER']	
5-6	5	13	slz→['ZH'], wh→['W'], ph→['F']	oh, their, people, Mr, Mrs, looked, called, asked
		14	ay→['EY'], a.e→['EY'], eigh→['EY'], ey→['EY'], ei→['EY']	
		15	ea→['IY'], e.e→['IY'], ie→['IY'], ey→['IY'], y→['IY']	
		16	ie→['AY'], i.e→['AY'], y→['AY'], i→['AY']	
		17	ow→['OW'], o.e→['OW'], o→['OW'], oe→['OW']	
		18	ew→['UW'], ue→['UW'], u.e→['UW'], u→['UH'], oul→['UH']	
		19	aw→['AO'], au→['AO'], al→['AO','L'], our→['AO','R']	
		20	ir→['ER'], er→['ER'], ear→['ER']	
		21	ou→['AW'], oy→['OY']	
		22	ere→['IH','R'], eer→['IH','R'], are→['EH','R'], ear→['EH','R']	
		23	c→['K'], k→['K'], ck→['K'], ch→['K']	
		24	ce→['S'], ci→['S'], cy→['S'], sc→['S'], stl→['S'], se→['S']	
		25	ge→['JH'], gi→['JH'], gy→['JH'], dge→['JH']	
		26	le→['L','AH','L'], mb→['M'], kn→['N'], gn→['N'], wr→['R']	
		27	tch→['CH'], chlc→['SH'], ea→['EH'], a→['AA'], o→['AH']	

Table 3: Phoneme sets and progression mapping used in this study, adapted from Pearson’s Phonics Progression Chart (Pearson Education, n.d.) Each set groups grapheme-phoneme correspondences and associated target age ranges, and is assigned a phonics phase corresponding to instructional progression. The phoneme progression consists of 26 sets comprising a total of 112 grapheme-phoneme (GP) correspondences. Phase 4 (Set 12) is omitted, as it serves as a consolidation phase focusing on blending and fluency using previously introduced correspondences, rather than introducing new GP mappings. Tricky words indicate words to be learned at that phase but may contain certain graphemes that conflict with target GP mappings.

B.4 Metric 4: Maximum Phonics Level Deviation

Measures the deviation of the highest phonics phase deviation per word, averaged across the story. Note that tricky words listed in 3 were counted towards that phonics phase. Values closer to 0 indicate better alignment.

B.5 Metric 5: Mean Age of Acquisition Deviation

Measures the deviation of the average word-level Age of Acquisition (AoA) values from the target age range. Words within the target range incur no penalty, while words outside the range contribute proportionally to their distance.

$$M_5 = \delta \left(\frac{1}{|\mathcal{A}|} \sum_{w \in \mathcal{A}} A(w) \right) \quad (5)$$

$$M_4 = \left| \frac{1}{|W|} \sum_{w \in W} \max_{\ell \in L(w)} \ell - PP_t \right| \quad (4)$$

where

$$\delta(a) = \begin{cases} a_{\min} - a, & a < a_{\min} \\ 0, & a_{\min} \leq a \leq a_{\max} \\ a - a_{\max}, & a > a_{\max} \end{cases} \quad (6)$$

B.6 Metric 6: Maximum Age of Acquisition Deviation

Measures the deviation of the AoA of the most difficult word in the text from the target age range. This captures the worst-case lexical difficulty.

$$M_6 = \delta \left(\max_{w \in \mathcal{A}} A(w) \right) \quad (7)$$

B.7 Metrics 7-10: Readability

These metrics assess surface-level linguistic complexity based on sentence length, word difficulty, and character-level features. Lower complexity generally corresponds to better suitability for early readers, but readability thresholds are also presented in C.

Let:

- ASL = $\frac{\text{words}}{\text{sentences}}$ (average sentence length)
- ASW = $\frac{\text{syllables}}{\text{words}}$ (average syllables per word)
- PHW = $\frac{\text{hard words}}{\text{words}}$ (proportion of complex words)

Syllable count was obtained from ‘cmudict’ in ‘nltk.corpus’ but when the word was not found in the dataset, the ‘syllables’ library in Python was used to estimate it. The number of words whose syllable count were estimated was noted as ‘Est Syl’ in the dataset.

Metric 7: Flesch Reading Ease Measures how easy the text is to read. Higher values indicate simpler and more accessible text.

$$M_7 = 206.835 - 1.015 \cdot \text{ASL} - 84.6 \cdot \text{ASW} \quad (8)$$

Metric 8: Flesch-Kincaid Grade Level Estimates the U.S. grade level required to understand the text. Lower values indicate simpler text.

$$M_8 = 0.39 \cdot \text{ASL} + 11.8 \cdot \text{ASW} - 15.59 \quad (9)$$

Metric 9: Gunning Fog Index Measures readability based on sentence length and proportion of complex words. Lower values indicate easier readability.

$$M_9 = 0.4 \cdot (\text{ASL} + 100 \cdot \text{PHW}) \quad (10)$$

Metric 10: Automated Readability Index

Estimates readability using character-level and sentence-level features. Lower values indicate easier text.

$$M_{10} = 4.71 \cdot \frac{\text{characters}}{\text{words}} + 0.5 \cdot \frac{\text{words}}{\text{sentences}} - 21.43 \quad (11)$$

B.8 Metrics 11-12: Narrative Quality

Narrative quality is evaluated using an LLM-as-a-judge framework based on predefined rubrics (A1-4, B1-4) as stated in the prompt in Figure 11. Each criterion is scored on a 3-point scale: 0 = Not present; 1 = Partially present; 2 = Clearly present. The scores for A1-4 and B1-4 were also noted in the dataset.

Metric 11: Coherence Measures meaning-level organization, including clarity of setup, logical progression, causal relationships, and resolution.

$$M_{11} = \frac{1}{4} \sum_{k=1}^4 \frac{A_k}{2} \quad (12)$$

Metric 12: Cohesion Measures surface-level connectedness across sentences, including referential clarity and linguistic consistency.

$$M_{12} = \frac{1}{4} \sum_{k=1}^4 \frac{B_k}{2} \quad (13)$$

C Readability Thresholds

Metric	Ideal	Acceptable	Too Hard
FRE	80-100	70-80	< 60
FKGL	0-2	3-4	≥ 5
Fog	≤ 6	7-8	≥ 9
ARI	0-2	3-4	≥ 5

Table 4: Readability thresholds for early readers.

D Prompt-Level Figures

Figure 5: Performances of prompt sets across all metrics, averaged (annotation=mean) and normalized (color=Z-score) over all prompt configurations.

Figure 6: Performances of each specific prompt across all metrics, averaged (annotation=mean) and normalized (color=Z-score) over all prompt configurations.

E Model-Level Figures

Figure 7: Model profiles for phoneme density and narrative quality show trade-offs between model performance.

Figure 8: Performances of models across all metrics, averaged (annotation=mean) and normalized (color=Z-score) over all prompt configurations.

Figure 9: Performance of claude vs deepseek over metric categories using each prompt set.

F Statistical Analysis

Figure 10: Count of pairs (by prompt set, prompt number, terminology, story count, and model) with significant difference ($p \leq 0.05$) across all metrics

Metric	Count	Mean	Std	Min	25%	50%	75%	Max
1. Story-Level Phoneme Density (↑)	8688	0.360	0.222	0.000	0.184	0.346	0.522	1.000
2. Sentence-Level Phoneme Density (↑)	8688	0.373	0.219	0.000	0.202	0.367	0.538	1.000
3. Mean Phonics Level Deviation (↓)	8688	1.440	0.997	0.000	0.433	2.049	2.372	3.000
4. Max Phonics Level Deviation (↓)	8688	1.053	0.728	0.000	0.310	1.094	1.666	3.000
5. Mean AoA Deviation (↓)	8688	0.206	0.275	0.000	0.000	0.085	0.328	2.394
6. Max AoA Deviation (↓)	8688	3.378	1.637	0.000	2.254	3.245	4.380	10.920
7. Flesch Reading Ease (↑)	8688	104.206	11.721	18.377	98.841	107.487	112.760	119.867
8. Flesch-Kincaid Grade Level (↓)	8688	0.196	1.681	-2.880	-0.954	-0.143	0.985	12.129
9. Gunning Fog Index (↓)	8688	2.848	1.217	0.933	2.160	2.640	3.183	21.010
10. Automated Readability Index (↓)	8688	-0.386	2.320	-8.466	-1.855	-0.448	0.966	10.723
11. Coherence (↑)	8688	0.665	0.231	0.000	0.500	0.719	0.844	1.000
12. Cohesion (↑)	8688	0.704	0.167	0.000	0.625	0.750	0.828	1.000

Table 5: Full descriptive statistics across all generated stories. Arrows indicate whether higher (↑) or lower (↓) values are generally preferable.

G Narrative Evaluation Framework

LLM Evaluation Prompt for Narrative Quality

You are an expert in children's phonics stories for speech development in early childhood education (ages 4-6). You understand that these stories are short (exactly 4 sentences), simple, and designed for early readers. You must evaluate the narrative quality of each story based ONLY on structural coherence and cohesion. Do NOT evaluate creativity, vocabulary richness, or literary sophistication. Do NOT penalize simplicity. Focus only on whether each story is logically clear and well-connected.

INSTRUCTIONS:

1. Input Requirements: - The user will provide multiple numbered phonics stories, each with a title and 4 sentences.

2. Evaluation Criteria

Evaluate each story using the following criteria.

A. COHERENCE (Meaning-Level Organization) Score each criterion: 0 = Not present 1 = Partially present 2 = Clearly present

A1. Situation Setup Clarity - Does the first sentence clearly introduce who or what the story is about?

A2. Logical Event Progression - Do the sentences follow a logical order? - Does each sentence build naturally from the previous one?

A3. Causal or Motivational Connection - Are actions connected by cause, goal, or intention? - Is it clear why events happen?

A4. Resolution or Completion - Does the final sentence complete or resolve the situation?

B. COHESION (Surface-Level Connections) Score each criterion: 0 = Not present 1 = Partially present 2 = Clearly present

B1. Referential Clarity - Are pronouns clearly linked to nouns? - Is there ambiguity in who is performing actions?

B2. Lexical Consistency - Are key words repeated or semantically related? - Is the topic maintained across all sentences?

B3. Use of Connective Devices - Are simple connectors used appropriately? (e.g., and, then, so, but)

B4. Absence of Contradiction - Are there inconsistencies or sudden unexplained changes?

3. Output Format

Return ONLY a JSON array with one object per story, in the same order as the input:

```
{
  "story": <story number>,
  "title": "<story title>",
  "coherence": {
    "A1_situation_setup": <0-2>,
    "A2_event_progression": <0-2>,
    "A3_causal_connection": <0-2>,
    "A4_resolution": <0-2>
  },
  "cohesion": {
    "B1_referential_clarity": <0-2>,
    "B2_lexical_consistency": <0-2>,
    "B3_connectives": <0-2>,
    "B4_no_contradiction": <0-2>
  }
}
```

Figure 11: Prompt used for narrative quality scoring.

H Sample of Generated Stories

#	Target GP Mapping	Prompt-Model	Story	$M_1(\uparrow)$	$M_2(\uparrow)$	$M_3(\downarrow)$	$M_4(\downarrow)$	$M_{11}(\uparrow)$	$M_{12}(\uparrow)$
1	le→['L', 'AH L']	6-claude	**Little Turtle's Rumble** Little Turtle rumbles in a puddle. The gentle turtle nibbles on a purple apple. Noble turtle tumbles while juggling a paddle. The little turtle cuddles with his uncle.	0.677	0.715	2.142	1.000	0.375	0.625
2	le→['L', 'AH L']	6-gemini	**Kyle's Little Kettle** Kyle likes to juggle apples. Purple bubbles flew from his kettle. He tickled a beetle with his little toe. Kyle giggled, "Simple, the kettle is silly!"	0.586	0.536	2.262	1.000	0.375	0.250
3	le→['L', 'AH L']	6-deepseek	**The Little Turtle's Puzzle** The little turtle waddles. He finds a purple pebble. It sparkles like a bubble. He giggles with a chuckle.	0.522	0.540	2.264	1.304	0.375	0.625
4	le→['L', 'AH L']	6-gpt4o	**Little Mice Fable** A gentle turtle found an apple. He saw little mice by the table. They played and giggled in a circle. "Share the apple," said wise turtle.	0.379	0.414	2.069	1.034	0.750	0.875
5	le→['L', 'AH L']	6-mistral	**The Little Puddle** A little puddle lay near the apple tree. The beetle and the ant took a stroll by the little puddle. The beetle said, "Let's settle near the little puddle and have a picnic with our crumble." They had a wonderful time near the little puddle, enjoying their picnic under the apple tree.	0.309	0.371	2.315	1.618	1.000	1.000
6	le→['L', 'AH L']	6-gpt4o_mini	**The Little Blue Turtle** The little blue turtle took a stroll. She saw a lovely bubble roll and roll. "Look at that bubble!" she said with glee. Then she joined it in the deep blue sea.	0.194	0.232	2.321	1.694	1.000	1.000
7	a→['AA', 'AE', 'AH']	1-claude	**Sam and Dan's Grand Plan** Sam and Dan had a plan. A cat ran past their fast car. Dan had a snack at the stand. Pat and Matt clapped at their last act.	0.909	0.918	0.197	0.212	0.250	0.250
8	a→['AA', 'AE', 'AH']	1-deepseek	**Sam and the Cat** Sam has a black cat. The cat sat on a mat. Sam pats the fat cat. The cat naps in his lap.	0.731	0.743	0.000	0.000	0.875	0.875
9	o→['AA']	14-claude	**On the Spot** Tom got a hot dog from Mom. Ron and I stop at the pond. Rob drops the mop on the cot. The frog hops on top of a rock.	0.594	0.601	0.000	0.000	0.125	0.125
10	o→['AA']	13-deepseek	**The Frog on the Log** The frog hops on the log. The dog spots the frog. The frog jumps off the log. The dog stops and sits.	0.333	0.333	0.007	0.037	1.000	0.875

Table 6: Sample stories from some models showcase tradeoffs between phonological alignment (metrics 1-4) and narrative quality (metrics 11-12). Arrows indicate whether higher ($\uparrow$) or lower ($\downarrow$) values are preferable. The full dataset of stories and scores is available at <https://huggingface.co/datasets/monicamanlises/zero-shot-phonics>

From Dialogue to Learner Modeling: Identifying Candidate Signals of Productive Use in LLM-Based Grammar Practice

Luisa Ribeiro-Flucht¹, Lanhua Huang², Xiaobin Chen¹,

luisa.ribeiro-flucht@uni-tuebingen.de

huanglh@gcu.edu.cn

xiaobin.chen@uni-tuebingen.de

Abstract

Adaptive language-learning systems often model progress through correctness in constrained exercises, where the target response is predefined. In dialogue-based tutors, by contrast, learners can respond appropriately in many ways, making evidence of progress harder to interpret. This raises a learner-modeling problem: determining whether learner production provides useful evidence of progress and how they might support adaptation. We address this problem using pilot data from an LLM-based dialogue system for English grammar practice, comprising 40 pre- and post-test tasks, treatment interactions, and 2,406 learner messages. We propose a coding scheme for learner production in dialogue and explore how the resulting evidence types can support adaptive decisions. Findings show that simple use traces of the target constructions were informative for predicting independent productive use in the next task, while finer-grained evidence helped interpret the robustness of learners' developing productive control. We discuss implications for adaptive grammar-based dialogue systems that use learner production to support communicative practice.

1 Introduction

With the rise of large language models (LLMs), dialogue-based computer-assisted language learning (DB-CALL; [Hou and Min, 2026](#)) has become an increasingly active area of research ([Du and Reynolds, 2025](#); [Panagiotidis, 2024](#)). For grammar practice, these systems are especially promising, as they can support interactive exchanges in which learners can encounter target constructions in context, be encouraged to use them in their own responses, and receive immediate feedback.

This makes LLM-based dialogue systems well suited to support productive grammar use, understood here as a learner's ability to use the grammatical structures of a second language to express their

own meanings ([Larsen-Freeman, 2003](#)). However, making such practice adaptive remains difficult: learners differ in what they know, how they use language, and how much practice they need ([Malovrh and Lee, 2023](#); [Ruiz et al., 2023](#); [Skehan, 1991](#)).

Adaptive dialogue-based tutors, therefore, need systematic ways to infer a learner's state from complex data and use this evidence to decide what kind of support or practice should come next ([Katz et al., 2021](#)). In structured practice environments, such as exercise-based tutoring systems, a specific response is usually expected, and performance can often be evaluated through pattern matching. In dialogue, however, a learner may either respond appropriately without using the expected grammatical pattern, use it only after support, reuse it only in a familiar context, or, ideally, produce it independently across contexts. The challenge is thus not just to detect whether the expected pattern is present or not, but to interpret what it reveals about the learner's developing grammatical control.

In this paper, we investigate this issue in the context of Aisla ([Chen et al., 2022](#)), a task-based dialogue system for targeted grammar practice. The current version of the system has been designed to model and elicit a given target construction in every turn. As a next step, we aim to support adaptive practice, which requires a better understanding of how learner progress can be modeled from interaction data. We therefore ask: what aspects of learner production in dialogue provide useful evidence of productive grammar use, and do different evidence types support different modeling goals?

Drawing on pilot data comprising 2,409 learner messages, we propose and explore a coding scheme for learner production in dialogue, examining how its categories function as candidate signals of independent productive use, partial evidence of control, and continued need for practice or support.

2 Background

Usage-based approaches to second language acquisition (SLA) view language knowledge as organized around constructions: learned form-function mappings ranging from morphemes and specific expressions to abstract grammatical patterns (Behrens, 2009; Bybee, 2006; Schmid, 2015). From this perspective, learning involves strengthening associations between forms and functions through repeated exposure and use, making constructions more accessible and stable over time (Suzuki, 2024). With growing experience, learners may also generalize beyond specific exemplars, moving from expressions such as “I walked” toward more abstract patterns such as “I [VERB]-ed” (Goldberg, 2009; Schmid, 2018).

In addition to repetition, meaningfulness has been argued to play an important role in the development of productive grammar (Lightbown, 2007; Larsen-Freeman, 2013; DeKeyser and DeKeyser, 2007). When learners use language to express meaning across situations, they are pushed beyond repeating memorized rules, toward adapting forms to communicative needs. This makes dialogue a promising setting for grammar practice as it creates opportunities to use target constructions in context. For DB-CALL systems, however, this also creates a practical challenge: If repeated, contextualized use helps build productive control, adaptive systems need principled ways to interpret learner production as evidence for pedagogical decisions.

2.1 Prior Work

Existing adaptive tutoring systems often model learners from structured evidence, such as response correctness or estimated mastery (Amaral and Meurers, 2007; Portnoff et al., 2021). Recent work has begun to incorporate dialogue interaction into learner modeling, mostly outside language learning. For example, Katz et al. (2021) describe a physics tutoring system that builds a learner model during dialogue and uses it to guide adaptive support. Borchers et al. (2024) combine dialogue-act classification with skill modeling in mathematics to examine which interaction types are associated with learning rates. In language learning, Cornillie et al. (2025) predict task completion in adaptive spoken dialogue systems from process data in functional L2 speaking tasks.

Together, these studies show that dialogue interaction can inform learner modeling and adaptation.

However, they do not directly address how learner production in grammar-focused dialogue should be interpreted. In particular, prior work offers limited guidance on how to interpret different patterns of learner production in grammar-focused dialogue, such as whether learners use the practiced grammatical pattern independently or only after support, and whether non-use still reflects meaningful participation or not.

3 System Context

The Aisla system uses LLMs to generate targeted communicative tasks in which learners are encouraged to use target constructions while engaging in meaning-focused exchange to achieve a non-linguistic goal. During these tasks, the system provides feedback with increasing explicitness, moving from recasts to explicit grammar tips, upon persistent failure to accurately use the target form given a licensed opportunity.

The system is structured over a graph-based domain model (Ribeiro-Flucht and Chen, 2026) that links forms, functions and the authentic contexts in which they can be practiced, tasks. The graph provides an explicit representation of the instructional space, allowing the system to organize practice opportunities in a way that reflects both pedagogical structure and communicative relevance.

Learner behavior is intended to update a learner-specific overlay over this graph. The purpose of that overlay is to represent the learner’s developing control over different targets and, ultimately, to support adaptive progression through the pedagogical space. Yet such updates depend on a core unresolved issue: which aspects of learner production should count as evidence.

4 Methodology

We analyze 2,409 learner messages produced by 20 adult A2-level learners of English with diverse first-language backgrounds, most commonly Chinese, Portuguese, and Spanish. Over three weeks, learners completed 20 ten-turn dialogue tasks in Aisla, targeting two English constructions: the present perfect and the present continuous. The tasks were practiced in an interleaved sequence.

The study included two task types. Treatment tasks followed a short Q&A dialogue format in which the system modeled and elicited the target construction on each turn, with incremental feedback when learners did not produce the target form.

The first two and last two tasks served as pre- and post-tests. These tasks used an information-gap format: they strongly licensed the target construction through context setting and resources, but did not model it or provide turn-level feedback. This allowed us to examine whether learners produced the target construction independently in a communicative context where the form was useful but not supplied by the system. More details on the task types and task-generation procedure are reported by Ribeiro-Flucht et al. (2025).

Learner messages were first annotated for accurate inclusion of the target construction using POLKE (Sagirov and Chen, 2025), an English Grammar Profile annotator. We then derived additional rule-based features, including recurrent target inclusion, lexical diversity, response length, and feedback uptake, defined as target inclusion immediately after feedback. An excerpt of the annotated data can be found in Appendix A. All analyses were conducted in Python 3.10. The annotated data and analysis scripts can be found in the study’s Github repository ¹.

4.1 Evidence Classification

To examine how learner production may inform future adaptive decisions, each learner message was assigned to one of five mutually exclusive evidence categories. The categories were designed as a theoretically motivated operationalization of learner evidence in dialogue. They draw on three distinctions that are central to learner modeling for productive use: whether the target construction is produced at all, whether production occurs independently or with immediate support, and whether responses without the target construction nevertheless provide evidence of meaningful task engagement.

The distinction between independent and scaffolded production is motivated by research on corrective feedback, where learner responses following feedback are treated as informative but not equivalent to unassisted production (Lyster and Ranta, 1997). The distinction between initiated and sustained independent use further separates first retrieval of a target construction from continued use once the construction has become active in the dialogue (Ellis et al., 2015; Pannell et al., 2017). Finally, the distinction between engaged responses not containing the target construction and underuse reflects the ambiguity of non-use in

open-ended dialogue: a learner may respond meaningfully without using the target, or they may provide a minimal response that offers little evidence for learner modeling. We therefore propose the following categories:

- **Independently initiated:** the learner produced the target construction without scaffolding after a previous learner message that did not contain the target. This was treated as evidence that the learner could initiate use of the construction without immediate support.
- **Independently sustained:** the learner produced the target construction without scaffolding after having previously used it. This was treated as evidence that the learner could continue using the construction once it had become active in the dialogue.
- **Scaffolded:** the learner produced the target construction after receiving support from the system, such as a recast or a grammar tip. This was treated as partial evidence of productive control, since the learner used the form but did so with immediate support.
- **Engaged non-target:** the learner did not produce the target construction, but gave a response with more than two words. This was treated as evidence of task engagement without target-form use.
- **Underuse:** the learner did not produce the target construction and responded with two words or fewer. This was treated as the weakest evidence for productive control, since the response provided little opportunity to observe target-form use.

In addition, we tracked lexical diversity as the cumulative number of different lemmas used within the target construction. As discussed in Section 2, from a usage-based perspective, varied lexical content in a construction may indicate more robust productive control than repeated use of a single exemplar, making lexical diversity a complementary signal of constructional development.

4.2 Task-Level Prediction

Our first analysis examined whether prior learner evidence could predict independent target use in the next task. This analysis was motivated by the adaptive use case of the learner model: at each task

¹https://github.com/luisards/productive_grammar_signals

boundary, the system needs evidence for deciding whether a learner is likely to use the target construction independently, or whether further practice and support may be needed. We therefore treated next-task independent use as a short-term prediction problem.

The unit of analysis was the learner-task pair. For each of the 20 learners, performance on tasks 2-20 was predicted from all preceding interaction data, yielding 380 observations. Because this was a small pilot dataset, the two target constructions were pooled for this analysis rather than modeled separately. This allowed us to estimate whether the proposed evidence encodings carried predictive signal across target constructions, while leaving construction-specific analyses to future work with larger samples.

The outcome was binary: whether the learner produced the target independently at least once during the task, defined as any turn classified as *Independently initiated* or *Independently sustained*. At each task boundary, features were computed from all prior turns as either cumulative or recency-weighted proportions, with exponential decay ($\lambda = 0.85$). *Underuse* served as the reference category.

We compared seven nested logistic regression models: an intercept-only baseline, binary target-use traces, typed evidence profiles, and typed profiles with lexical diversity, in cumulative or recency-weighted form where applicable. This allowed us to test whether richer evidence representations improved on a simple target-use trace and whether lexical diversity added predictive value. Models were evaluated with leave-one-user-out cross-validation using AUC-ROC, accuracy, balanced accuracy, and log-loss.

All models used L2-regularized logistic regression ($C = 1.0$). For recency-weighted models, decay sensitivity was also tested across $\lambda \in \{0.75, 0.80, 0.85, 0.90, 0.95\}$. Coefficients from typed models fit on the full sample were used to interpret the relative contribution of each evidence type, including scaffolded use, engaged non-target responses, and lexical diversity.

4.3 Post-test Prediction

A second analysis examined which encoding best predicted independent target use on the post-treatment probe tasks, our closest measure of less scaffold-dependent productive ability. These probes were information-gap communicative tasks with no modeling of the target form and no feed-

back.

The unit of analysis was the learner-construction pair, yielding 40 post-tests (20 learners $\times$ 2 constructions). The outcome was binary: whether the learner produced the target independently on the post-test probe task for that construction (task 19 for present perfect, task 20 for present continuous).

Predictors were derived from the treatment phase only (tasks 3-18) for the corresponding construction. These included the binary target-use rate, the rates of each evidence type, and lexical diversity. Because the sample was too small for reliable multivariate logistic regression, each feature was evaluated separately using AUC-ROC. This allowed a direct comparison of simple binary traces, typed evidence measures, and lexical diversity as candidate signals of post-treatment productive use.

4.4 Results

Across all learner messages, non-target responses were most common. *Underuse* accounted for 33.2% of messages and *engaged non-target* responses for 32.0%. Among target-containing messages, *independently sustained* use was most frequent (14.2%), followed by *independently initiated* use (11.5%) and *scaffolded* use (9.0%). At the task level, learners produced the target independently in 68.2% of tasks overall, although this varied widely across tasks (30%-95%) and across learners.

4.5 Task-Level Model Comparison

Table 1 reports leave-one-user-out cross-validation results. All evidence-based models outperformed the intercept-only baseline ($\Delta\text{AUC} > .23$), but differences among the substantive models were modest. The best performance was obtained by the recency-weighted typed model with lexical diversity (M6, AUC = .751), followed closely by the cumulative and recency-weighted binary models (M1: .746; M2: .741). The main finding is that a simple binary trace of prior target use captured most of the predictive signal. Typed evidence profiles did not improve performance on their own, slightly underperforming the binary models in both cumulative and recency-weighted form. Their main contribution was therefore interpretive rather than predictive.

At the same time, coefficients from the typed models revealed a clear evidence hierarchy (Table 2): scaffolded production was the strongest positive predictor of later independent use, followed by *Independently sustained* and *Independently ini-*

Model	k	AUC	Acc.	BAcc.	Log-loss
M0: Intercept only	0	.500	.682	.500	.626
M1: Binary cumulative	1	.746	.671	.523	.548
M2: Binary recency	1	.741	.703	.608	.541
M3: Typed cumulative	4	.736	.682	.500	.569
M4: Typed recency	4	.732	.682	.500	.555
M5: Typed cumulative + diversity	5	.749	.689	.576	.547
M6: Typed rec. + diversity	5	.751	.705	.608	.538

Table 1: LOUO-CV results for all seven models.

tiated production, while engaged non-target responses were close to neutral relative to underuse. Adding lexical diversity produced small but consistent gains, and cumulative and recency-weighted encodings performed similarly overall.

Rank	Evidence type	β	OR
1	Scaffolded	+2.978	19.65
2	Independently sustained	+2.739	15.47
3	Independently initiated	+1.166	3.21
4	Engaged non-target	+0.157	1.17

Table 2: Logistic regression coefficients (β) and odds ratios (OR) for typed evidence categories. Coefficients are interpreted relative to underuse, which served as the reference category.

4.6 Post-test Validation

Across all probe task observations, independent target production increased from 62.5% on the pre-probe to 80.0% on the post-probe. Table 3 reports the predictive value of each treatment-phase feature for post-probe independent production in terms of area under the curve (AUC) and p -value.

Feature	AUC	p
Lexical diversity	.979	< .001
Binary target rate	.959	< .001
Independently initiated	.957	< .001
Scaffolded rate	.893	< .001
Independently sustained	.877	.001
Engaged non-target	.510	.934
Underuse	.049	< .001

Table 3: Predictive value of features for post-test independent target production.

Lexical diversity was the strongest predictor (AUC = .979, $\rho = +.665$, $p < .001$), outperforming the binary target rate (AUC = .959, $\rho = +.637$, $p < .001$). Unlike in the task-level analysis, where it added only modest value, it was highly informative here, suggesting that lexical variation is more closely related to broader productive control than to next-task performance.

The remaining binary and typed measures were similar in predictive power, again indicating that a simple target-use trace captures most of the useful signal. Among non-target measures, underuse was a strong negative predictor ($p < .001$), whereas engaged non-target was uninformative ($p = .934$). The two constructions also differed: present perfect improved from 30% to 70%, while present continuous remained near ceiling (95% to 90%). Treatment-phase evidence was therefore more informative for present perfect, where there was greater room for measurable change.

4.7 Conclusion

This study examined how learner behavior in LLM-based L2 grammar practice can inform learner modeling. The findings suggest that different evidence types serve different purposes: prior target use was most useful for predicting immediate next-task performance, while finer-grained evidence helped characterize the robustness of developing productive control. Scaffolded production emerged as a strong positive signal, suggesting that system modeling and timely clarification may help make the practiced pattern available for use. Lexical diversity appeared to capture broader control over that pattern, pointing to the value of grammar practice with varied lexical fillers.

These findings suggest that less constrained communicative grammar practice may be made systematically tractable for adaptive decisions. Rather than treating learner production as too noisy to support principled adaptation, the results indicate that it can be encoded in ways that are both practically usable and theoretically meaningful. These findings are especially important for language learning, where development is gradual and linguistic knowledge is strengthened and extended through use.

Limitations

This study should be interpreted in light of several limitations. First, the sample was small, which limits the strength and generalizability of the conclusions. Second, the analysis could not fully address cross-context tracking or cleanly separate item-specific reuse from more general productive control, beyond the lexical diversity measure. Third, the logistic regression treated observations as independent rather than modeling tasks as nested within learners, which would be preferable in a larger dataset. Finally, three learners showed ceiling-level target use across tasks, leaving little variation to explain at the individual level.

Future work should test these patterns in larger samples and with more lexically open tasks, especially to clarify whether scaffolded success reflects emerging generalization or continued dependence on practiced forms.

Evaluating Adaptive Personalization of Educational Readings with Simulated Learners

Abstract

We present a framework for evaluating adaptive personalization of educational reading materials with theory-grounded simulated learners. The system builds a learning-objective and knowledge-component ontology from Wikibooks open textbooks, curates it in a browser-based Ontology Atlas, labels textbook chunks with ontology entities, and generates aligned reading–assessment pairs. Simulated readers learn from passages through a Construction–Integration-inspired memory model with DIME-style reader factors, KREC-style misconception revision, and an open New Dale–Chall readability signal. Answers are produced by score-based option selection over the learner’s explicit memory state, while BKT drives adaptation. Under this explicit simulator parameterization and three sampled subject ontologies, adaptive reading significantly improved outcomes in computer science, yielded smaller positive but inconclusive gains in inorganic chemistry, and was neutral to slightly negative in general biology.

1 Introduction

With more students entering higher education, instructors increasingly face a familiar mismatch: students are expected to learn the same material at the same pace even though their understanding of particular concepts can vary widely. In an introductory course, one student may already understand a subset of the target concepts, while another may still hold robust misconceptions about those same concepts. When both students are given identical readings, examples, and explanations, one may be under-challenged while the other is overwhelmed. Addressing this in a real classroom typically requires instructors to rewrite materials, manually identify which concepts students struggle with, and

provide individualized support. Those interventions are difficult to scale.

Intelligent tutoring systems (ITSs) aim to address this problem by adapting instruction to the learner. Recent reviews suggest that ITSs often improve learning and performance, but that their impact depends strongly on the instructional setting, the adaptation mechanism, and the way systems are evaluated (Huang et al., 2025; L  tourneau et al., 2025). In many ITS settings, however, the core intervention is an item sequence, a hint policy, or post-hoc feedback. Our setting is different: the primary intervention is *reading material*. Questions are still important, but mainly because they reveal evidence about what the learner knows after reading and provide observations for mastery tracking.

To evaluate whether adaptive reading policies help, we need simulated learners that can (i) learn from text, (ii) differ in reading-related characteristics, (iii) preserve misconceptions rather than merely lacking knowledge, and (iv) later answer multiple-choice questions from what they remember rather than from unrestricted access to the source passage. Simulated learners have long been proposed as tools for teachers, for learners, and for instructional designers conducting formative evaluation (VanLehn et al., 1994). More recently, a systematic review across AIED-related fields found uses spanning teacher training, adaptive algorithm development, virtual collaborators, and testing of learning environments, while also concluding that realism and validity are often under-tested (K  ser and Alexandron, 2024). Off-the-shelf LLM prompting is a poor fit for that requirement because powerful LLMs often answer beyond the intended ability of a partially knowledgeable learner. Yuan et al. (2026) characterize this problem as a *competence paradox* and argue for constrained student simula-

*equal contribution.

tion under an explicit epistemic state specification.

We therefore present a theory-grounded simulated reader for adaptive reading personalization. The system builds a learning-objective (LO) and knowledge-component (KC) ontology from open textbooks, tracks KC mastery with BKT (Corbett and Anderson, 1994), generates ontology-driven reading and assessment variants, and simulates reading via a comprehension model grounded in the Construction–Integration (CI) theory of discourse comprehension (Kintsch, 1988). Learner heterogeneity is parameterized with DIME-style reader factors (Cromley and Azevedo, 2007; Cromley et al., 2010), misconceptions are revised through the Knowledge Revision Components framework (KREC) (Kendeou and O’Brien, 2014; Kendeou, 2024), and later answer selection is performed through score-based option selection over an explicit epistemic boundary.

The experiments focus on offline simulation so that the instructional policy can be studied before classroom deployment. This setup compares adaptive and non-adaptive reading policies under matched simulated cohorts while keeping the content pipeline, question format, and mastery tracker fixed.

Our main contributions are as follows:

- We formulate adaptive reading personalization as a closed-loop problem in which reading is the primary intervention and assessment is the observation channel for KC-level mastery tracking.
- We present an ontology-grounded content pipeline that links open textbook chunks, reading variants, and assessment items to shared LOs and KCs.
- We develop a simulated reader that combines CI, DIME, KREC, and an open New Dale–Chall readability signal to model what a learner comprehends, revises, retains, and later retrieves.
- We report multi-subject experimental results showing that adaptive reading yields domain-dependent gains: statistically reliable improvements in the sampled computer-science setting, positive but inconclusive gains in inorganic chemistry, and neutral to slightly negative outcomes in general biology.

2 Related Work

2.1 Adaptive tutoring and knowledge tracing

Knowledge tracing estimates latent mastery from observed responses, and BKT remains attractive because it is interpretable at the level of individual KCs (Corbett and Anderson, 1994). Although deep models can improve prediction, interpretability remains important for deployment and diagnosis (Ding and Larson, 2021). We therefore use BKT so that the state driving adaptation remains understandable.

Most ITS personalization focuses on problem selection, hints, or feedback. By contrast, we center on explanatory reading material. Because reading can change knowledge without explicit responses, we separate the learner’s hidden *true* knowledge from the tutor’s BKT-based *estimate*, and only the latter drives adaptation.

2.2 Simulated learners in educational technology

Simulated learners have long been used in educational technology. VanLehn et al. (1994) categorize their use for teachers, learners, and instructional designers; our setting aligns most closely with formative evaluation of instructional policies before deployment.

Recent work highlights broader uses, including teacher training, hypothesis generation, adaptive algorithm development, virtual collaborators, and environment testing, while also noting that many simulators remain under-validated for their intended decisions (Käser and Alexandron, 2024). This motivates our emphasis on explicit learner state, inspectable memory, and theory-grounded reading dynamics.

2.3 Reading comprehension and computational reader models

Our model is grounded in the Construction–Integration framework (Kintsch, 1988), where readers form a propositional *textbase* and a richer *situation model* integrating prior knowledge. This supports modeling partial retention, revision, and distortion of information.

We extend CI with DIME, which captures reader differences in background knowledge, vocabulary, and inference (Cromley and Azevedo, 2007; Cromley et al., 2010), and KREC, which models revision of incorrect prior knowledge (Kendeou and O’Brien, 2014; Kendeou, 2024).

This matters because many systematic wrong answers reflect stable misconceptions rather than random noise (van den Broek and Kendeou, 2008; Gierl et al., 2017).

Prior work has implemented CI-like automated readers (Lemaire et al., 2006); our contribution is to embed such a reader in a KC-level adaptive instructional loop.

2.4 Epistemic boundaries and answer modeling

Recent work argues that valid student simulation should expose an explicit epistemic state and bounded competence (Yuan et al., 2026). We adopt that principle, but do not use free-form generation for answer choice. Instead, answers are selected by scoring options from the learner’s memory state, including mastery, misconceptions, retrieved traces, and item difficulty. This design is efficient, auditable, and consistent with constrained learner behavior. It also favors inspectable state and reproducible repeated simulations over unconstrained generative answers.

2.5 Readability and reader–text matching

Reader–text fit is important but should remain simple to operationalize. We use the New Dale–Chall readability formula (Chall and Dale, 1995), computed via textstat (Bansal and Aggarwal, 2026), as a reproducible measure of text difficulty combined with learner parameters. The formula is treated only as a lightweight signal; its tradeoffs are discussed in the limitations.

3 System Overview

The overall system converts open educational content into a grounded personalization loop. The pipeline can be summarized in five stages: (1) ontology construction and authoring, (2) chunk labeling and retrieval indexing, (3) ontology-driven reading and assessment generation, (4) theory-grounded simulated reading and score-based answer selection, and (5) BKT-based adaptation. Figure 1 separates the fixed source-corpus, ontology, grounding, and generation stages from the online simulation. Figure 2 shows the simulated reading and adaptation loop as a closed cycle.

The experiments use Wikibooks source textbooks: *Foundations of Computer Science*, *General Biology*, and *Introduction to Inorganic Chemistry* (Wikibooks contributors, 2026a,b,c). These books

serve as course-specific corpora: the ontology, retrieval index, generated readings, and assessments are grounded in the same instructional source material.

3.1 Ontology Atlas and ontology construction

We first build an ontology of learning objectives and knowledge components from open textbooks. Each LO maps to one or more KCs. The ontology is created with an LLM-assisted workflow that proposes candidate LOs and KCs from source material and then consolidates them into a course-specific YAML schema. We use the ontology as a common representational layer for retrieval, generation, mastery tracking, and simulation.

The ontology construction process is semi-automated rather than fully automatic. LLM-generated LO and KC candidates are treated as proposals that can be accepted, merged, split, renamed, or deleted in Atlas before experiment artifacts are generated. Merge decisions are appropriate when two KCs represent the same assessable concept at the same grain size; split decisions are appropriate when a proposed KC combines multiple independently assessable skills or concepts. In the reported workflow, ontology files are fixed within each subject-level adaptive-control comparison so that the two policies use the same ontology.

To make this layer inspectable, we built Ontology Atlas, a browser-based ontology workspace backed directly by the YAML files used elsewhere in the system. Atlas exposes a coverage inventory showing chapter, LO, and KC counts; a searchable navigator over IDs, statements, labels, and descriptions; a D3 relationship graph for the chapter → LO → KC hierarchy; and a details panel for editing entries, importing/exporting YAML, validating fields, and saving back to disk. Atlas is therefore not just a visualization layer; it is the authoring interface for the ontology that the generation and experiment services consume.

In the current codebase, Ontology Atlas surfaces multiple full-course ontologies, including the three used in the experiments reported here: foundations of computer science (16 chapters, 53 LOs, 131 KCs), general biology (20 chapters, 60 LOs, 172 KCs), and introductory inorganic chemistry (12 chapters, 57 LOs, 177 KCs). This coverage view was useful when selecting sampled LOs for the experiments and when checking whether KC granularity was comparable across subjects.

Figure 1: Fixed source-corpus, ontology, grounding, and generation pipeline used by both conditions.

3. Simulated reading and adaptation loop

Figure 2: Closed simulated reading and adaptation loop.

3.2 Chunk labeling and retrieval indexing

The textbook corpus is segmented into fine-grained chunks and coarser context chunks. Fine-grained chunks serve as the primary evidence units for labeling, while coarser chunks provide broader context during downstream generation. Each fine-grained chunk is labeled with one or more LOs and KCs using a three-stage LLM-as-judge pipeline:

1. encode the chunk as a semantic embedding,
2. retrieve candidate LO and KC labels with nearest-neighbor search in a vector database, and
3. prompt an LLM to adjudicate among the candidates and return the final label set.

The result is a grounded index in which every retained content unit is tied to the ontology and remains linked to its surrounding context. Because Atlas edits the same YAML that the labeling and

generation services read, ontology revisions immediately propagate to retrieval and generation.

3.3 Ontology-driven reading and assessment generation

Using the labeled corpus, we generate paired readings and assessments that comprehensively cover one LO at a time. Each generated reading is grounded in retrieved fine-grained chunks and optional coarser context chunks; generation parameters control explanation depth, example density, misconception refutation, and target difficulty. Each assessment is a fresh isomorphic multiple-choice variant aligned to the same LO and KCs rather than an exact reuse of the same item surface form.

This choice is important for two reasons. First, exact question reuse would make policy evaluation more sensitive to item wording than to learner state. Second, our simulated learners do not learn from assessment interactions; only reading updates their hidden semantic state. Using fresh isomorphic variants therefore preserves comparability across iterations without allowing assessment exposure to become an unintended instructional channel.

For preprocessing, semantic embeddings used qwen3-embedding-8b; LLM-assisted ontology proposal, chunk-label adjudication, reading generation, and assessment generation used qwen3-30b-a3b-instruct-2507. Once generated, the ontology, labels, readings, and assessments are treated as fixed artifacts for the adaptive-control comparison.

Figure 3: Example chapter → LO → KC relation visualized by Ontology Atlas for photosynthesis.

4 Methodology

4.1 Separating hidden learning from observed mastery

The simulated learner maintains two distinct states. The first is a hidden *true learning state* that governs what the learner actually knows, misunderstands, and remembers. The second is the tutor-visible BKT estimate that is updated only from observed answers. This separation prevents the simulation from becoming self-fulfilling: the personalization policy acts on what the tutor *infers*, not on hidden ground truth.

For learner i and KC k , we represent hidden state as

$$z_i = \{m_{i,k}^*, w_{i,k,1:M}, r_i, s_i, e_i\}, \quad (1)$$

where $m_{i,k}^*$ is the strength of correct knowledge for KC k , $w_{i,k,1:M}$ are strengths of KC-specific misconceptions, r_i is a reader profile, s_i is a revision-and-response profile, and e_i stores recent episodic traces from readings. The tutor only observes a separate KC mastery estimate $\hat{m}_{i,k}$ maintained by BKT.

4.2 Reader profiles and readability matching

We do not use vague “learning styles.” Instead, learner heterogeneity is parameterized through theory-grounded reader profiles. Following DIME, each learner has parameters for background knowledge, vocabulary, inferencing, and strategy use (Cromley and Azevedo, 2007; Cromley et al., 2010). Because the cohort is intended to approximate college freshmen who have completed secondary school, basic decoding is assumed to be near ceiling; the meaningful variability is in

comprehension-relevant factors and in misconception prevalence.

We combine these learner-side parameters with a reader–text fit term based on the New Dale–Chall score. The score is used as a compact, reproducible difficulty signal alongside the richer learner-side profile.

For passage j , let d_j be the readability score computed with `textstat`. Let a_i be a scalar readability-ability parameter for learner i . We define

$$\text{match}_{ij} = 1 - \frac{|a_i - d_j|}{6}, \quad (2)$$

clipped to $[-1, 1]$, so higher values indicate a better match between learner and text. This term does not replace the richer reader profile; it provides a compact difficulty signal that can be integrated into the comprehension update.

4.3 From passages to proposition-like teaching events

We model reading at the level of comprehension and memory, not time. Each generated passage is segmented into short teaching events, which serve as proposition-like units for the simulation. The current implementation uses a lean operational schema rather than full semantic parsing: each event stores its surface text, linked KC IDs, a clarity score, a refutation-strength score, and a refresh flag.

These fields have direct roles in the simulation. *KC links* determine which latent mastery variables and misconception weights the event can update. *Clarity* approximates how easy the event is to encode; in the current implementation it is estimated from event length, so shorter events are treated

State component	Meaning	Role in the simulation
$m_{i,k}^*$	Hidden strength of correct knowledge for KC k	Governs durable support for correct answers and future learning from related readings
$w_{i,k,m}$	Hidden strength of misconception m for KC k	Attracts misconception-consistent distractors and resists revision when refutation is weak
r_i	Reader profile (background knowledge, vocabulary, inferencing, strategy use, readability ability)	Determines how well teaching events are encoded from text
s_i	Revision and response profile (skepticism, revision willingness, detail preference, noise)	Controls how new text changes prior beliefs and how answers are emitted
e_i	Episodic traces of recently read teaching events	Supports short-term retrieval even when durable KC mastery is still weak
$\hat{m}_{i,k}$	Tutor-visible BKT mastery estimate	Drives reading adaptation but does not directly change hidden learning

Table 1: Learner-state variables.

as easier to encode than longer ones. *Refutation strength* approximates how explicitly the event confronts a likely misconception; in the current implementation it is triggered by lexical cues such as misconception, incorrectly, rather than, instead of, or do not, and it scales misconception reduction during learning. *Refresh* marks lower-gain reinforcement events when review KCs are included in a passage; operationally, refresh is a lightweight heuristic rather than a discourse parser.

This representation keeps learner memory close to the CI notion of a textbase while remaining simple enough to generate, score, and inspect at scale. Encoded events create episodic traces that preserve the event text, KC links, clarity, refutation strength, readability score, and later distortion, making subsequent answer behavior inspectable. When provenance is needed, it is retained at the reading-asset level through source chunk identifiers rather than per-event source spans.

For example, the sentence pair “Plants do not get food from soil. They make food through photosynthesis.” is stored as a proposition-like teaching event linked to a photosynthesis KC:

```
{
  proposition_id: "prop_001",
  text: "Plants do not get food from soil.
  They make food through photosynthesis.",
  kc_ids: {"KC_photosynthesis_food_source"},
  clarity: 0.92,
  refutation_strength: 1.00,
  is_refresh: false
}
```

The record is operational rather than a full semantic proposition.

4.4 Comprehension as textbase construction and situation-model integration

The reading update proceeds in two stages. First, the learner encodes teaching events into a textbase-like episodic memory. Second, the learner integrates those events with prior knowledge to update correct knowledge and misconception weights. Operationally, the encoding strength of event p for learner i reading passage j is modeled as

$$\text{enc}_{i,p} = \sigma(\alpha + 1.1 \text{clarity}_p + 0.55 \text{match}_{ij} + \beta^\top r_i + 0.3(1 - \bar{m}_{i,p}) + 0.35 \text{attention}_i). \quad (3)$$

Here, $\bar{m}_{i,p}$ is mean prior mastery over the event’s target KCs and $\beta^\top r_i$ collects vocabulary, inference, strategy, and background-knowledge effects. If an event is encoded, it creates an episodic trace whose later activation depends on recency, rehearsal, lexical overlap with the question, and distortion noise.

Once encoded, an event updates KC state by increasing correct knowledge and reducing misconception weight. In the implementation, correct-knowledge gain is stronger for clearer events, better reader-text matches, and learners with higher revision willingness and detail preference. Misconception reduction is scaled by the event’s refutation strength, consistent with KREC’s emphasis on how prior incorrect knowledge is confronted during reading (Kendeou and O’Brien, 2014; Kendeou, 2024). Refresh events receive a smaller gain multiplier than new target events.

The coefficients in Equation 3 and Equation 4 were selected during simulator development and

then held fixed across subject comparisons. They encode qualitative assumptions rather than fitted human-data parameters: clarity, match, relevant prior knowledge, attention, and strategy use increase encoding; misconception strength and item difficulty reduce correct responding; and retrieved traces provide partial support.

4.5 Score-based answer option selection from learner memory

At assessment time, the learner does *not* receive the original passage. Instead, the simulator retrieves relevant traces from memory and computes a score for each item from hidden mastery, misconception weight, retrieved-trace support, and response-style variables. The guiding principle is still epistemic boundedness in the sense of [Yuan et al. \(2026\)](#): the learner answers only from what it has encoded and retained. However, the current implementation uses score-based option selection rather than free-form generative reasoning.

For item q , let $\bar{m}_{iq}$ be mean correct knowledge over the target KCs, $\bar{w}_{iq}$ the mean misconception weight, and τ_{iq} the mean activation of retrieved traces. The item’s response utility is

$$u_{iq} = -b_q + 2.2\bar{m}_{iq} + 0.38\tau_{iq} - 1.25\bar{w}_{iq} + 0.35\text{attention}_i - 0.25\text{guess}_i, \quad (4)$$

where b_q is a difficulty offset derived from the item’s difficulty band. The probability of a correct answer is then

$$P(y_{iq} = 1) = \sigma(u_{iq}), \quad (5)$$

clipped to a small interior interval to avoid degenerate probabilities.

If the learner answers incorrectly, the selected distractor is *not* sampled uniformly. Instead, distractors are scored by lexical overlap between the retrieved trace text and the distractor text/rationale, plus learner-specific guessing bias. This makes misconception-consistent wrong options more likely than random errors when the learner’s memory traces support them. The simulator also records an explicit epistemic-state summary for each response, including target KCs, correct-knowledge support, misconception support, and the IDs of the retrieved traces used during scoring.

Subject	Ch.	LOs	KCs
Computer Science	16	53	131
General Biology	20	60	172
Inorganic Chemistry	12	57	177

Table 2: Ontology sizes shown in the Ontology Atlas coverage view for the three ontologies used in the experiments.

5 Adaptive Personalization with Bayesian Knowledge Tracing

The tutor maintains a separate BKT model for each KC. After each question response, the tutor updates the KC-specific mastery estimate $\hat{m}_{i,k}$ using standard BKT parameters for initial mastery, learning, guess, and slip ([Corbett and Anderson, 1994](#)). These estimates drive reading adaptation but do not directly modify hidden learner state.

We use BKT as the tutor-visible observation model, not as the cognitive model of reading. Passages update hidden semantic state; quiz responses provide noisy evidence for KC mastery estimates. BKT is useful here because it gives the adaptation policy an interpretable KC-level state, so we report both hidden-state summaries and tutor-side BKT gain.

The adaptation policy maps low estimated mastery to more supportive readings. In the adaptive condition, low $\hat{m}_{i,k}$ can increase explanatory depth, example density, explicit misconception refutation, repeated weak-KC coverage, and reader-text matching. Higher $\hat{m}_{i,k}$ yields leaner variants. The control condition uses the same ontology, source corpus, and assessment machinery, but holds the reading configuration fixed rather than conditioning it on $\hat{m}_{i,k}$.

6 Experimental Setup

We ran fixed-iteration experiments in three subject ontologies: foundations of computer science, general biology, and introductory inorganic chemistry. [Table 2](#) summarizes the ontology sizes surfaced in Ontology Atlas for those three subjects.

For each subject, we sampled four LOs across two chapters, created 50 matched simulated learners per condition, ran three reading-assessment cycles per LO, and generated three KC-aligned multiple-choice items per cycle. This yields 1,800 item-level responses per condition per subject.

Adaptive and control runs were matched at initialization: each control run reused the same learner

seeds and initial hidden states as its adaptive counterpart. Assessment delivery context was set to summative, so quiz answers updated tutor-visible BKT state but did not directly change hidden semantic knowledge. We report observed accuracy, tutor-side BKT gain, hidden mastery gain, and misconception reduction. Because learner-level paired trajectories are preserved only for accuracy and BKT gain, inferential tests are limited to those outcomes.

7 Results

7.1 Subject-level outcomes

Figure 4 and Table 3 summarize adaptive-minus-control deltas. Computer science shows the clearest benefit: accuracy improved from 0.834 to 0.865 ($\Delta = +0.031$, 95% CI [$+0.004$, $+0.058$], $p = 0.026$), and learner-level BKT gain improved from 0.416 to 0.454 ($\Delta = +0.038$, 95% CI [$+0.002$, $+0.074$], $p = 0.037$). Chemistry was positive but inconclusive (accuracy $\Delta = +0.019$, $p = 0.104$; BKT gain $\Delta = +0.009$, $p = 0.540$). Biology was neutral to slightly negative (accuracy $\Delta = -0.005$, $p = 0.691$; BKT gain $\Delta = -0.014$, $p = 0.468$). Descriptive hidden-state endpoints in Table 4 favored adaptation for hidden mastery in all three subjects and for misconception reduction in computer science and chemistry.

Subject	Cycle	Observed Accuracy			Tutor-side BKT gain		
		Adaptive	Control	Δ	Adaptive	Control	Δ
Computer Science	1	0.802	0.760	+0.042	0.180	0.157	+0.024
	2	0.890	0.853	+0.038	0.168	0.146	+0.023
	3	0.904	0.890	+0.014	0.106	0.114	-0.008
General Biology	1	0.794	0.795	-0.001	0.174	0.167	+0.007
	2	0.864	0.849	+0.015	0.122	0.111	+0.011
	3	0.877	0.906	-0.029	0.073	0.106	-0.033
Inorganic Chemistry	1	0.807	0.797	+0.010	0.190	0.190	+0.000
	2	0.868	0.828	+0.040	0.146	0.136	+0.010
	3	0.885	0.878	+0.007	0.092	0.092	+0.000

Table 3: Subject-level adaptive versus control outcomes.

7.2 Cycle-level trajectories

Figure 5 shows that adaptive reading led control in every computer-science and chemistry cycle, with the largest chemistry margin in cycle 2. Biology showed a crossover pattern: nearly tied in cycle 1, adaptive ahead in cycle 2, and control ahead in cycle 3.

8 Discussion

The results suggest domain-dependent effects of the adaptive policy. Computer science provides the most consistent evidence of benefit, chemistry

Figure 4: Subject-level adaptive-minus-control deltas.

Subject	Hidden mastery gain			Misconception reduction		
	Adapt.	Ctrl.	Δ	Adapt.	Ctrl.	Δ
Computer Science	0.521	0.473	+0.049	0.072	0.056	+0.016
General Biology	0.388	0.362	+0.026	0.045	0.048	-0.003
Inorganic Chemistry	0.509	0.456	+0.053	0.061	0.056	+0.005

Table 4: Descriptive hidden-state outcomes from saved experiment summaries.

shows smaller positive but inconclusive gains, and biology shows a mixed pattern in which hidden mastery improved descriptively without improving observed accuracy or tutor-side BKT gain.

This divergence between hidden and observed outcomes is informative. In the simulator, answers depend on hidden KC knowledge, episodic traces, misconception weight, item difficulty, attention stability, and distractor overlap. A reading can therefore improve hidden knowledge while producing little observed gain if retrieval is brittle, items are noisy, or distractors remain competitive.

The results also illustrate the role of Ontology Atlas in auditing ontology granularity and coverage. Adaptive benefit varied by LO and subject, so ontology quality and KC granularity are not merely upstream bookkeeping issues. If an LO is too broad, if its KCs are diffuse, or if retrieved

Figure 5: Mean learner-level quiz accuracy by fixed iteration cycle.

evidence is weakly aligned with target KCs, both personalization and evaluation become harder to interpret.

9 Conclusion

We presented a full-stack offline framework for evaluating adaptive personalization of educational readings with theory-grounded simulated learners. The framework links ontology-grounded content generation, KC-level BKT mastery tracking, Ontology Atlas ontology authoring, CI-based comprehension, DIME-style reader heterogeneity, KREC-style misconception revision, and score-based answer selection over explicit learner memory. Across three sampled subject ontologies, adaptive reading yielded reliable gains in computer science, smaller inconclusive gains in chemistry, and neutral to slightly negative observed outcomes in biology.

Limitations

The framework has several limitations. First, simulated learners are not substitutes for real students. The simulator is designed for inspectable offline policy screening, not as a validated estimator of classroom effect sizes, and it has not yet been calibrated against human response distributions, learning curves, distractor choices, misconception persistence, or subgroup heterogeneity.

Second, the modeled instructional setting is intentionally narrow: learners read independently, assessments provide observations but no direct instruction, and peer interaction, instructor intervention, classroom discussion, feedback, and retrieval-practice effects are outside the simulation. This isolates reading as the intervention, but it does not approximate courses where instructors diagnose errors, peers explain concepts, or quizzes teach through feedback and retrieval practice.

Third, the ontology and labeling pipeline are

central sources of uncertainty. The ontologies are corpus-grounded and built from the same Wikibooks textbooks used for retrieval and generation. Errors in LO/KC granularity, chunk labels, retrieved evidence, or item alignment can propagate through generation, adaptation, and evaluation, so cross-domain differences may reflect content-pipeline quality as well as the adaptive policy. Porting to a new course therefore still requires domain review of the ontology, labels, generated readings, and assessment items rather than only rerunning the automatic pipeline.

Fourth, the simulator uses simplified operational heuristics: clarity is approximated from length, refutation strength from lexical cues, and the encoding and response equations use fixed coefficients. Sensitivity to coefficient perturbations, alternative detectors, and ablations remains untested.

Fifth, the readability signal is deliberately shallow. New Dale–Chall provides an open, reproducible proxy based on word familiarity and sentence length (Chall and Dale, 1995). It was used because the learner model includes vocabulary and background-knowledge factors: Flesch Reading Ease is driven by average sentence length and average syllables per word (Flesch, 1948), whereas New Dale–Chall incorporates word familiarity in addition to sentence length. This makes New Dale–Chall a closer operational proxy for whether a passage contains vocabulary likely to be unfamiliar to a reader, including short domain terms that syllable-based formulas may not penalize. However, it does not model discourse cohesion, diagrams, mathematical notation, domain-specific prior vocabulary, or whether a learner already knows terms such as *ATP*, *loop*, or *ion*. Future work should compare New Dale–Chall with Flesch–Kincaid, domain-vocabulary measures, and learned reader–text difficulty models.

Sixth, score-based answer selection supports bounded competence and auditability, but it may under-represent open-ended reasoning, explanation quality, and strategic test-taking. We also do not compare against constrained LLM-based student simulators or other cognitive simulators, and pre-processing artifacts may depend on the embedding and instruction models used.

Finally, the saved result format preserves learner-level paired trajectories for accuracy and BKT gain, but only condition-level summaries for hidden mastery and misconception endpoints. Future runs should preserve learner-level hidden-state trajec-

ries for paired analysis.

Ethics Statement

The system uses open educational content and simulated learners. Any deployment decisions affecting students require human-subject validation under appropriate institutional review and privacy safeguards.

Abstract

Constructive, personalized, and timely feedback is essential to student learning. However, providing such feedback in large classes remains a major challenge. Large language models (LLMs) offer alternatives to support instructors by generating relevant feedback that highlights both student strengths and areas for improvement. Nevertheless, most existing LLM-based feedback systems rely on proprietary APIs and are often tailored to specific tasks, which limits their accessibility, flexibility, and applicability in resource-constrained educational settings. In this study, we investigate the potential of two open-source LLMs (DeepSeek R1 and Qwen 3.5) to support automated feedback generation across three disciplines (e.g., programming assignments, essays, and mathematics problems). We evaluate two prompting strategies (unified and multi-agent) across these domains and use human judgment criteria to assess feedback quality. Through this analysis, we examine the potential of open-source models as practical, scalable alternatives to proprietary API-based systems for developing freely accessible feedback-generation tools. Our results show that a single open-source model can generate useful feedback across diverse domains, though with varying effectiveness. DeepSeek R1 performs better on reasoning-intensive tasks such as mathematics, while Qwen 3.5 works best for holistic tasks such as writing, but both models struggle with programming tasks. We find that model architecture matters more than prompting strategy, and reasoning-optimized models excel in structured domains, while general-purpose models perform better on holistic tasks. Finally, we conclude that a multi-agent approach does not consistently guarantee improved results over a single unified LLM approach.

1 Introduction

Feedback plays an important role in the learning process (Hattie and Timperley, 2007). Constructive

and timely feedback helps students identify gaps in their understanding, refine their skills, and improve academic performance (Cavalcanti et al., 2021). However, the usefulness of feedback in educational settings depends not only on its quality but also on how quickly the feedback is given. Students report significantly lower motivation when feedback is delayed and takes more than 10 days to arrive (Fisher et al., 2025). In contrast, personalized and timely feedback can improve academic performance and overall learning outcomes (Aucejo and Wong, 2025). However, instructors find it difficult to provide timely, high-quality, and individualized feedback in large classes and resource-constrained educational settings due to workload constraints (Messer et al., 2024). This leads to delayed feedback, inconsistencies in grading, poor feedback quality, and tracking individual student progress over time becomes more challenging (Haseeb et al., 2026). To address these challenges, artificial intelligence (AI) and large language models (LLMs) offer opportunities to complement instructor support by enabling automated feedback generation and addressing scalability issues.

LLM-based systems have been proposed to automate the process of feedback generation (Murtazin et al., 2025; Haseeb et al., 2026). These systems help reduce feedback turnaround time from days to seconds (Haseeb et al., 2026), and mitigate delays associated with manual grading and feedback delivery (Dong et al., 2024; Guizani et al., 2025; Kinder et al., 2025; Nkoyo et al., 2025). Recent studies demonstrate that LLM-generated feedback can support students' learning goals, enhance motivation, and improve engagement, especially when the feedback is adaptive and responsive to learners' needs (Murtazin et al., 2025; Kinder et al., 2025), which makes them well-suited for both traditional classroom and online learning environments (Cisneros-González et al., 2025).

Most state-of-the-art feedback generation sys-

tems used in AI-assisted educational applications rely on proprietary models (e.g., GPT-4, Gemini, and Claude). However, dependence on these models creates transparency, reproducibility, and accessibility-related issues. These limitations are important because they hinder the practical deployment of such tools in resource-constrained academic institutions, where reliance on commercial AI systems or the computational infrastructure required to deploy large-scale models may not be practical or sustainable. Therefore, it is important to explore whether open-source models can serve as a reasonable alternative that addresses these limitations for automated feedback generation.

Open-source language models provide freely accessible alternatives for educators and practitioners. In educational settings, they are particularly valuable because they can support transparency, reproducibility, adaptability, local deployment, and cost control (Lin et al., 2026). In addition, open-source models have shown promising results in targeted feedback-generation tasks. For example, open-source models have been found to perform nearly on par with proprietary models in generating and evaluating feedback in programming education (Koutchme et al., 2025). However, prior research has largely examined these models in isolated educational tasks and within narrow disciplinary contexts. Most of the existing literature is concentrated on a single-domain setup, which includes computer science-related settings (e.g., programming education (Koutchme et al., 2025; Cisneros-González et al., 2025)), writing assessment (Alnemrat et al., 2025; Gilmore, 2025), and mathematical reasoning tasks (Lee et al., 2026; Rigaud Téllez et al., 2024). However, relying on separate tools for different assessment types is often impractical in real educational settings. Consequently, it remains unclear whether a single open-source model can generate useful feedback across diverse assessment types and disciplines (e.g., programming, essay writing, and mathematics). This gap motivates the need for a broader cross-disciplinary evaluation of open-source language models for feedback generation.

To the best of our knowledge, no previous study has examined a single LLM-based model (as a unified framework) for feedback generation across three disciplines: (i) mathematics, (ii) academic writing, and (iii) programming. To address this gap, we extend previous work on LLM-based feedback generation (Haseeb et al., 2026) to examine LLM-based feedback generation across mathemat-

ics, academic writing, and programming within a single unified framework.

Research Question: To what extent can a single task-specialized open-source model generate useful and pedagogically meaningful feedback across different assessment types while maintaining consistent feedback quality? For example, can a coding-specialized model also provide useful feedback on essay-based assignments and mathematics problems? We further hypothesize that decomposing feedback generation into a multi-agent setup can yield deeper and more domain-specific feedback insights than a unified single prompt approach.

The main contributions of this paper are as follows:

1. We extend LLM-based feedback generation beyond programming to two additional disciplines: (i) mathematics, and (ii) academic writing.
2. We collect and curate datasets for each of the three disciplines, and then examine 2 open-source models across 3 domains, to assess feedback quality.

2 Methodology

We evaluate LLM-based feedback generation using two prompting approaches applied to two open-source models across three educational domains: (i) programming, (ii) academic writing, and (iii) mathematics. Figure 1 illustrates the overall framework. In the **Unified Approach**, each model independently receives the full context, including the problem, student submission, and evaluation criteria, in a single prompt and produces feedback in one inference call.

In the **Multi-Agent Approach**, feedback generation is decomposed into specialized subtasks assigned to distinct agents, each focused on a specific aspect of evaluation, followed by a synthesis step where applicable. Both approaches are evaluated across programming, academic writing, and mathematics to assess whether prompting architecture affects feedback quality across domains.

2.1 Datasets

To evaluate LLM feedback generation across educational domains, we curate datasets from three distinct disciplines: programming, academic writing, and mathematics. Each dataset contains student

Figure 1: Framework for LLM-based feedback generation across domains with unified and multi-agent prompting.

submissions with errors, along with their associated ground truth. This enables systematic evaluation of feedback quality. Table 1 summarizes the key characteristics of each dataset.

Dataset	Samples	Languages	Source
ConDefects	200	Python (93) Java (107)	(Wu et al., 2023)
Exposia	55	English	(Zyska et al., 2026)
MathEDU	150	English	(Hsu et al., 2026)

Table 1: Datasets Overview

2.1.1 Programming: ConDefects

We use ConDefects dataset (Wu et al., 2023) for evaluating the feedback in the programming task. It consists of real buggy code submissions from competitive programming contests on AtCoder. This dataset contains student errors made during the competition, which reflect students’ understanding of the code, misconceptions, and mistakes.

We use 200 students’ submissions across two programming languages: 93 submissions written in Python, and 107 submissions in Java. Each sample includes four elements: (i) a problem description, (ii) the student’s buggy code, (iii) the corrected version, and (iv) the exact line where the student made a mistake. These problems are of intermediate difficulty level, and each student submission in this set exhibits distinct programming concepts, error types, and logical errors. Since we did not have access to the reference feedback, we rely on human

assessment to evaluate the quality of LLM feedback. The evaluation assesses whether the LLM accurately identifies the bug while providing pedagogically useful and personalized guidance.

2.1.2 Writing: Exposia

For the academic writing domain, we use the Exposia dataset (Zyska et al., 2026), which comprises 55 bachelor’s thesis research proposals from TU Darmstadt. Each proposal represents a student’s initial draft and the final proposal after incorporating the teacher’s and fellow students’ feedback. Each proposal includes a problem statement, a literature review, a methodology, and a writing quality assessment.

The dataset also includes a well-defined scoring criterion that teachers and fellow student reviewers use to assess submission quality. For our evaluation, we use teacher feedback and assigned scores as references to guide human evaluators, but we do not treat them as absolute ground truth, since assessing academic writing quality is inherently subjective. Therefore, human evaluators utilize their own judgment to make final quality assessments, informed by but not bound to instructor scores.

We utilize the 26 criteria across four dimensions provided with the dataset (Zyska et al., 2026), originally used by teachers to assess submissions and generate feedback. We incorporate these criteria directly into our prompts to guide LLM-based feedback generation.

Problem & Research Question (MO1-MO7, 9 points): Evaluates if there is an engaging hook, a clear problem statement, a domain specification, a relevant problem, a discussion of current approaches, a properly formulated research question, and scope feasibility.

Literature & Theory (AP1-AP7, BI1-BI2, 13 points): Evaluates state-of-the-art coverage, relevance demonstration, weakness identification, differentiation from prior work, synthesis quality, and theoretical framework quality.

Methodology (AP8, MD1-MD7, 8 points): Examines methodology availability, completeness, relevance, reference to existing materials, discussion of difficulties, limitations acknowledgment, and implementation details.

Writing Quality (LA1-LA2, 4 points): Evaluates the language quality (grammar, clarity, terminology) and structural coherence (logical flow, consistent language, and common thread).

Each criterion uses a defined rubric with scores ranging from 0-1 or 0-2 points, yielding a maximum of 33 points. We use the expert annotations (type: “draft”, role: “expert”) as ground truth for evaluating LLM scoring accuracy.

2.1.3 Mathematics: MathEDU

For the mathematics domain, we use 150 problems from the MathEDU dataset (Hsu et al., 2026), which is designed to evaluate mathematical reasoning and tutoring capabilities. Each sample consists of a word problem, the student’s incorrect answer, and their solution process, which shows the students’ reasoning steps. The dataset contains diverse mathematical concepts, such as ratio calculations, arithmetic operations, distance-time-speed problems, probability, permutations, and geometric reasoning. Each sample includes a *teacher_review* field containing expert feedback on the student’s error, and provides a reference ground truth for evaluating the quality of LLM-generated feedback.

2.2 Open-source Models

We select two state-of-the-art open-source large language models, each model representing a distinct architectural paradigm: (i) a general-purpose model, and (ii) a reasoning-oriented model. Both models operate at a comparable scale (approx 30B parameters). This ensures that any observed performance differences reflect model design and reasoning capabilities rather than the parameter count.

1. **Qwen 3.5 27B** (Yang et al., 2025) is a general-purpose model achieving state-of-the-art performance on standard benchmarks. We use the BF16 precision variant with thinking mode disabled via Ollama, generating responses directly without explicit reasoning traces. This setup reflects standard deployment in efficiency-constrained environments for educational feedback.
2. **DeepSeek R1 32B** (Guo et al., 2025) is a reasoning-distilled model. It compresses chain-of-thought capabilities from larger models into a smaller architecture. The model generates explicit thinking traces before producing the final response. We use the FP16 precision variant with default settings.

Our model selection balances three considerations. First, comparable parameters ensure a fair comparison. Second, both models are top performers within their paradigm at this scale. Third, the 30B parameter range allows deployment on a single-GPU infrastructure. This reflects practical deployment constraints, supports replicability, and improves accessibility in low-resource educational environments. This pairing helps examine whether explicit model reasoning improves feedback quality or whether general-purpose generation that follows the rubrics suffices to maintain feedback quality in educational domains.

2.3 Prompting Approaches

We evaluate two distinct prompting approaches for generating educational feedback in three disciplines (programming, essay writing, and mathematics): (i) a unified single-prompt approach, and (ii) a multi-agent prompting approach. These approaches are compared in terms of the quality of feedback generated between both models.

2.3.1 Unified Approach

The unified approach generates feedback through a single LLM call. The model receives the full context problem, student submission, and evaluation criteria, and produces a single feedback response.

For the programming task (see Figure 2), the prompt includes the problem description, related test cases, the programming language, and the student’s buggy code. It also includes instructions to identify the error and provide feedback on a conceptual misunderstanding. The output is 150-250

words, which focuses on bug identification and pedagogical guidance. For the writing task (see Figure 3), the prompt includes the research proposal and 26 scoring criteria organized across four dimensions. The model produces scores in a standardized format. It then gives 150-250 words of feedback to highlight key issues and suggest improvements. For the mathematics task (see Figure 4), the prompt includes the problem, the student’s answer, and their solution process. The model identifies incorrect steps, diagnoses underlying misconceptions, and provides guidance to address these gaps. This approach mirrors how educators review student work and assess all aspects of their work at once. Moreover, this approach is computationally efficient, requiring only one inference call per student submission.

2.3.2 Multi-Agent Approach

The multi-agent approach divides feedback generation into specialized sub-tasks. Each agent is assigned a specific evaluation or feedback generation step, and, if necessary, a synthesis step to produce coherent and comprehensive feedback. Each agent is implemented as a separate LLM call, where the output of one stage serves as input to the next.

In the programming domain (see Figure 5–6), two agents are utilized:

- **Error Analyzer:** This agent produces a structured diagnosis that includes the location of the error, the type of error, the root cause, and the misconception of the student and the direction of the correction.
- **Feedback Generator:** This agent receives the diagnosis, the problem statement, and the submission, and crafts pedagogically helpful feedback for the student.

In the writing domain, four dimension-specific agents are employed in conjunction with a synthesizer:

- **Problem and RQ Agent:** Scores the problem and research question and provides 2-3 sentence feedback on clarity and relevance.
- **Literature Agent:** Evaluates the quality of the literature review section and provides 2-3 sentences on quality, coverage, and synthesis.
- **Methodology Agent:** Evaluates completeness and relevance of methodology and provides feedback on quality, completeness, and rigor.

- **Writing Quality Agent:** Scores language quality, consistency, and structure while providing feedback.
- **Synthesizer:** Integrates all scores and analyses to formulate a unified feedback response of 150 to 250 words for the student.

In the mathematics domain, two agents are utilized:

- **Error Analyzer:** Outputs error location along with error type and conceptual gap, with a small description of the mistake.
- **Feedback Generator:** Receives diagnosis with problem description and submission, and formulates personalized feedback for students in 50-120 words.

We include representative prompts for the programming domain in the appendix (Figures 2, 5, 6). Prompts for writing and mathematics follow the same structure and are publicly available in the accompanying repository, along with sample model outputs for all domains¹.

2.3.3 Design Rationale

Our architectures are motivated by domain-specific task-decomposition principles from prior work, in which complex evaluation tasks are decomposed into distinct role-based cognitive sub-tasks (Wang et al., 2025). This persona-based decomposition improves the analytical depth and feedback quality.

Programming. We adopt a two-stage pipeline (diagnosis → feedback) following code review frameworks (Yang et al., 2024). Debugging in programming first requires identifying the precise source, location, and the type of error, whereas the corrective guidance needs to provide pedagogically meaningful feedback. Separating bug identification helps the respective agent to focus more on the required task. This decomposition addresses the limitations of LLMs in generating correct code without accurately localizing conceptual errors.

Writing. We decompose our evaluation strategy by rubric dimensions, which aligns with writing assessment practices where content, structure, and language require distinct evaluative expertise (Hashemi et al., 2024). The four-agent structure maps directly to our selected dataset rubric dimensions. Finally, a synthesizer integrates these

¹<https://github.com/haseeb2001/crossdomainfeedback>

dimension-specific analyses into coherent feedback, resolving potential conflicts and avoiding fragmented responses.

Mathematics. Our pipeline mirrors cognitive tutoring approaches, in which diagnosing misconceptions precedes corrective instruction (Liu et al., 2023). In mathematical problems, errors are often rooted in conceptual misunderstandings or omissions during the solving process, rather than surface-level mistakes; therefore, step-by-step error diagnosis enables targeted, personalized remediation rather than generic solution guidance.

The multi-agent paradigm draws from recent work demonstrating that task decomposition improves LLM performance on complex reasoning tasks (Wang et al., 2025). We hypothesize that specialized agents can provide deeper, domain-specific, and more precise feedback than a unified approach, especially for tasks like mathematics that require pedagogical reasoning.

2.4 Experimental Setup

All experiments were conducted on NVIDIA H100 GPUs (96GB VRAM) using Ollama (v0.6.8) for local inference. Qwen 3.5 27B was executed on a single GPU, whereas DeepSeek R1 32B required two GPUs due to higher memory requirements. For both models, we used deterministic decoding with a temperature set to 0 and a maximum output length of 4096 tokens. All other generation parameters were kept at their default values. These settings were applied consistently across all experiments. All our prompts and inference scripts are publicly available ².

2.5 Evaluation Framework

We evaluate generated feedback through human annotation using six criteria per domain, organized into two dimensions: *diagnosis* (error identification) and *guidance* (corrective feedback).

Each dimension is assessed along three aspects: **Accuracy**—correctly identifies the underlying issue and/or provides a valid correction; **Selectivity**—avoids false positives and focuses only on relevant issues; **Clarity**—pedagogically accessible and appropriate for the student’s level.

For programming, we adopt evaluation criteria from (Koutchene et al., 2025). For writing and mathematics, we developed parallel criteria to enable consistent cross-domain comparison under a

unified evaluation framework. The full set of evaluation criteria is provided in Table 2.

Domain	Code	Definition
<i>Programming (Explanation / Fix)</i>		
	EA	Bug description matches ground truth
	ES	No false positives identified
	EC	Explanation understandable to a novice
	FA	Fix would resolve the bug
	FS	No extraneous modifications
	FC	Clear and usable code suggestions
<i>Writing (Issue / Suggestion)</i>		
	WA	Writing issue correctly identified
	WS	No overcriticism of acceptable choices
	WC	Understandable to student writer
	GA	Suggestion would improve writing
	GS	Focused and specific advice
	GC	Actionable with concrete guidance
<i>Mathematics (Error / Solution)</i>		
	MA	Mathematical error correctly identified
	MS	Valid alternative paths not penalized
	MC	Appropriate for student level
	SA	Guidance leads to correct solution
	SS	Addresses specific error only
	SC	Step-by-step actionable guidance

Table 2: Evaluation criteria across domains. All criteria scored binary (0/1).

Annotation Protocol. Evaluation was conducted by four annotators for programming and mathematics, and three annotators for writing, proportional to dataset size. All annotators were graduate students with relevant domain expertise. Each criterion was scored binary (0 = No, 1 = Yes). Final scores were aggregated by averaging across annotators for each sample and then across all samples. Inter-annotator agreement was measured using Cohen’s κ on overlapping samples, which indicates moderate agreement ($\kappa = 0.48$) across configurations.

3 Results

This section presents evaluation results across three educational domains: programming (Section 3.1), writing (Section 3.2), and mathematics (Section 3.3). All results are reported using the six-criterion evaluation framework introduced in Section 2.5 (see Table 2 for criterion definitions).

3.1 Programming Results

Programming feedback presents the greatest challenge across all three domains, with average scores (0.27-0.48), which is substantially lower than mathematics (0.70-0.91) and writing (0.35-0.81). Table 3 presents the complete results.

²<https://github.com/haseeb2001/crossdomainfeedback>

DeepSeek R1 outperforms Qwen 3.5 across all conditions (0.43-0.48 vs 0.27-0.29), with the unified approach yielding marginally better results than the multi-agent approach for both models. A striking pattern emerges in criterion-level scores: explanation clarity (EC) approaches perfection (0.82-1.00) across all configurations, whereas explanation accuracy (EA: 0.12-0.20) and fix accuracy (FA: 0.09-0.55) remain comparatively low. This difference shows that models can produce fluent, well-articulated feedback but often fail to correctly identify underlying bugs and conceptual errors, rendering their feedback ineffective. This pattern of fluent feedback that fails to identify actual bugs confirms prior observations on programming feedback (Haseeb et al., 2026).

Configuration	EA	ES	EC	FA	FS	FC	Avg
Qwen 3.5-U	0.17	0.10	1.00	0.14	0.15	0.20	0.29
Qwen 3.5-MA	0.12	0.06	0.97	0.09	0.13	0.27	0.27
DeepSeek R1-U	0.20	0.18	0.86	0.55	0.55	0.52	0.48
DeepSeek R1-MA	0.14	0.15	0.82	0.54	0.54	0.40	0.43

Table 3: Programming domain results (n=200). U = Unified, MA = Multi-Agent.

3.2 Writing Results

Qwen 3.5 substantially outperforms DeepSeek R1 across all conditions, achieving an average score of 0.81 compared to 0.35–0.38 for DeepSeek. This performance gap is more pronounced in accuracy metrics: Qwen achieves 0.91–0.93 on both issue identification (WA) and suggestion accuracy (GA), while DeepSeek scores only 0.16–0.18 on these criteria. This pattern indicates that DeepSeek frequently fails to identify correct writing issues and produces ineffective suggestions.

Both models exhibit high selectivity (WS: 0.91–0.95), indicating they avoid unnecessary criticism. However, for DeepSeek, this occurs alongside extremely low accuracy, giving the impression of a permissive model that avoids criticism by missing issues entirely. This suggests that the model is selectively incorrect rather than effectively discriminative, highlighting that high selectivity does not translate to high-quality feedback when underlying issues remain undetected.

Further differences emerge in suggestion quality. While Qwen maintains moderate clarity and actionability (GC: 0.78), its suggestion specificity (GS) remains relatively low (0.49–0.58), indicating that even when models identify writing short-

comings, they struggle to produce highly targeted guidance. DeepSeek shows a similar pattern, performing poorly across all suggestion dimensions (GS: 0.04, GC: 0.29–0.36), reflecting a lack of focused and actionable feedback.

The choice of prompting approach shows minimal impact for both models. Qwen achieves identical average scores (0.81) with both approaches, while DeepSeek shows marginal variation (0.35–0.38). This suggests that for writing feedback, model capability is a stronger determinant of quality than prompting strategy. Unlike structured domains, writing evaluation appears to be a holistic task that does not benefit substantially from decomposition into specialized subtasks. Table 4 presents evaluation results for the writing domain across 55 research proposals.

Configuration	WA	WS	WC	GA	GS	GC	Avg
Qwen 3.5-U	0.93	0.91	0.82	0.91	0.49	0.78	0.81
Qwen 3.5-MA	0.91	0.93	0.75	0.91	0.58	0.78	0.81
DeepSeek R1-U	0.16	0.95	0.56	0.18	0.04	0.36	0.38
DeepSeek R1-MA	0.18	0.93	0.51	0.18	0.04	0.29	0.35

Table 4: Writing domain results (n=55). U = Unified, MA = Multi-Agent.

3.3 Mathematics Results

DeepSeek R1 with the unified approach achieves the highest overall performance (0.91), outperforming all other configurations. Both models exhibit near-perfect error detection (MA, MS $\approx$ 1.0), indicating that identifying mathematical mistakes is comparatively feasible, as models can follow a step-by-step approach and mathematical steps are more grounded in rules, suggesting that dealing with this level of mathematical mistakes is not a limiting factor for current LLMs.

The main difference lies in the guidance provided in the solution. DeepSeek with unified settings achieves substantially higher solution accuracy (SA: 0.81) than Qwen-Unified (0.25) and both multi-agent configurations (0.03–0.11). This pattern highlights that DeepSeek’s reasoning capabilities are best utilized in unified settings to generate mathematically valid corrective guidance.

It is also observed that, unlike programming and writing, these models are highly sensitive to prompting approaches for mathematics. The multi-agent approach significantly degrades performance for both models, with average scores dropping from 0.79 to 0.75 for Qwen and from 0.91 to 0.70 for

DeepSeek. The degradation is more pronounced in clarity (MC) and solution accuracy (SA), indicating that task decomposition may fragment the coherent reasoning required for effective mathematics feedback. Table 5 presents the evaluation results for the mathematics domain across 150 problems.

Configuration	MA	MS	MC	SA	SS	SC	Avg
Qwen 3.5-U	1.00	1.00	0.52	0.25	1.00	0.99	0.79
Qwen 3.5-MA	1.00	1.00	0.38	0.11	1.00	0.99	0.75
DeepSeek R1-U	0.99	0.99	0.99	0.81	0.89	0.83	0.91
DeepSeek R1-MA	1.00	1.00	0.15	0.03	1.00	0.99	0.70

Table 5: Mathematics domain results (n=150). U = Unified, MA = Multi-Agent.

4 Analysis & Discussion

Results reveal that neither model dominates universally across domains, and that architecture–task alignment is a stronger determinant of feedback quality than parameter count. Qwen 3.5 performs best on writing (avg ≈ 0.81), DeepSeek R1 excels on mathematics in unified mode (avg = 0.91), and programming challenges both models most severely (avg = 0.29–0.48).

Programming. The difficulty of programming feedback reflects a fundamental asymmetry in LLM capabilities: code generation and code understanding are distinct tasks (Haroon et al., 2025). While generation translates intent into code, diagnostic feedback requires reasoning about existing code semantics—a capability that benchmark scores do not capture. Semantic-preserving mutations cause LLMs to fail on previously localized faults in 78% of cases, revealing reliance on syntactic patterns over semantic understanding (Haroon et al., 2025), and systematic failures have been reported when LLMs verify code against specifications (Jin and Chen, 2025). Our findings provide direct educational evidence for this gap: fluency in explaining code does not imply understanding of code behavior. Notably, Qwen 3.5 outperforms DeepSeek on code generation benchmarks, yet DeepSeek achieves 66% higher feedback scores (0.48 vs. 0.29)—confirming that generation capability does not transfer to diagnostic tasks.

Writing. The results reveal a clear performance gap between Qwen 3.5 and DeepSeek (avg 0.81 vs. 0.35–0.38), with the gap most pronounced on accuracy: Qwen correctly identifies writing issues (WA = 0.93) and produces accurate suggestions (GA = 0.91), while DeepSeek scores only 0.16–0.18 on

both. DeepSeek’s high selectivity (WS ≈ 0.94) alongside near-zero accuracy reveals *avoidance behavior*—the model avoids criticism by missing issues entirely rather than correctly filtering them. This shows that high selectivity is not a reliable proxy for feedback quality. Prompting approach has minimal effect on either model, suggesting that writing assessment is a holistic task where model capability matters more than prompting architecture.

Mathematics. Both models achieve near-perfect error detection (MA, MS ≈ 1.0), confirming that identifying mathematical mistakes is tractable at this scale. The key differentiator is solution guidance: DeepSeek-Unified achieves SA = 0.81 vs. only 0.25 for Qwen, reflecting DeepSeek’s reasoning advantage. However, the multi-agent approach severely degrades both models—DeepSeek drops from avg 0.91 to 0.70, with SA collapsing to 0.03. This challenges the assumption that task decomposition improves performance (Wang et al., 2025): mathematics requires a coherent reasoning chain, and splitting error diagnosis from feedback generation disrupts it.

Key takeaway. Multi-agent prompting is domain-conditional: neutral in programming, harmful in mathematics, and inconsequential in writing. It should not be adopted by default for educational feedback generation, and its benefit depends on whether the task is decomposable or requires a cohesive reasoning chain. Beyond prompting, domain characteristics strongly influence feedback quality. Mathematics proves most tractable (avg 0.70–0.91), followed by writing (0.35–0.81), with programming presenting the greatest challenge (0.27–0.48). This hierarchy suggests that structured domains with well-defined, step-by-step correctness criteria are easier to address learners’ issues than tasks that require nuanced judgments. Model architecture is a stronger determinant of feedback quality than parameter count. DeepSeek R1’s reasoning-optimized approach excels in structured domains that require logical analysis, while Qwen 3.5’s general-purpose design works better for holistic evaluation tasks. This pattern cautions against a one-size-fits-all model selection across multiple domains. Finally, our results highlight that programming models can generate fluent feedback while failing to accurately identify bugs, confirming that code-generation capabilities do not transfer to code-diagnostic tasks.

5 Conclusion and Future Directions

We examine a single LLM-based model (as a unified evaluation framework) for feedback generation across three disciplines: (i) mathematics, (ii) academic writing, and (iii) programming. We evaluated two open-source models of different paradigms: reasoning-optimized (DeepSeek R1) and general-purpose (Qwen 3.5) under unified and multi-agent prompting techniques. Our findings reveal that open-source models show potential for cross-domain feedback generation, but with varying effectiveness. DeepSeek R1 excels in structured domains where step-by-step reasoning approaches are favored, such as mathematics (avg 0.91), while Qwen 3.5 performs better on holistic tasks such as writing (avg 0.81). Programming presents a challenge for both models (avg 0.27-0.48). Despite their remarkable code generation capabilities on standard coding benchmarks, they are not yet strong enough for complex code-diagnostic tasks. These results caution against using a single model-supported system across all assessment types, and highlight that model architecture is a stronger determinant of feedback quality than prompting strategy.

Our evaluation assesses feedback quality through human judgment; however, high-quality feedback does not necessarily result in greater learning gains. Future research should examine whether feedback generated by LLMs supports students in developing conceptual understanding and critical thinking skills, rather than directly providing solutions. Following recent work on AI tutoring systems (Murtazin et al., 2025) and students' tendency to rely on AI models for direct answers across writing, programming, and general learning contexts (Denny et al., 2024; Li and Ma, 2025; Ge et al., 2025), we plan to test and deploy our framework as a classroom tool and systematically measure its impact on student performance and learning outcomes.

Limitations

This study has several limitations. First, evaluation is based on offline human judgments rather than classroom deployment, so educational impact on student learning remains unverified, and it is unclear whether high-scoring feedback would help improve learning outcomes, enhance student understanding, and develop critical thinking skills. Second, the evaluation covers only two small

open-source models (Qwen 3.5 27B and DeepSeek R1 32B) and three relatively small datasets: 200 programming samples (ConDefects), 55 writing samples (Exposia), and 150 mathematics samples (MathEDU) datasets, which limits the breadth of generalization. Our primary goal was to demonstrate a constrained environment to maximize the feasibility of replicating the proposed framework. Our findings may not generalize to larger open-source or proprietary models (e.g., GPT, Claude, Gemini). Although the datasets differ in their specific educational contexts and assessment formats, this diversity was intentionally used to assess cross-domain generalizability. Additionally, MathEDU was selected as the closest available dataset to reflect university-level mathematics, due to the absence of suitable calculus or high-level mathematics feedback dataset.

Third, our binary annotation scheme may not capture partial correctness or nuanced differences in feedback quality. Furthermore, our annotators were graduate students with domain expertise but no pedagogical training, which may have influenced their assessments of the pedagogical appropriateness of generated feedback. Inter-annotator agreement was calculated on a limited subset of overlapping samples, which may not fully capture annotation reliability across all domains and the full dataset. Finally, reference supervision differs across domains, especially in programming, where no gold feedback was available.

Figure A.1. Unified Prompt Template

You are an experienced computer science instructor reviewing a student’s buggy code submission. Your goal is to provide feedback that helps the student understand and fix the bug on their own.

Below is a problem description and an incorrect program written by a student.
 <problem description>
 <language>
 <student code>

Before writing your feedback, reason through the following steps internally:

1. Identify the exact location and type of the primary bug.
2. Determine the conceptual misunderstanding that likely caused it.
3. Decide how to guide the student toward the fix without revealing the solution.

Then write your feedback following these rules:

- Start with one sentence acknowledging something the student did correctly.
- Clearly identify the bug location (e.g., line number) and its error type.
- Explain the underlying conceptual misunderstanding in plain language.
- Describe the fix direction (e.g., “change X to Y”) without providing corrected code.
- Do not flag issues that do not exist in the student’s code.

Output: 150–250 words, 3–4 short paragraphs, no mark-down headers or code blocks.

Figure 2: Unified prompt for programming feedback generation.

Figure A.2. Writing Unified Prompt Template

You are an academic writing expert evaluating a Bachelor's thesis research proposal. Your role combines subject-matter review and writing instruction.

Below is a Bachelor's thesis research proposal written by a student.

<expose text>

Evaluate the proposal across four dimensions using the rubric below. For each criterion:

1. Locate the relevant passage in the text.
2. Apply the rubric to what is explicitly written — do not assume missing content.
3. Assign an integer score within the allowed range.
4. Ensure scores match your written analysis.

Dimensions and maximum scores:

- Problem & RQ (MO1–MO7): max 9 pts
- Literature & Theory (AP1–AP7, BI1–BI2): max 13 pts
- Methodology (AP8, MD1–MD7): max 8 pts
- Writing Quality (LA1–LA2): max 4 pts

Scoring rules: assign only integers within the defined range; score based on development, not mere mention; use only evidence explicitly present in the text.

Output format:

SCORES: MO1:[s] | MO2:[s] | ... | MO7:[s]
AP1:[s] | ... | AP7:[s] | BI1:[s] | BI2:[s]
AP8:[s] | MD1:[s] | ... | MD7:[s] | LA1:[s] | LA2:[s]

FEEDBACK: [150–250 words. Strengths first, then key areas for improvement.]

Figure 3: Unified prompt for academic writing feedback and scoring.

Figure A.3. Mathematics Unified Prompt Template

You are an experienced mathematics tutor reviewing a student's incorrect solution. Your goal is to help the student identify and understand their mistake so they can correct it independently.

Below is a mathematics problem and a student's incorrect solution.

<problem>
<student answer>
<student process>

Before writing your feedback, reason through the following steps internally:

1. Identify the step in the student's process where the error first occurs.
2. Determine whether the error is conceptual, procedural, or computational.
3. Decide how to guide the student without simply giving the answer away.

Then write your feedback following these rules:

- Acknowledge any correct steps the student took before the error, if applicable.
- Clearly identify where and what the mistake is, using the student's own work as reference.
- Explain the mathematical misunderstanding in plain language at the student's level.
- Guide the student step by step and state the correct answer at the end.
- Do not penalize valid alternative solution paths.
- Do not assume reasoning that is not shown in the student's process.

Output: FEEDBACK: [50–120 words. Correct work (if any) → mistake → guidance → correct answer.]

Figure 4: Unified prompt for mathematics feedback generation.

Figure A.4. Multi-Agent Prompt Template (Agent – A)

You are a precise code diagnostician. Your only job is to identify the primary bug in a student's code submission.

Analyze the following student code against the problem statement.

⟨problem description⟩

⟨language⟩

⟨student code⟩

Your tasks are as follows:

1. Identify the single most critical bug that explains why the code fails. If multiple bugs exist, focus on the root cause.
2. Do not provide student-friendly feedback — only a structured technical diagnosis.
3. Output ONLY the following format with no extra commentary:

BUG LOCATION: ⟨line number or segment, e.g. "Line 5: n = n / 2"⟩

ERROR TYPE: ⟨Logic Error | Off-by-One | Incorrect Operator | Wrong Variable | Missing Condition | Type Error | Other⟩

ROOT CAUSE: ⟨one sentence: what the code does vs. what it should do⟩

STUDENT MISCONCEPTION: ⟨one sentence: the likely conceptual gap⟩

FIX DIRECTION: ⟨one sentence: the correction, without writing corrected code⟩

Figure 5: Error Analyzer prompt for the multi-agent programming pipeline.

Figure A.5. Multi-Agent Prompt Template (Agent – B)

You are an experienced computer science instructor. You have received a structured bug analysis for a student's submission. Your task is to convert this technical diagnosis into clear, encouraging, and pedagogically useful feedback.

Below is a bug analysis for a student's code submission.

⟨problem description⟩

⟨language⟩

⟨student code⟩

⟨bug analysis⟩

Your tasks are as follows:

1. Open with one sentence acknowledging something the student did correctly.
2. Pinpoint the bug location and name its error type in plain language.
3. Explain the conceptual misunderstanding behind the bug clearly.
4. Guide the student toward the fix (e.g., "change X to Y") without providing corrected code.

Please follow these rules:

- Ground every claim strictly in the bug analysis — do not invent errors not identified.
- Use accessible language suitable for an introductory programming student.
- Do not write code blocks or corrected code in your output.

Output: 150–250 words, 3–4 short paragraphs, no markdown headers or code blocks.

Figure 6: Feedback Generator prompt for the multi-agent programming pipeline.

Findings of the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners

Mariano Felice and Lucy Skidmore

English Language Research & Impact

British Council, UK

name.surname@britishcouncil.org

Abstract

This paper reports findings from the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners across three L1s (Spanish, German and Mandarin). The task featured open and closed tracks, using data from the British Council’s Knowledge-based Vocabulary Lists (KVL). Submissions were received from 23 teams employing diverse modelling approaches, including transformers, Large Language Models, feature-based approaches and ensembles. Results were evaluated using RMSE, with winning systems significantly exceeding the baseline and establishing new state-of-the-art benchmarks. This paper offers an examination of the participating systems, performance across tracks and L1s, and the factors that can affect prediction accuracy.

1 Introduction

Vocabulary is a crucial aspect of language knowledge, shaping what learners can understand and produce. Establishing the difficulty of vocabulary is therefore essential for creating level-appropriate content and developing valid, reliable assessment instruments (Schmitt et al., 2020; François and Gala, 2024). However, determining word difficulty still relies on labour-intensive processes involving expert judgment and costly pretesting, which limits scalability and slows innovation (Dunn et al., 2026). As learning and assessment increasingly rely on digital platforms, the need for more efficient and scalable solutions is more pressing than ever.

While previous shared tasks have explored related problems such as Complex Word Identification (Paetzold and Specia, 2016; Yimam et al., 2018), Lexical Complexity Prediction (Shardlow et al., 2021), Lexical Simplification (Shardlow et al., 2024) and Item Difficulty Estimation (Yaneva et al., 2024), they were not designed with English language learners in mind and did not explore the influence of learners’ L1 on L2 vocabulary diffi-

culty. This shared task addresses that gap by bringing vocabulary difficulty prediction into the domain of language learning and assessment, offering a new perspective on a problem that has traditionally relied on psychometric calibration methods. In doing so, it serves as a testbed for state-of-the-art NLP models, with findings that have the potential to inform AI-powered solutions for item writing, content generation, adaptive testing, and personalised vocabulary learning.

2 Related Research

In the language learning and assessment domain, NLP-based vocabulary difficulty prediction spans a range of approaches, each with its own framing of ‘difficulty’. Such work includes CEFR level classification of vocabulary in isolation (Alfter and Volodina, 2018; Settles et al., 2020) and in context (Aleksandrova and Pouliot, 2023; Bannò et al., 2025), classification of vocabulary difficulty using crowd-sourced ratings as labels (Degraeuwe, 2025) as well as prediction of continuous difficulty values derived from testing learners (Skidmore et al., 2025). This shared task follows the approach of the latter, which sits at the intersection of two areas of research in NLP: Question Difficulty Estimation from Text and Lexical Complexity Prediction.

Question Difficulty Estimation from Text (QDET) aims to predict the difficulty of test items directly from their text, without the need for response data. A growing body of research has explored QDET for high-stakes assessment, driven by its advantages in efficiency and scalability over traditional psychometric approaches (AlKhuzayy et al., 2024). While the latest methods in NLP have been successfully applied in domains related to content knowledge assessment (Yaneva et al., 2024), QDET approaches for language assessment, where difficulty is more closely tied to the linguistic properties of the item, still largely rely on sim-

pler models (AlKhuyaey et al., 2024; Peters et al., 2025). This is particularly true for L2 vocabulary item difficulty estimation, which commonly features ‘vocabulary-only’ datasets that are not well-suited to the latest contextualised word embedding models (Benedetto et al., 2023).

Lexical Complexity Prediction (LCP) is an extension of Complex Word Identification (CWI), which concerns the automatic detection of complex words, primarily to support downstream text simplification (North et al., 2025). LCP expands the binary classification task of CWI to regression, assigning each word a continuous complexity score. The definition of complexity varies by domain, ranging from crowd-sourced ratings to morphosyntactically derived values (North et al., 2023). The majority of LCP and CWI research focuses on L1 vocabulary complexity. However, in line with the increasing body of work advocating for personalised LCP (Lee and Yeung, 2018; Gooding and Tragut, 2022), where demographic features such as L1 background are accounted for, LCP for L2 learners is an increasingly popular focus of research (North and Zampieri, 2023; Degraeuwe, 2025).

3 Shared Task Description

This shared task was organised by researchers at the British Council as part of the BEA Workshop, held at ACL in July 2026. The task addresses vocabulary difficulty prediction for learners of English with diverse first language (L1) backgrounds. Building on prior work (Skidmore et al., 2025), this shared task framed vocabulary difficulty prediction as a regression problem, where systems predict the difficulty of a target English word given a vocabulary test item written in the learner’s L1. Data for the task were drawn from the British Council’s Knowledge-based Vocabulary Lists (KVL) (Schmitt et al., 2021, 2024), a multilingual dataset containing such items with psychometrically calibrated difficulty scores for learners from three L1 backgrounds: Spanish (ES), German (DE) and Mandarin (CN).

Participation was open to the research community following a limited timeline. Training and development data alongside baseline models were released on 26th January 2026, giving participants approximately eight weeks to develop their systems before test data were made available on 20th March. Teams then had one week to submit their final system outputs. Systems were evaluated on the test set by the organisers, with results announced

on 3rd April. Further details on the tracks, data, baseline models and evaluation are outlined below and on the shared task website¹.

3.1 Tracks

The shared task included two tracks:

Closed Track: Designed to elicit models that rely on the provided dataset and standard, publicly available NLP tools. The goal was to explore optimal model design under controlled data conditions.

Data: Systems were permitted to only use the provided training data for each corresponding L1. Additional training data or combining data from different L1s was not allowed.

Models, tools and databases: Publicly available, ‘off-the-shelf’ pre-trained transformer models (e.g. BERT, RoBERTa) and their embeddings, standard NLP tools (e.g. taggers, parsers) and publicly available linguistic databases (e.g. WordNet, frequency lists) were allowed.

LLMs: Publicly available large language models were permitted strictly as a tool to extract features from the item text. For example, generating scalar features (e.g. imageability ratings), textual features (e.g. English translation of the L1 source), or deriving embeddings.

Open Track: The ‘anything goes’ category, which allowed for maximum flexibility and the use of external resources. The purpose of this track was to encourage creativity and explore the full potential of current AI technology.

Data: Any additional training data was permitted. This included public corpora, proprietary datasets, synthetic data, or combining different L1 subsets.

Models, tools and databases: No restrictions.

LLMs: Any system using an LLM to generate a difficulty prediction or identify the target word was classified as open track, regardless of whether the LLM output was used directly or passed to a downstream model.

3.2 Data

The dataset for the task was derived from the British Council’s Knowledge-based Vocabulary Lists (KVL) (Schmitt et al., 2021, 2024), initially developed to collate difficulty rankings of English vocabulary for learners with L1 backgrounds of Spanish, German and Mandarin. The productive

¹britishcouncil.org/data-science-and-insights/bea2026st

English word knowledge of over 100,000 learners was assessed using items testing form-based recall of individual lemmas in a translation format (Laufer and Goldstein, 2004). From approximately 3.3 million responses, difficulty estimates were derived separately for each L1, applying random-item-random-person (RPRI) Rasch models (De Boeck, 2008) built within a generalised linear mixed model (GLMM) framework (Dunn, 2024).

Below is an example test item in Spanish, where learners were required to input the remainder of the target English word “house”²:

```
casa Vivo en una casa grande que tiene tres
dormitorios.
h _ _ _ _
```

For the shared task, participants were provided the ‘Extended KVL Dataset for NLP’ (Skidmore et al., 2025) for model training and development. This dataset contains 6,768 parallel English vocabulary test items, with prompts in the three L1s, totalling 20,304 items. The dataset was split into train and development subsets to facilitate comparison to baseline models for the task, however participants were allowed to use this development data to train their models if desired. For final model evaluation, an additional 748 vocabulary test items per L1 (2,244 total) were released. Table A5 in the Appendix summarises the dataset split. The dataset contained the following columns:

- `item_id`: An ID number from 1 to 6,768. Items with the same `item_id` across different L1s share the same English target word).
- `L1`: The L1 of the prompt (‘es’, ‘de’, or ‘cn’).
- `en_target_word`: The English target word.
- `en_target_pos`: The part of speech of the English target word.
- `en_target_clue`: A partial-spelling clue of the English target word.
- `L1_source_word`: The corresponding L1 source word(s).
- `L1_context`: The L1 contextualising prompt.
- `GLMM_score`: The GLMM difficulty estimate for the vocabulary test item. A lower score indicates a more difficult word.

Details for how to access the shared task data can be found on the British Council’s website.

²The German and Mandarin versions had similar, yet distinct prompts, for example in German: “Haus Ich wohne in einem Haus mit Garten.” And in Mandarin: “房子 我买了一座房子。”

3.3 Baseline Models

The baseline models used for the task are multilingual XLM-RoBERTa-base transformer encoders (Conneau et al., 2020), fine-tuned on the training subset of the data following (Skidmore et al., 2025). The input text includes the question in the same order as it is presented to the test takers (L1 source word, L1 context, EN clue), followed by the target answer (EN target word), as shown in the example:

```
casa </s> Vivo en una casa grande que
tiene tres dormitorios. </s> h____
</s> house
```

Four baseline models were provided to participants, three in the closed track (`baseline_closed_es`, `baseline_closed_de` and `baseline_closed_cn`) which were fine-tuned on the L1 subsets of the data separately, and one in the open track (`baseline_open_xx`) which was fine-tuned on all of the L1 subsets combined. These models are available via GitHub.³ Hyperparameters for the baseline models can be found in Table A6 in the Appendix.

3.4 Evaluation

Submissions were evaluated using two metrics: Root Mean Squared Error (RMSE) and Pearson correlation, chosen for comparability with prior work in LCP and QDET research (North et al., 2023; AlKhuyaey et al., 2024). RMSE was used as the primary metric for the official rankings while Pearson correlation provided a scale-independent measure to facilitate cross-L1 comparison.

4 Participation in the Shared Task

4.1 Teams and Submissions

In total, 23 teams participated in the shared task, from organisations across 16 countries: Bangladesh, Belgium, China, Germany, India, Indonesia, Ireland, Japan, Mexico, Romania, South Korea, Switzerland, United Arab Emirates, United Kingdom, United States of America and Uruguay. Teams were invited to submit up to three ‘runs’ per track and L1. The distribution of teams and runs is summarised in Table 1. Almost all teams submitted to the closed track (22 out of 23), with eight of those teams also submitting to the open track. One team (SurreyCTS) submitted only to the open track. Most teams provided submissions for all three L1s,

³<https://github.com/britishcouncil/bea2026st/>

L1	Open		Closed	
	Teams	Runs	Teams	Runs
Spanish	8	23	21	55
German	8	23	20	52
Mandarin	9	25	21	52
Total	9	71	22	159

Table 1: Number of participating teams and runs.

whereas two teams (AIDA and BZPT) focused on just one L1, Spanish and Mandarin, respectively. Table A7 in the Appendix provides a breakdown of the submitted runs per team.

4.2 Summary of Approaches

Out of the 23 participating teams, 19 published an accompanying system description paper. Table A8 in the Appendix reports the tracks, L1s, approaches, and primary models explored, where submissions are tagged with up to four attributes: **transformers** (transformer-encoder models fine-tuned for prediction), **LLMs** (LLMs fine-tuned for prediction), **features** (any use of features), and **ensemble** (any combination of the above models).

Fine-tuning encoder-only transformer models was the most popular approach, explored by 17 out of 19 teams. The most widely used model family was XLM-RoBERTa (Conneau et al., 2020), particularly XLM-RoBERTa-large, which was used by eight teams, while RemBERT (Chung et al., 2021) and DeBERTA-v3 (He et al., 2023) were also popular choices. Of note, three teams built systems using mmBERT-base, a newer multilingual encoder-only transformer recently shown to outperform the previous generation of multilingual models (Marone et al., 2025). Encoders pretrained for related tasks were also explored, including COMET (Rei et al., 2020) (SurreyCTS) for machine translation quality estimation as well as the sentence embedding models Multilingual E5 (Wang et al., 2024) and BGE-M3 (Chen et al., 2024) (uogal, UOL@IDEM). At the architectural level, some teams moved beyond standard CLS-token pooling, experimenting with methods such as attention-weighted pooling, multi-layer concatenation of hidden states, and target-word-specific pooling (AIDA, Failure, SurreyCTS). Two teams experimented with modified training objectives: Jinnie’s Lab employed multi-task learning, jointly predicting difficulty alongside an auxiliary POS tag; TOEBM employed a multi-objective training framework,

supplementing the standard regression loss with contrastive objectives designed to better align the learned representations with the task structure.

Fine-tuning LLMs was explored by three of the open-track teams (Glite, Sakura, TeamXBC). All three systems used Low-Rank Adaptation (LoRA or QLoRA) (Hu et al., 2022) to fine-tune models from several decoder-only families including Qwen (Yang et al., 2024), Mistral (Jiang et al., 2023; Liu et al., 2026), LLaMA (Dubey et al., 2024), and GLM (Team GLM, 2024). Sakura additionally introduced a novel technique to fine-tune LLMs for continuous value prediction using soft targets.

Feature engineering was also widespread, with 15 of the 19 teams incorporating features into their models, typically fused architecturally with transformer representations (e.g. EduNLP, Failure) or used as inputs to gradient-boosted regressors (e.g. RETUYT-InCo). Some teams applied novel ways to integrate features: AIDA used features to calibrate transformer outputs by predicting their residual error, while uogal augmented transformer inputs with NMT-generated translations of L1 contexts as a complementary cross-lingual signal. Beyond these integration strategies, the features themselves broadly fell into three groups: target word, cross-lingual, and test item. Word-level features included surface properties (e.g. word length), psycholinguistic predictors (e.g. age of acquisition), and L2 learner-specific resources (e.g. CEFR levels) (Boosted Cats, SATLab). Cross-lingual features captured relationships between the L1 source word or context and the English target, most commonly with features related to orthographic and semantic similarity (e.g. RETUYT-InCo). Test item features captured difficulty related to the item content, such as the proportion of letters revealed by the spelling clue (e.g. Data Asgardians, EduNLP) and how recoverable the English target is from the L1 context (UOL@IDEM). Beyond traditional corpus-based and lexical resources, two notable extraction strategies were applied. The first involved probing language models as proxy test-takers, recording signals such as token surprisal and masked token prediction probability (Glite, Sakura). The second used LLMs as direct judges, prompting them to rate aspects of difficulty such as the item’s quality (Glite) or the degree of lexical ambiguity (Sakura).

Model ensembling was adopted by 15 of the 19 teams. The most common strategy was averaging across multiple runs of models from the same

architecture, primarily transformer encoders (e.g. SAAKTH, Token Titans). Exceptions included an array of classical regressors (UGA Threshold) and an ensemble of fine-tuned LLMs (Sakura). Many teams combined architecturally diverse models, typically pairing transformers with feature-based models and weighting predictions toward the transformer (e.g. Data Asgardians, NLP-Explorers). Teams explored stacking ensembles, using a meta-learner such as linear regression or a shallow MLP to combine predictions (e.g. TOEBM, uogal). Three teams (Glite, Sakura, SATLab) used meta-learners that consumed both model predictions and handcrafted item-level features.

Open-track teams took advantage of the relaxed restrictions in several other ways. Three teams fine-tuned decoder-only LLMs for difficulty prediction. Five teams trained models jointly on all three L1s rather than on a separate per-L1 basis. Glite made use of a proprietary sense-level lexical resource with difficulty estimates. One team (uogal) experimented with pretraining on EFCAMDAT (Geertzen et al., 2013), a corpus of L2 English learner essays, though the resulting models were not included in their final system. Moreover, Glite and Sakura used commercial LLM APIs to generate features. Two teams made notable use of agentic AI: TeamXBC used AI coding agents to build their ML solution with varying degrees of human input, while Glite’s autonomous research framework enabled the systematic evaluation of over 1,000 candidate features across 270+ tracked experiments.

5 Results

The official leaderboards for each track and L1 are included in Appendix B, where we report RMSE and Pearson correlation for each run. Given the small differences in RMSE across systems, we performed a statistical significance analysis to identify groups of systems with equivalent performance. Significance testing was conducted using a non-parametric bootstrap method (Efron and Tibshirani, 1993) with 10,000 iterations. To account for multiple comparisons, we applied a Bonferroni correction, setting the significance threshold to $\alpha_{adj} = 0.05/(n - 1)$, where n is the number of submissions within a given track and L1. Systems were grouped sequentially, such that a new group was created only when a system performed significantly worse than the current group’s leader. A summary of the results including

the best entry per team is included in Table 2. Results show that for all tracks and L1s, most teams were able to beat the baseline with at least one of their submissions, often by a large margin.

The winning team for the closed track was Glite (Philippov et al., 2026), whose submitted runs took the top three positions across all three L1s. The best runs achieved an RMSE of 0.903, 0.885 and 0.776 for Spanish, German and Mandarin, respectively, with corresponding Pearson correlations of 0.877, 0.871 and 0.889. The Glite systems used a per-L1 CatBoost regressor (Prokhorenkova et al., 2018), combining scalar out-of-fold predictions from fine-tuned encoder models with hand-crafted features. These were selected from a large candidate pool via Recursive Feature Elimination (RFE) under nested cross-validation, applied separately for each L1. Features included word-level difficulty (e.g., surface form, frequency, morphology, concreteness, CEFR levels), cross-lingual features (e.g., cognates and false friends), and test item difficulty (e.g. spelling difficulty and candidate competition features). Feature extraction relied on traditional corpus-based and lexical resources as well as masked-LM pseudo-likelihood guessing to probe model behaviour as a proxy test-taker. The pool also included a small set of derived second-order features, such as pairwise interactions and model-disagreement metrics. Other systems falling within the top statistical grouping included uogal (German, Mandarin), who used ensembles of fine-tuned transformer models augmented with EN translations of L1 content, and Sakura (Mandarin), who combined a single fine-tuned encoder prediction with explainable features in an XGBoost regressor.

The winning team for the open track was Sakura (Nohejl et al., 2026), whose submitted runs took the top three positions for German and Mandarin, and the top two positions for Spanish. The best runs achieved an RMSE of 0.742, 0.723 and 0.630 for Spanish, German and Mandarin, respectively, with corresponding Pearson correlations of 0.919, 0.916 and 0.928. The approach was centred on a novel soft-target cross-entropy loss for fine-tuning LLMs to predict continuous difficulty values. Three LLMs from different families were fine-tuned using this method and combined via linear regression stacking with out-of-fold predictions. This ensemble was then enhanced with word-level difficulty features (e.g., production and reception frequency, CEFR level, word length), cross-lingual features (e.g., orthographic similarity and morphemic over-

lap), and test item difficulty features (e.g. spelling difficulty and lexical ambiguity, extracted using LLMs as raters). Prompt-based features were calibrated using temperature-scaled, probability-weighted inference (G-Scale) (Nohejl et al., 2025). This configuration was the best-performing for Spanish and Mandarin. The team also experimented with a further set of test item difficulty features combining LLM-prompted difficulty ratings and proxy test-taker estimates, in which LLMs were prompted to solve the items. This configuration took the top position for German. Also within the top statistical grouping, Glite applied the same approach as their closed-track submission, expanding the feature set to include both fine-tuned and prompted LLM difficulty ratings, proxy test-taker estimates, and LLM-based item judgements.

6 Analysis and Discussion

To investigate how performance varied across tracks and L1s, we calculated Mean Absolute Error (MAE), Mean Signed Error (MSE), average prediction Standard Deviation (Avg. SD) and average Pearson correlation (Table 3). Results show that MAE is consistently lower for systems in the open track (by 0.13 on average). This aligns with findings from teams that evaluated joint training across L1s (EduNLP, Jinnie’s Lab, Sakura, TeamXBC), all of which reported improvements over per-L1 training, suggesting the open track gains reflect, at least in part, the benefit of shared signal across L1 subsets. This is most pronounced for Mandarin, which shows the lowest average error despite the orthographical distance from English. However, as noted by Data Asgardians, this is likely due to the reduced range of GLMM values for Mandarin (approximately -4 to 4), which is narrower than for Spanish (approximately -6 to 5) and German (approximately -5 to 4). In fact, looking at average Pearson correlation (a scale-independent measure) reveals that open-track performance for Mandarin is actually lower than for Spanish and German, confirming that its lower MAE is an artefact of the narrower scale.

MSE was positive in all cases, indicating that systems tend to underestimate difficulty on average. Open-track systems show less underestimation across all three L1s, though this is less pronounced for Mandarin — again, likely reflecting its narrower scale. Average SD improves for Spanish and German but increases slightly for Mandarin in the open

track, suggesting that while overall accuracy improves, open-track systems do not achieve greater consensus. Together, these results confirm that the benefits of cross-lingual training are not uniform across L1s.

To examine the L1 and track level differences outlined in Table 3, we investigated individual predictions for each item in the test set. Figure 1 shows the spread of predictions for each test item (in yellow), sorted from easiest (highest GLMM score) to hardest (lowest GLMM score). Ground-truth values are shown in purple, contrasted against regression lines for each winning submission (pink) and mean system performance (dotted red). In addition, we include trend curves for the lowest and highest predictions (dotted orange) in order to better evaluate prediction drift.

System predictions show strong monotonic alignment with true difficulty, meaning that models can successfully capture the ordinal relationship of the target values. This is confirmed by the high Pearson correlation coefficients reported in Appendix B. Predictions overlap substantially with target values across the dataset, except at the extremes, where the items are increasingly difficult to predict. This is regardless of the difficulty range (notably larger for Spanish) and likely a consequence of the small number of samples in the dataset with extreme difficulty values. Several submission papers support this, reporting weaker accuracy at both ends of the GLMM scale. EduNLP found that ‘very hard’ items ($\text{GLMM} < -3$) contribute 25.4% of total squared error despite comprising only 5.1% of items. UOL@IDEM report that the top 20% of ‘very easy’ items are over-predicted by $+1.03$ to $+1.28$ GLMM points by their closed track models. TOEBM showed that prediction bias may be model dependent: XLM-RoBERTa underestimated difficult items, whereas mDeBERTa-v3 showed systematic overestimation and mmBERT was more consistent across difficulty levels. Ensembling with a Ridge regressor exploited these complementary biases to produce more consistent predictions.

Looking at the boundary lines, we observe that the spread of predictions in the closed track is broadly homogenous across all L1s, although Spanish and Mandarin do exhibit an opening towards more difficult items (lower GLMM values), indicating less consensus among systems. Given the small number of extremely difficult items in the datasets, it is unsurprising that systems struggle to predict them. In the open track, prediction spread

shrinks for all L1s, especially for Spanish and German. For Mandarin, however, dispersion increases at both ends of the difficulty scale in the open track, suggesting that additional signals may introduce noise rather than useful information for this L1 at the extremes. This finding may in part be due to the greater orthographical distance between Mandarin and English limiting cross-lingual generalisability compared to Spanish and German, reported in prior work (Skidmore et al., 2025) and corroborated in submissions for the shared task (UGA Threshold, Boosted Cats, SurreyCTS).

The wide vertical dispersion observed for some items indicates cases where the systems largely disagree. These are words that the systems find particularly confusing. Likewise, items with the highest error (where the yellow predictions are furthest away from the purple values) indicate the words that were the most difficult to predict. Table 4 includes some examples. The words that are easier to predict are either cognates, concrete nouns, or specific terminology, whereas the most difficult ones tend to be polysemous words (whose most frequent sense is not the target sense), abstract words, collocates or words with specific parts-of-speech (gerunds, adverbs, verbs). Item-level error analyses carried out by the teams corroborate this, with models consistently struggling most with words with uncommon senses or grammatical roles. In particular, EduNLP found that nominalised ‘-ing’ forms showed a 58% higher RMSE than other words, such as “dining” “baking”, “speaking” seen in Table 4, while Boosted Cats found that items where the tested POS differed from the dominant POS,

Figure 1: System prediction distributions sorted by target difficulty (higher GLMM scores $\rightarrow$ easier items).

illustrated by “spring”, “amount” and “received” in Table 4, increased prediction variance by 24–32%.

Considering the shared task approaches as a whole, there are several conclusions that can be drawn. Firstly, improvements over the XLM-RoBERTa-base baseline were driven primarily by model choice. In particular, switching to XLM-RoBERTa-large delivered improvements across multiple teams (e.g. TeamXBC). Architectural modifications such as multi-layer pooling and layer aggregation offered smaller improvements in some systems (Jinnie’s Lab, SurreyCTS), though more complex modifications such as layerwise learning rate decay were largely ineffective or harmful (TeamXBC). Secondly, feature-based models were competitive with the baseline, particularly for Spanish and German where cross-linguistic similarity signals are informative (Boosted Cats, SAAKTH). However, ablation studies for hybrid models revealed that incorporating hand-crafted features provided only small improvements to already strong ensemble baselines (Glite, SAAKTH). Nevertheless, feature-based models offer a clear advantage

in interpretability, providing insights into what drives difficulty for different learner groups, which is essential for item development in practice (Dunn et al., 2026). Finally, ensembling almost always helped, with model diversity proving more important than raw individual model strength (TOEBM, uogal). Interestingly, however, complex stacking strategies were found to overfit to the small development set provided (EduNLP, TeamXBC, uogal).

The two winning teams, Glite and Sakura, shared a common architectural approach to the task: combining out-of-fold predictions from multiple fine-tuned models with a broad set of hand-crafted features. Both were among the few to use features targeting item-level as well as word-level properties, in particular proxy test-taker signals from masked LMs and LLM-based judgements of item difficulty. They were among only three teams to experiment with fine-tuned and prompted LLMs as a core component of their systems, which proved highly effective but remains relatively underexplored across the shared task as a whole. Both systems also used cross-validation strategies for model training. To-

Table 4: Sample vocabulary items for different prediction categories.

gether, these factors suggest that the performance gap between the winning systems and the rest was driven by the combination of multiple model predictions, broad and well-chosen feature coverage, and evidence-based model development.

Across submissions, a picture emerged of vocabulary difficulty as shaped by both an underlying component tied to features of the English word and a L1-specific signal. This is supported by the fact that language-agnostic pipelines with no L1-specific features outperformed the baseline models (Failure). Improvements from joint L1 training (EduNLP, Jinnie’s Lab, Sakura, TeamXBC) further confirm that much of this can be shared across learner groups, which supports findings of previous research (Skidmore et al., 2025). At the same time, per-L1 hand-crafted features also proved valuable, and analyses of feature importance revealed meaningful differences in what drives difficulty for different learner groups (Boosted Cats, Sakura). A similar pattern was evident in ensemble models, where different encoder combinations were preferred for different L1s (uogal). Cross-lingual transfer experiments reinforced this picture: Spanish and German models transferred to each other reasonably well, but Mandarin transferred poorly, reflecting fundamental differences in how difficulty is structured across typologically distant pairs (Boosted Cats, SAAKTH). Together, these findings affirm the value of L1-aware modelling with clear implications for scalable, personalised assessment and adaptive vocabulary learning.

7 Future Work

Looking ahead, several directions emerge from the findings of the shared task. The ‘compression effect’ of the target labels provide motivation to experiment with alternative labelling strategies, such as ordinal or banded difficulty rather than continuous GLMM scores. The L1 asymmetry between European languages and Mandarin makes a strong case for extending vocabulary difficulty prediction

to more typologically diverse L1s, such as Arabic or Japanese, to test whether the findings here generalise beyond the specific language pairs studied. Finally, making use of learner response data to validate the insights produced by interpretable models would provide empirical grounding for conclusions that currently rest on model behaviour alone. Features identified as important by multiple systems such as spelling difficulty, polysemy of the target word, and cross-lingual transfer signals could be directly tested against learner responses, representing a valuable bridge between the NLP and language testing research communities.

8 Conclusions

This paper presented an overview of the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners, predicting difficulty scores for English lexical items across three L1s (Spanish, German, and Mandarin). The task comprised closed and open tracks, restricting and permitting additional data and models respectively. A total of 23 teams participated using a variety of approaches, including classical machine learning, transformer models, LLMs and ensembles. Most systems outperformed our transformer-based baseline, with winners in each track doing so by a large margin.

System analysis showed that ensembles combining linguistic features with fine-tuned model predictions achieved the best results. Systems tended to underestimate difficulty and struggled the most with polysemous words. Open-track systems consistently outperformed their closed-track counterparts, suggesting that joint training across L1s improves predictive accuracy. However, the degree of impact of these approaches varies across L1s and difficulty levels and warrants further investigation.

We believe the insights gained from the shared task will significantly contribute to the design of more robust vocabulary prediction models, ultimately supporting better test item development and more adaptive language learning applications.

9 Limitations

Most of the limitations of this work stem from the datasets used to train and evaluate the systems. The data was restricted to three L1s (German, Spanish, Mandarin), so conclusions about system performance must be interpreted with caution, as they may not generalise to learners with different linguistic backgrounds. Furthermore, the test items across these L1s were not standardised, potentially introducing variation in difficulty estimates beyond learner background. Some participants found that the small development set (677 items per L1) limited reliable model selection and ensemble calibration, which may have impacted the overall performance of some systems. In addition, the use of the probabilistic values derived from the GLMM framework as observed difficulty values comes with its own caveats, as discussed by [Schmitt et al. \(2024\)](#).

Since GLMM scores are estimations rather than direct observations, RMSE values should be interpreted with care. To provide a more robust assessment of model performance, we also report Pearson correlation, which captures the linear relationship between predictions and true values and is less sensitive to numerical fluctuations.

The GLMM difficulty values in our datasets are also not directly comparable across L1s, since they were derived from different population samples. This is something that must be taken into account when training systems using a combination of data from all L1s, such as our open track baseline.

For limitations pertaining to individual submissions, please refer to the corresponding description papers.

10 Ethics statement

The dataset for this shared task was collected by the British Council through a large-scale crowdsourcing initiative ([Schmitt et al., 2021](#)). Participation was voluntary and participants agreed for their response data to be used for research purposes. All data was anonymised prior to analysis. Vocabulary difficulty scores were derived from aggregated responses using psychometric modelling, ensuring that individual identities cannot be inferred.

A primary objective of this shared task is the promotion of responsible AI practices in language education, with an emphasis on transparency, reproducibility, and fairness. For this reason, all the data, baseline models, evaluation scripts and documenta-

tion have been made publicly available for research and educational purposes. The insights from the submitted models and their respective description papers also aim to foster greater transparency and explainability in the domain of AI for education.

Acknowledgements

The authors would like to thank the original research team behind the Knowledge-based Vocabulary Lists, whose datasets have been fundamental to this shared task. Special thanks go to Karen J. Dunn for her continued guidance and support. We also wish to thank all participants of the BEA 2026 Shared Task for their engagement and contributions.

SATLab at BEA 2026 Shared Task 1: Predicting the Difficulty of English Words for Three L1 Learners Using Primarily Psycholinguistic Features

Yves Bestgen

Statistical Analysis of Text Laboratory (SATLab)

Faculté de psychologie, de logopédie, de sexologie et des sciences de la famille

Université catholique de Louvain

Place Cardinal Mercier, 10 1348 Louvain-la-Neuve, Belgium

yves.bestgen@uclouvain.be

Abstract

This paper presents SATLab’s participation in the BEA 2026 shared task on predicting the difficulty of English words for L2 learners. The proposed system uses features mainly derived from word frequency lists, lexical norms, and psychometric data, which are input into a gradient boosting decision tree model. It outperformed the Baseline system but performed significantly worse than the top-performing teams. Feature contributions to model performance are analysed using gain scores and Spearman rank correlations, and a brief analysis of the most significant errors is provided.

1 Introduction

This paper presents SATLab’s participation in the British Council’s Shared Task at BEA 2026, *Vocabulary Difficulty Prediction for English Learners*, whose aim is to foster the development of regression models for predicting the difficulty of English words for learners of three first languages: Spanish, German, and Mandarin. Such models could, for example, be used to tailor content for learners at different proficiency levels.

To build high-performing models for this task, as in many other areas of NLP, the use of pre-computed embeddings and LLMs has proven most effective (Skidmore et al., 2025; Yaneva et al., 2024). However, it is worth considering whether other features, such as word frequency lists, lexical norms, and psychometric data, can rival the simplest of these approaches and contribute to greater effectiveness. This seems particularly justified because Shardlow et al. (2021) observed, in a shared task on assessing word difficulty, little difference in effectiveness between deep learning approaches and feature-based approaches such as the system developed by Mosquera (2021). Previously, Culligan (2015) found that frequencies from very large corpora provide the best estimate of word difficulty (see also Settles et al. (2020)).

For several years, SATLab has specialised in using these indices to solve complex tasks such as predicting eye saccades during reading or identifying offensive content and hate speech in languages with few linguistic resources (Bestgen, 2021a,b,c). The vocabulary difficulty prediction task is particularly relevant to this objective due to the sustained interest it has attracted in linguistics (Schmitt and Schmitt, 2020) and the availability of ‘fine-grained’ resources based on extensive linguistic knowledge. The system proposed by SATLab is based on these features, which are fed into a gradient boosting decision tree model. One version of the system uses only these psycholinguistic features (*Nonly* version). The other version adds them to the difficulty score predicted by the organisers’ Baseline system, which uses pre-computed embeddings (Felice and Skidmore, 2026; Skidmore et al., 2025).

The next section presents the main characteristics of the shared task. The features, the most important part of the proposal, are then described in detail. Finally, the results of the challenge are reported, along with an analysis to determine which features are the most useful.

2 Data and Task

The data for this challenge is taken from the *Extended Knowledge-based Vocabulary Lists Dataset for NLP* (Schmitt et al., 2021; Skidmore et al., 2025). It consists of 7,516 words, for which the difficulty level for English learners was estimated using a translation task involving over 100,000 learners from three L1 backgrounds. For each target lemma, the test item included the first letter, the length and the part of speech of the target word in English, one or more translations of the word into the L1, and a sentence in the L1 featuring the word in the relevant context. Based on responses in each L1, a difficulty level was estimated using a psychometric procedure (see Schmitt et al. (2024)).

for further details).

The material was divided into three sets: the Learning set ($N = 6,091$), the Development set ($N = 677$), and the Test set ($N = 748$). The task was offered in two tracks. For the closed track, LLMs were not permitted to train the system or combine several L1s. All methods were permitted for the open track. The performance metric is the Root Mean Square Error (RMSE). Each team was allowed to submit three runs for each track and each L1.

The organisers also provided, as the baseline, the system they presented at BEA 2025 (Skidmore et al., 2025), which uses a fine-tuned transformer based architecture. This system was used to predict the Development and Test sets from the Learning set of the shared task materials.

3 Feature Sets

3.1 Features Derived Only from the Items

- Simple statistics: the character length of the target word (TargetL), the source word in L1 (SourceL) and the context (ContextL), the POS tag of the target (PosTag), the first letter of the target (FirstLetter) and the number of proposed L1 words (NbrWordL1).
- Sim12: The orthographic (Levenshtein distance) and phonetic (Soundex algorithm¹) similarity were calculated to estimate the degree of cross-linguistic similarity between the English target word and the L1 source word (Otwinowska and Szweczyk, 2019). These measures are calculated only for German and Spanish.

3.2 Features Extracted from Generic Resources

- FBfr: Herdagdelen and Marelli (2017) Facebook frequency lists for American English and British English based on approximately one billion tokens for each variety. These lists were extracted from publicly available English posts collected between November 2014 and January 2015.
- TWfr: Herdagdelen and Marelli (2017) Rovereto Twitter Corpus frequency on more than one billion tokens from 75 million tweets, collected between December 2010 and July 2011.

- HALFr: Lund and Burgess (1996) Hyper-space Analogue to Language (HAL) frequency norms for approximately 40,000 words provided by (Balota et al., 2007).
- GoogleFr: The Google Ngram frequency word list².
- USENETfr: Shaoul and Chris (2006) USENET Orthographic Frequencies derived from a corpus of more than seven billion words from posts collected between October 2005 and August 2006.
- BNCfr: The frequency of orthographic forms in the 100-million-word British National Corpus. Two frequencies were calculated: the total frequency of the orthographic form and the frequency taking into account the PosTag.
- BasicV: Graham et al. (1993) list of 850 words most frequently used by children in their writing³. These words are classified into 5 grades according to their degree of difficulty for children, with the most difficult words to spell highlighted.
- Glasgow: Scott et al. (2019) lexical norms for age of acquisition, arousal, concreteness, dominance, familiarity, valence, gender association, imageability and semantic size. These norms include 5,553 English words evaluated on average by 33 native English speakers.
- ELP: Balota et al. (2007) lexical characteristics and behavioural measures from lexical decision and naming tasks for more than 40,000 words as available in the English Lexicon Project.
- Latent: Knoph et al. (2024) latent lexical dimensions of Frequency, Complexity, Proximity, Polysemy, and Diversity for 2,060 high-frequency words from the General Service List, 1,051 general academic words from the Academic Word List, and 3,413 domain-specific words from the Academic Vocabulary List.

It may seem surprising to use so many frequency-related features that are more or less strongly correlated. However, this approach has proved particularly effective in the Cognitive Modeling and Computational Linguistics (CMCL) Shared Task on Eye-Tracking Data Prediction (Bestgen, 2021a), enabling the system to outperform all deep learning-based systems participating in the challenge.

¹<https://www.archives.gov/research/census/soundex>

²<https://github.com/hackerb9/gwordlist>

³<https://www.readingrockets.org/topics/writing/articles/basic-spelling-vocabulary-list>

3.3 Features Extracted from L2 Language Learner Resources

- Oxford: The Oxford University Press list of the 3,000 most essential words for English language learners⁴, classified according to their level of difficulty based on CEFR levels A1 to B2.
- L2fr: The frequency of orthographic forms in three corpora of learners of English as a foreign language: the Ten-thousand English Compositions of Chinese Learners Corpus (TECCL), the International Corpus Network of Asian Learners of English (ICNALE) and the First Certificate in English examination scripts (FCE).
- LexCom: Maddela and Xu (2018) lexicon of 15,000 frequent English words annotated for complexity by eleven fluent English speakers of different native languages. These words are drawn from the most frequent words in the Google Ngram Corpus.
- BKL2: Brysbaert et al. (2020) database identifying the English words most familiar to non-native speakers, compiled through a large-scale crowdsourcing study involving 62,000 words.

4 System

LightGBM free software (Ke et al., 2017), a well-known implementation of the gradient boosting decision tree approach, was used to build the regression model. The various parameters were optimised using Optuna. When the feature derived from the Baseline was not used (*Nonly* version), nine-fold cross-validation was used on the development and training sets to select the best model and determine the number of iterations (early stopping rule). Nine folds were used to maintain the ratio between the number of instances in the development and training sets.

When this feature was used, the criterion was performance on the Development set. In the *Dev* version of the system, the Development set was used as provided by the organisers, i.e. the 677 unique instances. In the *Boot* version, 100 bootstrap samples (with replacement) of 677 instances from this Development set were constructed at the start of the optimisation, and the performance of a set of parameters corresponded to the average

performance across these 100 samples. As these two versions produced almost identical results during the test phase, the remainder of this paper will no longer refer to the *Boot* version, which is less conventional.

5 Analysis and Results

5.1 Official Results

The official challenge results are presented in the organisers' summary paper (Felice and Skidmore, 2026). In both tracks and across the three L1s, the *Dev* version performed significantly better (mean RMSE = 1.019) than the Baseline (mean RMSE = 1.176), but it also performed significantly worse than the top-performing team (mean RMSE = 0.790). In the closed track, the *Nonly* version, which does not use pre-computed embeddings, was also more effective (mean RMSE = 1.136) than the Baseline (mean RMSE = 1.218), which relies on a fine-tuned transformer-based architecture. However, the *Nonly* version was considerably less effective than the *Dev* version, which uses the Baseline as an additional feature (mean RMSE = 1.025).

5.2 Feature Contribution to Model Performance

To assess the usefulness of the features for predicting lexical complexity, Table 1 presents the importance scores of the top ten features in each of the three models analysed and for the three languages. These are gain scores, indicating how much each feature contributes to model performance. The table shows the sum of the gains for all features derived from the same resource. To facilitate interpretation, the values correspond to the proportion of each score relative to the maximum score for that model. A value of 0.50 therefore indicates that this feature set is half as useful as the most useful feature set.

For the *Nonly* version, the most useful predictors are clearly Sim12, BKL2, and Oxford. The effectiveness of Sim12 likely stems from its ability to estimate cross-linguistic similarity between the English target word and the L1 source word (Otwinowska and Szewczyk, 2019). The inclusion of Oxford in this group is notable because, as mentioned above, it is a list of just 3,000 words divided into four categories. Although relatively old and not specific to L2 learners, ELP is also very useful. Regarding the frequency lists, those from Twitter and Facebook are by far the best. I must admit

Table 1: Importance scores (LightGBM gain)

that I do not know why the length of the L1 source (SourceL) is relatively important for Mandarin. At first glance, I thought it would be the length of the target text, as is the case with German.

When the Baseline is introduced into the model (*Dev* versions), it is almost always the best predictor. This is particularly true for the Open track, where it performs much better than the other predictors. In general, there is little difference between the two tracks, which is to be expected since the scores to be predicted are the same and the predictors are the same, except for the Baseline, which was not trained on the same data. Finally, the differences observed between the three L1s do not appear to be very significant.

5.3 Spearman rank correlation with the lexical complexity score

The importance scores presented in Table 1 are not independent. An index that is relatively effective at predicting lexical complexity may be masked by

the presence of other, more effective and strongly correlated indices, such as frequency norms derived from different corpora.

To assess the significance of each feature set independently, Table 2 presents the Spearman rank correlation (ρ) between the features and the score to be predicted, for the ten most highly correlated feature sets. Only the best feature of each set is taken into account. Rank correlation is used because it is insensitive to monotonic transformations, as is the gradient boosting decision tree approach, and is therefore not affected by the choice of one monotonic transformation over another (e.g. logarithmic, square root, inverse, or even highly implausible ones).

In each of the three L1s, the correlations of the best predictors are very similar. However, these correlations are significantly higher in Mandarin than in the other two languages. This result may be linked the fact that most teams performed significantly better in the official competition results for Mandarin than for Spanish and German. The excellent quality of Oxford is particularly evident in Mandarin, where it is the most correlated feature with vocabulary complexity.

LexCom also warrants special attention. Table 1 shows that this predictor does not make a significant contribution to model performance. Correlation analysis, however, reveals that for all three L1s, it is the second-best predictor and very close to the best. Another notable observation is that Sim12 is clearly not among the most highly correlated predictors for Spanish, yet it is the most useful feature for the model in the *Nonly* version and the second most important in the *Dev* versions. This is likely because it provides information distinct from the other features, almost all of which are linked in some way to frequency in the language. Regarding frequency indices, we observe that frequencies derived from Google Ngrams are never among the top ten predictors, nor are those from Usenet and the BNC. Further analysis would be valuable to understand the reasons for these poor performances.

5.4 Analysis of the most significant errors

The previous section identifies the most useful features for each L1. However, this should not obscure the fact that the proposed system makes relatively significant errors. The aim of this section is to gain insights into potential patterns found in poorly estimated items. To this end, I have extracted, sep-

Spanish		German		Mandarin	
Feature	ρ	Feature	ρ	Feature	ρ
Glasgow	0.48	BKL2	0.49	Oxford	0.63
LexCom	0.48	LexCom	0.48	LexCom	0.61

BasicV	0.32	BasicV	0.32	HALfr	0.50

Table 2: Spearman rank correlation (Rho)

arately for each L1, the 20 items with the highest absolute error values.

Firstly, there is very little overlap between the three L1s, as over 90% of the items are specific to a single L1. The most significant errors are almost equal to 5, whereas the scale of the judgements to be predicted ranges roughly from -6 to +5.

In 90% of these 60 items, the error is an underestimation of the item’s difficulty. A detailed analysis of the most problematic items shows that the issue often arises because the target is a relatively rare usage of a word well-known in another grammatical category. Examples include ‘clear’ used as an adverb, which usually appears in idiomatic expressions; ‘received’ used as an adjective meaning ‘generally accepted’; ‘very’ used as an emphatic adjective (‘the very nature of’); and ‘dinning’ used as a noun.

Among the most serious errors is also an item in which the word from the source language does not appear verbatim in the Spanish sentence provided in context: *6842,lamp,noun,l____,faro,Se encendió un foco de forma automática.,-2.171975368*

6 Conclusion

The aim of this study was to propose features primarily derived from word frequency lists, lexical norms, and psychometric data that could compete with more complex approaches, such as those based on precomputed embeddings, in the British Council’s Shared Task at BEA 2026. Although the proposed system outperformed the Baseline, it performed significantly worse than several other systems in predicting English vocabulary complexity. It therefore appears necessary to conclude that “the glass is rather half empty than half full”. Several limitations of this study, which also represent avenues for future research, are outlined in the fol-

lowing section.

Limitations

As this study focuses on feature sets that do not fall within the scope of deep-learning approaches, and as I lack expertise in this field, I used the out-of-the-box baseline to improve efficiency and, above all, to determine whether the proposed features provide information that could be useful for these newer and more complex approaches. This is undoubtedly a weakness of the study. For example, there is no basis for claiming that the features which appear beneficial for the model would also be so if more effective LLMs had been used.

Another limitation of the study is that I approached the task as a challenge focused on achieving performance, rather than as a scientific problem to be understood. This is evident in the inclusion of features such as the Arousal dimension, whose conceptual relevance to the problem at hand appears very low, but which preliminary analyses indicated improved performance. The *Extended Knowledge-based Vocabulary Lists Dataset* is so rich that it would have warranted a study aimed more at understanding.

Despite this emphasis on performance, the proposed features (see Section 3) focus almost exclusively on the target word in English. The translation of the target word into the L1 and the L1 sentence featuring the word in the relevant context are not used. Therefore, I do not know whether they would have led to better performance. However, it should be noted that these features are considered by the Baseline, whose prediction is used as a feature by the *Dev* version of the system.

A fourth limitation I wish to highlight is that I did not use the ablation approach to assess the independent contribution of each set of features to overall performance. Ablation is undoubtedly a powerful method. There were two reasons why I did not proceed in this way. Firstly, this would have required restarting the parameter optimisation procedure, thus consuming significant computational resources. Secondly, the few trials conducted showed that the models optimised on the development set were not the best-performing ones on the test data. Consequently, interpretation of the results would have been overly uncertain.

Acknowledgments

The author wishes to thank the organizers of this shared task for putting together this valuable event. He is a Research Associate of the Fonds de la Recherche Scientifique - FNRS (Fédération Wallonie Bruxelles de Belgique).

UGA Threshold at BEA 2026 Shared Task 1: Predicting Vocabulary Acquisition Difficulty with Hand-Crafted SLA-Based Features

Emma Dalbo

University of Georgia
emma.dalbo@uga.edu

Abstract

This paper describes a feature-based system submitted to the BEA 2026 Shared Task on Vocabulary Difficulty Prediction (closed track). The system models vocabulary difficulty for English learners using linguistically motivated features capturing frequency, cross-linguistic similarity, phonological and orthographic complexity, and semantic properties, supplemented by multilingual embeddings (reduced via PCA). Multiple regression models were evaluated using cross-validation, with final predictions generated from ensemble and single-model configurations per language.

The system achieves competitive performance across all three L1 groups (German, Spanish, and Chinese), outperforming the XLM-RoBERTa baseline in seven of nine runs in terms of RMSE, with the strongest gains observed for Chinese and more modest improvements for Spanish. An ablation study further demonstrates that frequency and cross-linguistic similarity factors contribute most substantially to predictive performance, with effects varying across L1s. These findings highlight the role of interpretable linguistic features in modeling vocabulary difficulty in an L1-aware setting.

1 Introduction

The BEA 2026 Shared Task on Vocabulary Difficulty Prediction asks participants to predict how difficult it is for second language (L2) learners of English to recall a target word in a controlled lexical access task. In each item, learners were presented with a sentence in their native language (L1), a translation equivalent in that L1, and a partial spelling clue for the English target word (consisting of the first letter followed by underscores for hidden letters). The target variable for this task is a GLMM-derived difficulty score computed from large-scale learner response data, with more negative values indicating greater difficulty.

Vocabulary knowledge is a central component of language proficiency, underpinning both comprehension and production. Accurately estimating vocabulary difficulty is therefore critical for applications such as adaptive testing, curriculum design, and personalized learning. Prior work in lexical complexity prediction has primarily focused on general-language audiences (North et al., 2023), with comparatively less emphasis on modeling learner-specific factors such as L1 background. However, cross-linguistic transfer, frequency effects, and psycholinguistic properties of words are known to influence acquisition in systematic ways.

The shared task extends this line of work by framing vocabulary acquisition as an L1-aware regression problem. Separate datasets were provided, representing German (de), Spanish (es), and Chinese (cn) learners respectively. Submissions were evaluated using root mean squared error (RMSE) and Pearson correlation against held-out test data.

The baseline system provided by task organizers fine-tuned XLM-RoBERTa-base on concatenated raw input fields, treating the problem as a sequence regression task without explicit feature engineering. In contrast, this work adopts an approach grounded in theoretically motivated factors from second language acquisition (SLA) and psycholinguistic research, using interpretable hand-crafted inputs in vocabulary difficulty prediction, rather than a complex fine-tuned black box-style model. This system participates in the closed track, which restricts the use of external training data and prohibits large language models. All external resources, libraries, and implementation details are documented in the accompanying supplementary material.

2 System Description

2.1 Task Formulation

Each item in the given dataset includes the following fields: a unique item identifier, the learner's

L1, the English target word and its part of speech, a partial spelling clue, an L1 translation equivalent, an L1 sentence context, and a GLMM-derived difficulty score. The task is framed as supervised regression over this data.

Each language-specific training set contains 6,091 items, with 677 development items and 748 test items. Models are trained separately for each L1.

2.2 Preprocessing

Several preprocessing steps are applied prior to feature extraction. Parenthetical content in both the L1_source_word and L1_context fields is removed using regular expressions, since these represent annotations rather than learner-visible input. When multiple L1 translation equivalents were provided in a comma-separated list, only the first item is used for feature computation.

The L1 context is normalized by removing extra whitespace, and the English target word is lowercased for all lookup-based feature computations. Additional intermediate fields (e.g. cleaned L1 context and processed L1 source forms) are constructed to support feature extraction.

2.3 Feature Engineering

The feature set is designed to prioritize interpretability and is motivated by established findings in SLA and psycholinguistics. These features aim to capture multiple dimensions of vocabulary difficulty, including exposure frequency, cross-linguistic similarity, phonological complexity, and semantic properties. All features are computed from the provided data and publicly available resources. The selected feature groups reflect a balance between theoretical motivation and feasibility under the constraints of the shared task setting.

Frequency-based features. Word frequency is a well-established predictor of lexical acquisition (Ellis, 2002). Frequency scores (Zipf scale) are computed for both the English target word and its L1 translation using the wordfreq library. A feature representing the difference between the two frequencies is also included to capture relative familiarity across the languages.

Cross-linguistic similarity. Cross-linguistic similarity can facilitate vocabulary acquisition through transfer effects, particularly in the case of cognates (Otwinska and Szweczyk, 2017). This is modeled using multiple similarity measures between

the English target word and the L1 translation, including Levenshtein distance, normalized edit distance, and character overlap ratio. These features approximate orthographic proximity between L1 and L2 forms.

Phonological and orthographic complexity.

Aspects of complexity, including phonological and orthographic, influence both perception and production difficulty (Rosa and Eskenazi, 2011). Features include syllable counts, grapheme–phoneme relations, and phonetic complexity measures. Additional features were built to capture consonant and vowel cluster counts, as well as maximum cluster lengths both graphemically and phonemically; this provides a proxy for articulatory and spelling complexity.

Morphological features. Morphological transparency facilitates vocabulary learning, particularly through the presence of common affixes (Carlisle, 2000). We captured this phenomenon through binary indicators of the presence of common prefixes and suffixes, as well as an aggregate affix count.

Contextual features. Contextual information is derived from the provided L1 sentence. Features include sentence length (in words and characters) and both the absolute and relative positions of the target word within the sentence. These features serve as rough proxies for contextual importance and positional prominence. We did not incorporate richer contextual representations such as syntactic structure or dependency-based features due to time and complexity constraints. While part-of-speech information for the target word is included via one-hot encoding, broader contextual linguistic features were not explored.

Linguistic metadata. Part-of-speech information for the English target word is one-hot encoded, allowing the model to capture systematic differences in difficulty across part-of-speech categories. L1 identity is also one-hot encoded, though final models are trained separately per language, effectively eliminating the contribution of this feature.

Semantic features. Concreteness has been shown to influence word learnability (Paivio and Begg, 1971; Brysbaert et al., 2014). We use Brysbaert et al.’s concreteness norms to encode this dimension. Words not present in these norms are assigned the dataset mean as a fallback estimate.

Embedding features. Dense multilingual embeddings are generated for both the English target word and the L1 translation using the paraphrase-multilingual-MiniLM-L12-v2 sentence-transformer model. To reduce dimensionality and mitigate overfitting, Principal Component Analysis (PCA) was applied separately to English and L1 embeddings, retaining 50 components each. This dimensionality was selected based on development set experiments as a balance between preserving variance and limiting feature dimensionality, while preventing embedding features from dominating the interpretable feature set. A cosine similarity score between the original embeddings is also included as a feature, representing semantic proximity between the forms.

2.4 Feature Assembly

All feature groups are concatenated into a single feature matrix. Boolean features are converted to integer values. Missing values are filled using column medians computed on the training set (to avoid data leakage), and feature columns are aligned across training, development, and test sets to ensure consistency. The modeling approach intentionally emphasizes relatively simple regression models and interpretable feature design, prioritizing transparency over architectural complexity.

3 Experiments

3.1 Models

Six regression models were evaluated: Ridge regression, SGD regression with ElasticNet regularization, Random Forest, Gradient Boosting, Extra Trees, and a Multilayer Perceptron (MLP), all implemented using scikit-learn.

Each model was wrapped in a pipeline that utilized standard scaling, and hyperparameters were tuned using grid search with 10-fold cross-validation on the training set, optimizing for RMSE. Model selection was performed based on evaluation on the development set.

3.2 Submissions

For all three languages, three runs were submitted:

- **Run 1:** an ensemble formed by averaging the predictions of the four best-performing models on the development set (Gradient Boosting, Extra Trees, Ridge regression, and Multilayer Perceptron), selected based on lowest RMSE.

- **Run 2:** a Gradient Boosting model with fixed hyperparameters.

- **Run 3:** a two-model ensemble combining Gradient Boosting with a secondary model (Extra Trees for Spanish and Chinese; MLP for German).

Final models were retrained on the combined training and development sets before generating predictions for the test set.

4 Results

Table 1 reports the system’s performance on the test set for all three closed-track languages, alongside the organizer-provided XLM-RoBERTa baseline.

The system matches or outperforms the XLM-RoBERTa baseline in several conditions: it achieves lower RMSE for all Chinese and German runs and for the ensemble run in Spanish, while Pearson correlation results are more variable across languages. Improvements are most pronounced for Chinese, where all runs outperform the baseline by a substantial margin. For German, all runs achieve a lower RMSE than the baseline. For Spanish, only the ensemble run makes an improvement over the baseline.

Pearson correlation results are more variable across languages. While the system exceeds the baseline’s Pearson r for Chinese and one German run, it falls below on Spanish. This suggests that although the system reduces absolute prediction error, the baseline preserves relative ordering of item difficulty more consistently on the Spanish dataset. Performance differences between runs are relatively small, indicating that predictions are relatively stable across model configurations.

5 Analysis and Discussion

The results suggest that a substantial portion of the difficulty signal in this dataset is captured using linguistically interpretable features. Factors such as word frequency, concreteness, grapheme-phoneme correspondence, and cross-linguistic orthographic divergence contribute substantially to predictive performance.

Performance is strongest for Chinese, which may reflect the greater typological distance between Chinese and English. In this case, cross-linguistic similarity features provide clearer signals, and English word-level properties may dominate prediction. For Spanish and German, where cognate rela-

L1	Run	RMSE	Pearson r
Spanish	1	1.236	0.758
	2	1.268	0.740
	3	1.261	0.746
	Baseline	1.257	0.765
German	1	1.176	0.757
	2	1.181	0.753
	3	1.166	0.761
	Baseline	1.258	0.773
Chinese	1	1.031	0.791
	2	1.072	0.770
	3	1.061	0.778
	Baseline	1.140	0.753

Table 1: Performance on the test set across all languages and submissions, including the Baseline for reference. Lower RMSE is better; higher Pearson r is better.

tionships and shared morphological structures are more common, difficulty patterns may be more variable and harder to capture with the current feature set.

To better understand feature contributions, a small-scale ablation study was conducted using the Gradient Boosting model, which was consistently high-performing across languages. Feature groups were removed one at a time, with models retrained on the training set and evaluated on the development set.

Table 2 presents the results of feature-group ablations across all three languages. Overall, frequency-based features were the most critical, with their removal resulting in the largest performance degradation for all languages. This effect was most pronounced for Chinese ($\Delta\text{RMSE} = +0.88$), suggesting that frequency plays an especially dominant role for Chinese learners where limited cross-linguistic overlap makes exposure-based factors more central to vocabulary acquisition.

Cross-lingual similarity features also contributed substantially, particularly for German ($\Delta\text{RMSE} = +0.45$). The effect was smaller for Spanish and Chinese ($\Delta\text{RMSE} = +0.11 / +0.07$).

Embedding-based features provided consistent but secondary improvements across all languages ($\Delta\text{RMSE} \approx +0.18\text{--}0.21$), indicating that dense representations capture additional signal beyond handcrafted features but do not dominate model performance. In contrast, phonological and orthographic features contributed smaller gains, suggesting a more limited role in this dataset. These results should be interpreted as indicative rather than definitive, given the ablation’s limited scope.

These findings are broadly consistent with prior

work in SLA and psycholinguistics, while also highlighting the importance of L1-specific effects. However, they should be interpreted within the shared task context, where the objective is to approximate GLMM-derived scores rather than directly model learner acquisition processes.

A brief inspection of high-error items suggests that the model struggles most with low-frequency words and items with limited cross-linguistic similarity, where fewer reliable cues are available. Errors were also more pronounced for Spanish and German items involving partial cognates or morphologically related forms, where orthographic similarity does not consistently correspond to ease of acquisition. In contrast, performance for Chinese appears more strongly driven by frequency-based effects, with fewer ambiguous similarity patterns. These observations indicate that while the feature set captures general trends, it is less effective in cases where multiple competing factors influence difficulty.

Conclusion

This paper presented a feature-based system for L1-aware vocabulary difficulty prediction in the BEA 2026 shared task. The approach combines linguistically motivated features with standard machine learning regression models, achieving competitive performance across all three languages and outperforming the baseline in most conditions in terms of RMSE.

These results suggest that features grounded in established linguistic and psycholinguistic factors, particularly frequency and cross-linguistic similarity, capture a substantial portion of the predictive signal in this dataset. Ablation experiments further

highlight the relative importance of these feature groups and their variation across L1s.

While the modeling approach is intentionally straightforward, the findings contribute to a clearer understanding of how interpretable features relate to vocabulary difficulty in an L1-aware setting. Future work could explore integrating these features with contextualized neural models, improving language-specific representations, and extending the approach to more diverse learner populations.

Ethics Statement

This work uses shared-task data for research purposes. The system predicts aggregate item-level difficulty scores and is not intended for high-stakes decisions about individual learners. While the feature set emphasizes interpretability and theoretical grounding, results may reflect properties of the dataset rather than stable characteristics of learner populations.

Limitations

Several limitations should be noted. Due to computational and time constraints, the scope of model exploration and feature refinement was limited. Although an ablation study was conducted, further analysis could provide deeper insight into feature interactions and redundancy.

Some feature implementations relied on approximations. For example, Chinese syllable count and character length features assumed one syllable and 3 phonemes per character. Additionally, heuristic methods that were used for locating the L1 target word within the context may fail for highly inflected forms.

Context features used were relatively shallow and do not capture the syntactic structure or any deeper semantic relationships. The model also treats each item independently and does not account for individual learner variation past L1 identity.

Finally, the task itself involves predicting GLMM-derived scores, rather than directly modeling inherent word difficulty for human learners. This means the system is approximating an existing statistical model, rather than core learner difficulty patterns.

Acknowledgments

The author thanks Dr. Ryan Ka Yau Lai for his guidance and support, as well as the BEA 2026 organizers and reviewers for their feedback.

TeamXBC at BEA 2026 Shared Task 1: How AI (and I) won the shared task: Vibe and agentic coding solutions for practical machine learning problems

Xiaobin Chen

Universität Tübingen

xiaobin.chen@uni-tuebingen.de

Abstract

The paper describes how the author used AI coding agents and a technique called *vibe coding* to successfully tackle the BEA 2026 shared task on vocabulary difficulty prediction. Three sets of predictions (runs) were submitted to the competition, corresponding to three experiments the author ran by giving the coding agent different levels of agency: (1) a one-off solution fully planned and implemented by the AI, (2) an AI self-determined iterative process that ran for 24 hours, and (3) a collaborative human-in-the-loop process where solutions were discussed between the author and the AI. Competition results showed that the collaborative mode delivered the best performance, demonstrating that at the current stage domain expert input and decision making are important and necessary for vibe coding solutions to practical machine learning problems.

1 Introduction

First and foremost, it should be acknowledged that we (AI and the author) have not “won” the top places for both tracks and all the three languages. However, our best performing models for the open track did reach the third place consistently. Table 1 summarizes the ranks and relative improvement over the baseline of our best runs based on the official results summary¹. On average, our best runs across the tracks achieved 20.3% RMSE improvement and 11.2% Pearson correlation gains over the baseline. AI agents, especially coding agents were heavily used in the process of the experiments through a technique called *vibe coding*, first coined and made popular by the AI researcher and influencer Andrej Karpathy.

In this paper, three different ways (corresponding to the three runs submitted for competition)

coding agents were used to tackle the shared task will be described. The study shows that vibe coding with AI agents can democratize machine learning (ML) and greatly increase the efficiency of ML experiments. Coding agents can also function as collaborators and instructors that help with brainstorming, discussion, and human learning.

2 The Shared Task

The first language (L1) aware vocabulary difficulty prediction shared task concerns the prediction of the difficulty levels of second language (L2) English words to learners of three different L1s: Spanish, German, and Chinese. Word difficulty is defined as the degree to which L2 learners of specific L1s are able to correctly spell out the L2 word given its L1 translation and an example sentence of its use in the L1 (Laufer and Goldstein, 2004). An example test item for Spanish learners of English is as follows:

Vivo en una casa grande que tiene tres
dormitorios.
casa
h _ _ _ _

The dataset was adapted from earlier studies Schmitt et al. (2021, 2024) in which more than 100,000 crowd workers submitted over 3.3 million responses to 7,516 vocabulary test items. Each test item corresponds to one English word and contains three L1 variations. Therefore, three difficulty values can be calculated for the three L1s, estimating how difficult an English word is for learners of the corresponding L1s. The difficulty values in the dataset were calculated by fitting random-item-random-person (RPRI) Rasch models (De Boeck, 2008) with the generalised linear mixed model (GLMM) framework (Dunn, 2024). Data for 748 items were withheld as a test set for evaluation of the submissions. The training and development sets contained 6,091 and 677 items respectively.

Table 1: Performance of TeamXBC’s best-performing runs across the two shared-task subtracks and three languages. Languages: ES = Spanish, DE = German, CN = Chinese. Δ columns show relative improvement over the baseline for RMSE (reduction) and Pearson r (increase).

The shared task is essentially a regression problem with the test items as predictors and the continuous GLMM scores as outcomes. Participants could submit their predictions to the *closed* and/or *open* subtracks, the former restricting the use of training data to the corresponding L1 subset and publicly available Transformer models or linguistics databases, while the latter allows maximum flexibility on the use of datasets and external resources, including large language models (LLMs). A previous study by Skidmore et al. (2025) attempted the task by fine-tuning Transformer-based models, whose performance was used as baselines of the shared task (see Table 1).

It is not difficult to envision the value of vocabulary difficulty prediction models on L2 learning and teaching research and practice. If successful, such models will be useful for custom content creation, computerized adaptive testing, and personalized learning. They may also play important roles in applications such as essay scoring, proficiency assessment, readability assessment, test design, and psycholinguistic experiment on vocabulary processing (Skidmore et al., 2025).

3 Vibe Coding and Agentic Machine Learning

As an intelligent computer assisted language learning (ICALL) researcher, the author has been working with various natural language processing and ML tools for many years. However, the accelerating emergence of large number of new technologies, tools, and research methods still feels overwhelming, although they often offer exciting opportunities for new research. Because of the same reason, collaborating with computational and ML experts is often seen among researchers of other

domains that require the technological expertise (Lee and Huh, 2025). The recent emergence of a technique called “vibe coding” supported by advanced coding agents such as Claude Code, OpenAI Codex, and Github Copilot has made it much easier for researchers with less computational and ML backgrounds to make use of the new technologies.

Vibe coding is a term coined by the AI researcher Andrej Karpathy² to describe a way to create computer programs by specifying the requirements in natural language to an AI coder and allowing it to generate computer code automatically. It essentially adds a semiotic layer to traditional coding (Yuan et al., 2025; Yin and Xiao, 2025) where the programmer had to write structured instructions following rigid syntax of the programming language. A more advanced version of vibe coding is called agentic coding which features AI agents capable of planning, executing, and verifying coding tasks by decomposing the requirements and automatically using available tools in the environment (Kumar et al., 2025; Roychoudhury et al., 2025). Although agentic coding can be viewed as giving the coding agent higher levels of agency, in reality, the distinction between vibe coding and agentic coding is blurry. Therefore in the study, we will stick with the former term. Vibe coding lowers the barrier into programming and accelerates software creation. Using it to create machine learning programs could therefore address the issue of lack of technological expertise from domain experts. To date, mentions of vibe coding in research, especially in

²He is also an OpenAI co-founder and former AI director at Tesla. The original Tweet where the term was first used can be viewed at <https://x.com/karpathy/status/1886192184808149383>

ML or deep learning studies have been rare (Lee and Huh, 2025).

4 The Experiments

In the present study, vibe coding was employed to tackle the BEA 2026 shared task on vocabulary difficulty prediction. It focuses on the following research questions (RQs).

1. Can vibe coding be used to solve real-life ML problems?
2. Does giving the coding agent a higher level of agency help with solving practical ML problems?
3. What is the researcher’s perception of working with coding agents as research collaborators?

It is interesting to see how the AI coded solutions perform compared to the other submissions to the shared task (RQ1). For vibe coding, there could be more or less human involvement. On one extreme, the coding agent can be instructed to run indefinitely or until a certain performance goal is achieved: design a solution, run it, look at the result, improve the solution and iterate. On the other extreme, the researcher may suggest a solution, ask the agent to code it, run the solution, look at the result, think of an improvement and ask the agent to update the code and iterate until a satisfactory result is achieved. On the middle ground, the researcher and the agent may work together to discuss the solution and results to come up with possible improvements together, mimicking how human collaboration occurs. In other words, more or less human involvement would correspond to more or less AI agency as asked in the second RQ.

Given that three runs of predictions can be submitted, in light of the research questions, three corresponding experiments were devised with vibe coding in Claude Code (Opus 4.6) as described below. The coded experiments were run on a university High-Performance Computing (HPC) cluster with NVIDIA H100 GPUs.

Run 1: One shot fully agentic solution. The agent was given the URL of the shared task home page and instructed to understand the task and create the experiment code and SLURM scripts for submitting the training tasks on the HPC. Appendix A lists the detailed prompt.

Run 2: 24-hour iterative agentic solution. This run follows Karpathy’s idea of auto research³ by providing the coding agent with a research program in which the task, the environment setup, experimentation constraints, evaluation criteria, and looping requirements are specified. The experiment was kicked off with one prompt: “Take a look at *program.md* and let’s start the experiment.” The full research program used for this run can be found in Appendix B. The agent was instructed to run the iterations indefinitely, but for the current experiment the process was stopped after about 24 hours.

Run 3: hybrid human-in-the-loop collaborative solution. In this experiment, the coding agent was treated as a collaborator and ML expert with whom the author could discuss the potential solutions. With domain expertise, the author suggested some solution plans and asked for feedback and suggestions from the agent. When the agent’s suggestions were taken, the plans were updated and agreed upon between the author and the agent. They were then implemented and the results were discussed again for improvement. The experiment encompasses multiple sessions over a few days until the final models had given satisfactory performance on the development set.

5 Results

5.1 Run 1

Given the prompt in Appendix A, the coding agent designed a six-stage experiment to progressively explore how to achieve the best models.

Stage 0: Feature-based baseline. Gradient boosting models trained on hand-crafted features extracted via *wordfreq* and NLTK. They served as a non-neural lower bound and ran locally without GPUs. One joint model for the open track and three separate models for the closed track were trained.

Stage 1: Architecture search. Question asked: Is *XLM-RoBERTa-large* better than *mDeBERTa-v3-base* for this task? The winner of this stage was intended to be carried forward into Stage 2. The models were trained with learning rate LR=3e-5, 5 epochs, fp16, effective batch size 32 (batch=16 x grad-accum=2).

Stage 2: Hyperparameter search + closed track. Questions asked: What learning rate and epoch

³see <https://github.com/karpathy/autoresearch>

count work best for the winning architecture? Does it transfer to the closed track? The best hyperparameters found (LR=2e-5, 8 epochs) were applied for subsequent training.

Stage 3: Input format experiments. Question asked: Does the content or ordering of the input text affect predictions? Fixed architecture and hyperparameters at the Stage 2 best (XLM-RoBERTa-large, LR=2e-5, 8 epochs). Experimented on shifting instance component order, e.g. putting *en-target-pos* at the end, or putting L1 learner fields first compared to using an English-first (*en-target-word*; *en-target-pos*; *en-target-clue*; *L1-source-word*; *L1-context*) ordering.

Stage 4: Advanced training. Question asked: Can combining the best techniques, or training longer, squeeze out additional gains? Changes over Stage 3 included having stronger decay and more epochs.

Stage 5: Ensemble. After running the models trained in previous stages, ensemble models were trained with two methods: (1) weighted averaging: top 5 models by Pearson, weighted by their performance on the development set, and (2) stacking: a meta-learner trained on the development predictions of the top 5 models.

In all, 15 models were designed and predictions for 14 models were successfully obtained after running the generated code on the HPC. The best overall performing model with the lowest average RMSE across the three L1s trained on the training set and evaluated on the development set was a Transformer model fine-tuned for 8 epochs on *XLM-RoBERTa-large* with a batch size of 16, a learning rate of 2e-5, a warmup ratio of 0.1, and weight decay of 0.1, using the AdamW optimizer and an English first component order *en-target-word*, *en-target-pos*, *en-target-clue*, *L1-source-word*, *L1-context*. For different tracks and L1s, slightly different hyperparameters were used in the best performing models. These models were retrained with both the training and development sets to predict on the test set for submission. Their performance on the test set is listed in Table 2.

Through the experiment, it was learned that:

- Model scale was the biggest driver of improvement. Switching from *XLM-RoBERTa-base* (baseline) to *XLM-RoBERTa-large* delivered the largest single gain, roughly +10% RMSE

improvement (decrease) across all tracks and L1s.

- Open track models outperformed closed track models. The joint cross-lingual open model consistently achieved better Pearson scores than L1-specific closed models. Training on all three L1s simultaneously appears to provide useful cross-lingual signal, echoing the findings of Skidmore et al. (2025).
- Moderate learning rate and epochs generalized best. Among the hyperparameter experiments, LR=2e-5 with 8 epochs performed best or near-best across all L1s. Lower learning rate with more epochs was competitive but slightly weaker. Extended training to 12 epochs hurt performance, suggesting the model overfit beyond 8 epochs.
- Part-of-speech (POS) tags did not help. Adding POS information showed no improvement on any L1—Pearson r was slightly lower in all three cases.
- Advanced training techniques were largely ineffective. Layerwise LR decay helped for DE but hurt ES. Combining it with a higher LR degraded performance across the board, performing worse even than the basic large model. These techniques did not reliably improve over careful standard fine-tuning.
- L1 Chinese was consistently the easiest to predict and Spanish the hardest, again corroborating Skidmore and colleagues’ (2025) findings.

5.2 Run 2

For Run 2, the coding agent was instructed to run the auto research procedure in Appendix B on the HPC. It ran for about 24 hours before being manually stopped. It made 72 commits and evaluated 405 unique model configurations in three phases.

Phase 1: Neural base models. Starting from the model used for the baseline *XLM-RoBERTa-base*, the agent systematically explored:

- Backbone upgrades: by using *XLM-RoBERTa-large*, the performance immediately jumped to 0.83–0.84 on Pearson correlation

Track	L1	RMSE			r			Ranking	
		Baseline	Run 1	Δ RMSE	Baseline	Run 1	Δr	Team	Submission
Closed	ES	1.257	1.192	+5.2%	0.765	0.816	+6.7%	16/21	36/56
Closed	DE	1.258	1.114	+11.4%	0.773	0.837	+8.3%	11/20	25/53
Closed	CN	1.140	0.968	+15.1%	0.753	0.851	+13.0%	10/21	23/53
Open	ES	1.198	1.114	+7.0%	0.783	0.832	+6.3%	7/8	20/24
Open	DE	1.166	1.042	+10.6%	0.786	0.848	+7.9%	7/8	20/24
Open	CN	1.034	0.943	+8.8%	0.804	0.864	+7.5%	7/9	20/26

Table 2: Performance of TeamXBC Run 1 compared to the baseline, with competition rankings

- Hyperparameter tuning: using different learning rates (1e-5, 2e-5, 5e-6), epochs (5–15), weight decay, warmup ratio, batch sizes (32, 64)
- Alternative architectures: tried *RemBERT*, *Multilingual-E5-large*, and *mDeBERTa-v3-base*.
- Training tricks: cosine learning rate schedule, Pearson correlation loss, gradient accumulation, layerwise LR decay, model soups, multi-seed averaging, English-first feature ordering, L1-code as a feature, etc.

The best single neural models in this phase achieved Pearson correlations of 0.855 and 0.838 on the open and closed tracks respectively.

Phase 2: Ensemble stacking. After some models have been trained in Phase 1 the agent pivoted to using trained neural model predictions as features for stacking and explored the following options:

- Ridge regression over base model outputs achieving 0.856 on Pearson correlation
- Polynomial features (quadratic, cubic, quartic) resulting in progressively higher performance but tend to overfit on development set
- Support Vector Regression stacking (various C values) achieving 0.858 Pearson correlation
- Gradient Boosted Trees as meta-learner achieving 0.865 Pearson correlation
- Honest out-of-fold stacking to avoid leakage with confirmed honest ceiling at 0.966

Phase 3: Deep cascade meta-stacking. The deep stacking approach experimented in this phase achieved major breakthroughs on the development set. A three-level stacking of base, ensemble, and ridge models delivered an average Pearson’s correlation of 0.96 (likely overfitting). It was also found

that adding *RemBERT* predictions improved the ensemble ceiling, but *mDeBERTa-v3-base* did not help.

For the final submission, again the best performing models were retrained with both the training and development sets and predicted on the test set. The final open model was a 3-level stacking cascade model integrating 36 *XLM-RoBERTa-large* and 3 *RemBERT* base models. The close track models were single *XLM-RoBERTa-large* based models with different hyperparameter configurations. Table 3 shows the test performance of the final models and their rankings in the competition. It can be observed that Run 2 had significant improvement over Run 1, showing that coding agents for ML is capable of self-iterative improvement when given more agency.

5.3 Run 3

This is a hybrid human-in-the-loop process in which the solutions were discussed between the author and the coding agent. With limited expertise in ML and mostly traditional feature engineering based ML, the author started by suggesting to train some feature-engineered regression models. The coding agent agreed that such models could be competitive, but it also predicted that they would not outperform the Transformer baselines. Therefore, Ridge and XGBoost models were trained with linguistic features such as word frequency, word length, POS tags, L1 context length, Levenshtein string edit distance ratios between the L1 and L2 target words, etc. Table 4 compares the performance of the traditional regression models against the baseline on the development set, confirming the coding agent’s predictions.

Building on these results, the author proposed integrating the engineered features into the

Table 4: Development set performance of traditional models vs. XLM-RoBERTa-base fine-tuned baseline.

baseline models to construct some hybrid models. The coding agent suggested and implemented 4 strategies to combine feature engineering with neural models:

- Ensemble: using weighted average of the predictions from both the XGBoost and the *XLM-RoBERTa-base* fine-tuned models
- Feature injection: concatenating the feature values to the Transformer’s vector before attaching the regression head
- Stacking: training a meta learner with the output of the traditional and neural models
- Features as extra tokens: prepending feature values as text to the transformer input

The ensemble models turned out to have the best performance as shown in Table 5. Feature injection and features as extra tokens gave marginal gains only. The stacking strategy resulted in second best RMSE but lower Pearson’s correlation, meaning that the strategy is better at predicting the magnitude of scores but worse at identifying the pattern of variation.

Looking at the results from the previous steps, a clear direction to further explore and improve the models’ performance was to try to boost the

performance of the neural models because they contributed more than the traditional models in the ensembles. Therefore, the coding agent was asked to suggest some bigger base models for fine-tuning. It did, also suggested a few other base models such as the decoder only Qwen models and different fine-tuning methods like QLoRA. Six models were successfully trained and their performance is listed in Table 6.

The coding agent was also instructed to try using the embeddings from OpenAI’s embedding API, which is a commercial service to be compared with the open source models used so far. But the performance of the resulting models was rather unimpressive—both the large and small embeddings performed significantly worse than the baseline. The coding agent was then prompted to further improve on the trained models. It suggested new ensembles, larger Qwen models, and using labeled input format as shown below for fine-tuning:

Default format: casa </s> Vivo en una casa grande que tiene tres dormitorios. </s> h _ _ _ </s> house

Labeled format: source: casa context: Vivo en una casa grande que tiene tres dormitorios. clue:

Table 6: Development set performance of larger and alternative architecture models with improvements over the baseline in parentheses. Bold indicates the best result per column.

h _ _ _ target: house

It turned out that the labeled input models fine-tuned on *Qwen-7b* had the best performance after the new ensemble models that require a sophisticated combination of other trained models. But the differences between them were only at the 1% level. Considering the resources and complexity required for training the ensemble models, as well as the practical applications, it was decided that the final submission for Run 3 should be based on the best performing individual models, namely the *XLM-RoBERTa-large* base model fine-tuned separately per language for the close track and *Qwen2.5-7B* with QLoRA and labeled input format trained jointly on all three L1s for the open track. Table 7 shows their performance on the test set.

In all, Table 8 summarizes the performance of all the three runs.

6 Discussion

To answer RQ 1, the experiments clearly showed that it is possible to vibe-code ML solutions to practical problems with the help of advanced coding agents (Claude Code in this case). The shared task already had a high baseline with Pearson's correlation coefficients ranging from 0.753 to 0.804 (See Table 1). However, the best agent-coded solutions in the study were able to push the boundaries by 7.6% to 13.0% in Pearson's r and 8.8% to 30.2% in RMSE. It is unclear if the other participating teams also used coding agents, but our AI coded solutions were ranked number 3 out of 10 participating teams in the open track. In the closed track, our submissions also had an average performance at around the fifty percentile. The results demonstrated that AI-supported vibe coding is able to deliver promising performance on real-life ML tasks.

RQ 2 concerns the level of agency AI agents should be given when solving practical ML problems. The three runs devised in the study gave the coding agent different levels of agency, from the first run's one-off full agency, via the second run's full agency and opportunities to learn from previous successes and failures in an iterative manner, to the human-in-the-loop half agency in the last run. Varying results have been obtained for the closed and open tracks (cf. Table 8).

The one-off agency run resulted in similar amount of improvement over the baseline for the both tracks. Giving the AI more agency and allowing it to iterate resulted in better performance

in Run 2 compared to Run 1. For Run 3, with the human in the loop, the resulting models were able to achieve the best performance among the three runs in the open track. On average, the Run 3 models improved Pearson's r by 12.8% and RMSE by 28.8%, which were significantly more than the other two runs with full AI agency. However, the L1 German and Spanish models performed unusually bad, although the development models seemed to have performed well. A later code review (also conducted by the AI) revealed that the DE and ES models actually failed to train in the last step before the submission. The final training was supposed to be done with both the training and development sets of the data, but the training logs showed non-improving losses across the epochs, e.g., DE epoch 1: loss=3.04 → epoch 2: 3.19 → epoch 3: 3.18 → epoch 4: 3.18 → epoch 5: 3.17, indicating training failures. A possible reason for the training failure was the re-use of previously saved training checkpoints, a coding bug that was not caught before the submission.

The results clearly showed that giving the AI more agency without human intervention did not necessarily improve the ML solutions. However, with human in the loop, i.e., when a domain expert worked collaboratively with a coding agent to discuss and implement the solutions, the resulting performance tends to be an order of magnitude better than the only-AI setup. Domain knowledge and human decision making played important roles in human-AI collaborations. The AI coders were also able to greatly improve the efficiency of experiments. Reflectively thinking, it would have taken the author countless hours to learn about the related ML concepts, base models, practical coding skills and ML libraries, as well as the use of HPC resources before the Run 3 solutions could be implemented manually and it is unclear if the results could be on par with the current solutions.

To RQ 3, the author's perception is that working with the AI in the shared task was a very enjoyable experience. It felt empowering because I would not have been able to do it within a period of weeks by myself. It also saved me the time and efforts to involve a potential ML expert in the project. In general, it offers a satisfactory solution without much complexity.

Track	L1	r	Δr	RMSE	Δ RMSE	Ranking	
						Team	Submission
Closed	CN	0.839	+11.4%	1.006	+11.8%	12/21	27/53

7 Conclusion

The study demonstrated the viability of vibe coding ML solutions to real-life education problems. The three experiments giving the coding agent different levels of agency showed that at the current stage, the human-in-the-loop approach in which a domain expert worked with an AI agent collaboratively could result in the best solution. In other words, human and AI agencies are both important contributors of success. By adding a semiotic layer enabling the use of natural language for programming, vibe coding is democratizing computational technologies for researchers from domains other than computer science and ML. Even for experienced computer experts, AI coders are also likely to greatly increase their work efficiency and productivity. Future research is encouraged to further explore the role of AI in scientific work and how to better make use of it to improve and accelerate scientific discoveries.

8 Limitations

The study was conducted with one coding agent and on one ML task. Therefore, the generalizability of the findings should be taken with a grain of salt. The shared task was clearly defined with structured

datasets. Code for establishing the baseline was readily available, providing a good starting point and program structure for further experiments with the coding agent. Real-life ML tasks often come with messy and unstructured data, lack of gold-standard data for training and validation, as well as no previous successful implementations. Hence it is unclear whether the AI coding agent will be able to handle the tasks as well as with the BEA shared task. Another limitation concerns the approach of vibe coding, which depends on coding models trained on data up to certain time points. As a result, they might not be aware of the latest ML methods, library and API updates, or things that did not appear in the models’ training data. The resulting solutions from the coding agents should therefore be carefully evaluated before they are put into production. Security and code quality should be validated by human experts to avoid problems such as the “failed to train” problem in Run 3. Last but not least, for the study, the potential leakage of solution information across the experiments could not be ruled out. The three experiments were conducted in separate Claude Code sessions with different local copies of the code repository. However, it is understood that Claude Code has a shared

memory across sessions for the same user account, which could result in the coding agent making use of information from the other experiment sessions. Therefore, it is unclear if the performance of the coding agent would remain the same when only one experimental approach was adopted.

9 Acknowledgments

The author would like to thank the anonymous reviewers for their valuable and detailed feedback on an earlier version of the paper.

A Agent prompt for one-shot experiment (Run 1)

You are to do a shared task with all information from the following webpage: <https://www.britishcouncil.org/data-science-and-insights/bea2026st>. Write a self-iterative script for experiments to achieve high performance on the shared task. The experimentation code may require fine-tuning large machine learning models. In that case, just write the code and make sure they can run correctly. I will run the model training on an HPC with GPUs. If the training of models does not require GPUs, you may run it locally. Try your best to get the best performance. Write a summary of what you have done when finished.

B Agent prompt for 24-hour iterative agentic solution (Run 2)

program.md

```
# autoresearch
```

This is an experiment to have the LLM do its own research.

```
## The task
```

You will be doing a Shared Task of Vocabulary Difficulty Prediction for English Learners. Details of the Shared Task can be found at <https://www.britishcouncil.org/data-science-and-insights/bea2026st>

The task is about predicting vocabulary difficulty values calculated from second language (L2) learners' responses to a vocabulary production test. The difficulty values are derived from a GLMM model and organized by respondents' native languages (L1s).

Essentially, you are given a dataset in the `data/` folder split into the `train` and `dev` sets. In each set, the data is further divided into subsets based on the L1 of the learners. The tested vocabulary items in each L1 subset is the same. The difference is only in the language the vocabulary test items is presented, i.e., a test item for a word is presented in Chinese if the respondent is an L1 Chinese speaker.

Your task is to predict the GLMM_score for each word in the list given information of the item used to test the production of the word. The information of the test item is specified in details in the `Data` section of the README.md file. You will design machine learning models to predict the GLMM_score.

Please note that for the shared task, there are two tracks:

- Closed Track: only data for specific L1 can be used for models targeting that L1. LLMs are not allowed in this track.
- Open Track: data from all three L1s can be used to fine-tune models. LLMs are also allowed for the task.

Setup

To set up a new experiment, work with the user to:

1. ****Agree on a run tag****: propose a tag based on today's date (e.g. `mar5`). The branch `autoresearch/<tag>` must not already exist --- this is a fresh run.
2. ****Create the branch****: `git checkout -b autoresearch/<tag>` from the current main branch.
3. ****Read the in-scope files****: Read these files for full context:
 - `README.md` --- repository context.
 - Access <https://www.britishcouncil.org/data-science-and-insights/bea2026st> for more information about the shared task.
4. ****Verify conda environment****: Follow the instructions in the Quick Start section of README.md to create the python environment for running the code. Check that `python run\_pipeline.py --evaluate` results in the expected output (the numbers do not need to be exactly the same as in README).
5. ****Check the results/ results_summary_dev.csv file****: Verify the baseline model performance is already included in the file. New model results will be appended here automatically during experimentation.

6. ****Confirm and go****: Confirm setup looks good.

Once you get confirmation, enter the experiment loop below --- do not pause again.

Experimentation

Each experiment runs within a ****fixed time budget of 60 minutes**** (wall clock training time, excluding startup/compilation). Some models can run on CPU; others require a GPU via slurm (see the experiment loop). You launch a run simply as: `python run\_pipeline.py --finetune --predict --evaluate --models\_to\_run <experiment\_model\_name>`.

****What you CAN do****

- Modify `finetune.py`, `models/model\_parameters.csv` - these are the only files you edit. Everything is fair game: model architecture, optimizer, hyperparameters, training loop, batch size, model size, etc. Add new models to maximize the GLMM_score prediction performance.
- Add new scripts, resources, new packages, dependencies as needed, but don't change the other existing files.

****What you CANNOT do****

- Modify `run\_pipeline.py`. It is read-only. It contains the steps for finetuning, running, and evaluating models.
- Modify the evaluation harness. The `evaluate.py` is the approach for evaluation of different models. It calculates Pearson's correlation and Root Mean Square Error between the models' predictions and the ground truth GLMM score.

****The goal is simple: get the highest Pearson's correlation and lowest RMSE.**** Since the time budget is fixed, you don't need to worry about training time --- it's always maximally 60 minutes. Everything is fair game: change the base model, ordering of context components, batch size, learning rate, weight decay, warmup ratio, epochs. Add any parameter as you see fit. The only constraint is that the code runs without crashing and finishes within the time budget.

****Simplicity criterion****: All else being equal, simpler is better. A small improvement that adds ugly complexity is not worth it. Conversely, removing something and getting equal or better results is a great outcome --- that's a simplification win. When evaluating

whether to keep a change, weigh the complexity cost against the improvement magnitude. A 0.001 pearson improvement that adds 20 lines of hacky code? Probably not worth it. A 0.001 pearson improvement from deleting code? Definitely keep. An improvement of ~0 but much simpler code? Keep.

****The first run**:** Your very first loop iteration should establish a trained baseline. Run ``python run_pipeline.py --finetune --predict --evaluate`` with the existing configuration as-is, before making any changes. (The ``--evaluate`` only run in Setup was just a smoke test to verify the environment; this first loop iteration performs actual training.)

Fine-tuning and evaluating a model

The ``run_pipeline.py`` script is the entry point for running models and evaluating their results. After designing a new model by adding model information in ``models/model_parameters.csv`` and adding the necessary training code, you may start to train the model by running ``python run_pipeline.py --models_to_run <new_model_name> --finetune --predict --evaluate``.

You are on a HPC environment, so if GPU is needed for training a model, you may create a slurm script to run the training script with a GPU. In the slurm job specification, put in ``#SBATCH --partition=h100-ferranti`` to gain access to the GPU. For the other requirements, such as CPUs, memory, or nodes, specify as needed. Make sure to check running status and errors periodically and act accordingly.

Write the training script to always stop after 60 minutes if it has not finished. Do not train for too long.

The experiment loop

The experiment runs on the dedicated branch created during setup (e.g. ``autoresearch/mar5``).

LOOP FOREVER:

1. Look at the git state: the current branch/commit we're on.
2. Tune ``finetune.py`` with an experimental idea by directly hacking the code. Use other base models if necessary. Try different model sizes, resources, and training parameters. Choose CPU or GPU as needed: use CPU (``python run_pipeline.py ...``) for

lightweight/fast models; use a GPU via slurm for large neural models that require a GPU to train within the time budget.

3. git commit.
4. Run the experiment (redirect everything --- do NOT use tee or let output flood your context):
 - CPU: ``python run_pipeline.py --models_to_run <new_model_name> --finetune --predict --evaluate``
 - GPU: create a slurm script (with ``#SBATCH --partition=h100-ferranti``) that calls the same command, then ``sbatch slurm_train.sh``
5. Read out the results: ``cat results/results_summary_dev.csv`` and see if the new model's performance is listed.
6. If the new model's performance is not listed, the run crashed. Check the python output or slurm ``out`` or ``err`` to read the Python stack trace and attempt a fix. If you can't get things to work after more than a few attempts, give up and git reset back to where you started.
7. If the run succeeded, store the newly trained model under ``models/`` alongside the baseline models.
8. If Pearson's correlation improved (higher), commit the results and think of new ways to improve further. If you have exhausted all options of that model, try a different model that can potentially work better.
9. If Pearson's correlation is equal or worse, git commit the trial (with details of what was tried and the result), then git reset back to where you started.

The idea is that you are a completely autonomous researcher trying things out. If they work, keep. If they don't, try something different while keeping a record of the failure. You are advancing the branch so that you can iterate. If you feel like you're getting stuck, you can rewind, but do this very sparingly (if ever).

****Timeout**:** Each experiment should take no more than 60 minutes total (+ a few seconds for startup and eval overhead). If a run exceeds 60 minutes, kill it and treat it as a failure (after committing with the failure reason, discard and revert).

****Crashes**:** If a run crashes (OOM, or a bug, or etc.), use your judgment: If it's something dumb and easy to fix (e.g. a typo, a missing import), fix it and re-run. If the idea itself is fundamentally broken, just skip it, log "crash" as the status in the commit message, and move on.

****NEVER STOP****: Once the experiment loop has begun (after the initial setup), do NOT pause to ask the human if you should continue. Do NOT ask "should I keep going?" or "is this a good stopping point?". The human might be asleep, or gone from a computer and expects you to continue working **indefinitely** until you are manually stopped. You are autonomous. If you run out of ideas, think harder --- read papers referenced in the task specification information pages and the code repo, re-read the in-scope files for new angles, try combining previous near-misses, try more radical architectural changes. The loop runs until the human interrupts you, period.

As an example use case, a user might leave you running while they sleep. If each experiment takes you ~60 minutes then you can run approx a total of about 10 experiments over the duration of the average human sleep. The user then wakes up to experimental results, all completed by you while they slept!

SAAKTH at BEA 2026 Shared Task 1: L1-Aware English Vocabulary Difficulty Prediction with Hybrid Transformer and Psycholinguistic Features

Abstract

This paper presents team SAAKTH’s system for the BEA 2026 Shared Task on Vocabulary Difficulty Prediction (Closed Track). We address the key challenge that English word difficulty is not fixed but varies with English learners’ native language. Our approach combines a fine-tuned XLM-RoBERTa-large encoder with handcrafted psycholinguistic features engineered separately for each L1 group. These features are integrated via a shallow multilayer perceptron and optimized separately per L1, with five-seed ensembling and XGBoost-based blending for stability. Our system achieves RMSEs of 0.997 (es), 1.002 (de), and 0.932 (cn) on the development set, improving 20–25% over the baseline. Results highlight the effectiveness of L1-aware modeling under limited data.

1 Introduction

Predicting English word difficulty for second language (L2) learners has clear value for language pedagogy, adaptive testing, and content recommendation (Settles et al., 2020). A key challenge, however, is that difficulty is not a fixed property of words; it depends on the learner’s first language (L1) background (Ringbom, 2007). For instance, an English learner whose L1 is Spanish may readily recognize *university* through its cognate *universidad*, whereas an English learner whose L1 is Mandarin has no such advantage.

Most prior work on lexical complexity has overlooked this L1-dependence. Shared tasks on Complex Word Identification (Paetzold and Specia, 2016; Yimam et al., 2018), Lexical Complexity Prediction (Shardlow et al., 2021), and Lexical Simplification (Shardlow et al., 2024) have advanced the field but were not designed to account for learner-specific factors such as L1 background despite cross-linguistic influence being central to vocabulary acquisition (Nation, 2001; Odlin, 2003).

The BEA 2026 Shared Task (Felice and Skidmore, 2026) frames English vocabulary difficulty prediction as an L1-aware regression task over three L1 groups: Spanish, German, and Mandarin. Our preliminary analysis of the training data reveals cross-L1 score correlations ranging from $r = 0.63$ to 0.68 , meaning approximately 40–46% of difficulty variance is shared across groups. The remaining variance is L1-specific, motivating separate models per language group.

We propose a hybrid system combining XLM-RoBERTa (Conneau et al., 2020) with targeted psycholinguistic features. While transformers capture cross-lingual patterns, they lack explicit access to extralinguistic properties (e.g., age of acquisition, Mandarin stroke complexity). Conversely, handcrafted features are interpretable but fail to capture context-sensitive usage. This tension motivates our hybrid approach. Our main contributions are: (1) A **hybrid architecture** integrating XLM-RoBERTa-large embeddings with psycholinguistic features via a dual-learning-rate MLP; (2) **L1-specific feature engineering**: cognate distance for Spanish and German, and stroke complexity for Mandarin; (3) A **robust ensembling framework** combining five-seed averaging with XGBoost blending, achieving 20–25% root mean square error (RMSE) reduction over the official baseline. All code, including data processing, feature extraction, modeling, and analysis scripts, is publicly available to support reproducibility and future research: <https://github.com/aditdhall/bea2026-vocab-difficulty>.

2 Related work

Lexical complexity prediction. Word difficulty prediction has been extensively studied in prior work. Earlier work framed the problem as binary Complex Word Identification, classifying words as either difficult or not (Paetzold and Specia, 2016;

Yimam et al., 2018). More recent shared tasks (e.g., BEA 2021; Shardlow et al., 2021; BEA 2024; Shardlow et al., 2024) have reformulated it as a regression problem, predicting continuous difficulty scores. This shift enables a more fine-grained and nuanced representation of lexical difficulty.

However, a key limitation of this line of work is that it largely treats word difficulty as universal across learners, without accounting for differences in learners’ L1 backgrounds. The BEA 2026 dataset (Skidmore et al., 2025), based on the British Council’s Knowledge-based Vocabulary Lists (KVL; Schmitt et al., 2024),¹ directly addresses this gap.

Multilingual transformers. Multilingual transformer models such as XLM-RoBERTa (Conneau et al., 2020), trained on large-scale multilingual corpora, are well suited to this task due to their ability to learn cross-lingual representations.

The official baseline models, provided by the shared task organizers (Felice and Skidmore, 2026),² fine-tuned XLM-RoBERTa-*base* separately for each L1 with a linear regression head, achieving RMSE of 1.357 (Spanish [es]), 1.328 (German [de]), and 1.175 (Mandarin [cn]).

Feature-based and L1-aware modeling. A substantial body of research shows that word-level features such as word frequency (Brysbaert and New, 2009), age of acquisition (Kuperman et al., 2012), concreteness (Brysbaert et al., 2014), and Common European Framework of Reference for Languages (CEFR) level (Council of Europe, 2001) are strong predictors of lexical difficulty (Laufer, 1997; Nation, 2001) and are associated with broader aspects of L2 proficiency, including lexical development (Crossley et al., 2016) and writing quality (Kim et al., 2018; Sung et al., 2025).

A limitation of previous approaches is that they relied on general lexical features, which may not capture L1-specific sources of difficulty. Additional features are therefore needed to account for cross-linguistic variation: for learners with European L1s, orthographic similarity to L1 translations tends to play a role (Schepens et al., 2012; Dijkstra et al., 2010), whereas for learners with Mandarin L1, character-level properties (e.g., stroke complexity) could be more informative (Shu et al., 2003).

¹KVL is a multilingual resource with psychometrically calibrated difficulty scores derived from real learner data, providing L1-specific estimates of vocabulary difficulty.

²<https://github.com/britishcouncil/bea2026st>

Figure 1: Architecture overview. The encoder produces a 1024-dimensional representation, which is concatenated with an N -dimensional handcrafted feature vector, where $N \in \{19, 20, 16\}$ depending on the L1 (ES/DE/CN). Model predictions are evaluated on the dev set.

3 Method

3.1 Architecture

Our system comprises three main components: a Transformer encoder, a feature extractor, and a fusion multilayer perceptron (MLP). An overview of the full architecture is shown in Figure 1.

Transformer encoder. Building on the organizers’ XLM-RoBERTa-*base* baseline, we adopt the larger XLM-RoBERTa-*large* model to leverage its greater representational capacity for capturing subtle lexical and cross-lingual patterns. This 24-layer model has 1024-dimensional hidden states and is pretrained on 2.5TB of multilingual CommonCrawl data (Conneau et al., 2020). Each input was constructed by concatenating four fields separated by [SEP] tokens: L1_source_word [SEP] L1_context [SEP] en_target_clue [SEP] en_target_word, and processed as a single sequence (Wolf et al., 2020). We used the first-token (<s>) representation (1024-dim) as the item-level embedding.

Feature extractor. We computed a vector of handcrafted features for each item: 19 features for Spanish, 20 for German, and 16 for Mandarin. These are drawn from a fixed set of 21 candidate features (see Section 3.2), where the active subset per L1 was selected once on the training data and kept fixed throughout all experiments.

Fusion MLP. We concatenated the transformer embedding with the feature vector and passed it through a two-layer feed-forward network with ReLU activation and 0.1 dropout to produce a single difficulty score. The model was trained end-to-end using mean square error (MSE) loss.

3.2 Feature engineering

We grouped our features into six categories based on the type of information they capture.

Orthographic features. We included word length, syllable count, the presence of a derivational suffix, and reveal ratio (i.e., the proportion of letters shown in the spelling clue). Reveal ratio proved particularly informative, correlating with GLMM scores at $r \approx 0.35$ – 0.45 across all L1s.

Frequency and psycholinguistic features. We included SUBTLEX-US log frequency (Brysbaert and New, 2009), age of acquisition (Kuperman et al., 2012), concreteness (Brysbaert et al., 2014), and CEFR proficiency level (Council of Europe, 2001), mapped from the Oxford 5000 word list. Frequency and age of acquisition were the strongest individual predictors ($r = 0.44$ – 0.62 and $r = 0.43$ – 0.56 , respectively), while CEFR level also showed substantial correlation ($r = 0.47$ – 0.53).

Semantic and lexical features. We included the number of WordNet synsets (Miller, 1995), maximum hypernym depth, and one-hot part-of-speech indicators (noun, verb, adjective).

Contextual features. We included context sentence length and the position of the target word within the sentence.

Cognate and cross-linguistic features. For Spanish and German, we included features that capture the orthographic similarity between the English word and its L1 translation. This included Levenshtein edit distance (Levenshtein, 1966) ($r = -0.24$ for Spanish, -0.34 for German), character n-gram overlap, a binary cognate flag (distance < 0.4), length ratio, and a German compound word

indicator. Together, these features model cross-linguistic similarity (Schepens et al., 2012; Dijkstra et al., 2010).

Stroke count. For Mandarin, we used the total stroke count of the Chinese character(s), obtained from the Unicode *UniHan* database (Unicode Consortium, 2024).³ This feature was the most predictive feature for Mandarin in our SHAP analysis (mean $|\text{SHAP}| = 0.078$).

We froze the feature inventory early to keep the feature space stable across experiments and avoid repeated tuning on the dev set. This results in 19 features for Spanish (15 shared + 4 cognate), 20 for German (15 shared + 5 cognate), and 16 for Mandarin (15 shared + 1 stroke). The shared feature set comprises 4 orthographic, 4 psycholinguistic, 5 semantic, and 2 contextual features.

4 Experiment

4.1 Setup

Data. Each L1 dataset contained 6,091 training items and 677 development items. Each instance included an English target word, its part-of-speech, a partial spelling clue, the L1 translation, and a context sentence in the learner’s language. The target variable was a GLMM-based difficulty score, where lower values indicate higher difficulty.

Implementation. Models were implemented in PyTorch (Paszke et al., 2019) using the HuggingFace Transformers library (Wolf et al., 2020), and trained on an A100 GPU.

4.2 Training

We trained a separate model for each L1 using AdamW (Loshchilov and Hutter, 2019), with learning rates of 1×10^{-5} for the transformer weights and 1×10^{-4} for the MLP head (Howard and Ruder, 2018). Training used a batch size of 16 on an A100 GPU, for up to 8 epochs and patience-3 early stopping based on dev RMSE. Hyperparameters (learning rate, batch size, warmup ratio, and epochs) were identified by evaluating 15 candidate configurations on the Spanish dataset and then applied consistently across all L1 models.

³Stroke complexity is known to affect character processing (Shu et al., 2003). We hypothesize that increased complexity may influence L1 processing and acquisition, which may in turn affect the perceived difficulty of corresponding English words for Mandarin learners.

4.3 Ensembling and blending

We found that single-seed runs had noticeable variance, so we trained five models per L1 with seeds [10, 42, 123, 456, 789] and averaged their predictions (Dodge et al., 2020). We further trained an XGBoost model (Chen and Guestrin, 2016) on handcrafted features and linearly blended it with the hybrid ensemble: $\hat{y} = \alpha \cdot \text{hybrid} + (1-\alpha) \cdot \text{xgboost}$. The blend weight α , tuned on the dev set, was 0.8 for Spanish and German and 0.9 for Mandarin, following the idea of stacked generalization (Wolpert, 1992).

4.4 Evaluation

We compared our system against two baselines. The first was the official closed-track baseline provided by the shared task organizers, which fine-tuned XLM-RoBERTa-base for each L1 using a linear regression head. The second was a feature-only XGBoost model trained exclusively on our handcrafted features, with no transformer component. All systems were evaluated on the dev set using RMSE.

5 Results

System	es	de	cn
Official baseline	1.357	1.328	1.175
XGBoost only	1.330	1.310	1.228
Hybrid (5-seed ensemble)	1.021	1.013	0.940
Hybrid + XGBoost blend (dev)	0.997	1.002	0.932
Hybrid + XGBoost blend (test)	1.045	0.994	0.900

Table 1: Dev and test set RMSE. Individual seed RMSE ranged from 1.04–1.16 (es), 1.00–1.10 (de) and 0.96–1.03 (cn). The blend weight α was tuned on the dev set ($\alpha=0.8$ for es/de; $\alpha=0.9$ for cn). Test results were obtained using the same ensemble and blend configuration as the dev set.

On the dev set, our best system—the Hybrid + XGBoost blend—achieves RMSEs of 0.997 (es), 1.002 (de), and 0.932 (cn), corresponding to reductions of 26.5%, 24.5%, and 20.7% over the official baseline. The 5-seed ensemble alone reduced RMSE by 24.8% (es), 23.7% (de), and 20.0% (cn). The XGBoost-only model also outperformed the baseline for Spanish (es) and German (de), indicating that the handcrafted features capture meaningful signal.⁴

⁴We did not evaluate a standalone XLM-RoBERTa-large without additional features; therefore, we could not isolate the extent to which performance gains are attributable to the larger model versus the inclusion of handcrafted features.

5.1 Ablation

We conducted ablation experiments on Spanish (single seed) by removing one feature group at a time (Table 2). Frequency and psycholinguistic features contributed the most, with their removal leading to the largest performance degradation ($\Delta = +0.012$). Cognate features improved performance for Spanish ($\Delta = +0.008$), but their removal unexpectedly improved performance for German ($\Delta = -0.034$).⁵ Orthographic and contextual features showed relatively smaller effects, suggesting that they were largely redundant with representations learned by the encoder.

Group Removed	es RMSE	Δ
None (all features)	1.092	—
– Frequency/norms	1.104	+0.012
– Cognate	1.100	+0.008
– Semantic	1.066	–0.026
– Orthographic	1.088	–0.004
– Context	1.046	–0.046

Table 2: Ablation on Spanish (single seed).

5.2 SHAP analysis

We analyzed feature importance using SHAP values computed on the MLP head. For Spanish and German, age of acquisition score and SUBTLEX-US log frequency emerged as the most influential features, followed by CEFR proficiency level. For Mandarin, stroke complexity was the most important feature by a substantial margin (mean $|\text{SHAP}| = 0.078$).

5.3 Cross-L1 generalization

We evaluated cross-L1 generalization by training XGBoost on one L1’s features and testing them on others. Models trained on Spanish and German transferred reasonably well to each other, with only modest performance degradation (+0.02–0.14). In contrast, models trained on Mandarin transferred poorly to European L1s, with a substantial increase in RMSE (+0.52).

6 Conclusion

Our findings highlight four main points. First, combining a multilingual encoder with psycholinguistic features yielded consistent improvements over the

⁵One possible explanation is that the transformer already captures orthographic similarity from the joint L1–L2 input, reducing the added value of explicit cognate features for German.

baseline across all L1 groups, with RMSE reductions of approximately 20–26%.

Second, feature contributions varied by L1. While handcrafted features were generally informative, particularly for Spanish and German, their impact differed across languages, suggesting that vocabulary difficulty reflects L1-specific patterns.

Third, cross-L1 transfer results provided additional evidence for this pattern: models trained on Spanish and German tended to generalize well to each other, whereas transfer to and from Mandarin was substantially weaker. From a practical perspective, these findings indicate that effective systems should balance generalizable features with L1-specific adaptations, particularly when extending to typologically distant learner populations.

Fourth, not all features were beneficial when paired with a strong encoder. Ablation results showed that removing contextual and orthographic features could improve performance, indicating that such information is already captured by the pretrained transformer. This underscores the importance of selectively incorporating features that provide complementary signals beyond what the model can learn from text alone.

7 Limitations

This study has several limitations. First, hyperparameter tuning was conducted only for Spanish due to computational constraints; as a result, the German and Mandarin models may not be optimally calibrated. Second, we did not evaluate a standalone XLM-RoBERTa-large baseline without feature augmentation, limiting our ability to isolate the contribution of the feature branch. Third, ablation experiments were conducted with a single random seed, which may introduce variability in the estimates.

In addition, attempts to use mdeberta-v3-base as an alternative encoder resulted in unstable training (NaN losses) across all L1 groups, and time constraints prevented further investigation. Finally, for words not covered by external psycholinguistic resources, median imputation was applied, which may degrade performance on rare or out-of-vocabulary items.

Abstract

This paper describes the SurreyCTS submission¹ to the BEA 2026 shared task on lexical difficulty prediction, entered in the Open Track. Our approach progressed from baseline multilingual encoders to a hybrid RemBERT architecture with extensive feature engineering, combining semantic funnelling, lexical similarity features, attention-derived signals, and language-aware representations. On our internal production validation set, the best single models achieved RMSE 0.8122 (prod-H) and Pearson correlation 0.8968 (prod-G). A weighted ensemble of the five strongest systems, with weights proportional to inverse squared validation RMSE, was submitted as our final entry. On the official shared-task test set, the ensemble achieved RMSE 1.034, 0.945, and 0.861 for Spanish, German, and Chinese respectively, outperforming the open-track baseline in all three settings and placing fifth among open-track teams.

1 Introduction

Lexical difficulty prediction aims to estimate how difficult a target word is for a language learner to understand in context. Difficulty is influenced by multiple factors, including morphological complexity, contextual informativeness, and cross-lingual similarity between the learner’s first language and the target language. In multilingual settings, these factors may vary substantially across learner populations, making the task particularly challenging. Lexical complexity prediction has been explored as a shared task previously, notably at SemEval-2021 Task 1 (Shardlow et al., 2021), which focused on single- and multi-word expression complexity for English.

The BEA 2026 shared task provides a structured setting for developing and evaluating such

systems, requiring participants to predict continuous difficulty scores for English vocabulary items across three typologically distinct learner populations: Spanish, German, and Chinese. These scores are derived from Generalised Linear Mixed Models (GLMMs), which estimate item difficulty as a continuous latent parameter by modelling learner responses while accounting for random variation across both items and individuals (De Boeck, 2008; Dunn, 2024). The scores are fitted to large-scale psychometric data from over 100,000 learners, making the regression target both fine-grained and linguistically motivated.

In this paper, we describe our system for lexical difficulty prediction across three learner settings: Spanish, German, and Chinese. Our experiments progressed through four stages: baseline multilingual encoders, hybrid feature engineering, split redesign, and final ensembling. Across these stages, the main pattern was that carefully designed linguistic and cross-lingual features consistently improved over encoder-only regression baselines.

The contributions of this paper are as follows:

- We propose a hybrid multilingual regression architecture for lexical difficulty prediction that combines contextual representations with linguistic and cross-lingual features.
- We provide an ablation study showing that selective feature additions consistently outperform broad feature bundles, and that the same feature strategy does not transfer equally across encoder backbones.
- We demonstrate that careful validation set construction has a meaningful effect on model performance in this setting.

2 Task and Data

The BEA 2026 shared task focuses on predicting the difficulty of English vocabulary items for learners from three L1 backgrounds: Spanish, German,

^{*}Equal contribution.

¹Code and configuration files are available at <https://github.com/surrey-nlp/bea2026-surrey>.

and Chinese, formulated as a regression over continuous GLMM difficulty scores. We describe the data below.

The data comes from the Extended KVL Dataset for NLP (Skidmore et al., 2025), which is derived from the British Council’s Knowledge-based Vocabulary Lists (Schmitt et al., 2021, 2024). The difficulty scores were estimated from approximately 3.3 million learner responses collected from over 100,000 learners in a translation-based recall setting. These estimates were derived separately for each L1 using random-item-random-person Rasch models within a GLMM framework (De Boeck, 2008; Dunn, 2024).

Each instance in the dataset contains five core input fields: an *L1* context sentence, an *L1* source word, a partial-spelling clue for the English target word, a part-of-speech tag, and the English target word itself. The target variable is the corresponding GLMM score. The dataset is split into training (18,273 instances), development (2,031), and test (2,244) sets, with each instance appearing once per *L1*.

The task poses several challenges. The target scores are continuous values derived from psychometric modelling, making the regression signal fine-grained. The three *L1*s also span typologically distinct languages and different writing systems, which requires a system capable of handling varied multilingual input within a unified framework.

3 Method

3.1 Baseline Encoders

We fine-tuned and evaluated baselines which used XLM-R base and large (Conneau et al., 2020), mDeBERTa (He et al., 2021), COMET (Rei et al., 2020), and RemBERT (Chung et al., 2021) as multilingual encoder backbones. Early experiments indicated that COMET² was a competitive baseline, while RemBERT with decoupled embeddings became the main focus for our experiments given its performance with the hybrid feature setup.

3.2 Hybrid Regression Model

The proposed architecture in Figure 1 extends the encoder-only setup with a Deep MLP-based hybrid regression head. The regression head is a 3-layer MLP ($1024 \rightarrow 512 \rightarrow 128 \rightarrow 1$) with LayerNorm, GELU activations, and decreasing dropout

²We use the Unbabel/wmt22-comet-da checkpoint, which uses an XLM-R encoder fine-tuned for MT quality estimation (Rei et al., 2022).

Figure 1: Architecture of the SurreyCTS system. The input sequence passes through a multilingual transformer encoder, producing multi-layer representations that are funnelled via mean-pooling, combined with attention-derived entropy features and string similarity features, and fed into a deep MLP regression head to predict GLMM difficulty scores.

(0.2, 0.15, 0.1), trained with Huber loss ($\delta = 1.0$) (Huber, 1964). It extracts target-word representations from the encoder, combines them with engineered features, and predicts lexical difficulty through this head. This design allows the model to combine contextual representations with explicit lexical and cross-lingual signals.

We also experimented with multi-layer semantic funnelling: rather than pooling target-word representations from a single transformer layer, we mean-pool target-token hidden states at several selected layers and concatenate them before the regression head. This gives the model access to multiple levels of abstraction simultaneously, from lower-level morphosyntactic features to higher-level contextual ones. The selected layers (RemBERT: 12, 20, 26, 32; COMET: 8, 10, 12) sample across each encoder’s depth, motivated by observations that different transformer layers encode distinct linguistic levels (Tenney et al., 2019; Rogers et al., 2020). Funnelling was an important component of our strongest RemBERT-based configurations.

3.3 Feature Engineering

Beyond the base encoder, we experimented with several families of additional features: **lexical similarity** (Levenshtein distance, normalized Levenshtein, Jaccard distance); **subword-based** (subword ratio); **language-aware** (language ID prefix,

language ID embeddings, pinyin-based Chinese similarity); **attention-derived** (target-to-context entropy (TC), target-to-source alignment (TSA) and entropy, context-to-target entropy, global CLS entropy, attention variance); and **representation-level** (multi-layer funnelling, target-word pooling across selected layers). Detailed descriptions of these features are provided in Appendix A.

Of these, the final ensemble systems share a base feature set of normalised Levenshtein distance, Jaccard distance, pinyin romanisation, and subword ratio. Subword ratio uses the backbone tokeniser’s segmentation rather than linguistic syllabification, providing a model-internal proxy for morphological complexity that requires no external resource. Individual ensemble members augment this base with multi-layer funnelling, language-ID prepadding, and selected attention-derived signals such as TSA and TC entropy (see Table 1 for per-system feature recipes). Remaining features (full entropy bundles, language-ID embeddings, attention variance, target-word pooling) were explored during model development but did not improve over the curated subsets. Target length and clue-mask ratio were examined in correlation analysis only and were not included as model features.

Table 1 reports all ten production candidates on the internal validation set, ordered by RMSE. The leaderboard supports both feature comparison (RemBERT funnelling variants vs. COMET, full vs. selective features) and ablation reading: prod-D (vanilla RemBERT) → prod-A (+ funnelling) → prod-F (+ TSA) → prod-H (+ LID prepad) traces the contribution of each major addition.

4 Experimental Setup

4.1 Training and Model Selection

Early experiments were conducted on the standard labelled train and development portions of the shared-task data. For the final production stage, we used an internal split with a 500-instance development set, which allowed more labelled data to be used for training while preserving a dedicated validation set for checkpoint selection. Development RMSE was used as the primary model-selection criterion, with Pearson correlation used as a secondary metric. The official development set (2,031 unstratified instances) failed to distinguish configurations that diverged clearly on our production validation split, making it unreliable for checkpoint selection.

Encoder-only experiments plateaued around RMSE 1.00 regardless of feature additions, motivating a redesign of the validation split. We divided the labelled data into 50 equal-frequency GLMM score quantile buckets and selected the 10 highest-scoring instances from each bucket, yielding a 500-instance development set biased toward harder examples. The remaining 19,804 instances were used for training. The 50-bucket choice balanced fine-grained difficulty stratification with sufficient instances per bucket to support stable selection. This design served two purposes: maximising the amount of labelled data available for training, and obtaining a validation signal sensitive to performance on difficult items, which are most discriminative for model selection. Because this split combines instances across all three *L1*s into a single training set, which is not permitted under closed-track rules, our submission was entered in the open track.

4.2 Production Models and Ensemble

Following the split redesign, a sweep of ten models spanning RemBERT and COMET backbones, alternative loss functions (Huber $\delta = 1.0$ and $\delta = 0.5$), and different feature subsets produced a best RMSE of 0.8122, a substantial improvement over the official-split plateau. These models were chosen to balance strong standalone performance with variation across backbone family, feature recipe, and loss function, while avoiding a larger search likely to add little beyond the strongest configurations.

Our final submission ensemble was built from the five best validation systems: prod-H, prod-G, prod-J, prod-E, and prod-F. Ensemble weights were set as $w_i \propto 1/\text{RMSE}_i^2$, normalised to sum to one, so that stronger individual models contributed more while still preserving diversity across backbone and feature choices. This design was motivated by the complementary strengths of the selected systems: prod-H gave the best RMSE, prod-G gave the strongest correlation metrics, and the remaining RemBERT variants contributed alternative feature combinations and training dynamics.

5 Results and Analysis

5.1 Main Results

Our production sweep establishes a clear hierarchy among the final systems. prod-H achieves the lowest RMSE (0.8122), prod-G achieves the highest Pearson and Spearman correlations (0.8968 and 0.8953), and prod-J provides the best bal-

System	Backbone	Feature recipe	RMSE	Pearson	Spearman	MAE
prod-H	RemBERT	funnelling + LID prepend	0.8122	0.8920	0.8910	0.6503
prod-G	COMET	Minimal	0.8127	0.8968	0.8953	0.6339
prod-J	RemBERT	funnelling + top features	0.8129	0.8923	0.8908	0.6522
prod-E	RemBERT	funnelling + Huber $\delta = 0.5$	0.8194	0.8898	0.8838	0.6545
prod-F	RemBERT	funnelling + TSA	0.8239	0.8887	0.8862	0.6604
prod-C	RemBERT	funnelling + full entropy	0.8244	0.8885	0.8867	0.6549
prod-I	RemBERT	Full feature set	0.8261	0.8881	0.8860	0.6669
prod-A	RemBERT	funnelling only	0.8266	0.8877	0.8860	0.6607
prod-B	COMET	Full + LID + entropy	0.8278	0.8920	0.8912	0.6503
prod-D	RemBERT	Vanilla	0.8415	0.8841	0.8804	0.6668

Table 1: Production-split leaderboard on the internal validation set (500 harder-biased instances; see §4.1). All hybrid models (all except prod-D) share a base feature set of normalised Levenshtein, Jaccard distance, pinyin romanisation, and subword ratio; the “Feature recipe” column describes additions beyond this base. Lower RMSE and MAE are better; higher Pearson and Spearman are better.

Run	ES RMSE	DE RMSE	CN RMSE
Open baseline	1.198	1.166	1.034
prod-H	1.046	0.968	0.883
prod-G	1.083	1.004	0.885
ensemble	1.034	0.945	0.861

Table 2: Official shared-task test results across the three L1 populations (Spanish, German, Chinese). Open baseline is the shared-task organisers’ open-track baseline. Lower RMSE is better

ance between error and rank-based metrics. The ensemble placed fifth among open-track teams, outperforming the open-track baseline across all three *L1* groups (Table 2). Chinese yielded the strongest result (RMSE 0.861) and Spanish the weakest (RMSE 1.034).

5.2 Training Dynamics

Figure 2 shows per-epoch development RMSE for the five ensemble members. The RemBERT models (prod-H, prod-J, prod-E, prod-F) converge smoothly within 7–12 epochs, with prod-H reaching its best checkpoint at epoch 11. The COMET model (prod-G) follows a slower, more oscillatory trajectory, peaking at epoch 21, consistent with its minimal feature setup requiring more updates to stabilise. prod-E (Huber $\delta = 0.5$) reaches a competitive checkpoint early but plateaus, confirming that the robust loss accelerates initial convergence without improving the final optimum.

5.3 Ablation Findings

Starting from the vanilla RemBERT baseline (prod-D), every targeted enrichment improves performance, but the gains are not uniform. Multi-layer semantic funnelling provides the clearest first improvement, TSA is the strongest single entropy feature, and LID prepend gives the best overall

Figure 2: Per-epoch development RMSE for the five ensemble members. Stars mark best checkpoints.

RemBERT result. By contrast, the full feature set (prod-I) offers little additional benefit, suggesting diminishing returns once the strongest signals are included. Selective feature additions outperform broad feature bundles: prod-H and prod-J are both substantially better than prod-I despite sharing the same funnelling and backbone.

More broadly, the comparison between RemBERT and COMET suggests that the same feature strategy does not transfer equally across backbones: COMET performed best in minimal form, while RemBERT responded clearly to targeted linguistic and representation-level additions. COMET is pre-exposed to a large-scale quality estimation corpus but we chose to extract weights from the base model with $d = 512$. We hypothesize that its smaller embedding dimension ($d = 512$) limits its capacity to capture fine-grained cross-lingual information compared to RemBERT ($d = 1152$).

5.4 L1-specific Patterns

Per-L1 correlations between external features and GLMM scores (Figure 3) reveal a clear typological split. Lexical similarity features (normalised Levenshtein, Jaccard) correlate moderately and negatively with difficulty for Spanish (-0.24 , -0.27) and German (-0.34 , -0.35) learners, consistent with cognate proximity easing recognition. For Chinese learners these correlations collapse to near zero (0.07 , 0.06), as character-level similarity to English carries no meaningful signal even after pinyin romanisation. Subword ratio, by contrast, correlates similarly across all three L1s, suggesting that morphological-complexity proxies generalise where orthographic ones do not.

6 Conclusion

We presented a multilingual system for lexical difficulty prediction that combines multi-layer semantic funnelling, attention-derived entropy features, and cross-lingual string similarity with a hybrid transformer regression head. Our best single model achieved RMSE 0.8122 and Pearson 0.8968 on the internal production validation set.

On the official test set, the ensemble achieved RMSE 0.861–1.034 across the three L1 groups, outperforming the open-track baseline in all settings. A small number of well-motivated features, combined with a strong multilingual encoder and a carefully constructed validation split, proved more effective than either the encoder alone or a larger undifferentiated feature bundle. The interaction between backbone choice and feature engineering warrants further investigation, particularly given how differently RemBERT and COMET responded to the same additions. More broadly, these results suggest that explicit linguistic feature design remains a useful component of multilingual lexical difficulty prediction, even in settings where large pretrained encoders are available.

7 Limitations

The system was developed and evaluated on data covering three L1 backgrounds. It is unclear how well the approach would generalise to learners from other L1 backgrounds, particularly those with writing systems or typological properties not represented in the training data. The collapse of orthographic similarity signal for Chinese learners suggests the feature set may not transfer to other non-Latin-script L1s without analogous romanisation steps.

The attention-derived and representation-level features are extracted from the same encoder used for prediction, meaning their usefulness is tied to the quality of that encoder’s internal representations. It is not clear whether those features would remain informative with a different or weaker backbone.

A Feature Inventory

A.1 Linguistic features

Lexical similarity features. We hypothesise that cognates across English and Romance languages (German and Spanish), given the context, will help identify a lexical difficulty signal. Unlike supervised cognate-detection approaches (Kanojia et al., 2021, 2020), we aim to capture shared features at the string level unsupervised, *i.e.*, without relying on existing resources or tools specifically for cognate detection. All string distance features are standardised using training-set statistics and applied consistently to development and test data. For Chinese, raw character-to-Latin distances are not meaningful, so *pinyin romanisation* is applied first (see language-aware features below).

Levenshtein distance: the raw edit distance between the *L1* source word and the English target word, counting insertions, deletions, and substitutions. Orthographically close pairs, such as cognates, tend to receive lower scores and be easier for learners.

Normalized Levenshtein distance: Levenshtein distance divided by the length of the longer word, making the measure length-invariant and comparable across word pairs of different sizes.

Jaccard distance: one minus the Jaccard similarity of character bigram sets from the source and target words. This captures shared character structure independently of word order, and is more robust than edit distance for morphologically related pairs.

Subword Ratio the number of subword tokens produced by the backbone tokenizer divided by the character length of the target word. Words that fragment into many subword units tend to be morphologically complex or low-frequency, making this a lightweight proxy for lexical difficulty that requires no external resource.

Language ID: optionally, we prepend a text tag (e.g. [*L1*: es]) to the input sequence before tokenisation, allowing the encoder to condition its representations on the learner’s *L1* from the first layer.

Language ID embeddings: a learned embedding lookup (Spanish $\rightarrow$ 0, German $\rightarrow$ 1, Chinese $\rightarrow$ 2) whose output is concatenated to the handcrafted feature vector before the regression head, providing an explicit $L1$ signal at the prediction stage.

Pinyin romanisation: for Chinese instances, the $L1$ source word is converted from CJK characters to pinyin before computing Levenshtein and Jaccard distances. This makes cross-lingual string similarity meaningful for a script that otherwise shares no characters with English.

A.2 Encoding-based Features

Attention-derived features. These features are computed from the encoder’s attention distributions using token-level masks that identify the target word, $L1$ context, and $L1$ source word spans within the input sequence.

Target-to-context entropy: Shannon entropy of the mean attention weights from target word tokens to context tokens, averaged across heads in the final layer. High entropy indicates the target word attends broadly and diffusely to its context.

Target-to-source alignment: total attention mass flowing from target word tokens to $L1$ source word tokens in the final layer. A high value indicates strong cross-lingual correspondence between the target and its $L1$ translation.

Target-to-source entropy: entropy of the attention distribution from target tokens to source tokens. Low entropy indicates focused, peaked alignment to specific source tokens; high entropy indicates diffuse or uncertain alignment.

Context-to-target entropy: entropy of attention from context tokens to the target word. High entropy means the context does not attend strongly or focally to the target, which may indicate lower contextual salience.

Global CLS entropy: entropy of the [CLS] token’s attention over the full input sequence. This provides a sequence-level signal about how broadly the model distributes global attention.

Attention variance: the variance of attention weights across heads rather than their entropy. This captures disagreement between attention heads, which may reflect ambiguity or heterogeneous cross-lingual signal.

Representation-level features These are derived from representations obtained from different layers of the Transformer backbones.

Multi-layer funnelling provides the regression head access to representations at different levels of abstraction, from lower-level morphological features to higher-level contextual ones. Inspired by (Sindhuja et al., 2025; Gurav et al., 2026), we propose extracting multi-layer semantic representations via *funnelling* where target-word hidden states are mean-pooled at each selected layer and concatenated.

$$\mathbf{p}^{(\ell)} = \frac{1}{|T|} \sum_{t \in T} \mathbf{h}_t^{(\ell)}, \quad (1)$$

$$\mathbf{f}_{\text{fun}} = [\mathbf{p}^{(\ell_1)}; \mathbf{p}^{(\ell_2)}; \dots; \mathbf{p}^{(\ell_K)}]. \quad (2)$$

where T is the set of target-word token positions identified via character-level offset tracking, $\mathcal{L}$ the selected transformer layers (12, 20, 26, and 32 for RemBERT; 8, 10, and 12 for COMET), and $[\cdot; \cdot]$ denotes vertical concatenation. This gives the regression head access to representations at different levels of abstraction and was an important component of our strongest RemBERT-based configurations.

Target-word pooling: rather than using the [CLS] token as the sequence representation, the model mean-pools over the hidden states of tokens that correspond to the target word, identified via character-level offset tracking. This grounds the prediction in the specific word being assessed rather than a global sequence summary.

B Additional Details

Figure 3 (discussed in §5.4) additionally shows correlations for target length and clue mask ratio, which were explored during analysis but not included as model features. These two features show consistent moderate negative correlations across all three L1s (-0.33 to -0.46), comparable in magnitude to the strongest similarity features, but were

Figure 3: Pearson correlations between external lexical features and GLMM difficulty scores, computed separately per learner $L1$.

excluded from the final model because they correlate with the structure of the task input itself (clue masking and word length) rather than with linguistic properties.

B.1 Hyperparameters

All production models share the following training configuration:

Hyperparameter	Value
Learning rate	3×10^{-5}
Train batch size	32
Gradient accumulation steps	1
Weight decay	0.01
Max sequence length	256
Loss function	Huber ($\delta = 1.0$)
Seed	42

Table 3: Hyperparameters across all production models.

Model-specific settings that differ: prod-E uses Huber $\delta = 0.5$; RemBERT models (prod-A, prod-C, prod-F, prod-H, prod-J) train for 12 epochs; prod-D and prod-I for 14; prod-E for 17; and COMET models (prod-B, prod-G) for 22 epochs, reflecting their slower convergence.

B.2 Ensemble Weights

The submitted ensemble combines the five best validation systems using weights proportional to $1/\text{RMSE}^2$, normalised to sum to one. The top models (prod-H, prod-G, prod-J) receive nearly equal weight due to their similar validation scores. The resulting weights are:

Model	Dev RMSE	Weight
prod-H	0.8122	0.2019
prod-G	0.8127	0.2017
prod-J	0.8129	0.2016
prod-E	0.8194	0.1984
prod-F	0.8239	0.1963

Table 4: Ensemble member weights for the final submission.

EduNLP at BEA 2026 Shared Task 1: Multi-Model Ensemble with Feature-Augmented Transformers for Vocabulary Difficulty Prediction

Avinash Kumar Sharma

Indian Institute of Technology Madras

avics2020@gmail.com

Abstract

We describe our system submitted to the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners. Our approach combines handcrafted linguistic features with fine-tuned XLM-RoBERTa transformers in a multi-model ensemble, participating in both the closed and open tracks. For the closed track, we ensemble a per-L1 transformer with a Light-GBM model trained on 12 features including word frequency, cognate similarity, and part-of-speech indicators. For the open track, we extend this with cross-lingual training across all three L1s and a feature-augmented transformer architecture that concatenates numeric features with the transformer’s pooled representation. Our system outperforms the baselines on both tracks across all three L1s (Spanish, German, and Mandarin), with best RMSEs of 1.058 (closed, CN) and 0.992 (open, CN). Post-hoc error analysis on the released test labels reveals that polysemous words in rare senses and nominalized *-ing* forms constitute the primary failure mode, contributing 58% higher RMSE than other words. We additionally report on a negative result where a post-hoc Ridge regression blend overfit on test despite strong development set performance.

1 Introduction

Vocabulary knowledge is a fundamental component of language proficiency, and accurately estimating the difficulty of vocabulary items is essential for adaptive learning systems, automated test construction, and personalized instruction. Traditional approaches to estimating word difficulty rely on large-scale testing with real learners followed by psychometric calibration, a process that is both costly and time-consuming (Schmitt et al., 2024).

The BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners (Felice and Skidmore, 2026) challenges participants to build regression models that predict psychometrically

calibrated difficulty scores (GLMM scores) for English vocabulary items, given the learner’s first language (L1). The task covers three L1s: Spanish (ES), German (DE), and Mandarin Chinese (CN). It offers two tracks: a **closed track** restricted to the provided data and standard pre-trained transformers, and an **open track** allowing external resources and cross-lingual data combination.

We present a multi-model ensemble system that combines handcrafted linguistic features with fine-tuned transformer models. Our approach is motivated by exploratory data analysis revealing that surface features such as word frequency and cognate similarity capture complementary information to what transformer models learn from text. Our system participates in both tracks and outperforms the baselines on all six track-L1 combinations.

Our contributions are: (1) a systematic comparison of feature-based, transformer-based, and hybrid approaches across three L1s; (2) a feature-augmented transformer architecture concatenating numeric features with the transformer’s pooled output; (3) detailed post-hoc error analysis revealing polysemy and nominalization as systematic failure modes; and (4) a report of a Ridge blend that overfit on test despite strong development set performance.

2 Task and Data

The shared task uses the Extended KVL Dataset for NLP (Skidmore et al., 2025), derived from the British Council’s Knowledge-based Vocabulary Lists (Schmitt et al., 2024). The dataset was created by testing over 100,000 English learners through a vocabulary recall task: learners see an L1 context sentence, an L1 source word, and a partial English spelling clue (first letter plus blanks), and must produce the English target word. Difficulty scores were estimated using a Generalized Linear Mixed Model (GLMM) with Rasch param-

Split	Items/L1	Total	Item IDs
Train	6,091	18,273	1–6,091
Dev	677	2,031	6,092–6,768
Test	748	2,244	6,769–7,516

Table 1: Dataset statistics. Each L1 (ES, DE, CN) has identical item counts with parallel item IDs.

Figure 1: GLMM score distributions across L1s (training set). All three L1s follow approximately normal distributions with similar shape but different spread.

terization, simultaneously estimating learner ability and item difficulty (Schmitt et al., 2021). Lower GLMM scores indicate harder words.

Each item consists of seven fields: item ID, L1 code, English target word, part of speech (POS), partial spelling clue, L1 source word, and L1 context sentence. The training data GLMM scores are approximately normally distributed with mean near zero and standard deviation of 1.67 (CN) to 1.86 (ES), ranging from approximately -6.5 to $+5.1$, as shown in Figure 1.

Notably, only 17.4% of test words appear in the training or development sets, meaning 82.5% of test predictions must generalize to entirely unseen words.

3 System Description

3.1 Exploratory Analysis and Motivation

We conducted exploratory data analysis prior to model development, which informed several key design decisions. Word frequency on the Zipf scale (Van Heuven et al., 2014) shows the strongest correlation with GLMM scores among simple features ($r = +0.43$ for ES). Word length correlates negatively with difficulty ($r = -0.33$ for ES, -0.44 for CN), with the stronger effect for Mandarin consistent with the absence of orthographic overlap between Chinese and English. Figure 2 illustrates these two key relationships.

Cross-L1 GLMM score correlations are moderate (ES–DE: $r = 0.684$, ES–CN: $r = 0.634$, DE–CN: $r = 0.662$), indicating approximately 40–47%

Figure 2: Key feature correlations with GLMM scores (Spanish training set). (a) Word frequency and (b) word length are the strongest individual predictors of difficulty.

shared variance across L1s.

These findings motivated three design choices: (1) including word frequency and cognate similarity as explicit numeric features; (2) combining per-L1 and cross-lingual training strategies; and (3) ensembling feature-based and transformer-based models.

3.2 Feature Engineering

We extract 12 numeric features from each vocabulary item, organized into four groups:

Word frequency. Zipf-scale frequency (Speer et al., 2017) for the English target word (`en_zipf`) and L1 source word (`l1_zipf`).

Cognate similarity. Normalized Levenshtein edit distance (`edit_distance`) and character-level Jaccard overlap (`jaccard_overlap`) between the English target and L1 source words.

Surface features. Word length (`word_len`), source word length (`source_len`), syllable count via vowel group counting (`syllable_count`), and clue ratio (`clue_ratio`).

POS indicators. Binary features for noun, verb, adjective, and adverb.

3.3 Model Architectures

We develop four complementary models:

Model 1: LightGBM (Ke et al., 2017). A gradient boosting model trained per-L1 on the 12 features with 1,000 estimators, learning rate 0.05, max depth 6, and subsampling 0.8. While this model alone does not match transformer baselines (dev RMSE 1.39–1.56), it produces more accurate predictions than the transformer for approximately 27% of individual words on the development set.

Model 2: Per-L1 XLM-RoBERTa (closed track). We fine-tune `xlm-roberta-base` (Conneau et al., 2020) separately for each L1. Input: `{source} </s> {context} </s> {clue} </s>`

System	Track	ES	DE	CN
Glite (1st)	Closed	0.903	0.885	0.776
EduNLP	Closed	1.176	1.124	1.058
Baseline	Closed	1.257	1.258	1.140
Sakura (1st)	Open	0.742	0.723	0.630
EduNLP	Open	1.143	1.071	0.992
Baseline	Open	1.198	1.166	1.034

Table 2: Official test results (RMSE ↓). Best EduNLP run per track shown. Double line separates tracks.

{target}. We use mean pooling over the final hidden states followed by dropout ($p = 0.1$) and a linear head.

Model 3: Cross-lingual XLM-RoBERTa (open track). A single model trained on all three L1s combined (18,273 examples), with an L1 identifier prefix (e.g., [ES]). This triples the training data.

Model 4: Feature-augmented XLM-RoBERTa (open track). The transformer’s mean-pooled output (768 dims) is concatenated with the 12 standardized features, and fed through an MLP ($780 \rightarrow 256 \rightarrow 1$) with ReLU and dropout. This directly combines text representations with surface features.

All transformers use AdamW with linear warmup (10%), learning rate 2×10^{-5} , weight decay 0.01, batch size 16, and 5 epochs. We average predictions across 3 seeds (42, 123, 456).

3.4 Ensemble and Calibration

Closed track. Weighted average of per-L1 transformer and LightGBM, with weights optimized on the dev set (65–70% transformer, 30–35% LightGBM).

Open track. Three-model ensemble of cross-lingual transformer, feature-augmented transformer, and LightGBM, with per-L1 optimized weights. We also experiment with a cross-notebook ensemble blending open and closed track models.

Calibration. We apply conservative scaling ($1.04\text{--}1.06\times$) around the mean to partially address prediction compression (Section 5.3).

For final predictions, we retrain on combined train+dev data (6,768 items per L1), as permitted by the organizers.

4 Results

4.1 Official Test Results

Table 2 presents our official test results alongside baselines and winning systems.

Model	ES	DE	CN
LightGBM (features only)	1.559	1.475	1.393
XLM-R per-L1	1.322	1.232	1.098
XLM-R cross-lingual	1.219	1.157	1.045
Feature-Aug XLM-R	1.169	1.164	1.014
4-model ensemble	1.158	1.127	1.018
Baseline (closed)	1.357	1.328	1.175
Baseline (open)	1.206	1.149	1.021

Table 3: Ablation study on development set (RMSE ↓). Each row adds capability. Double line separates our models from baselines.

Figure 3: RMSE progression across model components on the development set. Dashed lines indicate organizer baselines (closed track).

Our system outperforms the baseline on both tracks across all L1s, with improvements of 0.081–0.134 (closed) and 0.042–0.095 (open) RMSE. A gap remains to the winning systems.

4.2 Ablation Study

To understand the contribution of each component, we evaluate four individual models and their ensemble on the development set (Table 3). LightGBM uses only the 12 handcrafted features described in Section 3.2. XLM-R per-L1 is a fine-tuned transformer trained separately for each language. XLM-R cross-lingual trains a single transformer on all three L1s combined. Feature-Aug XLM-R concatenates the transformer output with the 12 numeric features before prediction. The 4-model ensemble computes a weighted average of all four models, with weights optimized on the development set.

Table 3 shows the contribution of each component on the development set.

The progression (Figure 3) shows consistent improvement: transformers reduce RMSE by 0.15–0.30 over features, cross-lingual training adds 0.05–0.10, and the ensemble consistently outperforms all individual models. Among the 12 features, word frequency (Zipf scale) and cognate similarity (edit distance) contribute most to the feature-augmented model’s gains. On the development set, remov-

Zone	N	RMSE	%Err	$\bar{\epsilon}$
Very Easy (>3)	44	0.920	3.8%	+0.66
Easy (1 to 3)	194	0.943	17.7%	+0.41
Medium (-1 to 1)	275	0.901	22.9%	-0.10
Hard (-3 to -1)	197	1.225	30.3%	-0.75
Very Hard (<-3)	38	2.552	25.4%	-2.19

Table 4: Error analysis by GLMM score zone (ES, open ensemble, test set). %Err = percentage of total squared error. $\bar{\epsilon}$ = mean signed error.

Word	POS	True	Pred.	Err	Issue
dining	noun	-4.67	+2.22	-6.89	Nominal.
baking	noun	-3.79	+0.77	-4.56	Nominal.
clear	adv	-4.14	+0.11	-4.25	Rare POS
amount	verb	-4.04	-0.55	-3.49	Rare POS
very	adj	-2.01	+1.27	-3.28	Rare POS
received	adj	-5.90	-2.26	-3.63	Rare POS

Table 5: Selected worst predictions (ES test). All involve polysemy or rare POS usage.

ing frequency alone increases RMSE by 0.08–0.12 across L1s, while removing cognate features increases RMSE by 0.04–0.07. POS indicators and word length provide smaller but consistent contributions.

5 Analysis and Discussion

5.1 Error Analysis by Difficulty Zone

Using the released test labels, we analyze prediction errors stratified by GLMM score zones for Spanish (Table 4).

The “very hard” zone contributes 25.4% of total error despite comprising only 5.1% of items, with systematic under-prediction of difficulty (mean error -2.19).

5.2 Polysemy and Nominalization Failures

Our worst predictions involve common words in rare senses (Table 5).

Words ending in “-ing” used as nouns are particularly problematic: these 39 words exhibit RMSE of 1.735 compared to 1.101 for all other words, a 58% increase. The model sees “dining” and associates it with the common verb “to dine,” predicting it as easy. However, producing “dining” as a noun in a vocabulary test requires knowledge of the nominalized form, which is substantially harder. We observe similar patterns across all three L1s. The same 18 nominalized *-ing* words appear as nouns in each test set. However, difficulty varies substantially across L1 backgrounds. For example, “dining” as a noun has GLMM scores of -4.67

Figure 4: Predicted vs. true GLMM score distributions (ES test set). Predictions are compressed relative to the true distribution.

(ES), -2.00 (DE), and -1.03 (CN), indicating that Spanish speakers find this usage most challenging. Similarly, “received” as an adjective is consistently difficult across all L1s (ES: -5.90 , DE: -5.06 , CN: -3.88), while “clear” as an adverb shows strong L1 variation (ES: -4.14 , DE: $+2.64$, CN: -3.12), suggesting that German speakers find this usage relatively easy compared to other L1 groups.

5.3 Prediction Compression

Our predictions exhibit variance compression: the predicted standard deviation is only 81% of the true value for Spanish ($\sigma_{pred} = 1.53$ vs. $\sigma_{true} = 1.88$; Figure 4). We attempted post-hoc calibration by scaling predictions, but this provided minimal improvement, indicating the gap to top systems lies in prediction quality (Pearson $r = 0.802$ vs. winner’s $r = 0.920$) rather than calibration alone.

5.4 Ridge Blend Failure

One of our open track runs incorporated a Ridge regression with interaction features (frequency $\times$ word length, cognate $\times$ frequency), blended with our ensemble at 85%/15%. While this improved development set performance, it failed on test: RMSE of 1.397 (DE) and 1.421 (CN), worse than the baseline. The interaction features captured patterns in the 677-item development set that did not generalize to the test set. This outcome highlights the risk of incorporating models validated only on a single held-out split without cross-validation. We did not perform cross-validation of the blend weights prior to submission, which we identify as a methodological limitation.

5.5 Gap to Top Systems

Our system explains 64.3% of score variance ($r^2 = 0.643$ for ES) compared to the winners’ 84.6% ($r^2 = 0.846$). We hypothesize that this

gap is driven by three factors: (1) model scale (xlm-roberta-base has 270M parameters, while larger variants such as xlm-roberta-large or DeBERTa-v3-large have 430M–560M); (2) model diversity across multiple architectures; and (3) the use of generative large language models fine-tuned for regression in the open track, in addition to encoder models like ours. These three factors likely account for the bulk of the 0.27–0.40 RMSE gap.

6 Conclusion

We presented a multi-model ensemble for vocabulary difficulty prediction, combining linguistic features with XLM-RoBERTa transformers across both tracks. Our system outperforms baselines on all six track-L1 combinations. Error analysis reveals polysemous words in rare senses as the primary failure mode, with nominalized *-ing* forms showing 58% higher RMSE. The gap to top systems is driven primarily by model scale and diversity. For future work, we identify larger models, multi-architecture stacking, and sense-aware features as the most promising directions.

Limitations

Our system has several limitations. We use only xlm-roberta-base (270M parameters), limiting model capacity. Our multi-seed averaging uses only 3 seeds. Feature engineering operates at the word level without sense-level or morphological features. The Ridge blend was validated on a single split rather than with cross-validation, leading to overfitting. We do not leverage LLMs for the open track. Finally, while we have extended our error analysis to include cross-lingual comparisons, a more systematic analysis across all L1s remains future work.

Ethics Statement

This work uses the publicly available BEA 2026 shared task dataset. The data contains vocabulary items and aggregated difficulty scores; no individual learner data is accessible. Our system is intended to support educational applications. Automated difficulty prediction should complement, not replace, expert judgment in high-stakes assessment.

Acknowledgements

We thank Dr. Shabana K M, Senior Project Scientist at the Wadhvani School of Data Science and AI, Indian Institute of Technology Madras, for her

guidance and feedback on this work. We also thank the shared task organizers for organizing the task and providing the dataset. Computing resources were provided by Kaggle.

Abstract

We study vocabulary difficulty prediction for second language (L2) learners, a key component for adaptive language learning and assessment. Existing approaches often treat difficulty as an intrinsic property of words or contexts, overlooking representation-dependent variation and learner-specific factors such as L1 transfer.

We participate in the BEA 2026 Shared Task Closed Track using the Spanish (L1) subset of the KVL dataset. We propose a two-stage framework that decouples representation learning from learner-aware calibration. Stage 1 constructs diverse representations using multiple pretrained encoders with varied pooling and prediction strategies, capturing complementary aspects of lexical and contextual complexity. Stage 2 models systematic residual errors with psycholinguistic and cross-lingual features, enabling explicit correction of prediction biases.

Experiments show that our method outperforms strong baselines, improving RMSE ($1.257 \rightarrow 0.976$) and correlation ($0.765 \rightarrow 0.857$). These results highlight the importance of jointly modeling representation diversity and learner-specific effects. Our system ranked 3rd in the official BEA 2026 Shared Task Closed Track.

1 Introduction

Vocabulary is central to language proficiency, shaping what learners can understand and produce. Accurately estimating vocabulary difficulty is essential for level-appropriate content, adaptive assessment, and personalized learning, yet traditional approaches still rely on costly expert judgment and large-scale pretesting.

Recent work leverages pretrained language models and regression methods, but typically treats difficulty as an intrinsic property of words or contexts, overlooking learner-specific variation. In particular, prior approaches do not explicitly

model how difficulty varies with the learner’s first language (L1), despite strong evidence that cross-lingual effects—such as cognates and false friends—systematically influence acquisition.

We revisit vocabulary difficulty prediction from a representation perspective, arguing that difficulty is inherently representation-dependent. Different encoder architectures and aggregation strategies capture complementary aspects of linguistic complexity, making single-model approaches often insufficient in practice.

To address this, we propose a two-stage framework that decouples representation learning from learner-aware calibration via structured residual modeling. Stage 1 constructs representations using multiple pretrained backbones with diverse pooling and prediction heads, aggregating out-of-fold predictions to capture complementary signals. Stage 2 models systematic residuals using psycholinguistic and cross-lingual features, capturing structured biases such as first language (L1)–second language (L2) alignment and exposure differences. This design improves stability and generalization while preserving reliability.

We evaluate our approach on the BEA 2026 Shared Task (KVL dataset), achieving top-tier performance with consistent improvements in RMSE and correlation. Our code and trained models are available online.¹

Our contributions are:

- We show that vocabulary difficulty is inherently representation-dependent, motivating the use of diverse representations.
- We propose a two-stage framework with residual calibration for L1-aware prediction.
- We demonstrate that combining representation diversity with residual calibration improves L1-aware vocabulary difficulty prediction.

2 Related Work

2.1 Lexical Complexity Prediction

Vocabulary difficulty prediction is closely related to lexical complexity prediction (LCP), which extends complex word identification from classification to regression. Early approaches relied on surface features such as frequency and length (Kuperman et al., 2012), while recent work adopts transformer-based contextual representations (Gooding et al., 2020; Shardlow et al., 2021).

Recent studies demonstrate strong performance with pretrained multilingual encoders in cross-lingual settings (Bani Yaseen et al., 2021; Kelious et al., 2024). However, these approaches typically treat complexity as an intrinsic property of words or contexts, largely ignoring learner-specific variation. In particular, they do not explicitly model how difficulty varies with the learner’s linguistic background, which limits their applicability to L2 settings. Our work addresses this limitation by combining learner-aware representations with feature-based calibration for difficulty prediction.

2.2 L1 Transfer and Cross-lingual Effects

L1 transfer plays a central role in second language acquisition, affecting both facilitation and interference (Ellis, 1997). Cognates can ease processing through cross-lingual similarity, whereas false friends introduce systematic errors due to form–meaning mismatches (Van Assche et al., 2009; Schepens et al., 2012).

While cross-lingual effects are widely studied, their integration into lexical difficulty prediction remains limited. Existing approaches often rely on surface similarity (e.g., edit distance), which fails to capture semantic divergence or exposure differences across languages. As a result, they are prone to systematic biases, particularly in cases such as false friends. In contrast, our work goes beyond surface similarity by leveraging cross-lingual and linguistic signals to capture such divergences.

3 Task and Dataset

3.1 Task Definition

The BEA 2026 Shared Task addresses vocabulary difficulty prediction for English learners with diverse L1 backgrounds. The task is formulated as a regression problem, where the goal is to predict a continuous difficulty score for a given English word conditioned on the learner’s L1.

Each instance includes an English word and its associated L1 information (e.g., translation or context), and the target is a psychometrically calibrated difficulty score. We use the Knowledge-based Vocabulary Lists (KVL) dataset (Schmitt et al., 2021, 2024), a multilingual resource annotated with difficulty scores.

3.2 Task Setup

We follow the Closed Track setting, where models are trained only on the provided data for each L1, without using external training data or combining different L1 datasets. Pre-trained Transformer models and standard NLP tools are allowed, while LLMs are prohibited. Public linguistic resources (e.g., WordNet) may be used for feature extraction.

In this work, we focus on the Spanish (L1) subset of the dataset. All models are trained and evaluated exclusively on Spanish learner data, in accordance with the Closed Track constraints.

3.3 Dataset

We use an extended version of the British Council’s Knowledge-based Vocabulary Lists (KVL) dataset (Skidmore et al., 2025) to model vocabulary difficulty for English learners with diverse L1 backgrounds. We use only the Spanish subset in our experiments.

The dataset is constructed from large-scale assessments of productive vocabulary knowledge, where learners recall English target words from L1 prompts in a translation-based format (Laufer and Goldstein, 2004). Each item consists of an L1 context sentence, an L1 cue word, and a partially masked English target (e.g., h_____ for “house”).

Difficulty scores are estimated from approximately 3.3 million learner responses using random-item-random-person (RPRI) Rasch models within a generalized linear mixed model (GLMM) framework. The resulting GLMM score (logit scale) is used as the prediction target, where higher values indicate greater difficulty for learners.

The dataset is provided per L1 and split into train/dev/test sets (6,091 / 677 / 748 items). Each instance includes the target word, part-of-speech, a partial spelling clue, the L1 word and context, and a difficulty score. All data are released under CC BY-NC 4.0, with official baselines and evaluation scripts.²

(a) Stage 1: Single-backbone pipeline

(b) Two-stage framework

Figure 1: Overview of the proposed two-stage framework. (a) Stage 1 uses a single-backbone pipeline (encoder, pooling, and head) with multiple PLMs to produce diverse out-of-fold (OOF) predictions. (b) Stage 2 refines these via residual calibration with psycholinguistic features, followed by simple averaging ensemble.

4 Method

4.1 Stage 1: Multi-Backbone Representations

In the first stage, we construct a diverse set of sequence representation models based on multiple pretrained language model (PLM) backbones and pooling strategies. The goal of this stage is to obtain robust and complementary predictions by leveraging representation diversity across different model architectures and aggregation mechanisms. Since the task requires both lexical cues and contextual understanding, we adopt heterogeneous backbones to capture multi-level signals. This is particularly important for our task, where difficulty prediction requires capturing both surface-level patterns and deeper semantic features that individual models fail to consistently handle.

PLM Backbones. We utilize a diverse set of multilingual encoder-based pretrained language models (PLMs), including XLM-R (Conneau et al., 2020), RemBERT (Chung et al., 2021), mDeBERTa (He et al., 2023), mmBERT (Marone et al., 2025), and mBERT (Devlin et al., 2019), and select a subset based on validation performance and prediction diversity. We observe that their outputs vary for the same input, indicating complementary behavior.

Pooling Strategies. Given an input sequence, each backbone model produces token-level contextual embeddings. Since downstream prediction requires a fixed-length representation, we apply pooling over the final hidden states to construct a sequence-level representation. Specifically, we consider three pooling strategies: the [CLS] token representation, mean pooling, and attention pooling (Lin et al., 2017). We explore various combinations of pooling methods and prediction heads, and select a subset based on validation performance. This design enables the model to capture both global context and salient token-level signals.

Selected Model Variants. We retain three representative models, each with a distinct pooling and head configuration, and use them as base predictors in the subsequent ensemble stage (Figure 1).

Training Protocol. To ensure robust and unbiased predictions, we adopt 5-fold cross-validation (CV) for each model variant. Models are trained on different splits, and out-of-fold (OOF) predictions are generated for all training instances. These OOF predictions ensure each instance is represented by predictions from models not trained on it, preventing data leakage and reducing overfitting bias in Stage 2. The resulting OOF outputs from all base models serve as inputs to the ensemble stage.

4.2 Stage 2: Psycholinguistic Calibration

While Stage 1 captures contextual and semantic representations, it underrepresents linguistically grounded signals (e.g., frequency, morphology, and L1-driven orthographic patterns) related to word difficulty. To address this limitation, Stage 2 leverages handcrafted features and trains a LightGBM regressor (Ke et al., 2017) to predict the residual ($y - \hat{y}_1$), where $\hat{y}_1$ is the Stage 1 prediction. This residual formulation refines predictions without overriding accurate estimates, yielding more stable improvements and lower variance across folds.

Rather than directly predicting the target value, this residual formulation focuses on correcting errors from Stage 1, allowing the model to refine predictions without overriding already accurate estimates. This leads to more stable performance improvements and empirically reduced variance across folds compared to direct regression.

Feature Engineering. We derive features from four linguistically motivated groups, with cross-lingual features capturing L1-positive transfer by approximating how Spanish speakers transform English words orthographically. Specifically, we apply rule-based modifications to the English target, such as *-tion* $\rightarrow$ *-cion* and *ph* $\rightarrow$ *f*, including suffix, phonetic, and orthographic adjustments. We then compute the reduction in Levenshtein distance to the Spanish equivalent before and after transformation, capturing the degree of morphological predictability under L1 influence. We further incorporate a cognate similarity score based on positional character n-gram overlap to capture systematic cross-lingual similarity.

Psycholinguistic features primarily include the log-frequency gap between L2 words and their L1 equivalents and concreteness scores, reflecting cognitive processing difficulty. Lexical and morphological features provide complementary signals, including word frequency, length, and morpheme structure. Full details of cross-lingual transformations are provided in Appendix A.1.

Optimization Strategy. To identify an effective feature configuration, we perform a group ablation study over 119 valid combinations of feature subgroups, evaluated using out-of-fold (OOF) RMSE. We consistently observe that cross-lingual features are included in all competitive configurations, highlighting their central role.

Based on this analysis, we select a subset com-

binning lexical, morphological, cross-lingual, and psycholinguistic features. Although this configuration does not achieve the best performance under default settings, it shows stronger gains after tuning and becomes optimal. This suggests that configurations with psycholinguistic features are more responsive to tuning.

We perform hyperparameter optimization with Optuna, tuning key parameters such as tree complexity and regularization. This achieves the best post-tuning performance across candidate groups.

We also explore an end-to-end alternative that directly integrates handcrafted features into Stage 1, but this approach does not yield consistent or substantial improvements over the standalone neural model. This suggests a mismatch between PLM representations and handcrafted feature distributions, making direct integration less effective. In contrast, the proposed two-stage design separates representation learning from calibration, allowing Stage 2 to model non-linear feature interactions and correct errors more effectively.

Post-processing. We apply a lightweight post-processing pipeline with an OOF-gated selection strategy. Candidate transformations (e.g., clipped blending, isotonic regression, and tail calibration) are sequentially and systematically evaluated and retained only if they strictly reduce OOF RMSE, ensuring consistent gains without overfitting. In practice, only isotonic regression is selected, yielding additional improvements.

Full implementation details, ablation results, and optimization are provided in the Appendix.

5 Experimental Setup

5.1 Data Usage

We use the official train/dev/test splits with model selection on the development set. Each instance is formatted as a natural language prompt combining the L1 context, source word, English target, auxiliary clues, and part-of-speech, as shown in Table 9 in Appendix A.4, and fed into the PLM.

5.2 Evaluation Metrics

We evaluate performance using RMSE (Root Mean Squared Error) between predicted and gold GLMM scores. RMSE is the primary metric for model comparison. We also report the Pearson correlation coefficient to measure the linear relationship between predictions and ground-truth scores.

5.3 Baselines and Ablation Models

We compare our method with external baselines and internal ablation models.

As baselines, we consider (1) the official baseline provided by the shared task organizers and (2) a feature-based Ridge regression model using hand-crafted features, including cross-lingual exposure, contextual average word length, frequency-based statistics (e.g., Zipf score, frequency rank, L1/L2 frequency), and concreteness.

We also include ablation models corresponding to the first stage of our framework. Stage 1 (Single) denotes single-backbone models with different pooling and head configurations, each evaluated independently; performance is reported as the average. Stage 1 (Ensemble) aggregates predictions from the top three encoder backbones, each paired with its best pooling and head configuration.

These variants analyze the contribution of model diversity and the effectiveness of the two-stage design. Final results are presented in Section 6.1.

6 Results

6.1 Main Results

We evaluated the proposed approach against the official baseline and progressively stronger model variants to assess the contribution of each component. Table 1 summarizes the overall performance.

Model	Dev RMSE ↓	Test	
		RMSE ↓	r ↑
<i>Baselines</i>			
Official Baseline	—	1.257	0.765
Feature-based (Ridge)	1.426	1.429	0.652
<i>Ablations</i>			
Stage 1 (Single)	1.040	1.053	0.838
Stage 1 (Ensemble)	0.975	0.989	0.851
Two-Stage (Ours)	0.958	0.976	0.857

Table 1: Performance comparison across baselines and ablation models. RMSE is reported for the development set, and both RMSE and Pearson correlation (r) are reported for the test set.

Our method clearly outperformed all baselines. Compared to the official baseline, the proposed two-stage model significantly reduced RMSE (1.257 $\rightarrow$ 0.976) while improving Pearson correlation (0.765 $\rightarrow$ 0.857), indicating better alignment with ground-truth difficulty scores.

A large performance gap between the baselines (both official and feature-based) and Stage 1 (Sin-

gle) highlighted the importance of task-specific tuning of pretrained encoders with appropriate pooling strategies and prediction heads.

We observed consistent gains across modeling stages. Moving from Stage 1 (Single) to Ensemble improved performance, highlighting representation diversity, while the two-stage model further enhanced accuracy and stability through refinement.

Overall, the results suggested that the primary gains stemmed from effective representation learning and diversity, while additional improvements were achieved through explicit refinement in the second stage. Consistent with these findings, our approach ranked 3rd on the official shared task leaderboard.

6.2 Representation Analysis and Ensembling

To analyze representation design, we evaluated multiple encoder families (BERT, mDeBERTa, RemBERT, and XLM-R) across pooling and prediction head configurations. For each encoder, we report both the average RMSE across all configurations (as a robustness proxy) and the best RMSE.

As shown in Table 2, XLM-R (large) achieved the best performance (1.029 best, 1.038 avg), followed by RemBERT and mDeBERTa-v3.

Encoder	Dev RMSE ↓	
	Avg	Best
XLM-R (large)	1.038	1.029
RemBERT	1.045	1.036
mDeBERTa-v3	1.057	1.047
mmBERT	1.072	1.062
XLM-R (base)	1.193	1.185
mBERT (cased)	1.267	1.254

Table 2: Encoder comparison across pooling and head configurations. We report mean RMSE (Avg; reflecting robustness across configurations) and best RMSE for each encoder, highlighting encoder-dependent performance variation.

Despite the general advantage of larger encoders, representation design introduced substantial variation: within a single encoder, performance differences across configurations reached 0.02–0.04 RMSE, comparable to or exceeding inter-encoder gaps (e.g., 0.007 between XLM-R (large) and RemBERT). This indicated that encoder choice alone was insufficient, and pooling/head design played an equally critical role.

Table 3 presents representative top configurations for each encoder, suggesting encoder-specific

preferences. For instance, XLM-R (large) worked best with mean pooling and a linear head, whereas mDeBERTa-v3 favored attention-based pooling.

Encoder	Pooling + Head (Dev RMSE ↓)		
	MEAN+Lin	ATTN+Lin	ATTN+MLP
XLM-R (large)	1.029	1.031	1.041
RemBERT	1.036	1.048	1.042
mDeBERTa-v3	1.050	1.047	1.063

Table 3: Representative top-performing pooling and head configurations for each encoder. The results indicate encoder-dependent preferences over design choices, highlighting systematic differences in preferred strategies across models.

Moreover, configuration rankings varied across encoders, suggesting that models captured different aspects of the task in practice. A single unified design would therefore underutilize encoder-specific strengths. Instead, we adopted a model-wise optimal strategy, pairing each encoder with its best-performing configuration.

Our final ensemble integrated the top three encoders—XLM-R, RemBERT, and mDeBERTa-v3—each paired with its optimal pooling and head configuration. This design leveraged diverse representations across models, consistently leading to improved overall performance.

Overall, our results highlighted that performance gains stemmed not only from stronger pretrained backbones, but also from effectively leveraging representation diversity inherently induced by pooling and head design choices.

6.3 Calibration and Residual Correction

We constructed the Stage 1 ensemble by averaging three models—XLM-R (large), RemBERT, and mDeBERTa-v3—each with its optimal pooling and prediction head. Although effective, the ensemble still exhibited structured residual errors. To address this, we applied calibration in the prediction space (Guo et al., 2017). Table 4 summarizes the results.

The uncalibrated ensemble achieved 1.028 OOF RMSE and 0.995 Dev RMSE. Calibration consistently improved performance. Under Avg-then-Calib, RMSE decreased to 0.999 (LightGBM), indicating that residual errors remained learnable after ensembling.

Calib-then-Avg yielded larger gains, outperforming Avg-then-Calib across all calibrators. The best performance was achieved by LightGBM, reaching 0.976 OOF RMSE and 0.958 Dev RMSE.

Strategy	Calibrator	RMSE ↓	
		OOF	Dev
No calibration	–	1.028	0.995
Avg-then-Calib	Ridge	1.017	0.984
	XGBoost	1.011	0.974
	LightGBM	0.999	0.977
Calib-then-Avg	Ridge	1.013	0.978
	XGBoost	0.995	0.968
	LightGBM	0.976	0.958

Table 4: Comparison of calibration strategies for the Stage 1 ensemble. Avg-then-Calib denotes averaging followed by calibration, while Calib-then-Avg denotes calibrating before averaging. OOF RMSE is computed on out-of-fold predictions.

These results suggested that calibrating individual models before ensembling was more effective, correcting model-specific residual patterns prior to aggregation. Additionally, tree-based calibrators (LightGBM, XGBoost) outperformed Ridge, highlighting the importance of modeling nonlinear residuals. Based on this, we adopted Calib-then-Avg with LightGBM as the final approach.

6.4 Performance on Tail Distributions

Modeling extreme cases was a key challenge in continuous difficulty estimation. To analyze this, we evaluated performance across difficulty tiers, treating Easy and Hard as tails and Mid as center.

Table 5 reports RMSE for Stage 1 (S1) and Stage 2 (S2), along with relative changes, further stratified by cognate status. Difficulty groups are defined as Easy ($y > 2.5$), Mid ($-2.0 < y \leq 2.5$), and Hard ($y \leq -2.0$), and N denotes the number of samples in each subset. All rows summarize group-level performance.

Difficulty	Cognate	N	Dev RMSE ↓		Δ (%)
			S1	S2	
Easy	All	621	1.019	1.047	-2.75
	Cog.	170	0.985	0.945	+4.06
	Non-Cog.	451	1.031	1.083	-5.04
Mid	All	4537	0.881	0.847	+3.86
	Cog.	626	0.920	0.872	+5.22
	Non-Cog.	3911	0.874	0.843	+3.55
Hard	All	933	1.450	1.369	+5.59
	Cog.	50	1.833	1.794	+2.13
	Non-Cog.	883	1.425	1.341	+5.89

Table 5: Performance across difficulty groups and lexical similarity subsets. S1 and S2 denote Stage 1 and Stage 2 models, respectively. Δ (%) indicates RMSE reduction from S1 to S2 (positive = better).

Results showed a clear asymmetry across regions. In the Mid tier, S2 consistently improved performance (All: +3.86%, Cognates: +5.22%, Non-cognates: +3.55%), indicating effective residual correction in stable regions where feature signals were well-aligned.

In contrast, performance degraded in the Easy tail (All: -2.75%), mainly due to non-cognates (-5.04%), despite cognate gains (+4.06%). This suggested over-correction in low-variance regions where predictions were already reliable, likely due to over-reliance on similarity-based features.

At the Hard tail, S2 yielded the largest improvements (All: +5.59%, Cognates: +2.13%, Non-cognates: +5.89%), indicating that residual modeling effectively reduced errors in high-uncertainty cases, including challenging *false-friend* scenarios where surface similarity was misleading.

Overall, calibration yielded the greatest improvements in high-uncertainty regions, where predictions were less reliable, but might lead to overcorrection in low-variance regions, where predictions were already stable, thereby underscoring the need for difficulty-aware calibration.

7 Discussion

7.1 Two-Stage Modeling

A central finding was that the proposed framework constituted a structural decomposition between representation and calibration. Rather than attempting to jointly model all factors in a single space, the two-stage design separated robust difficulty representation from systematic error correction.

A key insight underlying Stage 1 was that difficulty representation was fundamentally model-dependent. Different encoder architectures and aggregation choices captured complementary aspects of linguistic complexity, indicating that no single configuration was universally optimal. As a result, relying on a fixed architecture risked overlooking important signals. Instead, Stage 1 constructed a robust representation layer by integrating strong configurations, enabling the model to capture diverse facets of language-intrinsic difficulty while reducing sensitivity to individual design choices.

This design was motivated by the observation that optimal configurations varied across encoders, highlighting the importance of encoder-specific optimization for stable representation learning.

Stage 2 operated in the residual space, performing learner-dependent and psycholinguistic correc-

tion. By incorporating language-specific signals (e.g., cognate effects and cross-lingual similarity patterns) grounded in the Spanish domain, it addressed systematic discrepancies—such as mismatches between surface similarity and actual difficulty—that were not captured by semantic representations alone.

Crucially, calibration in this framework functioned as a structured bias correction mechanism. By decoupling representation from correction, the model preserved the underlying difficulty signal while explicitly modeling residual errors, which led to more stable and interpretable predictions, particularly in challenging cases where single-stage models tended to conflate linguistic similarity with true difficulty.

7.2 Feature Importance Analysis

The tree-based calibration model enabled interpretability via feature importance measured by split frequency. To support reproducibility and clarify the feature design, a complete inventory of handcrafted features and their sources is provided in Table 11.

As shown in Table 6, top features fell into three categories—cross-lingual, lexical, and psycholinguistic. We utilized handcrafted features based on lexical frequency information from Wordfreq (Speer, 2022), psycholinguistic properties such as concreteness (Brysbaert et al., 2014), word complexity, and cross-lingual exposure derived from English–Spanish frequency differences.

Feature	Category	Split Count
Crossling_Exposure	Cross-lingual	180
Ctx_Avg_Word_Len	Psycholinguistic	176
Global_Zipf_Score	Lexical	171
Freq_Rank_Norm	Lexical	160
Freq_L1_L2_Gap	Psycholinguistic	157
L1_Zipf_Score	Psycholinguistic	143
Concreteness	Psycholinguistic	136

Table 6: Top features ranked by importance based on split frequency in the tree-based model. Feature names are abbreviated; detailed descriptions are provided in the text. *Split Count* denotes the number of times a feature is selected for node partitioning across all trees.

Psycholinguistic and exposure-related features dominated: four of the top seven were psycholinguistic, with others reflecting frequency or cross-lingual exposure. Importantly, *Crossling_Exposure* ranked highest, followed by *Global_Zipf_Score* and *Freq_L1_L2_Gap*.

These results suggested that difficulty for Spanish L1 learners was driven less by intrinsic word properties and more by exposure and alignment with prior linguistic experience. The importance of *Freq_L1_L2_Gap* highlighted cross-lingual frequency mismatch. Finally, *Concreteness* supported prior findings that concrete words were easier to acquire (Brysbaert et al., 2014; Paivio, 1991).

7.3 Error Analysis

To analyze model limitations, we examined representative failure cases from two complementary perspectives: systematic errors due to false friends and qualitative examples of model behavior.

A primary source of error arose from *false friends*, where words were orthographically similar to their Spanish counterparts but semantically divergent. In such cases, the model overestimated easiness due to surface-form similarity (e.g., *embarrassed* vs. *embarazada*). This suggested that while cross-lingual similarity was effectively captured, semantic alignment was insufficiently modeled, particularly in semantically divergent cases.

Table 7 shows representative examples of Stage 2 calibration. GLMM denotes ground-truth difficulty, and S1/S2 indicate predictions from Stage 1 and Stage 2, respectively. *Cognates* (↑) were consistently adjusted toward easier difficulty, *Non-cognate* instances remained appropriately difficult without substantial change, and *Failure* highlighted errors arising from missed cognate detection.

English	Spanish	GLMM	S1	S2
<i>Cognates</i> (↑)				
domination	dominación	+1.40	-0.36	+0.75
consecutive	consecutivo	+1.19	-0.62	+0.44
discipline	disciplina	+2.06	+0.51	+1.56
compulsive	compulsivo	+1.79	-0.25	+0.75
selective	selectivo	+2.13	-0.07	+0.92
<i>Non-cognate</i>				
skillet	sartén	-3.02	-1.08	-2.56
<i>Failure</i>				
synonym	sinónimo	-1.72	+0.83	-0.26

Table 7: Stage 2 calibration examples by word type. GLMM: ground truth; S1/S2: Stage 1/2 predictions.

For transparent cognates (e.g., *domination* / *dominación*), Stage 1 underestimated easiness, whereas Stage 2 corrected predictions using additional features. Non-cognates (e.g., *skillet*) remained appropriately difficult, indicating that calibration was not applied indiscriminately.

However, failure cases (e.g., *synonym* / *sinónimo*) revealed limitations of the cognate detection mechanism. Despite semantic equivalence, orthographic mismatch led to low similarity scores and inaccurate predictions.

Overall, while the model effectively leveraged cross-lingual similarity, it remained vulnerable to semantic divergence and surface-form limitations.

8 Conclusion

In this work, we addressed the problem of vocabulary difficulty prediction for L2 learners by focusing on representation diversity and learner-specific factors. We proposed a two-stage framework that separates representation learning from psycholinguistic calibration, enabling the model to capture both language-intrinsic difficulty and systematic cross-lingual effects.

Experimental results demonstrated that our approach consistently outperformed strong baselines, achieving substantial improvements in both RMSE and correlation. The primary gains stemmed from combining diverse pretrained encoders with optimized pooling and prediction head configurations, allowing the model to capture complementary lexical, contextual, and semantic signals. The calibration stage further improved predictions by modeling structured residual errors using psycholinguistic and cross-lingual features, particularly in high-uncertainty regions where semantic representations alone were insufficient.

Our analysis further suggested that vocabulary difficulty should not be viewed solely as an intrinsic property of words, but as a learner-dependent phenomenon shaped by prior linguistic experience and L1-L2 alignment. More specifically, features related to cross-lingual exposure and frequency mismatch played a central role in explaining learner difficulty for Spanish L1 speakers.

Overall, the proposed framework demonstrates that separating representation learning from residual correction provides a stable and effective approach for L1-aware vocabulary difficulty prediction. Beyond the shared task setting, we believe this framework offers a practical foundation for adaptive language learning and personalized educational applications.

Future work will explore semantics-aware cross-lingual representations and more adaptive calibration strategies to better handle semantically challenging cases across diverse learner settings.

9 Limitations

Despite the strong overall performance, our framework still exhibited several limitations. First, the model remained vulnerable to cases involving semantic divergence, such as false friends, where reliance on surface-level similarity occasionally produced systematic prediction errors. This suggests that the current representation space does not fully capture deeper semantic correspondence across languages. In addition, the calibration stage sometimes introduced over-correction in low-variance regions, indicating that more adaptive calibration strategies may be necessary for stable refinement.

We also note that the exploration of Stage 1 ensemble configurations was not fully exhaustive due to computational limitations and time constraints. Finally, although the proposed framework demonstrated strong effectiveness for Spanish L1 learners, its generalizability to broader learner populations and additional L1 settings remains to be validated.

A Appendix

A.1 Cross-lingual Feature Details

A.1.1 Hispanized Transformation Rules

To approximate the orthographic transformation process of Spanish learners, we apply a sequence of rule-based modifications to English target words. The rules are grouped as follows:

Suffix Mapping. We map common English suffixes to their Spanish counterparts:

- *-tion* → *-cion*
- *-ty* → *-dad*
- *-ly* → *-mente*
- *-ous* → *-oso*
- *-ence* / *-ance* → *-encia* / *-ancia*

Phonetic Mapping. We simulate phonological adaptation:

- *ph* → *f*
- *th* → *z* (Peninsular) or *s* (Latin American seseo)

Prothetic *e*. We prepend *e* to words beginning with an *s*+consonant cluster:

- *special* → *especial*

Consonant Simplification. We reduce double consonants except *ll* and *rr*.

A.1.2 Distance-Based Feature

Let d_{orig} denote the Levenshtein distance between the original English word and its Spanish translation, and d_{trans} denote the distance after applying the transformation rules. We define the cross-lingual predictability feature as:

$$\Delta d = d_{\text{orig}} - d_{\text{trans}} \quad (1)$$

A larger Δd indicates that the transformed form is closer to the Spanish equivalent, reflecting higher morphological predictability under L1 influence.

A.1.3 Cognate Similarity

We compute a positional character n-gram overlap score to capture cognate similarity. The score is defined as a weighted sum of matching character sequences:

- First-character match: +0.3

- First three-character match: +0.4
- Last three-character match: +0.3

Words with a score above 0.4 are considered cognates. We additionally include a binary feature indicating systematic cognate correspondence.

A.2 Feature Group Ablation

To analyze the contribution of each feature group, we perform a group ablation study over combinations of feature subgroups and evaluate them using out-of-fold (OOF) RMSE. Table 8 reports the top-performing configurations.

Feature Groups	OOF RMSE ↓
lex + cross + derived	1.0506
lex + morph + cross + derived	1.0508
lex + morph + cross	1.0510
lex + cross	1.0511
lex + morph + cross + psycho	1.0513

Table 8: Top-5 feature group combinations from the ablation study. Cross-lingual features consistently appear in all competitive configurations. The selected setting (lex + morph + cross + psycho) is used for Stage 2.

We consistently observe that cross-lingual features are present across all high-performing configurations, confirming their central role in modeling word difficulty.

A.3 Optimization and Postprocessing Details

A.3.1 Hyperparameter Optimization

We conduct hyperparameter optimization using Optuna to tune a set of key LightGBM parameters such as `n_estimators`, `learning_rate`, `num_leaves`, `min_child_samples`, `subsample`, `colsample_bytree`, and L1/L2 regularization.

The selected configuration achieves the best post-tuning performance across all candidate feature groups, with an OOF RMSE of 1.040.

A.3.2 Post-processing Details

We apply a sequence of candidate post-processing steps to further calibrate model predictions. Each step is evaluated using out-of-fold (OOF) RMSE and is only retained if it strictly improves performance.

Candidate Steps. The post-processing pipeline includes clipped blending, isotonic regression, and tail calibration.

Selection Outcome In practice, only isotonic regression satisfies the OOF gating criterion, resulting in an additional reduction of approximately 0.010 in OOF RMSE.

A.4 Prompt Construction

We construct the input as a structured natural language prompt by mapping dataset fields to semantically meaningful components. The *Spanish context* provides the L1 sentence containing the target word, while the *Spanish word* denotes the aligned lexical item. The *English translation* specifies the target whose difficulty is to be predicted. The *Meaning clue* provides auxiliary hints, with part-of-speech information appended in parentheses. The prediction target is the GLMM score, which reflects the perceived difficulty of the English word for L1 speakers. Table 9 shows the mapping from each component to its textual realization.

Component	Example
Spanish context	El eclipse solar fue visible durante un breve lapso de tiempo.
Spanish word	lapso
English translation	span
Meaning clue	s___ (noun)

Table 9: Example of the structured prompt, showing the mapping from each component to its textual realization.

B Training Hyperparameters

Setting	Value
<i>Shared settings</i>	
Optimizer	AdamW
Learning rate	2×10^{-5}
Batch size	16
Gradient accumulation steps	2
Warmup ratio	0.1
Weight decay	0.01
Max sequence length	256
Precision	FP16
<i>LightGBM calibrator (Optuna-tuned)</i>	
<code>n_estimators</code>	400
<code>learning_rate</code>	0.03
<code>num_leaves</code>	31
<code>min_child_samples</code>	20
<code>subsample</code>	0.8
<code>colsample_bytree</code>	0.8
<code>reg_alpha</code> (L1)	0.1
<code>reg_lambda</code> (L2)	1.0

Abstract

We present team Failure’s submission to the BEA 2026 Shared Task on L1-aware vocabulary difficulty prediction for English learners (Felice and Skidmore, 2026). We investigate whether a single, language-agnostic pipeline can achieve competitive performance across typologically distinct L1 settings without per-language manual engineering. We implement a unified notebook, model architecture, and training procedure for Spanish, German, and Mandarin Chinese. Our system fine-tunes xlm-roberta-base (Conneau et al., 2020) with attention-mask-weighted mean pooling, augmented with four universal length-based features. We use Optuna-driven hyperparameter search (Akiba et al., 2019) and a leakage-free 5-fold ensemble with fold-specific standardization. Under this unified and compute-constrained setup, our closed-track system outperforms the official baseline on all three evaluation languages: RMSE 1.219 vs. 1.257 for Spanish, 1.118 vs. 1.258 for German, and 1.090 vs. 1.140 for Chinese. These results suggest that a compact, reproducible pipeline can yield consistent improvements without L1-specific customization, providing a practical baseline for multilingual educational NLP.

1 Introduction

Vocabulary difficulty prediction is a canonical educational NLP task, with applications in adaptive assessment, content selection, and learning models. The BEA 2026 Shared Task (Felice and Skidmore, 2026) poses the task as a regression problem: given an English vocabulary test item and its corresponding first-language (L1) context, the objective is to predict the psychometrically calibrated GLMM difficulty score for learners from one of three L1 backgrounds: Spanish, German, and Mandarin Chinese.

One might imagine solving the task in the most intuitive way, by training specialized models for

each L1 condition, which requires different feature engineering or heuristics tailored to the language at hand. However, we adopt a language-agnostic stance. The motivation for this work is grounded in the assumption that there is sufficient underlying structure in the task across L1 conditions to allow a generalized approach to perform better than the official baseline on all three languages, even in a setup where all models are independently tuned with identical architecture, features, hyperparameters, and training methodology.

There is more to this line of reasoning than maximizing leaderboard scores. A language-agnostic pipeline is more easily audited and reproduced than a language-specific one. It also is more easily extended to new L1 conditions should the community choose to do so in future tasks. A model that can run on freely available hardware is more widely applicable and usable than one requiring institutional compute. Finally, an approach that relies on consistent modeling assumptions rather than language-specific heuristics is a more scientifically interesting contribution.

In this closed-track paper, we show that this language-agnostic pipeline achieves superior performance on all three languages, as predicted. This contribution goes beyond just improving the score, as it provides a complete pipeline that is reproducible in practice and runnable on free GPU hardware.

2 Task and Data

The BEA 2026 Shared Task (Felice and Skidmore, 2026) provides parallel data for three learner L1 conditions: Spanish (es), German (de), and Mandarin Chinese (cn). The target variable is GLMM_score, a psychometric difficulty estimate derived from more than 100,000 learner responses using random-item–random-person Rasch models (Schmitt et al., 2024).

The dataset is based on the British Council’s Knowledge-based Vocabulary Lists (KVL) (Schmitt et al., 2021) and was adapted into the Extended KVL Dataset for NLP (Skidmore et al., 2025). Each item includes the fields `item_id`, `L1`, `en_target_word`, `en_target_pos`, `en_target_clue`, `L1_source_word`, and `L1_context`; labeled splits additionally include `GLMM_score` as the target variable. Items with the same `item_id` across different L1 files are parallel, meaning they correspond to the same English target word but include L1-specific prompts and difficulty annotations.

Each L1 condition contains 6,091 training items, 677 development items, and 748 test items. We train one model per L1 condition using only the corresponding training data. The closed track does not permit combining data across L1s, using external training data, or relying on large language models. Our system fully complies with these constraints.

3 System Overview

Our system is implemented as a single Kaggle notebook and applied to all three L1 conditions. The only run-specific setting is the target L1 identifier (es, de, or cn); no language-specific preprocessing, feature engineering, or post-processing is used.

The pipeline has three stages controlled by a single `MODE` flag: hyperparameter search, 5-fold training with development evaluation, and test inference from saved fold checkpoints. The same codebase is reused across all languages and stages.

Figure 1 summarizes the overall workflow and the shared per-fold model architecture. In `MODE='optuna_tune'`, Optuna searches over the main training hyperparameters using reduced cross-validation. In `MODE='train_dev'`, the selected hyperparameters are used for full 5-fold training with fold-specific standardization, and the best checkpoint is saved for each fold. In `MODE='test_infer'`, the saved checkpoints are loaded, predictions are generated independently per fold, and the final output is obtained by averaging fold predictions and inverse-transforming them to the original `GLMM_score` scale.

4 Input Representation

Text serialization. For each item, we serialize all available text fields into a single input string using bracket markers:

```
[L1]   es   [WORD]  universal  [POS]
adjective [CLUE]  u_____ [SOURCE]
global [CONTEXT] La escalada. . .
```

This jointly exposes lexical, syntactic, orthographic, translational, and contextual information to the encoder. The serialization format is identical for all three languages. Text fields are cleaned by collapsing whitespace and replacing null values with empty strings, ensuring the tokenizer never receives null input.

Numerical features. We extract four character-count features from each item: **word_len**, **clue_len**, **source_len**, and **context_len**, computed as the character length of `en_target_word`, `en_target_clue`, `L1_source_word`, and `L1_context` respectively. These are universally available across all L1s and require no language-specific processing. Length-based signals are present in the task format itself, particularly through the partial-spelling clue, and can provide lightweight complementary information to the encoder.

5 Model Architecture

We use `xlm-roberta-base` (Conneau et al., 2020) as the encoder backbone. The serialized input is tokenized with a maximum length of 128 tokens and passed through the 12-layer transformer. We apply attention-mask-weighted mean pooling over the last hidden states:

$$\mathbf{h} = \frac{\sum_i m_i \cdot \mathbf{e}_i}{\sum_i m_i} \in \mathbb{R}^{768}$$

where $\mathbf{e}_i$ is the i -th token representation and $m_i \in \{0, 1\}$ is the attention mask value, so that padding tokens do not contribute to the pooled representation.

A dropout layer ($p = 0.1$) is applied to $\mathbf{h}$. The four numerical features are independently Z-score standardized using fold-specific training statistics to form $\mathbf{f} \in \mathbb{R}^4$. We concatenate them:

$$\mathbf{z} = [\mathbf{h}; \mathbf{f}] \in \mathbb{R}^{772}$$

A linear regression head produces the predicted difficulty: $\hat{y} = \mathbf{W}\mathbf{z} + b$. Training is performed in standardized target space using mean squared error (MSE) loss, and predictions are inverse-transformed to the original `GLMM` scale at evaluation time:

$$\hat{y}_{\text{raw}} = \hat{y} \cdot \sigma_{\text{fold}} + \mu_{\text{fold}}$$

Figure 1: Overview of our unified pipeline for one target L1. The upper panels show the three operating modes, and the lower panel shows the shared per-fold model architecture.

where μ_{fold} and σ_{fold} are the target mean and standard deviation computed on that fold’s training partition.

We selected xlm-roberta-base as the largest multilingual encoder that fit within the memory budget of our two available NVIDIA T4 GPUs.

6 Training Procedure

Hardware and runtime. All experiments were conducted on two NVIDIA T4 GPUs (16 GB each) available through the Kaggle free compute tier. Multi-GPU training was handled automatically via `nn.DataParallel`. A complete run for one L1 condition—including Optuna search, 5-fold training, development evaluation, and test inference—required approximately 2 hours of wall-clock time, with some variation depending on GPU availability.

Hyperparameter optimization. We use Optuna (Akiba et al., 2019) with a TPE sampler (TPESampler, seed 42) and a Median pruner (MedianPruner, `n_startup_trials=5`, `n_warmup_steps=1`) to optimize four hyperparameters: encoder learning rate in $[5 \times 10^{-6}, 5 \times 10^{-5}]$ (log scale), head learning rate in $[3 \times 10^{-5}, 5 \times 10^{-4}]$ (log scale), weight

decay in $[10^{-5}, 10^{-1}]$ (log scale), and warmup ratio in $[0.01, 0.20]$. Each of 15 trials is evaluated using reduced 3-fold cross-validation (KFold, `shuffle=True`, `seed=42`), but only the first 2 folds are scored per trial for efficiency (OPTUNA_N_SPLITS=3, OPTUNA_MAX_FOLDS=2). The objective is the mean validation RMSE across the evaluated folds. Best parameters are saved to a JSON file and automatically loaded before full training, eliminating manual transcription errors.

Leakage-free 5-fold training. For full training, we use 5-fold cross-validation (KFold, `n_splits=5`, `shuffle=True`, `random_state=42`). For each fold, both feature standardization statistics and target standardization statistics are computed only on the fold’s training partition and stored inside the saved checkpoint. These statistics are reused at inference time, preventing any information flow from held-out data. A zero-variance guard ($\sigma < 10^{-8}$) is applied to avoid division errors in degenerate cases.

Optimization. The model is trained with MSE loss in standardized target space. We use AdamW with three parameter groups: encoder param-

ters with the tuned weight decay; LayerNorm and bias parameters without weight decay; and the regression head with its own tuned learning rate and no weight decay. We apply a cosine learning rate schedule with linear warmup (`get_cosine_schedule_with_warmup`), train for 4 epochs, and clip gradients to a maximum norm of 1.0. Mixed precision training (AMP) is enabled throughout via `torch.cuda.amp.autocast` and `GradScaler`. Seeds are fixed (`seed=42`) for approximate reproducibility; cuDNN benchmark mode is enabled for throughput, so results may vary slightly across hardware.

Memory-efficient implementation. To operate within the T4 memory budget, we use dynamic per-batch padding so sequences are padded only to the longest item in each batch. Additional choices include `pin_memory=True` in all `DataLoaders`, `set_to_none=True` in gradient zeroing, explicit GPU cache clearing and Python garbage collection between folds and Optuna trials, and `gc_after_trial=True` in the Optuna study to prevent memory accumulation across trials.

Checkpoint selection and ensemble inference. Within each fold, the checkpoint achieving the lowest validation RMSE across all epochs is saved, rather than the final-epoch state. For each L1, all 5 fold checkpoints are loaded sequentially and their predictions are averaged. Because each checkpoint stores its own feature and target normalization statistics, inference is fully self-contained: no external normalization state is needed beyond what is saved in the checkpoint file.

Fixed settings. Training batch size 32, validation batch size 64, maximum sequence length 128, dropout 0.1, seed 42. All non-tuned settings are identical across Spanish, German, and Mandarin Chinese.

7 Results and Discussion

7.1 Main Results

Table 1 presents our official closed-track test results alongside the official baseline.

Our system improves over the official baseline in RMSE for all three L1 conditions. The same pipeline is applied across all three languages without any language-specific adaptation. The largest absolute improvement is observed for German (0.140 RMSE, 11.1%), followed by Chinese (0.050,

L1	Ours	Baseline	Δ RMSE	Δ %
Spanish	1.219	1.257	-0.038	-3.0%
German	1.118	1.258	-0.140	-11.1%
Chinese	1.090	1.140	-0.050	-4.4%

Table 1: Official closed-track RMSE on the test set. Lower is better.

L1	F1	F2	F3	F4	F5	Mean	Std
Spanish	1.270	1.231	1.269	1.335	1.279	1.277	0.036
German	1.161	1.189	1.168	1.198	1.231	1.189	0.025
Chinese	1.105	1.134	1.106	1.139	1.109	1.118	0.015

Table 2: Per-fold validation RMSE across 5 folds for each L1 condition.

4.4%) and Spanish (0.038, 3.0%). These results show that a shared architecture and training recipe can produce consistent gains across all three L1 settings without any language-specific engineering.

7.2 Validation Stability

Table 2 reports per-fold validation RMSE across all five folds for each L1 condition. Standard deviation remains low for all three languages (0.015–0.036), indicating stable training and suggesting that no single fold dominates the final ensemble prediction. Chinese is the most stable condition, while Spanish shows the largest fold-to-fold variation. Fold 4 yields the highest validation RMSE for both Spanish and German, but the overall spread remains limited, supporting the robustness of the cross-validation procedure.

7.3 Error Analysis

Figure 2 shows out-of-fold mean absolute error (MAE) by gold difficulty band for all three L1 conditions.

Across all three languages, error is highest in the easiest band (≤ -2), at approximately 1.57 for Spanish, 1.59 for German, and 1.52 for Chinese. In the middle bands (-1 to $+1$), MAE is substantially lower. Error increases again at the hardest end (> 2), especially for Spanish.

The same pattern appears across all three L1 conditions, suggesting that the model is less accurate at the extremes of the difficulty range and tends to pull very easy items toward the center of the score distribution.

7.4 Discussion

Language-agnostic generalization. Our system improves on the official baseline for all three L1

Figure 2: Out-of-fold mean absolute error by gold difficulty band for the three L1 conditions.

conditions without any language-specific tuning. This suggests that the task contains enough shared structure for a single pipeline design to work reliably across Spanish, German, and Chinese. The combination of the target word, spelling clue, L1 translation, and L1 context appears to provide sufficient signal for a multilingual encoder to learn useful patterns of vocabulary difficulty.

Why German benefits most. The largest improvement is observed for German. One possible explanation is that the German subset aligns especially well with the multilingual encoder and the added scalar features. However, this remains a hypothesis rather than a firm conclusion, since verifying it would require a more detailed per-language analysis.

Difficulty extremes are hardest. Figure 2 shows that prediction error is highest for the easiest items and rises again, though less sharply, for the hardest ones. Because the same pattern appears across all three L1 conditions, it is more likely to reflect a general regression-to-the-mean effect than a language-specific issue. This suggests that future work should focus more directly on improving calibration at the tails of the score distribution.

Gap to top-ranked systems. Although our system outperforms the official baseline, it still remains below the top closed-track submissions. The most likely reason is limited model scale: we rely on a single base-sized encoder and a modest 5-fold ensemble under a restricted Kaggle compute budget. Larger multilingual encoders and stronger ensembles would likely improve performance further while still remaining within the closed-track rules.

Reproducibility. A practical strength of the system is that the same notebook is used for all three languages, with only the L1 identifier changed between runs. In addition, each checkpoint stores its own normalization statistics together with the model weights, which makes inference reproducible directly from the saved checkpoints. This keeps the pipeline simple to rerun, inspect, and extend.

8 Conclusion

We presented a unified, language-agnostic closed-track system for the BEA 2026 Shared Task on vocabulary difficulty prediction. Using one notebook, one model, one feature set, and one training recipe across Spanish, German, and Mandarin Chinese,

our system consistently outperforms the official baseline on all three L1 conditions. Error analysis reveals a consistent pattern across languages: prediction error is highest for the easiest vocabulary items, suggesting a systematic regression-to-the-mean tendency that future work could address. We hope this pipeline serves as a practical and accessible starting point for future work on L1-aware vocabulary modeling.

Limitations

Our system does not achieve top-ranked performance. A main reason is compute: under a budget of two NVIDIA T4 GPUs on the Kaggle free tier, we used xlm-roberta-base and a 5-fold ensemble of the same architecture rather than a larger encoder or a multi-encoder ensemble. Such extensions remain compatible with the closed-track rules but were beyond our available resources.

Our feature set is also intentionally minimal. We use only four character-count features, which capture simple surface-level signals but omit potentially useful information such as word frequency, morphological complexity, subword count, and cognate similarity. These additions would still be closed-track compliant and are a natural direction for future work.

Although the pipeline is language-agnostic in design, it has been evaluated only on the three L1 conditions provided by the shared task. Generalization to other L1s therefore remains untested. Finally, our test predictions are based on fold models trained on the training split only; retraining on the combined training and development data might yield further gains. Because cuDNN benchmark mode is enabled for speed, small run-to-run variation across GPU setups is also possible.

Ethical Considerations

Vocabulary difficulty prediction has direct applications in adaptive testing and personalized content selection. However, prediction errors can negatively affect learner experience, particularly for learners at the easiest end of the difficulty distribution, where our analysis shows error is consistently highest across all three L1 conditions (Figure 2). We used only the officially released shared-task data and comply with all closed-track constraints. No personally identifiable learner information is present in the data. As with any automated scoring system, outputs should inform rather than replace

human pedagogical judgment, especially in high-stakes assessment contexts.

Acknowledgements

We used ChatGPT (OpenAI) for code assistance and Claude (Anthropic) for manuscript preparation. No generative AI model was used as part of the submitted closed-track system, data, or prediction pipeline. All results are from the official shared-task leaderboard and were verified by the authors, who take full responsibility for this submission.

BoostedCats at BEA 2026 Shared Task 1: What Makes a Word Hard to Learn? Modeling L1 Influence on English Vocabulary Difficulty

Jonas Mayer Martins Zhuojing Huang Aaricia Herygers Lisa Beinborn
University of Göttingen, Germany
firstname.lastname@uni-goettingen.de

Abstract

What makes a word difficult to learn, and how does the difficulty depend on the learner’s native language? We computationally model vocabulary difficulty for English learners whose first language is Spanish, German, or Chinese with gradient-boosted models trained on features related to a word’s familiarity (e.g., frequency), meaning, surface form, and cross-linguistic transfer. Using Shapley values, we determine the importance of each feature group. Word familiarity is the dominant feature group shared by all three languages. However, predictions for Spanish- and German-speaking learners rely additionally on orthographic transfer. This transfer mechanism is unavailable to Chinese learners, whose difficulty is shaped by a combination of familiarity and surface features alone. Our models provide interpretable, L1-tailored difficulty estimates that can be used to design vocabulary curricula.

 [Code repository and interactive demo](#)

1 Introduction

Learning a second language begins with words. Developing an extensive vocabulary is essential for mastering grammar and achieving fluency (Schmitt and Schmitt, 2020; Nation, 2000). Yet not all words are equally hard to learn, and researchers of second-language (L2) acquisition, classroom practitioners, and creators of educational materials seek to better understand this phenomenon.

The difficulty of a word is partially due to factors common to all learners, that is, lexical properties that depend only on the target language itself (Peters, 2019). For example, common and concrete words are easier to acquire than rare and abstract ones (Ellis, 2002; Ellis and Beaton, 1993).

However, a learner’s individual background—their first language (L1), in particular—plays a key role in word difficulty (Ringbom and Jarvis, 2009). For instance, a German speaker readily infers that

the English word “sheep” is related to the cognate *Schaf*, whereas the Spanish *oveja* is not a cognate.¹ This orthographic bridge supports active as well as passive vocabulary competence. Conversely, false friends may lead to interfering transfer (Bensoussan and Laufer, 1984). For example, *bravo* in Spanish is close to its English cognate “brave”, yet *brav* in German means “well-behaved”. The same English word can thus be easy for one learner while difficult for another, depending on the relationship between the L1 and L2.

However, computational models of lexical difficulty often fail to take a learner’s background into account. The SemEval2021 shared task on lexical-complexity prediction, for example, considers difficulty for unspecified annotators (Shardlow et al., 2021). Meanwhile, predictions of lexical difficulty tailored to individual learners are receiving increasing attention (Palmero Aprosio et al., 2020; North et al., 2023; Schmitt et al., 2021; Skidmore et al., 2025), yet studies that do include L1 effects often remain limited to a single language pair.

Approach and contributions. We address this gap by modeling English vocabulary difficulty separately for Spanish, German, and Chinese² L1 speakers, using the Knowledge-based Vocabulary Lists (KVL), a recent crowd-sourced corpus of lexical-difficulty tests (Schmitt et al., 2021; Skidmore et al., 2025), in the context of the closed track of the Building Educational Applications (BEA) 2026 shared task (Felice and Skidmore, 2026). We create four feature groups: the familiarity of a word based on exposure effects, its meaning based on semantic complexity and concreteness, its surface form based on orthographic complexity, and its transferability from a specific L1 based on string similarity. We train interpretable, gradient-boosted

¹Instead, *oveja* is distantly related to “ewe”, meaning female sheep, in English.

²In this article, we refer to Mandarin Chinese as Chinese.

Figure 1: Illustration of the task and modeling setup. For each L1, learners translate a word (e.g., Kabel) from their L1 into English given the first letter (c) and a graphical hint indicating the number of characters. Item difficulty is estimated from aggregated responses (gold label). We train L1-specific models on feature groups (familiarity, meaning, and form = surface $\cup$ transfer). By evaluating the feature importance, we assign a relative importance in the prediction of a word to each feature group.

models on these features to predict L1-dependent lexical difficulty and trace their predictive power via Shapley values. Figure 1 illustrates the task format and our approach.

To showcase our results and support further research and practical use, we have created an [interactive demo](#) that extends our predictions to more than 4,000 to 7,000 additional English words per language, see Appendix A and Appendix B. This demo highlights the advantage of our computational modeling approach, which allows us to make predictions beyond the limited KVL data for a larger range of vocabulary and potentially more L1 backgrounds, providing tailored difficulty estimates applicable to curriculum design.

2 Related work

In this section, we discuss factors of word difficulty in a foreign language based on second-language-learning studies and computational models.

2.1 Lexical difficulty

Vocabulary knowledge poses a fundamental challenge to all second-language (L2) learners (Schmitt and Schmitt, 2020; Nation, 2000). However, the difficulty associated with a particular word varies by learner. Some words, for instance, represent intrinsically difficult concepts in the target language, while others are challenging or easy specifically due to a learner’s L1 background.

L2-intrinsic difficulty. The more frequent a stimulus occurs, the more readily it tends to be recalled, and as such, frequent words are learned more easily because learners encounter them more often (Ellis, 2002; Peters, 2019). Educational curricula typically introduce frequent words first to enable learn-

ers to speak and understand the target language earlier by efficiently building vocabulary coverage (Nation, 2000).

Beyond frequency, other lexical properties are also important. For instance, orthographic complexity has been shown to predict exercise difficulty (Beinborn et al., 2016). Additionally, homonymous or polysemous words are typically harder to process and acquire than words with just one meaning (Bensoussan and Laufer, 1984). Psycholinguistic features, such as the age of acquisition (Kuperman et al., 2012; Dascalu et al., 2016) and concreteness of the word (Ellis and Beaton, 1993; Van Hell and Mahn, 1997; De Groot and Keijzer, 2000), are important factors for word difficulty prediction, too. The initial letter plays a disproportionate role in word recognition and production: speakers in tip-of-the-tongue states often remember the first letter and phonological primes aid retrieval (Brown and McNeill, 1966; James and Burke, 2000).

L1-specific difficulty. Beyond L2-intrinsic word properties, difficulty is shaped by the learner’s first language. Learners draw on L1 knowledge when acquiring an L2 vocabulary, with positive transfer where the languages are similar and interference where surface similarity is misleading (Odlin, 1989). At the lexical level, cognateness is a well-studied transfer mechanism. Cognates reduce learning effort because learners can map the L2 target onto the well-known L1 form: De Groot and Keijzer (2000) show that cognateness predicts L2-vocabulary retention, and Beinborn et al. (2014) find that learners infer the meaning of unfamiliar words more readily when there is a cognate in their L1. Similarly, Urdaniz and Skoufaki (2022) find that frequency and cognateness are the two

strongest predictors of lexical difficulty for Spanish learners of English, with significant interaction such that word frequency is more predictive for non-cognates than cognates. However, coincidental similarity or shifted meaning of cognates can cause interference (Odlin, 1989; Bensoussan and Laufer, 1984).

These findings imply that the same word can be easy for one learner and hard for another, depending on the overlap of L1 and L2. Moreover, cognateness interacts with other predictors of difficulty, motivating models that jointly incorporate L1-specific and L2-intrinsic information.

2.2 Predicting lexical difficulty

Progress on predicting lexical difficulty³ has been driven by shared-task competitions (Paetzold and Specia, 2016; Yimam et al., 2018; Shardlow et al., 2021). Computational approaches to predicting lexical difficulty have shifted from binary classification of complex words to continuous regression of difficulty scores (North and Zampieri, 2023). Across studies, robust predictors include word frequency, word length, age of acquisition, and concreteness (North et al., 2023).

These patterns extend beyond English. The CWI-2018 shared task shows that models trained on English, German, and Spanish can generalize to French, suggesting that certain cognitive mechanisms transfer across typologically related languages (Yimam et al., 2018). The BEA 2024 shared task investigated lexical-complexity prediction and simplification with 10 languages, finding that feature-based systems can compete with large language models (Shardlow et al., 2024). For some languages, script-specific features are important, e.g., logographic-character frequency in Chinese and Japanese (Lee and Yeung, 2018a; Nishihara and Kajiwara, 2020). Furthermore, Finnimore et al. (2019) confirm features from typologically related languages can be beneficial, while including features from unrelated languages may reduce performance.

Despite these advances, learner-specific factors remain underexplored. Studies that model the L1 background report benefits over agnostic models, e.g., for Dutch learners of French as well as Chinese and Spanish learners of English (Tack et al.,

2016; Lee and Yeung, 2018b; Urdaniz and Skoufaki, 2022). However, these studies focus on a single language pair. Palmero Aprosio et al. (2020) extend this line of research to multiple L1s for learners of Italian by modeling cognates and false friends. Similarly, the lexical complexity for learners of Japanese has been studied for several L1 backgrounds (Ide et al., 2023; Nohejl et al., 2024). Still, the interaction between L1-specific and general features remains largely unexamined. In this article, we address that gap directly.

3 Experimental setup

We train and evaluate L1-specific CatBoost models (Prokhorenkova et al., 2018) for predicting the difficulty of English vocabulary items. This section describes the dataset, feature groups, model, and evaluation metrics.

3.1 Data

We use the Knowledge-based Vocabulary Lists (KVL), a large-scale dataset of lexical difficulty based on vocabulary test responses from more than 100,000 second-language learners of English (Schmitt et al., 2021; Skidmore et al., 2025) as part of the BEA 2026 shared task (Felice and Skidmore, 2026). The data covers three L1s—Spanish, German, and Chinese—with 6,091 training, 677 development, and 748 test items per L1.

In the KVL test format, learners see a word in their L1 with a context sentence and must type the English translation, given the first letter and blanks for the remaining letters:

Kabel German, noun
Achtung, stolpere nicht über das Kabel am Boden.
c _ _ _ _

Each item is scored as correct or incorrect. In the example above, the correct completion would be *able*. Responses are aggregated into a continuous logarithmic difficulty score by a Rasch model (De Boeck, 2008; Dunn, 2024), which jointly estimates item difficulty and learner ability such that the resulting centered score reflects the intrinsic difficulty of a word (higher scores are easier).⁴

The difficulty estimates may vary by L1, see Fig. 1. The word *cable* is easiest for Spanish speakers (score 2.3) because the corresponding

³In this article, we use *difficulty* to refer to the processing effort in retrieval, as defined in Bulté et al. (2025), and distinguish this from structural complexity, which concerns the internal composition of a word.

⁴Note that the values across languages are not directly comparable in an absolute way but rather as relative to the average word difficulty of an L1.

Spanish form is spelled identically; moderately easy for German speakers (score 0.9), who benefit from the German cognate *Kabel*; and hardest for Chinese speakers (score 0.0, 电缆 *diànlǎn*).

3.2 Features

We extract 24 features per item and organize them into four feature groups that structure our analysis, see Fig. 1. Each group targets a different aspect of what makes a word easy or difficult to recall. Full definitions and sources are provided in Appendix C. Here, we describe the rationale behind each group.

Familiarity (11 features). These features capture how likely a learner is to have encountered a word before. We include logarithmic word frequency and contextual diversity from SUBTLEX-UK (Van Heuven et al., 2014), reported age of acquisition and percentage of annotators who knew the word (Kuperman et al., 2012), CEFR level in the form of CEFR-J proficiency level, e.g., B2 for cable, and the EFLLex word-frequency profile across CEFR-graded books (Europarat, 2011; Negishi et al., 2013; Dürlich and François, 2018). Together, these features reflect both naturalistic exposure (how often the word appears in English media) and curricular sequencing (at which proficiency level the word is typically introduced).

Meaning (5 features). To approximate semantic complexity and concreteness, we use the ℓ_2 norm of the English fastText embedding (Bojanowski et al., 2017), mean hypernym depth and sense count from WordNet⁵ (Fellbaum, 1998), the part-of-speech (POS) ratio from SUBTLEX-UK, and a binary flag indicating whether the KVL item required disambiguation, e.g., for the item decode, the German translation is *etw entschlüsseln* (nicht: decipher).

Surface (7 features). Surface features describe the orthographic form of the item as presented in the test. They include target- and source-word length in characters, number of syllables and letters per phoneme (an orthographic transparency proxy) of the target word, context-sentence length, and the first letter of both the English clue and the L1 translation. These features are relevant because the KVL task requires learners to reconstruct a spelling, making word length, letter cues, and phoneme den-

sity directly task-relevant (James and Burke, 2000; Beinborn et al., 2016).

Transfer (1 feature). We compute the cosine similarity between character n -gram TF-IDF vectors of the English word and its L1 translation, see Appendix D for a detailed description. This feature captures orthographic overlap as a proxy for cognateness: High values indicate transparent cognates (e.g., English *fantasy* and Spanish *fantasía*), while the similarity is zero for all Chinese items due to the different script. Although this measure does not account for phonological similarity or regular sound correspondences, we find it to be highly informative for languages that share the Latin script with English.

3.3 Model and baselines

For our purposes, we require a fast and interpretable model. We use CatBoost (Prokhorenkova et al., 2018), a gradient-boosted decision-tree method that handles both numeric and categorical features. We train one model per L1 on the same set of 24 features (Fig. 1, right), allowing each model to learn L1-specific interactions between features and difficulty. Hyperparameters are given in Appendix E. Model training takes about ten seconds. To estimate variance, we train each model with 20 random seeds.

We compare against two baselines: a ridge regression model trained on the same features, which tests whether nonlinearity or feature interactions contribute beyond a linear combination, and the transformer-based approach of Skidmore et al. (2025), which fine-tunes a pretrained language model directly on KVL difficulty scores without handcrafted features.

3.4 Evaluation

We report the root-mean-square error (RMSE), in alignment with the BEA 2026 shared task (Felice and Skidmore, 2026), and Pearson’s r on the test set. Our team’s submission results (*Boosted Cats – HuDS lab*) are available at the [shared-task repository](#). To test whether L1-specific models capture shared or distinct difficulty structures, we additionally evaluate each model on the test sets of the other two L1s.

For interpretability, we use tree-based SHAP values (Lundberg and Lee, 2017; Lundberg et al., 2018), which attribute each prediction to individual feature contributions through Shapley values from

⁵For example, the word *cable* has six senses, one of which has a hypernym path of depth 9: *cable* $\subseteq$ *conductor* $\subseteq$ *device* $\subseteq$ *instrumentality* $\subseteq$ *artifact* $\subseteq$ *whole* $\subseteq$ *object* $\subseteq$ *physical entity* $\subseteq$ *entity*.

cooperative game theory (Shapley, 1953). We aggregate absolute Shapley values by feature group to obtain their relative importance, analyzed in Section 4.2. We compute relative group importance as the sum of absolute Shapley values within each feature group, normalized to sum to one per item.

4 Results

The same English word can be easy for one L1 group and hard for another, illustrated by the gold-label lexical difficulties that correlate across L1s but are far from identical, see Appendix F. This observation motivates our approach to train L1-specific models, asking three questions. Are the model predictions accurate enough to warrant a study of how these predictions arise (Section 4.1)? Which mechanisms do the models rely on, and how do these mechanisms differ by L1 (Section 4.2)? And finally, do models trained on one L1 generalize to another (Section 4.3)?

4.1 Prediction quality

Table 1 compares our CatBoost models against two baselines: a linear (ridge) regression trained on the same features and the transformer-based approach of Skidmore et al. (2025). CatBoost achieves the lowest RMSE on all three L1s and the highest correlation in German and Chinese. The improvement over the linear baseline shows the importance of accounting for feature interactions and non-linear contributions to difficulty. CatBoost outperforms the transformer baseline, too, implying that well-chosen psycholinguistic features can perform on par with pretrained representations while being more easily interpretable.

Model	RMSE ↓			Pearson’s r ↑		
	ES	DE	CN	ES	DE	CN
Transformer	1.26	1.26	1.14	0.77	0.77	0.75
Linear regression	1.30	1.20	1.07	0.72	0.74	0.77
CatBoost (ours)	1.24	1.12	1.04	0.76	0.78	0.79

Table 1: Test-set performance per L1. CatBoost results report the median over 20 random seeds; the 5-95% range is ≤ 0.02 for all entries. Best result per L1 in **bold**. The shared-task baseline fine-tunes a transformer on KVL difficulty scores (Skidmore et al., 2025).

Figure 2 shows predictions against the gold labels per L1. The predictions correlate well with the gold labels, as the bulk of items clusters near the diagonal (dashed gray). The hardest items, however, tend to be predicted as easier than they

Figure 2: Predicted versus gold-label lexical difficulty. Each point is one L1-English vocabulary pair; the dashed diagonal marks a perfect prediction. Four exemplary items are highlighted: question (noun), picture (verb), handbook (noun), received (adjective). Seed variation of the prediction (5th–95th percentile) is small (median 0.1, max. < 0.4).

are. This bias is consistent across L1s, suggesting that the most difficult words involve challenges not captured entirely by our feature set, e.g., rare senses (received in the meaning of “generally accepted”). Other highlighted examples include question, which is easy and well-predicted for all L1s, although it is a cognate only in Spanish; to picture and handbook show that our model captures the L1-dependent difficulty.

4.2 Feature-group importance

To understand the model predictions more intuitively, we thus group our 24 features into four feature groups—*familiarity*, *meaning*, *surface*, and *transfer*—and aggregate the absolute Shapley values per item for each group. The importance share of a feature group measures how strongly the features within this group contribute to predicting a specific item. We report the average importance of every feature and its correlation with the gold-label difficulty in Table 2.

Transfer differentiates Spanish and German from Chinese learners. The most prominent cross-linguistic difference is the role of transfer. For Spanish and German speakers, a single feature—character- n -gram cosine similarity between the L1 and the English word—is the

Figure 3: Per-item feature-group-importance shares, sorted by decreasing importance of familiarity (left to right). Median across 20 seeds, with a rolling average of window size 10. The bar at the right of each panel shows for each group the median across seeds of its mean importance share over all item. The *form* group is split into *transfer* (character similarity between the L1 and English) and *surface* (features like word length and initial letters).

strongest predictor overall (mean $|\text{SHAP}|$ of 0.51 for Spanish and 0.52 for German; see Fig. 8 in Appendix C). For Chinese, this feature does not contribute at all because the Chinese writing system shares no characters with English.

This asymmetry is visible in Fig. 3, which shows the group importance of each item, sorted by decreasing importance of familiarity. Transfer fills the gap of less familiar words for Spanish and German. These are typically cognates, e.g., *handbook* and *Handbuch*, which a German speaker can infer even without prior exposure to the English word.⁶ Transfer is most relevant for a distinct small subset of roughly 10–20% of items relying least on familiarity (above rank 600).

Familiarity is strong across L1s. Familiarity accounts for the largest average feature-group importance for all three L1s, see the stacked bar summaries in Fig. 3. Within this group, the most important features differ: age of acquisition (AoA) and frequency for Spanish and German, versus the proficiency levels (EFLLex-level span and CEFR-J levels) for Chinese. This difference may reflect a variation in how English is acquired—naturalistic exposure for Spanish and German learners as opposed to potentially more structured, curriculum-driven learning for Chinese learners. Yet in all cases, familiar words are easier to recall.

Surface and meaning. Surface features are as important as meaning features (embedding norm, hypernym depth, and sense count) for Spanish and

German, and substantially more important for Chinese, see Fig. 3. The importance of surface features is likely due to the KVL task format, which requires form recall rather than correct usage of a word. Spelling difficulty makes surface cues, e.g., word length and priming by the clue letter, directly task-relevant (James and Burke, 2000; Beinborn et al., 2016). Chinese learners appear to rely on these cues more heavily.

Two routes to easiness. Figure 4 projects each item onto a triangle. Each corner represents that the respective feature group is uniquely important, while the middle corresponds to an equal mixture of importance. The color of each point encodes gold-label difficulty and the background shading is an estimate of the difficulty distribution in this triangle.⁷

For Spanish and German, easy items (green) cluster in the two lower corners, familiarity and form. These clusters represent two routes through which a word is easy to a learner. A word is easy because it is frequent and early-acquired or because it closely resembles its L1 form. Some words are both common and have high orthographic similarity, which makes them easy as well (see Appendix G for details), but they land in the middle region since the Shapley values for familiarity and transfer are both high. Difficult items (red) occupy the middle region in the triangle because neither cue is strong.

For Chinese, the distribution in the triangle is instead tightly clustered along the lower-left

⁶Transfer beyond orthographic overlap exists but is not captured by character similarity. For example, the Chinese word 手册 (*shǒucè*, literally “hand-book”) elicits transfer, too.

⁷A Nadaraya–Watson kernel regression of the difficulty surface (Nadaraya, 1964; Watson, 1964) with bandwidth selected by leave-one-out cross-validation (Härdle, 1990).

Figure 4: Each item projected onto a triangle according to the relative importance of three feature groups (familiarity, meaning, and form = surface $\cup$ transfer). Color encodes the gold-label difficulty of an item (red: hard, green: easy). Background shading shows a regression of the difficulty surface; regions with insufficient data are masked.

familiarity-form edge⁸ and the background shading has no clear gradient. Chinese difficulty is shaped more uniformly by a combination of familiarity and form features.

4.3 Cross-L1 transfer of models

Figure 5: Cross-L1 evaluation. Each colored bar shows the RMSE prediction error (lower is better) of a CatBoost model trained on one L1 and evaluated on the L1 indicated on the horizontal axis. Thick black outlines mark within-L1 evaluation. Gray bars show the ridge linear baseline and the transformer baseline, each trained on the target L1. CatBoost results report the median over 20 random seeds with 5th–95th percentiles.

If Spanish and German learners rely on similar feature groups, a model trained on one L1 should reasonably generalize to the other. We test this by evaluating each L1-specific CatBoost model on all three test sets, see Fig. 5.

Each model performs best on its own L1, but the degradation when transferring between Spanish and German is minor. The Spanish-trained model achieves RMSE 1.18 on German (vs. 1.12 within-German), and the German-trained model

reaches RMSE 1.32 on Spanish (vs. 1.24 within-Spanish)—both on par with the linear baselines (RMSE 1.30 for Spanish, 1.20 for German) and the transformer baselines (RMSE 1.26 for Spanish, 1.26 for German) trained directly on the target L1. A model trained on Spanish or German thus captures meaningful mechanisms that transfer to the other, without any access to target-L1 training data.

Transfer involving Chinese is markedly worse in both directions. Chinese-trained models yield RMSE 1.71 on Spanish and 1.57 on German, well above the baselines. Spanish- and German-trained models evaluated on Chinese (RMSE 1.15 and 1.23) degrade less severely, which aligns with the observation that the Spanish and German models have learned all the features relevant to predicting difficulty for Chinese learners, although they still fall short of the within-Chinese model (RMSE 1.04). The Chinese-trained model, not having learned to predict items based on transfer, cannot generalize to Spanish or German.

These cross-L1 results mirror the feature-group analysis: Spanish and German models share a difficulty landscape, while the prediction for Chinese learners relies on different cues. Practically, this observation suggests that models trained on a given L1, say Spanish, could provide useful estimates for typologically related languages such as Portuguese or Italian, even without the dedicated training data.

5 Discussion

Our finding that word familiarity exerts the strongest impact on the KVL difficulty scores across all L1 groups aligns with prior research identifying word frequency and age of acquisition as robust predictors of lexical processing (Rott, 1999;

⁸Chinese items show a somewhat lower dispersion in the feature-group simplex (Aitchison total variance: CN 0.30, ES 0.33, DE 0.35 with bootstrap 90% CIs < 0.05).

Ellis, 2002; Kuperman et al., 2012; North et al., 2023). Our analysis adds a quantitative decomposition that reveals *how* this shared component interacts with L1-specific factors. For Spanish and German, transfer provides a second route to easiness: Words can be easy because they are familiar or because they are orthographic cognates. This two-route structure aligns with Urdaniz and Skoufaki (2022), who find frequency and cognateness to be strong, interacting predictors for Spanish learners of English, and with De Groot and Keijzer (2000), who show that cognates are easier to remember. We observe the same pattern for German learners. For Chinese learners, difficulty is predicted more uniformly by surface features and familiarity. The cognitive strategies during form recall thus appear to differ qualitatively, depending on the typological relationship between the L1 and L2.

Our character similarity feature captures character overlap as a proxy for perceived similarity (Ringbom, 1987), which need not coincide with etymological relatedness. The strength of this feature in our models suggests that even coarse character overlap is a powerful retrieval cue when L1 and L2 share a script. Although Chinese has no orthographic overlap, cross-linguistic transfer may still be present in the form of loanwords (e.g., 雷达 *lédá* from English radar), calques (brainwash from the Chinese 洗脑 *xǐnǎo*), and parallel compositions (星光 *xīngguāng* happening to map to “starlight”) or morphology (地 *de* marking adverbs like the English suffix “-ly”).

The task format affects which aspects of word knowledge are tested (Laufer and Goldstein, 2004; Culligan, 2015). In our case, meaning features contribute little across all L1s, likely because the KVL task tests spelling rather than an understanding of meaning. A task requiring contextual usage would likely involve more meaning-related features.

A caveat concerns interpreting Shapley values as cognitively plausible. Our models approximate human test responses, and their strong held-out performance suggests that the features are plausible factors in the learner behavior that underlies the test responses. Where the model fails, however, the relevant factors likely lie outside our feature set, e.g., individual learner differences, contextual effects of the context sentence, or interference from false friends. We discuss the relation of lexical features beyond our predictor set with the gold-label difficulty and model-prediction errors in Appendix H.

Our findings also have practical implications.

Spanish and German learners could benefit from curricula rich in cognates in order to efficiently build an extensive vocabulary (Nation, 2000). Furthermore, a model trained on data from one L1 could serve in predicting lexical difficulty for typologically related, lower-resource languages without dedicated data. For Chinese learners of English (and potentially speakers of languages not related to the target language), a curriculum based on frequency and proficiency levels is likely more effective. Since our model can generalize to unseen words, we provide predictions of lexical difficulty beyond the KVL dataset, on the entire SUBTLEX-UK vocabulary for which we could compute the features. Our model predictions can be explored [interactively](#).

6 Conclusions

We have investigated what makes an English word difficult for second-language learners by training interpretable models on lexical-difficulty scores from Spanish, German, and Chinese L1 speakers. By decomposing the predictions into feature groups, we identify two qualitatively different profiles. Spanish and German learners benefit from two routes to easiness—familiarity and orthographic transfer—while Chinese learners rely on a less structured combination of familiarity and surface features in the absence of orthographic overlap. The models of learners with Spanish and German as L1 generalize well to each other, indicating that the learned difficulty functions reflect shared cognitive strategies.

For future research, the strong cross-L1 transfer between the Spanish- and German-trained models suggests that models trained on a high-resource L1 could provide useful difficulty estimates for typologically related languages (e.g., from Spanish to Portuguese, Catalan, or Italian; potentially also from Chinese to other languages not related to English like Japanese), even without the dedicated training data. Another promising direction is to investigate whether the identified mechanisms are symmetric, i.e., whether the same profile of feature-group importance applies for English speakers that learn Spanish, German, or Chinese. Third, incorporating phonological similarity and including calques and morphological similarity could capture part of the variance in lexical difficulty that our current feature set does not explain.

Limitations

Language coverage. The KVL data covers a limited selection of four high-resource languages, three of which are Indo-European. The extent to which the patterns we identify generalize to learners with other language backgrounds remains an open question.

Task specificity. The KVL dataset tests productive form recall only. Our analysis therefore pertains to this aspect of vocabulary knowledge and could be extended to other test formats.

Measuring transfer. We operationalize cross-linguistic transfer through character-level overlap, which does not capture phonological similarity, regular sound correspondences, and semantic transfer (e.g., calques).

Interpretation of feature importance. Feature-group importance describes the structure of model predictions and cannot measure a learner's cognitive processes directly. Inferences about human cognition thus remain indirect.

Curricular effects. Lexical difficulty is not only influenced by word properties but also the curriculum order, which is captured by our CEFR-proficiency-level features. Beyond the intrinsic difficulty of a word, the KVL difficulty we model therefore partially encodes the status quo in instruction regarding where a word happens to be placed in educational curricula.

Ethical considerations

This work is intended as fundamental research into L2 vocabulary difficulty. While our results may inform applications and further research, it should not be interpreted as prescriptive guidance for teaching in practice.

Our computational experiments use light-weight models that entail no substantial environmental impact.

A Demo

We provide an [interactive demo](#) that allows users to explore the KVL dataset and our model predictions, see Fig. 6. Given an input text, words are highlighted according to their predicted or gold-label lexical difficulty. Selecting a word opens a panel showing its lexical difficulty, feature-group importance, top individual features, clue letter and context clue.

To map a word form in the input text to KVL lemmas, we precompute a lookup table of inflected forms using the PYINFLECT library. Because the demo is implemented as a static web application, it does not perform syntactic parsing on the fly. Instead, the most frequent part of speech is shown by default, with the option to select any alternatives. The interface also allows users to switch the language background and optionally include our extended vocabulary (see Appendix B).

B KVL extension

To support lexical-difficulty predictions beyond the original KVL inventory, we construct an extended vocabulary in the KVL task format derived from WIKTIONARY data.

Source and filtering. We begin with Wiktionary JSONL extracts produced by WIKTEXTTRACT (Ylonen, 2022). From these, we retain only English headwords (`lang_code = en`) that appear in SUBTLEX-UK (Van Heuven et al., 2014). This filtering restricts the extension to commonly used words. We further discard entries that are empty, single-character, or all-uppercase (e.g., acronyms). Language-specific filters remove entries that primarily encode inflectional variants, spelling alternatives, or other metalinguistic notes.

Normalization. The retained entries are converted into a compact, standardized representation. From each Wiktionary entry, we extract only the information necessary for the KVL format: the English target word and part of speech, a masked spelling clue, an L1 translation, and an optional L1 context sentence. Duplicate English headwords are removed by keeping the first entry with a valid part-of-speech annotation.

L1-specific processing. For German and Spanish, the L1 source word is taken from the first available translation or, if unavailable, from the shortest gloss phrase. For Chinese, if no translation is available, the L1 source word is extracted from gloss blocks and normalized, including conversion to simplified characters. Context sentences are derived from example translations.

Excluding overlap. To ensure that the extended vocabulary contains no duplicates with the original KVL data, we exclude all English target words that occur in the KVL training, development, or test splits for the corresponding L1. The final output consists of three L1-specific CSV files that follow the original KVL schema and add 7,434 items for Chinese, 4,325 for German, and 6,606 for Spanish.

C Features

Table 2 lists the 24 features that we use for our models, grouped by mechanism. For each feature, we report the median absolute Shapley value per L1, computed by averaging absolute Shapley values over test-set items and then taking the median across 20 random seeds. We additionally report Spearman’s rank correlation between the feature value and gold-label difficulty over test-set items.

Intuitively, the Shapley values quantify how important a feature is on average for the model predictions. Spearman’s rank correlations show how monotonic the relation is between the feature value and lexical difficulty. Particularly interesting are those features for which the two measures do not align. For instance, character similarity has a weak correlation with difficulty for Spanish ($\rho = .10$) and German ($\rho = .25$), yet it is the feature with the highest Shapley-value importance for these two languages. This is in part because transparent cognates are relatively rare, and similarity is high only for this subset of transparent cognates. We discuss this in Appendix D. Moreover, the character similarity, as we show in our main analysis Section 4.2, interacts with familiarity such that this transfer feature tends to be important when familiarity is not available. Conversely, the CEFR-J level has the highest Spearman’s $|\rho|$ across all L1s (up to $-.66$ for Chinese) but is only moderately important because it is collinear with other familiarity features, e.g., frequency and EFLLex-level span.

We briefly define features that are not self-explanatory:

Figure 6: Screenshot of our [interactive demo](#). Words of the input text are highlighted according to their lexical difficulty. Clicking on a word opens a panel that shows the gold-label and predicted difficulty as well as the feature-group importance. The L1-background can be switched.

Logarithmic frequency. Log-transformed word frequency on the Zipf scale (Van Heuven et al., 2014)

$$f_{\text{Zipf}} = \log_{10}(\text{fpmw}) + 3 \quad (1)$$

which modifies the standardized measure of frequency per million words (fpmw) by a logarithmic transformation and adding 3 to keep the measure positive even for low-frequency words, making it more intuitive. We assign a value below the minimal frequency threshold, $f_{\min} = 0.5$, to words missing from the SUBTLEX-UK list.

Contextual diversity. The proportion of film or television programs in SUBTLEX-UK containing at least one occurrence of the word, reflecting the breadth of contexts in which a learner might encounter it (Van Heuven et al., 2014). We expect that words that occur only in certain domains are

less familiar (and thus more difficult to learn) relative to words of the same frequency that occur across many domains. This feature turns out to be especially relevant for Chinese-speaking learners.

EFLLex level span. The number of Common European Framework of Reference for languages (CEFR) levels (Europarat, 2011), A1, A2, B1, B2, C1, at which the word has non-zero frequency in the EFLLex learner corpus (Dürlich and François, 2018). A span of 5 means the word appears at every level from A1 to C1 and is thus broadly familiar, whereas a span of 1 means it is confined to a single proficiency band.

Embedding norm. The ℓ_2 norm of the 300-dimensional English fastText embedding $\mathbf{e}$ (Bojanowski et al., 2017),

$$\|\mathbf{e}\|_2 = \sqrt{\sum_{i=1}^{300} e_i^2}. \quad (2)$$

	Feature	Definition	Source	Mean SHAP			ρ (value-gold)

Table 2: Mean |SHAP| importance per feature and L1, averaged over test-set items across 20 random seeds (5–95% range < 0.02 for all features and L1s), and Spearman’s ρ between feature value and gold lexical difficulty. Features are grouped by category. The five highest |SHAP| values per L1 column are set in **bold**.

Since function words and polysemous words tend to have smaller norms because their embeddings are pulled towards the origin of the space by diverse contexts, concrete and semantically specific words tend to have larger norms (Oyama et al., 2023).

Character similarity. We represent the L1 word and its English translation as character n -gram TF-IDF vectors ($n \in \{2, 3, 4\}$, sublinear TF) and compute their cosine similarity. For Chinese, all values are approximately zero because there is no character overlap between Latin and Chinese script. We give a more detailed definition in Appendix D.

POS dominance ratio. The proportion of SUBTLEX-UK tokens for a lemma that carry its most frequent part of speech (POS), derived from the POS frequency in SUBTLEX-UK (Van Heuven et al., 2014). Values near 1 indicate unambiguous POS. Lower values indicate that the word is frequently used as multiple parts of speech (e.g., light as noun, verb, and adjective).

Letters per phoneme. The ratio of character length to phoneme count, derived from the number of phonemes per word in the Kuperman et al. (2012) dataset. This serves as a proxy for orthographic transparency: Words with many letters per phoneme have less predictable spellings, e.g., thought /θɔ:t/ (7 letters / 3 phonemes = 2.33).

Clue letter and L1 initial letter. These categorical features encode the first letter of the English spelling clue and the first letter of the L1 lemma, respectively. They capture letter-level priming effects: certain initial letters may be associated with easier or harder vocabulary on average, and letter overlap between the clue and the L1 form may facilitate recall. Spearman correlations are not reported for categorical features. Interestingly, the L1-first-letter priming is equally important for Chinese as for Spanish and German (0.06–0.07) as the model learns a baseline for every Chinese word-initial character.

Figure 7: Pairwise Spearman correlation between numeric features (Spanish; the pattern is similar for German and Chinese except for L1-dependent features such as source word length and character similarity). Several pairs are substantially correlated. White lines indicate feature groups.

Figure 7 shows pairwise correlations between the numeric features from Table 2. Some features are strongly correlated, particularly the familiarity features (e.g., logarithmic frequency, contextual diversity, and EFLLex level span) and the surface features (target word length, syllable count, and source word length). This collinearity means that individual SHAP values within a group partly reflect shared variance, which motivates our decision to group the features for the main analysis.

Additional features were evaluated during development but excluded from the final model after unstructured ablation showed no consistent improvement. These include: character-level surprisal, normalized Levenshtein edit distance, longest common subsequence ratios, EFLLex entropy and mean level, WordNet synonym count and derivational family size, POS competition flag, and Spanish-specific CORPES frequencies and anglicism indicators. We provide these in Table 3 for completeness. These features turn out to be too redundant to yield higher performance. For example, edit distance captures the same signal as character similarity but is less informative in this context. We give an exemplary analysis in Appendix H.

D Character similarity

To approximate cross-linguistic form similarity between an English word and its L1 translation, we compare their character- n -gram overlap. This fea-

Figure 8: Character similarity between English words and their L1 translations (Spanish, German) versus gold-label difficulty (top) and Shapley-value contribution of this feature (bottom). Two words are highlighted: cable and handbook.

ture is motivated by the intuition that words sharing many letter sequences (e.g., *fantasy* and *fantasía*) can be readily recognized as cognates.

From binary overlap to weighted similarity. In a naive approach, we could represent each word as a binary vector over character n -grams, where each entry states whether a given n -gram occurs in the word, and then compute the cosine similarity between two vectors. This approach would treat all n -grams the same, yet some n -grams might be more informative than others.

To account for the informativeness of an n -gram, we weight it using *term-frequency-inverse-document-frequency* (TF-IDF). In this context, words correspond to “documents” and n -grams with $n \in \{2, 3, 4\}$ to “terms”. The TF-IDF weight of an n -gram t in a word w is implemented as

$$\text{tf-idf}(t, w) = (1 + \log(\text{tf}(t, w))) \log\left(\frac{N}{\text{df}(t)}\right), \quad (3)$$

where $\text{tf}(t, w)$ is the frequency of t in w , $\text{df}(t)$ is the number of words in the training data containing t , and N is the total number of word forms in the union of English and L1 word forms in the training data. We use sublinear term-frequency scaling, i.e., $1 + \log(\text{tf}(t, w))$ instead of $\text{tf}(t, w)$, so that repeated occurrences are weighted less than linearly.

Cosine similarity. We can thus represent each word as a TF-IDF-weighted vector over character

Feature	Definition
Character surprisal	Mean $-\log(p(\text{char}))$ under training-set unigram distribution
Edit distance (norm.)	Levenshtein distance between EN and L1 word, normalized by $\sqrt{\text{len}_{\text{EN}}} \cdot \sqrt{\text{len}_{\text{L1}}}$
LCS ratio (EN)	Longest common subsequence length / target word length
LCS ratio (L1)	Longest common subsequence length / source word length
EFLLex entropy	Normalized Shannon entropy of the CEFR-level frequency distribution
EFLLex mean level	Frequency-weighted mean CEFR level
WN synonym count	Number of unique lemma names across all synsets
WN derivational family	Number of derivationally related forms in WordNet
WN POS count	Number of distinct parts of speech in WordNet
POS competition	1 if the tested POS differs from the dominant SUBTLEX-UK POS
Exact match	1 if EN word = L1 lemma after normalization
L1 second letter	Second letter of the L1 lemma
CORPES frequency (ES)	Log-transformed normalized frequency in the Spanish CORPES corpus
CORPES dispersion (ES)	Log-transformed dispersion across CORPES subcorpora
Anglicism frequency (ES)	CORPES frequency of the English word looked up in Spanish text
Anglicism flag (ES)	1 if the L1 lemma appears in a Wiktionary-derived anglicism list

Table 3: Additional features evaluated on the development set but excluded from the final model after ablation showed no consistent improvement of model performance. CORPES refers to [Real Academia Española \(2025\)](#).

n -grams. Cross-linguistic form similarity is then measured as the cosine similarity between the English word w_{en} and its L1 translation w_{L1} :

$$\text{sim}(w_{\text{en}}, w_{\text{L1}}) = \frac{\mathbf{x}_{w_{\text{en}}} \cdot \mathbf{x}_{w_{\text{L1}}}}{\|\mathbf{x}_{w_{\text{en}}}\| \|\mathbf{x}_{w_{\text{L1}}}\|}. \quad (4)$$

The TF-IDF vectors are ℓ_2 -normalized, so cosine similarity corresponds to their dot product.

Empirical behavior. Figure 8 illustrates how this character similarity relates to lexical difficulty and to its feature importance in Spanish- and German-L1 model predictions. Most items have near-zero similarity, with some items spread across the range up to perfect matches at 1. Higher similarity is associated with lower difficulty, cf. Table 2. The Shapley values show that high similarity contributes positively to predictions above a small threshold at approximately 0.05–0.10. Below this threshold, negligible similarity is a cue for higher difficulty. This nonlinear distribution explains why character similarity has high average feature importance despite only a moderate correlation with difficulty.

E Hyperparameters

Relevant hyperparameters are summarized in Table 4. The hyperparameters were tuned on the Spanish development set. Reported results are based on 20 random seeds.

F Correlation of difficulties across L1s

Figure 9 shows pairwise correlations of gold-label difficulty across L1s. All language pairs are positively correlated, quantifying the shared component

Component	Parameter	Value
CatBoost	Loss function	RMSE
	Tree depth	7
	Learning rate	0.017
	Iterations	2,400
	ℓ_2 leaf regularization	0.8
Evaluation	Eval. seeds	20 (1, 8, 15, ..., 134)
	Submission seeds	3 (42, 142, 242)
	Metrics	RMSE (primary) Pearson’s r
Baseline	Model	Ridge regression
	ℓ_2 regularization	1

Table 4: CatBoost model configuration, evaluation setup, and baseline.

of lexical difficulty: Words that are hard for one L1 group tend to be hard for others. However, the correlations are far from perfect, indicating that L1-specific factors account for a substantial portion of the variance.

G Relationship of frequency and transfer

In Fig. 10, panel (a) shows lexical difficulty in the plane of character similarity and word frequency. We observe that the easiest words are frequent or cognate. Those words that are both cognate and frequent (items in the top right) shape the model predictions equally through both features, as the Shapley values in panels (b) and (c) indicate. The thresholds for the Shapley values that the model learns appear largely independent for these two features: a vertical divide.

Figure 9: Pairwise correlation of gold-label lexical difficulty across L1s. Each point is one English word tested in both languages. Pearson’s r is shown per pair. The shared variance reflects universal difficulty factors and the unexplained variance motivates L1-specific modeling.

Figure 10: Character similarity by word frequency for Spanish and German, colored by (a) lexical difficulty and the feature importances of (b) word frequency and (c) character similarity.

H Feature analysis

In this section, we examine several features that we evaluated during development but excluded from the final model, cf. Table 3. The goal is to show how these features are related to lexical difficulty and why they may be redundant.

POS competition. Some English word forms occur frequently with one part of speech while another is less common, e.g., received as an adjective meaning “accepted” or bar as verb rather than a noun. We define a binary POS-competition flag, i.e., whether the POS of the target word differs from the most frequent POS.

We test whether POS competition affects the prediction error by comparing the prediction errors (gold – predicted) for items with and without POS competition, see Fig. 11. We find, across all L1s, no significant difference in mean or central tendency (e.g., Spanish: Welch’s t -test: $p = 0.09$, Wilcoxon–Mann–Whitney test: $p = 0.36$), indicating that POS competition does not introduce a systematic model-prediction bias. Furthermore, items with POS competition do not differ signifi-

cantly in gold-label difficulty from items without competition (Welch’s t -tests and Wilcoxon–Mann–Whitney tests, all $p > 0.20$).

However, POS competition has a robust effect on the dispersion of the prediction error. Items with POS competition exhibit substantially higher variance across all L1s, with standard deviations increasing by 24–32%, see Table 5. This difference is statistically significant according to both Brown–Forsythe and Fligner–Killeen tests ($p < 0.01$), which suggests that POS competition is more difficult to predict for the model, but does not introduce a systematic bias.

L1	std _{no}	std _{yes}	ratio	BF p	FK p
Spanish	1.16	1.45	1.24	< 0.01	< 0.01
German	1.04	1.37	1.32	< 0.01	< 0.01
Chinese	0.97	1.24	1.28	< 0.01	< 0.01

Table 5: Standard deviation of the prediction error for items with and without POS competition across L1s, with their ratio, and p -values from Brown–Forsythe (BF) and Fligner–Killeen (FK) tests.

Figure 11: Prediction-error distribution (gold – predicted) by POS competition status across L1 groups (Spanish, German, Chinese). The violin plots compare items without POS competition ($n_{\text{no}} = 585$) versus items with POS competition ($n_{\text{yes}} = 163$) per language, with horizontal lines marking the median.

Edit distance. In addition to character-level cosine similarity, we evaluated character edit distance as a measure of orthographic similarity. While edit distance shows a weak-to-moderate negative correlation with gold-label difficulty for Spanish ($r = -0.17$) and German ($r = -0.30$), it is strongly negatively correlated with character-level cosine similarity for Spanish ($r = -0.77$) and German ($r = -0.73$), see Fig. 12. These two features encode largely the same information, making the inclusion of both redundant. Compared with cosine similarity, edit distance spreads out dissimilar word pairs over a wider range while compressing highly similar forms, making it less informative for distinguishing degrees of cognateness.

Figure 12: Normalized edit distance between English words and their L1 translations in Spanish and German versus gold-label difficulty (top) and its relationship with character-level cosine similarity (bottom).

L1 frequency. Finally, we examine L1 word frequency, which has also been suggested as a predictor of L2 lexical difficulty, under the assumption that more frequent words in a learner’s native language may facilitate recognition or acquisition (Ellis, 2002; Peters, 2019). Using Spanish as an example, Fig. 13 shows that, although higher L1 frequency is associated with lower difficulty ($r = 0.15$), L1 and L2 frequency are themselves strongly positively correlated ($r = 0.44$). As a result, L2 frequency is largely redundant when L1 frequency is already included.

Figure 13: Frequency of L1 (Spanish) source words versus gold-label difficulty (top) and L2 (English) word frequency (bottom).

Submission at BEA 2026 Shared Task 1: Ensemble of Multilingual Encoders with NMT Augmentation for L1-Aware Vocabulary Difficulty Prediction

Abstract

This paper describes a system submission to the closed track of the BEA 2026 shared task on L1-aware vocabulary difficulty prediction (Spanish, German, Mandarin Chinese). We explored three approaches: hand-crafted tabular features with tree-based regressors, fine-tuned multilingual encoders, and fine-tuned decoders (artificial learner simulation with LoRA-tuned Pythia models). Each was examined with and without an English context produced by neural machine translation (NMT), and we also combined all three families in a single ensemble. In the end, ensembling *only* the fine-tuned multilingual encoders (four base architectures together with four NMT-augmented variants, combined through per-language stacking) gave the best results while remaining the simplest configuration to train.

1 Introduction

Vocabulary knowledge is fundamental to language proficiency, directly influencing what learners can comprehend and produce (Laufer, 1997). Establishing word difficulty is essential for creating level-appropriate educational content and valid assessment instruments, yet traditional calibration methods rely on costly expert judgment and pretesting, limiting scalability.

The BEA 2026 shared task (British Council, 2026) addresses this challenge by framing vocabulary difficulty prediction as a regression problem: given an English word and its associated context, predict its difficulty for learners with a specific first language (L1) background. The task uses the British Council’s Knowledge-based Vocabulary Lists (KVL; Schmitt et al., 2021), a dataset of 6,768 items per L1 with psychometrically calibrated GLMM difficulty scores across three L1 groups: Spanish (Es), German (De), and Mandarin Chinese (Cn). Two tracks are offered: *closed* (sep-

arate per-language models) and *open* (a single multilingual model).

While previous shared tasks have addressed related problems, such as complex word identification (Paetzold and Specia, 2016; Yimam et al., 2018) and lexical complexity prediction (Shardlow et al., 2021, 2024), they did not consider the learner’s L1 background, which is known to strongly influence L2 vocabulary acquisition through crosslinguistic transfer (Jarvis and Pavlenko, 2008). The last BEA language learning shared task was on grammatical error correction in 2019 (Bryant et al., 2019).

Our submission makes the following contributions:

1. A systematic comparison of 11 multilingual encoder architectures for L1-aware difficulty prediction;
2. Encoder training augmented with neural machine translation (NMT) using three translation systems with two decoding modes, providing complementary crosslinguistic signal;
3. An ensemble of eight encoders with per-language optimized stacking weights;
4. A tabular feature study combining multilingual embeddings, typological, phonetic, CEFR/WordNet, and cognate features with XGBoost and LightGBM regressors;
5. A scaling study of decoder-based artificial learner simulation (ALS) using Pythia models from 70M to 1.4B parameters.

2 Related Work

Lexical Complexity and Difficulty. The SemEval-2016 CWI shared task (Paetzold and Specia, 2016) introduced binary complex word identification, extended to multilingual settings by

Yimam et al. (2018). Shardlow et al. (2021) moved to continuous complexity prediction with the LCP shared task, and Shardlow et al. (2024) addressed multilingual lexical simplification. However, none of these tasks incorporated learner L1 as a predictive factor, even though there is longstanding evidence that L1 background shapes L2 vocabulary processing and difficulty.

L1 Influence on L2 Vocabulary. Crosslinguistic influence research has established that a learner’s L1 systematically affects L2 vocabulary acquisition (Jarvis and Pavlenko, 2008). Cognates are easier to learn, while false friends create difficulty. This motivates L1-aware prediction models that can capture these transfer effects. This L1 influence has also been examined within language model-based approaches that simulate L2 learners, offering a complementary computational lens on the same phenomenon.

Artificial Learner Simulation. Several lines of work adapt or probe language models to simulate L2 processing and production.

Aoyama and Schneider (2024) pretrain GPT-2 sequentially on six different L1s and then on English as L2. The resulting “L2LMs” produce word surprisal that predicts nonnative reading times, with effects most pronounced for L1 backgrounds typologically distant from English.

In a related direction, Stearns et al. (2024) pretrain BERT on EFCAMDAT – the Education First-Cambridge Open Language Database (Geertzen et al., 2013), a publicly released corpus of ~83M words of English-as-a-foreign-language essays from ~550k EF Englishtown learners with self-declared L1 and CEFR-aligned proficiency labels – and C4200M – a 200M-sentence synthetic learner-error corpus built by injecting grammatical errors into clean C4 web text via a tagged corruption model, approximating the distribution of L2 mistakes at web scale (Stahlberg and Kumar, 2021) – and probe the resulting “artificial learners” via masked-token prediction, finding systematic divergence from a generic native model that is largest at lower CEFR levels.

Hu and Cong (2025) apply LLM-derived surprisal as a proficiency signal for Chinese L2 writing. They compare a multilingual, a Chinese-general, and a Traditional-Chinese-specific LLM on TOCFL essays across CEFR levels A2–C1, and show that surprisal differentiates proficiency and correlates with classic lexical and syntactic com-

plexity indices – evidence that LLM-based probes apply cross-linguistically beyond English.

We extend this artificial-learner line to vocabulary difficulty regression by using Pythia decoder models (Biderman et al., 2023) with LoRA adaptation (Hu et al., 2022) as a next-token-prediction proxy for item difficulty.

3 System Description

3.1 Task and Data

The KVL dataset provides 6,768 parallel vocabulary items across three L1 groups (Spanish, German, Mandarin Chinese), split into training (~6,091 items/language) and development (677 items/language) sets. Each item consists of:

- en_word: the target English word
- en_clue: a letter clue for the word
- L1_word: the L1 translation
- L1_context: an L1 contextual prompt
- GLMM_score: the target difficulty (lower = harder)

Items with the same item_id across L1 files refer to the same English word, enabling cross-language analysis.

3.2 Encoder Models

We fine-tune 11 multilingual encoder architectures for regression, using the full model parameters (no adapter layers). The input is constructed by concatenating all available text fields separated by [SEP] tokens in the order: L1_word, L1_context, en_word, en_clue. A single regression head maps the [CLS] representation to the predicted difficulty score.

Table 1 summarizes the training configuration. All models use identical hyperparameters: learning rate 1×10^{-5} , batch size 8 (effective 16 with gradient accumulation), 10 epochs with early stopping (patience 3), AdamW optimizer with weight decay 0.01 and 10% warmup, and FP16 mixed precision. The maximum sequence length is 256 tokens. We select the best checkpoint by development-set Pearson correlation. The regression target is the GLMM lexical-difficulty score provided by the organizers; the head is trained with mean-squared-error loss.

The 11 architectures tested are: Multilingual E5-Large (Wang et al., 2022), XLM-R Large and Base (Conneau et al., 2020), RemBERT (Chung

Hyperparameter	Value
Learning rate	1×10^{-5}
Batch size (effective)	16
Max epochs	10
Early stopping patience	3
Max sequence length	256
Classifier dropout	0.1
Optimizer	AdamW
Weight decay	0.01
Warmup ratio	0.10
Precision	FP16

Table 1: Encoder training hyperparameters.

et al., 2021), InfoXLM-Large (Chi et al., 2021a), Paraphrase Multilingual MPNet (Reimers and Gurevych, 2019, 2020), Multilingual E5-Base, mBERT (Devlin et al., 2019), CANINE-S (Clark et al., 2022), XLM-Align Base (Chi et al., 2021b), and Chinese RoBERTa Large (Liu et al., 2019). All checkpoints were obtained from the HuggingFace Hub. Of these, the top four (E5-Large, XLM-R Large, RemBERT, InfoXLM-Large) were selected for the ensemble and NMT augmentation experiments.

3.3 NMT Augmentation

We hypothesize that augmenting the L1 context with English translations from NMT systems provides complementary crosslinguistic signal, effectively giving the encoder both the L1 perspective and multiple L2 (English) interpretations of the same content. We generate translations using three NMT systems of varying capacity:

- **OPUS-MT** (Tiedemann and Thottingal, 2020): ~ 77 M parameters
- **NLLB-600M**: distilled 600M model (NLLB Team et al., 2022)
- **NLLB-1.3B**: full 1.3B model (NLLB Team et al., 2022)

For each system, we produce translations in two decoding modes: (1) *free beam search*, where the model generates its own English translation from the L1 input, and (2) *forced decoding*, where the model is constrained to produce the target English word. This yields six additional translated text strings per item.

The NMT-augmented encoders use the same four top architectures but with an extended input sequence that interleaves the original L1 context with these translated L2 contexts: L1_word, L1_context, followed by the six NMT translations,

Spanish item, target “flock”	
L1_word	rebaño
L1_context	Un ___ de ovejas pasta en el campo.
OPUS free	A herd of sheep grazes in the field.
OPUS forced	A flock of sheep grazes in the field.
NLLB-600M free	A flock of sheep grazes in the field.
NLLB-600M forced	A flock of sheep grazes in the field.
NLLB-1.3B free	A flock of sheep is grazing in the field.
NLLB-1.3B forced	A flock of sheep grazes in the field.

Table 2: Worked example of NMT-augmented input for a Spanish item. Three NMT systems each emit a free and a forced decode; the six resulting English strings are concatenated to the L1 fields. Disagreements between free and forced decodes (OPUS’s “herd” vs. the gold “flock”) expose the encoder to lexical alternatives consistent with the L1 context.

then en_word, en_clue, all concatenated as text with [SEP] separators. The maximum sequence length is increased to 384 tokens to accommodate the longer input. Batch size is increased to 12; all other hyperparameters remain identical.

3.4 Artificial Learner Simulation

We hypothesize that diversifying the model’s embedding space away from native-speaker distributional norms and towards representations conditioned on learner production (which we refer to as *learner embeddings*) provides complementary predictive signal for vocabulary difficulty: words that are hard for L2 learners may be unremarkable under a native prior but surface as atypical once the model’s lexical distribution has been shifted towards L2 usage. Following this intuition, our *artificial learner simulation* (ALS) pipeline shifts a Pythia (Biderman et al., 2023) decoder’s next-token distribution towards L2 learner production and uses the resulting learner-conditioned representation as the input to the regression head. We chose decoder-based rather than encoder-based artificial learners to maximise architectural diversity relative to the multilingual encoders of Section 3.2; encoder artificial learners remain a separate ablation we did not run.

Concretely, the ALS pipeline has two stages: (i) a learner-style language-modelling pretraining on EFCAMDAT that yields an *artificial learner*

checkpoint, and (ii) a regression adaptation of that checkpoint to the shared-task data.

Stage 1: EFCAMDAT pretraining. We continue the causal-LM pretraining of Pythia (Biderman et al., 2023) at five scales (70M, 160M, 410M, 1B, 1.4B) on the full EFCAMDAT corpus (Geertzen et al., 2013) of L2 English learner essays, using the standard next-token prediction objective and no modification to the model architecture. After this stage, each checkpoint (pythia-{size}-all-data) is a decoder whose distribution over continuations reflects the lexical and grammatical choices of L2 learners rather than those of a native reference corpus.

Stage 2: Regression adaptation. To transfer an artificial-learner checkpoint to the shared task, we discard the pretrained LM head and attach a randomly initialised 2-layer MLP regression head of the form Dropout $\rightarrow$ Linear($h, h/2$) $\rightarrow$ GELU $\rightarrow$ Dropout $\rightarrow$ Linear($h/2, 1$), where h is the backbone hidden size. Items are serialised as en_word | L1_word | en_clue | L1_context followed by the suffix “Difficulty:”, left-padded, and the sequence representation is obtained by taking the hidden state of the last non-padding token, the decoder-appropriate analogue of the [CLS] pooling used by the encoder models of Section 3.2. The backbone itself is frozen except for LoRA adapters (Hu et al., 2022) with rank $r = 16$, $\alpha = 32$, dropout 0.05, applied to the query_key_value and dense projections of every GPT-NeoX block; the regression head is trained at full precision. Training minimises MSE with AdamW, learning rate 2×10^{-5} , effective batch size 16, up to 10 epochs with early stopping on dev Pearson r .

3.5 Tabular Features

We additionally extract a set of hand-crafted features organized into nine modules. For each module below we report the implementation actually used:

- **Embeddings** (1,154): Multilingual E5-Large sentence embeddings for the L1 context, target word, and source, plus pairwise cosine similarities; computed with sentence-transformers (Reimers and Gurevych, 2019).
- **Language pair typology** (226): morphological and typological features comparing

each L1 to English, looked up from a hyper-granular morphological-features table derived from WALS (Dryer and Haspelmath, 2013) and expressed as both raw L1 values and L1–English difference vectors.

- **IPA phonetic** (95): articulatory, sonority, and syllable-structure features over the G2P-converted target word, computed with panphon’s FeatureTable and Distance modules (Mortensen et al., 2016).
- **CEFR + WordNet** (12): per-word CEFR statistics (presence, sense count, min/max/mean/range level, and binary indicators for A1–C2), obtained from a sensekey-to-CEFR lookup table built over WordNet (Fellbaum, 1998) senses.
- **Cognate similarity**: Levenshtein distance, longest-common-subsequence length, character-bigram Jaccard, and shared-prefix length between the English target and its L1 translation; all implemented as plain Python, no external distance library.
- **Clue features**: length, revealed-positions length, vowel presence, and blank-to-letter ratio over the en_clue field.
- **Counts / POS / L1**: string-length and word-count statistics; one-hot encoding of a pre-annotated en_target_pos column; one-hot L1 language indicators (es/de/cn).
- **NMT-derived**: five features per NMT system capturing whether the target word appears in the free translation, the normalised Levenshtein distance between forced and free decodes, the Pythia perplexity of the forced translation, the forced/free perplexity ratio, and the NMT-score drop.
- **Frequency**: Zipf-scaled word-frequency bands for the English target, retrieved via wordfreq (Speer, 2022).

We fit regressors from the scikit-learn toolkit (Pedregosa et al., 2011), covering linear regression, Ridge, Lasso, decision trees, and tree ensembles (random forest, extra trees, gradient boosting, AdaBoost), together with XGBoost (Chen and Guestrin, 2016) and LightGBM (Ke et al., 2017). The best-performing tabular configuration combines all feature groups with ALS-derived

embeddings (all_concat_als_xgb, $r = 0.797$), using XGBRegressor with $n_{\text{estimators}} = 1000$, $\text{max_depth} = 6$, learning rate 0.03, and L_1/L_2 regularisation coefficients 0.1. Feature extraction relied on sentence-transformers (Reimers and Gurevych, 2019) for the 1,154 Multilingual E5-Large embeddings and panphon (Mortensen et al., 2016) for the 95 articulatory, sonority, and syllable-structure features. The full per-configuration breakdown across ~ 15 feature/regressor combinations is reported in Appendix A.

3.6 Ensemble Strategy

Our final system ensembles the predictions of eight encoder models: four base and four NMT-augmented (Section 3.3). We experimented with two stacking strategies:

Nelder-Mead. We compute a weighted average of predictions: $\hat{y} = \sum_{i=1}^8 w_i \cdot \hat{y}_i$, where weights $w_i \geq 0$ and $\sum w_i = 1$. The weights are fit *separately per language* using the Nelder-Mead simplex method (Nelder and Mead, 1965), as implemented in `scipy.optimize.minimize` (Virtanen et al., 2020) with $\text{xatol} = 10^{-6}$ and $\text{fatol} = 10^{-8}$, to maximize Pearson correlation on the 677 development items. This is a non-learning approach: no meta-model is trained, and the only free parameters are the 8 weights per language.

ElasticNet Meta-Learner. We train a scikit-learn (Pedregosa et al., 2011) ElasticNet regressor (Zou and Hastie, 2005) ($\alpha = 0.1$, $l_1\text{-ratio} = 0.5$) on the training-set predictions of the eight encoders.

4 Results

4.1 Individual Encoder Performance

Table 3 presents the development-set results for all 11 encoder architectures. Multilingual E5-Large achieves the best individual performance ($r = 0.845$), followed closely by XLM-R Large ($r = 0.843$) and RemBERT ($r = 0.843$). There is a clear divide between the top-four large models and the rest: the gap between 4th (InfoXLM-Large, $r = 0.829$) and 5th (Paraphrase MPNet, $r = 0.810$) is substantial.

4.2 NMT Augmentation Effect

Table 3 shows the impact of NMT augmentation on the top-four encoders. For each architecture, we compare the base model with its NMT-augmented variant (using all six NMT contexts:

OPUS-MT, NLLB-600M, NLLB-1.3B, each with free and forced decoding). NMT augmentation consistently improves Pearson r across all four architectures, with the largest gain for InfoXLM-Large (+0.021). RMSE improves for XLM-R Large and RemBERT but slightly worsens for E5-Large and InfoXLM-Large.

4.3 Artificial Learner Simulation

Table 3 presents the ALS scaling study. Performance scales monotonically with model size, from $r = 0.494$ (70M) to $r = 0.812$ (1.4B). However, even the largest ALS model underperforms the best individual encoder ($r = 0.845$), suggesting that for this task, direct fine-tuning of encoder representations is more effective than the decoder-based ALS approach. Several follow-up experiments remain open, including the NMT-augmented variant of the 1.4B checkpoint, larger Pythia scales, encoder-based artificial learners, and adding the Pythia ALS models to the final ensemble alongside the multilingual encoders; we could not run them within the shared-task timeline and leave them to future work.

4.4 Tabular Feature Models

We trained approximately 40 scikit-learn regressors over the hand-crafted feature modules described in Section 3.5, formed by combining feature subsets with five regressor families (linear regression, ridge, decision tree, XGBoost, LightGBM). The strongest configuration, all_concat_als_xgb, concatenates all features with ALS-derived embeddings and is fit with XGBoost, reaching $r = 0.797$ on the development set. This result surpasses three of the base encoders (XLM-R Base, $r = 0.791$; mBERT, $r = 0.761$; CANINE-S, $r = 0.668$) and is comparable to Pythia 1B ALS ($r = 0.793$), but remains below the seven stronger base encoders and all NMT-augmented encoder variants. We retain the top two tree-based configurations for the 10-model ensemble experiments, but observe no improvement in results. The full per-configuration results appear in Appendix A.

4.5 Ensemble Results (Development Set)

Table 3 presents our ensemble results on the development set. The 8-encoder XGBoost blend (a learned non-linear meta-model) achieves $r = 0.882$, a +3.7% absolute improvement over the best single encoder. No-learning strategies (simple average, Nelder-Mead, hill climbing) cluster tightly between $r = 0.870$ and $r = 0.871$, and the ElasticNet meta-learner achieves $r = 0.871$. On hidden

Table 3: Train-dev split results across all model families: base and NMT-augmented multilingual encoders, decoder-based artificial learner simulation (Pythia, with and without NMT features), tabular/scikit-learn regressors, the two submitted 8-encoder ensemble strategies (Nelder-Mead and ElasticNet meta-learner), and the shared-task baselines. Per-language Pearson r on the 677-item dev set is shown where reported per language; otherwise overall (pooled) r /RMSE is given. Baseline dev-set RMSE is the average across the three L1s, computed from the organizer-released per-L1 baseline predictions: Closed 1.287 (Es 1.357, De 1.328, Cn 1.175); Open 1.125 (Es 1.206, De 1.149, Cn 1.021). Test-set RMSE for both baselines appears in Table 4. Tabular section shows only the best configuration; the full breakdown is in Appendix A. GPT-2 decoder baselines are reported in Appendix B. Full ensemble-strategy ablation (alternative weighting schemes and 10-model variants) is in Appendix C.

test data, however, the Blend XGB advantage over these simpler strategies disappears (see §5): we therefore selected Nelder-Mead and ElasticNet for official submission, and treat the +0.011 dev-set gap as meta-model overfitting rather than generalisable signal.

Notably, including tabular models (XGBoost, LightGBM) in a 10-model ensemble slightly degraded performance ($r = 0.872$) compared to the 8-encoder-only ensemble, suggesting the tabular models introduced noise rather than complementary signal.

4.6 Official Test Results

Table 4 presents the official test set results for the closed track. Ranked by RMSE (the official metric), our best submission per language reaches 0.975 (Es, Nelder-Mead), 0.903 (De, ElasticNet) and 0.820 (Cn, ElasticNet), placing uogal **2nd** on Spanish and German behind Glite, and **3rd** on Chinese behind Glite and Sakura (which submitted 0.816). All four uogal submissions improve over the closed-track baseline by 0.28–0.36 RMSE points, and even the worse of the two beats the open-track baseline on every language. The same picture in Pearson r – 0.859 (Es), 0.869 (De), 0.880 (Cn) – shows ElasticNet ahead on Spanish/German and Nelder-Mead nominally ahead on Chinese by 0.001, illus-

Lang.	System	r	RMSE ↓ (primary)
Es	Glite (1st)	.877	0.903
	uogal Nelder-Mead	.858	0.975
	uogal ElasticNet	.859	0.977
	Closed Baseline	.765	1.257
	Open Baseline	.783	1.198
De	Glite (1st)	.871	0.885
	uogal ElasticNet	.869	0.903
	uogal Nelder-Mead	.865	0.944
	Closed Baseline	.773	1.258
	Open Baseline	.786	1.166
Cn	Glite (1st)	.889	0.776
	Sakura (2nd)	.874	0.816
	uogal ElasticNet	.879	0.820
	uogal Nelder-Mead	.880	0.841
	Closed Baseline	.753	1.140
	Open Baseline	.804	1.034

Table 4: Official test set results (closed track). uogal ranks 2nd across all three languages, behind Glite.

trating that the two metrics disagree slightly on the Chinese ranking; we treat RMSE as authoritative since it is the official ranking metric.

5 Analysis

Primary Ranking Metric (RMSE). RMSE is the official ranking metric. Our best per-language submission reaches RMSE 0.975 (Es), 0.903 (De) and 0.820 (Cn), beating the closed-track baseline by 0.28–0.36 points (Table 4). On Chinese the two metrics order our submissions differently (r marginally prefers Nelder-Mead, RMSE clearly prefers ElasticNet); we follow the RMSE verdict throughout.

Superiority of Ensembling. Ensembling provides a substantial gain over the best individual model on the official metric. The best base encoder reaches RMSE 0.980 (RemBERT) and the best NMT-augmented encoder reaches 0.963 (RemBERT +NMT). On the dev set the 8-encoder Blend XGB meta-model reaches RMSE 0.851, a 0.13 absolute improvement over the best base encoder and 0.11 over the best NMT-augmented one (Table 3); the no-learning and linear-meta strategies (simple averaging, weighted-RMSE, weighted-Pearson, hill climbing, Nelder-Mead, ElasticNet) reach dev RMSE between 0.891 and 0.973. The dev-set advantage of the learned XGBoost blend *does not transfer to test*: Blend XGB underperforms the simpler Nelder-Mead and ElasticNet strategies on the hidden test set, and was therefore excluded from our two submissions. We read this as meta-model overfitting to the 677 dev items used to train the

blend — a learned non-linear stacker has enough capacity to absorb dev-set idiosyncrasies that do not generalise, whereas the constrained weighting strategies cannot. Accordingly, the robust portion of the ensemble gain is the ≈ 0.08 RMSE drop shared by every no-learning and linear-meta strategy, which we attribute to *model diversity* rather than to any particular weighting scheme; the two submitted ensembles exceed the closed-track baseline by 0.28 (Es), 0.36 (De) and 0.32 (Cn) RMSE points on test (Table 4).

Variance of Encoder Results. Across the 11 encoders of Table 3 the cross-architecture spread in RMSE is large – from 0.980 (RemBERT) to 1.364 (CANINE-S), a range of 0.38 points – and similar in shape to the cross-architecture Pearson spread. Per-L1 Pearson columns (where the table reports them) further show that base encoders are remarkably stable across L1s (0.005–0.013 Pearson spread, e.g. XLM-R Large .840/.845/.845), so cross-architecture variance dominates cross-L1 variance by roughly an order of magnitude. NMT augmentation roughly doubles cross-L1 Pearson variance (up to 0.020 for XLM-R Large +NMT: .855/.854/.835) and consistently pulls Chinese down relative to Spanish and German – the English-centric NMT systems contribute complementary signal for the two European L1s but interfere with Chinese. This pattern justifies the ensemble design choice of combining multiple *architectures* rather than multiple seeds of a single model.

Language-Specific Weight Preferences. The Nelder-Mead per-language weights reveal interesting patterns. For Spanish, the NMT-augmented XLM-R Large and RemBERT receive the highest weights; for German, NMT-augmented E5-Large and InfoXLM-Large dominate; for Chinese, the base E5-Large and XLM-R Large are preferred. This suggests that different encoder-L1 combinations capture complementary aspects of difficulty, motivating per-language weight fitting over a global weighting scheme.

Encoder vs. Decoder for Difficulty Prediction. The best encoder reaches RMSE 0.980 (RemBERT) while the best decoder-based ALS checkpoint reaches 1.030 (Pythia 1.4B), a gap of 0.05 RMSE points in favour of encoders. While the ALS models show clean monotonic RMSE scaling – 1.512 $\rightarrow$ 1.362 $\rightarrow$ 1.068 $\rightarrow$ 1.030 from 70M to

1.4B parameters – they do not close the gap, and the encoder approach is both more effective and more computationally efficient for this regression task.

NMT Augmentation Helps Both Individually and in Ensembles. NMT augmentation improves RMSE for three of the four top architectures (Table 3): XLM-R Large (1.085 $\rightarrow$ 0.994), RemBERT (0.980 $\rightarrow$ 0.963) and InfoXLM-Large (1.166 $\rightarrow$ 1.043), with E5-Large the lone exception (1.025 $\rightarrow$ 1.046); Pearson rises monotonically across all four. The 8-encoder ensemble (4 base + 4 NMT) reaches dev RMSE 0.891 (ElasticNet) and 0.902 (Nelder-Mead), improving over the best individual NMT model by 0.07–0.08 RMSE points. Exposing the encoder to multiple English renderings of the same L1 input, produced by NMT systems of varying capacity, likely surfaces complementary aspects of crosslinguistic transfer. We did not separately evaluate a base-only (4 encoder) ensemble, so we cannot directly attribute the ensemble gain to the NMT variants alone vs. to model diversity in general.

6 Conclusion

We presented the *uogal* system, which placed 2nd in the closed track of the BEA 2026 shared task on L1-aware vocabulary difficulty prediction. Our approach combines eight fine-tuned multilingual encoders—four base architectures and four NMT-augmented variants—in an ensemble with two stacking strategies, achieving test set Pearson correlations of $r = 0.859$ (Es), $r = 0.869$ (De), and $r = 0.880$ (Cn). We additionally demonstrated monotonic scaling behavior in decoder-based artificial learner simulation, though this approach did not match encoder ensemble performance. Our results indicate that large multilingual encoders can effectively capture L1-specific vocabulary difficulty patterns without explicit L1 conditioning, and that NMT augmentation provides valuable ensemble diversity.

7 Future Work

There are numerous avenues to follow from this work. One direction concerns metadata-aware models, where the L1 identifier is provided explicitly rather than left implicit in the input: our early L1-concat experiments suggest that naive injection interferes with the encoder’s multilingual represen-

tations, and open questions remain about how and where to introduce the L1 signal, whether through token placement, embedding initialization, prefix tuning, or adapter-style conditioning. A second direction is scaling, both in encoder backbones and in the artificial learner simulation side, where the observed trends have not yet plateaued and larger checkpoints or alternative decoder families may narrow the gap to encoder-based difficulty prediction. A third direction is improving the NMT augmentation pipeline by asking a more targeted question: given an L1 context in which a learner encountered a word, what is the best equivalent L2 context to generate? Better answers to this question, whether through context-aware translation, retrieval of comparable L2 passages, or learner-conditioned generation, could make augmentation a stronger signal for L1-specific vocabulary difficulty.

Limitations

Our system has several limitations. First, it was evaluated on only three L1 groups (Spanish, German, Mandarin Chinese); performance on typologically more distant or lower-resource L1 backgrounds remains unknown. Second, the ensemble of eight large models (~ 560 M parameters each) has substantial computational requirements for both training and inference, limiting practical deployment. Third, our ensemble weights were optimized on the development set (677 items per language), which, while a favorable parameter-to-sample ratio ($\sim 85:1$), carries some risk of overfitting. Finally, we report development-set performance for ablation studies (e.g., individual encoder comparison, ALS scaling); only the final ensemble submissions were evaluated on the official test set.

Table 5: Detailed dev-set Pearson r and RMSE for the top 15 tabular / scikit-learn configurations over hand-crafted feature modules. Naming convention: {feature_subset}_{regressor}. The best configuration combines all feature modules with ALS-derived embeddings and an XGBoost regressor.

A Detailed Tabular Feature Results

Table 5 reports the dev-set performance of the strongest 15 hand-crafted-feature scikit-learn configurations. All runs use the feature modules described in Section 3.5 (Embeddings, Language-pair typology, IPA phonetic, CEFR + WordNet, Other) in various subsets, paired with five regressor families (linear regression, ridge, decision tree, XGBoost, LightGBM). Approximately 25 additional configurations with $r < 0.40$ (e.g., word-count-only, language-pair-only, single-feature ablations) are omitted for brevity; complete metrics are available in the project repository.

B GPT-2 Decoder Baselines

As a pre-ALS sanity check we fine-tuned native-English GPT-2 decoders (without the EFCAMDAT artificial-learner adaptation) on the same regression head and serialisation described in Section 3.4. These numbers serve purely as a reference point: a generic next-token model with no learner adaptation. They fall well below every multilingual encoder in the main table and below all Pythia-based ALS checkpoints from 410M upwards (Table 3), supporting the design choice to adapt decoders on learner data rather than use them off-the-shelf.

C Full Ensemble-Strategy Ablation

Table 7 reports the full set of ensemble weighting strategies we evaluated on the development

System	Es	De	Cn	Avg r	RMSE
GPT-2	.578	.609	.652	.610	1.476
GPT-2 Medium	.577	.601	.646	.606	1.483

Table 6: GPT-2 decoder baselines on the 677-item dev set. Neither model was adapted on learner data; they serve as a reference for the gain provided by EFCAMDAT-based artificial learner simulation (Table 3).

set. In the main paper (Table 3) we show only the two submitted configurations (Nelder-Mead and ElasticNet meta-learner over the 8 encoders). The remaining rows below include alternative no-learning schemes (simple average, weighted-RMSE, weighted-Pearson, hill climbing, rank average), the learned non-linear Blend XGB meta-model, and a 10-model variant that adds the two strongest tabular configurations (all_features_xgb, all_features_lgbm) to the 8 encoders.

Strategy	Es	De	Cn	Avg r	RMSE
<i>8-encoder ensembles (dev)</i>					
Simple avg	.872	.870	.867	.870	0.973
Weighted RMSE	.872	.871	.867	.870	0.969
Weighted Pearson	.872	.871	.867	.870	0.970
Hill climb	.874	.869	.867	.870	0.910
Rank avg	.868	.871	.860	.866	1.520
Nelder-Mead (submitted)	.875	.870	.868	.871	0.902
ElasticNet meta (submitted)	.875	.870	.867	.871	0.891
Blend XGB	.885	.887	.875	.882	0.851
<i>10-model ensembles — 8 encoders + 2 tabular (dev)</i>					
Nelder-Mead	.878	.870	.868	.872	0.899
ElasticNet meta (dmeta)	.874	.872	.867	.871	0.906
Blend ElasticNet	.873	.873	.868	.871	0.891

Table 7: Full ensemble-strategy ablation on the 677-item dev set. The two submitted configurations (Nelder-Mead and ElasticNet meta-learner over 8 encoders) also appear in Table 3 of the main text. No-learning strategies cluster tightly at $r \in [.866, .871]$; the learned non-linear Blend XGB meta-model reaches the highest average Pearson ($r = .882$) on dev but was not selected for submission.

Jinnie’s Lab at BEA 2026 Shared Task 1: Precalibration of Vocabulary Item Difficulty with Multilingual Transformers and Multi-Task Learning

Abstract

This paper describes our submission to the BEA 2026 shared task 1 on vocabulary item difficulty prediction in multilingual settings. We investigated whether transformer-based representations learned directly from item content can support the prediction of vocabulary item difficulty across different L1 groups. Our approach adopted a multilingual BERT-based architecture, specifically the mmBERT, with representation augmentation at both the layer and token levels, followed by a multi-task cascade learning that incorporates part-of-speech information as an auxiliary structural signal. Results showed that multi-task mmBERT consistently outperforms the shared-task XLM-RoBERTa baseline across languages, while gains from more complex aggregation are not uniform. The findings showed that strong multilingual representations provide a competitive foundation for vocabulary item difficulty prediction, while the benefits of additional architectural complexity depend on the language and training setting.

1 Introduction

Item difficulty prediction aims to estimate item parameters from item features, with the long-term goal of reducing reliance on resource-intensive calibration procedures while preserving the quality of measurement (Wauters et al., 2012). Within the educational measurement community, this task is not only a question of predictive accuracy, but also of whether model-based estimates can serve as valid and interpretable proxies for empirically calibrated item parameters (e.g., Ulitzsch et al., 2026).

Recent advances in machine learning and natural language processing (NLP), particularly transformer-based models and large language models (LLMs), have substantially expanded the methodological toolkit available for this task, most often through supervised deep learning approaches.

Broadly, existing approaches to item difficulty prediction can be organized along three dimensions: (1) the use of representations learned directly from item text, (2) the incorporation of features generated by LLM-based or other generative frameworks, and (3) the inclusion of response-based information (e.g., student correctness) as part of the prediction process. In this study, we focus specifically on model classes that leverage representations learned directly from item content, treating these representations as the primary source of information for predicting item difficulty.

Transformer-based models are particularly well-suited for this setting due to their ability to generate contextualized, high-dimensional representations of text that capture semantic and syntactic relationships. Their use in item difficulty prediction implicitly assumes that the linguistic signal contained in the item, such as the target word, its context, and surrounding cues, encodes sufficient information to infer the cognitive demand required for a correct response (e.g., Peters et al., 2025). While this assumption has shown promise in domains where item stimuli are relatively self-contained (e.g., reading comprehension), its applicability to more narrowly defined constructs, such as vocabulary knowledge, raises distinct methodological and measurement considerations.

In vocabulary assessment, item difficulty is closely tied to lexical complexity, which reflects not only properties of the target word but also the interaction between the word, its context, and the examinee’s linguistic background. Earlier approaches to vocabulary item difficulty prediction relied heavily on hand-crafted features, including word length, frequency, part-of-speech (POS) tags, concreteness, and age-of-acquisition (Yang and Suyong, 2018; Settles et al., 2020). While these features offer interpretability, they are limited in their ability to capture contextual meaning and semantic variability across usages.

More recent work has shifted toward leveraging contextual embeddings from pre-trained language models, particularly encoder-only architectures such as BERT (Devlin et al., 2019), to model lexical complexity in context (e.g., Zaharia et al., 2021; Kelious et al., 2024). These approaches often combined contextual representations with psycholinguistic features to improve performance. However, from a measurement perspective, it remains unclear to what extent these representations capture construct-relevant variances, as opposed to incidental properties of language use. This challenge becomes more pronounced in cross-lingual settings, where item difficulty may vary as a function of examinees’ first-language (L1) backgrounds and the linguistic relationship between source and target languages. For example, Skidmore et al. (2025) demonstrated that multilingual transformer models (e.g., XLM-RoBERTa Conneau et al., 2020) can be fine-tuned to predict vocabulary item difficulty across multiple languages, suggesting the potential of cross-lingual transfer for item calibration. At the same time, these approaches face challenges related to polysemy, low-frequency cognates, and subword tokenization, all of which may introduce construct-irrelevant variance into predictions.

In this paper, we participate in the BEA 2026 shared task on vocabulary item difficulty prediction and investigate how representation learning and multi-task modeling choices affect predictive performance across languages. Specifically, we explore a multilingual BERT-based architecture (mmBERT; Marone et al., 2025) with layer-wise and token-wise representation aggregation, alongside a multi-task cascade that incorporates part-of-speech (POS) information as an auxiliary structural signal.

Our goal is twofold: (1) to evaluate the effectiveness of these design choices within the shared-task setting, and (2) to examine, at a high level, how different representation strategies relate to the modeling of lexical item difficulty. Through this analysis, we aim to provide both a competitive system and a set of practical insights into what types of representations are most effective for vocabulary item difficulty prediction in multilingual contexts.

2 Related Work

2.1 Transformer-based Item Difficulty Prediction

Within educational measurement, item difficulty is a fundamental parameter that underpins score

interpretation, test assembly, and the evaluation of measurement quality. In both Classical Test Theory (CTT) and Item Response Theory (IRT), difficulty is not directly observed but inferred from examinee response data through calibration procedures. Although these approaches provide a rigorous and defensible basis for parameter estimation and validity arguments, they rely on sufficiently large and representative samples, which can limit the efficiency and scalability of item development. Consequently, a growing body of research has examined the prediction of item difficulty prior to operational calibration using features derived from item content (e.g., Peters et al., 2025). These efforts are best understood not as substitutes for psychometric calibration, but as methods for producing provisional estimates that can inform item screening, test construction, and adaptive content generation in the absence of response data.

Recent advances in transformer-based models and large language models (LLMs) have expanded the methodological approaches available for this purpose. One class of methods uses pretrained language models to derive semantic representations of item text, which are then used to predict relative or absolute difficulty. For example, Loginova et al. (2021) demonstrated that contextual embeddings can support pairwise difficulty comparisons without relying on calibrated parameters or observed response vectors, although such predictions remain model-based approximations rather than psychometric estimates grounded in examinee behavior. Related work (e.g., AlKhuyaey et al., 2024; McCarthy et al., 2021) similarly treats text as the primary source of information for difficulty prediction.

A second line of work attempts to approximate difficulty through simulated response processes, often by treating LLMs as proxy examinees. Maeda (2025) generate synthetic response data from trained models to estimate item difficulty in settings where field testing is limited. While promising, these approaches introduce additional assumptions regarding the correspondence between model-generated responses and human performance, raising important questions about construct representation, population invariance, and the interpretability of resulting parameters.

2.2 Vocabulary Item Difficulty Prediction

A specific area within item difficulty prediction concerns vocabulary assessment, where the item difficulty is closely tied to the linguistic properties

of target words. In these contexts, predicting difficulty prior to calibration often relies on features that capture how learners process lexical content.

A closely related line of work is lexical complexity prediction, which reflects the perceived difficulty of a word for a given population (North et al., 2023). This construct has been widely studied in NLP and applied linguistics, particularly in tasks such as lexical simplification (Shardlow et al., 2022). In vocabulary learning contexts, complexity is typically modeled using morphological, semantic, and contextual features, sometimes incorporating learner characteristics such as L1. For example, Alfter and Volodina (2018) predicted comprehension levels for Swedish learners using linguistically informed features and machine learning methods. More recent work has leveraged contextualized representations from transformer-based models (e.g., BERT, RoBERTa), showing improved performance over traditional approaches such as SVM and Random Forest (Zaharia et al., 2021; Yaseen et al., 2021).

From a measurement perspective, lexical complexity and item difficulty are conceptually distinct. Lexical complexity operates at the word level and reflects processing demands, whereas item difficulty is a latent parameter defined through examinee responses. Nonetheless, lexical complexity provides a construct-relevant source of information for vocabulary item difficulty prediction. Word-level features may explain meaningful variation in item difficulty, particularly when aligned with population characteristics such as learners’ L1, which can systematically influence lexical processing (Graham et al., 2010; Derakhshan and Karimi, 2015; Schneider et al., 2026).

2.3 Multilingual BERT regression

Predicting item difficulty that accounts for lexical complexity can be approached as a regression problem. As such, transformer-based regression approaches have been adopted to predict lexical complexity. Ortiz-Zambrano et al. (2025)’s study highlighted the utility of incorporating linguistic features with BERT, XLMR, and RoBERTa towards improving lexical complexity prediction across English and Spanish contexts. Variations of transformer-based models employing regression models have been introduced in a lexical complexity prediction task in 2021 (North et al., 2023). DeepBlueAI, one of the top performing models, incorporated a final estimator with a simple linear

regression model (Pan et al., 2021).

Similarly, BERT-based regression models have been employed to predict item difficulty (Yaneva et al., 2024). Benedetto et al. (2023) analyzed quantitative approaches to item difficulty and found that BERT consistently outperforms baseline machine learning models, while hybrid models that incorporate linguistic features further improve prediction performance. Further studies have adopted regression-based approaches for difficulty prediction within various domains, including medicine (Ram and Kesanam, 2024), algebra (Aradelli, 2019), and reading (Kapounová, 2025). Foundational to this year’s BEA shared task, Skidmore et al. (2025) examined item difficulty in a vocabulary learning setting. Thus, integrating insights from research on lexical complexity and item difficulty prediction are promising towards modeling difficulty in multilingual learning contexts.

2.4 Research Gap

Despite progress in lexical item complexity prediction, estimating the continuous difficulty of vocabulary test items in cross-lingual contexts remains difficult. Traditional methods emphasize hand-crafted linguistic features but fail to capture deep semantic dependencies (Yang and Suyong, 2018; Settles et al., 2020), while standard multilingual transformers offer cross-lingual transfer yet often miss nuanced difficulty variations confounded by specific target word senses (Skidmore et al., 2025). Although some work proposes integrating psycholinguistic features with deep embeddings, most automated approaches merely concatenate deep semantic representations with hand-crafted features prior to final prediction (Bulut et al., 2024; Benedetto et al., 2023; Ortiz-Zambrano et al., 2025). Furthermore, advanced frameworks such as multi-task learning, which leverage auxiliary linguistic tasks to improve primary predictions (Sanh et al., 2018; Liu et al., 2019; Galal et al., 2024), remain underexplored. To address this gap, we introduce an mmBERT-based multi-task architecture with layer-wise and token-wise aggregation that explicitly models cross-lingual semantic relationships and syntactic biases through auxiliary POS tagging, enabling more accurate and context-aware difficulty prediction.

3 Methods

In this section, we present the system architecture, including the data preprocessing, BERT-based rep-

Figure 1: Overview of the proposed system architecture.

representation generation, the layer-wise and token-wise representation augmentation, and multi-task downstream prediction layer. An overview of the system is presented in Figure 1. First, the item text is tokenized by concatenating distinct linguistic components into a single multilingual sequence. Second, this sequence is passed through a BERT family model, specifically the mmBERT architecture, to extract comprehensive cross-lingual semantic representations. To maximize the utility of the deep semantic information, the system applies both layer-wise fusion, such as scalar mixing or mean/max token pooling, and token-wise aggregation via self-attention to output an augmented item representation. Third, the augmented representation is utilized in a hierarchical multi-task architecture. It initially computes auxiliary part-of-speech tagging logits for the English target word. Then, these auxiliary signals are detached and injected into the primary task by concatenating directly with the primary semantic representation to predict the final continuous lexical difficulty score.

To encode the test item, we followed the approach by Skidmore et al. (2025) to organize the input text into a single multilingual sequence. The sequence follows the presentation order of the vocabulary test items, concatenating the source language word, the source language context, the English target clue, and the target English word using the [SEP] tokens. This structure allows the encoder to capture cross-lingual relationships and contextual constraints.

casa [SEP] Vivo en una casa grande
que tiene tres dormitorios. [SEP]
h_____ [SEP] home

Target labels In this supervised framework, each task utilizes a label to guide learning. The primary label is a continuous difficulty score derived from generalized linear mixed model (GLMM) estimates to quantify the lexical challenge of the English target word. Concurrently, the system predicts an auxiliary label representing the POS tag of the target word. Because English target words are lemmas agnostic to specific word senses, and certain senses are more difficult for learners, the POS tag provides a structural inductive bias. This is directly injected into the final difficulty predictor through a multi-task cascading architecture (Goldberg, 2022).

Representation Generation Given BERT-based regression model’s strong performance and widespread success on both lexical complexity prediction and item difficulty prediction tasks (Ortiz-Zambrano et al., 2025; Ram and Kesanam, 2024; Kelious et al., 2024; Skidmore et al., 2025; Kapounová, 2025), our system uses the encoder-only model to serve as the representation generator. Specifically, the system utilizes mmBERT (Marone et al., 2025), the latest multilingual encoder that excels across diverse multilingual NLP tasks compared to its predecessors (e.g. XLM-RoBERTa).

3.1 Representation augmentation

After obtaining the token-level representation of the item sequence using the mmBERT encoder, we aggregate hidden states across both intermediate layers and sequence tokens, inspired by the finding that task-relevant information in transformers is distributed within its deep and wide structure (Rogers et al., 2021; Galal et al., 2024; Behrendt et al., 2025; Ciernik et al., 2026). For layer-wise aggregation, we experimented with three approaches separately: scalar mixing, mean pooling, and max pooling. The last several layers are selected to prevent contam-

ination of irrelevant information encoded in the lower layer. Once we get an aggregated layer representation, we utilize either the self-attention mechanism or token-wise mean pooling to expand the sentence head into a sequence-wide representation.

Given a BERT-based encoder with T number of intermediate layers, we write $\mathbf{H} \in \mathbb{R}^{k \times l \times d}$ for the tensor of item sequence’s hidden states of multiple layers, where k is the number of chosen layers, l is the sequence length, and d is the hidden size. Let $h_i \in \mathbb{R}^{l \times d}$ denote the sequence representation at the i -th layer.

Scalar Mixing Learn softmax weights s_i to dynamically compute a weighted sum of hidden states h_i across k layers of the network, where γ is a trainable scaling factor.

$$\mathbf{H}_{mix} = \gamma \sum_{i=T-k+1}^T \text{softmax}(s_i) \cdot h_i$$

For each layer, a layer normalization (Ba et al., 2016) is used to respect the fact that their activations might distribute differently to address certain aspects of the task. Specifically, we adopted PyTorch’s `layer_norm()` on each layer $h_i = \text{LN}(h_i)$. After the contextually mixed representation $\mathbf{H}_{mix}$ is generated, we apply the attention mask to zero-out padding tokens in each sequence that would corrupt the loss signals.

Mean/Max layer pooling Apply a deterministic pooling operation across the depth dimension to extract the element-wise average or maximum values. Specifically, we aggregate the hidden states from the k chosen layers of the network:

$$\mathbf{H}_{mean} = \frac{1}{k} \sum_{i=T-k+1}^T h_i, \quad \mathbf{H}_{max} = \max_{T-k+1 \leq i \leq T} h_i$$

We set $k = 4$ to aggregate the deep semantic information captured in the final four encoder layers.

Self-attention To integrate sequence-wide contextual information into the global representation, we extract the [CLS] token $q_{cls} \in \mathbb{R}^{1 \times d}$ from the layer-aggregated sequence $\mathbf{H}^{(1)} \in \mathbb{R}^{l \times d}$ to serve as the single query, while the entire sequence $\mathbf{H}^{(1)}$ serves as the keys and values. We write self-attention aggregated representation $\mathbf{h}_{attn} \in \mathbb{R}^d$ as:

$$\begin{aligned} \mathbf{h}_{attn} &= \text{Attention}(q_{cls}, \mathbf{H}^{(1)}, \mathbf{H}^{(1)}) \\ &= \text{Weight} \cdot \mathbf{H}^{(1)} \cdot W_V \end{aligned}$$

where the attention weights are defined as

$$\text{Weight} = \text{softmax} \left(\frac{(q_{cls} \cdot W_Q)(\mathbf{H}^{(1)} \cdot W_K)^T}{\sqrt{d}} \right)$$

where $W_Q, W_K, W_V \in \mathbb{R}^{d \times d}$ are trainable projection matrices. Here, $\text{Weight} \in \mathbb{R}^{1 \times l}$ represents the attention weights between the [CLS] token and each token in the item sequence. This mechanism enables the global representation to selectively attend to relevant segments of the source, context, and clue components, producing a contextualized representation that informs the final prediction.

Mean token pooling Same as the depth-wise mean pooling, it applies a deterministic token-wise mean pooling operation that aggregates the sequence into a unified representation. It computes the element-wise average of the hidden states across all existing tokens in the sequence. A binary attention mask $m \in \{0, 1\}^l$ is applied to filter out padding tokens, where $m_j = 1$ for valid tokens and 0 for padded tokens. The mean-pooled sequence representation $\mathbf{h}_{mean} \in \mathbb{R}^d$ is given as:

$$\mathbf{h}_{mean} = \frac{1}{\sum_{j=1}^l m_j} \sum_{j=1}^l m_j \cdot h_j$$

3.2 Multi-task Cascade Learning

To capture the interdependency between syntax and lexical complexity, the system employs a multi-task learning (MTL) strategy utilizing hard parameter sharing. Instead of concatenating the one-hot POS labels with continuous deep representation, which introduces numerical incompatibility, our model is jointly supervised by the primary difficulty prediction task and the auxiliary POS tagging task. In this way, the auxiliary task training loss introduces a strong inductive bias for regularizing the training of shared hidden layers (Liu et al., 2019).

Furthermore, rather than deploying two isolated task heads on top of the shared hidden layers, our system utilizes a cascade architecture for hierarchical feature injection (Sanh et al., 2018; Aziz et al.). The model first computes a C -dimensional real-valued POS logit vector $\hat{y}_{pos}$ from the auxiliary classification head, where C represents the number of POS classes. To prevent the primary continuous regression loss from introducing noisy interference into the auxiliary syntactic head, these logits are detached from the primary gradient computation. The detached syntactic signals are then concatenated with the augmented deep representation for

the regressor, p_{reg} , to form the combined vector for the final difficulty prediction:

$$X_{combined} = [p_{reg} \oplus \text{detach}(\hat{y}_{pos})]$$

Note that while both tasks share the same backbone hidden layers, their additional augmentation modules are optimized independently. Consequently, the augmented deep representation utilized for POS classification, p_{pos} , remains distinct from the regression representation p_{reg} . This structural separation allows each head to specialize in its respective objective while ensuring the learned syntactic signals act as a fixed structural hint to guide the primary difficulty estimation.

Dynamic loss For the primary difficulty regression task, we calculate the mean squared error loss L_{reg} , while applying cross-entropy loss L_{pos} for the auxiliary POS tagging task. Because these two tasks operate on different scales, a naive summation would cause one objective to dominate the gradient updates. To jointly optimize the network without the need of extensive manual search for task weights, we employ dynamic precision weighting based on homoscedastic task uncertainty (Kendall et al., 2018). The total loss adaptively scales each task’s contribution:

$$\mathcal{L}_{total} = \frac{1}{2\sigma_0^2}\mathcal{L}_{reg} + \log \sigma_0 + \frac{1}{\sigma_1^2}\mathcal{L}_{pos} + \log \sigma_1$$

where σ_0 and σ_1 represent the task-dependent observation noise. In practice, we utilize the log-variance of each task to avoid zero division error.

4 Experiments

4.1 Dataset

The dataset for the shared task is taken from the "Extended KVL Dataset for NLP" released by Skidmore et al. (2025) and is organized into two independent tracks with specific data constraints.

Closed Task Contains 6,091 training, 677 development, and 748 test items for each of three source languages (German, Spanish, and Mandarin). Each item is associated with the POS label of the target English word and its GLMM score. Systems in this track are restricted to using L1-specific training data and publicly available pre-trained transformer models and their embeddings.

Open Task Permits the integration of all available data, allowing the combination of the three L1 subsets into a unified training set of 18,273 items.

Systems may train on this joint training set and evaluate on the L1-specific development set and test set. No algorithmic or architectural restrictions are imposed. Because the proposed system relies exclusively on the publicly available mmBERT encoder for representation generation, it complies with the constraints of both tracks.

4.2 Setup

We fine-tuned all models utilizing the mmBERT-base architecture, which contains roughly 307M parameters. Inputs are processed using the Gemma 2 tokenizer, which is a native implementation employed by mmBERT to support multilingual pre-training (Marone et al., 2025). The augmented classification token from the sequence representation serves as the input for both the classification and regression tasks. Specifically, this 768-dimensional hidden representation is passed into a two-layer MLP prediction head consisting of an initial linear layer, a GELU activation, layer normalization, dropout, and a final linear layer to generate the output logits. Our baseline employs the ordinary single-task MLP regressor which uses only the representation of the first token of the last hidden layer on top of mmBERT and XLM-RoBERTa base.

All models were trained for 10 epochs using the AdamW optimizer with a fixed learning rate of $2e-5$, a weight decay of 0.1, and 100 warmup steps, with a batch size of 64 and a dropout rate of 0.1 throughout training. The best model checkpoint was selected and saved based on the lowest RMSE on the development set, with Pearson’s correlation coefficient (ρ) reported as a supplementary evaluation metric. The system was trained and validated on the provided training and development sets, and the top three performing configurations were subsequently selected for hyperparameter optimization before generating final test set predictions for each L1 as the submission (See Table 6 in the Appendix).

5 Results

This section presents the evaluation results of our mmBERT-based multi-task cascade models (MTL) for the shared task. We present four specific augmentation configurations: self-attention token aggregation (MTL+SelfAttn), mean token pooling (MTL+MeanToken), scalar mixing layer aggregation followed by self-attention token aggregation (MTL+ScalarMix+SelfAttn), and mean layer pooling followed by mean token pooling (MTL+MeanLayer+MeanToken). They were eval-

uated on the German (DE), Spanish (ES), and Mandarin (CN) test sets across both the closed and open tracks, and compared against the reference baselines (Section 4.2). Results are summarized in Tables 1 and 2 for the open and closed tracks, respectively. Detailed comparisons across all configurations are provided in Table 4 and Table 5 in the Appendix for both tracks.

Our top configurations ranked 13th/24 for Spanish and German and 14th/26 for Mandarin in the open track, and 16th/56 for Spanish and 13th/53 for both German and Mandarin in the closed track. As expected, performance in the open track consistently exceeded that of the closed track across all languages, reflecting the advantage of access to larger and combined training data.

Across both tracks, models built on the mmBERT encoder consistently outperformed the XLM-RoBERTa baseline, indicating that improved multilingual representations provide a strong foundation for item difficulty prediction. In particular, the base mmBERT model already yielded substantial gains, with further improvements observed when incorporating selected representation aggregation strategies. Among these aggregations, methods such as self-attention token aggregation and mean layer pooling plus mean token pooling yielded consistent improvements, with the former excelling in the open track and the latter in the

closed track. The mean token pooling produced comparable results. The only exception was the most complex mechanism (self-attention-based aggregation, scalar mixing). It led to performance degradation in almost all languages, particularly in the closed track.

The impact of multi-task learning with auxiliary POS prediction consistently improved the results across languages and tracks, and performance in the closed track was boosted more prominently than the open track. It suggests that syntactic information provided useful signals that contribute to the lexical difficulty prediction, with the degree of improvement depending on the data conditions. Lastly, performance patterns varied across languages. Mandarin generally exhibited larger gains from representation learning and aggregation strategies, whereas results for German and Spanish were more stable but showed smaller improvements.

6 Discussion

6.1 Effect of the mmBERT Encoder

Table 1 and 2 show that fine-tuning mmBERT encoder yielded substantially better performance than the standard XLM-RoBERTa encoder baseline across almost all languages and data conditions. In the open track, replacing the XLM-RoBERTa backbone with mmBERT reduced the average RMSE

from 1.133 to 1.042, and increased the average ρ from 0.791 to 0.815. The performance gain largely persisted in the restricted data condition of the closed track, where mmBERT reduced the overall average RMSE from 1.218 to 1.033 and increased average ρ from 0.764 to 0.812.

As the multilingual adaptation of the ModernBERT (Warner et al., 2025), mmBERT is pretrained on the 3T tokens and 1,833 languages with innovative training recipes. Its superior performance over XLM-RoBERTa may be attributed to a combination of modernized architectural enhancements, a more diverse and larger pretraining corpus, and highly optimized data scaling (Marone et al., 2025). Our results showed that mmBERT provides a better alternative to encoder-only models in cross-lingual vocabulary item difficulty prediction.

6.2 Multitask performance

Table 1 shows that in the open track, which provides an expanded joint training set, the multitask approach produced similar performance regarding the difficulty prediction objective. In the restricted data conditions (Table 2), the MTL showed some marginal improvements, with average RMSE decreasing from 1.033 to 1.020, and average ρ increasing from 0.812 to 0.817.

A further benefit of the MTL extension that we observed involves improved robustness in difficulty prediction. As shown in Figure 2, the MTL model demonstrated more consistent performance, particularly under the restricted data condition in the closed track. The incorporation of POS-tagging signals may help the model disambiguate target English words with variable semantic roles, thereby supporting more stable predictions of the word-level item difficulty.

Table 3: Fixed-effects regression results on Δ RMSE.

Predictor	Coef.	SE	<i>t</i>	<i>p</i>	95% CI
Intercept	0.452	0.382	1.183	0.238	[-0.300, 1.204]
$\mathbb{I}(\text{Closed-DE})$	0.001	0.004	0.204	0.838	[-0.008, 0.009]
$\mathbb{I}(\text{Closed-ES})$	-0.000	0.006	-0.009	0.993	[-0.012, 0.012]
$\mathbb{I}(\text{Open-CN})$	0.014	0.004	3.121	0.002	[0.005, 0.022]
$\mathbb{I}(\text{Open-DE})$	0.012	0.004	2.756	0.006	[0.003, 0.020]
$\mathbb{I}(\text{Open-ES})$	0.017	0.004	4.025	< 0.001	[0.009, 0.026]
POS Accuracy	-0.478	0.392	-1.219	0.223	[-1.248, 0.293]

Despite the robustness against semantic noises, accurate POS tagging did not show statistically significant correlations with difficulty prediction improvement. We operationalized the performance improvement as the RMSE difference on the test set

Figure 2: Test RMSE performance between mmBERT base model and its MTL variant across tracks and L1s

between each pair of the MTL model and the base model (i.e. Δ RMSE = $\text{RMSE}_{\text{MTL}} - \text{RMSE}_{\text{Base}}$) across tracks and L1s.

The regression plots in Figure 3 did not reveal a consistent linear relationship between POS prediction accuracy and Δ RMSE across tracks and L1 conditions. Although slight negative trends appeared for some language-track combinations (e.g., CN and DE), the overall patterns were weak and inconsistent, with substantial variability around the fitted regression lines. To further isolate the effect of POS accuracy on RMSE differences, we conducted a fixed-effects linear regression controlling for track and L1 conditions. The results (Table 3) likewise did not support a significant association between POS prediction accuracy and RMSE improvement. One possible explanation is that word-level POS tagging provides only limited linguistic information, making it insufficient to substantially enhance the difficulty prediction objective.

In general, MTL learns a more robust and generalized representation on related tasks by ignoring data-dependent noise and reduces overfitting risks (Ruder, 2017; Goldberg, 2022), which is especially beneficial with restricted data in the closed track. However, the benefit to the primary difficulty prediction objective appears to be limited as the MTL model did not yield significantly better RMSE results than the baseline model. This may be because the auxiliary POS tagging task is relatively simple and may not provide sufficiently rich linguistic information to substantially improve word-level difficulty prediction. It suggested that POS tagging is a related task that can be jointly trained

Figure 3: The regression plot between RMSE improvement and POS Acc across tracks and L1s. The x-axis refers to the POS prediction accuracy by MTL model, while the y-axis refers to the difference between RMSEs scored by the MTL model and the base model on the same L1 test set. Color stands for which track has been used as the training set.

with lexical difficulty prediction without introducing conflicting signals. This aligns with the finding that different word senses of a polysemy contribute differently to the difficulty of the vocabulary item (Skidmore et al., 2025).

6.3 Mixed Outcomes by Representation Augmentation

Systematic comparison of configurations revealed mixed outcomes by hidden states aggregation (see Table 4 and Table 5). Prior studies demonstrated that allowing the classification token to attend to the full sequence via an additional multi-head attention module consistently enhances the standard BERT baseline, with strong benefits observed in low-resource scenarios (Behrendt et al., 2025). Consistently, our results indicated that token-wise self-attention aggregation alone provided a slight performance boost, while it severely conflicted with layer-wise aggregation methods. A possible explanation is that naively aggregating intermediate layers through simple deterministic operations, such as mean/max pooling, failed to adapt to task-specific requirements and introduced severe optimization instability during training (Ciernik et al., 2026).

To mitigate this instability, scalar mixing computes a weighted average of hidden layers by dynamically determining the importance of each layer during the training. In theory, it would allow optimal exploitation of deeper information and surpass naive deterministic pooling methods (Gombert et al., 2024). However, our results showed a con-

tradicting image, with the scalar mixing being the worst approach. An investigation into the module showed that all trained scalar weights s collapsed into a delta distribution with a single layer sticking out and all else muted. Also, the scaling factor γ either exploded or vanished. This indicated that the training with scalar mixing virtually failed to learn meaningful weights as expected.

Moreover, the simple mean token pooling approach only trailed the self-attention approach by a small margin. Most importantly, our result indicated that it worked smoothly with other deterministic layer aggregation approaches, especially with limited data. This suggested mean token pooling as a robust and efficient alternative.

7 Conclusions

In this paper, we examined the precalibration of vocabulary item difficulty in multilingual settings using transformer-based representations and multi-task learning. Across both open and closed tracks, our findings showed that mmBERT provided a stronger foundation than the shared-task XLM-RoBERTa baseline. Moreover, the auxiliary POS-based multi-task learning further improved the performance. At the same time, the benefits of additional architectural complexity, including layer-wise and token-wise aggregation, were not uniform across language and data conditions.

8 Limitations

As discussed in section 6.3, while some representation aggregation strategies offered promising results, their improvements over the baseline were context-dependent and not uniform. This indicates that, within the multi-task learning regime for this specific task, there may not be a universally superior representation aggregation strategy. Consequently, any future research seeking to utilize internal encoder states may benefit from extensive and systematic model selection to identify the optimal configuration. Also, the reason behind our failed training with scalar mixing needs to be further researched. Given that the performance gains are marginal and unstable, the standard last-layer [CLS] approach still remained a highly competitive and computationally efficient default.

Second, our study largely relied on a multilingual encoder that provides a language-agnostic foundation for cross-lingual transfer. However, we did not evaluate language-specific monolingual encoders. Previous studies indicated that specialized monolingual models may capture distinct, language-dependent morphological and syntactic patterns more effectively (Ortiz-Zambrano et al., 2025; Skidmore et al., 2025). The absence of experiments using language-specific encoders, such as Chinese ModernBERT (Zhao et al., 2025) or ModernGBERT (Wunderle et al., 2025), limits our understanding of whether specialized pre-training could yield superior lexical difficulty estimations. This limitation is particularly relevant for the closed track, where models were trained and evaluated within each language space.

Abstract

This paper describes our submission to the BEA 2026 Shared Task on L1-Aware English Vocabulary Difficulty Prediction. We build per-L1 CatBoost regressors over 1,161 candidate linguistic, psycholinguistic, dictionary, and LLM-derived features drawn from 129 feature sets; out-of-fold predictions from fine-tuned encoder and decoder-LLM regression heads enter the model as additional features. Features are selected via Recursive Feature Elimination with nested cross-validation, producing compact per-L1 models of 29–150 features per run. For the closed track we introduce a per-feature-column compliance audit that classifies 57 of 129 feature sets as track-eligible under the organiser rulings, an audit that forced a rebuild of the selection and ensembling pipelines in the final week. We further show that decoder-LLM LoRA regression heads — LLaMA-3.1-8B being the single strongest model in our pool — provide the largest marginal gains in the open track, and that a simpler per-L1 CatBoost on RFE-selected features matches or exceeds Ridge-stacking ensembles over the same base models. Our systems ranked 1st in the closed track and 2nd in the open track on all three L1s (Spanish, German, Mandarin), reducing baseline RMSE by 29.9% in the closed track and 35.9% in the open track on average.

1 Introduction

Vocabulary knowledge is a cornerstone of L2 language proficiency and a primary determinant of reading comprehension, listening, and writing ability. Reliable per-item difficulty calibration is the bottleneck for adaptive language assessment, CEFR-aligned curriculum design, learner-knowledge prediction, and personalised learning. Traditional calibration requires costly pretesting against representative learner populations; data-driven NLP methods offer a scalable alternative, provided they can be shown to recover the psychometric difficulty that learners actually experience.

The BEA 2026 Shared Task introduces two features absent from earlier shared tasks on word difficulty. First, *L1-awareness*: items are presented with a localised prompt in the learner’s first language, and the task is to predict difficulty for Spanish, German, and Mandarin Chinese L1 speakers separately. Second, labels are *psychometrically calibrated*: the target is a GLMM-based difficulty estimate drawn from the British Council’s Knowledge-based Vocabulary Lists (Schmitt et al., 2024), fit over roughly 3.3M test responses from more than 100,000 learners. Unlike most public vocabulary benchmarks, the task measures *productive* knowledge with an exact-spelling requirement: the learner must produce the target from a partial-spelling clue (first letter + word length), an L1 translation, and a localised context — a setup that materially shifts what difficulty is being measured. Prior work addressed related problems — CWI (Paetzold and Specia, 2016; Yimam et al., 2018), LCP (Shardlow et al., 2021), and MLSP (Shardlow et al., 2024) — without learner-specific context or psychometric targets. The task’s closed/open split — closed (no LLMs, no extra data) vs. open (unrestricted) — adapts the Restricted/Unrestricted distinction used in the BEA 2019 grammatical-error-correction shared task (Bryant et al., 2019), and isolates the contribution of resource access.

We describe a system that places first in the closed track and second in the open track across all three L1s. The contributions are:

- **A closed-track system that places 1st on all three L1s**, reducing baseline RMSE by 28.2–31.9% (average 29.9%).
- **An open-track system placing 2nd on all three L1s**, with an average baseline reduction of 35.9%.
- **A per-feature-column closed-track compliance framework** applied to 129 feature sets,

classifying 57 as eligible and 72 as ineligible under the organiser rulings — a 56% rejection rate that required rebuilding selection and ensembling pipelines in the final week of the competition.

- **Empirical evidence that end-to-end holistic predictors are the dominant signal.** A leave-one-family-out ablation shows removing the holistic-models family costs +0.102 RMSE (an order of magnitude more than any other), driven by decoder-LLM LoRA regression heads — LLaMA-3.1-8B alone attains 0.831 at 0.13% trainable parameters. The holistic family is considerably larger than comparator families (68 vs 5–14 sets), which amplifies the ablation effect; per-set performance in Table 7 confirms the gap is not due to size alone. The second-largest lever is the *virtual-learner* family (+0.006 RMSE): weak LLMs used as proxy learners rather than difficulty judges.
- **A candid post-mortem of a data-leakage incident** in which four feature sets leaked the target variable into LLM prompts or cross-fold predictions; the leaked ensemble scored RMSE 0.609 before invalidation, and was caught by structural verification of every feature artefact.
- **An autonomous research framework** (§4) that evaluated more than 1,000 candidate features across 270+ tracked experiments, with specified artefacts and an immutable audit trail.

Section 2 reviews prior shared tasks; Section 3 describes the data; Section 4 describes the system; Section 5 details the experiments; Section 6 presents results; and Section 7 analyses per-L1 errors, what worked, and what did not.

2 Related Work

Shared tasks on word difficulty. Complex Word Identification framed difficulty as binary classification for L2 readers (Paetzold and Specia, 2016; Yimam et al., 2018). Lexical Complexity Prediction moved to continuous regression with multiple annotators per item (Shardlow et al., 2021), and the Multilingual Lexical Simplification Pipeline extended the setup to multiple languages and the downstream simplification task (Shardlow et al., 2024). None of these tasks conditions prediction on the learner’s L1 or uses psychometrically calibrated targets; the BEA 2026 task (Felice and Skidmore, 2026; Schmitt et al., 2024) is, to our knowledge, the first shared task to combine both.

Track structure. Our closed/open split follows the Restricted vs. Unrestricted distinction introduced by the BEA 2019 grammatical-error-correction shared task (Bryant et al., 2019), which also defined a third Low-Resource track. BEA 2019 enforced track compliance through submitted system descriptions; our closed-track compliance framework (§4.4) is a finer-grained realisation that audits eligibility at the level of individual feature columns.

Methodology precedents. Gombert et al. (2024) won the BEA 2024 Item Difficulty shared task with a transformer-encoder regression that uses scalar mixing across encoder layers, multi-task training on item difficulty and response time, and rational-network regression heads. Several other BEA 2024 systems stacked multiple encoder regressors via linear meta-learners. We combine elements of both patterns while diverging in three respects: (i) the pool is enlarged to include decoder-LLM LoRA regression heads alongside encoder regressions; (ii) per-L1 gradient boosting replaces the linear meta-learner as the fusion layer; and (iii) features are selected by Recursive Feature Elimination with nested cross-validation rather than all-in stacking, which reduces dimensionality before the final fit and limits overfitting on the relatively small (~16k-row) out-of-fold validation set.

External resources. Individual feature families rely on established psycholinguistic norms and L2-oriented vocabulary lists, including concreteness and prevalence norms (Brysbaert et al., 2014, 2019), the SCOPE psycholinguistic metabase (Gao et al., 2023), the CEFR-J wordlist (Tono, 2019), CEFR-annotated WordNet (Kikuchi et al., 2025), Chinese–English L2 AoA norms (Wang and Chen, 2020), the MorphoLex morphological database (Sánchez-Gutiérrez et al., 2018), the LADEC database of English compounds (Gagné et al., 2019), the language-specific SUBTLEX subtitle frequency corpora for Chinese, German, and Spanish (Cai and Brysbaert, 2010; Brysbaert et al., 2011; Cuetos et al., 2011), and the OpenSubtitles parallel corpus (Lison et al., 2018). Our open-track submission additionally uses a proprietary sense-level English lexical resource with per-sense difficulty estimates. We cite all of these in-line in §4.2.

Split	# items / L1	# L1s	# rows
Train	6,091	3	18,273
Dev	677	3	2,031
Test	748	3	2,244
Total	7,516	3	22,548

Table 1: Dataset statistics. Item ids are shared across L1s, so the same English word appears in all three L1 views. Train, dev, and test splits are disjoint by item id (ranges 1–6091, 6092–6768, and 6769–7516 respectively).

3 Task and Data

Task. Given an English target word presented to a learner whose L1 is Spanish (ES), German (DE), or Mandarin Chinese (CN), together with a localised prompt (a partial-spelling clue, a translation, and a context sentence in the L1), predict the word’s psychometric difficulty as a continuous GLMM score (lower score = more difficult). A canonical Spanish example presents the cue “*h_____*” alongside a Spanish context sentence and the translation *casa*, with the target English word being *house*. Responses are graded correct only when the spelling matches exactly, so orthographically irregular forms carry a spelling-error component in the GLMM difficulty alongside the lexical-knowledge component.

Data. The task distributes item-level data for 7,516 English target words, each presented in three L1 variants. Table 1 summarises the splits. The labels are derived from a GLMM fit over approximately 3.3M real learner responses from more than 100,000 British Council KVL test-takers (Schmitt et al., 2024). Test labels were withheld during the shared-task evaluation period and have since been released publicly on the shared-task GitHub repository.¹

Metrics. The shared task ranks systems by Root Mean Squared Error (RMSE, lower is better) averaged across L1s, with Pearson correlation reported as a secondary metric. We use RMSE as the primary decision metric throughout: all feature selection, ensemble pruning, and submission choices are made on K-fold RMSE.

Tracks. The *closed* track forbids large language models and additional training data beyond the shared task release, while allowing publicly avail-

able off-the-shelf pretrained transformers and linguistic databases. The *open* track places no restrictions. A team may submit up to three runs per track per L1.

4 System

4.1 Overview

Our submission is a per-L1 gradient-boosted regressor consuming a broad pool of heterogeneous features, including the out-of-fold (OOF) predictions of fine-tuned encoder and decoder-LLM regression heads. Figure 1 gives the end-to-end picture. The feature pool comprises 129 feature sets totalling 1,161 numeric columns, organised by seven domain families plus a small derived bucket (§4.2). Per L1, features are reduced with Recursive Feature Elimination under nested cross-validation, yielding compact sets of 29–150 features that train a single CatBoost regressor (Prokhorenkova et al., 2018) on the union of train and dev.

Autonomous research framework. Our submission was developed inside the Glite Autonomous Research Framework.² The framework enforces task isolation (one directory, one branch, one pull request per experiment), artefact specifications checked by verifiers before commit, and an immutable log of every experiment step. This enabled us to evaluate over 1,000 candidate features across 270+ tracked experiments, with automatic metric aggregation and append-only audit trails. The data-leakage incident described in §7.3 was detected precisely because every feature CSV is spec-verified and every fold-level score is traceable to its code revision.

4.2 Features

We organise our 129 feature sets around *what the feature measures about item difficulty* rather than how it was produced. Seven domain families — plus a small derived bucket — follow. Appendix B has per-family counts and the top-ranked sets per family (Table 7).

Target-word lexical properties (14 sets). Surface form, frequency, morphology, and semantic-lexical properties of the English target word itself: word length, corpus log-frequency, morphological decomposition (Sánchez-Gutiérrez et al., 2018), compound transparency (Gagné et al., 2019), neighbourhood density, concreteness (Brysbaert et al.,

¹<https://github.com/britishcouncil/bea2026st>

²<https://github.com/GliteTech/glite-arf>

129 feature sets → 1,161 numeric feature columns, grouped by seven domain families

Figure 1: System architecture. Seven feature families feed into per-L1 RFE with nested CV, which yields compact per-L1 feature sets consumed by CatBoost. Transformer and decoder-LLM signals enter as out-of-fold predictions rather than via a separate stacking layer. Three submission runs differ in which feature sets and models are permitted.

2014), prevalence (Brysbaert et al., 2019), the SCOPE psycholinguistic metabase (Gao et al., 2023), and lemma-level features from a proprietary sense-level English lexical resource. These are the features a lexicographer would call out first when asked why a word is hard.

Sense-level disambiguation (7 sets). For polysemous words the tested sense is often not the dominant sense, so features that model *which* sense is tested matter. Each KVL item is first mapped to a sense in a proprietary English dictionary via an LLM word-sense-disambiguation prompt given the target, clue sentence, and L1 translation. The family then covers sense-level dictionary features (212 columns; solo Pearson 0.704), morphological headword decomposition, soft sense distributions, sense entropy, and a polysemy-contrast LLM feature.

Cue / prompt difficulty (6 sets). Features that analyse the *clue* (partial spelling + L1 translation

+ L1 context), not the target word itself: clue-ambiguity (dictionary words that match the same first-letter + word-length pattern), a retrieval-game information-theoretic model of candidate competition, semantic-competition counts of viable alternatives, LLM-rated prompt quality, prompt-framing variants, and a context-only guess feature. These capture how tightly the cue constrains the answer.

L1 → L2 transfer (14 sets). Cross-linguistic features about whether the learner’s L1 helps or hurts: cognate distance, CogNet-detected cognates, a Spanish expert cognate list, anglicism detection, false-friend flags, LLM language-similarity ratings, phonological transfer, cross-lingual orthographic neighbourhood, Chinese script-complexity, L1-side frequency (corpus and subtitle), etymology, translation ambiguity, and LLM back-translation quality.

L2 proficiency positioning (8 sets). Empirical evidence of where the target word sits on

the learner- developmental scale: CEFR levels from EFLLex and Words-CEFR (Tono, 2019), the CEFR-J / JACET Asian-learner wordlists, sense-level CEFR from CEFR-annotated WordNet (Kikuchi et al., 2025), Brysbaert’s L2 yes/no word-knowledge norms, L2 age of acquisition (Wang and Chen, 2020), empirical learner production rates, and Cambridge cloze-exam presence. Every set in this family is closed-track eligible.

Virtual-learner simulation (7 sets). A distinctive family in our system: features produced by letting a weaker or ability-graded model *attempt to answer* the item and recording whether it succeeds, its confidence, or its surprisal. The LLM here acts as a proxy learner, not as a difficulty judge. This family includes an ability ladder over four OpenAI models of graded size, guesses from four local small models, LLM clue- and description-based guessing, LLM answer entropy, token-surprisal features, and masked-LM pseudo-likelihood guessing. All are open-track-only except the masked-LM variant (closed-eligible).

Holistic difficulty models (68 sets). End-to-end predictors that read the full item and emit a scalar difficulty estimate, entering the pipeline as out-of-fold features. Covers fine-tuned encoders — XLM-R (Conneau et al., 2020), RemBERT (Chung et al., 2021), ELECTRA-base (Clark et al., 2020), and mBERT per L1 with TAPT (Gururangan et al., 2020) and R-Drop (Liang et al., 2021) under multiple seeds; scaled encoders (XLM-R-XL 3.5B, XLM-R-XXL 10.7B) trained with LoRA (Hu et al., 2022); decoder-LLM LoRA regression heads for LLaMA-3.1-8B (Dubey et al., 2024), Qwen-2.5-7B (Yang et al., 2024), and Mistral-7B (Jiang et al., 2023); LLM rubric variants; and LLM embeddings. LoRA uses rank 16, $\alpha = 16$, targeting $q_proj/k_proj/v_proj$ (0.13% trainable) with a scalar regression head on the last-token hidden state. LLaMA-3.1-8B achieves the single strongest K-fold RMSE (0.831), beating the 10.7B XLM-R-XXL encoder (0.966) despite fewer parameters; Mistral-7B scores 0.951 on average but suffers a fold-4 collapse (§7.3).

Derived / second-order (5 sets). Features whose inputs are other features’ outputs: pairwise interactions, model-disagreement metrics, per-item CatBoost feature-group ablation sensitivities, and a Ridge distillation from the SemEval-2021 LCP dataset.

4.3 Feature selection and final model

Selection. For each L1 and each submission run, we run Recursive Feature Elimination with nested cross-validation (5-fold outer, 4-fold inner). The outer folds partition item ids; inner folds select the smallest feature set whose K-fold RMSE is within 0.001 of the optimum. The resulting per-L1 feature counts are summarised in Appendix A.

Final model. For each (track, run, L1) combination we train a single CatBoost regressor with `iterations=1000`, `learning_rate=0.05`, `depth=6`, `l2_leaf_reg=3.0`, and `seed=42` on the union of the train and dev splits. No early stopping is used. The CatBoost feature matrix contains the RFE-selected subset of linguistic, psycholinguistic, and dictionary features, plus the OOF predictions of the fine-tuned transformer and decoder-LLM regression heads treated as ordinary numeric features.

Architecture alternatives considered. A 10-model Ridge meta-learner over three global CatBoost variants plus seven transformer OOF columns (per-L1 $\alpha = 500, 500, 100$) scored K-fold RMSE 0.745 versus 0.740 for the CatBoost pipeline. Its coefficients corroborated two observations used later in §7.3: gradient-boosted features dominate ($\approx 88\%$ of total weight), and Mistral-7B receives near-zero weight. We submitted the simpler CatBoost pipeline; a greedy pruning over the 63-model Ridge pool (Figure 2) further confirms that six models match the full ensemble.

Three submission runs per track. The three runs differ in which feature sets and models are permitted at RFE time. Run 1 is the full RFE-optimal pipeline. Run 2 is a resource-robust variant: for the open track it excludes the proprietary dictionary; for the closed track it excludes the large XLM-R-XL encoder. Run 3 is the most conservative: transformers-only for the open track, and a larger feature-rich RFE set for the closed track. Appendix A lists per-run feature counts and K-fold RMSE.

4.4 Closed-track compliance engineering

The closed track prohibits generative LLMs, paid APIs, additional training data, and cross-L1 training, while allowing publicly available off-the-shelf pretrained transformer encoders, standard NLP tools, and public linguistic databases (WordNet, CEFR wordlists, SUBTLEX, EFLLex, MorphoLex,

LADEC, SCOPE, etc.). Feature selection and final CatBoost training were performed separately for each L1, using only that L1’s provided train and dev rows. Because features are generated from heterogeneous code paths and our feature pool is large, we developed a per-column compliance schema that records, for each feature column, which external models, APIs, datasets, and computation paths were used to produce it. Every feature set is audited against five organiser rulings issued in March 2026: (1) difficulty-in-prompt leakage, (2) LLMs predicting the target word, (3) paid embedding APIs, (4) LLMs estimating learner production probability, and (5) LLMs used purely for rubric scoring without the target. Seventeen features were reclassified after these rulings, and two further reclassifications came from our internal audit (inadvertent training-data contamination and external-data usage). Of 129 feature sets (1,161 columns), 57 (249 columns) remained closed-track-eligible after the audit — a 56% rejection rate that forced a full rebuild of the RFE and submission pipelines in the final week. A 469-line closed-track LLM-usage disclosure submitted with our system enumerates all 14 pretrained models used in the closed-track submission; all are encoder-only or encoder-decoder, with no generative LLMs and no paid APIs. We view this per-column audit as a generalisable methodological contribution for any shared task with resource restrictions.

5 Experiments

Folds. We use a single $K=5$ fold assignment over item ids, shared across L1s, so that any English word appears in the same fold in all three L1 views. This prevents cross-L1 leakage via joint training. The fold assignments are persisted deterministically and reused across every experiment in the project.

Hyperparameters. CatBoost uses `iterations=1000`, `lr=0.05`, `depth=6`, `l2_leaf_reg=3.0`, `seed=42`. Encoder regressors (XLM-R, RemBERT, ELECTRA, mBERT) use batch size 16 (or 4 for XL/XXL), max length 128, AdamW with linear warmup and decay, 3 epochs for per-L1 variants with TAPT+R-Drop ($\lambda = 1.0$), and seed sweep over $\{123, 456, 789\}$. LoRA adapters target `q_proj/k_proj/v_proj` with rank 16, $\alpha = 16$, dropout 0.1; decoder-LLM regression heads read the last-token hidden state through an MLP of width 2048 with GELU. Full

hyperparameters are listed in Appendix C.

Hardware and compute. CatBoost models and small-encoder fine-tuning ran locally on Mac Silicon (48 GB unified memory); scaled encoders (XLM-R-XL 3.5B, XLM-R-XXL 10.7B) and the 7–8B decoder-LLM regression heads (LLaMA-3.1-8B, Qwen-2.5-7B, Mistral-7B) were trained on rented A100-class GPUs. Total compute was approximately 100 wall-hours and roughly \$500 in commercial LLM API spend.

6 Results

Main result. Our system placed 1st in the closed track on all three L1s and 2nd in the open track on all three L1s (Table 2). The average RMSE reduction over the official baseline is 29.9% closed (28.2% ES, 29.6% DE, 31.9% CN) and 35.9% open (37.1% ES, 34.5% DE, 36.2% CN).

Ablation by domain family (Table 3). Table 3 reports two complementary analyses. *Leave-one-out* (left block) removes one family at a time and re-runs RFE; *family alone* (right block) keeps only that family and runs RFE over it. Together these measure *necessity* and *sufficiency*. *Holistic difficulty models* are both: removing the family costs +0.102 RMSE (an order of magnitude more than any other), and alone the family attains K-fold RMSE 0.772 / Pearson 0.900 with just 29 features — within 0.03 of the full system. *Virtual-learner simulation* is the clearest second-tier contributor: +0.006 RMSE to remove and Pearson 0.743 alone. The other five families show a striking asymmetry: their leave-one-out costs are small (+0.001 to +0.003), yet alone they reach Pearson 0.68–0.78 — classical-tabular signal that is largely absorbed by the holistic models when present but remains substantive when isolated. *Cue / prompt difficulty* is the strongest standalone classical family (r 0.782).

Top features per L1. The top-15 RFE features per L1 (Appendix D, Table 10) reveal a universal core: all four LLaMA-3.1-8B seeds, all four Qwen-2.5-7B seeds, the ability-ladder mean success rate, the LLM-based counterfactual cue-sensitivity score, and the learner’s L2 vocabulary-knowledge rank — all appear in the top 15 for every L1. L1-specific features surface in the mid-ranks: surprisal and interaction features for ES, an additional XLM-R-XL variant for DE, and a frequency-based cue-sensitivity variant plus a closed-eligible per-L1 XLM-R-large-TAPT model for CN.

Track	System	ES		DE		CN		Avg
		RMSE	r	RMSE	r	RMSE	r	RMSE
Closed	1. Ours	0.903	0.877	0.885	0.871	0.776	0.889	0.855
Closed	2. Best other team [†]	0.975	0.858	0.903	0.869	0.816	0.874	0.898
Closed	3. Best other team [‡]	0.976	0.857	0.963	0.844	0.820	0.879	0.920

Table 3: Open-track ablation by domain family (§4.2). Left block (*leave-one-out*) deletes the named family and re-runs RFE over all remaining features, reporting the rebuilt system’s K-fold RMSE and its gap to the full system (full system: 66 RFE-selected features, K-fold RMSE 0.740). Right block (*family alone*) keeps only the named family and runs RFE over its features, reporting the optimal feature count, K-fold RMSE, and Pearson of the family-only system. Same folds, hyperparameters, and RFE procedure throughout. Rows sorted by Δ RMSE (most damaging removal first).

K-fold $\rightarrow$ test calibration. Sixteen of 18 submitted runs scored *better* test RMSE than K-fold RMSE (mean $\Delta = -0.022$ closed, -0.012 open); test Pearson exceeded K-fold Pearson on every comparable run (Appendix B). The two runs where test was worse than K-fold have small magnitude ($+0.001$ and $+0.015$ RMSE). We therefore find no empirical evidence of substantial K-fold overfitting across our 1,000+ feature search, and this pattern is consistent with the leak audit described in §7.3, since a residual leak would inflate K-fold relative to test.

Greedy ensemble pruning. For the 10-model Ridge architecture considered in §4.3 we independently ran greedy forward selection over a larger 63-model Ridge pool (Appendix A, Figure 2). The best single model achieves 0.814 (a CatBoost RFE variant). Adding the second (LLaMA-3.1-8B) drops RMSE by 0.056. Six models suffice to match the full 63-model ensemble (0.745 vs 0.745). The

optimum is reached at 39 models (0.739). Beyond that, the next 24 additions are neutral or harmful, and the 63rd model added — *mistral_7b* — is the single worst addition, raising RMSE by 0.004.

Gap to first place in the open track. Sakura placed first on all three open-track L1s with test RMSE 0.742 / 0.723 / 0.630 (ES / DE / CN). Our second-place gaps are small on Spanish ($+0.012$) but widen on German ($+0.041$) and Mandarin ($+0.030$). We suspect Sakura’s fine-tuned-LLM pipeline captures L1-specific morphology — Germanic compounding in particular — that our classical tabular features under-represent; closing these gaps is a concrete direction for future work.

Closed-track margin is wider. Our closed-track first-place margins over the second-best team (*uogal* for ES/DE, *Sakura* for CN) are 0.072 / 0.018 / 0.040 RMSE — roughly $3\times$ our open-track gap to Sakura on ES and CN, and about $4\times$ on DE.

This asymmetry is consistent with the closed-track restrictions penalising systems whose open-track advantage depends on paid LLM APIs: once generative LLMs are removed, the per-column compliance audit (§4.4) and our 57-set eligible pool produce a feature base competitive enough to lead each L1.

7 Analysis

7.1 Per-L1 error patterns

The three L1s show systematically different residual structure. Spanish items with Latinate roots are under-predicted as easier than they are; items with Germanic roots or noun morphology shared with French cognates are the opposite. German residuals are reduced most by the length-ratio feature and by the XLM-R-XL OOF column, which carries German-sensitive morphology signal absent from the 7B decoder-LLMs. Mandarin has the lowest RMSE on all systems — the CN target distribution is narrower — and benefits least from cognate-style features, instead drawing on the character-level Chinese script-complexity feature and per-L1 RemBERT OOF. All three L1s exhibit regression-to-mean compression of roughly 20% (slope ≈ 0.80) that shrank between ensemble versions but did not vanish (quantified further in the Limitations section).

7.2 What worked

Holistic predictors are necessary and nearly sufficient. Seven of the top-10 RFE-ranked features for every L1 are decoder-LLM OOF columns. A single LLaMA-3.1-8B head (0.831 K-fold RMSE) beats XLM-R-XXL (0.966, 42% more parameters) at 0.13% trainable parameters; adding Qwen-2.5-7B drops RMSE a further 0.010. The ceiling analysis in Table 3 sharpens this: an RFE pass restricted to the 68 holistic sets converges to 29 features at K-fold RMSE 0.772 / Pearson 0.900 — within 0.03 RMSE of the full system. In greedy forward selection LLaMA is the second model added (-0.056 RMSE) and Qwen the third (-0.010).

Virtual-learner simulation is a distinct signal. Removing the *virtual-learner* family costs $+0.006$ RMSE (Table 3), larger than any classical-tabular or cue/sense family; alone the family reaches Pearson 0.743. Letting a weak LLM *attempt* the item therefore adds signal the decoder-LLM regression heads do not already absorb — a

different way of using LLMs from the dominant regression-head paradigm.

Simpler ensemble beat Ridge stacking. A single per-L1 CatBoost consuming transformer and LLM OOF predictions as plain features matched or exceeded every Ridge-stacking alternative; greedy pruning shows only 6 of 63 models suffice to saturate the Ridge ensemble.

Column-level compliance preserved signal. Operating the March 2026 compliance audit at the column level rather than the feature-set level preserved 249 columns across 57 closed-eligible sets that a set-level audit would have discarded, including the per-L1 RemBERT and XLM-R-large-TAPT OOF columns that dominate closed-track feature importance.

7.3 What did not work

Data-leakage post-mortem. Our ensemble v13 reached K-fold RMSE 0.609 — implausibly strong. Four leaking feature sets were identified: two passed the GLMM target into LLM prompts asking the model to judge annotation quality; a third used cross-L1 out-of-fold predictions with an item-id split shared across L1s; a fourth produced residual-prediction features circular with the training loss. Quarantining all four and rebuilding every downstream artefact yielded a clean v14 at 0.802. We cannot rule out undetected remaining leaks, but the K-fold $\rightarrow$ test calibration (§6, Appendix B) is consistent with the audit: test RMSE beats K-fold on 16 of 18 runs, whereas a residual leak would invert that pattern.

Mistral-7B is actively harmful in the ensemble. Of three decoder LLMs trained with the same LoRA recipe, LLaMA (0.831) and Qwen (0.840) were useful, but Mistral-7B (0.951) was not. Its average hides a fold-4 collapse to 1.36 (folds 0–3: 0.83–0.89), suggesting an initialisation pathology rather than a data issue. In greedy forward selection over the 63-model Ridge pool Mistral is the final addition and adds $+0.004$ RMSE — the single largest harmful contribution — and a parallel 10-model Ridge independently assigns it near-zero weight. The submitted system excludes Mistral.

Seven recurring failure patterns. Across 37 negative experiments we observed seven recurring patterns: (i) transformer architectural surgery (scalar-mix, multi-task, CharCNN) made no difference over a tuned XLM-R-base; (ii) adversarial

training did not help at 20k rows; (iii) tabular features saturated at ~ 20 sets; (iv) derived features (SHAP, counterfactual sensitivity, residual regressors) tended to be circular with the target; (v) only 3 of 13 psycholinguistic databases added marginal signal; (vi) HPO and bagging moved Pearson by ≤ 0.001 per 100 trials; (vii) Pinyin/script normalisation destroyed information XLM-R’s tokeniser handles natively.

8 Conclusion

Our system placed 1st closed / 2nd open on all three BEA 2026 L1s. The architecture is a per-L1 CatBoost on RFE-selected features plus OOF predictions from fine-tuned transformer and decoder-LLM regression heads. Three findings stand out: decoder-LLM LoRA heads dominate open-track importance (LLaMA-3.1-8B strongest); column-level compliance preserved 249 closed-eligible columns a set-level audit would have rejected; and six models match a 63-model Ridge ensemble, with Mistral-7B actively degrading it. Future work: distil the decoder-LLM signal into closed-track-legal form, and extend to more L1s.

Limitations

Our open-track system relies on a proprietary sense-level English lexical resource with difficulty estimates; reproducing the exact open-track numbers requires licensing of this resource. The closed-track system uses only public resources and can be reimplemented from the feature descriptions and hyperparameters given in §4 and Appendix C. We evaluated only three L1s — Spanish, German, and Mandarin Chinese — all drawn from the British Council KVL test-taker population; generalisation to typologically distant L1s such as Arabic or Japanese, and to learner populations outside paid-test-taker demographics, is untested. Our feature search explored more than 1,000 candidate features using autonomous agents under human supervision; while every artefact is spec-verified and every cross-validation fold is deterministic, the scale of the search creates an *a priori* risk of overfitting to the K-fold protocol. In practice this risk did not materialise: 16 of 18 submitted runs scored better on the held-out test set than on K-fold (mean Δ RMSE = -0.017), and test Pearson exceeded K-fold Pearson on every comparable run (Appendix B) — indicating that nested cross-validation plus dev-set diagnostics were sufficient

for calibration at this search scale. Our best ensembles exhibit roughly 20% regression-to-mean compression (slope ≈ 0.80): the hardest items are systematically under-predicted by -0.55 GLMM units and the easiest over-predicted by $+0.43$; this pattern shrank between ensemble versions but did not disappear. Several of our strongest open-track features rely on commercial LLM APIs (approximately \$500 total across the project) and on GPU-hosted decoder-LLM regression heads requiring 55–83 GB of VRAM, available only via cloud GPU rental; despite our best submission reducing baseline RMSE by 35.9% in the open track and 29.9% in the closed track, per-item residuals of 0.6–0.9 RMSE remain, indicating the task is far from solved.

Acknowledgments

We thank the BEA 2026 Shared Task organisers — Lucy Skidmore, Mariano Felice, and Karen Dunn — for designing the task and releasing the KVL-based dataset, and the British Council for making the underlying psychometric data publicly available under a Creative Commons licence. We also thank our colleagues at Glite for supporting the development of the autonomous research framework used to coordinate the experiments reported here, and the anonymous reviewer whose comments on the submission version of this paper improved the exposition of §3 and Figure 1.

A Submitted runs

Tables 4–5 give the per-run feature composition and per-L1 K-fold RMSE for every submitted run.

Figure 2: Greedy forward selection over a 63-model Ridge pool. Six models already match the full ensemble; the optimum is reached at 39; the last model added (Mistral-7B) is the single most harmful.

B Feature catalogue

Due to space constraints, we do not list the full 129-set catalogue here. Table 6 summarises per-family statistics, and Table 7 drills into the top feature sets in each family.

Table 7 drills into the top feature sets in each family, showing the single-set K-fold Pearson correlation and RMSE against the GLMM target. Decoder-LLM regression heads dominate, and the top closed-track-eligible signals are per-L1 encoder OOFs (RemBERT and XLM-R-large TAPT); classical linguistic and psycholinguistic features saturate around Pearson 0.55–0.59 individually, well below the transformer band.

K-fold vs test generalisation. Table 8 gives the full per-run comparison between our K-fold CV metrics (on the 5-fold item-id split of train+dev) and the official test-set metrics released by the organisers. All 18 submitted runs are listed. Sixteen of 18 runs have negative Δ RMSE (the two exceptions, open-track ES Run 3 and DE Run 1, are small in magnitude); all comparable Pearson values improve on test. K-fold Pearson is missing for Runs 2–3 where documentation recorded only RMSE.

C Hyperparameters

D Per-L1 RFE importance

Table 10 gives the top-15 RFE-ranked features per L1 for the open-track submitted system. Our

RFE pipeline records the full elimination trajectory (elimination order, per-round RMSE, optimal cut) per L1 and per track for each submitted run.

E Representative LLM prompts

We illustrate two representative prompt templates covering the two main families of LLM-derived features.

Rubric scoring (holistic LLM rater).

You are an expert L2 English teacher. Rate how difficult the target word is for an adult learner whose first language is {{L1}}, on a 0–10 scale. 0 = a near-beginner will know it; 10 = only an advanced learner will.

Target word: {{word}}
Part of speech: {{pos}}
Context sentence (English): {{clue}}
L1 translation(s): {{l1_word}}

Output only the integer score.

Ability-ladder (open track only). Four OpenAI models of graded ability are each asked to attempt the item; the feature records the fraction that recovered the target. The target word is *not* supplied; only the clue, L1 translation, and context are. Because the feature invokes generative LLMs, it is ineligible for the closed track regardless of whether the model ever sees the label.

F Compliance audit

Table 11 lists the categories of the 17 features reclassified as ineligible after the March 2026 organiser rulings. Per-column compliance metadata was maintained throughout for every feature set, including a 469-line closed-track LLM-usage disclosure submitted with our system.

G LLM API cost breakdown

Table 12 lists the ten most expensive LLM-API-based feature experiments and their positive/negative status. Total LLM spend across the project was approximately \$498. Local MLX inference (llama1b, gemma2b, phi3b, qwen1b for the local-LLM guessing feature) and GPU training were separate and not included in this table.

Run	Strategy	# features			K-fold RMSE			Avg
		ES	DE	CN	ES	DE	CN	
1	Compact (RFE-optimal)	58	49	48	0.775	0.768	0.676	0.740
2	No proprietary dict.	66	86	47	0.781	0.770	0.683	0.745
3	Transformers only	8	9	37	0.822	0.796	0.703	0.774

Table 4: Open-track runs.

Run	Strategy	# features			K-fold RMSE			Avg
		ES	DE	CN	ES	DE	CN	
1	Compact (RFE-optimal)	29	49	30	0.925	0.916	0.805	0.882

L1 $\rightarrow$ L2 transfer	14	57	9	0.442	0.307	1.261	0.696
Proficiency positioning	8	36	8	0.586	0.507	1.286	0.684
Virtual-learner simulation	7	108	1	0.576	0.458	1.194	0.743
Holistic difficulty models	68	432	24	0.884	0.752	0.772	0.900
Derived / second-order	5	81	0	0.835	0.740	—	—
Total	129	1,161	57	0.884		0.740	—

Table 6: Per-domain-family totals under the seven-family taxonomy (plus a small Derived/second-order bucket for features that operate over other families’ outputs). *Solo r* columns report the best and mean single-set K-fold Pearson within the family, taken from each set’s `feature_info.json`; *Family alone* reports an RFE pass over the family-only feature pool (Table 3 right block). The *Total* row’s *Family alone* RMSE (0.740) is the full-system K-fold result over all seven families, for reference.

Ensemble of LLM rubric difficulty ratings	22	0.786	1.096

Table 7: Top feature sets per domain family ranked by single-set K-fold Pearson correlation against the GLMM difficulty target. Seed variants collapsed to the base row. Families describe *what the feature measures about difficulty*: surface properties of the target word, sense disambiguation, cue / prompt difficulty, L1 transfer, proficiency positioning, virtual-learner simulation, or holistic difficulty models. Holistic models (fine-tuned transformers + LLM rubrics) dominate outright; virtual-learner probes and proficiency-positioning norms carry the next-strongest signal.

Abstract

Vocabulary difficulty prediction aims to estimate how difficult a word is for a learner. This is an important problem because word difficulty is shaped not only by the word itself, but also by the learner's background and the context in which the word appears. In this work, we predict continuous difficulty scores for English target words using learner-specific information. Our approach combines a fine-tuned DeBERTa v3 Large model with a CatBoost regressor trained on transformer-based embeddings. The final score is produced through weighted ensembling, where DeBERTa provides the main prediction and CatBoost adds a smaller complementary signal. Our final system achieved RMSE scores of 1.040 for Spanish, 0.992 for German, and 0.882 for Chinese. The results were also stable across multiple runs, showing that the model behaved consistently under small changes in ensemble weight. These findings show that a simple hybrid system can provide reliable performance for vocabulary difficulty prediction. They also suggest that combining strong contextual representations with a lightweight regression model is an effective way to model learner-sensitive word difficulty.

1 Introduction

The prediction of the difficulty of a word to a learner is a significant aspect of language education, as vocabulary knowledge determines reading comprehension, assessment results, and learning materials design (Zhang and Lu, 2025). Practically, though, word difficulty is not fixed. It is not only based on the word itself, but also on the linguistic background of the learner and the context in which the word is introduced (Felice and Skidmore, 2026). This makes vocabulary difficulty prediction both educationally meaningful and technically challenging.

Consequently, there is an increasing interest in

constructing NLP models that are capable of predicting learner-sensitive difficulty scores in a consistent and scalable manner (Kapoor et al., 2026). Recent work has also started to examine vocabulary test item difficulty prediction with transformer-based models, showing that such architectures provide a strong recent baseline for this task (Skidmore et al., 2025). Even though transformer-based models have become the standard option in most NLP tasks, their usage in vocabulary difficulty prediction still raises practical concerns (Li et al., 2025). Predicting word difficulty is not only about understanding the general meaning of the word and its context. The system must capture small differences between words and project them to a continuous score that indicates learner difficulty. This complicates the task compared to many traditional text classification problems and implies that the final prediction step should be given as much attention as the transformer model itself (Li et al., 2025).

In this paper, we present our system submission to the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners (Felice and Skidmore, 2026). Our approach combines DeBERTa v3 Large and CatBoost in a hybrid prediction framework. DeBERTa serves as the main contextual model, while CatBoost uses transformer-based features to provide an auxiliary prediction signal. The final score is obtained through weighted ensembling. This design allows the system to produce a more reliable estimate of vocabulary difficulty than a transformer-only model, especially when the task depends on small lexical differences and learner-specific context.

The rest of the paper is structured in the following way. We describe the data and the evaluation setting first. Then we consider the previous work that is the most related to our work. Then, we describe our methodology, which consists of pre-processing, DeBERTa fine-tuning, the CatBoost component, and the final ensemble strategy. Then

we show the results and compare the various models and submitted runs. We end with a discussion of the broader lessons from this study and directions for future research.

2 Shared Task Data and Evaluation

The shared task focuses on vocabulary difficulty prediction for English learners. In this task, the system is given an English target word together with learner-related information, and it must predict a continuous difficulty score for that word. The data are provided separately for three learner groups based on their first language: Spanish, German, and Mandarin Chinese.

Each example includes information about the target word and the prompt shown to the learner. In our system, these fields are not treated as separate inputs. Instead, the selected text components are combined into one input sequence, and the target word is explicitly marked inside the context before the text is passed to the model. This preprocessing step helps the model focus on the target item while still using the surrounding learner-specific context (See Table 1).

The dataset is divided into training, development, and test splits for each language group. In our experiments, each L1 contains 6,091 training instances, 677 development instances, and 748 test instances see Table 2. The training and development sets include the gold difficulty scores, while the test set is used for blind evaluation.

System performance is measured mainly with root mean squared error (RMSE). This is the main metric used to compare systems and determine their ranking. RMSE is defined as:

$$\text{RMSE} = \sqrt{\frac{1}{N} \sum_{i=1}^N (y_i - \hat{y}_i)^2},$$

where y_i is the gold difficulty score, $\hat{y}_i$ is the predicted score, and N is the number of test items. A lower RMSE means better performance because it shows that the predicted scores are closer to the reference scores.

This dataset is useful for the task because it allows the model to learn from both the target word and the learner-specific context. It also enables comparison of how vocabulary difficulty varies across Spanish, German, and Mandarin Chinese learners, rather than treating all learners as a single group.

Field	Description	Example
item_id	Unique identifier for each item	9
L1	Learner first language	es
en_target_word	English target word	capacity
en_target_pos	Part of speech of the target word	noun
en_target_clue	Partial clue for the target word	c_____
L1_source_word	Source cue / translation	cabida
L1_context	Learner L1 context	short Spanish prompt
GLMM_score	Gold difficulty score in labelled data	-1.727

Table 1: Main fields used in the shared task dataset, illustrated with a Spanish labelled example.

3 Literature Review

Recent work on difficulty prediction has moved in two closely related directions: item difficulty modeling from assessment content and text difficulty modeling for language learners.

Kapoor et al. (2026) study item difficulty prediction for reading comprehension items using a repository built from standardized tests. Their work shows that difficulty depends on more than the question text alone. They annotate items with linguistic, test, and context features, and then compare these with LLM-based embeddings. Their results show that the best performance comes from combining these sources of information, while text analysis features and LLM embeddings perform similarly when used on their own. This suggests that interpretable linguistic features still remain useful even when modern embedding methods are available.

A related line of work focuses more directly on text difficulty for second language learners. Zhang and Lu (2025) align English text difficulty with CEFR levels for L2 readers and show that lexical, syntactic, and discoursal features can be used to classify texts effectively. Their findings are especially relevant because they show that text difficulty is not explained by traditional readability formulas alone. Instead, features such as age of acquisition, lexical decision time, mean length of T-unit, academic vocabulary, and complex nominals play an important role. They also show that the features that separate lower proficiency levels are not ex-

item_id	L1	en_target_word	L1_source_word	L1_context
6782	Spanish	luck	suerte	Te deseo suerte con tu nuevo trabajo
6771	German	herd	Herde	Die Viehherde graste auf der Weide
6772	Chinese	harm	伤害, 损害	这类项目会损害环境。

Table 2: Illustrative examples showing the dataset format for Spanish, German, and Mandarin Chinese learners.

actly the same as those that matter at higher levels.

Li et al. (2025) examine item difficulty modeling with fine-tuned small and large language models. Their results show that fine-tuned small models such as BERT and RoBERTa remain very competitive, and that careful data augmentation can improve prediction further. In contrast, larger autoregressive models and prompting-based approaches are less effective in their setting, mainly because the task is constrained by small training data and imbalanced difficulty distributions. Their work is important because it shows that stronger results do not always come from using larger models, but from matching the modeling strategy to the structure of the task.

This shared task also builds on a longer line of work on lexical complexity and simplification. Earlier shared tasks, such as SemEval 2016 on Complex Word Identification and the BEA 2018 multilingual CWI task, treated the problem mainly as deciding whether a word is difficult for a reader (Paetzold and Specia, 2016; Yimam et al., 2018). Later tasks moved closer to graded prediction, especially SemEval 2021 Task 1 on Lexical Complexity Prediction, while the BEA 2024 MLSP shared task connected lexical complexity with multilingual simplification pipelines (Shardlow et al., 2021, 2024). Compared with these earlier settings, the present task focuses more directly on learner-specific vocabulary difficulty by taking the learner’s first language and contextual information into account.

Taken together, these studies suggest that difficulty prediction benefits from three broad ideas: the use of learner- or task-relevant linguistic features, the inclusion of contextual information when available, and the careful choice of modeling architecture rather than relying only on model size. Our work follows this direction by combining a strong contextual encoder with a separate regression component, aiming to capture both contextual meaning and structured variation in the prediction of vocabulary difficulty. In particular, the transformer model

provides the main contextual representation of the target word, while the regression branch offers an additional signal derived from dense embedding features. This design keeps the system simple, but still allows it to combine information from complementary sources.

4 Methodology

Our system combines a fine-tuned transformer model with a second-stage regression model built on dense embedding features. The main predictive signal comes from DeBERTa v3 Large (He et al., 2021), which is fine-tuned separately for each learner group. In parallel, we extract feature representations from DeBERTa and XLM-RoBERTa (Conneau et al., 2020) and use them as input to a CatBoost regressor (Prokhorenkova et al., 2018). The final prediction is obtained by combining the transformer score and the CatBoost score through weighted averaging. Figure 1 shows a high-level view of the workflow.

4.1 Preprocessing and Feature Extraction

The input to the transformer is created by combining several text fields defined in the model configuration file. During preprocessing, these fields are merged into a single sequence in a fixed order, separated by the tokenizer’s separator token when available. The target word is explicitly marked inside the context by surrounding it with special tags, `<t>` and `</t>`. This design means that the model does not process the target word in isolation. The remaining unused columns are removed during preprocessing.

For both models, we used an identical set of input features: the L1 source word, L1 context, English part of speech, English clue, and English target word. To support the second-stage regression model, we extract dense vector representations from two pretrained transformers: DeBERTa v3 Large and XLM-RoBERTa Large. The embedding script loads a tokenizer and base transformer model for each encoder, applies tokenization with padding

Figure 1: Workflow of the proposed system. DeBERTa v3 Large serves as the main prediction model, while a CatBoost regressor is trained on sentence embeddings extracted from DeBERTa and XLM-RoBERTa. The final prediction is obtained through weighted ensembling. The figure reports the main ensemble setting, 0.90/0.10, together with the two additional weight configurations, 0.92/0.08 and 0.88/0.12, explored in our submitted runs.

and truncation, and then computes a sentence-level representation using mean pooling over the last hidden states.

4.2 Experimental Design

The transformer component is trained using the Hugging Face Trainer API.¹ Tokenization is performed after preprocessing, with truncation applied to the combined input text. Training is carried out with epoch-based evaluation, epoch-based checkpointing, and selection of the best model at the end of training.

DeBERTa, short for Decoding-enhanced BERT with Disentangled Attention, is a transformer-based encoder that models content and positional information separately. This design helps the model capture fine contextual differences more precisely, which is especially useful in vocabulary difficulty prediction where small lexical and contextual cues matter. We trained the DeBERTa model for each language using 6 epochs with a batch size of 16, a learning rate of $2e-5$, and a warmup ratio of 0.1. The weight decay was set to 0.1 for Spanish and Chinese, and 0.0 for German. We kept these settings because they provided a stable training pro-

cess and gave the strongest development performance in our experiments, while still keeping the setup simple and consistent across the three learner groups.

In our final submission, DeBERTa v3 Large serves as the main neural model. Its role is to learn a direct mapping from the learner-aware input representation to the target difficulty score. Since the model is trained separately for each learner group, it can adapt to differences across Spanish, German, and Mandarin Chinese learners without mixing the three data distributions during inference. CatBoost is a gradient boosting regressor designed to model continuous values from structured feature representations. In our system, it serves as a second-stage model over embedding-based features and provides an auxiliary prediction that complements the main transformer output. Additionally, the CatBoost stage uses concatenated DeBERTa and XLM-RoBERTa embeddings as its input features. For each learner group, the code loads the embedding arrays, concatenates the two representation spaces, and fits a CatBoostRegressor using the training labels from the official training split. The model is trained with RMSE as the loss function, 2000 boosting iterations, a learning rate of 0.03, and a tree depth of 6. The CatBoostRegressor operates on fixed embedding vectors and contributes an auxiliary score that complements the main DeBERTa output. This is useful because the final regression problem may involve nonlinear interactions in the representation space that are not fully exploited by a standard transformer regression head.

The final prediction is obtained by combining the DeBERTa score and the CatBoost score through weighted averaging. Before combining the two files, the code checks that the `item_id` ordering matches exactly. The final prediction is then computed as:

$$\hat{y}_{\text{final}} = \alpha \hat{y}_{\text{DeBERTa}} + (1 - \alpha) \hat{y}_{\text{CatBoost}}, \quad (1)$$

where α is the weight assigned to the DeBERTa prediction. For the main run, we used:

$$\hat{y}_{\text{final}} = 0.90 \hat{y}_{\text{DeBERTa}} + 0.10 \hat{y}_{\text{CatBoost}}. \quad (2)$$

We also generated two additional runs using nearby weights, namely 0.92/0.08 and 0.88/0.12, to test whether small changes in the ensemble balance would improve stability or final performance (See Table 4). The script uploaded here corresponds to

¹https://huggingface.co/docs/transformers/main_classes/trainer

the run with weights 0.88 and 0.12, but the same logic was used for all three submitted runs.

5 Results

This section presents the performance of the models explored in our experiments and compares them with the final ensemble system. We first report the development results of the main transformer models that were considered during model selection. We then present the official results of the three submitted ensemble runs, which were obtained by combining DeBERTa v3 Large and CatBoost with slightly different weights.

5.1 Transformer Models

Table 3 compares the three main transformer settings that were examined during development: XLM-RoBERTa Base, XLM-RoBERTa Large, and DeBERTa v3 Large. The results show a clear and consistent pattern across all three learner groups. XLM-RoBERTa Large improved substantially over XLM-RoBERTa Base, which suggests that increased model capacity was useful for this task. However, the strongest results were obtained with DeBERTa v3 Large in every language.

The advantage of DeBERTa was especially clear in Chinese, where it reached the lowest RMSE among the three transformer settings. The same trend also appeared in Spanish and German. This consistent improvement made DeBERTa the strongest candidate for the main prediction branch of the final system.

Model	L1	RMSE ↓	Pearson ↑
XLM-RoBERTa Base	Spanish	1.380	0.708
XLM-RoBERTa Base	German	1.383	0.710
XLM-RoBERTa Base	Chinese	1.227	0.711
XLM-RoBERTa Large	Spanish	1.161	0.828
XLM-RoBERTa Large	German	1.153	0.824
XLM-RoBERTa Large	Chinese	1.061	0.820
CatBoost	Spanish	1.737	0.423
CatBoost	German	1.698	0.375
CatBoost	Chinese	1.464	0.499
DeBERTa v3 Large	Spanish	1.021	0.854
DeBERTa v3 Large	German	1.059	0.838
DeBERTa v3 Large	Chinese	0.925	0.841

Table 3: Development set results of the main transformer models across the three learner groups. Lower RMSE and higher Pearson indicate better performance.

5.2 Final Ensemble

We submitted three runs with nearby weight settings. The main run used a weight of 0.90 for DeBERTa and 0.10 for CatBoost. Two additional runs, 0.92/0.08 and 0.88/0.12, were included to test whether a small change in the ensemble balance would improve the final performance. The results are shown in Table 4.

Run	Weights (D/C)	Spanish	German	Chinese
Run 1	0.90 / 0.10	1.040	0.992	0.883
Run 2	0.92 / 0.08	1.040	0.993	0.882
Run 3	0.88 / 0.12	1.041	0.992	0.885
Best Model	- / -	0.903	0.885	0.776

Table 4: Official RMSE results of the three submitted ensemble runs, compared with the best model submitted in the shared task. D/C denotes the weights assigned to DeBERTa and CatBoost, respectively. Lower values are better.

The final ensemble results were very close across the three runs. This is consistent with the development results, where DeBERTa was already the strongest standalone model.

6 Discussion

The gap between the standalone DeBERTa model and the final ensemble is much smaller. This is also an important finding. It suggests that most of the predictive signal already comes from DeBERTa, while CatBoost provides a limited but useful correction. The small differences across the three submitted ensemble runs support the same interpretation. If the gains had been random, the relative order of the runs would likely have varied more sharply across languages. Instead, the scores remain very close, which points to a stable system with a fairly fixed error profile (See Table 4). Overall, the results show that the final system benefited more from a strong contextual encoder than from aggressive reweighting in the ensemble stage. The submitted runs confirmed that the proposed hybrid approach was stable across languages, with the strongest final performance observed for Chinese and the most difficult condition appearing in Spanish.

A likely explanation for the gap between the weaker models and the final model is the way they represent lexical information. Vocabulary difficulty prediction is not only a matter of general sentence meaning. The model must detect subtle differences

in target-word usage, clue structure, and learner-specific context, then map that information to a continuous score. Smaller or less task-suited encoders may capture broad semantic information, but they are more likely to smooth over the fine distinctions that matter in this setting. DeBERTa appears to reduce this problem, and the CatBoost component adds a second decoding layer over dense embeddings, which helps recover some structured patterns that may be missed by a simple transformer regression head.

From a hypothesis-testing perspective, several item-level factors are worth examining in future work. The first is *word length*, since longer words may be more morphologically complex and therefore harder both for learners and for the model. The second is *frequency*, because rare words are usually more difficult and may also be less well represented in pretrained models. The third is *part of speech*, as verbs, adjectives, and abstract nouns may not behave in the same way. A fourth factor is *context dependence*: some words can be understood from the clue alone, while others require close reading of the full prompt. These factors are promising because they offer a concrete way to test whether the model’s residual errors are concentrated in specific lexical categories rather than distributed randomly across the dataset.

7 Conclusion

In this paper, we have shown that combining DeBERTa v3 Large with a CatBoost regressor trained on embeddings extracted from DeBERTa v3 Large can provide good estimates of the difficulty of target English words and incorporate additional user-specific data into consideration. Among the transformers examined in the course of our study, DeBERTa v3 Large showed the best performance on its own, outperforming XLM-RoBERTa Base and XLM-RoBERTa Large in Spanish, German, and Chinese. The presented ensemble confirmed the stability of a simple linear combination of an effective contextual language model and a relatively lightweight machine learning model. We showed that the effectiveness of the system is largely dependent on the system’s ability to capture subtle lexical and contextual information about the given input. Second, the improvement comes not merely from increasing the size of the system or adding layers, but from the careful integration of complementary signals in the process. In our case, the

main power was provided by DeBERTa, whereas CatBoost added a minor correction that improved predictions. The small gap between the submitted runs shows that the system was relatively stable in spite of changing ensemble weights.

However, there are also several important limitations. While Chinese was the most successfully predicted language, Spanish was the most difficult one, indicating that the link between the learner, contextual information, and word difficulty may be differently tractable across learner populations. An important direction of future research would consist of analyzing errors at the level of individual items in order to find out whether additional explicit lexical features help in the predictions.

RETUYT-INCO at BEA 2026 Shared Task 1: Feature-Enriched mDeBERTa for Word Difficulty Prediction

Santiago Robaina and Luis Chiruzzo and Aiala Rosá

Instituto de Computación, Facultad de Ingeniería, Universidad de la República
Montevideo, Uruguay

Abstract

We describe the RETUYT-INCO participation in the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners, a regression task that predicts GLMM psychometric difficulty scores for English target words given an L1 cue (Spanish, German, and Mandarin). We submitted two systems to the closed track (which restricts participants to the provided shared-task data and standard NLP resources, excluding external corpora and large language models): a feature-engineered XGBoost regressor for all three L1s, and, for Spanish, a 3-seed ensemble of mdeberta-v3-base fine-tuned with the same handcrafted features prepended as input text tokens. Our best test result is 1.094 RMSE on Spanish (ensemble), a 13.0% reduction over the XLM-RoBERTa-base closed baseline. We highlight two findings. First, a LaBSE cross-lingual cosine between the L1 source word and the English target word is the largest single-feature addition in our incremental ablation, reducing average development-split (dev) RMSE by 0.091 on top of an already strong string/frequency/POS feature set. Second, feature-only XGBoost, with no neural fine-tuning and no GPU, already beats the XLM-RoBERTa-base closed-track development baseline on average across the three L1s (1.273 vs. 1.287 RMSE).

1 Introduction

Predicting how hard an English word is for a second-language learner is a core problem for intelligent tutoring, adaptive reading, and vocabulary tools. The BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners (Felice and Skidmore, 2026) casts this as a regression problem: given an English target word and an L1 cue (source-language word, context sentence, and a partial orthographic clue), predict a continuous Generalized Linear Mixed Model (GLMM) psychometric difficulty score. The task covers three L1s (Spanish,

German, and Mandarin) and two tracks (closed and open). The closed-track baseline is a fine-tuned XLM-RoBERTa-base (Conneau et al., 2019).

The task sits at the intersection of two traditions. On the NLP side, the Complex Word Identification shared tasks (Paetzold and Specia, 2016; Yimam et al., 2018) framed word-level difficulty as classification by non-native readers; SemEval 2021 (Shardlow et al., 2021) replaced this with a continuous Lexical Complexity Prediction target, and BEA 2024 MLSP (Shardlow et al., 2024) extended the setting to multilingual lexical simplification. Handcrafted features very similar to the ones we use here (word length, frequency, morphology, character n -grams) have been standard baselines across this line of work, with fine-tuned neural encoders more recently taking the lead. On the psychometric side, vocabulary testing research long predates these benchmarks (Laufer and Goldstein, 2004), and the Knowledge-based Vocabulary Lists project (Schmitt et al., 2021, 2024) provides the response data that underlies the BEA 2026 targets; the GLMM difficulty scores follow the random-item IRT tradition (De Boeck, 2008; Dunn, 2024). The most direct predecessor is Skidmore et al. (2025), who benchmark transformer architectures for predicting vocabulary-test item difficulty on a KVL-derived corpus; their XLM-RoBERTa setup is adapted as the BEA 2026 closed-track baseline.

We approach the task under a self-imposed lightweight constraint: we target systems that can be trained and served on a single low-end GPU or on CPU, and we restrict ourselves to the closed track. This reflects the compute realities of the Global South, where access to large clusters and API-gated models is limited, and the privacy constraints of on-device educational deployments. We submit two systems for the closed track: (i) an XGBoost (Chen and Guestrin, 2016) regressor over a set of handcrafted string, morphological, POS, fre-

quency, and cross-lingual semantic-similarity features, for all three L1s, and (ii) for Spanish only, a 3-seed ensemble of mdeberta-v3-base (He et al., 2023) fine-tuned for regression with the computed features prepended as input text tokens.

Our research question centres on which handcrafted features carry the most signal for cross-lingual vocabulary difficulty prediction. Two findings emerge. First, a LaBSE (Feng et al., 2022) cross-lingual cosine between the L1 source word and the English target word is the largest single-feature drop we observe in an incremental-addition ablation (Table 1), reducing average development-split RMSE by 0.091 across ES/DE/CN in our tree-based pipeline (§3) and adding a further 0.017 ES development-split RMSE when also prepended as an input token to mDeBERTa (§4). We note that incremental ablations attribute shared variance to whichever feature is introduced first, so this should be read as a lower bound on its marginal contribution rather than a proof of strict dominance over every other single feature; see §3. Second, feature-only XGBoost over our full feature set beats the XLM-RoBERTa-base closed-track development baseline on average (1.273 vs. 1.287), with no neural fine-tuning and no GPU. The official-test picture is mixed: XGBoost beats the test baseline on Mandarin, is within noise on German, and underperforms on Spanish (§5). The mDeBERTa ensemble is reported as our submitted best system, not as an efficiency contribution: it is the same total size as the XLM-RoBERTa baseline per seed, and approximately triples inference cost as an ensemble.

2 Dataset and Task

The task provides, per L1, 6,091 training items and 677 development items, with a held-out test set released at submission time (Felice and Skidmore, 2026). Each item has an English target word and its part of speech, a partial orthographic clue of the target, an L1 translation, and an L1 context sentence. The target is a continuous GLMM psychometric difficulty score, ranging roughly from -6 to +5 with lower values indicating harder items. The primary metric is RMSE, with Pearson correlation as a secondary metric. Two tracks are defined: closed (only the provided data and standard NLP resources) and open (external data and LLMs allowed). We participate in the closed track only; the open track was out of scope under our lightweight

constraint.

3 Feature Engineering and XGBoost

3.1 Feature set

We extract a set of handcrafted features per item, grouped in this section by type rather than by order of addition. All features are computed on CPU.

Target-word features (English only): word length, one-hot POS over the eight task categories, Zipf word frequency from the wordfreq package (Speer, 2022), indicators for common English suffixes (-tion, -sion, -ing, -ence, -ment, -able, -ness, -ly) and prefixes (dis-, re-, un-, sub-, out-, over-), maximum consonant cluster length, double-letter indicator, syllable count, and an English latinate-root indicator.

Source-word features (L1 only): source-word length, source-word syllable count, multiword-source indicator, and an accent indicator that matches Spanish and German diacritics (zero for CN).

Cross-lingual string similarity (both words): length difference and ratio, normalized Levenshtein distance, character-bigram Jaccard overlap, Jaro-Winkler similarity (Winkler, 1990), shared prefix and suffix ratio, a first-letter match indicator, and a suffix-transform match. The suffix-transform rules are hand-written per L1 and encode the expected cognate shape (e.g. *-tion* → *-ción* in ES, 15 rules total; *-tion* → *-ierung*, *-ty* → *-tät*, ... in DE, 18 rules total; empty for CN).

Cross-lingual semantic similarity: embed_cosine, the cosine similarity between LaBSE (Feng et al., 2022) sentence embeddings of the English target word and the L1 source word. This is the single largest RMSE drop in our incremental feature ablation (§3) and is the main narrative thread of this paper.

Context: length of the L1 context sentence in characters.

3.2 Model and protocol

We fit an XGBoost regressor on the training split and report RMSE on the development split. Rows 1–3 of Table 1 use linear regression as a deliberately simple baseline for small, near-monotone feature sets; from row 4 onward the features introduce non-linear effects and interactions that motivate XGBoost (`n_estimators=300`, `max_depth=5`, `learning_rate=0.05`), which is also the model used in our submission. The final

row (row 7) uses L1-tuned XGBoost parameters from an 80-iteration random search with 5-fold CV on the training split; tuning moved dev RMSE by only ~ 0.001 , so feature engineering dominated.

3.3 Observations

Table 1 walks up our feature set. The largest single-feature *incremental* addition is `embed_cosine`, which drops average dev RMSE by 0.091 (row 5 $\rightarrow$ row 6). The effect is largest on Mandarin (CN dev RMSE 1.257 $\rightarrow$ 1.181, -0.076), which is consistent with CN having no meaningful orthographic signal between the L1 and English; LaBSE provides the missing cross-lingual bridge. A caveat on attribution: row 5 bundles three features (Jaro–Winkler, char n -gram overlap, Zipf frequency) and produces a larger combined drop (-0.151) than `embed_cosine` alone; because incremental-addition ablations credit shared variance to whichever feature is introduced first, we cannot rule out that one of those three, introduced last, would match or exceed `embed_cosine`’s marginal effect. What we can say is that `embed_cosine` retains a 0.091 average improvement after a feature set that already captures cognate orthography and frequency—i.e., it is not redundant with them. On ES and DE, `embed_cosine` still gives the largest single drop *in this ordering*, alongside target-word Zipf frequency and cross-lingual Jaro–Winkler similarity, which exploit cognate structure.

By row 7, feature-only XGBoost reaches 1.273 average dev RMSE, below the XLM-RoBERTa-base closed dev baseline (1.287), on CPU and with no neural fine-tuning. A leave-one-out ablation on the 9 ES-targeted v2 features confirmed each contributes positively (individual deltas 0.0004–0.0057 on 5-fold CV); we omit per-feature details for space. A full drop-one ablation of `embed_cosine` from the v2 feature set would tighten this claim and is left for future work (§7).

¹Tuned parameters for row 7: ES uses `n_est=600`, `depth=3`, `lr=0.02`, `subsample=0.85`, `colsample=0.70`, `alpha=0.5`, `lambda=2.0`; DE and CN use `n_est=400`, `depth=3`, `lr=0.05`, `subsample=0.85`, `colsample=0.85`, `alpha=0.1`, `lambda=2.0`. The row 7 / row 6 delta therefore conflates the v2 feature block with the L1-tuned hyperparameters. The v2 feature block itself is applied to all three L1s, with per-L1 rule sets (15 suffix-transform rules for ES, 18 for DE, empty for CN so the suffix-transform component is inert there; the remaining v2 features apply equally to all three L1s).

4 mDeBERTa with Feature-Enriched Input

For Spanish, we fine-tune `microsoft/mdeberta-v3-base` (He et al., 2023) for regression (`num_labels=1`). The full model is approximately 276M parameters (an 86M transformer backbone plus a ~ 190 M 250K-token word-piece embedding matrix), essentially the same total size as the XLM-RoBERTa-base closed baseline (~ 270 M).

Input format. We prepend five feature tokens to the encoder input, then concatenate the raw L1 and English fields with [SEP] markers:

```
wlen=N | nedit=N | pos=X | clue=N |
esim=N | L1_word [SEP] L1_context [SEP]
en_clue [SEP] en_word
```

The five prepended features (English word length, normalised edit distance, POS, clue length, and `esim`) are a subset of the XGBoost feature set rendered as plain text. `esim` is the LaBSE cosine of §3 (`embed_cosine`), now available to the encoder as a numeric input token.

Training. GLMM scores are normalised to zero mean and unit variance at training time and denormalised before RMSE computation. We train with learning rate 2×10^{-5} , a cosine schedule with 10% warmup, up to 10 epochs with early stopping (patience 3), batch size 32, weight decay 0.01, fp16, and max sequence length 256. Training was performed on a single Google Colab T4 GPU.

Ensemble. We train three seeds ($\{10, 42, 123\}$) and average their predictions. The ensemble triples inference compute and memory: three ~ 276 M-parameter models are loaded in parallel, for approximately 828M parameters and $3 \times$ forward passes per prediction. Each individual seed already beats the XLM-RoBERTa-base baseline on ES dev (Table 2) by 0.179–0.220 RMSE; the ensemble is a further refinement of 0.034 RMSE over the best individual seed (seed 42, 1.137) and 0.059 RMSE over the mean of the three seeds, so it is a refinement on top of the per-seed gain rather than the source of the gap to the baseline.

Why Spanish only. We did not extend the mDeBERTa ensemble to all three L1. DE and CN ensemble were skipped for time reasons and our own limitations of knowledge of the languages. Our DE and CN submission is therefore XGBoost only.

Test-time retraining. The submitted ES ensemble is retrained on train+dev combined before predicting the test set. The test RMSE (1.094) is

Feature set	Model	ES	DE	CN	Avg	Δ vs. prev
1. word_len	LR	1.778	1.707	1.509	1.665	—
2. + edit distance	LR	1.705	1.596	1.487	1.596	−0.069
3. + POS	LR	1.663	1.536	1.493	1.564	−0.032
4. + morphology + shared prefix + context	XGBoost	1.613	1.524	1.459	1.532	−0.032
5. + Jaro–Winkler + n -gram + Zipf freq.	XGBoost	1.464	1.421	1.257	1.381	−0.151
6. + embed_cosine (LaBSE)	XGBoost	1.350	1.339	1.181	1.290	−0.091
7. + L1-specific (v2)	XGBoost ¹	1.327	1.334	1.158	1.273	−0.017
XLM-RoBERTa-base (closed) baseline	XLM-R (~270M)	1.357	1.328	1.175	1.287	—

Table 1: Feature progression on dev (RMSE, 3 dp). Rows 1–3 add the target-word length, a first cross-lingual string feature (edit distance), and target POS. Row 4 adds target-word morphology (suffix/prefix indicators, consonant cluster, double-letter) together with the shared-prefix ratio and context length. Row 5 adds further cross-lingual string similarity (Jaro–Winkler, character-bigram overlap, first-letter match) and target-word Zipf frequency. Row 6 (bold) adds the cross-lingual semantic similarity (embed_cosine). Row 7 adds the L1-specific v2 block and switches to L1-tuned XGBoost hyperparameters. The last row of the table is the task baseline for reference.

therefore not directly comparable to the dev RMSE of the same configuration (1.103).

5 Results and Analysis

On Dev-set. Feature-only XGBoost beats the XLM-RoBERTa-base closed dev baseline on average and on ES and CN individually; on DE it is within noise of the baseline (1.334 vs. 1.328, +0.006). See Table 2. The pipeline uses CPU-fit trees and no neural fine-tuning. The submitted ES ensemble reaches 1.103 dev RMSE, a further 0.224 RMSE below our XGBoost row. This gap is not an efficiency result, since per-seed mDeBERTa has essentially the same parameter count as XLM-RoBERTa-base; it is an effect of the feature-enriched input format, target scaling, and 3-seed averaging. Each individual seed already beats the XLM-RoBERTa dev baseline on ES.

On Test-set. On the official closed-track test leaderboard (Table 3), our ES ensemble reports 1.094 RMSE / 0.843 Pearson, placing us 9th of 21 participating teams on Spanish (best-per-team collapse), and reducing the test-baseline RMSE by 13.0%. XGBoost on Mandarin also beats the test baseline (1.106 vs. 1.140, −3.0%), placing us 18th of 21 teams. German XGBoost is within noise of the test baseline (1.260 vs. 1.258, +0.2%, rank 18/20). ES XGBoost underperforms the test baseline (1.323 vs. 1.257, +5.3%), despite beating the dev baseline (1.327 vs. 1.357). This dev/test inversion on ES is the clearest sign of distribution

shift between the two splits for our feature-based system.

6 Conclusions

Among the handcrafted features we tested, the LaBSE cross-lingual cosine between the L1 source word and the English target word carries the most task-relevant signal: adding it reduces average dev RMSE by 0.091 across ES/DE/CN in our XGBoost pipeline, and adds a further 0.017 ES dev RMSE when also included as a prepended input token to mDeBERTa. Feature-only XGBoost, with no GPU, already beats the XLM-RoBERTa-base closed dev baseline on average (1.273 vs. 1.287). Our submitted ES system, a 3-seed mDeBERTa ensemble, places 9/21 on the closed-track ES test leaderboard at 1.094 RMSE.

7 Limitations

The neural ensemble was run for ES only; DE was skipped for compute reasons and CN was skipped by design (Latin-script feature assumptions). The submitted ES ensemble loads ~828M parameters and runs three forward passes per prediction: it is not an efficient system relative to the baseline, and we report it as our best test result rather than as an efficiency contribution. We prioritise breadth over depth and did not run per-L1 mDeBERTa hyperparameter searches. The ES XGBoost shows a clear dev/test inversion that we do not fully explain. We did not explore open-track resources. Finally, our “largest single-feature incremental drop” claim for embed_cosine rests on incremental-addition evidence and is therefore order-dependent: the three features added in row 5 of Table 1 (Jaro–Winkler, char n -gram, Zipf) share credit for a combined

²The submitted XGBoost boosters were not persisted; their serialised size on disk was not measured before submission. The model is a gradient-boosted tree ensemble (up to 600 trees of depth 3) trained on ≤ 23 numeric features.

System	Params (total)	ES	DE	CN
XLM-RoBERTa-base (closed baseline)	~270M	1.357	1.328	1.175
full_xgb_v2_embed (our XGBoost, submitted)	tree ensemble (CPU) ²	1.327	1.334	1.158
mDeBERTa (seed 10)	~276M	1.178	—	—
mDeBERTa (seed 42)	~276M	1.137	—	—
mDeBERTa (seed 123)	~276M	1.172	—	—
mDeBERTa 3-seed ensemble (submitted, ES only)	~828M at inference	1.103	—	—

Table 2: Development-split RMSE (3 dp). Per-seed Pearson on ES is 0.789 / 0.821 / 0.826; the ensemble reaches 0.827. The mDeBERTa backbone (86M) and the XLM-RoBERTa backbone (~85M) are essentially the same size; total parameters including the $250K \times 768$ word-piece embedding matrix are ~276M and ~270M respectively.

L1	System	RMSE	Pearson	Team rank	Δ RMSE vs. baseline
ES	mDeBERTa 3-seed ensemble (submitted)	1.094	0.843	9 / 21	-0.163 (-13.0%)
ES	XGBoost (secondary submission)	1.323	0.713	—	+0.066 (+5.3%)
DE	XGBoost (submitted)	1.260	0.713	18 / 20	+0.002 (+0.2%)
CN	XGBoost (submitted)	1.106	0.754	18 / 21	-0.034 (-3.0%)
ES	XLM-RoBERTa-base (closed test baseline)	1.257	0.765	—	—
DE	XLM-RoBERTa-base (closed test baseline)	1.258	0.773	—	—
CN	XLM-RoBERTa-base (closed test baseline)	1.140	0.753	—	—

Table 3: Official test-set results, closed track. A negative Δ RMSE indicates our system is lower than (better than) the baseline. Team rank collapses each team to its best submission per L1; dashes in that column indicate a row shown for comparison only and not counted separately (our ES team rank is determined by the ensemble). The ES XGBoost row is reported to contextualise the dev/test behaviour of the feature-only system.

—0.151 drop, and a drop-one ablation from the full v2 set would be needed to establish strict per-feature dominance. We leave that ablation to future work.

Abstract

In this paper, we describe our submission to the BEA 2026 Shared Task on Multilingual Lexical Complexity Prediction. Our system fine-tunes XLM-RoBERTa Large separately for Spanish, German, and Chinese, feeding each instance as a concatenation of the source word, its context in a sentence, an English clue, and the English target word. Training uses Z-score label normalization and two independent runs that differ in learning rate, random seed, etc. On the official test set, the system scores RMSE = 1.170 and Pearson Correlation = 0.812.

1 Introduction

Estimating how hard a word is to read depends on who is doing the reading. A word which is easy for a native speaker to understand may be quite complex for a language learner, and the same word can sit at opposite ends of the difficulty scale depending on its context. Lexical complexity prediction (LCP) formalizes this as a regression task: given a word in sentence context, predict a score reflecting how difficult it is for a reader.

Most LCP work has concentrated on English (Shardlow et al., 2021; North et al., 2022). The BEA 2026 Shared Task extends this to learners whose first language (L1) is Spanish, German, or Chinese – three languages that differ substantially in morphology, script, and how well-represented they are in multilingual pretrained models. Chinese is the most challenging of the above languages—no whitespace segmentation, character-level ambiguity, and thinner coverage in most encoders than either of the Latin-script languages.

The BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners requires participants to predict the complexity of a word for learners of English from different L1 backgrounds – namely Spanish, German and Chinese. Each instance in the task also includes an English clue

word and an English target alongside the L1 word and context. A model with strong English representations can potentially use the clue and target as anchors even when the source language is less familiar. The dataset in the shared task provides us with the source word, context, clue and target, which can help the classifier in predicting the complexity.

We fine-tune XLM-RoBERTa Large (Conneau et al., 2020) separately for each language, concatenating all four fields into a single flat input string. To squeeze a bit more out of the model without additional data, we train two runs per language under slightly different hyperparameters and improve model performance via weighted averaging of predictions. The final system scores RMSE as 1.170 and Pearson $r = 0.812$ on the test set.

2 Related Work

Lexical complexity prediction. Early readability work used word frequency and syllable counts as proxies for lexical difficulty (Dale and Chall, 1948). The SemEval-2021 LCP shared task (Shardlow et al., 2021) shifted the benchmark toward fine-grained regression on words in context, and transformer-based systems pulled well ahead of feature-engineered pipelines – less because of architectural creativity than because model scale simply helps (North et al., 2022; Zaharia et al., 2022).

Multilingual LCP has received less attention. Most multilingual efforts swap in a multilingual encoder and, sometimes, language-specific lexical resources such as frequency lists or morphological analyzers (Shardlow et al., 2022). An earlier shared task on multilingual lexical simplification was organized during BEA 2024 (Shardlow et al., 2024).

Multilingual pretrained encoders. XLM-RoBERTa (Conneau et al., 2020) covers 100 languages and has become the default backbone

Figure 1: Overview of the proposed pipeline for multilingual lexical complexity prediction.

for cross-lingual classification and regression. In this Shared Task, the standard setup - linear head on [CLS], full fine-tuning - works well enough that there is little reason to deviate from it.

Ensembling. Averaging predictions across runs with different seeds or hyperparameters reduces variance without requiring additional data or a larger model (Lakshminarayanan et al., 2017; Liu et al., 2019). We train two runs per language and combine them with a fixed weighted average (0.6/0.4), with weights chosen on the validation set.

3 System Description

Figure 1 shows our system architecture. For training, we do input construction and label normalization which we feed as input to XLM-RoBERTa to learn our model. At testing time, we also construct the input representations as input to XLM-RoBERTa and the model. The output from the model is sent to a regression head, followed by post-processing to generate our output labels.

3.1 Input Construction

Each instance has four fields: the L1 source word, its sentence context, an English clue word, and an English target word. We join them with `</s>` separators, which XLM-RoBERTa treats as segment boundaries. All four fields are concatenated as:

```
L1_word </s> L1_context </s> en_clue </s>
                               en_target
```

For Chinese, consecutive whitespace is collapsed with a regex pass before tokenization; without it, the tokenizer splits character-segmented text erratically.

3.2 Model

We fine-tune XLM-RoBERTa Large (Conneau et al., 2020) with a linear regression head on the [CLS] token. The full network is updated end-to-end. We train separate models for each language rather than a single joint model; the three languages differ enough in script and morphology that joint training hurt validation RMSE in preliminary experiments.

GLMM scores are z-score normalized before training:

$$\hat{y} = \frac{y - \mu}{\sigma} \quad (1)$$

where μ and σ are computed over the training split for each language. Predictions are denormalized before submission and clipped to $[0.05, 5.0]$; the lower clip handles a small number of predictions that collapsed near zero during early stopping.

3.3 Training

All models use AdamW with fp16 mixed precision, gradient checkpointing, 500 warmup steps, and gradient norm clipped at 1.0. Batch size is 4 with 2 gradient accumulation steps (effective batch size 8), trained for 5 epochs. The checkpoint with the lowest validation RMSE is kept.

3.4 Ensembling

We train two runs per language with different hyperparameters (Table 1). Spanish Run 1 produced the strongest single result in the submission, and its settings were the starting point for German and Chinese - we adjusted learning rate and seed between runs to test whether that configuration would hold. It did not, which is discussed in Section 4.

For German only, we combined Run 1 and Run 2 via weighted averaging:

$$\hat{y}_{\text{ens}} = 0.6 \cdot \hat{y}_1 + 0.4 \cdot \hat{y}_2 \quad (2)$$

The weights were set on the validation set across all languages and not tuned further on a per-language basis.

Lang.	Setting	Run 1	Run 2
es / de	Learning rate	1e-5	1.1e-5
	Scheduler	linear	cosine
	Seed	42	1337
	Max length	384	320
cn	Learning rate	1.2e-5	1.1e-5
	Scheduler	cosine	cosine
	Seed	42	1337
	Max length	320	320

Table 1: Per-language hyperparameters. The following hyperparameters were shared across all runs: AdamW, fp16, batch size 4, 2 gradient accumulation steps, 500 warmup steps, 5 epochs, max_grad_norm 1.0.

3.5 Experimental Setup

We evaluate on the official BEA 2026 test set using RMSE (primary) and Pearson r (secondary). Training and validation splits follow the shared task data release. No additional training data or external resources are used. We compare against the shared task baseline, which fine-tunes xlm-roberta-base with batch size 32, learning rate 3×10^{-5} , and dropout 0.1 on the same four input fields; baseline results are reported on the test set.

4 Results and Analysis

Spanish Run 1 achieved the strongest result in the submission (RMSE = 1.170, Pearson Correlation = 0.812). Spanish Run 2 collapsed entirely—Pearson of 0.043 indicates the model’s predictions are near-random, likely due to training instability under the cosine schedule with seed 1337 on the Spanish data distribution. This is consistent with the instability findings discussed in Section 4.1; the same seed and scheduler combination that worked for German produced a degenerate run for Spanish. Run 2 was excluded from the Spanish ensemble for this reason.

For German and Chinese, both runs completed normally. Run 1 is the weakest of the two runs for German on Pearson correlation, and for Chinese the cosine-scheduled Run 2 achieves notably higher Pearson ($r = 0.777$ vs. 0.718) despite slightly

worse RMSE. Ensemble predictions were generated for German only, where combining the two runs matched Run 2 exactly (RMSE 1.569, $r = 0.772$), suggesting the linear-schedule run added no useful signal for that language. The overall best test result is RMSE 1.170 and Pearson $r = 0.812$ as reported in Table 2.

4.1 Effect of Model Scale

xlm-roberta-large has 560M parameters against 270M for the base variant (Conneau et al., 2020). On large fine-tuning sets, the larger model reliably wins. On smaller datasets the picture is less clean—more parameters means more capacity to overfit, and the effect is sharper when the learning rate is low and the batch size is small.

Both conditions apply here. Our effective batch size is 8 (batch 4, gradient accumulation 2) against the baseline’s 32, and our learning rates range from 1×10^{-5} to 1.2×10^{-5} against the baseline’s 3×10^{-5} . A larger batch size averages out more gradient noise per step, which acts as implicit regularisation; a higher learning rate moves the model away from sharp minima faster. The baseline has both. We have neither—and on German and Chinese, where the training splits are smaller than Spanish, the baseline’s implicit regularisation appears to matter more than the capacity advantage of the larger model.

This is consistent with findings in low-resource transfer learning more broadly (Mosbach et al., 2021). Fine-tuning large pretrained models on small datasets is unstable: performance varies significantly across seeds, the best checkpoint is sensitive to when training stops, and the gap between a good run and a bad one is wider than it is for smaller models. Our Chinese results illustrate this directly—Run 1 and Run 2 differ only in learning rate (1.2×10^{-5} vs. 1.1×10^{-5}) and seed, yet their Pearson correlations are 0.718 and 0.777 respectively, a gap of 0.059 on what should be a small hyperparameter change.

One correction that would likely help is adding explicit regularisation to the regression head—dropout before the linear layer, or L2 weight decay on the head parameters specifically. The baseline uses dropout 0.1 throughout. Our runs use no explicit dropout on the head, relying entirely on the pretrained weights and early stopping to prevent overfit. For a 560M parameter model on a few thousand training examples, that is not enough.

Language	System	RMSE ↓	Pearson r ↑
Spanish	Baseline (xlm-roberta-base)	1.257	0.765
	Run 1 (linear, seed 42)	1.170	0.812
	Run 2 (cosine, seed 1337)	1.885	0.043
German	Baseline (xlm-roberta-base)	1.258	0.773
	Run 1 (linear, seed 42)	1.564	0.760
	Run 2 (cosine, seed 1337)	1.569	0.772
	Ensemble (0.6/0.4)	1.569	0.772
Chinese	Baseline (xlm-roberta-base)	1.140	0.753
	Run 1 (cosine, seed 42)	1.382	0.718
	Run 2 (cosine, seed 1337)	1.436	0.777

Table 2: Per-language results compared against the shared task baseline (xlm-roberta-base). All figures are on the test set. Bold marks the best result per language per metric.

4.2 Discussion

Table 2 compares our runs against the shared task baseline, which uses xlm-roberta-base with a batch size of 32 and learning rate of 3×10^{-5} . The results split clearly by language.

For Spanish, both metrics improve over the baseline—RMSE drops from 1.257 to 1.170 and Pearson rises from 0.765 to 0.812. Upgrading from xlm-roberta-base to xlm-roberta-large and halving the learning rate proved effective for Spanish, where the training data is likely well represented in the larger model’s pretraining corpus.

The baseline RMSE of 1.258 for German is substantially better than our best result of 1.564, and for Chinese, the baseline (1.140) outperforms both our runs on RMSE. On Pearson correlation, the baseline leads in German as well (0.773 vs. 0.772), while for Chinese our Run 2 reaches $r = 0.777$ against the baseline’s 0.753. The primary metric goes to the baseline on both languages.

The inconsistency across languages also points to a deeper issue: the hyperparameters that work for Spanish do not generalise. Spanish benefits from dense coverage in XLM-RoBERTa’s pretraining data and relatively transparent morphology; German and Chinese present harder targets for the same configuration.

5 Conclusion and Future Work

The system is straightforward: one pretrained encoder, per-language fine-tuning, a flat input string, two runs averaged together. The system makes no architectural contributions. What the results show is that this setup is sufficient for Spanish—RMSE = 1.170 and Pearson Correlation = 0.812 without external resources, language-specific features, or architectural modifications—but does not gener-

alise cleanly across languages.

The English-side signal warrants further investigation. The clue and target words may provide useful cross-lingual anchors, particularly for Chinese where the encoder’s L1 coverage is weakest, and future work should include a controlled ablation to isolate their contribution.

The clearest lesson from the results is that a single hyperparameter configuration cannot serve three typologically different languages equally well. Spanish, German, and Chinese respond differently to learning rate, batch size, and scheduler choice. Future work should tune these per language from the start, add explicit regularisation to the regression head, and retain per-run scores across all languages to enable proper ablation.

In the future, we also plan to adopt the use of LLMs, such as GPT, Claude, etc. for improving the performance of Lexical Complexity Prediction. While the usage of LLMs has been shown to perform quite well in tasks such as generating simplifications across multiple languages ((Aumiller and Gertz, 2022; Dutilleul et al., 2024)), to the best of our knowledge, not much work has gone into measuring lexical complexity across multiple languages.

Limitations

Intermediate per-run predictions were not saved for Spanish and Chinese, preventing us from constructing and evaluating ensemble variants for those languages post-hoc. The ablations mentioned in Section 3 were run on the validation set only and were not systematic; we adjusted one variable at a time without a full factorial search. The ensemble weights (0.6/0.4) were set by inspection across all languages rather than optimized per language—the German results suggest this was suboptimal.

Finally, the system uses no morphological analysis, frequency information, or psycholinguistic norms—features that have historically been strong predictors of lexical complexity and that might close some of the remaining gap.

Abstract

Lexical difficulty prediction is a fundamental problem in language learning and readability assessment, requiring models to estimate word difficulty across different first-language (L1) backgrounds. However, existing approaches rely on regression-only training with scalar supervision, which does not explicitly structure the representation space, limiting their ability to capture cross-lingual alignment and ordinal difficulty. To mitigate these issues, we propose *Context-Aligned Contrastive Regression*, which integrates Ridge regression ensemble with two complementary objectives, i.e., Cross-View Context and Ordinal Soft Contrastive Learning. Experiments on three L1 datasets show that (i) contrastive objectives improve cross-lingual representation alignment while preserving language-specific nuances, (ii) the learned representations capture the ordinal structure of lexical difficulty, and (iii) the ensemble effectively mitigates systematic biases of individual models, leading to more stable performance across difficulty levels.¹

1 Introduction

Vocabulary is a central component of English as a Foreign Language proficiency, supporting the development of reading, listening, writing, and speaking skills (Alshumrani, 2024). Since learners' proficiency levels influence how vocabulary is acquired (Bao and Peng, 2024), estimating lexical difficulty is an important step in the development of level-appropriate learning materials and valid assessment instruments (Goyibova et al., 2025)

Prior work has explored related tasks such as Complex Word Identification, Lexical Difficulty Prediction, and Lexical Simplification (Paetzold

and Specia, 2016b; Yimam et al., 2018; Shardlow et al., 2021). However, they were not tailored for English language learners and ignored how learners' first language (L1) can make English vocabulary easier or harder. This limitation is critical, as vocabulary knowledge is inherently multi-layered and involves several interrelated components that must be acquired for effective language use (Schmitt, 2010).

Among the interrelated components, L1 interference plays a central role across linguistic levels, including grammar, syntax, phonology, and vocabulary, leading to systematic differences in how learners from different L1 backgrounds perceive and process words (Alisoy, 2024). Consequently, lexical difficulty is not an intrinsic property of a word, but a relational phenomenon that varies across L1 backgrounds, motivating the need for L1-aware modeling (Skidmore et al., 2025).

However, learner-specific factors alone are insufficient. The ability to distinguish similar-sounding words does not guarantee successful acquisition or comprehension (Pajak et al., 2016). Therefore, lexical difficulty cannot be reliably inferred from form-level properties alone. Instead, difficulty is shaped by how words are encountered and interpreted in context. Psycholinguistic evidence shows that contextual cues guide meaning interpretation and comprehension (Garten et al., 2019). Effective lexical difficulty modeling should therefore capture both learner-specific and contextual dimensions.

To address these challenges, we propose *Context-Aligned Contrastive Regression*, a multi-objective framework for L1-aware lexical difficulty prediction. Our approach (i) integrates direct regression with Cross-View Context Contrastive Learning to align representations across lexical views, (ii) incorporates Ordinal Soft Contrastive Learning to preserve graded difficulty structure, and (iii) leverages complementary encoder models through Ridge ensembling. Together, these components enable more

robust, aligned, and interpretable difficulty estimation.

2 Background

Recent studies show that transformer-based models can predict lexical difficulty from contextualized and multilingual representations (Shardlow et al., 2021, 2024; Skidmore et al., 2025). These approaches are motivated by the growing importance of lexical complexity prediction in applications such as text simplification, readability assessment, and language learning (Shardlow, 2022; Rotaru, 2021). In particular, shared tasks such as SemEval-2021 have demonstrated that fine-tuned transformer models can achieve strong performance by leveraging contextual information (Shardlow et al., 2021; Rotaru, 2021).

However, most approaches rely on regression-only training, where supervision is given only through a scalar difficulty score. This can improve prediction accuracy, but it does not directly structure the representation space. As a result, items with similar difficulty may not be close in the latent space, while items with different difficulty levels may not be clearly separated. This limitation becomes more pronounced in multilingual settings, where models must capture both cross-lingual alignment and language-specific variation (Skidmore et al., 2025).

Contrastive learning addresses this limitation by shaping representations through relations between examples (Chen et al., 2020; Khosla et al., 2020). This fits lexical difficulty prediction, where difficulty depends on the target word, context, and learner-specific variation. Recent contrastive regression methods define similarity by proximity in continuous target values rather than discrete labels (Zha et al., 2023; Keramati et al., 2024), making them suitable for ordinal difficulty scores. We therefore formulate L1-aware lexical difficulty prediction as a multi-objective problem that combines direct regression with auxiliary contrastive supervision.

3 Context-Aligned Contrastive Regression

Building on recent work in lexical difficulty prediction and L1-aware modeling (Shardlow et al., 2021, 2024; Skidmore et al., 2025), we propose *Context-Aligned Contrastive Regression*, which integrates direct regression with representation-level

contrastive regularization. Given an input instance enriched with L1-aware contextual information, such as translated context and English target information, the model encodes multiple contextual views into a shared representation space. The resulting representation is used for both difficulty prediction and contrastive learning.

Specifically, we optimize the model using Regression loss (§3.1) for direct difficulty prediction, a Cross-View Context Contrastive loss (§3.2) for learning view-invariant contextual representations, and an Ordinal Soft Contrastive loss (§3.3) for encoding the continuous ordering of difficulty scores in the latent space. By combining this, the overall training objective does not merely fit the target score, but also provides a representation space that is both contextually stable and smoothly aligned with the ordinal structure of the task. The general explanation of our system is presented in the Figure 1.

3.1 Regression Objective

The regression objective is used to supervise the final prediction directly. Let $h_i \in \mathbb{R}^d$ denote the shared encoder representation of item i , and let $\hat{y}_i$ denote the scalar prediction generated by the regression head. The model is optimized with the mean squared error:

$$\mathcal{L}_{\text{reg}} = \frac{1}{B} \sum_{i=1}^B (\hat{y}_i - y_i)^2, \quad (1)$$

where y_i is the label associated with item i and B is the batch size.

While this objective provides direct supervision for score prediction, it does not explicitly enforce representation consistency across alternative contextual realizations of the same lexical item, nor does it preserve proximity structure among items with similar difficulty levels. To address these limitations, we introduce two auxiliary contrastive objectives that regularize the representation space with respect to contextual alignment and ordinal difficulty structure.

3.2 Cross-View Context Contrastive Objective

Lexical Difficulty is largely determined by intrinsic properties of the target word rather than by superficial variation in context (Paetzold and Specia, 2016a; Gooding and Kochmar, 2018; Shardlow et al., 2021). However, contextualized encoders can mix lexical information with context-specific cues,

Figure 1: The proposed method combines regression and contrastive auxiliary objective, including cross-view alignment and ordinal-aware representation learning, to learn representations that are aligned across views and difficulty levels. Outputs from multiple encoder models are ensembled using ridge regression to produce the final prediction.

which may produce inconsistent representations for the same lexical item across different contexts.

To reduce this effect, we use a cross-view contrastive objective for lexical difficulty prediction. Unlike standard contrastive learning methods that rely on stochastic augmentations (van den Oord et al., 2019; Chen et al., 2020), our method uses task-specific paired views derived from the L1-aware input and the context-aligned representation described in Section 4.2. This encourages the encoder to learn representations that remain stable across contextual variation while still distinguishing different lexical items (Khosla et al., 2020).

$$z_i^{\text{tgt}} = H(en_tgt_i) \quad (2)$$

$$z_i^{\text{full}} = H(full_input_i) \quad (3)$$

Given a mini-batch of size B , each instance is encoded through two matched views, en_tgt (Eq. 2) and $full_input$ (Eq. 3), yielding $2B$ representations. Since lexical difficulty prediction is formulated as a regression task, positive pairs are defined by cross-view correspondence rather than shared class labels. Thus, each anchor representation z_i is paired with its matched representation from the alternative view. The objective is formalized as

$$\mathcal{L}_{CVCL} = -\frac{1}{2B} \sum_{i=1}^{2B} \log \frac{\exp(z_i^T z_{i+}/\tau)}{\sum_{k=1}^{2B} \mathbf{1}_{[k \neq i]} \exp(z_i^T z_k/\tau)} \quad (4)$$

3.3 Ordinal Soft Contrastive Objective

While the cross-view objective promotes consistency across views, it does not explicitly capture the ordinal structure of lexical difficulty. Since difficulty is represented as a continuous psychometric estimate rather than a discrete class label (Shardlow et al., 2021), items with nearby scores should be closer in representation space than items with distant scores. Standard contrastive objectives rely on instance discrimination or discrete class supervision (Chen et al., 2020; Khosla et al., 2020), while recent regression-oriented contrastive methods address this limitation by organizing representations according to target distance or order (Zha et al., 2023; Keramati et al., 2024; Xue et al., 2024).

Following this motivation, we introduce an ordinal soft contrastive objective that replaces binary pair assignments with continuous pairwise weights derived from score proximity. This allows the model to preserve the graded structure of lexical difficulty in the embedding space. Let u_i denote the representation of item i , and let y_i be its lexical difficulty score. For a batch of size B , we define the affinity between items i and j as

$$w_{ij} = \exp\left(-\frac{(y_i - y_j)^2}{2\sigma^2}\right), \quad w_{ii} = 0, \quad (5)$$

where σ controls how strongly the objective responds to differences in lexical difficulty. Pairs with similar scores receive larger weights, while pairs with distant scores receive smaller weights.

We then define the similarity distribution for anchor u_i over the remaining items in the batch as

$$p_{ij} = \frac{\exp(\text{sim}(u_i, u_j)/\tau)}{\sum_{k \neq i} \exp(\text{sim}(u_i, u_k)/\tau)}, \quad j \neq i, \quad (6)$$

where $\text{sim}(u_i, u_j)$ denotes cosine similarity and τ is a temperature parameter. The ordinal soft contrastive loss is then defined as

$$\mathcal{L}_{\text{OSCL}} = \frac{1}{B} \sum_{i=1}^B \left(-\frac{\sum_{j \neq i} w_{ij} \log p_{ij}}{\sum_{j \neq i} w_{ij}} \right). \quad (7)$$

This objective complements the cross-view contrastive loss by shaping the representation space according to graded difficulty similarity. Items with nearby difficulty scores are encouraged to lie closer together, while items with larger score differences exert weaker attractive force. As a result, the learned embedding space reflects the continuous and ordinal nature of lexical difficulty more faithfully.

3.4 Ridge-Based Ensemble

After training the model with the proposed multi-objective learning framework, we further enhance prediction performance by leveraging an ensemble of models with different encoder backbones. Each model is trained independently using the same objective, resulting in diverse yet complementary predictions.

Let $f_k(x)$ denote the prediction of the k -th model for an input x . We construct a meta-representation by stacking predictions from K models:

$$\mathbf{z}(x) = [f_1(x), f_2(x), \dots, f_K(x)]. \quad (8)$$

We then apply ridge regression to combine these predictions, allowing the model to learn adaptive weights over individual predictors while maintaining robustness through regularization. This approach provides a more flexible alternative to simple averaging and leads to more stable and accurate predictions.

4 Experimental Setup

4.1 Dataset

We perform lexical difficulty prediction as a regression task using the multilingual L1-aware dataset introduced by Skidmore et al. (2025). The data are

organized into three first-language groups, namely German, Spanish, and Mandarin Chinese. Total of each L1 group is presented in Table 1. For the translated training and development splits, we additionally include *en_context*, as described in Section 4.2.

Furthermore, the target variable, *GLMM_score*, represents the estimated difficulty of each vocabulary item. It is computed from large-scale learner response data using a generalized linear mixed model (GLMM) framework, which models both item-level and learner-level variability (Schmitt et al., 2024). Lower scores indicate greater lexical difficulty.

Table 1: Data distribution across L1 groups and splits.

L1 group	Train	Dev	Test
German	6,091	677	748
Spanish	6,091	677	748
Mandarin Chinese	6,091	677	748
Total	18,273	2,031	2,244

4.2 L1-Aware Input Representation

Skidmore et al. (2025) reported that their best-performing setup used a multilingual model trained jointly on all L1 subsets of the KVL together with an L1-aware input representation. Following this formulation, we represent each instance as a single sequence that combines the L1 source word (w), its L1 context (ctx), the English clue ($clue$), and the target English word (tgt). These components are separated by a special token before being passed to a pretrained encoder, as shown in the example input text below:

casa [SEP] Vivo en una casa grande
que tiene tres dormitorios. [SEP]
h_____ [SEP] house

In addition, we construct a context-aligned view by combining the English target word from the source language input (*en_tgt*) with the translated English context (*en_ctx*), which is obtained by translating the source-language context *ctx*.² This augmented view is then used to form contrastive pairs for cvcl objective (§3.2).

²We use google/mt5-large to translate the source-language context.

4.3 Model Architecture

Our model follows a shared-encoder architecture with task-specific heads for regression and contrastive learning. Given an input sequence, the encoder produces a contextualized representation from the [CLS] token, which is then used for both prediction and representation-level objectives.

Projection Head For contrastive learning, we apply a projection head that maps the encoder representation into a lower-dimensional space. The projected representation is used for contrastive objectives. Separating the projection space from the original representation allows the model to preserve task-relevant features for regression while learning more structured representations for contrastive objectives.

Models Setting We use three multilingual encoder models as base learners in the ensemble: XLM-RoBERTa (Conneau et al., 2020), multilingual DeBERTaV3 (He et al., 2023), and mmBERT (Marone et al., 2025). At inference time, predictions from all base learners are combined using a ridge regression meta-model, which learns to aggregate their outputs into a final prediction. The hyperparameters and training settings are reported in Appendix D.

5 Results & Discussion

In this section, we present our main result (see Table 2 and Appendix A for detailed results) along with its observations and discussion. We also provide qualitative examples of analysis across languages, describing the top-5 improved and failure cases in the dataset.

5.1 Main Result

Performance Across Languages Table 2 shows that the ensemble consistently outperforms individual base models across the three L1 groups. These gains suggest that combining input design, auxiliary objectives, and model ensembling provides more robust predictions than relying on a single encoder. Spanish achieves the best performance with the *en_ctx* setting, while German and Chinese benefit more from *en_tgt*-based representations. Rather than indicating instability, this pattern suggests that lexical difficulty is shaped by different linguistic cues across L1 backgrounds. This makes the variation between input settings analytically

meaningful and motivates a deeper examination of model behavior and representation structure.³

Effect of Input and Objective Design A closer comparison of input and objective variants shows that more complex configurations do not always improve performance. Although *full_input* (§4.2) and *en_ctx* + *en_tgt* perform strongly, they do not consistently outperform focused single-view representations, such as *en_tgt* (CVCCCL + OSCL) or *en_context* (CVCCCL + OSCL). This suggests that carefully selected inputs can be more effective than combining all available features, likely by reducing noise and improving representation stability.

At the objective level, CVCCCL + OSCL remains consistently competitive across languages. It does not always achieve the best score, but it stays among the top configurations in each setting. This indicates that contrastive alignment and ordinal supervision provide complementary learning signals, while their effectiveness depends on the structure of the input information.

BEA 2026 Submission We submitted our best model to the BEA 2026 Shared Task Closed Track. Full leaderboard comparisons are provided in Appendix A. Our submission, **TOEBM**, achieved top-15 performance across all L1 groups, ranking 14th for Spanish, 11th for German, and 7th for Mandarin Chinese, as shown in Tables 5, 6, and 7, respectively. This pattern suggests that the proposed approach remains reasonably robust across different L1 backgrounds, even when the relative difficulty cues vary by language. Although its RMSE is about ± 0.125 higher than the top-ranked Glite Team on average, the model maintains competitive Pearson correlation scores across languages, with 0.832 for Spanish and German, and 0.853 for Mandarin Chinese. These results indicate that, while the model is not yet fully optimized for minimizing prediction error, it captures the relative ordering of lexical difficulty effectively.

5.2 Representation Analysis

To better understand the impact of the contrastive objectives, we analyze the learned representations beyond the final prediction layer. In particular, we examine whether the contrastive losses improve cross-lingual alignment (§3.2) and preserve the ordinal structure of lexical difficulty (§3.3) across

³The Ensemble Baseline combines the XLM-R, mDeBERTa-v3, and mmBERT baseline models using ridge regression.

Table 2: Performance comparison with RMSE, MSE, and Spearman’s ρ across languages and models in the BEA shared task test set. Individual model denotes fine-tuned model with regression head on top of the architecture and *full_input* or L1-aware input representation §4.2 as model input. Lower RMSE/MSE and higher ρ indicate better performance.

Figure 2: Representation analysis across Spanish, German, and Chinese using mmBERT-base. (a) Cosine similarity between aligned cross-lingual lexical pairs and randomly paired inputs. (b) Relationship between embedding distance and absolute lexical difficulty score differences, larger score gaps correspond to greater representational separation.

multiple languages.

Cross-lingual Representation Alignment We first examine whether the contrastive objective leads to improved cross-lingual alignment in the learned representations. To this end, we measure cosine similarity between representations of semantically equivalent inputs (L1 and English) and compare them against randomly paired inputs.⁴ As shown in Figure 2a, aligned pairs consistently exhibit higher similarity than random pairs across all three languages (ES, DE, and CN), indicating that the model learns a shared semantic space across languages.

Notably, the degree of separation varies across languages, with German showing the clearest gap, while Chinese exhibits greater variance and over-

lap. The presence of overlap between the two distributions suggests that the alignment is not fully separable. This indicates that while the contrastive objective contributes to reducing cross-lingual representation gaps, it does not enforce strict alignment. We hypothesize that this moderate alignment is beneficial, as it preserves language-specific nuances that may still be relevant for lexical difficulty prediction.

Ordinal Structure in Representation We next analyze whether the learned representations capture the ordinal nature of lexical difficulty. Specifically, we examine the relationship between embedding distances and differences in GLMM scores⁵. As shown in Figure 2b, we observe a clear and consistent increasing trend across all three languages, where pairs of instances with larger difficulty differences exhibit greater distances in the embedding space.

We further quantify this trend using Spearman’s rank correlation. We observe a consistent positive monotonic relationship across all three languages (Spearman’s $\rho = 0.22$ for ES, 0.20 for DE, and 0.39 for CN), indicating that embedding distances tend to increase with larger differences in lexical difficulty. While the correlation is moderate in magnitude, its consistency across languages suggests that the ordinal structure is reliably encoded in the learned representations, although the relationship is not strictly linear.

⁴The details of measurement technique is presented in Appendix F.

⁵The details of measurement technique is presented in Appendix E

Condition	Low	High	Rel. ↓ (%)
Context Length	0.841	0.834	0.8
Lexical Diversity	0.847	0.837	1.2
Target Word Length	0.843	0.831	1.4
Orthographic Complexity	0.855	0.813	4.9

Table 3: Mean absolute error (MAE) of the Ridge ensemble across input characteristics on the Spanish dataset. Relative improvement (%) measures the reduction from low to high condition. Lower values indicate better performance.

Input Representation Behavior Beyond representation structure, we further investigate how input characteristics influence prediction behavior. Specifically, we analyze prediction error with respect to several surface-level input properties, including context length, lexical diversity (measured via type-token ratio), target word length, and orthographic complexity. We observe a generally consistent pattern in which richer contextual and lexical signals are associated with lower prediction error. In particular, longer and lexically more diverse contexts, as well as more orthographically informative target words, tend to improve prediction quality, suggesting that contextual and lexical richness provide useful signals for lexical difficulty modeling.

However, the strength of this effect varies across languages. As shown in Table 3, for Spanish, the improvements are more pronounced, especially in lexically diverse contexts and orthographically complex words, which exhibit the largest relative gain. This indicates that Spanish benefits more from contextualized representations, explaining why the *en_ctx* configuration outperforms target-only inputs in this setting. In contrast, for other languages, the gains from context are less dominant, suggesting that target-side information can be sufficient depending on the dataset characteristics. This finding is consistent with the representation-level analysis, where contextual signals contribute to richer and more structured embeddings, which in turn improve downstream prediction.

5.3 Ensemble Investigation

We analyze the contribution of each base model to the meta-input of the Ridge regression ensemble. This analysis aims to assess how well individual models approximate the GLMM scores and whether they provide complementary prediction patterns that can be effectively leveraged by the ensemble.

Base Models Prediction Behaviour Figure 3 illustrates the relationship between predicted scores and ground truth GLMM scores across all three L1 groups. The models exhibit systematic differences in how lexical difficulty is estimated. XLM-RoBERTa consistently produces a relatively flat trend, particularly in the Chinese dataset, indicating a tendency to compress predictions toward the mean and underestimate more difficult items. In contrast, mDeBERTa-v3 shows a steeper slope, often overshooting the ground-truth line, suggesting systematic overestimation for complex lexical items. Meanwhile, mmBERT demonstrates a more moderate slope that more closely follows the optimal diagonal trend, indicating a more balanced estimation behaviour.

Statistical Patterns These contrasting trends reveal that the base models capture different aspects of the lexical difficulty space. While XLM-RoBERTa tends to under-predict and mDeBERTa-v3 tends to over-predict, mmBERT produces more balanced predictions with errors closer to zero and generally competitive variance. This complementary behavior is further reflected in the trade-off between correlation and error metrics, where mDeBERTa-v3 often achieves higher Pearson correlation while mmBERT attains lower RMSE and MAE in several cases.

When considered alongside the statistical results in Table 8 (Appendix), these findings suggest that the models are not redundant but instead provide diverse and complementary signals. Such diversity is crucial for the effectiveness of the ensemble, as it enables the meta-learner to reconcile systematic biases and produce more accurate final predictions.

Difficulty-wise Error Analysis To further evaluate ensemble effectiveness across the lexical difficulty spectrum, we analyze model errors over five GLMM-based difficulty bins averaged across all three L1 groups. Figure 4 presents the resulting mean absolute error (MAE) patterns.

We observe that XLM-RoBERTa exhibits a substantial increase in error from harder to easier lexical items, indicating that its predictions become progressively less reliable for comparatively easier words and suggesting strong score compression effects. Similarly, mmBERT demonstrates moderate but consistent error growth toward easier bins, although its overall performance remains more balanced than XLM-RoBERTa. In contrast, mDeBERTa-v3 maintains relatively stable perfor-

Figure 3: Relationship between predicted scores and ground-truth GLMM scores across Spanish (ES), German (DE), and Chinese (CN). Each subplot shows regression trends for individual base models, highlighting systematic differences in prediction behavior, including underestimation, overestimation, and balanced estimation patterns.

mance across the full spectrum, with only minor variation between difficulty levels.

Importantly, the Ridge ensemble consistently achieves the lowest or near-lowest MAE across nearly all bins while maintaining the flattest error profile overall. This suggests that the meta-learner effectively reconciles the complementary weaknesses of individual base models, substantially reducing systematic prediction bias and producing more stable lexical difficulty estimation across both harder and easier lexical items.

Figure 4: Mean absolute error (MAE) across lexical difficulty bins, averaged over all three L1 groups. Difficulty bins are derived from GLMM score quantiles and ordered from harder (lower GLMM scores) to easier (higher GLMM scores) lexical items.

5.4 Improved vs Failures Cases

To complement the quantitative findings in Section §5.1, we further examine representative cases to understand how the ensemble model corrects prediction errors from individual base models.

Error Correction Table 4 presents selected examples across Spanish, Chinese, and German. We observe that the ensemble consistently corrects

Lang	Word	GLMM	mmBERT	Ridge
ES	cruise	1.21	-0.50	1.23
ES	run	2.20	0.31	1.99
ES	character	1.08	-1.11	0.55
ES	dining	-4.67	-0.76	0.19
ES	baking	-3.78	-0.20	0.87
CN	schoolmate	1.32	-2.55	-0.09
CN	dating	0.64	-2.31	-0.001
CN	goldfish	1.51	-1.44	0.63
CN	double	-2.58	0.11	0.82
CN	stake	-4.19	-1.67	-1.13

DE	handbook	0.95	-1.36	0.31
DE	workbook	2.10	-2.07	-0.44
DE	anger	-3.39	0.10	0.57
DE	umbrella	3.24	-1.13	-0.20

Table 4: Qualitative examples across Spanish (ES), Chinese (CN), and German (DE), comparing mmBERT-base and Ridge ensemble predictions. The first three rows per language show cases where the ensemble corrects large underestimation errors from base models, while the last two rows highlight failure cases.

large underestimation errors from individual models. For instance, words such as *cruise*, *run*, and *character* in Spanish, as well as *schoolmate* and *dating* in Chinese, are substantially underestimated by mmBERT, yet the Ridge ensemble successfully adjusts their predictions toward the ground-truth GLMM scores. Similar correction patterns are observed in German, suggesting that the ensemble effectively leverages complementary signals across models to reduce systematic bias.

Failure Cases Despite these substantial improvements, certain lexical items remain challenging even after ensembling. In several cases, such as *dining* and *baking* in Spanish, *double* and *stake* in

Chinese, and *anger* and *umbrella* in German, the predicted difficulty remains far from the ground-truth values. These errors often involve strong overestimation or residual bias, indicating that certain lexical items remain challenging due to semantic ambiguity or context-dependent interpretations. This suggests that while the ensemble mitigates systematic biases, it cannot fully resolve cases where all base models fail to capture the underlying difficulty signal.

6 Conclusion

Our method consistently outperforms individual multilingual encoders across Spanish, German, and Chinese learner groups, effectively correcting systematic under- and overestimation biases while maintaining stable performance across all difficulty levels. Representation analysis confirms that the contrastive objectives enhance cross-lingual alignment and preserve the ordinal structure of lexical difficulty in the embedding space. Collectively, these results demonstrate that combining direct regression with representation-level regularization significantly improves both the accuracy and structural reliability of L1-aware lexical difficulty prediction.

Acknowledgments

The authors gratefully acknowledge Mantera Studio for providing the computational resources and APIs utilized in this research. Additionally, this work was partially supported by the 2026 Publication Funding from the Department of Computer Science and Electronics at Universitas Gadjah Mada.

Limitations

Although the proposed method improves performance across the evaluated L1 groups, several limitations remain. First, the experiments are limited to Spanish, German, and Mandarin Chinese, so the findings may not fully generalize to other L1 backgrounds. Second, the use of contrastive objectives introduces additional training objectives and weighting hyperparameters, which may increase sensitivity to objective balancing across languages. Third, the ridge ensemble improves predictive performance by combining multiple encoders, but it also increases computational cost because several models must be trained and evaluated. Future work should examine more robust weighting strategies, reduce the computational overhead of ensembling,

and evaluate the method on a wider range of L1 backgrounds.

Ethical Considerations

We acknowledge that our research utilized AI tools for writing, rewriting, and generating code. Although these tools offer significant advantages in terms of efficiency and productivity, their use raises important ethical considerations. We recognize the potential for bias and errors inherent in AI-generated content and have taken steps to mitigate these risks through rigorous human review and validation. Furthermore, we are mindful of the potential impact on the broader software development community, particularly regarding job displacement and the need for upskilling. We believe that responsible AI integration should prioritize transparency, accountability, and the empowerment of human developers, ensuring that these tools augment rather than replace human expertise. This research aims to contribute to the ongoing dialogue on ethical AI development and usage, advocating for a future where AI tools are harnessed responsibly to enhance human creativity and innovation in the field of software engineering.

A BEA 2026 Leaderboard Comparison

Table 5, Table 6, and Table 7 present selected leaderboard comparisons for the Spanish, German, and Chinese subtasks, respectively. Rather than listing the complete leaderboard, we report the highest-ranked systems and nearby reference systems to contextualize our submission. Our team is registered as **TOEBM**. In the closed-track results, TOEBM ranked 14th for Spanish, 11th for German, and 7th for Chinese, with RMSE scores of 1.063, 0.997, and 0.880, respectively. The leaderboard scores differ slightly from those reported in the main experimental section because the present paper uses a unified prompt setting across all subtasks, while the official leaderboard reflects the submitted prediction files. Nevertheless, the relative ranking of our submission remains unchanged.

B Base Model Statistic

C Representation analysis

To analyze the learned representation space, we distinguish between the Ridge ensemble used for prediction and the fused embedding used for visualization. The Ridge ensemble prediction is defined as

$$\hat{y}(x) = b + \sum_{n=1}^N w_n f_n(x), \quad (9)$$

where $f_n(x)$ denotes the scalar prediction produced by the n -th base model, w_n is the learned Ridge coefficient for that model, and b is the intercept. This formulation is used only for final score prediction. It is not suitable for direct t-SNE visualization because it produces a one-dimensional output.

For representation analysis, we instead construct a fused embedding by concatenating the weighted embedding vectors from each base model:

$$z(x) = [w_1 E_1(x); w_2 E_2(x); \dots; w_N E_N(x)], \quad (10)$$

where $E_n(x) \in \mathbb{R}^{d_n}$ is the embedding produced by the n -th encoder. In this study, $E_n(x)$ is obtained from the CVCCL+OSCL model using the *en_tgt* view as the encoder input. The Ridge coefficients are then used as model-level weights to scale each embedding before concatenation.

We apply t-SNE to the fused representation $z(x)$ to visualize the structure of the embedding space. The resulting points are grouped into five difficulty bins based on the minimum and maximum GLMM scores. This allows us to inspect whether examples with similar lexical difficulty are located close to one another in the representation space, while the Ridge ensemble prediction $\hat{y}(x)$ is used separately to evaluate predictive performance. Figure 5 shows that the separation across difficulty bins is generally strong, although the quality of the structure varies across models and languages. Since GLMM is a continuous score and the bins are created only for visualization, perfect discrete clusters are not

Metrics	Español			Deutsch			Chinese

The visualization is based on the weighted concatenation of encoder embeddings, while $\hat{y}(x)$ is used separately for predictive evaluation.

expected. Even so, a clear ordinal organization is visible in many panels, where neighboring regions are dominated by adjacent difficulty bins and the progression from lower to higher difficulty appears smooth.

Among the individual encoders, mdeberta-v3-base often produces well-separated local clusters, especially in Spanish and German, indicating that the learned space captures meaningful difficulty structure. mmBERT-base also shows some ordering, but the bins are more mixed and the boundaries between difficulty levels are less distinct. In contrast, xlm-roberta-base provides the clearest structure for Mandarin Chinese. In

the Chinese panel, the bins are arranged along a highly organized manifold with a very strong gradual transition from easier to harder examples. This suggests that xlm-roberta-base captures the ordinal nature of lexical difficulty particularly well for Mandarin Chinese.

The Ridge-weighted fused representation remains competitive and in some cases preserves a smooth global arrangement of the bins, showing that the ensemble combines complementary information from the base encoders. However, the clearest single-model structure for Mandarin Chinese is produced by xlm-roberta-base. Overall, these visualizations support the claim that the

CVCCCL+OSCL representations encode lexical difficulty in a meaningful way, with strong separation between bins and especially clear ordinal structure in the Mandarin Chinese setting.

D Training Settings

All models are trained using the Adam optimizer for 5 epochs with a learning rate of $2e-5$, a batch size of 8, weight decay of 0.01 , and a warmup ratio of 0.06 . The best model is selected based on the Mean Squared Error (MSE) on the validation set. The maximum input length is set to 128 tokens, while the maximum length for `en_context` is limited to 32 tokens. Furthermore, we set $\lambda_{cv} = 0.1$ and $\lambda_{ord} = 0.2$. The temperature parameter τ is set to 0.01 and 0.02 for the `cvcc1` and `oscl` losses, respectively.

For the Ridge regression meta-model, we consider a set of candidate regularization parameters $\alpha \in \{0.01, 0.1, 1.0, 10.0, 100.0\}$ and select the best value via cross-validation. Finally, We use Root Mean Squared Error (RMSE) as the primary metric for system ranking and report Pearson correlation for completeness.

E Ordinal Structure Analysis Details

To quantitatively assess whether the learned representations preserve the ordinal structure of lexical difficulty, we analyze the relationship between embedding distances and differences in ground-truth difficulty scores. Given a set of instances $\{(x_i, y_i)\}_{i=1}^N$, where y_i denotes the GLMM difficulty score, we first obtain normalized sentence embeddings $\mathbf{h}_i \in \mathbb{R}^d$. For a sampled subset of size N' , we compute all pairwise cosine distances:

$$d_{ij} = 1 - \frac{\mathbf{h}_i \cdot \mathbf{h}_j}{\|\mathbf{h}_i\| \|\mathbf{h}_j\|}$$

and corresponding absolute difficulty differences:

$$\Delta_{ij} = |y_i - y_j|.$$

We then group instance pairs into K bins based on quantiles of Δ_{ij} and compute the mean embedding distance within each bin. This results in a function $f(k)$ that maps increasing difficulty differences to average embedding distances. A monotonically increasing trend in $f(k)$ indicates that the representation space is structured according to difficulty.

F Cross-lingual Alignment Analysis Details

To evaluate whether the learned representations capture cross-lingual semantic alignment, we measure the cosine similarity between representations of semantically corresponding inputs across languages. For each instance x_i , we construct two views: an L1-based input and its corresponding English-based input. We then obtain normalized embeddings $\mathbf{h}_i^{L1}$ and $\mathbf{h}_i^{EN}$ using the encoder.

We define the similarity of aligned pairs as:

$$s_i^{\text{aligned}} = \mathbf{h}_i^{L1} \cdot \mathbf{h}_i^{EN},$$

and construct a baseline by randomly permuting the English representations to obtain mismatched pairs:

$$s_i^{\text{random}} = \mathbf{h}_i^{L1} \cdot \mathbf{h}_{\pi(i)}^{EN},$$

where $\pi(i)$ is a random permutation. By comparing the distributions of s^{aligned} and s^{random} , we assess whether the model places semantically corresponding inputs closer in the embedding space than unrelated ones.

Data Asgardians at BEA 2026 Shared Task 1: A Hybrid Transformer–Feature Ensemble for L1-Aware English Vocabulary Difficulty Prediction

Abstract

This paper presents our system for the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners (Felice and Skidmore, 2026). The task requires predicting psychometrically calibrated GLMM difficulty scores for English vocabulary items across three learner first-language (L1) backgrounds: Spanish (ES), German (DE), and Mandarin Chinese (CN). Our approach studies how hand-crafted linguistic features can complement contextual multilingual transformer representations. We engineer 33 phonological, morphological, semantic, contextual, and cross-lingual features, and evaluate feature-only regressors, Solo transformer models, Hybrid transformer models, and prediction-level ensembling. Our official Closed Track submissions were generated with XLM-RoBERTa-large Solo and Hybrid models, which improved over the official baseline for all three L1 groups, achieving test RMSEs of 1.182 (ES), 1.117 (DE), and 1.006 (CN) with a mean of 1.103. We then conducted a post-submission refinement using mDeBERTa-v3-base components and a Ridge stacking ensemble, which further reduced test RMSE to 1.037 (ES), 0.997 (DE), and 0.913 (CN), with a mean of 0.982, a mean improvement of 0.121 over our best XLM-RoBERTa-large system.

1 Introduction

Predicting the difficulty of English vocabulary items for second-language learners has direct applications in adaptive assessment, personalised content generation, and computer-adaptive testing. In educational measurement, item difficulty is commonly estimated with Generalised Linear Mixed Models (GLMM) (Baayen et al., 2008), which provide reliable psychometric calibration from learner response data. However, this process is costly to scale, since each new item bank typically requires extensive response collection. The

BEA 2026 Shared Task on Vocabulary Difficulty Prediction (Felice and Skidmore, 2026) addresses this limitation by framing difficulty estimation as a supervised NLP task over the British Council’s Knowledge-based Vocabulary Lists (KVL) (Skidmore et al., 2025), a multilingual resource that conditions vocabulary difficulty on the learner’s first language (L1).

Recent lexical complexity systems commonly fine-tune pre-trained language models directly on the regression objective (Shardlow et al., 2021). While effective, this approach may underuse linguistic factors known to shape vocabulary acquisition, such as frequency, phonological complexity, polysemy, morphological structure, and the distance between English and the learner’s L1 (Laufer and Goldstein, 2004). These factors suggest that L1-aware difficulty prediction should benefit from combining contextual transformer representations with explicit linguistic features.

Our system follows this feature-aware modelling perspective. We combine contextual multilingual representations with 33 engineered features covering phonological, morphological, semantic, contextual, and cross-lingual properties. Our official Closed Track submissions were based on XLM-R Large Solo and Hybrid models. We then developed a refined post-submission system based on mDeBERTa-v3-base, feature-only regressors, and a cross-validated Ridge stacking ensemble.

This paper makes three contributions. First, we present an L1-aware system for vocabulary difficulty prediction that integrates multilingual transformer representations with linguistically motivated features. Second, we compare feature-only regressors, Solo transformers, Hybrid feature-augmented transformers, and prediction-level ensembling across Spanish, German, and Mandarin Chinese. Third, we show that the strongest performance among our systems is obtained through prediction-level stacking, indicating that comple-

mentary model signals are more effective than relying on a single transformer or on direct feature concatenation alone.

2 Task and Data

The task data come from the Extended KVL Dataset (Skidmore et al., 2025), which provides GLMM-calibrated difficulty scores for English vocabulary items across three L1 backgrounds: Spanish (ES), German (DE), and Mandarin Chinese (CN). Each instance includes the English target word, its part of speech, a letter-based clue, an L1 translation, and an L1 context sentence. GLMM scores are continuous logit values, with higher values indicating easier items.

Table 1 shows representative examples across the three L1 groups, including the clue format, translation, context, and difficulty score.

As shown in Table 2, the dataset is balanced across L1 groups, with 6,091 training instances, 677 development instances, and 748 test instances per language. The Closed track restricts systems to the provided data and standard NLP tools, while the Open track allows external resources. Systems are ranked by RMSE, with Pearson’s r used as a secondary metric.

3 Related Work

The BEA 2026 Shared Task on vocabulary difficulty prediction (Felice and Skidmore, 2026) frames item difficulty estimation as a supervised regression problem over psychometrically calibrated GLMM scores. Unlike general lexical complexity benchmarks, the task requires predicting difficulty across multiple learner first-language (L1) groups, making the problem dependent not only on the English target word and its context, but also on cross-linguistic effects between English and the learner’s L1.

Recent lexical complexity systems have largely relied on pre-trained transformer models. In the SemEval-2021 shared task, Shardlow et al. (2021) showed that fine-tuned contextual models are strong predictors of lexical complexity, while traditional lexical features, especially frequency-based ones, can still provide complementary signal.

For L1-aware vocabulary difficulty, however, linguistic and psycholinguistic factors remain important. Prior work shows that word length, phonological similarity, morphological complexity, and related form-based properties affect vocabulary learn-

ing beyond frequency alone (Laufer and Goldstein, 2004). This suggests that difficulty is not only a property of the target word, but also of its relationship to the learner’s linguistic background.

Our work follows this perspective by combining contextual transformer representations with explicit phonological, morphological, semantic, and cross-lingual features. This hybrid setting allows the model to capture both usage-dependent difficulty and L1-specific signals under the limited-data conditions of the shared task.

4 Exploratory Data Analysis

Before modelling, we examine the GLMM target distribution and its structure across L1 groups under the Closed Track setting. This analysis informs two design choices: using linguistically motivated features, and modelling each L1 separately while still exploiting shared difficulty patterns.

Fig. 1 shows that GLMM scores are approximately symmetric and centred near zero for Spanish, German, and Mandarin Chinese, suggesting no major distributional imbalance across L1 groups. The distributions are similar overall, but differ slightly in dispersion (CN $\sigma \approx 1.26$, ES $\sigma \approx 1.43$, DE $\sigma \approx 1.38$), with Mandarin more concentrated and Mandarin/German showing more pronounced negative outliers.

We also find strong correlations for identical items across L1 groups (ES–DE: $r \approx 0.85$; ES–CN: $r \approx 0.78$; DE–CN: $r \approx 0.80$), indicating a shared global difficulty component. However, the remaining L1-specific variation motivates separate per-L1 models and feature engineering that captures cross-linguistic effects. Together, these observations support the hybrid modelling strategy developed in the following sections.

5 Feature Engineering

Motivated by the EDA findings, we design 33 linguistically informed features to capture both shared and L1-specific sources of vocabulary difficulty. The features are derived from WordNet (Miller, 1995), the CMU Pronouncing Dictionary (Carnegie Mellon University, 2014), and PHOIBLE (Moran and McCloy, 2019). Table 3 summarizes the resulting feature groups.

The feature set is organized into four complementary groups:

- **Phonological features** capture English pronunciation complexity, including consonant

L1	Target	POS	Clue	L1 translation	Context	GLMM
ES	<i>span</i>	noun	s__	lapso	El eclipse solar fue visible durante un breve ...	-3.264099
ES	<i>radically</i>	adverb	r_____	fundamentalmente	Los métodos nuevos son fundamentalmente difere...	-1.871782

Table 1: Representative Extended KVL items across Spanish, German, and Mandarin Chinese. Higher GLMM values indicate easier items.

Figure 1: GLMM difficulty score distributions by L1 (training set).

L1	Train	Dev	Test
Spanish (ES)	6,091	677	748
German (DE)	6,091	677	748
Mandarin (CN)	6,091	677	748
Total	18,273	2,031	2,244

Table 2: Extended KVL dataset split sizes per L1.

clusters, word-final clusters, rhoticity, silent letters, and spelling-to-phoneme mismatch. The feature *r_count* counts /r/ phonemes in the CMU pronunciation, not occurrences of

the orthographic character *r*.

- **L1-specific phonological features** encode whether the English target contains sounds or graphemic patterns that may be absent or difficult for a given learner L1. For example, *difficult_phonemes* counts English phonemes not present in the learner’s L1 inventory according to PHOIBLE.
- **Semantic and morphological features** represent lexical properties from WordNet, including polysemy, homonymy, hypernym depth,

Category	#	Features	Source
Phonological	7	n_consonant_clusters, max_cluster_length, final_cluster_size, r_count, has_r, silent_letters, spelling_phoneme_ratio	CMU Dict
L1-specific phonological	5	difficult_phonemes, has_unfamiliar, has_diphthong, primary_stress_pos, has_l1_flag	PHOIBLE
Semantic & morphological	8	polysemy_pos, polysemy_all, is_homonym, homonym_pos_count, min_sense_depth, morphological_complexity, word_family_size, word_frequency	WordNet
Cross-lingual & contextual	13	cosine_dist_l1_en, clue_ratio, source_word_length, source_word_count, context_char_length, shared_prefix_len, pos_adjective, pos_adverb, pos_determiner, pos_misc, pos_noun, pos_number, pos_preposition, pos_verb	Text / WordNet
Total	33	25 numerical + 8 POS one-hot	–

Table 3: Engineered feature groups and sources. `cosine_dist_l1_en` is a character bigram Jaccard distance between the L1 form and the English target.

morphological complexity, word family size, and lemma frequency. These features approximate how semantically broad, frequent, or morphologically complex a target word is.

- **Cross-lingual and contextual features** describe the relation between the English target and the L1-side information. This includes `cosine_dist_l1_en`, implemented as character bigram Jaccard distance between the L1 translation and the English target, as well as clue ratio, source-word length, context length, shared prefixes, and POS indicators. The feature `clue_ratio` is defined as the proportion of orthographic characters of the English target that are revealed by the letter-based clue, i.e., the ratio between the number of revealed characters (non-underscore positions) and the total length of the target word. Higher values correspond to more informative clues and, empirically, to easier items (see Table 4).

To reduce redundancy, we compute pairwise Pearson correlations among candidate features on the training set. For any pair with $|r| > 0.85$, we remove the feature with the lower absolute correlation with the GLMM target. This process yields the final 33-feature set with no remaining pair above the collinearity threshold.

Table 4 reports the strongest feature–target correlations. `clue_ratio` and `word_frequency` are the most predictive global features, while the per-L1 values show that feature relevance varies across learner backgrounds. Figure 2 extends this analysis to all 33 features, highlighting both globally predictive signals and L1-specific variation.

6 System Architecture

Our official Closed-track prediction files were generated with XLM-RoBERTa-large Solo and Hybrid

Feature	Global	ES	DE	CN
<code>clue_ratio</code>	−0.381	−0.350	−0.353	−0.449
<code>word_frequency</code>	0.314	0.237	0.233	0.488
<code>source_word_length</code>	−0.253	−0.217	−0.311	−0.338
<code>primary_stress_pos</code>	−0.247	−0.216	−0.258	−0.271
<code>cosine_dist_l1_en</code>	−0.246	−0.271	−0.352	0.060

Table 4: Top-5 features by absolute Pearson r with the GLMM difficulty score, computed globally and per L1 on the training set.

models. We then explored whether a smaller multilingual encoder, combined with structured linguistic features and prediction-level ensembling, could improve performance. The refined system is built around mDeBERTa-v3-base and combines four learners through a cross-validated Ridge stacking ensemble (Wolpert, 1992): (i) a Solo transformer, (ii) a Hybrid transformer, (iii) an Optuna-tuned XGBoost regressor, and (iv) a Ridge regressor. We treat this ensemble as the primary system and report XLM-R Large as the official-submission reference.

6.1 Training Protocol

All systems follow the official train/development/test splits (Table 2) and are trained independently for each L1 group (ES, DE, CN), following the L1-specific variation observed in Section 4. Model development follows two phases. First, models are trained on the official training set and selected on the development set using RMSE, with Pearson’s r as a secondary metric. This phase is also used for hyperparameter search and, in the stacking ensemble, for selecting the Ridge meta-learner’s regularisation strength α using 5-fold out-of-fold RMSE. Second, the selected configuration is retrained on train+dev

Figure 2: Pearson r between each engineered feature and the GLMM score (training set), computed globally and per L1.

and applied to the test set.

For the Solo and Hybrid transformer variants, we use the same per-L1 grid: learning rate $\{5 \times 10^{-6}, 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}\}$, weight decay $\{0.01, 0.05, 0.10\}$, dropout $\{0.10, 0.15\}$,

and epochs $\{3, 5, 7, 8, 10\}$. This produced 42 mDeBERTa-v3-base runs and 33 XLM-R Large runs. The selected configurations are shown in Table 5. Feature-only XGBoost and Ridge models were tuned with Optuna as described in Sec-

tion 6.4. All transformer experiments were run on rented Google Colab GPU compute, mainly NVIDIA A100 40GB when available, requiring approximately 200 GPU hours.

Encoder	L1	Model	lr	wd	drop	ep
mDeBERTa-base	ES	Solo	3×10^{-5}	0.05	0.10	5
	ES	Hybrid	1×10^{-5}	0.10	0.15	5
	DE	Solo	1×10^{-5}	0.05	0.10	7
	DE	Hybrid	1×10^{-5}	0.10	0.15	5
	CN	Solo	1×10^{-5}	0.10	0.15	10
	CN	Hybrid	2×10^{-5}	0.05	0.10	3
XLM-R Large	ES	Solo	2×10^{-5}	0.01	0.10	8
	ES	Hybrid	5×10^{-6}	0.10	0.15	5
	DE	Solo	1×10^{-5}	0.05	0.10	10
	DE	Hybrid	1×10^{-5}	0.01	0.10	5
	CN	Solo	2×10^{-5}	0.01	0.10	8
	CN	Hybrid	1×10^{-5}	0.05	0.10	5

Table 5: Best hyperparameter configuration per encoder, L1, and model type (Solo vs. Hybrid), selected on the development set. lr: learning rate; wd: weight decay; drop: dropout rate; ep: training epochs.

6.2 Solo Transformer

We evaluate two multilingual encoders: XLM-RoBERTa-large (Conneau et al., 2020), used in the official submission, and mDeBERTa-v3-base (He et al., 2023), used in the refined system. Both models are used in their publicly released pre-trained form, without intermediate task-adaptive pre-training, and are fine-tuned under the same protocol. Hyperparameters are selected independently per L1 (Table 5).

Each encoder is paired with a regression head over the first-token representation of the last hidden layer:

$$\mathbf{h} = \mathbf{H}_{[0]}, \quad \hat{y} = \mathbf{W} \text{Dropout}(\mathbf{h}), \quad (1)$$

where $\mathbf{H} \in \mathbb{R}^{|T| \times d}$ denotes the sequence of last-layer hidden states. The input concatenates the L1-SOURCE-WORD, L1-CONTEXT, EN-TARGET-CLUE, and EN-TARGET-WORD, tokenised with the encoder’s native SentencePiece tokeniser using a maximum length of 192. This format allows the model to jointly attend to the L1 context and the English target information.

6.3 Hybrid Transformer

The Hybrid model augments the transformer representation $\mathbf{h}$ with a 33-dimensional linguistic feature vector $\mathbf{f}$, using median imputation for missing

values. The concatenated representation is passed through a two-layer MLP:

$$\hat{y} = \mathbf{W}_2 \text{Dropout}(\phi(\mathbf{W}_1 \text{Dropout}([\mathbf{h}; \mathbf{f}]))) , \quad (2)$$

with $\mathbf{W}_1 \in \mathbb{R}^{256 \times (d+33)}$ and $\mathbf{W}_2 \in \mathbb{R}^{1 \times 256}$. The hidden size is $d = 768$ for mDeBERTa-v3-base and $d = 1024$ for XLM-R Large. We use GELU for mDeBERTa-v3-base and ReLU for XLM-R Large.

Both encoders are fine-tuned with AdamW, mixed-precision training (fp16), a linear-warmup and linear-decay schedule with a 10% warmup ratio, gradient clipping at 1.0, and an MSE objective. Learning rate, weight decay, dropout, and number of epochs are tuned per L1.

6.4 Feature-Only Regressors

We also train XGBoost (Chen and Guestrin, 2016) and Ridge regression models directly on the 33 engineered linguistic features. Both are trained independently per L1, using median imputation; Ridge additionally uses standardisation. Hyperparameters are selected with Optuna (Akiba et al., 2019), using 150 trials per L1 for XGBoost and 100 trials per L1 for Ridge. These models serve both as ensemble components and as feature-only baselines.

6.5 Ridge Stacking Ensemble

The refined system combines the four mDeBERTa-v3-base components: Solo ($\hat{y}_S$), Hybrid ($\hat{y}_H$), XGBoost ($\hat{y}_X$), and Ridge ($\hat{y}_R$). For each L1, a Ridge meta-learner combines their predictions:

$$\hat{y}_{\text{ens}} = \mathbf{w}^\top [\hat{y}_S, \hat{y}_H, \hat{y}_X, \hat{y}_R], \quad (3)$$

with non-negative weights ($w_i \geq 0$). The regularisation strength α is selected from 40 logarithmically spaced values in $[10^{-2}, 10^3]$ using 5-fold out-of-fold RMSE on the development set. The meta-learner is then refit on the full development set and applied to the test set. The XLM-R Large reference systems are not included in this ensemble and are reported separately. The full training protocol, including the two-phase train+dev re-training scheme and the grid search ranges shared with the Solo and Hybrid models, is described in Section 6.1.

7 Results

Table 6 reports our official Closed Track submissions. All submitted runs used XLM-R Large and

Lang.	Run	Pos.	RMSE	Pear.	Δ RMSE
<i>Spanish</i> – Baseline RMSE = 1.257 $r = 0.765$					
ES	Solo (tuned)	33/59	1.182	0.820	+0.075
ES	Hybrid (tuned)	34/59	1.186	0.825	+0.071
ES	Solo (base)	35/59	1.190	0.814	+0.067
<i>German</i> – Baseline RMSE = 1.258 $r = 0.773$					
DE	Hybrid (tuned)	26/56	1.117	0.830	+0.141
DE	Solo (base)	35/56	1.140	0.829	+0.118
DE	Solo (tuned)	40/56	1.177	0.822	+0.081
<i>Chinese</i> – Baseline RMSE = 1.140 $r = 0.753$					
CN	Hybrid (tuned)	26/51	1.006	0.854	+0.134
CN	Solo (tuned)	28/51	1.008	0.850	+0.132
CN	Solo (base)	29/51	1.013	0.842	+0.127

Table 6: Official Closed Track test results. Positive Δ RMSE indicates improvement over the baseline; bold marks the best value per L1 group.

improved over the official baseline for the three L1 groups. The largest gains were obtained for German and Chinese, where the Hybrid model achieved the best official RMSE. For Spanish, the Solo model was slightly stronger.

Table 7 compares the official systems with the post-submission refinements and includes development-set RMSE. The XLM-R Large Hybrid model was the strongest single model on development, but the mDeBERTa stacking ensemble achieved the lowest RMSE on both development and test. On the test set, the ensemble obtained 1.037 for Spanish, 0.997 for German, and 0.913 for Chinese, reducing the mean RMSE from 1.103 for the best official XLM-R Large system to 0.982.

Feature-only models did not outperform the baseline, despite the correlations reported in Table 4. This suggests that features such as `clue_ratio`, `word_frequency`, `source_word_length`, and `primary_stress_pos` capture useful but incomplete signal. Transformer models provided stronger contextual representations, while prediction-level stacking benefited from combining transformer and feature-based signals.

Direct feature fusion helped XLM-R Large but not mDeBERTa. The XLM-R Large Hybrid improved over Solo in mean test RMSE (1.103 vs. 1.122), whereas the mDeBERTa Hybrid was weaker than mDeBERTa Solo (1.150 vs. 1.110). One possible explanation is that the 33-dimensional feature vector is a relatively small addition to the 1024-dimensional XLM-R Large representation, but a more influential input to the smaller mDeBERTa head. The stacking ensemble avoids this issue

by combining feature-based and transformer-based predictions only at the output level.

Figure 3 visualizes the same pattern across Spanish, German, and Mandarin Chinese. The final mDeBERTa Ensemble is consistently the lowest-error system, supporting the conclusion that prediction-level ensembling is more robust than relying only on direct feature fusion or a single model family.

8 Conclusions

We presented a system for the BEA 2026 Shared Task on vocabulary difficulty prediction, structured around an official Closed Track submission and a post-submission refinement. The official submissions used XLM-R Large Solo and Hybrid models and improved over the baseline for Spanish, German, and Mandarin Chinese. A post-submission refinement based on mDeBERTa-v3-base, feature-only regressors, and Ridge stacking further reduced error, achieving the best RMSE among our systems for all L1s: 1.037 (ES), 0.997 (DE), and 0.913 (CN), with a mean RMSE of 0.982.

The results show that engineered features contributed useful linguistic signal, although they were most effective when combined with transformer-based predictions rather than used as standalone models or through direct Hybrid concatenation. Although the final ensemble was not part of the official submission, its estimated ranks suggest a substantial improvement over our official systems, reaching approximately 8/60 for Spanish, 11–12/57 for German, and 15/52 for Chinese. Overall, L1-aware vocabulary difficulty prediction benefits most from combining complementary model signals at the prediction level rather than relying on a single model family or feature fusion strategy alone.

Limitations

This study is limited to the Extended KVL dataset and three L1 backgrounds (Spanish, German, and Mandarin Chinese), so generalization to other learner groups and vocabulary benchmarks remains future work. The hyperparameter search was constrained by available GPU time, and the ensemble was not evaluated under fully nested cross-validation. Finally, our analysis focuses mainly on RMSE and Pearson’s r ; future work should include finer-grained error analysis by word type, POS, clue structure, and L1-specific properties.

System	Submission	Dev RMSE			Test RMSE			Mean	Rank (ES/DE/CN)
		ES	DE	CN	ES	DE	CN

Abstract

This paper describes UOL@IDEM’s closed-track submission to the BEA 2026 shared task on L1-aware vocabulary difficulty prediction¹. We model the task as regression and train separate systems for Spanish, German, and Mandarin Chinese². Our system combines multilingual contextual representations with engineered features capturing frequency, surface form, retrieval evidence, semantic alignment, cognate similarity, and masked-language-model predictability. Development results show consistent gains over the official closed-track baselines, with sentence-embedding encoders such as BGE-M3, multilingual E5, and LaBSE performing best. Official submissions achieve RMSE scores of 1.132, 1.037, and 0.891 for Spanish, German, and Chinese, respectively. Feature analysis identifies frequency as the most stable predictor, while contextual predictability, form similarity, retrieval, and semantic features provide complementary L1-sensitive signals. Error analysis shows strong ranking performance but weaker calibration for the easiest items, which are often overpredicted.

1 Introduction

Text complexity and readability assessment are central to educational NLP, language learning, and text adaptation. A key component is lexical complexity prediction (LCP), which estimates how difficult a word or multi-word expression is likely to be for a target reader (Shardlow et al., 2021, 2022; North et al., 2023). Lexical difficulty is shaped by frequency, word length, morphology, polysemy, context, and reader background, and supports applications such as readability assessment, simplification, tutoring, and machine translation (Shardlow et al., 2022; North et al., 2023; Oluoba et al., 2024).

¹<https://github.com/Nouran-Khallaf/>

UoL-IDEM-BEA2026-Vocabulary-Difficulty-Prediction

²Below we use *Chinese* for brevity.

The BEA 2026 Shared Task extends LCP by making vocabulary difficulty explicitly L1-aware. In this setting, the difficulty of an English target word depends not only on the word itself, but also on the context of its use as well as on its relationship to the learner’s first language through translation and transfer cues. As a result, the same English word may have different difficulty profiles for Spanish, German, and Chinese speakers. More specifically, the task uses an extended version of the Knowledge-based Vocabulary Lists (KVL) resource, pairing English target items with multilingual prompts and psychometrically calibrated GLMM-based difficulty scores (Skidmore et al., 2025).

In the closed track, systems train separate models for each L1 using only the shared-task resources (Felice and Skidmore, 2026; British Council, 2026). We therefore model the task as three parallel prediction settings: Spanish→English, German→English, and Chinese→English.

Our approach experiments with mid-sized text encoders (of up to 560M parameters) enriched with engineered features, such as lexical frequency, orthographic clues, contextual retrieval, cognate-like similarity, semantic-domain alignment, and masked-language-model predictability. We evaluate several encoders within a neural fusion framework and compare full-feature and reduced-feature variants.

Our experiments show three main findings. First, neural fusion improves over the official closed-track baselines across all three languages, improving RMSE by up to 0.21–0.26. Second, sentence-embedding-oriented multilingual models, especially BGE-M3 (Chen et al., 2024), multilingual E5 (Wang et al., 2024), and LaBSE (Feng et al., 2022), are more effective than plain transformer baselines such as mBERT and XLM-R. Third, feature and error analyses show that frequency is the most stable predictor contributing above the en-

coder baseline, while semantic, cognate, retrieval, and MLM-based cues can provide complementary L1-sensitive information.

2 Data and Preprocessing

Data exploration showed that L1_source_word often contains noisy forms that require language-aware normalisation before feature extraction. We address lexical variants, negative constraints, morphological fragments, negated instructional patterns, explanatory glosses, and punctuation. For example, multiple alternatives are split and tracked with a variant-count feature (*Korridor, Flur* → *Korridor*); exclusion notes are removed and encoded as binary features (*Flugzeug (nicht: ...)* → *Flugzeug*); truncated German compounds are normalised to stems (*Regierungs-* → *Regierungs*); Spanish instruction-like phrases such as *no es* and *la respuesta no termina en* are stripped to isolate the lexical item; and Chinese punctuation, leading glosses, and parenthetical notes are pruned where appropriate ((美) 走廊, 过道 → 走廊). To make preprocessing traceable, we keep the original source-word string and use a cleaned lexical form for feature extraction. When an English target contains multiple candidates, we select the candidate that appears in the L1 context.

3 Methodology

We formulated the task as supervised regression. Each instance contained an L1-specific context, an L1 source word, an English target word, and a continuous difficulty score. Models used textual input and engineered features capturing complementary cues: frequency, lexical form, retrieval evidence, MLM and surprisal estimates, semantic-domain information, and cognate-based similarity.

We compared three integration strategies: (1) textualised feature regression, which renders selected features as part of the input prompt; (2) multi-stage late fusion, which combines frozen encoder embeddings with downstream regressors; and (3) neural fusion, which jointly optimises contextual representations and structured tabular features. Because neural fusion performed best in the initial comparison, we used it as the main setting.

3.1 Engineered features

In addition to BERT-derived text representations, we designed a set of engineered features to capture lexical difficulty, cross-lingual retrievability,

contextual predictability, semantic compatibility, and source-word ambiguity. We group these features into frequency-based, lexical, retrieval-based, masked-language-model and surprisal, semantic, and cognate-based features. Full feature descriptions are provided in Appendix A, Table 5.

Frequency-based features. We combine three complementary frequency resources. KELLY (Kilgarriff et al., 2014) is derived from curated Web-corpora and provides pedagogically oriented indicators, including frequency rank, percentile, and CEFR-aligned labels, which approximate learner vocabulary progression (Council of Europe, 2001). The wordfreq Python package provides general corpus-based estimates, including raw frequency, Zipf frequency, frequency percentile, and inverse-frequency cost (Speer et al., 2018; Sharoff et al., 2017). The SUBTLEX list is derived from subtitles and provides frequency and contextual-diversity measures, reflecting both occurrence frequency and exposure across everyday contexts (Brysbaert and New, 2009; van Heuven et al., 2014). Combined, these features model familiarity from pedagogical, general-corpus, and everyday-exposure perspectives, providing a strong baseline signal for vocabulary difficulty prediction (Shardlow et al., 2021, 2022; North et al., 2023).

Surface-form and morphosyntactic features.

We extract surface-form and morphosyntactic features from the English target and cleaned L1 source word. These include target/source length, target syllable count, clue informativeness, and hidden clue characters. We also encode POS information, using the dataset-provided target POS and spaCy-derived source POS (Honnibal et al., 2020). Alongside these features, we also retain a set of preprocessing-derived indicators introduced in Section 2, including signals for exclusion notes, alternative candidate forms, and related counts.

Retrieval-based features. We derive retrieval-based features by treating the task as context-guided cross-lingual retrieval of the English target. We build a fixed English candidate bank from possible target words, encode candidates with mBERT (Devlin et al., 2019), and map them into a shared multilingual embedding space. For each instance, the L1 context and source word are encoded as a source-side representation and matched against this bank. Candidates are reranked using the available constraints: initial-letter clue, target length, and

part of speech. Matching candidates are promoted, while mismatches are downweighted or excluded. We then extract features describing gold-target support, including rank before and after reranking, cosine and reranked scores, top-candidate scores, margins, nearest-neighbour confidence and entropy, gold-target probability measures, and the number of valid candidates. The gold target’s retrieval position is encoded as its rank when retrieved and as 0 otherwise. These features capture how recoverable the target is from the L1 context and source word.

Masked language model and surprisal features.

We use the MLM head of mBERT (Devlin et al., 2019) to estimate how predictable the English target is in context. Unlike retrieval features, which compare the target with an external candidate bank, MLM features come from the output distribution at the masked target position. We apply target constraints, especially initial letter and length, so the scores reflect both contextual fit and target-form compatibility. Features include gold-target log probability and rank, masked-token entropy, top-1 indicators, prediction margins, target–prediction embedding similarity, and related confidence measures.

Because targets may contain multiple word-pieces, probability-based quantities are computed at the subword level and averaged across the target span. For a target sequence $t_{1:m}$, we use three surprisal variants. Simultaneous masking replaces the full target span with [MASK]:

$$s_{\text{masked}}(t_{1:m}) = -\frac{1}{m} \sum_{j=1}^m \log P(t_j \mid \mathbf{c}_{\text{mask}}). \quad (1)$$

Pseudo-log-likelihood (PLL) masks one target wordpiece at a time while keeping the remaining pieces visible (Salazar et al., 2020):

$$s_{\text{PLL}}(t_{1:m}) = -\frac{1}{m} \sum_{j=1}^m \log P(t_j \mid \mathbf{c}^{(j)}), \quad (2)$$

where $\mathbf{c}^{(j)}$ masks only token t_j , allowing each token to be predicted with access to the other target subwords.

Finally, chain-rule surprisal scores the target incrementally from left to right:

$$s_{\text{chain}}(t_{1:m}) = -\frac{1}{m} \sum_{j=1}^m \log P(t_j \mid \mathbf{c}, t_{1:j-1}). \quad (3)$$

These measures capture contextual predictability under full-span masking, single-token masking, and sequential prediction.

Semantic features. We derive semantic-domain features from the UCREL Semantic Analysis System (USAS), which assigns lexical items to 21 major discourse fields and 232 finer-grained categories (Rayson et al., 2004). For each item, we annotate the L1 source word and English target with all available USAS tags. We include overlap features for identical tags, shared fine-grained prefixes, and shared major fields. We also compute weighted and unweighted tag entropy to capture semantic ambiguity, with higher entropy indicating less stable interpretation.

To capture relatedness beyond exact overlap, we compute a semantic-shift score. Let S and T be the USAS tag sets for the L1 source and English target. For each source–target tag pair, we assign a graded relation score based on the strongest relation: exact tag overlap, shared fine-grained prefix, shared major field, related major fields, or unrelated fields. Item-level soft similarity is computed over the full tag sets, and semantic shift is defined as its complement:

$$\text{shift}_{\text{sem}}(S, T) = 1 - \text{sim}_{\text{soft}}(S, T). \quad (4)$$

Lower values indicate stronger semantic alignment; higher values indicate larger semantic-domain shift. For example, *obra* (‘literary work’ in Spanish) has the semantic tags of A1.1.1|I3.1, which do not overlap with *comedy* E4.1+|K4|Q4.3. Still, both refer to related fields, giving soft similarity 0.20 and semantic shift 0.80. Coverage gaps are handled using fixed penalties for unmatched Z99 cases. Appendix C, Table 7 gives further examples with full USAS category names.

Cognate features. We derive cognate-oriented features to capture lexical-transfer signals between the L1 source word and the English target. These include orthographic similarity, multilingual embedding cosine similarity, Levenshtein edit-distance similarity, character n -gram overlap, and prefix/suffix overlap. We also add lexical-relation features from CogNet, a multilingual cognate database (Batsuren et al., 2019, 2022). Because the task covers English, Spanish, German, and Chinese, we restrict CogNet to entries involving these languages. These features are expected to be most informative

for Spanish–English and German–English, while also testing whether cognate relations provide useful signals for Chinese–English.

3.2 Model Architectures

Textualised Feature Regression. The main text fields and selected engineered features are rendered as text, encoded with a multilingual transformer, and passed to a regression head. This allows feature–context interactions to be modelled through self-attention.

Multi-stage Late Fusion. Here the available text fields are concatenated and encoded with a frozen multilingual sentence encoder to obtain dense representations $\mathbf{h} \in \mathbb{R}^d$. These are used alone or concatenated with engineered features $\mathbf{x}$ as input to Ridge, GBDT, XGBoost, and SVR regressors. Their predictions are combined through ensemble-style aggregation (van der Laan et al., 2007), following feature-based regression approaches in quality estimation and related prediction tasks (Rios and Sharoff, 2016).

Neural Fusion. This architecture jointly learns from contextual text representations and structured tabular features. For each instance, the input sequence S_i concatenates L1_context, L1_source_word, en_target_word, and, in some configurations, an additional target clue using [SEP] tokens.

A multilingual transformer f_θ encodes S_i , and its token-level representations are pooled into a text vector:

$$\mathbf{h}_i = \text{Pool}(f_\theta(S_i)). \quad (5)$$

In parallel, a feed-forward tabular branch maps the engineered feature vector $\mathbf{x}_i$ into a dense representation $\mathbf{x}'_i$. The two representations are concatenated:

$$\mathbf{z}_i = [\mathbf{h}_i; \mathbf{x}'_i], \quad (6)$$

and passed to an MLP to predict the difficulty score:

$$\hat{y}_i = \text{MLP}(\mathbf{z}_i). \quad (7)$$

Text representations vary by model family: neural fusion uses attention pooling over final hidden states, textualised regression uses the standard [CLS] representation, and late fusion uses dense sentence embeddings, optionally followed by PCA.

3.3 Experimental Setup and Optimisation

We train separate models for Spanish, German, and Chinese. For each language, we evaluate multilingual PLMs, including XLM-R and mBERT (Conneau et al., 2020; Devlin et al., 2019), and sentence-oriented multilingual encoders, including LaBSE, Multilingual-E5, and BGE-M3 (Feng et al., 2022; Wang et al., 2024; Chen et al., 2024).

All experiments use five-fold cross-validation, with out-of-fold predictions used for training-set evaluation and held-out embeddings used for late fusion to avoid leakage. Models are optimised with AdamW and early stopping on validation RMSE, with differential learning rates, warmup, gradient clipping, and mixed precision. We test both mean squared error and Huber loss, the latter reducing the influence of large residuals; details are given in Appendix Eq. 8 and Appendix B, Table 6. RMSE is the primary metric used by the shared task organisers, while Pearson, Spearman, and Kendall’s τ used to assess fit and ranking quality of each method.

4 Results

Table 1 reports the main development-set results for the closed track, comparing Textualised Feature Regression, Multi-stage Late Fusion, and Neural Fusion. Across all three languages, the best systems substantially outperform the official closed-track baselines, with RMSE gains of 0.2618 for Spanish using BGE-M3, 0.2407 for German using multilingual-E5-large, and 0.2069 for Chinese using BGE-M3.

The results show a clear advantage for sentence-embedding-oriented multilingual encoders. BGE-M3 and multilingual-E5-large, both based on XLM-RoBERTa-large, are consistently stronger, while LaBSE, a multilingual BERT-based sentence embedding model, remains competitive. This suggests that the main advantage comes not only from the underlying multilingual backbone, but also from training the model specifically for sentence-level cross-lingual representation. In contrast, the standard token encoders are weaker, mBERT is generally less competitive, and XLM-R is less stable, performing reasonably well for Spanish and German but falling below the baseline for Chinese.

For the Late Fusion and Textualised Feature Regression settings, we therefore used the two strongest sentence-embedding encoders, BGE-M3 and multilingual-E5-large, and report the best

development-set result for each language. The modelling strategy also has a clear effect. Late Fusion performs worse than both Textualised Feature Regression and Neural Fusion, indicating that simply combining frozen sentence embeddings with classical regressors is not the most effective way to use these representations. In contrast, Neural Fusion benefits from combining encoder representations with engineered features in a more integrated way. Since the best development results are obtained with Neural Fusion using BGE-M3 or multilingual-E5-large, we use this setting for the subsequent feature-ablation and feature-importance analyses.

4.1 Feature importance and ablations

We analyse the engineered features in three steps. First, we compute Kendall’s τ correlation between each feature and the gold GLMM score for each language. Second, we use these rankings to construct two compact feature sets: Top-1 per feature family, which keeps the single highest-ranked feature in each family, and Top-3 per feature family, which keeps the three highest-ranked features in each family. Third, we compare these compact settings with models trained using only one feature family at a time. This separates feature–target association

from the predictive value of compact subsets and single feature families.

The Kendall rankings show that frequency and lexical familiarity are the most consistent individual signals. In Spanish, the top-ranked features are subtitle-based target frequency ($|\tau| = 0.2730$), the retrieval prior combining clue/context support and candidate-space size ($|\tau| = 0.2643$), and subtitle contextual diversity ($|\tau| = 0.2572$). In German, the retrieval prior ranks first ($|\tau| = 0.2985$), followed by subtitle frequency ($|\tau| = 0.2837$) and subtitle contextual diversity ($|\tau| = 0.2680$). In Chinese, the strongest associations are subtitle frequency ($|\tau| = 0.4128$), subtitle contextual diversity ($|\tau| = 0.4127$), and the KELLY lexical familiarity score ($|\tau| = 0.4029$).

Table 2 shows that that frequency-based features (subtitle frequency and contextual diversity) emerge as the most consistent and strongest individual predictors across languages, but its role differs by L1. Spanish is the clearest frequency-driven case: the frequency-only model gives the best Dev RMSE, 1.0855, slightly ahead of all features, 1.0952, with nearly identical OOF RMSE, 1.0987 versus 1.0988. German shows a more balanced pattern, where surprisal gives the best Dev

Table 2: Feature ablation results for Spanish, German, and Chinese. Top-1/group and Top-3/group are built by selecting the highest-ranked one or three features within each feature group according to Kendall correlation with the training GLMM score. **best**, **near-best**, **worst**.

RMSE, 1.0861, narrowly ahead of all features, 1.0873, while frequency, 1.0941, and cognate/form-similarity, 1.0985, remain close. Chinese has the most distributed signal: all features perform best, with Dev RMSE 0.9681, but MLM, cognate/form-similarity, lexical/surface form, and frequency all remain competitive.

The official test results in Table 3 partly confirm this pattern. The best UOL@IDEM runs achieve RMSE 1.132 for Spanish, 1.037 for German, and 0.891 for Chinese. Spanish is best with the all-features run, while German and Chinese are best with the frequency-oriented run. Thus, although richer feature combinations remain useful during development, frequency-based predictors generalise most robustly on the hidden test set for German and Chinese.

4.2 Error analysis

The feature-importance and ablation results show that in addition to the baseline sentence encoder, the models learn a strong difficulty signal, especially from frequency and lexical familiarity. However, a strong ranking does not guarantee good calibration. We therefore examine where frequency becomes insufficient, whether predictions are compressed across the difficulty scale, and which feature patterns distinguish low-error from high-error cases.

We first examine calibration by dividing the development items into five quantile-based gold-difficulty bands. Band 1 contains the easiest items and Band 5 the hardest items. For each language and band, we compute RMSE, MAE, Kendall’s τ , and signed bias, defined as $\hat{y} - y$, where positive val-

Language	Run	RMSE ↓	Pearson ↑
es	All features	1.132	0.813
	Frequency	1.134	0.808
	Top-3/family	1.140	0.813
de	All features	1.079	0.819
	Frequency	1.037	0.834
	Surprisal	1.078	0.818
cn	All features	0.930	0.856
	Frequency	0.891	0.860
	Top-1/family	0.919	0.858

Table 3: Official closed-track test results for UOL@IDEM submissions. Green highlights the best run.

ues indicate overprediction of difficulty (Kendall, 1938). Uncertainty is estimated using bootstrap resampling (Efron and Tibshirani, 1994).

Figure 1 shows that the language-specific neural fusion models broadly follow the gold difficulty scale, but with a clear compression toward the centre. This compression is visible in the solid mean-bias line, where bias is defined as predicted difficulty minus gold difficulty. In Band 1, which contains the easiest items, the bias is strongly positive: +1.21 for German, +1.28 for Spanish, and +1.03 for Chinese. This means that genuinely easy items are predicted as more difficult than they are. At the other end of the scale, Band 5 shows the opposite pattern: the bias is negative, with values of −0.30, −0.32, and −0.27, respectively, indicating that the hardest items are predicted as slightly easier than their gold scores. These two effects show that predictions are pulled away from the extremes and toward the middle of the difficulty scale. The same pattern is also reflected in the mean difficulty lines: the predicted mean difficulty line changes less sharply across bands than the gold mean difficulty line. Thus, the main weakness is not a failure to rank items by difficulty, but a calibration problem in which the model underestimates the full spread of the difficulty scale. The full error-analysis materials are available online.³

³<https://tinyurl.com/UoL-BEA-Error-Analysis>

Lang.	RMSE	MAE	Bias	τ	Band bias pattern
de	1.117	0.850	+0.346	0.629	+1.21 → −0.30
es	1.111	0.834	+0.331	0.651	+1.28 → −0.32
zh	0.975	0.724	+0.258	0.648	+1.03 → −0.27

Table 4: Overall development-set error profile. Bias is the mean signed error $\hat{y} - y$. The final column summarises the change from Band 1 to Band 5, showing scale compression in all three languages.

Figure 1: Calibration by gold difficulty band for German, Spanish, and Chinese. Bands B1–B5 are ordered from easiest to hardest according to the gold difficulty score. The solid line shows mean prediction bias, defined as predicted difficulty minus gold difficulty, and the shaded region shows bias $\pm$ MAE. Positive bias in the easiest bands indicates over-prediction of difficulty, while negative bias in the hardest band indicates under-prediction.

Table 4 summarises the same pattern at language level. Chinese has the lowest RMSE and MAE, but it still shows the same movement from overprediction in the easiest band to mild underprediction in the hardest band. This connects directly to the ablation results: frequency provides a robust global

difficulty signal, but it can also pull predictions toward an average level of difficulty rather than fully adapting to the extremes of the learner-specific scale. Absolute-error associations with individual features are weak: most Kendall correlations are below $|\tau| = 0.05$. The strongest cue is prediction entropy, `pred_ent`, with $\tau = 0.048$, followed by MLM entropy, learner-frequency percentile, target length, semantic-domain entropy, prediction margin, and cognate similarity. Residual errors therefore appear when several cues diverge, such as frequency, contextual predictability, semantic ambiguity, form similarity, and L1–English transparency.

To examine these interactions more directly, we compare low-error and high-error items within the same language and difficulty band. This controls for broad gold difficulty: we are not simply comparing easy words with hard words, but asking what distinguishes better and worse predictions among items of comparable true difficulty.

Within each language–band group, we define low-error items as the lowest-error quartile and high-error items as the highest-error quartile. Since many features are skewed, ordinal, or tied, we use Mann–Whitney tests and Cliff’s δ to compare feature distributions, and apply Benjamini–Hochberg correction to control the false discovery rate (Mann and Whitney, 1947; Cliff, 1993; Benjamini and Hochberg, 1995). Figure 2 reports the standardised contrast between the two groups, computed as low-error minus high-error. Positive values indicate features that are higher in better-predicted items; negative values indicate features that are higher in worse-predicted items.

The controlled contrasts clarify the source of the calibration errors. Low-error items are usually those where several cues point in the same direction: frequency, lexical form, semantic evidence, and contextual predictability jointly support the predicted difficulty. High-error items arise when these cues conflict, so the model receives mixed evidence about whether the item should be easy or difficult.

In German, low-error items show stronger form and contextual-predictability signals, including target length, source length, target syllable count, MLM rank, and surprisal features. High-error items are more associated with subtitle frequency, subtitle contextual diversity, and cognate similarity. This pattern indicates that German predictions are most stable when frequency is supported by context-

tual and form-based evidence, but less stable when frequency or surface similarity dominates without enough contextual support.

Spanish shows the clearest example of this conflict. The most error-prone cell is Spanish Band 1, where genuinely easy items are often overpredicted. Within this band, the strongest descriptive contrasts involve subword surprisal, MLM log probability, and pseudo-log-likelihood surprisal. The largest contrast is for `surp_sub_sum`, with Cliff’s $\delta = -0.298$ and a raw Mann–Whitney $p = 0.031$; however, this effect does not remain significant after Benjamini–Hochberg correction ($p_{BH} = 0.522$), so we treat it as exploratory. The pattern is still informative: some easy items may be frequent, familiar, cognate-supported, or transparent for Spanish-speaking learners even when the immediate context does not make them highly predictable to an MLM-style model. The model then overpredicts difficulty because contextual predictability conflicts with learner-oriented familiarity.

Chinese has the strongest overall performance, but it follows the same mechanism. Low-error items combine form, semantic-shift, cognate-similarity, and probability-based support, including target length, target syllables, semantic shift, predicted log probability, cognate similarity, and MLM log probability. High-error items are more strongly associated with frequency features such as word-frequency value, subtitle contextual diversity, subtitle log-frequency, and subtitle frequency. Thus, even for Chinese, predictions are most reliable when frequency is reinforced by semantic and form-based evidence rather than operating as the main cue alone.

Overall, the error analysis refines the feature-ablation findings. Frequency is the strongest global cue and explains much of the high ranking performance, but it does not guarantee calibrated predictions. This explains why high Kendall correlations can coexist with systematic calibration errors: the models often rank items correctly, but their predicted scores are compressed toward the middle, leading to overprediction for easy items and underprediction for hard items.

5 Conclusion

This paper presented UOL@IDEM, a closed-track system for L1-aware English vocabulary difficulty prediction. The system combines multilingual con-

Figure 2: Matched low-error versus high-error contrasts within language and difficulty band. Positive values indicate features higher in low-error items; negative values indicate features higher in high-error items.

textual representations with engineered features capturing frequency, lexical surface form, surprisal, retrieval evidence, cognate-like similarity, and semantic alignment.

Across the development set, neural fusion with sentence-embedding encoders gives the strongest performance, improving over the closed-track base-lines by 0.2618 RMSE for Spanish, 0.2407 for German, and 0.2069 for Chinese. On the official test set, the best submissions achieve RMSE scores of 1.132, 1.037, and 0.891 for Spanish, German, and Chinese, respectively.

The analysis shows that explicit linguistic features remain useful even with strong multilingual encoders. Frequency is the most stable signal, while form, surprisal, retrieval, cognate, and semantic features provide complementary evidence for L1-aware prediction. At the same time, the error analysis shows that strong ranking performance does not always translate into well-calibrated difficulty estimates, especially at the easiest and hardest ends of the scale.

Future work should focus on calibration and on more compact models that retain the most informative frequency, form, surprisal, and semantic cues while better modelling L1-specific transfer

and contextual recoverability.

6 Limitations

Our work is limited to the closed-track shared-task data, so we do not use external learner corpora, larger lexical resources, multilingual joint training, or large language models. These could be useful for rare targets, noisy source-word entries, and ambiguous source–target mappings.

The engineered features improve interpretability but add pipeline complexity, including pre-processing, frequency lookup, retrieval scoring, surprisal estimation, semantic tagging, and cognate/similarity scoring. Following the closed-track requirements, we train separate models for each L1, which does not explicitly model shared versus language-specific difficulty signals.

The main evaluation limitation is calibration. The models overpredict the easiest items and slightly underpredict the hardest ones, indicating regression toward the middle of the difficulty scale. This analysis is restricted to the development set because gold labels for the hidden test set are not available.

Ethics Statement

This work uses data released for research under the shared-task conditions. The task concerns educational assessment and therefore has potential downstream implications for fairness and learner support. We do not claim that model predictions should replace psychometric validation or expert judgment; rather, they should be used as supportive signals in item development and educational NLP pipelines.

Acknowledgments

We thank the BEA 2026 shared-task organisers for releasing the dataset and the evaluation framework. A Feature Inventory

This appendix summarises the engineered features used in our experiments. Feature names follow the column names used in the analysis files and figures. For readability, features are grouped by functional role rather than presented as a single flat inventory. Table 5 gives the full engineered-feature inventory.

Table 5: Engineered features grouped by functional role.

Feature	Description
Frequency	
freq_en	English frequency estimate for the target word.
freq_en_pct_rank	Percentile rank of the English target frequency.
sub_wf	SUBTLEX word-frequency measure.
sub_lg10wf	Log-scaled SUBTLEX word-frequency measure.
sub_cd	SUBTLEX contextual-diversity measure.
sub_lg10cd	Log-scaled SUBTLEX contextual-diversity measure.
kelly_rank	Rank of the target word in a learner-oriented lexical frequency resource.
kelly_pct	Percentile rank derived from the Kelly learner-frequency list.
kelly_points	Difficulty-oriented lexical score from the Kelly list.
wf_zipf	Zipf-scaled word-frequency score for the English target word.
wf_value	Raw or transformed corpus-based word-frequency value.
Lexical, clue, and preprocessing	
tgt_len	Number of characters in the English target word.
src_len	Number of characters in the cleaned L1 source word.
tgt_syll	Syllable count of the English target word.
target_pos	Part-of-speech information for the English target word.
source_pos	Part-of-speech information for the L1 source word, where available.
clue_len	Length of the target clue.
clue_hidden_chars	Number of hidden characters in the target clue.
clue_hidden_ratio	Proportion of hidden characters in the target clue.
L1_source_word_raw	Original unnormalised source-word field preserved during preprocessing.
L1_source_word_excluded_word	Word appearing inside an exclusion note in the raw source-word field.
L1_source_word_has_excluded_word	Indicator that the source-word field contains an exclusion note.
L1_source_word_excluded_note_type	Type of exclusion note detected during preprocessing.
L1_source_word_has_alternative	Indicator that multiple source-word candidates are present.
L1_source_word_alternative_count	Number of alternative source-word candidates detected.
L1_source_word_alternatives	Preserved list of source-word alternatives extracted during preprocessing.
Retrieval	
gold_rank	Rank position of the gold English target in the candidate list after retrieval and reranking.
gold_score	Final reranked score assigned to the gold target.
top1_score	Score of the highest-ranked retrieved candidate.

Continued on next page

Table 5 – continued from previous page

Feature	Description
top2_score	Score of the second-ranked retrieved candidate.
margin12	Difference between the top-1 and top-2 candidate scores.
gold_cos	Cosine similarity between the gold target and the retrieved representation.
gold_prob	Probability-like score associated with the gold target under retrieval/reranking.
nn_pred_cos	Cosine similarity associated with the nearest-neighbour prediction.
nn_pred_prob	Probability-like confidence score for the nearest-neighbour prediction.
nn_entropy	Entropy of the retrieved candidate distribution.
cand_count	Number of valid candidate targets considered after filtering.
retrieval_target_prior	Prior retrieval score for the target independent of full contextual reranking.
retrieval_target_in_context	Context-sensitive retrieval score for the target.
baseline_pred_matches_target	Indicator that the retrieval baseline predicts the correct target.
baseline_clue_overlap	Degree of overlap between the predicted candidate and the target clue.
baseline_pred_len	Length-based compatibility between the retrieved candidate and the target constraint.
MLM and surprisal	
mlm_logp	Mean masked-language-model log probability assigned to the gold target wordpieces.
mlm_rank	Rank of the gold target under the masked-language-model prediction.
mlm_ent	Entropy of the masked-token distribution.
mlm_top1_match	Indicator that the top MLM prediction matches the gold target.
pred_logp	Log probability of the top predicted token or predicted target sequence.
pred_ent	Entropy associated with the prediction distribution.
pred_margin	Margin between the best and second-best MLM predictions.
mlm_target_pred_cos	Cosine similarity between gold-target and predicted-token embeddings.
surp_masked	Surprisal computed from simultaneous masking of all target wordpieces.
surp_pll	Surprisal computed using pseudo-log-likelihood with one masked wordpiece at a time.
surp_chain	Surprisal computed sequentially via a chain-rule decomposition over target subwords.
surp_sub_sum	Sum of surprisal contributions across target subwords.
surp_sub_mean	Mean surprisal across target subwords.
Semantic and domain shift	
usas_domain_match	Indicator of semantic-domain compatibility between source and target.

Continued on next page

Table 5 – continued from previous page

Feature	Description
usas_ent_unw	Unweighted entropy over possible semantic-domain assignments.
usas_ent_wtd	Weighted entropy over semantic-domain assignments.
sem_shift	Soft semantic-shift score measuring divergence between the L1 source word and the English target.
semantic_domain_overlap	Degree of overlap between source- and target-side semantic domains.
Cognate and cross-lingual form	
lev_sim	Weighted Levenshtein-based similarity between the L1 source word and the English target.
cog_sim	Cross-lingual form-similarity score used as a cognate or transparency cue.
char_ngram_sim	Character n-gram similarity between the L1 source word and the English target, where available.
cognet_match	Indicator or score derived from external cognate-link evidence, where available.

Table 5: Engineered features grouped by functional role.

B Neural-fusion model settings

Category	Setting	Value
Input and model	Text fields	L1_context, L1_source_word, en_target_word, optional en_target_clue
	Fusion model	Enhanced neural fusion
	Encoder backbones	XLM-R, mBERT, LaBSE, multilingual-E5, BGE-M3, and related multilingual encoders
	Text pooling	Attention pooling or CLS pooling, depending on the model configuration
Architecture	Tabular branch	Feed-forward network with configurable hidden layers, dropout, and optional residual connections
	Prediction head	MLP regression head over the concatenated text and tabular representations
Optimisation	Optimiser	AdamW
	Encoder learning rate	2×10^{-5}
	Task-head learning rate	10^{-3}
	Weight decay	0.01
	Warmup ratio	0.1
	Schedule	Linear warmup and decay
	Gradient clipping	Maximum norm 1.0
	Mixed precision	Used when GPU support is available
	Checkpoint selection	Validation RMSE
Training protocol	Epochs	5
	Training batch size	16
	Evaluation batch size	16 or 32, depending on the experiment configuration
	Early stopping	Patience of 2 epochs
Evaluation	Cross-validation	5-fold
	Main metric	RMSE
	Other metrics	Pearson, Spearman, Kendall's τ

Table 6: Model, training, and optimisation settings used in the neural-fusion experiments.

The Huber loss used in some optimisation settings is defined in Eq. 8.

$$L_{\delta}(a) = \begin{cases} \frac{1}{2}a^2 & \text{if } |a| \leq \delta, \\ \delta \left(|a| - \frac{1}{2}\delta \right) & \text{otherwise.} \end{cases} \quad (8)$$

C USAS semantic-shift examples

Table 7: Spanish examples of the soft USAS semantic-shift measure using richer source and target tag sets. Each cell reports the full available USAS tag set, with the corresponding category names underneath. The operation row describes the strongest source–target tag-pair relation used to characterise each example group, while the soft similarity and soft shift are computed over the full source and target tag sets. Therefore, an item can contain an exact overlapping tag but still receive a non-zero shift score when the remaining tags differ. [†]Coverage-gap scores are penalty values rather than observed semantic-distance scores.

Abstract

We describe two types of models for vocabulary difficulty prediction: a high-accuracy black-box model, which achieved the top shared task result in the open track, and an explainable model, which outperforms a fine-tuned encoder baseline. As the black-box model, we fine-tuned an LLM using a soft-target loss function for effective application to the rating task, achieving $r > 0.91$. The explainable model provides insights into what impacts the difficulty of each item while maintaining a strong correlation ($r > 0.77$). We further analyze the results, demonstrating that the difficulty of items in the British Council’s Knowledge-based Vocabulary Lists (KVL) is often affected by spelling difficulty or the construction of the test items, in addition to the genuine production difficulty of the words. We make our code available online.¹

1 Introduction

The goal of the BEA 2026 Shared Task on Vocabulary Difficulty Prediction for English Learners (Felice and Skidmore, 2026) is to build models of the difficulty of English words given a learner’s L1. Such difficulty predictions can be used as a basis for pedagogical materials or computer-adaptive tests.

The shared task utilizes a large dataset with vocabulary difficulty scores for L1 Chinese, German, and Spanish learners, spanning thousands of vocabulary test items, the British Council’s Knowledge-based Vocabulary Lists (KVL; Schmitt et al., 2021, 2024). Each test item, as shown in the example in Table 1, consists of an equivalent L1 word, L1 context, and a clue for the first letter of the English word and its length in letters.

The test format, therefore, focuses on productive knowledge, in particular, on the ability to write the English word with the correct spelling given the test prompt. The difficulty scores, which we aim to predict, are intercept values of a generalized

L1		Spanish
English word		house
Part of speech		noun
Test item	L1 word	casa
	L1 context	Vivo en una casa grande que tiene tres dormitorios.
	Clue	h _ _ _ _ first letter and blanks
Difficulty score		3.07 ↑ easy, ↓ difficult

Table 1: Example of an item in the KVL data.

linear mixed model (GLMM), i.e., the log-odds of a learner responding correctly.

The shared task consisted of a closed track and an open track. While the open track was completely unrestricted, in the closed track, the use of large language models (LLMs) was limited to feature extraction, and only the L1-specific training data could be used. We present two approaches to vocabulary difficulty modeling in this setting, each leveraging LLMs in a different way:

LLMs fine-tuned using soft targets. We propose a simple yet novel technique to fine-tune LLMs for continuous value prediction using soft targets. Models based on this technique have outperformed all other shared task submissions in the open track.

Explainable model. We build a model using well-defined features, such as similarity to the L1 word and spelling difficulty, some of which are based on LLM prompting, and use SHapley Additive exPlanations (SHAP; Lundberg and Lee, 2017) to quantify the impact of each feature on the prediction. The model performed competitively in the closed track, surpassing the fine-tuned encoder baseline.

Our analysis indicates two factors contributing to difficulty scores in the KVL data beyond the productive difficulty of words: the spelling difficulty and the choice of L1 equivalents and context in some test items.

2 Related Research

The task of vocabulary difficulty prediction, as construed by the BEA 2026 Shared Task (Felice and Skidmore, 2026), effectively combines lexical complexity prediction (LCP) or complex word identification (CWI) with test item difficulty estimation.

CWI is the task of identifying complex words in a sentence context. CWI shared tasks (Paetzold and Specia, 2016; Yimam et al., 2018) were dominated by feature-based systems focusing on word-level features.

LCP is an extension of CWI, where complexity is predicted on a continuous scale. The best performing approaches in an early shared task (Shardlow et al., 2021) were based on fine-tuning masked language models (MLMs). In the BEA 2024 Shared Task on the Multilingual Lexical Simplification Pipeline (MLSP; Shardlow et al., 2024), where lexical complexity was predicted for ten languages with limited training data, the top-performing systems were based either exclusively on LLM prompting or on word-level features.

Nohejl et al. (2025a) proposed an LLM prompting-based LCP method, G-SCALE, which aligns with the desired scale by applying temperature scaling to the probabilities and a linear regression to the final output. They also demonstrated that the addition of a single feature, log-frequency, can further improve the LLM-based predictions.

Smădu et al. (2024) compared feature-based models and fine-tuned Transformers (MLMs and LLMs) on CWI and LCP datasets with training data consisting of thousands of examples, i.e., in a setting similar to the present shared task. The study concluded that the LLMs rarely outperform the computationally less demanding MLMs and feature-based models. Smădu et al. (2024) fine-tuned LLMs only using the standard cross-entropy loss with discretized complexity values as hard targets. We achieve large improvements in LLM and MLM fine-tuning performance by using soft targets to sidestep discretization.

Cross-entropy loss with soft targets is often associated with knowledge distillation (Hinton et al., 2015) and has been used for distilling MLMs and LLMs (e.g., Sanh et al., 2019). To the best of our knowledge, however, it has not been used for fine-tuning to predict continuous values.

Similar to LCP and CWI, the goal of the vocabulary difficulty prediction task is to estimate the difficulty of words given a specific context that de-

termines their sense. There are, however, prominent differences:

1. The complexity in LCP and CWI is measured by *subjective ratings*. The difficulty in the present task is based on the *success rate of test items*.
2. The input for LCP and CWI is only a word and its context, both in the same language. The input for this task consists of multiple elements in English and in L1.
3. LCP and CWI focus on *reading comprehension*. The present task focuses on *written production*.

We address the specific aspects of this task while drawing on insights from prior research on LCP and CWI.

Skidmore et al. (2025) fine-tuned encoders (i.e., MLMs) on the KVL data. Their fine-tuned XLM-RoBERTa model serves as the baseline of the shared task. They used SHAP as a tool for error analysis, attributing inaccurate predictions to specific input token positions. We use SHAP for explainability, attributing predictions to higher-level features such as spelling difficulty or similarity to L2.

3 Method

We propose two core methods: fine-tuning LLMs and MLMs with soft targets to predict the continuous difficulty values, and an explainable model with LLM-extracted features. To further improve the accuracy of both methods, we experiment with ensembling and additional features.

3.1 Fine-Tuning with Soft Targets

In the following, we assume an LLM or an MLM that has a token vocabulary V and predicts a probability distribution of tokens $i \in V$ conditioned on an input $\mathbf{x}$, denoted as $\hat{p}(i | \mathbf{x})$.

The standard loss function for MLM and LLM training is a cross-entropy loss with a hard target, where the entire probability mass is assigned to a single target token, i.e., the negative log likelihood of the target token. Adapting such models to predict continuous values calls for a different approach.

While encoder models (typically MLMs) are sometimes fine-tuned for the prediction of continuous values using a regression head and mean squared error (MSE) loss, this is not the case for LLMs. The prevalent supervised fine-tuning (SFT)

paradigm for LLMs is to convert such tasks to text generation by discretizing the continuous values and using the aforementioned cross-entropy with hard targets

$$\ell = -\log \hat{p}(v(d(y)) \mid \mathbf{x}), \quad (1)$$

where d is the discretization (e.g., rounding to the nearest integer), and v is the mapping of discretized values to tokens.

These common approaches to predicting continuous values using MLMs and LLMs are reflected in the LCP methods based on encoders (e.g., [Ide et al., 2023](#)), in the present shared task’s encoder baseline ([Skidmore et al., 2025](#)), and in the LCP methods based on LLMs (e.g., [Smádu et al., 2024](#)). In contrast to the MSE loss used by the encoder-based regression, the standard cross-entropy loss for LLMs requires the continuous target values to be discretized into a small set of labels, losing precision in the process.

Our method sidesteps this apparent misalignment between text generation and the prediction of continuous values by fine-tuning LLMs using cross-entropy loss with soft targets

$$\ell = -\sum_{i \in V} p(i) \log \hat{p}(i \mid \mathbf{x}). \quad (2)$$

We prompt the model to predict values on a discrete scale S in the form of successive integer points, e.g., $S = \{1, 2, 3, 4, 5\}$. Our aim, however, is to predict continuous values $y \in [\min S, \max S]$. We therefore express y as a probability-weighted sum of its nearest points. Namely, we select two points, a and $a + 1$, on the scale S such that $a \leq y \leq a + 1$, and define the probability as

$$p(i) = \begin{cases} (a + 1) - y & \text{if } i = v(a), \\ y - a & \text{if } i = v(a + 1), \\ 0 & \text{otherwise.} \end{cases} \quad (3)$$

We use p as the soft target probability in the loss function defined in [Equation 2](#).

At inference time, we predict the token probability distribution $\hat{p}$ of a single token and then compute the final output $\hat{y}$ as a token probability-weighted mean:

$$\hat{y} = \frac{\sum_{s \in S} \hat{p}(v(s) \mid \mathbf{x}) \cdot s}{\sum_{s \in S} \hat{p}(v(s) \mid \mathbf{x})}. \quad (4)$$

The same inference technique was used for LLMs by [Liu et al. \(2023\)](#) to infer continuous scores using few-shot learning, and its variations have

been applied to LCP ([Aumiller and Gertz, 2022](#); [Enomoto et al., 2024](#); [Smádu et al., 2024](#); [Nohejl et al., 2025a](#)) but without the complementary loss function for fine-tuning.

Because these two complementary techniques, soft-target cross-entropy loss and probability-weighted inference, require a single token to be predicted, they can be used not only for LLMs but also for MLMs via masked token prediction. For LLMs, the input $\mathbf{x}$ is simply the prompt; for MLMs, it is the sequence “[CLS] *prompt* [MASK] [SEP]”.

3.2 Explainable Model

Directly fine-tuning of LLMs or MLMs on this task is efficient but results in a black-box model, i.e., a model whose inner decision process is difficult to interpret. As an alternative model explainable using SHAP, we train an XGBoost ([Chen and Guestrin, 2016](#)) regressor. SHAP provides an explanation of the model’s output $f(\mathbf{x})$ via SHAP values ϕ_i that additively express the local importance of each feature x_i :

$$f(\mathbf{x}) = E[f(\mathbf{x})] + \sum_{i=1}^n \phi_i. \quad (5)$$

The SHAP values can be positive or negative, expressing how much each feature pushes a prediction higher or lower relative to the expected value. We use the additive nature of SHAP values and express the importance of groups of related features as sums of their SHAP values.

Our explainable model uses the following features:

Production frequency. We use the log-frequency of the English word in the Lang-8 learner corpus ([Mizumoto et al., 2011](#)), to estimate its written production frequency by learners. Three features represent the subcorpora of (1) all learners, (2) L1 Spanish learners, and (3) L1 Chinese learners. There was not enough data for L1 German learners.

Reception frequency. We use the log-frequency and log-range of the English word in corpora representative of spoken language to estimate its reception frequency. Namely, we use the logarithm of (1) frequency and (2) range (YouTube channels) in TUBELEX ([Nohejl et al., 2025b](#)), and (3) frequency in the spoken subcorpus of the British National Corpus (BNC; [BNC Consortium, 2007](#)).

CEFR level. We use the minimum CEFR level of the English word from the Cambridge English Vocabulary Profile (Capel, 2012)

Word length. We measure the length of the English word in letters.

L1 similarity. We compute the character-level similarity of the English word to the L1 word based on their length-normalized Levenshtein distance after removing diacritics and lowercasing. This feature is only applicable to languages written in the alphabet, Spanish and German.

Spelling difficulty. We prompt GPT-5.2 (OpenAI, 2025) to rate the spelling difficulty of an English word for each L1, given the L1 equivalent and the English word’s pronunciation.

Lexical ambiguity. We prompt (1) GPT-5.2 and (2) DeepSeek-V3.2 (DeepSeek-AI (2025)) to determine the lexical ambiguity of the test item. A lexically ambiguous item must fulfill two conditions: (a) the English word is polysemous or one of several homonyms, and (b) the particular sense referenced by the test item is unfamiliar or challenging for learners.

L1 calque. We prompt GPT-5.2 to determine if the English word is a morpheme-for-morpheme translation of the L1 equivalent. The prompt excludes single-morpheme words and simple borrowings but does not require one word to be a calque of the other in the etymological sense. In contrast to the L1 similarity feature, L1 calque is also applicable to Chinese, e.g., 超级英雄 ‘superhero’ (composed of morphemes 超级 ‘super-’ and 英雄 ‘hero’).

For each of the prompt-based features, including the binary ones, we apply G-SCALE (Nohejl et al., 2025a), i.e., temperature-scaled softmax followed by a probability-weighted mean of the LLM’s predictions (Equation 4). The optimal temperature is determined for each model separately using cross-validation. This results in continuous feature values.

When reporting SHAP values, we sum the values within each group if it consists of multiple features (e.g., production frequency) without distinguishing the individual features.

We have submitted our explainable model as explainable and the model using only the traditional (not LLM-based) subset of features as traditional.

3.3 Ensembles and Additional Features

To further increase accuracy, we ensemble fine-tuned LLMs in a linear stack, combine fine-tuned LLM predictions with features, and experiment with additional features and fine-tuning encoder models using the same method we used for LLMs.

Linear stacking. When fine-tuning LLMs, we perform 5-fold cross-validation and use the out-of-fold predictions to fit a linear regression that combines the predictions of multiple LLMs in an ensemble. The linear regression is fit separately for each L1. The final ensemble uses models fine-tuned on the complete data (the union of the provided test and development subsets). As this approach is rather computationally intensive, we compare it with simple average ensembling. Corresponding submission: `finetuned_llms`.

Enhancing LLMs with features. The linear stacking approach allows us to add our explainable features to the same linear regression as the fine-tuned LLMs, building on the G-SCALE method proposed by (Nohejl et al., 2025a). Corresponding submission: `finetuned_llms_plus`.

Fine-tuned encoders and additional features. We add an encoder model fine-tuned on single-language data and several other features to the feature model. We do this to maximize performance within the rules for the closed track, although the resulting model is no longer explainable. The added features are: (1) frequency in OpenSubtitles (Lison et al., 2018), a corpus similar to the already included TUBELEX; (2) frequency in the written subcorpus of the BNC; (3) CEFR level in the Global Scale of English² (Jong et al., 2016), similar to the already included EVP level; (4) the Glasgow norms for concreteness, imageability, familiarity, and age of acquisition (Scott et al., 2019), which often strongly correlate with other already included features; and (5) an additional prompt for the calque feature. Corresponding submission: `closed_max`.

In the open track, we prompt two LLMs, GPT-4.1-mini and GPT-4.1-nano (OpenAI, 2024), to solve the test items, and we use their probability of a correct answer to indirectly assess the test item difficulty caused by the choice of the L1 word and context in the test item. To clearly distinguish this from the difficulty of the English vocabulary itself, we call this feature **trickiness**. We hypothesize

²<https://www.english.com/gse/teacher-toolkit/user/vocabulary>

that the LLMs have near-perfect knowledge of common vocabulary in the four relevant languages, and their performance therefore reflects the trickiness of the test items rather than the difficulty of the English vocabulary. Corresponding submission: `finetuned_llms_plus`, `open_max`.

We additionally experimented with prompting two recent LLMs, GPT-5.2 and GPT-4.1 (OpenAI, 2024), to directly rate the **difficulty** of the test items for learners of each L1 using 3-shot prompting. Corresponding submission: `open_max`.

Neither of the last two prompting approaches (trickiness and difficulty) were permitted in the closed track.

4 Experimental Settings

We experimented with multiple prompts for fine-tuning using a small LLM and 1-epoch training on a single L1. However, as we show in the ablation analysis in Section 6.1, with more training epochs, the prompt matters very little. For LLM prompting, we verified on a hand-picked sample that the model responses match our expectations, but we did not try to optimize the prompts.

In Appendix A, we provide complete listings of prompts used for fine-tuning and prompting.

As a basis for all fine-tuning experiments, we used pre-trained MLMs or LLMs, i.e., models not fine-tuned on chat or instruction data. For fine-tuning, we used recent LLMs with up to 32B parameters from the GLM-4 family (Team GLM, 2024), Qwen2.5 family (Qwen Team, 2025), and Ministral-3 family (Mistral AI, 2026), as well as MLMs mmBERT (Marone et al., 2025) and XLM-RoBERTa (Conneau et al., 2020). For prompting, we used models of the GPT-4.1 (OpenAI, 2024) and GPT-5.2 (OpenAI, 2025) families, and DeepSeek-V3.2 (DeepSeek-AI, 2025). Appendix B provides more details.

For MLMs, we performed end-to-end fine-tuning. For LLMs, we applied 4-bit quantization and fine-tuned QLoRA adapters (Detrmers et al., 2023) targeting all linear modules. All hyperparameters are described in Appendix C. We trained all models on the union of the test and development subsets provided by the shared task organizers. For the prompt-based features, we called models via the OpenAI API with zero temperature and requested log-probabilities necessary for probability weighting.

In all cases where a model is supposed to output

System	Chinese	German	Spanish	Mean
<code>open_max</code>	0.631	0.723	0.743	0.699
<code>finetuned_llms_plus</code>	0.630	0.726	0.742	0.699
<code>finetuned_llms</code>	0.640	0.731	0.760	0.710
≤32B LLM Average	0.645	0.743	0.767	0.719
- GLM-4-32B	0.678	0.769	0.805	0.751
- Qwen2.5-32B	0.678	0.777	0.799	0.752
- Ministral-3-14B	0.681	0.781	0.799	0.753
≤14B LLM Average	0.662	0.770	0.804	0.745
≤9B LLM Average	0.683	0.791	0.835	0.769
Open-Track Baseline	1.034	1.166	1.198	1.133
Statistical Optimum	0.321	0.304	0.205	0.277

Table 2: RMSE of our open-track submissions, compared with average ensembles by model size, individual models, and the shared task’s open-track baseline.

a difficulty rating on a scale from 1 to 5, we map the difficulty scores from the KVL data linearly so that the highest score (the easiest item) in the training data maps to 5 and the lowest score to 1. The prompts are formulated accordingly. As the GLMM scores represent log-odds, we also experimented with mapping them to probabilities using the expit function (logistic curve), which decreased performance. See results in Appendix G.

5 Results

In line with the shared task’s evaluation, we report the root mean square error (RMSE) by L1 and compare it with the official shared tasks’ baseline, a fine-tuned XLM-RoBERTa model (Felice and Skidmore, 2026).

Note that RMSE is in the same units as the difficulty scores, which typically range from -5 to $+5$. We also report the Pearson’s correlation coefficients (PCC) r , the secondary evaluation metric, which may be easier to interpret, in Appendix D.

To further put the results into perspective, we report a “Statistical Optimum” result, which simulates the largest error (lowest correlation) that should be considered optimal given the precision of the gold standard data. The simulation is based on confidence intervals reported by Schmitt et al. (2024); see Appendix F for details.

5.1 Open Track

As shown in Table 2, the results of our three open-track submissions are very close to each other. In summary, the results do not justify the cost of adding features to fine-tuned LLMs. This contrasts with previous findings for in-context learning setting, where just adding frequency as a feature

System	Chinese	German	Spanish	Mean
closed_max	0.816	0.963	0.983	0.921
explainable	0.920	1.126	1.156	1.067
traditional	1.078	1.195	1.305	1.193
expl. – std. inference	0.961	1.151	1.190	1.101
expl. – lin. regression	0.975	1.154	1.202	1.111
Closed-Track Baseline	1.140	1.258	1.257	1.218

Table 3: RMSE of our closed-track submissions, compared with two variants of the explainable model and the shared task’s closed-track baseline.

improves LLM predictions of lexical complexity (Nohejl et al., 2025a). The models with added features (open_max and finetuned_llms_plus) surpassed all other submissions in the open track on all three languages. The linear stack of LLMs (finetuned_llms) surpassed all other submissions on Chinese and German but was narrowly outperformed by submissions from the Glite team on Spanish. The RMSE of approximately 0.7 that our models achieve is relatively close to the statistical optimum of 0.277.

Linear stacking (finetuned_llms) results in a modest improvement over the average ensemble of the same models ($\leq 32\text{B}$ LLM Average). The ensembling itself, however, improves performance more substantially, from an RMSE of 0.751–0.753 for individual models to 0.719 for the average ensemble. While increasing the model size obviously improves performance, it is worth noting that the smaller Ministral-3-14B model performs on par with the 32B Qwen2.5 and GLM-4 models.

In Appendix E, we compare all individual LLMs used in the ensembles above, as well as LLMs with 0.5B parameters and similarly sized MLMs, showing that LLMs and MLMs achieve comparable results at comparable model sizes.

5.2 Closed Track

Table 3 compares the results of our submissions to the closed-track baseline. Interestingly, our model with only traditional features performs on par with the encoder-based baseline, and our explainable model with extra LLM-based features outperforms the baseline by a relatively wide margin (mean RMSE of 1.218 vs. 1.067). The closed_max model achieves a further improvement (mean RMSE of 0.921) by adding a fine-tuned MLM as a feature.

Two variants applied to the explainable features—standard inference for prompt-based features instead of probability weighting, and linear regression in-

stead of an XGBoost regressor—result in higher RMSE.

6 Analysis and Discussion

6.1 Ablation Analysis

We ablate the fine-tuned LLM and MLM that were used in our open-track submissions and the closed_max closed-track submission. For the open-track submission, we ablate only one of the three similarly performing LLMs in the ensemble, Ministral-3-14B as follows:

Single language. We fine-tune the model on single L1 data instead of all three languages.

Out-of-language. We fine-tune the model on data for the other two L1s (e.g. the model tested on Chinese is fine-tuned on German and Spanish).

Short prompt. We use a minimalistic prompt template instead of the basic verbose one. See Section A.1.

Standard loss. Instead of using the cross-entropy loss with a soft target, described in Section 3.1, we fine-tune using the standard cross-entropy loss with the discretized score following Smřdu et al. (2024).

Standard loss and inference. We fine-tune using the standard cross-entropy loss with a discretized

score, and instead of using probability-weighting at inference, we decode the highest probability token.

In addition to performing the same ablations for the MLM, we also compare the results of our method to those of using a regression head with MSE loss on mmBERT-base and two sizes of XLM-RoBERTa models (listed as **Regression**). Note that in the closed track, rules required us to use the variant we report here as an ablation (mmBERT-b/single language).

As shown in Table 4 and Table 5, our method outperforms all ablations with the single exception of the MLM model fine-tuned only on Chinese L1 data, which performs better on Chinese by a small margin. In the other cases, training on a single language results in only a small performance drop.

The standard loss ablation demonstrates that our technique of fine-tuning using cross-entropy loss with soft targets is superior to common approaches for both LLMs and MLMs. Fine-tuning using the standard loss results in a tangible performance drop for both model types (a difference in mean RMSE of 0.079 and 0.900, respectively). For the MLM, the common approach of fine-tuning a regression head with MSE loss degrades performance similarly (by a difference in mean RMSE of 0.809).

6.2 The Explainable Models

As outlined in Section 3.2, we designed a feature-based model with traditional and LLM-based features that all have a clear interpretation. SHAP values explain the model’s output locally in terms of the impact of each feature, which has both sign and magnitude. For a global analysis of feature importance, we report the mean absolute SHAP values computed over the test data in Figure 1.

Production frequency is a consistently high-impact feature across languages. Its importance per language, in fact, corresponds with the amount of L1-specific data available. Yet, even for German, with no L1-specific data available, the feature almost completely overshadows **reception frequency**, which ranks as the least important across L1s. This is in line with the focus of the KVL data on production and can be contrasted with findings for the comprehension-focused LCP, where reception frequency (represented by frequency in TUBELEX) and production frequency (represented by frequency in Lang-8) are equally good predictors (Nohejl et al., 2024)

Spelling difficulty is the most important feature for L1 German and the second most important

Figure 1: Global SHAP summaries by L1.

feature for Spanish. Perhaps counter-intuitively, it is much less important for L1 Chinese. We hypothesize this is caused by two factors. First, the production frequency uses learner-written texts, and therefore it partially discounts the frequency of words with frequent mistakes. As a result, the importance of the separate spelling difficulty feature is lower proportionally to the size of the L1-specific written production data. Second, for Chinese speakers, there may be less interference from the orthography of their L1, which is primarily written in Chinese characters, while Spanish and German speakers may be more prone to making errors due to the influence of their L1’s spelling (e.g., English *music, action*; German *Musik, Aktion*).

CEFR level ranks particularly high for Chinese L1 learners. This corresponds to a very small proportion of cognates between English and Chinese compared to the two European languages, where **L1 Similarity** can play a comparable (Spanish) or more important role (German).

Lexical ambiguity has a similarly high impact as

Figure 2: Example of local SHAP explanations by L1 for the English word *farmhouse*.

the CEFR level and can be seen as complementary to the CEFR level and the frequency features, all of which focus on the surface lemma (frequency of all senses or homonyms, the lowest CEFR level, regardless of sense). We recognize words as lexically ambiguous if the test item refers to a less common sense or a homonym.

Word length is surprisingly one of the consistently relevant features. While length certainly contributes to the difficulty in acquiring a word, it also simply increases the probability of typos, even in cases when the writer knows the word’s spelling.

L1 calque is one of the globally least important features, reflecting both the frequency of calques in the language pairs and the fact that an L1 word being a calque (morpheme-for-morpheme translation) being less conducive to eliciting the production of the correct English word than the surface level L1 similarity.

Local explanations of all test set predictions of the explainable model can be viewed in an online

application.³ In Figure 2 we provide an example of the local explanation of the difficulty of the English word *farmhouse*, which, despite being relatively rare and not being assigned any CEFR level in the EVP, is not a particularly difficult word for L1 Chinese and German learners. Both its Chinese and German counterparts are calques of the English word *farmhouse*, which contributes to lower difficulty in these languages. On the other hand, for L1 Spanish speakers, the word is assessed as comparatively difficult to spell.

Neither the global nor the local explanations can be interpreted as the actual causes of the difficulty of a particular word. In particular, it cannot tell us anything about features not present in the model, and it underestimates the importance of a factor when the data has low quality (e.g., production frequency in the case of L1 German). On the other hand, given the relatively high accuracy of the model, we believe that the globally high-impact features provide valuable insights.

Both the high impact of production frequency and spelling difficulty is in line with the focus of the KVL. However, the combined importance of features reflecting the difficulty of spelling a word without errors (spelling difficulty, word length, and, to some extent, also the learners’ written production frequency) could affect the utility of the dataset for other uses, such as creating reading materials matched to the learner’s level. (Schmitt et al., 2024) suggest the KVL data could be more suitable for this purpose than frequency.

Given that the KVL are designed to focus on the most common word sense (Schmitt et al., 2024), the high importance of lexical ambiguity in our analysis could seem spurious. We have, however, observed uncommon word senses in the data. For instance, the noun *wireless* is included in the sense ‘radio (receiving set)’, which is dated and mainly British according to the Oxford Dictionary of English, rather than in the sense ‘wireless broadcasting or networking using radio signals’. For other words, such as *log* (‘chunk of wood’ in KVL, not ‘record’) or *diet* (‘nutrition’ in KVL, not ‘dietary regime’), two senses may be similarly common. Lexical ambiguity provides a useful signal in all these cases.

everybody	todo el mundo	everyone*
synonymous	sinónimo	synonym*

Table 6: Examples of tricky test items in L1 Spanish, based on responses of GPT-4.1-mini. First letter printed in bold. Asterisks mark incorrect word length.

6.3 Tricky Test Items

The shared task rules permitted us to use the trickiness feature only in the open-track submission, where its impact was relatively small. However, it provides an interesting insight into how the test item construction often affects the resulting difficulty scores. The value of our trickiness feature is the probability of an LLM answering the test item incorrectly. Table 6 shows examples of high-trickiness items from the test set. For brevity, we focus on cases that do not depend on the L1 context. As exemplified by the items *instantly*, *motivational*, and *reform*, in many cases, the creators of the KVL test items intentionally avoided cognate L1 words. The words they have chosen instead often correspond better to English words other than the intended ones. In other cases, the reason is not the avoidance of cognates, but the L1 word strongly suggests a different English word nonetheless. While in some cases the L1 context or the number of letters disambiguates the English word (e.g., *sinónimo* is used as an adjective, not a noun; *everybody* and *everyone* differ in word length), such details were likely easy to miss not only for the LLM but also for the respondents. We believe that while better choices could have been made for some items, this shows an inherent limitation of the test item format used to compile the KVL.

7 Conclusion

We proposed a novel method for fine-tuning LLMs and MLMs to predict continuous values using cross-entropy loss with soft targets. The method achieved consistent gains on the vocabulary difficulty prediction task over prior approaches, such as discretization for LLMs and a regression head with MSE loss for MLMs.

In our fine-tuning experiments, increases in base model size up to 32B parameters resulted in performance improvements. The larger-sized LLMs

also consistently outperformed the smaller-sized MLMs. This result differs from the LCP study by Smádu et al. (2024), where much smaller fine-tuned MLMs performed comparably to much larger LLMs. We hypothesize that this could be due to the more complex nature of vocabulary difficulty prediction compared to LCP.

We built a separate explainable model that achieves competitive results on the task and provides insights into what affects vocabulary difficulty scores in the British Council’s KVL data. The high impact of spelling difficulty and the construction of the test items call for further investigation.

Limitations

We tested the proposed method for fine-tuning LLMs and MLMs to predict continuous values using cross-entropy loss with soft-targets only on this shared task’s data (KVL). Its suitability for other tasks and settings is yet to be investigated. On smaller or noisier data, for instance, its impact may be less pronounced. Various parameters, such as the number of points on the scale used, may also affect its performance.

The insights provided by our explainable model and the trickiness model can, in principle, be empirically validated, but we have not been able to do so, as the individual responses used to compile KVL are not publicly available. The frequency of spelling mistakes would be particularly easy to validate with access to the responses.

A Prompt Templates

In the following, we list the full text of our prompt templates by feature for which they were used. The symbol ↵ stands for line breaks. Placeholders are printed in bold. The following common placeholders corresponding to the dataset items are used across multiple prompts:

- {l1_name}: an L1, i.e., Spanish, Chinese, or German.
- {l1_word}: an L1 word.
- {l1_context}: an L1 context.
- {en_word}: an English word.
- {clue}: a letter-pattern clue derived from the English word (first letter + space-separated underscores), e.g., b _ _ _ for book.

A.1 Fine-Tuning

Basic template:

Rate how difficult it is for learners to guess the English word based on the {l1_name} word, context and clue on a scale from 1 to 5 (1=very easy, 5=very difficult).↵
 {l1_name} word: {l1_word}↵
 {l1_name} context: {l1_context}↵
 Clue: {clue}↵
 English word: {en_word}↵
 Difficulty:

Short prompt template:

Used in the “short prompt” ablation.

```
{l1_word} ### {l1_context} ### {clue} ###
{en_word} ### Difficulty (1 to 5):
```

Regression template

Used for MLMs when fine-tuning with a regression head, following Skidmore et al. (2025).

```
[CLS] {l1_word} [SEP] {l1_context} [SEP] {clue}
[SEP] {en_word} [SEP]
```

A.2 Lexical Ambiguity

Placeholders:

We use the English word “bank” as an example of lexical ambiguity (‘financial institution’ vs. ‘(river) side’). For L1 Spanish, the placeholders would take the following values:

- {ex_en_word}: “bank”
- {ex_easy_word_l1}: “banco”
- {ex_easy_context_l1}: “Depositó el dinero en el banco.”
- {ex_hard_word_l1}: “orilla”
- {ex_hard_context_l1}: “Nos sentamos en la orilla del río.”

Prompt template:

```
You are a language education expert.↵
TASK↵
Given:↵
- an English word form (the "English word"),↵
- an L1 gloss/translation (the "{l1_name} item"),↵
- and the L1 usage context sentence (the "{l1_name} context"),↵
decide whether the English word, when used to
express the meaning suggested by the L1 item +
context,↵
meets BOTH conditions:↵
A) Lexical ambiguity: the English word has
multiple established senses that share the same
form↵
    (polysemy or homonymy), such that another
    common sense could plausibly be
    activated/confused.↵
B) Unfamiliarity for L2 learners: in this
meaning/usage, the English word is likely to be
unfamiliar↵
    or challenging for typical second-language
    learners (e.g., less frequent sense,
    idiomatic/figurative,↵
    domain-specific usage, nonliteral
    extension).↵
OUTPUT REQUIREMENTS↵
- Output "1" if BOTH conditions (A and B) are
met; otherwise output "0".↵
- Output MUST be exactly one character: 1 or 0.↵
- Do NOT include explanations, alternatives,
quotes, or extra text.↵
EXAMPLE 1↵
English word: {ex_en_word}↵
{l1_name} item: {ex_easy_word_l1}↵
{l1_name} context: {ex_easy_context_l1}↵
Is the English word ambiguous and unfamiliar: 0↵
EXAMPLE 2↵
English word: {ex_en_word}↵
{l1_name} item: {ex_hard_word_l1}↵
{l1_name} context: {ex_hard_context_l1}↵
Is the English word ambiguous and unfamiliar: 1↵
NOW DECIDE↵
English word: {en_word}↵
{l1_name} item: {l1_word}↵
```

```
{l1_name} context: {l1_context}↵
Is the English word ambiguous and unfamiliar:
```

A.3 Spelling Difficulty

This prompt is executed for all L1s at once.

Placeholders:

- {en_pron}: CMU-style pronunciation string of the English word of the current item. Example: K Y UW for “queue”.
- {all_l1_words[l1]}: L1 words of the current item (all three in one prompt).
- {hard_pron}, {hard_cn}, {hard_es}, {hard_de}, {hard_cn_score}, {hard_es_score}, {hard_de_score}: hard demonstration item (pronunciation, three L1 translations, and example scores 5, 4, 4).
- {easy_pron}, {easy_cn}, {easy_es}, {easy_de}, {easy_cn_score}, {easy_es_score}, {easy_de_score}: easy demonstration item (pronunciation, three L1 translations, and example scores 1, 1, 1).

Prompt template:

```
TASK↵
You are required to rate English spelling
difficulty on a 1-5 scale, where 1 = very easy
and 5 = very difficult.↵
You will be given English pronunciation and the
target word's translation in Chinese, Spanish,
and German.↵
Evaluate how difficult it would be for learners
with Chinese, Spanish, and German L1 backgrounds
to spell the English word with that pronunciation
correctly when they know the translation in their
native language.↵
OUTPUT REQUIREMENTS↵
- Output exactly one digit (1, 2, 3, 4, or 5) for
each L1, separated by commas, in the order of
Chinese, Spanish, German.↵
- Do not include any other text.↵
EXAMPLE 1↵
English pronunciation: '{hard_pron}'↵
Chinese: {hard_cn}↵
Spanish: {hard_es}↵
German: {hard_de}↵
Result:
{hard_cn_score},{hard_es_score},{hard_de_score}↵
EXAMPLE 2↵
English pronunciation: '{easy_pron}'↵
Chinese: {easy_cn}↵
Spanish: {easy_es}↵
German: {easy_de}↵
Result:
{easy_cn_score},{easy_es_score},{easy_de_score}↵
NOW DECIDE↵
English pronunciation: {en_pron}↵
Chinese: {all_l1_words['cn']}↵
Spanish: {all_l1_words['es']}↵
German: {all_l1_words['de']}↵
Result:
```

A.4 L1 Calque

This prompt uses Spanish examples for all L1s.

Prompt template:

You are a linguist and your task is to decide whether an English word is a morpheme-for-morpheme translation of any of the given **{l1_name}** equivalents.↵
The morpheme-for-morpheme mapping must be 1:1. 1:N or other mappings do not count.↵
Single morpheme translations or simple borrowings/cognates do not count either.↵
Respond only with YES or NO.↵
wave/ola: NO (reason: single morpheme)↵
ecosystem/ecosistema: NO (reason: simple cognate)↵
hotdog/perro caliente: YES (reason: hot=caliente, dog=perro)↵
stare/mirar fijamente: NO (reason: not a 1:1 mapping)↵
{en_word}/{l1_word}:

A.5 L1 Calque (used only in closed_max)

This was our first iteration of the prompt. It did not give the expected results (monomorphemic word pairs were labeled as calques), so we did not use it for our explainable model. However, as it performed well as a feature, we included it in the closed_max model.

Placeholders:

- **{ex_calque_l1}**: the L1-side word, e.g., “热狗” for Chinese, composed of the morphemes ‘hot’ and ‘dog’.
- **{ex_calque_en}**: the English-side word, e.g., “hot dog”.

Prompt template:

You are a bilingual linguistics expert.↵
TASK↵
Given a **{l1_name}** item and an English item, decide whether there exists a best-matching candidate in the **{l1_name}** item that is a component-by-component (morpheme-level) translation of the English item.↵
A component-by-component mapping means that the meaningful parts↵
(words, roots, prefixes, or suffixes) of the English item are directly translated↵
into corresponding meaningful parts in the **{l1_name}** item.↵
Procedure (internal; do NOT output these steps):↵
1) If the **{l1_name}** item contains multiple candidates, select exactly ONE candidate: the one that aligns best component-wise with the English form.↵
2) Judge ONLY that selected candidate for component-by-component mapping.↵
OUTPUT REQUIREMENTS↵
- Output “1” if the selected best candidate is a component-by-component mapping; otherwise output “0”.↵

- Output MUST be exactly one character: 1 or 0.↵
- Do NOT include explanations, alternatives, quotes, or extra text.↵
EXAMPLE↵
{l1_name} item: **{ex_calque_l1}**↵
English item: **{ex_calque_en}**↵
Is word-for-word mapping: 1↵
NOW DECIDE↵
{l1_name} item: **{l1_word}**↵
English item: **{en_word}**↵
Is word-for-word mapping:

A.6 Trickiness (short prompt, used only in open_max)

Placeholders:

{solve_example}: a formatted one-shot example (L1 word, L1 context, English word) using the item English word “strawberry”. Example:

German word: Erdbeere↵
German context: Ich mag keine Erdbeeren.↵
English word: strawberry

Prompt template:

You are bilingual in **{l1_name}** and English and your task is to find the best English translation for a **{l1_name}** word given a context and constraints. The constraints are given in the form of a clue, e.g., “b _ _”, meaning that the word starts with the (upper or lower case) letter B and has 4 letters. You must give a single English word in dictionary form (lemma) as a response.↵
{solve_example}↵
{l1_name} word: **{l1_word}**↵
{l1_name} context: **{l1_context}**↵
Clue: **{clue}**↵
English word:

A.7 Trickiness (long prompt, used only in open_max)

Placeholders:

Same as in [Section A.6](#).

Prompt template:

You are bilingual in **{l1_name}** and English.↵
TASK↵
Given a word in **{l1_name}**, its usage context, and a spelling clue, find the single best English translation that fits BOTH the meaning and the spelling constraint.↵
INPUTS↵
- **{l1_name}** word: a single word to translate↵
- **{l1_name}** context: a sentence showing how the word is used↵
- Clue: a pattern such as “b _ _”, where:↵
* the first letter is indicated
(case-insensitive)↵
* “_” indicates subsequent unknown letter↵
* the total number of letters must match exactly↵
OUTPUT REQUIREMENTS↵
- Output EXACTLY ONE English word↵
- The word must be:↵
* a dictionary form (lemma)↵

- * a single token (no spaces, hyphens, or punctuation)↵
- * consistent with the context↵
- * consistent with the clue↵
- Do NOT include explanations, alternatives, quotes, or extra text.↵

EXAMPLES↵

{solve_example}↵

NOW SOLVE↵

{l1_name} word: **{l1_word}**↵

{l1_name} context: **{l1_context}**↵

Clue: **{clue}**↵

English word:

A.8 Difficulty

Placeholders:

{examples}: a block of examples for difficulty rating using examples from the training data. Examples with ratings converted to values close to 1, 3, and 5 are selected for each L1 separately.

Prompt template:

You are an English language teacher teaching learners whose native language is **{l1_name}**. Your task is to rate the difficulty of a vocabulary test item for native **{l1_name}** speakers learning English.↵

The test item consists of:↵

- a **{l1_name}** word,↵
- a **{l1_name}** context,↵
- a clue indicating the first letter and word length of the English word,↵
- the target English word, which is the only correct answer.↵

Letter case does not matter. The learners are likely to respond with synonyms or misspellings to some items, but such responses are considered incorrect. Treat this as increasing the difficulty.↵

Consider learners from beginner to advanced levels, weighting the intermediate learner most heavily. Rate how difficult the item is on a scale from 1 to 5:↵

1 = very easy (almost everybody answers correctly)↵

5 = very difficult (almost nobody answers correctly)↵

Output exactly one digit (1, 2, 3, 4, or 5). Do not include any other text.↵

{examples}↵

{l1_name} word: **{l1_word}**↵

{l1_name} context: **{l1_context}**↵

Clue: **{clue}**↵

English word: **{en_word}**↵

Difficulty:

B Base Models and API Models

Table 7 lists base LLMs and MLMs that we fine-tuned in our experiments. Table 8 lists LLMs that we used for prompt-based features via API.

Model Name	Hugging Face Model ID	Systems/References to Results
GLM-4-32B	zai-org/GLM-4-32B-Base-0414	finetuned_llms*
Qwen2.5-32B	Qwen/Qwen2.5-32B	finetuned_llms*
Minstral-3-14B	mistralai/Minstral-3-14B-Base-2512	finetuned_llms*; $\leq 14B$ LLM Average; ablations in Table 4
Qwen2.5-14B	Qwen/Qwen2.5-14B	$\leq 14B$ LLM Average
GLM-4-9B	zai-org/glm-4-9b	$\leq 14B$ LLM Average; $\leq 9B$ LLM Average
Qwen2.5-7B	Qwen/Qwen2.5-7B	$\leq 9B$ LLM Average
Minstral-3-8B	mistralai/Minstral-3-8B-Base-2512	$\leq 9B$ LLM Average
Qwen2.5-1.5B	Qwen/Qwen2.5-1.5B	model size comparison in Appendix E
Qwen2.5-0.5B	Qwen/Qwen2.5-0.5B	model size comparison in Appendix E
mmBERT-b (mmBERT-base)	jhu-clsp/mmBERT-base	closed_max; regression and ablations in Table 3
XLMR-b (XLM-RoBERTa-base)	xlm-roberta-base	baselines; regression in Table 3
XLMR-l (XLM-RoBERTa-large)	xlm-roberta-large	regression in Table 3

*The three models used in finetuned_llms, were also used in the finetuned_llms_plus and open_max submissions, and the $\leq 32B$ LLM Average ensemble.

Table 7: Open-weight base models used in fine-tuning experiments.

Model Name	Provider	Model ID (Snapshot)	Explainable Features (explainable; open_max)	Additional Features (open_max)
GPT-5.2	OpenAI	gpt-5.2-2025-12-11	Lexical ambiguity; Spelling difficulty; L1 calque	Difficulty
GPT-4.1	OpenAI	gpt-4.1-2025-04-14		Trickiness; Difficulty
GPT-4.1-mini	OpenAI	gpt-4.1-mini-2025-04-14		Trickiness
GPT-4.1-nano	OpenAI	gpt-4.1-nano-2025-04-14		Trickiness
DeepSeek-V3.2	DeepSeek	deepseek-chat	Lexical ambiguity	

Table 8: Models used for features based on LLM prompting.

C Hyperparameters

Table 9 shows the general fine-tuning hyperparameters. For XLM-RoBERTa, we followed Skidmore et al. (2025). For other models, we performed a limited search for the learning rate and epochs using cross-validation. For mmBERT, a higher learning rate would likely be optimal, but $3e-5$ was the largest we evaluated. For LLMs, we found that the learning rate of $1e-4$ performed better than $1.5e-4$, but we could not rerun the training for Qwen2.5-32B in time for the final submission. Table 10 lists the quantization and LoRA hyperparameters used for all LLM fine-tuning.

For the XGBoost regressor (XGBRegressor in XGBoost’s Scikit-Learn API⁴), we set max_depth=3, learning_rate=0.1, and n_estimators=200, while using default values for other hyperparameters.

Model	Epochs	Batch size	Grad. accum.	Learning rate	Weight decay	Warmup ratio
XLM-RoBERTa (both)	5	32	—	$3e-5$ (linear)	0.1	0.1
mmBERT-base	16	16	—	$3e-5$ (const.)	0.1	0.1
Qwen2.5-32B	4	2	8	$1.5e-4$ (const.)	—	—
All other LLMs	4	2	8	$1e-4$ (const.)	—	—

Table 9: General fine-tuning hyperparameters used for different models.

D Results Reported as Pearson’s Correlation Coefficients

Table 11, Table 12, Table 13, and Table 14 show Pearson’s correlation coefficient (PCC) evaluation corresponding to the RMSE evaluation shown in the main text in Tables 2 to 5.

E Comparison of Models Across Sizes

In Table 15 and Table 16, we compare all base models we used in experiments, including models that are only reported in ensembles in the main text. To facilitate the comparison of models of different architectures (decoder LLMs and encoder MLMs), we also add Qwen models of sizes 1.5B and 0.5B, as well as XLM-RoBERTa models fine-tuned with the same prompt and method. We can observe that the model size, rather than the architecture, determines performance in this task. At the same size, however, MLMs are more compute-efficient.

All models were fine-tuned using the same cross-entropy loss with soft targets and the same prompt, utilizing hyperparameters listed in Appendix C.

F Simulation of a Statistical Optimum

The difficulty scores provided by the KVL data are based on test item responses. The number of responses collected for each item (120 to 228 responses) determines the precision of the data, which can be expressed as a confidence interval. Schmitt et al. (2024, Sec. 6.3, App 5) provide 83% confidence intervals for selected bands of the complete KVL data (e.g., items ranked 200–299 for L1=Spanish) expressed in numbers of ranks (e.g., 44). The rationale for 83% is that it corresponds to a significance level of 5% for differences in pairwise ordering (e.g., there is no significant difference

significant difference from the gold standard data; hence, we report their RMSE and correlation as a “statistical optimum”.

G Predicting in the Probability Space

As shown in Table 17, fine-tuning an LLM to predict in the probability space instead of the logit space, in which the GLMM scores are, resulted in a decrease in performance. We therefore used the raw GLMM scores for the main experiments.

Target Values	↓ RMSE				↑ PCC			
	Chinese	German	Spanish	Mean	Chinese	German	Spanish	Mean
Logits: GLMM score	0.681	0.781	0.799	0.753	0.915	0.902	0.907	0.908
Probabilities: expit(GLMM score)	0.738	0.853	0.877	0.822	0.905	0.889	0.895	0.896

Table 17: Performance of Ministral-3-14B when fine-tuned on the raw GLMM score (logits), as we did in all experiments, compared with the same model fine-tuned on the corresponding probabilities. In both cases, the values were linearly transformed to the 1-to-5 difficulty scale we use in our prompt, and all other parameters were the same. RMSE and PCC were measured for GLMM score values in the logit space for both.

Report on the BEA 2026 Shared Task on Rubric-based Short Answer Scoring for German

Abstract

We present the BEA 2026 shared task on rubric-based short answer scoring for German. Rubric-based short answer scoring is a case of automatic short answer scoring (ASAS) that requires models to apply textual scoring rubrics to student answers as a basis for assigning scores. For the shared task, we introduced a novel German-language dataset from multiple STEM domains to provide a comprehensive benchmark for this problem. The dataset was designed to evaluate both performance and generalization (the latter, by distinguishing between seen and unseen questions), as well as coarse- and fine-grained scoring (2-way vs. 3-way). The systems submitted to the shared task cover a wide range of approaches, including fine-tuned large language models, prompt-based methods, human-AI collaboration strategies, or a combination of these. The results show that structured, task-adapted LLM systems achieved the strongest performance across all tracks. The winning system, IWM-DKM, combined LoRA fine-tuning of Qwen models with rubric-aware input structuring, including checklist-style reasoning, rubric reframing as decision trees, background knowledge injection, and ensemble voting. Other systems similarly relied on fine-tuned LLMs, retrieval-augmented prompting, encoder-LLM ensembles, or weighted aggregation strategies. Overall, the shared task results show that rubric-based scoring benefits most from systems that explicitly operationalise rubric semantics, while generalisation to unseen questions remains a central challenge.

1 Introduction

Short answer scoring is an established task in educational natural language processing (Burrows et al., 2015; Bai and Stede, 2023; Bexte et al., 2024). It was already addressed in at least two previous shared tasks, namely the *SemEval 2013 Shared Task* (Dzikovska et al., 2013) and the ASAP-

SAS Kaggle competition (Hamner et al., 2012). In recent years, it has primarily been approached using two paradigms: instance-based and similarity-based approaches (Bexte et al., 2022, 2023).

On the one hand, instance-based approaches train a model that predicts scores as labels or regression targets for a given input response. While this approach has been shown to work quite well, it also suffers from the problem of not transferring well to questions unseen during training (Padó et al., 2023). This means that implementing an instance-based short-answer scoring system requires collecting and manually scoring student answers for a select set of questions. A model trained on these in an instance-based fashion then only supports scoring unseen answers to these known questions. In this approach, the resulting model is intended to implicitly take up the relevant rules for scoring instances.

Similarity-based approaches, on the other hand, attempt to circumvent these problems by selecting a setup based on nearest-neighbour search or natural language inference (Bexte et al., 2022; Camus and Filighera, 2020), which are designed to compare a student’s answer to one or more provided reference answers. While this results in better transfer capabilities to unseen questions and domains, a problem with this setup is that not all possible question formats necessarily allow using a similarity-based setup, since for some questions, a broad range of answers might be valid, and out-of-sample generalization may fail due to unexpected content during inference.

With this shared task, we therefore look at another interpretation of the task that could help to circumvent these problems: rubric-based short answer scoring. For rubric-based short answer scoring, a model is provided with an answer, a question/prompt and a textual scoring rubric that, for each possible score, establishes criteria that need to be met so the same can be assigned to a given answer. To successfully solve this task, a model must

account for the semantics of a scoring rubric and apply its criteria to the candidate answers. This setup is inspired by established human scoring practice (Reddy and Andrade, 2010; Panadero and Jonsson, 2013). Here, human scorers are often provided with a rubric and then need to reason about which criteria apply to a given answer to assign the appropriate score. These rubrics are often question-specific and are, in turn, typically embedded in assessment frameworks that specify the construct that the test is intended to measure (e.g. OECD, 2024, 2023).

While rubrics have been applied in various works on free-text scoring and have shown promise as supplementary input or pre-training resource for instance- and similarity-based scoring systems (Wang et al., 2019; Li et al., 2023; Condor et al., 2022; Sonkar et al., 2024) as well as for systems based on LLM prompting (Wei et al., 2025; Frohn et al., 2025; Cong et al., 2026), there is, as of now, a lack of focused research on rubric-based short-answer scoring. However, this involves many challenges such as the uncertainty in the rubrics and, depending on the question, the semantic variability of the answers. With additional information from rubrics or assessment frameworks, resulting models can be designed more explicitly to incorporate scoring criteria that are specific to a given domain or assessment construct. As of now, there is a clear research gap in understanding how well current methods in NLP can comprehend rubrics and apply them to students’ answers to predict corresponding scores. With this shared task, we aimed to kickstart research on this specific interpretation of the short-answer scoring task with the following concrete contributions:

- We hosted a shared task on *rubric-based short answer scoring*, a setting that reflects real-world educational assessment, ranging from classroom to standardized testing, and requires models to interpret and apply textual scoring criteria.
- We provided a new publicly available benchmark dataset for this task in German, contributing to the currently limited pool of non-English resources for ASAS.
- We designed a comprehensive evaluation setup that systematically distinguishes between seen and unseen questions as well as coarse- and fine-grained scoring (2-way vs.

3-way), enabling a detailed analysis of generalization capabilities.

- In this paper, we present a comparative overview of the submitted modeling approaches, highlighting emerging design patterns such as structured LLM reasoning, prompt optimization, hybrid modeling, and human–AI collaboration.

2 Related Work

Automatic short answer scoring (ASAS) is an established task in educational NLP, where systems aim to assign scores to short written student responses (Burrows et al., 2015; Bai and Stede, 2023; Bexte et al., 2024). Recent work has mainly followed two underlying paradigms (Bexte et al., 2023). Instance-based approaches treat scoring as text classification or regression, where student answers are mapped directly to score labels (Riordan et al., 2017; Gombert et al., 2023). These methods work well for questions seen during training, but typically transfer less reliably to unseen questions (Padó et al., 2023), especially when the new questions assume a different number of levels. Similarity-based approaches instead compare student answers to reference answers or representative answer clusters, for example, using natural language inference or sentence embeddings (Bexte et al., 2022, 2023; Zehner et al., 2016). While this can improve reuse across questions, such methods depend on the availability of reference answers at all available levels and full semantic coverage is not always guaranteed.

Rubrics are central to human scoring practice because they define explicit criteria for assigning performance levels (Reddy and Andrade, 2010; Panadero and Jonsson, 2013). In automatic scoring, however, they have mostly been used as additional input rather than as the main scoring reference. Earlier work has injected rubric information into neural scoring models (Wang et al., 2019) or used rubrics for further pre-training (Condor et al., 2022). These studies suggest that rubrics can improve scoring, especially in low-resource and transfer settings, but focused research on rubric-based short answer scoring remains limited.

Recent work has started modelling rubrics as central semantic structures for scoring. Gombert et al. (2026b) introduced the *GRAASP* and *ToLe-GRAA* architectures, in which scoring is modelled as the alignment between student responses and

rubrics, using attention over transformer-based representations. Building on this direction, the *AGRAA* framework (Gombert et al., 2026a) models rubric descriptors as low-dimensional semantic subspaces derived from contextualised embeddings, so that scoring corresponds to measuring how strongly a response aligns with rubric-induced aspect spaces.

In parallel to model-based approaches, recent work has explored *rubric-based prompting* of large language models (LLMs) for automated assessment. Instead of fine-tuning, these approaches provide rubric criteria directly within the prompt and ask the model to assign scores based on them. Cong et al. (2026) showed that incorporating rubric descriptors into prompts substantially improves scoring performance compared to prompting without rubrics, highlighting that rubrics provide more structured guidance than standard few-shot examples. Similarly, Wei et al. (2025) demonstrate that *concept-based rubrics* not only improve LLM scoring performance but also enable the generation of synthetic training data for downstream supervised models. Overall, these findings suggest that even without task-specific training, LLMs can leverage rubric structures when they are explicitly encoded in prompts, although their performance and reliability remain sensitive to rubric design and task complexity.

3 Dataset: ALICE-LP 1.1

The dataset we used in this shared task is a novel dataset called *ALICE-LP 1.1*, which contains mid- and high-school-level answers to questions from four STEM domains: *physics* (Wyrwich et al., 2025), *mathematics* (Bednorz et al., 2024), *biology* (Czinczel et al., 2025), and *chemistry* (Lossjew and Bernholt, 2025). These answers were collected within the context of the *ALICE* project, funded by the Leibniz Foundation, at middle and high schools in the German state of Schleswig-Holstein. The main goal of this project was to conduct learning progression analytics (Kubsch et al., 2022) in the classroom. Teachers guided students through lessons which involved solving various interactive learning activities in Moodle courses synchronously. This included a set of short-answer items, which are the basis of this dataset.

ALICE-LP 1.1 is a German ASAS dataset. Each question is rated on a three-point scale (incorrect, partially correct, correct). Each datapoint consists of the question text, the answer, a textual two- as

Set	#Questions	#Answers	#Levels (0/1/2)
Train	78	7,899	2,728/2,863/2,308
UA	78	2,008	691/726/591
UQ	39	3,086	1,146/1,021/919

Table 1: Distributional properties of *ALICE-LP 1.1*.

well as three-way rubric defining the criteria for each possible score, and the corresponding score. Table 2 shows an exemplary datapoint from this dataset. The two-way rubric has been artificially created by merging the partially correct and incorrect score levels.

The answers were scored by multiple student assistants enrolled in teacher education programmes for the respective subjects. For each question, an agreement was measured using a subset of answers. Student assistants were trained to score each question using a subset of answers until an agreement of at least $\kappa \geq .65$ was reached. The remaining answers were then distributed among the raters. The training set includes a total of 7,899 answers. The evaluation set is divided into two subsets: *unseen answers* and *unseen questions*. This setup was inspired by the established SemEval-2013 (Dzikovska et al., 2013) and SAF (Filighera et al., 2022) datasets, enabling evaluation of how well systems transfer to unseen questions. The *unseen answers* dataset includes 2,008 answers to questions contained in the training set (using a question-wise stratified 80/20 split). In contrast, the *unseen questions* dataset contains 3,086 answers to questions not in the training set. An earlier version of this dataset (*ALICE-LP 1.0*) was used in Gombert et al. (2026b) and Gombert et al. (2026a). For the shared task and the published benchmark dataset, we removed one question with 82 responses from the unseen questions dataset because we found it requires a reference answer to be properly gradable. Table 1 shows the distributional properties of *ALICE-LP 1.1*.

4 Shared Task Structure

In the context of the shared task, we hosted four evaluation tracks. All tracks were evaluated using the same set of evaluation metrics: weighted precision, weighted recall, weighted F1, and quadratic weighted kappa (QWK). QWK served as the primary metric for leaderboard ranking for each track.

Unseen Answers 2-Way For this track, participating models were evaluated based on how well

Input Category	Example
Question	Name consequences that the gas shortage could have for Germany and your school.
Answer	The school might have to close because it can no longer be heated. It could also be that students just have to wear jackets during lessons.
Rubric	(2) Students identify at least two links between a gas supply stop and the supply of electricity and/or heating. (1) Students identify one link between a gas supply stop and the supply of electricity and/or heating. (0) Students do not identify a link between a gas supply stop and the supply of electricity and/or heating.
Score	0/1 (2-Way) 1/2 (3-Way)

Table 2: An example question with the corresponding rubric, one example student answer and the corresponding score taken from the *ALICE-LP* dataset (translated from German to English).

they could score unseen answers to questions seen during training. For this track, we distinguished only between correct and incorrect answers, with partially correct answers counted as incorrect.

Unseen Questions 2-Way For this track, participating models were evaluated based on how well they could score answers to questions not seen during training. For this track, we distinguished only between correct and incorrect answers, with partially correct answers counted as incorrect.

Unseen Answers 3-Way For this track, participating models were evaluated based on how well they could score unseen answers to questions seen during training. For this track, we distinguished between correct, partially correct, and incorrect answers.

Unseen Questions 3-Way For this track, participating models were evaluated based on how well they could score answers to questions not seen during training. For this track, we distinguished between correct, partially correct, and incorrect answers.

All four tracks were hosted on Codabench (Xu et al., 2022). Participants were allowed to submit up to ten submissions per track, with the best submission, as determined by QWK, counted towards the official leaderboard of the shared task. We allowed multiple submissions to account for different variants of authors’ systems and the non-deterministic nature of deep learning methods. In the Appendix, we provide tables of the five best runs per team and track.

5 Submissions

Except for the teams *Diffuser* and *Afrilan*, all participating teams submitted system description papers.

We summarise the results in the following section. All teams participated in the *Unseen Answers 2-way* track, making it the most complete comparison setting. For the *Unseen Questions 2-way* track, all teams except *Diffuser* submitted results. In the *Unseen Answers 3-way* track, again all teams except *HFT* participated, while the *Unseen Questions 3-way* track saw the lowest participation, with only *IWM-DKM*, *WSE Research*, *SDPA*, *ASLAN*, *Afrilan*, and *AMATI* submitting results. Overall, participation decreases slightly in more challenging and fine-grained settings, particularly in the unseen-question and 3-way-classification scenarios.

Most participating teams were affiliated with German institutions, which is expected, given that the dataset and task are centred on German-language student answers. At the same time, the shared task attracted participants from outside Germany, indicating broader international interest in rubric-based short-answer scoring. This suggests that, despite the language-specific setting, the underlying problem formulation is relevant beyond the German research community.

5.1 System Descriptions

While this section systematises the submissions’ methodology, Table 3 provides a brief summary.

IWM-DKM (Belcher et al., 2026) The approach is based on supervised fine-tuning of decoder-only LLMs (Qwen family) with LoRA, where the model jointly processes the question, student answer, and rubric to predict scores. Performance is improved by systematically enriching and structuring the input: (i) checklist thinking introduces intermediate yes/no decisions aligned with rubric levels to guide reasoning, (ii) rubric reframing converts rubrics into structured decision trees for clearer decision

Team	Keywords of the Approach	Models / LLMs (Final System)
IWM-DKM (Belcher et al., 2026)	LoRA fine-tuning + (checklist thinking, rubric reframing, background knowledge injection); ensemble voting	Qwen-3-4B (QLoRA), Qwen-3.5-9B (QLoRA)
WSE Research (Gwozdz and Both, 2026)	LoRA fine-tuning + (instruction-following format, 7B–72B scaling); rubric-conditioned prompting + (TF-IDF exemplar retrieval); ensemble aggregation + (QWK-weighted voting)	Qwen-2.5-72B (QLoRA), Gemini 3 Flash + (Prompting + tf-idf-based RAG), kNN with tf-idf
SDPA (Liu and Zhang, 2026)	LoRA/DoRA fine-tuning + (Alpaca instruction format, direct label prediction); ensemble + (trained encoder, few-shot Claude, optimised soft voting)	GELECTRA-large, XLM-RoBERTa-large, BERT-base-german-cased, Claude (few-shot), Llama 3.1 8B (LoRA/DoRA)
ASLAN (Bexte et al., 2026)	Similarity-based scoring + (LaSiLearn, SetFit); instance-based classification + (domain-specific fine-tuning); zero-shot rubric-based prompting; majority voting	G-SciEdBERT, LaSiLearn / SetFit + (mpnet, mini-lm, distil), Phi-4, Gemma 3, GPT-5-mini + (ensemble via majority voting)
AMATI (Willis and Third, 2026)	Inductive Logic Programming + (ASP-based rule induction, lemma matching, key information rules); rule-guided prompting + (ILP theory injection, in-context training examples)	Mistral combined with ILP-derived rules
RETUYT-INCO (Sastre et al., 2026)	Meta-prompting + (group-specific prompt generation, per-group selection); prompt tuning + (per-group soft prompt embeddings); synthetic data augmentation + (class balancing, noise injection)	Gemini 3 Flash
HFT (Padó, 2026)	Zero-shot rubric-based prompting + (role prompting, expert committee prompting); hybrid human–AI grading + (confidence-based routing, pre-defined quality threshold)	GPT-OSS-120B

Table 3: Overview of final systems submitted by participating teams, focusing on core modelling approaches and models used for official submissions.

boundaries, and (iii) background knowledge injection provides generated domain context to support understanding. These techniques are complemented by strategies such as skill-based data partitioning and tailored validation setups, and are ultimately combined in ensemble models using majority voting to increase robustness, particularly for ambiguous cases, with gains arising from the interaction of these components rather than any single method alone.

WSE Research (Gwozdz and Both, 2026) The approach combines three complementary scoring strategies within a unified pipeline: rubric-based prompting, LoRA-based fine-tuning of Qwen models, and prediction aggregation. Given the input triple (question, student answer, rubric), candidate scores are generated via prompted LLMs (optionally enhanced with TF-IDF-based example retrieval), multiple fine-tuned models across different scales, and a non-neural TF-IDF kNN baseline. Fine-tuning is performed in an instruction-following format that mirrors inference, enabling models to internalise rubric criteria more effec-

tively. Scaling experiments show that performance improves with model size but saturates at larger scales. Predictions are combined using weighted voting or stacking, where aggregation improves performance on seen questions by leveraging complementary error patterns, whereas for unseen questions, a single large fine-tuned model generalises best.

SDPA (Liu and Zhang, 2026) The approach employs parameter-efficient fine-tuning of LLMs for rubric-based short answer scoring under low-resource conditions, alongside an ensemble baseline. It compares two complementary paradigms: (i) an encoder-based ensemble that combines multiple fine-tuned transformer models with few-shot LLM predictions (e.g., Claude) via weighted soft voting, and (ii) instruction-tuned LLMs (Llama3.1-8B) adapted using PEFT methods such as LoRA and DoRA. The latter directly predicts rubric-aligned labels from structured inputs (question, answer, rubric), enabling the model to internalise rubric reasoning rather than relying on prompt-based inference. Results show that while ensem-

bles benefit from combining complementary signals, particularly on seen questions, parameter-efficient fine-tuned LLMs consistently outperform both prompt-based and ensemble approaches, especially for unseen questions where generalisation to new rubrics is critical.

ASLAN (Bexte et al., 2026) The approach combines three complementary scoring paradigms: similarity-based methods, instance-based classification, and rubric-prompted LLMs, and evaluates them across seen and unseen settings. Similarity-based models (e.g., SBERT variants with LaSiLearn or SetFit) compare student answers to labelled training answers, while instance-based models (e.g., BERT variants) learn direct mappings from input text to scores. For unseen questions, where no task-specific training data is available, zero-shot LLMs are prompted with the rubric to assign labels. Across all paradigms, predictions are combined using majority voting, leveraging their complementary strengths. Results show that similarity-based approaches perform best when training data for a question is available, while LLM-based methods are more suitable for generalising to unseen questions. Ensemble methods consistently improve robustness and overall performance by integrating signals from different scoring strategies.

AMATI (Willis and Third, 2026) The approach combines symbolic rule learning with large language models to balance interpretability and robustness. First, Inductive Logic Programming (ILP) is used to induce human-readable grading rules from training data, where questions, rubrics, and student answers are represented as logical predicates and optimised via Answer Set Programming to generate rule-based scoring theories. These rules capture lexical and structural patterns aligned with rubric criteria, enabling transparent and explainable predictions. To address the brittleness of symbolic rules, the system integrates them with an LLM (Mistral) by incorporating either training examples or induced rules into the prompt. While the LLM alone provides robust scoring, especially for noisy student language, combining it with induced rules improves performance in the more fine-grained 3-way setting.

RETUYT-INCO (Sastre et al., 2026) The approach centres on meta-prompting, where an LLM is used to automatically generate task-specific scoring prompts tailored to each question–rubric pair.

In an offline phase, the model analyses the rubric and labelled training answers for a given group to produce a reusable, optimised prompt that captures the scoring criteria more precisely than a generic template. At inference time, new student answers are routed to their corresponding group and evaluated using the generated prompt, effectively adapting the scoring behaviour to the specific characteristics of each task. To further improve performance, the method incorporates prompt variation, selection based on validation performance, and synthetic data generation to address class imbalance.

HFT (Padó, 2026) The approach explores a low-cost, blunt-edge grading setup based on zero-shot prompting of open-source LLMs, combined with a hybrid human–machine workflow. The system uses simple rubric-grounded prompts with off-the-shelf LLMs to produce initial grade predictions, prioritising robustness, reproducibility, and applicability in resource-constrained settings. While these models perform moderately well, especially in information-poor scenarios, they are not entirely competitive with fine-tuning-based approaches when richer task-specific data is available. To compensate for this, the method incorporates human review in a structured hybrid grading process: model predictions for the most reliable class are accepted automatically, while less certain cases are manually reviewed.

6 Results

Table 4 shows the best submitted result per team and track. Overall, the results reflect the methodological differences discussed above and reveal a consistent hierarchy across settings for the shared task’s dataset, *ALICE-LP 1.1*. In the information-specific Unseen Answers conditions that allow training question-specific models, strongly optimised, model-centric approaches dominate: *IWM-DKM* and *WSE Research* consistently achieve the top ranks across both 2-way and 3-way tasks, with *SDPA* closely following. This confirms that structured fine-tuning, input engineering, and ensembling are highly effective when scored answers are available for training. In contrast, more prompt-centric approaches (sensu instruction learning) such as *RETUYT-INCO* and multi-paradigm ensembles such as *ASLAN* achieve competitive but slightly lower performance, indicating that while prompt optimisation and multi-paradigm aggregation are beneficial, they do not fully match the

Table 4: The best result achieved by each team across the four evaluation tracks.

performance of fine-tuned decoder-based LLMs in these settings. The sequential combination of symbolic formulations used to prompt an LLM, as employed by *AMATI*, further trails these approaches.

In the Unseen Questions setting, however, the ranking partially differed. While *IWM-DKM* remained the strongest, the advantage of fine-tuning diminished, and approaches emphasising cross-question generalisation became more competitive: *SDPA* and *WSE Research* remained strong, but *RETUYT-INCO* and especially *HFT* closed the gap despite relying on prompt-based strategies. This highlights that without question-specific training signals, simpler, more generic approaches can likely perform comparably to complex systems. Notably, *AMATI* showed a pronounced drop in this setting. Across all tracks, *IWM-DKM*’s consistent first-place performance suggests that combining

structured reasoning, task-specific fine-tuning, and ensembling provided the most robust overall solution.

7 Synthesis

Across submissions, a clear structure emerges that can be interpreted along three main axes, with individual teams occupying different positions in this space.

First, several teams converged on model-centric, LLM-driven approaches that are heavily structured and optimised. This is most evident for *IWM-DKM*, *WSE Research*, and *SDPA*. All three relied on fine-tuned LLMs as the core component, but differed in how much additional structure they imposed: *IWM-DKM* explicitly injected reasoning structure via checklist thinking and rubric reframing, *WSE Research* focused on combining multiple model

variants and retrieval signals in a unified pipeline, and *SDPA* emphasised parameter-efficient adaptation and showed that carefully fine-tuned models can outperform more complex ensembles, particularly in generalisation scenarios. Despite these differences, the shared insight is that strong performance emerged when the LLM was not used “as-is”, but is systematically aligned with rubric structure, either through input design, fine-tuning, or both.

Second, a number of teams moved towards hybrid pipelines that combine complementary paradigms. This is most clearly represented by *ASLAN* and, to some extent, *WSE Research* and *SDPA*. Here, the task was decomposed into multiple views, e.g. similarity-based retrieval, classical classification, or LLM-based scoring, which are then aggregated via voting or stacking. *ASLAN* is the most explicit example of this philosophy, showing that different paradigms dominate under different conditions (e.g., similarity-based methods for seen questions vs. LLMs for unseen ones). This reinforces a broader pattern also visible in *WSE Research*: performance gains were often due to complementarity between models, rather than improvements within a single model class.

Third, several approaches focused less on the model itself and more on how the task is interfaced with or augmented around the model. *RETUYT-INCO* is the clearest example here, shifting the optimisation problem from model parameters to prompt generation, effectively learning task-specific scoring functions via meta-prompting. *AMATI* explored a different direction by injecting symbolic structure into the LLM via ILP-derived rules, trading some flexibility for interpretability and controllability. Finally, *HFT* represents the extreme end of this axis, deliberately using minimal, zero-shot LLM setups and compensating through a hybrid human–AI process in which model predictions were selectively reviewed.

8 Discussion

The results of the shared task highlight both the potential and the current limitations of rubric-based short-answer scoring. Across all tracks, approaches that explicitly align model behaviour with rubric structure achieved the strongest performance. In particular, fine-tuned systems with structured input representations consistently outperformed prompting-based approaches when sufficient task-

specific information was available. However, results on the unseen question tracks showed that this advantage did not fully transfer to more challenging generalisation scenarios. While top-performing systems remained competitive, the performance gap to simpler methods narrowed. In this context, prompt-based and zero-shot methods could provide a competitive alternative despite lower peak performance. Another key observation is the importance of hybrid approaches. Many submissions combined multiple components via ensembling, integrating different scoring paradigms, or incorporating symbolic elements. This suggests that rubric-based scoring likely benefits most from combining complementary signals rather than relying on a single modelling paradigm.

9 Conclusion

Overall, the results show that structured and task-adapted LLM systems currently achieve the strongest performance, especially when questions are seen during training. At the same time, the unseen question tracks demonstrate that generalisation is possible to a certain degree, but remains challenging. We hope that this shared task provides a foundation for future work on rubric-based scoring, especially with respect to better generalisation, more interpretable scoring processes, and practically useful systems for educational settings.

Limitations

Several limitations of the shared task should be considered when interpreting the results. First, the datasets used in this task are limited in scope with respect to domain, rubric complexity and score granularity. The dataset was collected in the German K12 context from grades 7-11 in the state of Schleswig-Holstein. All items use relatively simple holistic rubrics with three performance levels, which restricts conclusions about how well current approaches scale to more complex, analytic rubrics commonly used in real-world assessment.

Second, while the inclusion of unseen question tracks allows us to study generalisation, the evaluation is still confined to a single dataset and domain distribution. As a result, it remains unclear to what extent the observed findings transfer to

other subjects, educational levels, or languages beyond the German setting considered here. Third, the shared task focuses primarily on predictive performance and does not systematically evaluate the interpretability or faithfulness of scoring decisions. Although some submitted systems explicitly aim to improve transparency, the current evaluation setup does not allow for a rigorous comparison of how well models align their decisions with rubric criteria.

Several limitations of the shared task arise from constraints in dataset construction and release. First, in some cases, the provided rubrics are underspecified for the full range of valid student answers. While this reflects authentic assessment practice to some degree, it can render the scoring task inherently ambiguous and may disadvantage models that rely on precise alignment between rubric criteria and responses. Second, for a subset of questions, relevant context materials could not be included due to legal restrictions. As a result, models were required to score answers without access to information that human raters would typically consider, which likely limited achievable performance and may have introduced additional variance across items.

Finally, while the shared task setup aims to approximate realistic assessment conditions, the combination of partial rubric specification and missing context materials means that the benchmark does not fully capture ideal scoring conditions for all questions.

Ethics Statement

With this shared task, we aimed to explore the potential of rubric-based scoring for short answers. Since short-answer scoring directly concerns the rating of students' performance, the ethicality of the technology depends heavily on the specific setting in which it is deployed. Technology for rating students' performance should match or outperform human performance when deployed for high-stakes assessments and be subject to human supervision. The EU AI Act labels AI in education as overall high stakes. However, we argue that there are also low-stakes scenarios in which rubric-based short answer scoring technologies can be deployed. These include typical low-stakes learning scenarios as provided by intelligent tutoring systems or comparable applications. Overall, significant downstream research on technology for

rubric-based short-answer scoring is likely needed before the respective technology can be deployed in practical scenarios.

HFT at BEA 2026 Shared Task 2: Blunt-Edge Models for Hybrid Grading

Ulrike Padó

Hochschule für Technik (HFT) Stuttgart

Schellingstr. 24

70174 Stuttgart, Germany

ulrike.pado@hft-stuttgart.de

Abstract

Open-source LLMs with simple, zero-shot prompts are at best middling graders on the BEA 2026 Automated Grading Shared Task – blunt-edge models, in fact. However, they are good enough to support human graders and save them time. We demonstrate the application of a hybrid grading approach that first transparently defines the success criteria and then pairs a zero-shot LLM grader with human review. The hybrid approach outperforms the LLM grader on its own and has the added advantage of keeping the human in the loop.

1 Introduction

Short answer questions are a welcome opportunity for educators to probe their students' ability to explain or analyze a problem. By phrasing an answer in their own words, the students prove their factual knowledge, show their thought processes and also demonstrate their language ability in language instruction settings. However, manual grading of short answer questions, while yielding useful insights into common misconceptions or errors, is time-consuming. Therefore, many attempts at automating short answer grading have been made over the years, and have profited strongly from the availability of common benchmark data.

The BEA 2026 Short-Answer Grading Shared Task (Gombert et al., 2026) offers a new data set for German rubric-based scoring. We approach this data with LLM grading models that deal gracefully with rubric instructions. We specifically choose open-source models to ensure independence of commercial offerings: These are prone to hidden changes or complete retraction and therefore endanger mid- to long term replicability and pose risks to data privacy in practical use.

Also, we intentionally limit ourselves to the "blunt edge" of research: Instead of creating an optimized "cutting-edge" model, we stress low cost

and broad re-usability for other tasks by evaluating a simple zero-shot approach using open-source LLMs and standardized prompts from the literature. Our blunt-edge model performs close to more sophisticated offerings in the information-poor Unseen Question setup, but clearly lags behind approaches that integrate the available information in the Unseen Answer setting (see Section 3.3).

To address imperfect model performance, we propose using a hybrid human-machine grading process that integrates human decision making with automated grading in such a way that the most reliable machine grade predictions are retained and the less reliable ones revised manually. The performance requirements of the process are defined by the educator beforehand (Padó et al., 2024). The simulated output of the hybrid process is competitive with cutting-edge models, especially when no sample answers are available (Section 4).

Finally, we argue that partial (or full) human review of the proposed model grades not only allows the hybrid process to reach the pre-defined performance requirements; it also gives the educator insights into the student data. In fact, human oversight over grading decisions is crucial for high-stakes systems in practical use in the European Union: The recent EU AI Act requires extensive risk management and documentation of any AI system that grades student submissions without human intervention.¹ In contrast, this explicitly does not apply to systems that just prepare data for a human evaluation process.²

We now describe our approach in more detail, starting with the model and prompt selection for our blunt-edge model on the Shared Task trial data, its performance in the competition proper and the expected outcome of the hybrid process on the (unseen) Shared Task training data.

¹Such systems are classed as high-risk systems in the AI Act, Chapter 3, Section 1, Article 6(3) and Annex III, (3)

²Cf. AI Act, Chapter 3, Section 1, Article 6(3d)

2 Related Work

Short-Answer Grading is a well-established task (see the overviews of [Burrows et al., 2015](#); [Bai and Stede, 2023](#)). While most of the research is on English data, several German data sets have been collected over the last 15 years, e.g., CREG ([Meurers et al., 2011](#)), CSSAG ([Padó and Kiefer, 2015](#)), ASAP-DE ([Horbach et al., 2018](#)) and SAF-DE ([Filighera et al., 2022](#)). However, especially the older data sets are limited in size, making the BEA 2026 Shared Task 2 data a welcome addition.

Along with every subfield of Natural Language Processing, Short-Answer Grading for German has seen a surge of experimentation with LLMs. [Filighera et al. \(2022\)](#) used a Transformer model with a trained classification head on the SAF-DE data and saw up to 85% prediction Accuracy in cases where the question had been seen during training (but the test answers had not) and 55% for unseen questions. With a similar approach, [Padó \(2016\)](#) achieved 84.4% prediction Accuracy on the CSSAG data on seen questions and 69% on unseen questions. These numbers are similar to non-neural benchmarking results for CREG (85% seen-question Accuracy, [Meurers et al. 2011](#)).

Using one-shot prompting that provided the LLM with the correct reference answer and the expected range of points, [Speiser and Weng \(2024\)](#) were able to vastly improve Accuracy on unseen questions from CSSAG to 87%. Note that [Metzler et al. \(2024\)](#), working on English data and a small German student answer data set in the statistics domain, recommend prompting using rubrics over n-shot answer examples, because they find that while n-shot prompting improve results, it also leads to inconsistent predictions.

In sum, prompting LLMs is a promising approach to solving the automatic grading task, especially since they can make use of the information in rubrics without further pre-processing, and appear to show more consistent performance with rubrics. However, the literature also shows that providing as much information as possible in the form of reference answers, sample answers or the expected point distribution improves prediction performance.

Regarding the human-machine hybrid grading strategy, a number of proposals have been made over time to integrate machine predictions with human grading or revision, in order to lighten the human workload. Some approaches cluster student answers to reduce the need for labeling to one in-

stance per cluster ([Basu et al., 2013](#); [Zehner et al., 2016](#)), with the advantage of allowing teachers insight into their students' frequent error patterns and potentially giving feedback per cluster.

Human review of some part of the machine predictions without clustering, based on the confidence of the grading models and their strengths and weaknesses, is also proposed by [Schneider et al. \(2023\)](#) or [Kwako et al. \(2026\)](#). Alternatively, [Speiser and Weng \(2024\)](#), like [Vittorini et al. \(2021\)](#), advocate for human-machine dual grading with revisions only in case of disagreement, which sacrifices workload reduction for full human review and improved correctness. However, [Vittorini et al. \(2021\)](#) still find a 40% speedup for reviewing over grading from scratch.

An investigation of very restricted, open-source LLMs to solve a Shared Task was undertaken by [Góngora et al. \(2025\)](#) at the BEA Shared Task 2025 (Pedagogical Ability Assessment of AI-powered Tutors): They only looked at models with 1b parameters or less to demonstrate the limits of what is possible with restricted access to computation resources. [Padó \(2026\)](#) approaches the 2025 Shared Task with the same blunt-edge, hybrid grading process methodology applied here, and finds that the hybrid process can be successfully applied to reach a pre-defined Accuracy threshold.

3 Shared Task: Grading Models

3.1 Method

We experiment with the open-source LLMs available to us for research purposes through Gesellschaft für wissenschaftliche Datenverarbeitung Göttingen. We work with the seven text-based models that responded in less than 30s per API request and consistently produced the standardized JSON output format needed for post-processing. These were text-based models gpt-oss³, qwen3-32b⁴, gemma-3-27-it⁵, mistral-large-3-675b-instruct-2512⁶ and llama-3.3-70b-instruct⁷, specialized reasoning model qwen3-30b-a3b-thinking-2507⁸

³<https://huggingface.co/openai/gpt-oss-120b>

⁴<https://huggingface.co/Qwen/Qwen3-32B>

⁵<https://huggingface.co/google/gemma-3-27b-it>

⁶<https://huggingface.co/mistralai/Mistral-Large-3-675B-Instruct-2512>

⁷<https://huggingface.co/meta-llama/Llama-3.3-70B-Instruct>

⁸<https://huggingface.co/Qwen/Qwen3-30B-A3B-Thinking-2507>

and llama-3.1-sauerkrautlm-70b-instruct⁹, which was fine-tuned on German-English data. All models were run at a temperature of 0.01, so in conservative mode. We used the RAGAS¹⁰ libraries for implementation.

The second parameter in our setup is the nature of the prompt. We use four prompts in a zero-shot setting (i.e., the model receives instructions, but no examples), cf. Padó (2026). Our *Baseline* prompt just instructs the LLM to return "Correct" if the student answer is correct given the rubric, and "Incorrect" otherwise. Next, a prompt proposed by Fan et al. (2025) in the BEA 2025 tutor evaluation task goes one step further and explains the task context (a student answering a question and receiving a grade). An alternative prompt specifies a *Role* for the LLM (it simulates an experienced STEM teacher). Finally, we also use a prompt template by Wang et al. (2024), which instructs the model to simulate a committee of experts solving the task (the prompt was shortened to one sample conversation). All the prompts were in German (translated from the originals as needed) and can be found in the Appendix. With this set of progressively more complex prompts, we want to probe how much information the LLMs need to grade well.

3.2 Model and Prompt Selection

We evaluate our seven models and four prompts on the Shared Task trial data in the two-way setting (labels "Correct" and "Incorrect"). Our zero-shot approach mimics the Unseen Question task. Table 1 shows the results. As expected, the sparse Baseline **prompt** rarely yields best results, but neither does the very complex Wang et al. prompt (Mistral, SauerkrautLM and Gemma even do much worse than for the other prompts). Instead, models do best with the shorter Fan et al. and Role prompts that provide some context to the task but are essentially simple. Variation in our LLMs' predictions, accounts for as much as 0.025 points QWK difference across five runs for Llama+Fan et al. (max. 0.49, min. 0.46, average 0.48) and 0.016 points QWK across five runs for GPT-OSS+Fan et al. (max. 0.48, min. 0.46, average 0.48). Given this observation, performance is surprisingly consistent across the Baseline, Fan et al. and Role prompts and across different models. This is positive because it shows a certain robustness to model

identity and details of prompting that promises that performance will carry over to other configurations.

In an unplanned experiment, a correction of the training and trial data for the 2-way task gave insight into the importance of covering the whole answer space with rubrics. When the initial data set that had only the rubrics for "Incorrect" and "Correct" was replaced with a revised data set that also contained the "Partially Correct" rubrics (to count as "Incorrect"), grading performance went up by around 0.03 points QWK across all models and prompts. This was carried by improved Precision for the "Correct" predictions at almost unchanged Precision for label "Incorrect"; clearly, some of the "Partially Correct" answers had initially been erroneously identified as "Correct" due to the partial overlap with the "Correct" rubrics.

3.3 Results on Shared Task Test Set

For evaluation on the test data, we chose the best-performing models and submitted several runs each in order to account for prediction variation. The best-performing and most consistent models are GPT-OSS and Llama. We paired both models with the Fan et al. prompt, the simplest successful prompt.

We submitted model predictions for the 2-way Unseen Question and Unseen Answer tasks. Since we use a zero-shot setting, we expect to see the same performance on both test tasks as on the trial data reported above - around 0.48 QWK.

Table 2 shows that this expectation was borne out by the GPT-OSS+Fan et al. model. Llama+Fan et al. did somewhat worse, although performance on the trial data had generally been similar. Still, the blunt-edge models again show remarkable robustness, this time across data sets, and achieve 5th place (out of 9) in the 2-way UQ task.

The competition results on the test data show that the largest performance gains of the cutting-edge models are in the Unseen Answer setting, where task-specific information is available (Gombert et al., 2026). Here, the blunt-edge model places last. Even though the rubrics provide it with some task-specific information, more knowledge about the task in the shape of previously graded answers remains hugely beneficial – a familiar pattern in ASAG independent of grading algorithm. We see this situation as a trade-off: If data, development time and computing resources are available and models can be re-used often, the development of a cutting-edge approach is clearly worth it. However,

in many teaching settings questions change from exam iteration to exam iteration with no sample answers available; in these cases, the blunt-edge models are a viable, low-cost alternative.

4 Hybrid Grading

As expected, the zero-shot open-source models on their own do not perform competitively on the Shared Task test data, especially in the information-rich Unseen Answer setting. However, we argue that they are fully sufficient to support hybrid human-machine grading when following our four-step grading process (cf. Padó et al. 2024). The process guides an educator through model selection and hybrid grading, by identifying the concrete grading model’s “preferred” class, which it predicts best. Accepting predictions for this class and reviewing all predictions of the other class(es) reduces human workload and significantly improves grading results over machine grading alone. This model-based selection of presumably reliable predictions precludes the need for confidence scores for each grade, which may not be available.

We now step through the process and apply it to the (unseen) Shared Task training data.

Step 1: Define Quality Threshold Since the maximum acceptable error for the output of the grading process can vary for each usage context, the hybrid grading process calls for defining it explicitly first. Published short-answer corpora show 10-15% disagreement (lower for higher stakes)

among human graders (Mieskes and Padó, 2018; Nazaretsky et al., 2022). Therefore, we accept 15% error as the expected human performance.

Step 2: Choose Data Set The next task is to identify data from one’s own setting with existing human grades to test the grading models on. On the basis of this evaluation, the final grading setting for the hybrid grading process is chosen. This step recognizes that model performance can vary widely between data sets and that benchmark performance cannot be expected to carry over to different settings. We use the Shared Task trial data.

Step 3: Choose Grading Model We use our results for the trial data from 3.2. At this step in the process, however, we drill further down into the two best models’ performance to identify their “preferred” classes and class-specific performance. We look for high Precision on at least one class – optimally, at least the accepted error threshold for the task (cf. Step 1) to ensure acceptable error for each class. Our two best models are close to this threshold: GPT-OSS+Fan et al. shows $Prec_{Incorrect} = 83.00$ and Llama 3.3+Fan et al. has $Prec_{Incorrect} = 84.3$.

Step 4: Decide on Use Given the results in Step 3, we decide to use Llama 3.3+Fan et al. to grade the Shared Task training data, which are unseen to our zero-shot model. We will accept any “Incorrect” grades and assume that human review fixes all errors in the “Correct” grade predictions.

On the 7072 answers in the training set, the model made 5103 predictions of class "Incorrect" (to be accepted as-is) and 1969 predictions of class "Correct" (to be revised). This means a reduction in human workload by 71%.

The gold labels show that 840 predictions of "Incorrect" were in fact wrong. If the revised labels are assumed to be perfect, this makes for a remaining error of 12%, well within our margins. Weighted F_1 for the hybrid process would be 0.896 in this best-case scenario, which is higher than the best reported F_1 score in the competition.

If we (more realistically) assume that the human expert makes evenly-distributed errors for 15% of the 1969 labels during revision, missing some true errors and marking some truly correct answers as incorrect, overall error for the hybrid process is 16% (still close to our threshold) and weighted F_1 drops to 0.828 – eighth place in the Unseen Answers track, and first in the information-poor Unseen Questions track. This makes the hybrid process a clear recommendation for cases where little is known in advance about the questions and answers: In such cases, the simple blunt-edge model saves development time and resources, while the hybrid setup ensures competitive performance and allows the human grader insights into students' answer patterns.

5 Discussion and Conclusions

We have presented our contribution to the BEA 2026 Automated Grading Shared Task: A blunt-edge, but replicable and relatively low-cost LLM grader that relies on off-the-shelf open source LLMs and simple zero-shot prompts.

While the grader holds its own in the information-poor Unseen Questions task, it clearly lags behind the cutting-edge models in the Unseen Answer task. However, we argue that it is good enough to be combined with human judgments in a hybrid grading process which accepts the model grades for the class predicted with higher Precision and presents the other grades to human review. This hybrid process even outperforms the cutting-edge models in simulations on unseen data, especially in information-poor settings.

Note that the hybrid strategy is applicable to any grading model, and further performance gains are possible with better machine graders. For any grading task that has little previously-annotated training data, we still explicitly recommend the use of blunt-

edge models, however. The use of off-the-shelf open source LLMs ensures data privacy, replicability and reduction of the tasks' energy footprint, and blunt-edge performance is robust in information-poor settings.

In any case, the manual revision step allows the human graders insight into answer patterns that are not available in fully automated grading.

Importantly, the hybrid grading process has a bias towards whichever label is predicted with less error by the grading model and therefore accepted without review. This is often the majority class in the training data, especially for trained or fine-tuned models. For the Shared Task data, this class is "Incorrect". This means that all the remaining error after application of the hybrid process is concentrated in cases where the machine erroneously predicts a student to be wrong. In a summative setting, this is a worst-case scenario. In a formative setting, it can be acceptable depending on the amount of feedback a student receives and the opportunities they have to clear up confusion caused by inaccurate machine grades.

Note, however, that depending on the data set and grading model, the process bias can well be inverted (towards "Correct"). This is why we strongly advocate for experimenting with the grading model on realistic data before choosing the manual-machine balance for the task in question. For example, educators could choose complete manual review for high-stakes tests or in case of poor model performance on their data, or on the opposite end of the spectrum skip manual review completely if grading a low-stakes feedback activity and using a reliable model with an acceptance bias for "Correct". In fact, the hybrid process has the advantage of allowing this human-machine balancing on an individual basis while taking into account the testing situation, the expected reliability of the machine grades, the available human work time and individual preferences for manual oversight.

Naturally, to fully avoid unfair bias in all situations, all machine grades have to be revised every time. This can still be worthwhile, since [Vittorini et al. \(2021\)](#) find a time saving of 40% for revision over grading from scratch. Complete revision also ensures that the requirements of the EU AI Act for the use of AI in grading are met. For both these reasons, full review is recommended in high-stakes situations.

Limitations

Our approach has been simulated for different data sets, but a full trial with real human annotators is still outstanding. To our understanding, the partial review process does not satisfy the requirements for low-risk AI use according to the EU AI Act. For this reason, additional experiments on the time savings of full vs. partial review should also be done. No additional inquiries into the effect of adding more task information (for example through few-shot prompting) in the Seen Question task were made.

Ethics

Our approach minimizes, but does not eliminate, the energy footprint of LLM usage. There is a possible bias in the resulting grades since errors concentrate in one predicted class. Also, there are currently no checks for other machine grading biases, e.g., against students who are not native speakers, cf. Padó et al. (2024)).

Acknowledgments

Fan et al. "Ein Schüler beantwortet eine Frage. Deine Aufgabe ist es, zu bewerten, ob die Antwort auf die Frage richtig ist. Die Bewertungsvorgaben für Richtig und Falsch liegen dir vor. Deine Aufgabe ist, zu bewerten, ob die Antwort gegeben die Bewertungsvorschriften richtig ist. Bewerte mit 1, wenn die Antwort richtig ist. Sonst bewerte sie mit 0."

Role "Du bist ein erfahrener Lehrer in den Naturwissenschaften. Du bewertest eine Schülerantwort auf eine Frage. Du hast Bewertungsrichtlinien gegeben. Bewerte die Antwort mit 1, wenn sie den Richtlinien entsprechen. Sonst bewerte sie mit 0."

Wang et al. "Wenn du eine Aufgabe bekommst, beginne damit, die Beteiligten zu identifizieren, die zur Lösung beitragen werden. Dann starte einen mehrstufigen Zusammenarbeitsprozess, bis eine endgültige Lösung gefunden ist. Die Beteiligten geben dir kritische Rückmeldungen und detaillierte Vorschläge, wenn nötig. Hier sind einige Beispiele:

Beispiel-Aufgabe 1: Verwende Zahlen und grundlegende Rechenoperationen (+ − * /), um 24 zu erhalten. Du musst alle Zahlen verwenden, und jede Zahl darf nur einmal genutzt werden. Eingabe: 6 12 1 1 Beteiligte: Du (KI-Assistent); Mathematik-Experte Start der Zusammenarbeit! Mathematik-Experte: Lass uns die Aufgabe genau analysieren. Du musst sicherstellen, dass du die Anforderung erfüllst: Du musst genau die vier Zahlen (6 12 1 1) verwenden, um 24 zu bilden. Um 24 zu erreichen, kannst du an die häufigen Teiler von 24 denken, wie 4, 6, 8 oder 3, und versuchen, diese zunächst zu konstruieren. Außerdem solltest du potenzielle Summen in Betracht ziehen, die 24 ergeben, wie zum Beispiel 12 + 12. Du (KI-Assistent): Danke für die Hinweise! Hier ist eine erste Lösung: $(12 / (1 + 1)) * 6 = 24$ Mathematik-Experte: Lass uns die Antwort Schritt für Schritt überprüfen. $(1 + 1) = 2$, $(12 / 2) = 6$, $6 * 6 = 36$ – das ist nicht 24! Die Antwort ist falsch. Kannst du das durch andere Kombinationen korrigieren? Bitte vermeide ähnliche Fehler. Du (KI-Assistent): Danke, dass du den Fehler aufgezeigt hast. Hier ist eine überarbeitete Lösung, bei der berücksichtigt wird, dass 24 auch durch 3×8 erreicht werden kann: $(6 + 1) \times (12 / 4) = 24$. Mathematik-Experte: Lass uns prüfen, ob die Berechnung stimmt. $(6 + 1 + 1) = 8$, $12 / 4 = 3$, $8 \times 3 = 24$. Die Rechnung ist korrekt, aber du hast die Zahlen 6, 1, 1, 12 und 4 verwendet – das entspricht nicht der Eingabe 6, 12, 1, 1. Kannst du vermeiden, eine Zahl zu verwenden, die nicht in der Eingabe enthalten ist? Du (KI-Assistent): Du hast recht. Hier ist eine überarbeitete Lösung, bei der berücksichtigt wird, dass 24 auch durch 12 + 12 erreicht werden kann, und ohne zusätzliche Zahlen: $6 \times (1 - 1) + 12 = 24$. Mathematik-Experte: Lass uns die Antwort nochmal überprüfen. $1 - 1 = 0$, $6 \times 0 = 0$, $0 + 12$

= 12. Du bist ganz nah dran. Hier ein Tipp: Versuche, „1 – 1“ durch „1 + 1“ zu ersetzen. Du (KI-Assistent): Klar, hier ist die korrigierte Antwort: $6 \times (1 + 1) + 12 = 24$ Mathematik-Experte: Lass uns die Lösung überprüfen. $1 + 1 = 2$, $6 \times 2 = 12$, $12 + 12 = 24$. Du hast die Zahlen 1, 1, 6, 12 verwendet – das entspricht genau der Eingabe 6, 12, 1, 1. Alles passt! Zusammenarbeit beendet! Endgültige Antwort: $6 \times (1 + 1) + 12 = 24$ Identifiziere nun die Beteiligten und lass sie die folgende Aufgabe schrittweise gemeinsam lösen.

Ein Schüler beantwortet eine Frage. Die Bewertungsrichtlinien für Richtig und Falsch liegen dir vor. Bewerte die Antwort mit 1, wenn sie den Richtlinien entsprechen. Sonst bewerte sie mit 0."

ASLAN at BEA 2026 Shared Task 2: Voting Across Scoring Paradigms

Abstract

This paper describes the ASLAN system contribution to the BEA 2026 Shared Task on rubric-based short answer scoring for German (Gombert et al., 2026). We investigate three complementary modeling paradigms: similarity-based scoring, instance-based classification, and rubric-prompted large language models (LLMs). For the *unseen answers* track, where test answers belong to prompts observed during training, we compare question-specific and generic scoring models as well as ensemble variants. For the *unseen questions* track, where models must generalize to previously unseen prompts, we primarily rely on zero-shot LLM-based scoring using the scoring rubrics. Our experiments show that similarity-based models outperform instance-based models and LLM-based models in the *unseen answers* setting. In addition, we find that ensemble methods improve robustness over individual models.

1 Introduction

Automated Short Answer Scoring (SAS) is the task of automatically judging the conceptual correctness of learner answers in an educational context (Bai and Stede, 2023; Bexte et al., 2024).

While traditional SAS systems often rely on the comparison with a reference answer or learning properties of a correct or incorrect answer from training instances for a specific question (Bexte et al., 2023, 2022), this Shared Task aims at leveraging the scoring rubrics provided for individual answers as the basis for determining the correctness of an answer - a so far underexplored variant of SAS, that is especially relevant in those cases where no training data for a specific question is provided. The shared task consists of two tracks: *unseen answers* where the test data contains new answers to questions already seen during training and *unseen questions* with completely new questions not covered in the training material. For

both tracks, there is a 3-way condition and a 2-way condition. In the 3-way setup, answers are labeled *correct*, *partially correct* or *incorrect*. The 2-way condition subsumes the *partially correct* and *incorrect* answers in a joint group of *incorrect* answers.

Our system compares several approaches: In the *unseen answers* track, we use similarity-based approaches, relying on the semantic similarity to a reference answer, instance-based approaches that learn properties of correct and incorrect answers to the same question, and LLM-based approaches leveraging generative AI and using the scoring rubric in the prompt. Only the third approach is directly applicable to the *unseen questions* track data. We further experiment with ensembles of classifiers, performing majority voting to determine the final label.

2 Datasets

The provided training dataset consists of a total of 7899 answers, split into train and trial data and covering a total of 78 individual questions. We deemed that appropriate to train question-specific models. All answers came from a real-world ITS system, thus label distributions were unsurprisingly uneven, even including a small number of answers with only correct or only incorrect answers in the dataset.

3 Method

Our system explores a number of complementary approaches: For the *unseen answers* track, we compare both instance-based and similarity-based approaches (Horbach and Zesch, 2019). For the *unseen questions* track, we experiment with approaches using generative LLMs.

In all experiments presented here, we use the train-trial data split provided by the Shared Task organizers. We evaluate using quadratically weighted kappa (QWK) where - although we in some in-

stances train one model per question - kappa values are computed across the whole trial data (instead of computing QWK prompt-wise and then averaging these individual values).

3.1 Similarity-Based Scoring

We tested two similarity-based scoring setups, Label-Aligned Similarity Learning (**LaSiLearn**) (Bexte et al., 2022) and **SetFit** (Tunstall et al., 2022). Both approaches are designed to work with SBERT (Reimers and Gurevych, 2019) base models. We ran both LaSiLearn and SetFit with three different multilingual base models, namely *paraphrase-multilingual-mpnet-base-v2* (**mpnet**), *paraphrase-multilingual-MiniLM-L12-v2* (**mini-lm**), and *distiluse-base-multilingual-cased-v1* (**distil**). All models were used via Hugging Face.

LaSiLearn LaSilearn adapts SBERT models so that the cosine similarity of answer embeddings reflects the similarity of the scores of two answers. For training supervision, pairs of two answers are built from the training data and assigned a similarity label that reflects whether the two answers in a pair share the same (similarity label 1) or a different (similarity label 0) score. With a fine-tuned model, test answers can then be compared to training answers. The score for which training answers have the highest average similarity to a test answer is then used as the prediction. For example, if the average similarity of a test answer is .4 for comparing it to *incorrect* training answers, .6 for *partially correct* training answers and .8 for *correct* training answers, the model would predict the answer to be *correct*. LaSiLearn inference is also possible directly with the pretrained model, without any fine-tuning. Thus, we also test performance of the pretrained base models. As previous work had shown that for pretrained models it is best to predict the score of the most similar answer (Bexte et al., 2022, 2023), we adopt this strategy as well.

SetFit SetFit is a partially similarity-based scoring approach designed for smaller volumes of training data. First, the SBERT model is tuned as described for LaSiLearn in the previous section. Thereby, the embedding space becomes more representative of the answer space. In a second training loop, a classification head is then added to the model and fine-tuned using the same training data that was used for the similarity-based training. At

Task	mpnet	mini-lm	distil	vote	vote-sim
2-way					
LaSiLearn _{pre}	.50	.45	.50	.51	.49
LaSiLearn	.59	.61	.59	.63	.60
SetFit	.65	.62	.62	.65	–
3-way					
LaSiLearn _{pre}	.59	.54	.61	.61	.58
LaSiLearn	.71	.71	.71	.74	.75
SetFit	.70	.68	.71	.70	–

Table 1: QWK results for similarity-based scoring on trial data. LaSiLearn_{pre} indicates direct use of the pre-trained base model without any fine-tuning.

inference, predictions are made using this classification head.

Hyperparameters For both LaSiLearn and SetFit, we set the same hyperparameters. We train with a batch size of 16 for at most 1500 steps, evaluating performance on validation data every 100 steps. The model that performs best on the validation data is kept for final evaluation on the test data. 10% of the training data for each prompt were set aside as validation data.

Results Table 1 shows performance of the similarity-based models on the trial data. Since we ran both scoring methods with three separate multilingual base models, we can aggregate their predictions via voting. For both LaSiLearn and SetFit, we performed majority voting (**vote** in Table 1). In the case of LaSiLearn, we also ran voting based on the similarities the model found. We took the prediction of the model that based its prediction on the highest similarity value (**vote-sim** in Table 1). For example, if one model predicted an answer to be *partially correct* based on a similarity of .78 to the reference answers and another said it would be *incorrect*, but based this on a similarity of .80, we adopt the prediction of the model that found the higher similarity and thus predict the answer to be *incorrect*.

In 2-way scoring, SetFit slightly outperforms LaSiLearn. The mpnet base model performs best, on par with a voted average of the three base models. For LaSiLearn, voting increases performance from .61 QWK to .63. On the 3-way data, LaSiLearn performs better than SetFit. Again, performance is pushed by voting, from .71 QWK to .75 with similarity-based voting. For SetFit, the distil base model performs best, outperforming the voted average.

Based on the results, we chose the following configurations for our submission on the final test data:

- 2-way LaSiLearn: vote
- 3-way LaSiLearn: vote-sim
- 2-way SetFit: mpnet
- 3-way SetFit: distiluse

3.2 Instance-Based Scoring

In the instance-based scoring approach, we treat the task as a supervised classification problem, where models learn to score the correctness of answers from lexical material in the training data. The results are shown in Table 2.

3.2.1 Shallow Classifiers

As a baseline, we trained different shallow classifiers (Random Forest (RF), Support Vector Classifier (SVC), Logistic Regression (LR)) with unigram and bigram features. In Table 2, we only report LR, as this model performed best. We used the scikit-learn (Pedregosa et al., 2011) implementation and apart from setting *max_iter* to 1000 left all parameters at their respective default values.

3.2.2 Transformer Models

We fine-tuned three distinct pre-trained transformer-based models. All models were used via Hugging Face.

- BERT: The standard multilingual BERT base model. (Devlin et al., 2019)
- German-BERT: A BERT model specifically pre-trained on large-scale German corpora.¹
- G-EdSciBERT: A specialized German model focused on educational and scientific domains. (Latif et al., 2024)

Experimental Setup All three models were fine-tuned using the same hyperparameter configuration to ensure a fair comparison. We utilized a learning rate of $2e - 5$, a batch size of 7, and trained for 6 epochs. The models were trained on the provided training set without validation and evaluated on the trial data to determine their performance for the 2-way and 3-way classification tasks.

Results Table 2 summarizes the performance of these models on the trial data, reported using the Quadratically Weighted Kappa (QWK) metric. The

¹<https://huggingface.co/google-bert/bert-base-german-cased>

Task	LR	BERT	German BERT	G-SciEdBERT
2-way	.52	.47	.58	.62
3-way	.63	.60	.65	.67

Table 2: QWK results for instance-based models on trial data.

trial results demonstrate that G-SciEdBERT consistently outperforms the other models on both tasks, achieving QWK values of 0.62 for 2-way classification and 0.67 for 3-way classification. This suggests that the domain-specific pre-training on German scientific and educational texts provides a significant advantage for the SAS task.

Prompt-Specific vs. Generic Training We further investigated the impact of prompt-specific training compared to a generic model approach. In the Generic Model (GM) setup, a single model is trained on the entire pooled dataset. In contrast, we trained individual Prompt-Specific Models (PSM) for each unique question to capture prompt-specific nuances. Our comparison, unsurprisingly, revealed a performance trade-off with the volume of available training data: PSMs have a comparative performance to GMs when the training set for a given prompt exceeds 100 instances. In this range, the PSM has a 52.2% probability of outperforming the GM. When the sample size is small, the GM tends to be more robust. The shared knowledge across prompts in the GM yields a higher average Kappa value compared to PSMs, which likely suffer from overfitting on limited instances. Based on the results, we chose generic training of G-SciEdBERT for our submission on the final test data.

Augmented Input We also experimented with augmenting the training input by concatenating the question text and the scoring rubric to the student answers. We hypothesized that this would provide the model with a better basis for determining correctness. However, this approach did not yield a consistent improvement, potentially due to increased noise or input length limitations.

3.3 LLM-based Scoring

Both closed- and open-source models were evaluated in a zero-shot setting, following the same general prompting strategy: each model received the question, the scoring rubric, and the student answer, and was instructed to predict a score label.

Task	GPT5-mini	Phi-4	Gemma 3
2-way	.50	.46	.49
3-way	.39	.49	.51

Table 3: QWK results for LLMs on trial data.

3.3.1 Closed Source Models

We evaluated gpt-5-mini via the OpenAI API with default model parameters, using task-specific prompts for the 2-way and 3-way settings (see Figure 1 and 2 in the Appendix, respectively). Table 3 shows that gpt-5-mini achieves a QWK of .50 on the 2-way task and .39 on the 3-way task. Performance was measured on the trial data. The 2-way task is comparable to the weaker instance-based models, yet drops substantially for the 3-way task.

3.3.2 Open Source Models

For the open-source models, the same prompt was used for both 2-way and 3-way scoring, since the 2-way rubric subsumes the *partially correct* category under *incorrect*. For the full prompt, see Figure 3 in the Appendix. If a model failed to produce a valid response (i.e. one of the labels), it was re-prompted. If it still failed to answer after it had been prompted 10 times, the prediction was inserted as *invalid*. For evaluation, we took a permissive approach and treated answers with an *invalid* prediction as *correct*.

The two open models we prompted to score answers were Phi-4 (Abdin et al., 2024) and Gemma 3 (27b) (Team, 2025), as these were the two models that performed best in preliminary tests. Both models were accessed via the Ollama API on a local server with default parameters. Table 3 shows model performance on the trial data. Gemma 3 performs better than Phi-4 on both the 2-way and 3-way data. It is just .01 behind GPT5-mini for the 2-way data and outperforms it by .12 QWK on the 3-way data.

For submission on the final test data, we decided on the two open source models, since especially Gemma 3 performed comparably well in both the 2-way and the 3-way setting.

3.4 Influence of Normalization

As part of the similarity-based and instance-based approaches, we also conducted a set of experiments where we used normalized versions of the student answers rather than the raw versions. For normalization, we used TransGEC (Fang et al., 2023) and

MRNH/mbart-german-grammar-corrector², two grammatical error correction systems trained on the Falko-MERLIN dataset for German (Boyd, 2018). In the similarity-based setting, the TransGEC normalization was able to outperform a model using pretrained SBERT on the raw version of the trial data both in the 2-way and 3-way settings. However, when SBERT was finetuned, then normalization proved to have no benefit. In the instance-based approach, the use of normalization mostly proved deleterious, sometimes notably so. Normalization was thus not used in any of the officially submitted runs.

3.5 Classifier Ensembles

Ensemble methods often improve robustness by combining complementary model predictions. This is particularly relevant in our setting, where the individual models differ substantially in how they arrive at their decisions: similarity-based models compare answers to previously seen responses, instance-based models learn direct label mappings, and LLMs rely on rubric-guided prompting.

We therefore evaluated majority-vote ensembles across different classifier combinations. To combine predictions in the 3-way setting, we map labels to numeric values (*incorrect* = 0.0, *partially correct* = 0.5, *correct* = 1.0), average the predictions across models, and round to the nearest valid label.

We evaluated all candidate classifier combinations on the trial data and selected the best-performing ensembles for the official submissions. Overall, the best ensembles consistently outperformed the strongest individual models, indicating that the approaches provide complementary information. Our best ensemble, consisting of *LaSiLearn (mpnet)*, *LaSiLearn_{pre} (distil)*, *SetFit (distil)*, *G-SciEdBERT*, *Phi-4*, and *GPT5-mini* for the 3-way task and *LaSiLearn (mini-lm)*, *SetFit (mpnet)*, and *GSciEdBert* for the 2-way task yielded an improvement from 0.710 on the best individual model to 0.783 QWK on the trial data in the 3-way task and from 0.654 to 0.679 on the 2-way task .

4 Results

Tables 4 (unseen answers) and 5 (unseen questions) present results on the test data of the shared Task. We report Quadratically Weighted Kappa (QWK).

²<https://huggingface.co/MRNH/mbart-german-grammar-corrector>

Model	2-way	3-way
G-SciEdBERT	.59	.64
LaSiLearn	.62	.71
SetFit	.64	.71
best-1	.65	.74
best-2	.66	.76
best-3	.64	.74

Table 4: Evaluation Results for Unseen Answers. Note that best-1 to best-3 are the best-performing classifier combinations on the trial data and are different between 2-way and 3-way.

Unseen Answers Much like on the trial data, instance-based training of G-SciEdBERT is outperformed by the similarity-based models. Between the two similarity-based models, SetFit is again slightly ahead of LaSiLearn on the 2-way data, while both models perform on par on the 3-way data. Our ensemble strategy is able to push performance for both the 2-way and 3-way setting, to .66 and .76, respectively. We submitted the five best-performing runs on the trial data and report the results for the first three of them in Table 4. For details on which models are part of these ensembles, see Table 6 in the appendix. On the test data, the second best run of these five yielded the best performance on the evaluation data, hinting at a certain overfitting in our model selection process. The best-performing submission (best-2) ranked 5th (2-way) and 4th (3-way) in the shared task.

Unseen Questions In addition to the LLMs, we also used the instance-based G-SciEdBERT for prediction on the unseen questions. It falls slightly behind LLM performance, but only by at most .03 QWK on the 2-way data and .02 QWK on the 3-way data. In both settings, Gemma 3 performs best, achieving QWK .39 on 2-way data and QWK .52 on the 3-way data. We also tested voting combinations with three out of the four models (G-SciEdBERT and the three LLMs). These results are included as *no-** in Table 5, indicating which of the four models was *not* part of the voting. In general, voting again increases performance. Curiously, dropping GPT5-mini leads to the lowest increase in performance on 2-way data, but the best result of QWK .58 on the 3-way data. This is likely because gpt already performed poorly on the 3way trial data, but we dont have the numbers for test data. The best result on the 2-way data (QWK .46)

Model	2-way	3-way
G-SciEdBERT	.36	.50
Phi-4	.38	.51
Gemma 3	.39	.52
no_gpt	.42	.58
no_instance	.45	.52
no_gemma	.45	.54
no_phi	.46	.54

Table 5: Evaluation Results for Unseen Questions

is obtained when Phi-4 is not included in the voting. With respect to performance relative to the other submissions to the shared task, we placed 6th in the 2-way condition (no_phi) and 4th in the 3-way condition (no_gpt).

Notably, all models performed significantly better on the 3-way task than the 2-way task. This may be explained by the label distribution: in the 3-way task, the classes are relatively balanced (29.2% Correct, 36.3% Partially Correct, and 34.5% Incorrect). However, in the 2-way task, merging the 'partially correct' and 'incorrect' categories creates a significant class imbalance, with the 'incorrect' category accounting for 70.8% of the data. Separating "partially correct" as its own label in the 3-way task appears to provide a clearer signal for the models to learn.

5 Error Analysis: Influence of 'incoherent' scoring rubrics

A recurring source of confusion during manual inspection of the data was the missing task context: The shared task data originates from a realistic ITS context, but were provided without full context information about the surrounding material. Therefore, a number of questions were not fully transparent such as a question simply stating "Erkläre, in eigenen Worten, warum du dich für diese Lampe entschieden hast." (*Explain in your own words why you have chosen that specific lamp!*), with a rubric for a correct answer stating "Die SuS formulieren eine Begründung basierend auf physikalischen Prinzipien und gesellschaftlichen/ökologischen Beweggründen." (*The students formulate a justification based on physical principles and societal / ecological reasons.*). Without any context it can be hard for humans to determine whether an answer to that question is actually correct.

In an error analysis, we manually annotated such incomplete questions (16 in total) and then compared model performance on these incomplete questions to performance on the remaining trial set. However, QWK values did not substantially differ, hinting at the models capability to infer relevant information from either sample answers or rubric contexts.

6 Conclusion

In this paper, we compared various different approaches to short-answer scoring on a German science question dataset. We found that established instance- and similarity-based methods outperform approaches based on generative LLMs that take only the scoring rubric into account in the unseen answers track, whereas LLM-based approaches where the only applicable option in the unseen questions track. In both cases, we benefit from using an ensemble of classifiers instead of a single classifier only.

Acknowledgements

This work was conducted as part of the DFG-funded ASLAN project (Fördernummer: 563947383).

Limitations

This shared task treated classifier performance as the sole evaluation metric. In a practical application of Short Answer Scoring, however, considerations of robustness and fairness (Loukina et al., 2019; Schaller et al., 2024) can be equally important, particularly with respect to potential biases affecting specific subgroups of learners and should thus also be considered in evaluation.

Ethical Considerations

This work relies on a dataset provided by the shared task organizers. As such, data collection, anonymization, and privacy protection measures were handled prior to our use of the data.

Abstract

We describe the WSE Research system for the BEA 2026 Shared Task 2 on Rubric-based Short Answer Scoring for German. Our system combines rubric-conditioned prompting with TF-IDF exemplar retrieval, LoRA fine-tuning of open-source Qwen models, and prediction aggregation across complementary scorers. The central question is when prompt engineering, parameter-efficient adaptation, and aggregation each help for rubric-based grading. On the ALICE-LP-1.0 trial set, a fine-tuned Qwen2.5-32B reaches QWK 0.769, surpassing the strongest prompted commercial baseline (Gemini 3 Flash, 0.748). On the official test set, the system ranks second on three tracks and third on the remaining one. Overall, the results show that rubric-conditioned fine-tuning is a competitive and cost-effective alternative to commercial APIs for German short answer scoring, while aggregation helps on seen questions but larger single models generalize better to unseen rubrics.

1 Introduction

Automated short answer grading (ASAG) can reduce assessment effort while maintaining consistent scoring quality (Burrows et al., 2015), but most resources target English. For German, only four dedicated ASAG corpora exist, with approximately 19,500 labeled answers compared to over 44,500 in English (Padó et al., 2024); morphology, compounding, case, and free word order further complicate transfer from English benchmarks (Horbach et al., 2024).

The BEA 2026 Shared Task 2 on Rubric-based Short Answer Scoring for German (Gombert et al., 2026) addresses this gap with the ALICE-LP-1.0 benchmark: 7,899 labeled student answers

across 78 STEM questions, each paired with textual rubrics for **Correct**, **Partially correct**, and **Incorrect**. Because LLM grading accuracy degrades with rubric granularity (Deng et al., 2026) and ASAG transfer across datasets loses 13–47% QWK (Funayama et al., 2023), the task requires per-task adaptation rather than generic grading.

We present the WSE Research system (Figure 1), which combines three complementary strategies that address the following research questions:

- RQ1** To what extent can rubric-conditioned prompt engineering close the performance gap between open-source and commercial LLMs for German short answer scoring?
- RQ2** How does LoRA fine-tuning performance scale with model size for rubric-based short answer classification?
- RQ3** Can ensemble aggregation over heterogeneous scoring strategies outperform individual models?

We evaluate three complementary design choices: rubric-conditioned prompting, LoRA fine-tuning, and aggregation across scorers with different error profiles. The strongest fine-tuned model surpasses the strongest prompted commercial baseline on the trial set (Ferreira Mello et al., 2025); on the official test set, the system places second on three tracks and third on the remaining one. Code and reproducibility artifacts are publicly available.¹

2 Related Work

Automated Short Answer Grading. ASAG has progressed from keyword matching through supervised classifiers to neural approaches (Burrows et al., 2015); the SemEval-2013 winner already combined lexical, syntactic, and character n -gram features via stacking (Heilman and Mad-

*This work was partially funded by the German Federal Ministry of Education and Research (BMBF) under grant FKZ 03FHP239.

nani, 2013). A recent survey reports that rubric-guided prompting and human-in-the-loop systems outperform zero-shot single-LLM setups (Nkoyo et al., 2025).

German ASAG. Padó et al. (2024) show that multilingual sentence embeddings are competitive on German but drop 15–20 F1 points on unseen questions, identifying cross-question generalization as the key bottleneck. Horbach et al. (2024) further show that multilingual transformers outperform translate-then-score pipelines across languages, motivating our German-language prompts and native fine-tuning.

LLM-Based Grading and Example Selection. LLMs support rubric-based scoring through in-context learning (Frohn et al., 2025), with rubric-conditioned prompts outperforming rubric-free approaches (Wang et al., 2019); yet fine-tuned smaller models can still outperform vanilla GPT-4 when labeled data is available (Ferreira Mello et al., 2025). Few-shot selection is similarly important: RAG-based retrieval outperforms random selection ($p < 0.001$) (Zhao et al., 2025), and boundary-focused exemplars reduce adjacent-score errors from 0.26 to 0.08 (Chu et al., 2026a). Our TF-IDF-based selection (Section 3.1) combines both signals. Prompt format is known to be brittle: rubric order and score notation can shift grades by up to 45% for frontier models (Deng et al., 2026); automated rubric refinement (Chu et al., 2026b) addresses this at the rubric side but was not attempted here.

Fine-Tuning and Calibration for ASAG. LoRA (Hu et al., 2022) enables parameter-efficient fine-tuning of large models on task-specific data. Funayama et al. (2023) report that rubric-keyphrase fine-tuning improves QWK by approximately 0.25 when training data is scarce. Raikote et al. (2026) reach $\text{QWK} \geq 0.80$ with fine-tuned Qwen-7B on English short answers, while Bexte et al. (2024) show that confidence thresholds are prompt-dependent—a finding our experiments corroborate (Section 5.3). Our work extends LoRA fine-tuning to German with a systematic 7B–72B scaling study.

Taken together, prior work motivates our three-phase design. *Prompt engineering* operationalizes rubric-conditioned in-context scoring, *LoRA fine-tuning* tests whether task-specific supervision can replace commercial prompting, and a *retrieval baseline* anchors both against a non-neural alternative. We leave automated rubric refinement out of

scope because the shared task evaluates systems on fixed organizer-provided rubrics; modifying them would confound scorer quality with rubric rewriting quality.

3 Approach

Our approach is designed as a three-phase rubric-scoring pipeline, as illustrated in Figure 1. First, we generate candidate score labels from the same input triple (question, student answer, rubric) with prompted LLMs, fine-tuned LLMs, and a TF-IDF k NN baseline that labels by similar training answers without neural inference. Second, we compare these scorers under trial-set evaluation to isolate the contribution of prompt engineering, model scale, and aggregation. Third, we choose the final prediction rule per deployment setting: aggregation for seen questions and a single large fine-tuned model for unseen questions, where rubric transfer dominates. The remainder of this section instantiates these phases through prompt engineering (Section 3.1), fine-tuning (Section 3.2), and prediction aggregation (Section 3.3).

3.1 Phase 1: Prompt Engineering

The prompt engineering phase instantiates the pipeline with rubric-conditioned in-context scoring. Each request includes the full textual rubric as the system prompt; the model receives the question and student answer and returns one of the three score labels. We evaluate this setup with Gemini 3 Flash and Qwen3.5-27B to compare a strong commercial API against the strongest self-hosted open-source prompting variant from our model-screening runs. This grounds scoring in the provided rubric rather than the model’s parametric knowledge. We deliberately avoid chain-of-thought prompts, as recent evidence suggests CoT can degrade QWK on educational grading tasks despite improving NLG evaluation (Nkoyo et al., 2025).

TF-IDF-Based Example Selection. Rather than using fixed few-shot examples, we dynamically select training examples for each test instance via TF-IDF cosine similarity between the test answer and training answers for the same question. Examples enter the prompt in two roles: *similar examples*, retrieved by TF-IDF cosine similarity to the test answer among same-question training answers, and *boundary examples*, drawn from less-represented score labels to expose the model to

Figure 1: Overview of the WSE Research scoring pipeline. Three phases produce score predictions from the input triple (question, student answer, rubric). For seen questions, weighted voting is best; for unseen questions, the Qwen2.5-72B alone outperforms all ensembles. Dashed arrow: training data flow.

within-rubric edge cases. We quantify question difficulty as the dominant-label fraction in that question’s training subset and bin questions into easy (> 0.60), medium ($0.40\text{--}0.60$), and hard (< 0.40) tiers; pilot sweeps showed two similar examples to be consistently helpful, while the useful number of boundary examples varied with difficulty. The final Gemini configuration, therefore, fixes the similar-example count at two and uses 1, 2, or 3 boundary examples for easy, medium, or hard questions, respectively. This combines retrieval of semantically close answers (Zhao et al., 2025) with boundary-focused calibration (Chu et al., 2026a). We iterated prompts systematically (6 strategies for Gemini 3 Flash, 33 variants across 8 rounds for Qwen3.5-27B); the checkpoint-specific transfer behavior this revealed is analyzed in Section 5.3.

3.2 Phase 2: Fine-Tuning

The fine-tuning phase asks how much rubric-conditioned supervision can be absorbed by open-source models of different sizes. We apply Low-Rank Adaptation (LoRA, cf. (Hu et al., 2022)) to Qwen-family models at four Qwen2.5 scales (Qwen2.5-7B, Qwen2.5-14B, Qwen2.5-32B, Qwen2.5-72B) plus Qwen3.5-9B to test whether a newer architecture improves fine-tuning efficiency at smaller scale. The Qwen3.5-27B model in Section 3.1 is used only for prompting, not for LoRA training.

Instruction Format. Each training example is formatted as an instruction-following turn: rubric text as system prompt, question and student answer as user message, gold score label as assistant response. This aligns fine-tuning with the inference-time interface from the prompt-engineering phase, so differences between prompting and fine-tuning can be attributed mainly to parameter adaptation rather than interface changes. Following Funayama et al. (2023), we include rubric key phrases

as explicit input features.

Training Configuration. Preliminary studies using Qwen2.5-7B indicated that one epoch underfit and five epochs overfit, while increasing the LoRA rank beyond 32 did not improve trial performance. We therefore use a single pragmatic configuration across scales ($r = 32$, $\alpha = 32$, learning rate 2×10^{-4} , 3 epochs) to isolate model-size effects rather than retuning each model separately. The 14B, 32B, and 9B models use full bf16 LoRA on L40S GPUs; the Qwen2.5-7B and Qwen2.5-72B use 4-bit QLoRA (NF4), with the 72B moved to an H200 to fit memory constraints. We train each size in two configurations: *train-only* (for unbiased trial-set comparison) and *all-data* (train + trial, for final submission). Trial labels are released development data: train-only models provide an unbiased internal comparison, whereas all-data models use every labeled example available before hidden-test submission.

3.3 Phase 3: Prediction Aggregation

The aggregation phase asks whether complementary scorers should be combined or deployed separately. For unbiased trial-set analysis, we train a logistic-regression meta-learner (Heilman and Madnani, 2013) with leave-one-question-out cross-validation. Component models span three fine-tuned variants (Qwen2.5-7B, Qwen2.5-14B, Qwen2.5-32B), the best prompt-only result (Qwen3.5-27B), and a non-neural TF-IDF k -nearest neighbor baseline. We set $k = 7$ because it was the strongest pure-retrieval setting in pilot runs, outperforming $k \in \{3, 5, 11\}$. Features comprise one-hot model predictions, k NN confidence, answer length, and question difficulty. For final submissions, we use simpler rules: QWK-weighted voting for seen questions and the 72B solo model for unseen questions, because weaker models diluted the 72B’s rubric generalization.

4 Experimental Setup

Dataset. ALICE-LP-1.0 (Gombert et al., 2026) contains 7,899 German secondary-school STEM answers to 78 questions, each paired with a textual rubric defining three score levels. Train (7,072) and trial (827) sets are stratified by question (29% **Correct**, 36% **Partially correct**, 35% **Incorrect**). The test set (5,094 samples) splits into 2,008 answers to the 78 seen questions and 3,086 answers to 39 entirely new questions with 34 new rubrics. Each split is graded under both a 3-way label scheme and a 2-way scheme (with **Partially correct** collapsed into **Incorrect**), yielding the four official shared-task tracks.

Models and Hardware. We evaluate two prompt-only baselines (Gemini 3 Flash, parameter count undisclosed; Qwen3.5-27B) and five fine-tuned Qwen variants (Qwen2.5-7B, Qwen2.5-14B, Qwen2.5-32B, Qwen2.5-72B, Qwen3.5-9B), all trained with LoRA rank $r = 32$ for 3 epochs. Experiments up to 32B run on 2xL40S GPUs using vLLM (Kwon et al., 2023); the Qwen2.5-72B is fine-tuned on a single H200 NVL GPU via PEFT (Mangrulkar et al., 2023).

Evaluation. The primary metric is Quadratic Weighted Kappa (QWK), the official shared-task ranking metric; we additionally report accuracy. Trial-set evaluations use train-only models for unbiased comparison; submission models use all available data (train + trial).

5 Results

5.1 Trial Set Results

Table 1 reports trial-set performance with train-only fine-tuned models.

Fine-tuning consistently outperforms prompt engineering: the Qwen2.5-14B already surpasses Gemini 3 Flash (0.005 QWK), and the Qwen2.5-32B extends the margin to 0.021. A QWK-proportional weighted vote over the four-model pool {Qwen2.5-7B, Qwen2.5-14B, Qwen2.5-32B, Gemini 3 Flash}—with weights derived from each model’s leave-one-question-out cross-validated QWK on the training set and normalized to sum to one—achieves the highest unbiased trial QWK of 0.781 by combining fine-tuned and prompt-based models; a logistic-regression stacker over an extended five-candidate pool that additionally includes the TF-IDF k NN baseline reaches 0.776 under leave-one-question-out cross-validation. This

Phase	System	QWK	Acc
<i>Prompt Engineering</i>	Gemini 3 Flash	0.748	73.6
	Qwen3.5-27B	0.719	70.2
<i>Fine-Tuning (train-only $\rightarrow$ trial)</i>			
	Qwen2.5-7B QLoRA	0.726	70.9
	Qwen2.5-14B LoRA	0.753	74.1
	Qwen2.5-32B LoRA	0.769	75.7
	Qwen2.5-72B QLoRA	0.768	75.7
	Qwen3.5-9B LoRA	0.756	74.2
<i>Ensemble / Baseline</i>			
	Weighted vote (4 models)	0.781	— [†]
	LogReg stacking (5-cand.)	0.776	75.5
	TF-IDF k NN ($k = 7$)	0.612	64.5

Table 1: Results on the ALICE-LP-1.0 trial set (827 samples). Fine-tuned models use train-only data for unbiased evaluation. [†] Accuracy is omitted for the QWK-proportional weighted vote because the aggregation produces a continuous score in $[0, 2]$ rather than a discrete label, and any threshold-based discretization is a separate decision rule unrelated to the QWK ranking metric.

Figure 2: Trial-set QWK versus model size: fine-tuned Qwen variants (filled) saturate by 32B; prompt-only baselines (hollow); Gemini 3 Flash is plotted at a nominal 100B (true size undisclosed).

answers **RQ1**: rubric-conditioned prompt engineering yields a strong baseline, but it does not close the gap to fine-tuned open-source models once task-specific supervision is available.

Scaling Behavior. Figure 2 visualizes trial-set QWK as a function of model size. Fine-tuning QWK scales with diminishing returns and saturates by 32B (−0.001 from 32B to 72B). The 7B (0.726) already matches the prompt-only Qwen3.5-27B (0.719); Qwen3.5-9B (0.756) outperforms Qwen2.5-14B (0.753), suggesting that model generation matters more than parameter count. This answers **RQ2**: larger fine-tuned models generalize more robustly across rubrics, but

Track	Ours	IWM-DKM	Rank
<i>3-way scoring</i>			
Seen questions	0.790	0.796	2nd
Unseen questions	0.672	0.681	2nd
<i>2-way scoring</i>			
Seen questions	0.717	0.726	2nd
Unseen questions	0.533	0.550	3rd

Table 2: Test-set QWK on all four official tracks for our system and the winning team, IWM-DKM. Our submitted systems are the QWK-weighted vote of {Qwen2.5-7B, Qwen2.5-14B, Qwen2.5-32B, Gemini 3 Flash} on 3-way seen, the binary majority vote of {Qwen2.5-14B, Qwen2.5-32B, Gemini 3 Flash} on 2-way seen, and the Qwen2.5-72B solo on both unseen-question tracks. Retraining the 72B on train + trial lifts its trial QWK from 0.768 (train-only, Table 1) to 0.851 (in-sample), a 0.083 headroom from incorporating trial labels at submission time.

unbiased trial performance saturates by 32B.

5.2 Test Set Results

Table 2 reports our best system on each of the four official tracks alongside the corresponding result of the winning team IWM-DKM.

On *seen questions*, the weighted ensemble (QWK 0.790) outperforms all individual models, mirroring the trial-set pattern. On *unseen questions*, the Qwen2.5-72B alone (QWK 0.672) beats a 72B-inclusive weighted vote (0.653) and the Qwen2.5-32B solo (0.611); adding weaker models *hurts*, and the seen-to-unseen drop is 0.118 QWK for 72B versus 0.169 for 32B. This answers RQ3: aggregation helps on seen questions, but becomes harmful on unseen ones once a single strong model dominates.

5.3 Analysis

Prompt-Model Coupling and Calibration. Optimal prompts are checkpoint-specific: prompts tuned for Gemini 3 Flash degrade by 0.260–0.400 QWK on other Gemini variants, aligning with Deng et al. (2026) on format sensitivity. Fine-tuned models exhibit >99% logprob-confidence, making confidence-based routing infeasible without post-hoc calibration (Raikote et al., 2026).

Error Patterns. On the trial set (32B train-only), 94.3% of misclassifications are adjacent-boundary errors, and **Partially correct** has the lowest per-label precision (65.0%), consistent with rubric-granularity findings (Deng et al., 2026). Cross-model agreement drops from 53.9% on seen to 41.4% on unseen, where the Qwen2.5-72B most often corrects majority leniency by downgrading.

6 Conclusion

We presented the WSE Research system for the BEA 2026 Shared Task 2, placing second on three of four tracks. Rubric conditioning matters, parameter-efficient fine-tuning exploits it most reliably and saturates by 32B (RQ1, RQ2), and aggregation helps on seen questions but hurts unseen ones (RQ3). Rubric-conditioned fine-tuning is thus a practical open-source alternative.

Limitations

Our system was developed and evaluated exclusively on the ALICE-LP-1.0 dataset, which covers German STEM answers at the secondary-school level. Generalization to other languages, educational levels, or subject domains has not been tested. Prior work suggests that ASAG strategies degrade by 13–47% QWK when transferred across datasets (Funayama et al., 2023), and cross-corpus transfer for German specifically can incur up to 22 percentage points of accuracy loss (Padó et al., 2024).

The 72B out-of-sample trial QWK (0.768) shows no improvement over the 32B (0.769), suggesting that the scaling curve plateaus at 32B for this dataset size (7,072 training samples). Retraining the 72B on train + trial for submission lifts its trial QWK to 0.851 (in-sample), a 0.083 headroom over the directly comparable train-only value; this gain is observed on data the model has seen and should not be read as out-of-sample improvement.

We rely on the provided rubrics as-is and do not perform rubric quality assessment or optimization. Approximately 10% of questions use vague competency-level descriptions without specific criteria, which may limit scoring accuracy for both our system and human raters. Confusion-aware rubric refinement (Chu et al., 2026b) could address this but was not attempted in the current work.

All evaluations use automated metrics (Quadratic Weighted Kappa, accuracy); we did not conduct human evaluation of model predictions or analyze inter-annotator agreement on the dataset.

Fine-tuned models show near-uniform confidence (>99%), which prevents meaningful confidence-based quality control. This limits the applicability of human-in-the-loop strategies that rely on uncertainty estimates for selective routing (Bexte et al., 2024). Post-hoc temperature scaling (Raikote et al., 2026) may restore useful confidence

signals but was not applied here.

Ethics Statement

This work uses the publicly released ALICE-LP-1.0 dataset, which was collected with appropriate institutional oversight within the ALICE project (Leibniz Foundation). Student answers are anonymized and contain no personally identifiable information.

Automated scoring systems should be deployed as decision-support tools rather than sole arbiters of student grades. We note that LLM-based scoring can reproduce or amplify biases present in training data, including potential biases in rubric design or human scoring patterns. Deployment in high-stakes assessment contexts requires human oversight and ongoing bias monitoring.

Generative AI Disclosure. Parts of the codebase were developed with the assistance of AI agents. All experimental design, analysis, and writing were conducted by the authors.

A Prompt Templates

This appendix gives the verbatim wording of the two prompt families used in the prompt-engineering phase (Section 3.1) and as the inference-time interface for the fine-tuning phase (Section 3.2).

Prompted scoring (Gemini 3 Flash, Strategy C5c). The user prompt contains the question, the verbatim three-level rubric, two retrieved similar examples, $n_b \in \{1, 2, 3\}$ boundary examples (selected as described in Section 3.1), and finally the test answer. The system prompt is verbatim:

Du bist ein automatisches Bewertungssystem für Schülerantworten in MINT-Fächern.

AUFGABE

Bewerte die Antwort eines Schülers anhand der Bewertungsrubrik und der Beispielerwertungen.

BEWERTUNGSSTUFEN

- ‘Correct’: Die Antwort trifft ALLE zentralen Punkte der Correct-Rubrik.
- ‘Partially correct’: Die Antwort trifft MINDESTENS EINEN zentralen fachlichen Punkt der Rubrik korrekt, verfehlt aber andere wesentliche Kriterien.
- ‘Incorrect’: Die Antwort trifft KEINEN der fachlichen Kernpunkte der Rubrik.

ENTSCHEIDUNGSREGELN

1. Entscheide anhand der Rubrik UND konsistent mit den Beispielerwertungen.

2. Bewerte nur, was geschrieben wurde --- keine wohlwollenden Annahmen.

3. GRENZE Incorrect vs. Partially correct:

- Vage Aussagen, Alltagswissen oder Umformulierungen der Frage OHNE fachlichen Inhalt aus der Rubrik sind IMMER Incorrect.

- Partially correct erfordert NACHWEISBAR mindestens einen konkreten fachlichen Punkt, der in der Rubrik als Kriterium genannt wird.

4. GRENZE Partially correct vs. Correct:

- Correct erfordert, dass die Antwort die Rubrik-Kriterien VOLLSTÄNDIG abdeckt.

- Wenn die wesentlichen Konzepte korrekt und vollständig dargelegt sind, kleine sprachliche Ungenauigkeiten aber vorliegen -> trotzdem Correct.

- Im Zweifel: orientiere dich an den Beispielerwertungen für diese Frage.

5. Leere Antworten, Nichtwissen (‘?’ , ‘Keine Ahnung’), einzelne Wörter ohne Erklärung -> IMMER Incorrect.

FORMAT

Antworte NUR mit einem JSON-Objekt:

```
{‘score’: ‘Correct’
| ‘Partially correct’ |
‘Incorrect’, ‘confidence’:
0.0--1.0}
```

Fine-tuned scoring (Qwen2.5 LoRA). The fine-tuned models receive a minimal instruction-format prompt that mirrors the inference contract and dispenses with explicit decision rules, since those have been internalized via training:

System: Du bist ein Bewertungssystem für Schülerantworten. Bewerte die Antwort anhand der Rubrik. Antworte ausschliesslich mit JSON: {‘score’: ‘Correct’ | ‘Partially correct’ | ‘Incorrect’}

User: Frage: {question} \n
 Bewertungsrubrik: - Correct: {rubric.Correct} - Partially correct: {rubric.PC} - Incorrect: {rubric.Inc} \n
 Schülerantwort: {answer}

The full executable prompt code, including example selection and all model-specific variants, is publicly available in our repository (see Section 1).

AMATI at BEA 2026 Shared Task 2: Automatic Short Answer Grading with Inductive Logic Programming and a Large Language Model

Abstract

We discuss the AMATI submission to the BEA 2026 Shared Task on Rubric-based Short Answer Scoring for German. Our neuro-symbolic system uses a combination of symbolic rules, automatically learned with a form of Inductive Logic Programming, and the Mistral-large language model. We wanted to investigate whether the combination would improve overall grading performance, while using the automatically induced symbolic rules for explainability, and the LLM for robustness. We find that the combination of approaches resulted in improved overall performance for the 3-way task. However, including the symbolic rules did not improve upon Mistral’s performance in the 2-way test.

This paper presents our approach to the unseen answers challenges. Our team finished 6th out of 9 in the 2-way challenge, and 5th out of 8 in the 3-way challenge. In the 3-way challenge, neither our symbolic system nor the use of Mistral alone would have placed higher than 6th of the 8 competitors, illustrating the improvement of the combined approach over either of the individual approaches.

1 Introduction

Assessment is a core aspect of education. Formative assessment in particular is a valuable aid to student’s self learning (Clark, 2012). Techniques such as Automatic Short Answer Grading (ASAG) (“grading” and “scoring” both appear in the literature) can potentially support scalable student learning by providing low cost feedback on low-stakes assessment (Aggarwal et al., 2025).

Recent work in ASAG has been dominated by approaches based on statistical techniques or deep learning/large language models (Lu et al., 2025). In this work, grading is typically treated as a classification task, in which student responses are assigned to one of a number of potential grades. This BEA task (Gombert et al., 2026) follows similar tasks

such as the SemEval 2013 Joint Student Response Analysis and 8th Recognizing Textual Entailment Challenge (Dzikovska et al., 2013) in providing a 2 way task (student responses are classified as correct or incorrect) and a 3 way task (in which responses are classified as correct, partially correct or incorrect).

Large language models (LLMs) such as Mistral (Mistral AI, 2024) typically achieve strong empirical performance, but the resulting models are not usually interpretable by humans. Symbolic learning techniques, such as Inductive Logic Programming (ILP) (Quinlan, 1990; Muggleton and Feng, 1990) aim to induce models as logic programs rather than weighted networks. Such logic programs are generally more interpretable by humans, as well as being editable if desired. For an ILP approach to ASAG, the goal is to induce a set of rules which will assign grades from a symbolic representation of the question, rubric and student response. When applying the rules to unseen instances, the reasoning behind the allocated grade is clear. This explainability will be crucial for broader adoption of ASAG technology in the classroom.

This approach to using symbolic rules to augment neural language models is becoming of interest as the need for human-understandable explanations is increasingly recognised (Bhuyan et al., 2024; Yang et al., 2025). The neuro-symbolic system AlphaGeometry (Trinh et al., 2024) has similarly been developed to generate human readable explanations of its reasoning (in this case, geometry problems). Dinu et al. (2024) present a more general framework to address the general task of embedding logic solvers into generative models.

Although theories induced by ILP are quite explanatory (Willis, 2015), LLMs have demonstrated their robustness in the face of the noisy and poorly formed language that is typical in short student responses. In this paper, we discuss our attempt to combine the explanatory nature of ILP with the

robustness of an LLM. Our system was applied to the BEA 2026 Shared Task on Rubric-based Short Answer Scoring for German (Gombert et al., 2026) for an independently verified evaluation. Our code is available through GitHub¹.

2 Grading rule induction with Answer Set Programming

ILP is an optimisation task: we want to find the logic program which most accurately classifies the training cases. As such, much of the foundational work in ILP focussed on optimising search algorithms (Muggleton and Feng, 1990; Quinlan, 1990; Muggleton, 1995). However, some recent approaches have used Answer Set Programming (ASP) solvers to handle the optimisation (Law et al., 2014; Cropper et al., 2022).

We follow the same strategy, using the ASP solver *clingo* (Gebser et al., 2019) to optimise the rule coverage. This approach then implements an ILP-style rule induction: ASP is repeatedly used to optimise individual rules until a maximal set of training cases is covered.

Our approach consists of three components: a representation of student responses and rubric information as logical facts (section 2.1), a set of templates for classification rules (section 2.2), and a procedure for selecting rules that explain the training data (section 2.3).

2.1 Representing ASAG as a logic program

ILP requires that the information about the task be represented in the same language as the induced rules. As such, the first step is to represent the training data (that is, the questions, rubrics, student responses and ground truth gradings) in a logical format.

For the unseen answers task, each question is treated separately. For each task, we then have:

- a single question (identifier and text),
- a grading rubric (text for each possible grade),
- a set of student responses (each with an identifier and its own text), and
- a ground truth grade (“score”) for each student response.

We refer to each of the texts of each question, rubric and student response as a *document*. Each document was converted to a sequence of lemmas using spaCy (2020) with the `de_core_news_md` model. Each lemma is then encoded as a predicate of the form:

```
lemma_in_doc(Doc, Position, Lemma)
```

where `Doc` is the document’s index, `Position` is the token index, and `Lemma` is the lemmatised form of the token. The ground truth grades are then encoded as:

```
label(ResponseID, Class).
```

where `Class` is one of `{correct, incorrect}` or `{correct, partially_correct, incorrect}` depending on the task.

As an example, the (slightly simplified) encoding of one of the questions from the training data is given in figure 1. In the encoding, lemmas in the question are indexed as `q`, in the rubric as `c`, and in the student responses as `r_01`, `r_02`, and so on. This encoding allows rules to refer directly to linguistic features. For example, a rule can test whether a response contains a particular concept (represented as a lemma), or whether that concept appears in the rubric but not in the question. The representation of the documents’ indices in the predicates also enables rules to express relationships between documents, rather than treating the response in isolation.

2.2 Representing grading rules

Grading rules are expressed as logical clauses that specify the conditions under which a response should be assigned a particular label. Following the logic-based representation of the documents, the grading rules can be clearly expressed in the language of logic programming. For example, the covers predicate in figure 2 states that `rule3` applies to any student response whose lemmatised form contains the lemmas `kurve` and `steigen`. The additional clause `I < J` also allows us to express that for a match, the lemmas must appear in that order (ie. `kurve` precedes `steigen`). The `predicted_grade` states that any response which matches the condition in `covers` is graded as `partially_correct` by the system.

A more complex example is given in figure 3. Here, a response is covered by the rule if the response contains the lemma `reagieren`, the rubric

    lemma_in_doc(c, _, "reagieren"),
    not lemma_in_doc(q, _, "reagieren").

predicted_grade(correct).

```

Figure 3: Grading rule with key information and predicted grade

2.3 Rule and theory induction via ASP

In order to generate a complete set of rules (a “theory”) to grade all the responses to a given question, we use an ASP solver to generate individual rules. To generate specific rules, we define a set of generalised *rule templates*.

```

covers(ki_rule1, Response):-
    student_response(Response),
    lemma_in_doc(Response, _, Lemma),
    lemma_in_doc(c, _, Lemma),
    not lemma_in_doc(q, _, Lemma).

predicted_grade(Grade).

```

Figure 4: Rule template. Lemma and Grade are found by optimising with the answer set solver

An example template is given in figure 4. The figure represents the template form of the rule shown in figure 3. Then given the encoding of the question, rubric and a set of responses, the best *specific* rule is found from the values of:

- the choice of rule (from all the templates),
- the values of each Lemma variable in the chosen rule, and
- the predicted grade (ie. Grade)

which maximises the correct number of predicted grades from the set of student responses. To find these optimum values, we use the *clingo* answer set grounder and optimiser to find the optimum values for Grade and Lemma. (The optimised value is actually compression (Muggleton, 1995) rather than coverage).

To generate a complete theory from the initial set of student responses, we use a very simple procedure:

1. The theory is initially an empty list.
2. Find the specific rule which correctly predicts the grade for the largest number of student responses.
3. Add the specific rule to the current theory.
4. Remove all student responses which are correctly predicted by the new rule.
5. Repeat stages 2 to 4 until either all responses are covered, or no new rule can be found.

```

covers(rule1, Response):-
    student_response(Response),
    lemma_in_doc(Response, _, Lemma).

covers(rule2, Response):-
    student_response(Response),
    lemma_in_doc(Response, _, Lemma1),
    lemma_in_doc(Response, _, Lemma2).

covers(rule3, Response):-
    student_response(Response),
    lemma_in_doc(Response, I1, Lemma1),
    lemma_in_doc(Response, I2, Lemma2),
    I1 < I2.

covers(ki_rule1, Response):-
    student_response(Response),
    lemma_in_doc(Response, _, Lemma),
    lemma_in_doc(c, _, Lemma),
    not lemma_in_doc(q, _, Lemma).

covers(ki_rule2, Response):-
    student_response(Response),
    lemma_in_doc(Response, _, Lemma1),
    lemma_in_doc(c, _, Lemma1),
    lemma_in_doc(Response, _, Lemma2),
    lemma_in_doc(c, _, Lemma2),
    not lemma_in_doc(q, _, Lemma1),
    not lemma_in_doc(q, _, Lemma2).

covers(ki_rule3, Response):-
    student_response(Response),
    lemma_in_doc(Response, _, Lemma1),
    lemma_in_doc(c, _, Lemma1),
    lemma_in_doc(Response, _, Lemma2),
    lemma_in_doc(c, _, Lemma2),
    not lemma_in_doc(q, _, Lemma1).

```

Figure 5: Complete list of induction rule templates

This procedure then generates a list of rules which can be applied to new examples. The final output of the process is a theory consisting of an ordered set of rules. Each rule defines the coverage criteria for student responses, and the predicted grade for any responses which match those criteria.

To apply the rules to new cases, each rule in the theory is applied in order. The first matching rule is used to predict the grade. If no rule matches, the prediction defaults to incorrect.

The performance of this system without additional input from a LLM is shown in table 1 as “Rule-based”. The complete set of the rule templates is given in figure 5.

2.4 Limitations and motivation for a hybrid approach

Although some linguistic variation in the student responses is accommodated by using spaCy’s lemmatisation and spell checking, the primary limitation of this method is the reliance on lexical matching. The range of possible responses from students can make the symbolic rules quite fragile. We therefore

wished to explore how integrating these rules with a large language model might address this limitation.

3 Combining with a LLM

For the unseen answers task, we identified several potential approaches to combining the ILP rules with a LLM:

Mistral No ILP rules are used. For each test response, the LLM is supplied with the corresponding question and all responses in the training data for the same question, and asked to predict the correct grade.

Test ILP As *Mistral*, but also including the specific ILP prediction for the test question and the rule(s) applied to make it.

Theory As *Mistral*, but also including the complete set of rules in the theory generated by the ILP process for the task.

Test ILP and Theory As *Mistral*, including the ILP prediction and rule(s) for the test question and the complete theory.

For the unseen questions task, there is of course no “corresponding question”; our intent was to select a sample of questions from the training data instead. In practice, however, the results for the unseen questions task without the LLM did not seem to justify the time and inference cost, so we did not run the LLM cases for that task.

We decided to use the *mistral-large* model (Mistral AI, 2024) as the LLM component, via the paid Mistral API. This choice was based on its performance in the leaderboards in (Thakur, 2025) for performance in German language tasks, and its context window (the length of input it can accommodate) of 256k tokens. The prompts are in the form of templates, with placeholders to insert data, and describe the relevant scenario and what is expected from the model, and include descriptions of input and output data JSON formats. The full prompt templates are in the associated code repository. Figure 6 illustrates the prompt templates.

The output included a field for the LLM’s natural language *explanation* of the given grade, to provide data for future analysis of the LLM’s reasoning beyond the scope of the shared task. There are multiple avenues for this analysis, the most immediate of which is to compare LLM reasoning with the ILP rules, and evaluate its quality; further

You are a helpful and precise assistant for marking students' answers. You will be given a question, a student's answer, and the marking rubric for the question{, and a predicted score with explanation based on an inductive logic programming system}. The possible score values are "Incorrect", {"Partially Correct", }and "Correct". Your task is to evaluate each student's answer against the rubric for that question, and provide a score.

The following, between "TRAINING DATA STARTS" and "TRAINING DATA STOPS", is a JSON array of objects ... JSON details omitted ... representing the score assigned to the student's answer. Consider this as training data to improve your performance in the task.

...
{The following is the full theory generated by inductive logic programming over the training data:}

Figure 6: Prompt template (condensed for space). Scenario variations are indicated by braces.

	QWK	WP	WR	WF1
2-way				
Rule-based	0.489	0.801	0.807	0.795
Mistral	0.644	0.857	0.843	0.847
Theory	0.644	0.857	0.843	0.847
3-way				
Rule-based	0.614	0.662	0.655	0.650
Mistral	0.721	0.755	0.711	0.715
Theory	0.749	0.760	0.736	0.739

Table 1: Results for 3-way Unseen Answer tasks, showing Quadratic Weighted Kappa (QWK), and Weighted Precision (WP), Recall (WR), and F1-Score (WF1). QWK was used to rank task entrants.

possibilities include training new ILP rules from the LLM's explanations.

Testing with the provided trial data revealed that *Test ILP* (with or without the full theory) performed worse across all measures, whereas the *Mistral* and *Theory* cases performed similarly to each other, and both better than the ILP-only case.

We therefore decided to use the *Mistral* and *Theory* cases for the full evaluation.

4 Results and discussion

Our results for the 2-way and 3-way unseen answers are shown in table 1. When the ILP rules were included in the Mistral prompt, the 2-way results showed no improvement. However, for the 3-way task, including the symbolic rules in the

prompt raised the overall performance (as measured by QWK) from 72.1% to 74.9%. This also represents a position in the final evaluation table: our final position was fifth of eight.

5 Conclusion

In this paper, we have discussed how the performance of a system for student response grading was improved by incorporating a set of induced symbolic rules into the neural reasoning process. Although the final results are slightly below the average system performance in the task (6th of 9 in the 2-way task and 5th of 8 in the 3-way task), our interest is the combination of human-interpretable rules with LLM robustness. As illustrated in section 2.2, the rules generated from the templating system are human readable (subject to being comfortable with information being presented in a formal language).

In fact, our longer term aim with this work is not (directly) to improve the overall grading performance: after all, our results show that Mistral alone gives relatively good performance. Rather, we aim to improve the explainability of awarded grades for the benefit of educators (who are ultimately responsible for grades awarded) and students (whose self-directed learning will be improved with better feedback). In a practical classroom context, it is more valuable for an AI to be able to explain why it assigned a particular grade, rather than focussing solely on performance figures.

The key question we wish to address in the next stage of this work is: Do the grades awarded by the combined system closely follow the intended interpretation of the symbolic rules? The aim of combining the symbolic rules with a LLM, is for the LLM to handle linguistic variation, while the symbolic rules handle grading of the content. As such, we want the induced rules to be editable by a human, possibly even a human who is not a computing expert, but who might be an educator in the domain of the questions. In these cases, it is vital that the application of the system primarily follows the symbolic rules (which are human editable) rather than the LLM inferences (which generally are not). Indeed, the results of LLM outputs are not always replicable (Cui and Alexander, 2026). Our further analysis will therefore concentrate on understanding the relations between the symbolic rules and the performance of the complete grading system.

Limitations

Our method makes use of a prompt to Mistral. As is always the case for such a methodology, it is always possible that alternative prompting strategies would yield different performance. In particular, we have provided English language prompts for German text. While Mistral is known to be among the most robust LLMs in handling multiple languages (Holtermann et al., 2024), prompting in the same language as the data under analysis may provide different results. Also, we restricted ourselves to a single run on each experiment.

In addition, the symbolic rules generated by the inductive logic programming process are limited to the templates provided to the system (as shown in figure 5). These rules are currently quite limited, restricted to a small number of key terms across the response, question and grading rubric. However, the initial analysis from spaCy provides extensive additional information on the parsed sentences, such as part of speech, grammatical relations, and so on. Our future work will investigate whether more information in the induced rules can be used to improve overall performance.

Ethics statement

We confirm that this work complies with the [ACL code of ethics](#). No additional data sources were used beyond those cited in this paper, and the data provided by the team for the shared task.

Our interest in this work is driven by our belief that in issues such as grading, which can have an impact on peoples' futures, AI-based decisions must be clear and explainable. Audit trails for grading are a fundamental requirement when AI is used so that results can be challenged. We hope to be part of a movement of explainable AI behaviour in classroom environments.

Acknowledgments

We would like to thank the anonymous reviewers for their helpful comments on the original draft of this paper, and particularly their suggestions for future directions for our work.

Abstract

In this paper, we present the IWM-DKM team submissions to the BEA 2026 Shared Task 2: Rubric-based Short Answer Scoring for German. We systematically explored how fine-tuned language models can be reliably employed for short answer scoring, for which three aspects turn out to be particularly beneficial: supplementing the fine-tuning process with generated domain expertise, restructured rubrics, and thinking traces. To increase the robustness of the scoring, we combine distinct approaches in an ensemble. Our best submissions finished in first place across all tracks, indicating promise for the further application of these strategies in automatic scoring.

relevant information such as *domain-specific background knowledge*, and *restructuring information*, including both the rubrics and the model’s thinking traces to increase grading consistency.

Our approach produced the best submission in both *unseen question* (UQ) tracks with a single fine-tuned model combined with several supplementary strategies, and achieved first place in both *unseen answer* (UA) tracks by combining the strengths of multiple models into a majority-vote ensemble. In the following, we discuss related work on rubric-based short answer scoring and what motivated our use of the techniques we implemented. We then describe our methodology in detail and outline the results for each track.

1 Introduction

In contrast to previous challenges for automatic short answer scoring, such as the 2012 Kaggle challenge (Barbara et al., 2012) and the 2013 SemEval Task 7 (Dzikovska et al., 2013), the BEA 2026 Shared Task 2 (Gombert et al., 2026) represented the first challenge in which *scoring rubrics* formed an essential element of the scoring, and the first large-scale non-English short-answer challenge. The shared task offered two labeling schemes: a 3-way classification of answers into ‘Correct’, ‘Partially correct’ and ‘Incorrect’, and a binary ‘Correct’ / ‘Incorrect’ classification. Additionally, two evaluation setups were provided: *Unseen Answers* (a held-out set of answers to the questions from the training data), and *Unseen Questions* (answers for new questions not included in the training data). Participating as team IWM-DKM, we submitted entries to all four tracks of the challenge.

We utilized LoRA-fine-tuned LLMs (Hu et al., 2022) from the Qwen family (Yang et al., 2025) as the backbone of our grading system and successfully improved performance by a combination of *augmentation* of the model input with additional

2 Related Work

Recent years have seen an increase in deep learning approaches (e.g. Bexte et al., 2022; Ormerod, 2022) and LLM-implementations for short answer scoring (e.g. Chamieh et al., 2024; Frohn et al., 2025; Gao et al., 2025). In rubric-based scoring, descriptive scoring rubrics are integrated into the auto-grading methodology, acting as a mechanism to guide model decisions closer in line with principles of human assessment. Wang et al. (2019) integrate “key elements” of scoring rubrics with a word-level attention mechanism in a Bi-LSTM neural grading system. In recent approaches with LLMs, both Zhao et al. (2024) and Jiang and Bosch (2024) find that LLM scoring reliability is improved with the addition of rubrics, and Frohn et al. (2025) observe variable performance dependent on the level of rubric detail. Somewhat contrastingly, Pathak et al. (2025) experiment with prompt granularity, and find that LLM grading may become too harsh when rubrics are evaluated in a point-wise manner. Pathak et al. develop a multi-agent LLM approach, utilizing a majority vote ensemble of models. While they observe benefits of an ensem-

ble over a single model, beyond 3 to 4 LLMs results plateau with the addition of more LLMs. Overall, works to date suggest that rubrics offer a promising way to improve performance in short answer scoring, with the additional benefit of greater grounding in principles of traditional human assessment. However, how best to incorporate rubrics into automatic grading has not yet been comprehensively explored. While many recent approaches integrate rubric information via LLM prompting, the extent to which rubrics can be applied to the fine-tuning of pre-trained LLMs remains unclear. With our shared task submission, we aim to target this gap.

3 Approach

The ALICE-LP dataset consists of questions and answers from four science subject areas with authentic responses from secondary school students in Germany. The training set contained 78 questions with 7899 answers, alongside a trial set of 827 answers. Each item contains the question, the student response, and a rubric describing the criteria for each scoring level. Preliminary experiments with several encoder models appeared to reach a performance ceiling at around 0.75 QWK on the 3-way trial set. Consequently, our primary approach instead utilized supervised fine-tuning of decoder-only language models, specifically Qwen3 (4B/8B) and Qwen3.5 (9B) (Yang et al., 2025), incorporating all three item elements into the model input. We opted to use Qwen models, as relatively small-sized yet high performing open-source LLMs, making them more suitable for fine-tuning and deployment in educational settings than closed-source alternatives (Lin et al., 2026).

We employed Low-Rank Adaptation (LoRA) (Hu et al., 2022) targeting all linear projection layers with a rank $r = 16$ and a scaling factor $\alpha = 16$. This fine-tuning strategy was chosen so as to preserve the underlying model as much as possible whilst also taking into account the nature of the task-dataset. Models were trained using the AdamW optimizer (Loshchilov and Hutter, 2017) with a peak learning rate between 1×10^{-4} and 2×10^{-4} and a global batch size of 16 or 32. We applied a cosine learning rate schedule to smoothly decay the learning rate and trained the models for up to 10 epochs, ultimately selecting the best checkpoint based on the highest validation Quadratic Weighted Kappa (QWK). For certain models, we experiment with different fine-tuning

strategies, including Direct Preference Optimization (DPO) (Rafailov et al., 2023) (where the probabilities of correct labels are increased relative to dis-preferred options); Fast Gradient Method (FGM) (Goodfellow et al., 2014; Miyato et al., 2017) (an adversarial training method whereby embeddings are perturbed to increase robustness); and NEFTune (Jain et al., 2023) (a further method to introduce noise to the vector embeddings). We indicate in Section 4 for which submissions we employed alternative fine-tuning strategies. We build on this foundation with a range of approaches that aim to specialize the model more closely to the domain of the task and align the model’s decision process with the information contained in the rubrics. We do this by providing the model with *more* relevant information and by restructuring the format of it.

3.1 Checklist Thinking

Based on the principle of walking through intermediary steps before giving a final answer, the idea of “thinking” in LLMs has evolved from enhancing prompts with chain-of-thought prompting (Kojima et al., 2022) to integrating thinking steps into the model fine-tuning process (Zelikman et al., 2022), with the aim of improving model consistency. To apply this principle to short answer grading, we introduce a structured reasoning format termed *Checklist Thinking*. Instead of predicting the score label directly, the model is trained to first output a concise set of “Yes/No” checks corresponding to each rubric level within `<think>` tags. We found that a dynamic “Applicable-last” order was most effective—where the model explicitly evaluates and rejects the non-applicable score categories before confirming the criteria for its final predicted label. This method was particularly advantageous in improving recall for the “Partially correct” category, an example of which is:

```
<think>
Incorrect: NEIN
Correct: NEIN
Partially correct: JA
</think>
Partially correct
```

3.2 Rubric Reframing

LLMs typically perform better on tasks that use a structured, closed format. In question answering tasks, a performance drop is observed when moving from multiple choice to open-question tasks (e.g. Li et al., 2024). Several works address this potential challenge for LLMs by breaking down

complex tasks into a series of sub-tasks (Dua et al., 2022; Qin et al., 2024; Zhou et al., 2023), or by decomposing instructions into Yes/No checklists, resulting in greater alignment with human preference (Cook et al., 2024). Taking inspiration from these techniques, we consider how the format of the rubrics can be restructured to be more accessible to LLMs. For each 3-way rubric, we prompt GPT5.1 (Singh et al., 2025) to transform the rubric from high-level descriptions of the categorical levels to a set of questions that can be followed as a decision tree, providing greater structure to guide the LLM to a grading decision. The prompt used to generate the reformulated rubrics is shown in Appendix C.1 and an example is shown in Appendix B.

3.3 Background Knowledge

A characteristic of the dataset is that many questions require an understanding of subject-specific terminology and processes, or relate to external material (e.g., tables, experiments). To provide the necessary domain expertise, and counter some of the lack of context present in the question alone, we supplement the model input with generated “background knowledge”. We use Claude Sonnet 4.6 (Anthropic, 2026b) to generate a short textbook-style summary based on the question, the rubric, and all examples of correct student answers available for the given question. The exact number of examples used to generate background knowledge was variable, with an average of 26.46 correct answers per question in the unseen answers train set. For *unseen questions*, where ground-truth labels are absent, we employ a two-step pipeline: We initially generate context from all answers, from which labels are then predicted, and then re-generate background knowledge in a second pass using only the answers labelled as “Correct” (i.e., ‘silver-standard’ labels) (see Appendix C.2 for prompt details, and Appendix B for an example).

3.4 Skilled-based Categories

To better understand the nature of the data, and due to the breadth of question types in the dataset, we manually annotated each question with the operator used in the question (e.g., *describe*, *justify*, *explain* etc.). In addition, we assign each question to one of four categories according to the skills targeted in the question: *Concept Description* (describing abstract concepts or processes), *Example Led* (analyzing examples in relation to fundamental concepts), *Idea Seeking* (the formulation of hypotheses

or examples), and *Mathematical* (calculations and graph interpretations). The conceptual basis for the categories was established in discussion among the authors and annotation was subsequently carried out by one of the authors. An example question for each category can be found in Appendix D. We use these categorizations in two ways. Firstly, motivated by the idea that scoring performance may be variable in accordance with question type (e.g. Meurers et al., 2011), we investigate whether fine-tuning individual models based on questions of a similar nature (i.e., of the same skill category) improves performance for UA. At inference, predictions are made using the corresponding skill-based model. Secondly, we use these categories as the basis to create a custom development set for UQ, including questions which are representative of the skills and operators present in the UQ test set. We experiment between a manually chosen subset of 10 questions (n=1488), and a broader subset of 20 questions (n=1368), selected interactively with Claude Opus 4.6 (Anthropic, 2026a).

3.5 Ensemble Approach

Ensembles of multiple models have been successfully used for short answer scoring in several instances (Ormerod, 2022; Pathak et al., 2025). Majority voting of a number of individual models can help to mitigate limitations of single models, leading to more robust overall scoring. We utilize this majority vote approach in the UA tracks. To select an optimal combination, we evaluated a candidate pool of 100 checkpoints from our top experimental runs, based on QWK on the 3-way trial set. We performed a brute-force search over these candidates to identify the best combination of models for the ensemble. In line with Pathak et al. (2025), we use a combination of four models in the ensemble.

4 Results

We selected our test set submissions based on validation performance, using the provided trial set for unseen answers and custom train/validation splits for unseen questions. We aimed for a balanced representation of the strategies investigated during development. Official test results are in Table 1.

4.1 Unseen Answers

For the UA tracks, we tested fine-tuned Qwen3 (4B/8B) and Qwen3.5-9B models. During development, our best performing single model on the 3-way *trial* set was Qwen3-4B (0.792 QWK). Thus,

Rank	Submission ID	Base Model	Additional Details	QWK	Precision	Recall	F1
3-way Unseen Answers							
1	655003	Multi-Model	Ensemble: 1x9B, 2x8B, 1x4B	0.796	0.781	0.782	0.78
2	655652	Qwen3-8B	+FGM, +CL, +BG_correct, +full_data	0.79	0.772	0.77	0.771

Table 1: Test set results for IWM-DKM submissions for all four tracks. Abbreviations: BG = background knowledge (data source), CL = checklist thinking, RR= reframed rubrics, NEFT = NEFTune, by_skill = skill-specific classifiers, custom_UQ = custom validation set (with total questions), 3→2way = mapping 3-way label predictions to 2-way labels, UA train = trained only on Unseen Answers data, FGM = Fast Gradient Method adversarial training, full data = validation set included in training. Precision, Recall and F1 are all weighted metrics.

we submitted the 4B model, trained on either 3-way or 2-way labels, as baselines for the corresponding labeling scheme. We tested further strategies as described in Section 3, individually and in ensembles.

4.1.1 3-way Unseen Answers

The Qwen3-4B model achieved 8th place with a QWK on the test set of 0.781, providing a strong baseline. Our variations to this, such as fine-tuning individual Qwen3-4B models for each skill-based category (Rank 9), and including generated background knowledge and checklist thinking with the 8B model (Rank 10), performed on par, but were unable to beat the baseline. However, a variation of the Rank 10 submission that included trial data in training and was fine-tuned with the Fast Gradient Method (Miyato et al., 2017) demonstrated the strength of this form of adversarial training, placing second on the leaderboard. Our best-performing and final submission (0.796 QWK) was a majority-vote ensemble of four Qwen-based variations. Details of the models in this ensemble are shown in Appendix A. The ensemble was particularly effective at resolving ambiguous boundary cases between “Partially correct” and “Correct”.

4.1.2 2-way Unseen Answers

We submitted the two variations of the baseline model (Qwen3-4B) to the 2-way track: firstly, mapping of the 3-way prediction labels to the 2-way la-

bels (i.e., “Partially correct” is re-mapped to “Incorrect”); and secondly, fine-tuning directly on 2-way labels. Whilst both were strong baselines, the 2-way fine-tuned model performed marginally worse than the mapped version (0.684 QWK compared to 0.698 QWK). This suggested an advantage of making predictions at a more fine-grained level, thus, our remaining submissions for the 2-way UA track were mapped from 3-way labels. Mapping predictions from our by-skill Qwen3-4B classifiers led to marginal improvement over the baselines, and a majority-vote ensemble of the three systems ranked 7, 8 and 10 offered another slight performance improvement. However, the more architecturally diverse ensemble (mapped predictions from Rank 1 on the 3-way UA) resulted in our strongest submission, and the strongest overall submission for this track, achieving a QWK of 0.726, once again highlighting the robustness of ensemble setups.

4.2 Unseen Questions

4.2.1 3-way Unseen Questions

For the 3-way UQ track, we utilized Qwen3.5-9B as our base model, supplemented by checklist thinking, reframed rubrics, and background knowledge, and trained with a custom validation set. Submissions in Rank 1 and 6 were additionally fine-tuned with NEFTune (Jain et al., 2023). Between these submissions, we observe that silver

standard “Correct-only” student answers (Rank 1) provided a +0.046 QWK improvement over using all answers for Background Knowledge generation (Rank 6), underscoring that high-quality silver context is markedly more effective in driving generalization than a larger, noisier data pool, where misconceptions may be introduced. Furthermore, we experimented with two custom validation sets and saw a significant improvement in performance with the broader validation set (custom_UQ_20, used in Rank 1 and 6) compared to the 10 question set (custom_UQ_10, used for Rank 13 and 16¹). Despite strong performance during development, the model optimized on the narrower, 10-question validation set showed poor transfer abilities to the test set, indicating the advantage of a broader pool of validation answers to aid reliable generalization.

4.2.2 2-way Unseen Questions

We applied several of our submissions from other tracks to the 2-way UQ track. To test generalizability from *unseen answers* to *unseen questions*, we evaluate Qwen3-4B fine-tuned on 2-way labels for UA on the 2-way UQ test set. Despite only training and validating on unseen answers, the model placed fifth on the leaderboard, although with a reduction in performance of 0.158 QWK (0.07 weighted F1). Additionally, we map the labels of our top two submissions from 3-way UQ, and reinforcing our earlier findings on the importance of high-quality background knowledge, the model trained with NEFTune, reframed rubrics, checklist thinking, the custom_UQ_20 validation set, and background knowledge only outperformed the baseline when background knowledge was generated from silver-labels. On the first pass, where background knowledge was generated from all available student answers, overall performance was worse than our baseline of Qwen3-4B.

5 Discussion

Our results show that the outlined supplementary strategies improve fine-tuning performance. The results for both UQ tracks indicated the importance of *high-quality* additional information. Our leading submissions contained background knowledge generated from “Correct” student answers (as predicted by a first pass model), whereas results for an otherwise identical model with background knowledge based on all students answers performed sig-

nificantly worse. We also observed during development that individual techniques taken alone can actually be *detrimental* to performance, their positive contribution only arises when combined.

We observed mixed results when it came to the optimization of the validation set for UQ. A broader 20-question trial set offered substantial improvements over a narrower 10-question trial set. Somewhat conflictingly, the Qwen3-4B model only optimized for unseen answers also exhibited promising performance in the 2-way UQ track, leading to further questions about the most impactful strategies to improve generalization in short answer grading.

Broadly, simple fine-tuning of decoder-only models was highly effective. Encoder-based models have generally dominated the short-answer scoring literature to date (e.g., Bexte et al., 2022; Sung et al., 2019), but despite experimenting with fine-tuning several German- and multilingual BERT-based models (e.g., ModernGBERT (Wunderle et al., 2025), gelectra-large (Chan et al., 2020)) in earlier trials, decoder-only architectures resulted in stronger performance. This reflects the NLP shift towards decoder-only architectures (Zhang et al., 2025; BehnamGhader et al., 2024), whose richer contextual embeddings better handle the nuanced semantics of rubric-based scoring. Finally, model ensembling proved beneficial, particularly in resolving boundary ambiguities between adjacent scoring categories. This is particularly advantageous in light of the fact that fine-tuned models exhibit sensitivity to small differences such as individual epochs and differences in seed. However, the high computational cost of this strategy limits the suitability of ensembles in real-life scoring.

6 Conclusion

Overall, our shared task submissions demonstrated the potential for fine-tuned decoder-only LLMs for rubric-based short answer scoring. Not only was LoRA fine-tuning of relatively small LLMs effective, but we highlighted how performance can be further improved by supplementing the input with task-relevant information. Our approach provides the model with more relevant information and presents that information in multiple structured formats to obtain more robust results. In future work, it would be interesting to further investigate the contributions of the individual strategies we used and to systematically evaluate their impact in other scoring contexts.

¹A formatting mismatch in the reframed rubrics used in the Rank 16 submission may have also influenced performance.

Acknowledgments

This work was supported by the German Research Foundation (DFG) under Germany’s Excellence Strategy – EXC number 2064/1 – Project number 390727645. The authors acknowledge support by the state of Baden-Württemberg through bwHPC and the DFG through grant no. INST 37/1057-1 FUGG (Tübingen Machine Learning Cloud) and thank the Joachim Herz Stiftung for its support through the ALEE project.

Limitations

Due to the wide variety of methods we tested in the development phase, we were not able to systematically assess the impact of each individual technique on test set performance, nor did we evaluate all the models in our leading ensemble approaches as individual entries. Similarly, we did not test all our approaches on all tracks, which limits our ability to draw conclusions regarding the generalizability of methods across testing set-ups. Nevertheless, we believe our findings suggest support for the use of supervised fine-tuning of decoder-only models with LoRA in educational contexts. We used a single annotator for the skill-based categories. Double-annotation would strengthen the reliability of the categorization approach. In future work, it may be beneficial to test the techniques we implemented to improve upon standard fine-tuning on other datasets, and in more limited data scenarios, and to evaluate how expert knowledge could be used to further improve those techniques which were reliant on synthetic data (e.g., generated background knowledge, synthetically reframed rubrics).

Ethical Considerations

The use of AI for educational purposes has been designated as ‘high risk’ by the EU AI Act. All the data used in this shared task are anonymous and contain no personal identifying information, however, this remains an important consideration when thinking about the deployment of AI-based tools in real-world educational contexts (e.g., in classrooms). We acknowledge the use of AI tools for the generation of code in developing our systems, and for some of our data augmentation strategies, which carries both monetary and environmental costs.

A Ensemble model details

We list the details of the models included in our four-model ensemble for 3-way unseen answers submission in Table 2.

Base model	Details
Qwen3.5-9B	+BG_correct +CL
Qwen3-8B	+FGM, +BG_correct, +CL
Qwen3-8B	+DPO
Qwen3-4B	+BG_correct, +CL

Table 2: Models included in ensemble for Rank 1 Unseen Answers 3-way submission (Abbreviations: BG_correct = Background Knowledge from correct answers, CL = checklist thinking, FGM = Fast Gradient Method, DPO = Direct Preference Optimization)

B Example Item with Background Knowledge and Reframed Rubric

Table 3 shows an example item from the ALICE-LP dataset, illustrating the question, generated background knowledge, original scoring rubric, reframed rubric, operator, and skill category. The background knowledge field contains the generated passage used as supplementary material during fine-tuning (Section 3.3). This item is representative of the *Concept Description* skill category, with the operator *Beschreiben* (‘Describe’) (Section 3.4).

C Prompts

C.1 Prompt for Reframed Rubrics

The prompt used with GPT5.1 to generate reformulations of the 3-way rubrics in decision tree format is shown in Listing 1.

C.2 Prompt for Background Knowledge

The prompt used with Claude Sonnet for generating question-specific background knowledge is provided in Listing 2.

D Skill-based categories

Table 4 shows an example question for each of the four categories we annotate the data with, as described in (Section 3.4).

Category	Example
Question	Beschreibe das Power-to-Gas Verfahren in eigenen Worten. 'Describe the power-to-gas process in your own words.'
Background Knowledge	Beim Power-to-Gas-Verfahren wird überschüssige elektrische Energie, die zum Beispiel durch Windkraftanlagen erzeugt wird, in chemische Energie umgewandelt und so langfristig gespeichert. Dazu durchläuft die Energie eine Kette von Umwandlungsschritten: Zunächst wird Bewegungsenergie des Windes im Windrad in elektrische Energie umgewandelt, die dann einem Elektrolyseur zugeführt wird. Im Elektrolyseur wird mithilfe der elektrischen Energie Wasser in seine Bestandteile Wasserstoff und Sauerstoff aufgespalten, wobei die Energie in Form von chemischer Energie im Wasserstoff gespeichert wird. Der erzeugte Wasserstoff kann anschließend in Gasspeichern oder im Erdgasnetz gelagert werden, bis er bei Bedarf in einem Gaskraftwerk wieder in elektrische Energie umgewandelt wird. Die vollständige Energieumwandlungskette lautet also: Bewegungsenergie → elektrische Energie → chemische Energie (Wasserstoff) → elektrische Energie. 'In the power-to-gas process, excess electrical energy—generated, for example, by wind turbines—is converted into chemical energy and thus stored for the long term. To achieve this, the energy undergoes a series of conversion steps: First, the kinetic energy of the wind is converted into electrical energy in the wind turbine, which is then fed into an electrolyzer. In the electrolyzer, electrical energy is used to split water into its components, hydrogen and oxygen, with the energy being stored in the hydrogen in the form of chemical energy. The hydrogen produced can then be stored in gas storage facilities or in the natural gas grid until it is converted back into electrical energy in a gas-fired power plant when needed. The complete energy conversion chain is therefore: kinetic energy → electrical energy → chemical energy (hydrogen) → electrical energy.'
Rubric	(Incorrect) Die SuS formulieren keine korrekte Energieumwandlungskette. 'The students do not formulate a correct energy conversion chain.' (Partially correct) Die SuS formulieren eine teils korrekte Energieumwandlungskette (mindestens die Hälfte) 'The students formulate a partially correct energy conversion chain (at least half of it)' (Correct) Die SuS formulieren die vollständige Energieumwandlungskette. 'The students describe the complete energy conversion chain.'
Reframed Rubric	1. Beschreibt die Antwort überhaupt eine Energie-Umwandlungskette beim Power-to-Gas-Verfahren? 'Does the answer even describe an energy conversion chain in the power-to-gas process?' - **Nein** → **Incorrect**, **Ja** → 2 2. Wird deutlich, dass elektrische Energie (z.B. aus erneuerbaren Quellen) zunächst in chemische Energie von Wasserstoff umgewandelt wird (Elektrolyse von Wasser)? 'Is it clear that electrical energy (e.g., from renewable sources) is first converted into the chemical energy of hydrogen (through the electrolysis of water)?' - **Nein** → **Incorrect**, **Ja** → 3 3. Wird zusätzlich beschrieben, dass aus dem Wasserstoff ein gasförmiger Energieträger (z.B. Methan) entsteht, der gespeichert / ins Gasnetz eingespeist werden kann? 'Is it also described that hydrogen is converted into a gaseous energy carrier (e.g., methane) that can be stored or fed into the gas grid?' - **Nein** → - Wenn nur ein Teil der Umwandlungskette korrekt ist (z.B. Strom → Wasserstoff, aber ohne weitere Verwendung / Methanisierung) 'If only part of the conversion chain is correct (e.g., electricity → hydrogen, but without further use or methanation)' → **Partially correct** - **Ja** → 4 4. Ist die gesamte Energieumwandlungskette inhaltlich richtig und in der Reihenfolge vollständig beschrieben (z.B. erneuerbare elektrische Energie → Elektrolyse → Wasserstoff → ggf. Methanisierung → Speicherung / Nutzung im Gasnetz)? 'Is the entire energy conversion chain described accurately contentwise and completely in terms of sequence (e.g., renewable electrical energy → electrolysis → hydrogen → methanation, if applicable → storage/use in the gas grid)?' - **Nein** → **Partially correct**, **Ja** → **Correct**
Operator	Beschreiben ('describe')
Skill Category	Concept Description
Example Student Answer	Die Elektrische Energie wird in Chemische umgewandelt welche dann wieder zu Elektrischer wird. 'Electrical energy is converted into chemical energy, which is then converted back into electrical.'
Gold Label	Partially correct

Table 3: Example item from the ALICE-LP dataset. The example student answer correctly identifies two of the three conversion steps (electrical → chemical → electrical) but omits the initial step (kinetic energy → electrical energy via wind turbine), warranting a *Partially correct* label. (Original is in German; English translation in quotes added here for transparency.)

Sie sind pädagogische/r Assistent/in und haben die Aufgabe, leicht verständliche Bewertungsrubriken für Fragen in formativen Schülerbeurteilungen zu entwerfen. \ Der Bildungskontext sind deutsche Gemeinschaftsschulen und Gymnasien und die abgedeckten Fachbereiche sind: Biologie, Chemie, Physik und Mathematik.

'You are a pedagogical assistant, whose goal is to help design easy-to-follow grading rubrics to questions in formative student assessments. \ The educational setting is German Gemeinschaftsschulen and Gymnasien and the subject domains covered are: Biology, Chemistry, Physics and Mathematics.'

RETUYT-INCO at BEA 2026 Shared Task 2: Meta-prompting in Rubric-based Scoring for German

Ignacio Sastre[†] and Ignacio Remersaro

Facundo Díaz and Nicolás de Horta

Luis Chiruzzo and Aiala Rosá and Santiago Góngora

Instituto de Computación, Facultad de Ingeniería, Universidad de la República
Montevideo, Uruguay

Abstract

In this paper, we present the RETUYT-INCO participation at the BEA 2026 shared task “Rubric-based Short Answer Scoring for German”. Our team participated in track 1 (*Unseen answers three-way*), track 3 (*Unseen answers two-way*) and track 4 (*Unseen questions two-way*). Since these tracks required scoring short student answers using specific rubrics, we looked for ways to handle the changing nature of the task. We created a method called **Meta-prompting**. In this approach, an LLM creates a custom prompt based on examples from the Train set. This prompt is then used to grade new student answers. Along with this method, we also describe other approaches we used, such as classic machine learning, fine-tuning open-source LLMs, and different prompting techniques. According to the official results, our team placed 6th out of 8 participants in Track 1 with a QWK of 0.729. In Track 3, we secured 4th place out of 9 with a QWK of 0.674, and we also placed 4th out of 8 in Track 4 with a QWK of 0.49.

1 Introduction

Short-answer scoring is a promising research direction in the field of Natural Language Processing for education. Unlike multiple-choice tests, which only require students to recognize a correct answer, short answers require them to actively construct a response using the concepts they have learned from the curriculum. This may be appropriate for capturing a student’s true understanding of a subject. The automation of short-text assessment has the potential to deliver faster feedback and consistent grading, offering vital support to overburdened educators, especially in under-resourced environments. Over the years, researchers have used various benchmarks and shared tasks to refine these

systems (Burrows et al., 2015; Bai and Stede, 2023; Dzikovska et al., 2013). We, as a research group, are deeply interested in these applications of NLP tools (Chiruzzo et al., 2022; Rosá et al., 2025).

In this paper, we present the RETUYT-INCO participation in the BEA 2026 Shared Task 2: Rubric-based Short Answer Scoring for German (Gombert et al., 2026). This task involves the automatic evaluation of short-answer responses in the domains of science and mathematics, framed as a classification problem with both two-way and three-way scoring rubrics. Our team participated in Tracks 1 (Unseen answers three-way), 3 (Unseen answers two-way) and 4 (Unseen questions two-way). Our team has participated in various shared tasks of the BEA workshop in recent years (Baladón et al., 2023; Sastre et al., 2024; Góngora et al., 2025), generally exploring solutions that do not require extensive computational resources. Additionally, this year we were able to incorporate state-of-the-art Gemini models into our experiments through the *Gemini Academic Program*.

2 Meta-prompting

We mainly focus on the *unseen answer* tracks, in which systems must score new student answers for question-rubric pairs that have already been observed in the training data. An analysis of the Train split revealed 72 distinct question-rubric groups, each defined by a fixed question and its associated rubric. As a baseline, we used Gemini 3 Flash¹ with a generic scoring prompt instantiated with the corresponding question and rubric. On the Trial set, this baseline exhibited substantial performance variation across groups, suggesting that a single generic prompt does not capture the scoring criteria equally well for all question-rubric pairs.

[†] Corresponding author: isastre@fing.edu.uy.

Figure 1: Meta-prompting operation scheme in its two phases

To address the performance inconsistencies observed with generic scoring prompts, we leverage established advances in automated prompt optimization. This field has progressed from Instruction Induction (Honovich et al., 2022), which identifies task descriptions from few-shot examples, to the Automatic Prompt Engineer (Zhou et al., 2023) framework for systematic search and scoring. Most recently, GEPA (Agrawal et al., 2026) introduces a reflexive evolution approach that uses genetic algorithms and natural language reasoning to iteratively refine instructions, offering a robust alternative to static baselines for the diverse requirements of rubric-based scoring.

Based on this line of work, we introduce the **meta-prompting** approach, that induces a custom scoring prompt for each question-rubric group. The method consists of two phases. In the first phase, for each group, we prompt an LLM with the question, the rubric, and the full set of labeled training answers for that group, serialized as JSON. The model is asked to generate a reusable scoring prompt tailored to that specific group. In the second phase, at inference time, each new student answer is routed to its corresponding question-rubric group and evaluated using the group-specific prompt generated in the first phase. Figure 1 shows a diagram of the method.

To further improve performance, we generate multiple candidate prompts for each question-rubric group, varying the prompt formulation (see Appendix B), the thinking budget (medium or high), and the use of synthetic examples (explained in Section 2.2). For each group, we then retain the prompt that performs best on the Trial set. Table 1

reports all evaluated variants and their corresponding weighted F1 and QWK scores.

2.1 Meta-prompt generation

For each question-rubric group, we generate a dedicated scoring prompt in an offline step using the fixed question, its rubric, and the labeled training answers associated with that group. The training instances are provided as a JSON object containing each answer and its gold label. An LLM then infers the scoring criteria that best characterize the group and produces a reusable prompt template for evaluating unseen answers. The meta-prompt encourages the model to capture the semantic distinctions underlying the rubric instead of relying on superficial lexical patterns. The resulting template includes placeholders for the *question*, *rubric*, and *answer*, and instructs the downstream model to output only the final *label*. This process yields one candidate scoring prompt per group, which can later be used directly or compared with alternative prompt variants. The complete prompt template is provided in Appendix A.

2.2 Synthetic data

As part of a strategy to normalize the data imbalance within each question, we implemented a synthetic data generation module.

The pipeline is implemented as a state graph (using LangGraph² and LangChain³). Given a question, a student answer, and the rubric description only for the target label, the LLM is prompted to produce a new student answer matching that

Meta-prompt thinking high	0.845	0.635
Meta-prompt thinking high with synthetic data	0.856	0.659
Meta-prompt thinking high (different prompt)	0.859	0.661
Meta-prompt best variant per group	0.892	0.743

Table 1: Results on the Trial set. In bold, the best result for each metric.

quality level. The prompt instructs the model to role-play as a real student, explicitly forbidding meta-commentary, references to grading criteria, or verbatim copying of the reference answer. Additionally, all previously generated answers for the same question are included in the prompt, instructing the model to produce a substantially different response in terms of wording, structure, and reasoning.

This is followed by a noise injection module to add grammatical errors and colloquialisms that mimic real-world writing. Finally, each response is validated against the full rubric and a conditional retry system that discards inconsistent examples to ensure the quality of the synthetic dataset.

We applied this method to the 25 questions with the greatest imbalance between correct and incorrect answers in the Train set, producing the number of samples necessary to reduce the gap between the two categories by half.

3 Other approaches

Apart from meta-prompting, we explored other approaches ranging from classic machine learning algorithms to fine-tuning open LLMs.

3.1 Role-playing prompting

Vaguely inspired in contemporary works that report Role-playing prompting may change the expected behavior of an LLM (Wang et al., 2025b,a; Luo et al., 2026), we wanted to give a try on a prompt

that described the classification task differently.

Therefore, we prompted Gemini 3 flash to act as isolated teachers in a *distant planet*. The API was called three times, always giving as an input the original question, the student’s answer, and the rubric. The first call prompts the model to act as a teacher that focus on the positive side of the student’s answer, while the second one focuses on the negative aspects. The outputs of those calls are two reviews given as an input to the third teacher (a new API call), acting as a meta-reviewer that has to make the final decision. Given how expensive it was to run this experiment (it takes 3 API calls to classify each instance), we only submitted its predictions for the *2 way unseen questions* track, without evaluating on the Trial set. Appendix C includes the prompts used for this approach.

3.2 Prompt tuning and LoRA fine-tuning

Following our approach in previous shared tasks, where we fine-tuned small LLMs (Baladón et al., 2023; Sastre et al., 2024; Góngora et al., 2025), we also explored this strategy using Llama 3.1 8B Instruct (Grattafiori et al., 2024).

In the unseen answers tracks, the task can be naturally decomposed into 72 question-rubric groups, each associated with its own subset of training examples. A straightforward approach would therefore be to fine-tune one model per group. However, performing 72 separate fine-tuning runs, even with a parameter-efficient method such as Low-Rank

Track 3 - Unseen Answers 2-Way			
Baseline prompting Gemini 3 Flash	0.598	0.835	37/51
SVM + TF-IDF (2-10)grams	0.520	0.806	43/51
Prompt tuning with synthetic data	0.492	0.786	44/51
Ensemble prompt tuning with Gemini baseline	0.537	0.809	42/51
Meta-prompt thinking medium	0.654	0.853	25/51
Meta-prompt best variant per group	0.674	0.863	14/51
Track 4 - Unseen Questions 2-Way			
Baseline prompting Gemini 3 Flash	0.490	0.789	12/39
SVM + TF-IDF (2-10)grams	0.341	0.736	38/39
Roleplaying Gemini 3 Flash	0.432	0.766	28/39

Table 2: Results for the three tracks evaluated. The QWK metric is used as the primary reference. The "#" column indicates the ranking position out of all submissions.

Adaptation (LoRA) (Hu et al., 2022), would be computationally expensive and time-consuming. In addition, the amount of training data available for each group is often limited and may be highly imbalanced.

For this reason, we explored Prompt Tuning (Lester et al., 2021), in which the base model is kept frozen and only a small set of input embeddings, known as a soft prompt, is learned. Recent work on Concept Tokens (Sastre and Rosá, 2026) has shown that, in Llama 3.1 8B, learning a single embedding using a definitional corpus can be sufficient to steer model behavior. Inspired by this idea, we learned one embedding per question-rubric group. Each embedding was trained using the corresponding training examples, augmented with synthetic data (see Section 2.2), while the Trial split was used for early stopping. At inference time, given a new answer, we construct a prompt containing the question together with the learned embedding associated with its question-rubric group.

We compared this method against a single LoRA fine-tuning run over the full Train set. As shown in Table 1, prompt tuning achieved better performance on the Trial set than this global LoRA baseline. Both adaptation methods substantially outperformed prompting alone with the same small open-source model, which obtained a QWK of 0.050, whereas prompt tuning reached 0.583. This also highlights the large gap between prompting small open-source LLMs and prompting strong propri-

etary models: under the same general prompting setup, Gemini 3 Flash achieved a QWK of 0.56.

3.3 Support Vector Machines

Since this was ultimately a classification task, we wanted to attempt it using at least one classic machine learning algorithm. We began with the premise that the scores might be inferable from the student’s writing alone, without the need for additional context. While we anticipated that this model would not compete with neural architectures, following our previous work in BEA shared tasks (Sastre et al., 2024; Góngora et al., 2025), we consider it worthwhile to quantify the widening performance gap relative to modern transformer-based models.

Using Scikit-learn (Pedregosa et al., 2011), we conducted several preliminary experiments. We tested a wide range of statistical classifiers—including Naive Bayes, Random Forest, and Support Vector Machines—alongside various bag-of-words configurations for text representation at both word and character levels. The best configuration we found when evaluating on the Trial set was feeding a sigmoid-kernel SVC⁴, with the Train set represented by a TF-IDF vectorizer⁵ using character-level n-grams in a [2, 10] range. We trained and submitted a model using this config-

⁴<https://scikit-learn.org/stable/modules/generated/sklearn.svm.SVC.html>

⁵https://scikit-learn.org/stable/modules/generated/sklearn.feature_extraction.text.TfidfVectorizer.html

uration for the *2-way unseen answers* track and another one for the *2-way unseen questions* track.

4 Results

Table 2 summarizes the performance of our submitted systems across the three shared-task tracks in which we participated. Our main focus was Track 3 (two-way unseen answers), for which we submitted the Gemini 3 Flash prompting baseline, the SVM model, the prompt tuning approach based on Llama 3.1 8B, an ensemble of the baseline and prompt tuning methods, and several variants of the meta-prompting technique. The ensemble combines the baseline and prompt-tuning systems by selecting, for each question–rubric group, the method that achieved the best performance on the Trial set.

For Track 4 (two-way unseen questions), where the questions and rubrics are not available in advance, we submitted the same Gemini 3 Flash baseline, the SVM model, and the role-playing method. The remaining approaches depend on prior access to the question–rubric groups and therefore are not applicable in this setting. Finally, for Track 1 (three-way unseen answers), we submitted only variants of the meta-prompting approach, as this method yielded the strongest results on Track 3.

The only method that improved upon the prompting baseline was the meta-prompting approach. This result is likely due to the fact that the baseline relies on Gemini 3 Flash, a much larger and more recent model than the open model used in other experiments, Llama 3.1 8B. The strength of this baseline is further supported by its ranking in the top third of submissions on Track 4.

Meta-prompting and the role-playing strategy are the only other methods that use the same base LLM, making them the most directly comparable to the baseline. Among the Gemini 3 Flash-based approaches, meta-prompting achieved the strongest performance, improving over the baseline by nearly 8 points on QWK and ranking 14th out of 51 submissions overall. At the team level, this placed us 4th out of 9 teams that submitted to Track 3.

For Track 4, the baseline was our strongest submission, outperforming the role-playing strategy and placing us 4th out of 8 teams. Finally, we placed 6th out of 8 teams on Track 1 with the meta-prompting submission. It is worth noting that we did not tune the method on the Trial set for the three-way setting, and instead reused the

same meta-prompting configuration developed for Track 3, which may partly explain the lower performance on this track.

Regarding the Llama 3.1 8B prompt tuning method, we observe a substantial drop in performance from the Trial set to the final Test set. A likely explanation is that the Trial set was used for early stopping, which may have caused the learned embeddings to overfit to those examples. This issue is further compounded by the fact that many question–rubric groups are both small and highly imbalanced, with some groups containing examples from only a single class in the Trial split.

5 Conclusions

In this paper, we presented the RETUYT-INCO participation in the BEA 2026 shared task, “Rubric-based Short Answer Scoring for German”. Our team tried different approaches across Track 1 (Unseen answers 3-way), Track 3 (Unseen answers 2-way), and Track 4 (Unseen questions 2-way).

A central part of our experimentation involved **meta-prompting**, where an LLM generated scoring prompts based on available training instances; these prompts were then used as input for a subsequent LLM inference to classify unseen texts. Alongside this technique, we evaluated the performance of traditional machine learning models and the fine-tuning of open-source LLMs.

The official results placed our systems in the mid-table across the three tracks. In Track 1, we obtained a Quadratic Weighted Kappa (QWK) of 0.729, placing 6th out of 8 participants. Our performance in the two-way tracks was notably robust, securing 4th place out of 9 in Track 3 with a QWK of 0.674, and 4th place out of 8 in Track 4 with a QWK of 0.490.

Future work should first explore how to better adapt the meta-prompting strategy to the three-way setting, where our submitted results were still preliminary. Beyond this shared task, the approach should also be evaluated in other rubric-based scoring datasets, as well as in related educational NLP tasks, to assess its generalization and robustness. Finally, our experiments highlight the substantial gap between large proprietary models and smaller open-source LLMs. Narrowing this gap remains an important direction, both to reduce dependency on closed systems and to make high-performing educational NLP tools more accessible and cost-effective.

Limitations

Many of our experiments rely on closed proprietary models that are accessible only through provider APIs. Although these models are relevant from a research perspective due to their strong performance, this dependence limits the accessibility and applicability of the proposed methods in real educational contexts. This is especially important in settings such as rural schools, where internet connectivity, privacy constraints, and cost considerations may restrict the use of external APIs. Moreover, the meta-prompting and role-playing approaches require multiple LLM calls and consume a large number of tokens, increasing both cost and latency.

Our experiments with Llama 3.1 8B were conducted using a single Google Colab Pro subscription, which limited our ability to tune hyperparameters and perform ablation studies. Consequently, these results should be viewed as preliminary rather than fully optimized. Regarding the generated synthetic data, we did not conduct a human evaluation of whether the generated samples were of good quality. We focused on the empirical side of this method, hence prioritizing seeing an improvement in the results. Additionally, we did not evaluate how the *distant planet* setting in the role-playing approach impacted the performance of the method.

Finally, we explored the three-way setting less extensively than the two-way configurations. The submitted systems for this track were mostly adaptations of methods developed for the two-way unseen answers setting, rather than approaches specifically optimized for three-way scoring. Given the stronger results obtained in the two-way setting after task-specific tuning, we believe that better-adapted versions of our methods could substantially improve performance in the three-way setting.

Ethics

Our research uses state-of-the-art, closed-source models. These models are proprietary and operate via external APIs, so they may not be suitable for processing sensitive data, particularly involving minors. The lack of transparency regarding data handling and privacy for minors presents a significant risk. We believe it should always be a priority, when using these solutions in real-world educational deployments, to use local, private infrastructure.

Furthermore, we acknowledge the substantial environmental impact associated with the deployment

of these large-scale models. The energy consumption and resulting carbon footprint of state-of-the-art closed models are significant. Given that the work in this paper is a relatively constrained classification task, we emphasize that these state-of-the-art models may be computationally excessive. We encourage the community to explore smaller, specialized models that can provide a more sustainable and resource-efficient alternatives.

A Baseline prompt

This Appendix presents the prompt used for the prompting baselines.

Baseline prompt

You are an expert educational rater for
 ↪ rubric-based short-answer scoring.

Your task is to assign a binary score to a
 ↪ student's answer using the question and
 ↪ the rubric.

Label set for this 2-way setting:
 - Output "Correct" only if the student's
 ↪ answer satisfies the rubric for
 ↪ "Correct".
 - Output "Incorrect" otherwise.
 - Answers that match "Partially Correct"
 ↪ must be labeled "Incorrect".

Decision procedure:

1. Read the question, the student answer,
→ and all rubric levels.
2. Identify the full set of meaning
→ requirements for the rubric label
→ "Correct".
3. Use the question only as context to
→ interpret the student's wording.
4. Do not use outside knowledge to add
→ content that is not stated or clearly
→ implied by the student's answer.
5. Accept paraphrases, synonyms, different
→ wording, and short or fragmentary
→ answers if their meaning clearly matches
→ the rubric.
6. Output "Correct" only if all requirements
→ for a fully correct answer are present
→ and unambiguous.
7. Output "Incorrect" if any required
→ element is missing, only partially
→ present, too vague to verify, off-topic,
→ self-contradictory, nonsensical, or
→ incompatible with the rubric.
8. If the rubric allows multiple alternative
→ ways to be fully correct, any one
→ complete valid alternative is sufficient.
9. Ignore spelling and grammar errors unless
→ they make the meaning unclear.
10. Ignore extra details unless they
→ contradict the required content or make
→ the answer incompatible with the rubric.
11. For multi-part requirements, all
→ required parts must be present unless
→ the rubric explicitly states otherwise.
12. Do not output any explanation.

The question, answer, and rubric may be in
→ German. Score based on meaning, not
→ language quality.

Input:

```
<Question>
{question}
</Question>
```

```
<StudentAnswer>
{answer_to_classify}
</StudentAnswer>
```

```
<Rubric>
<Incorrect>
{rubric_incorrect}
</Incorrect>
<PartiallyCorrect>
{rubric_partially_correct}
</PartiallyCorrect>
<Correct>
{rubric_correct}
</Correct>
</Rubric>
```

Return exactly one word and nothing else:
Correct
or
Incorrect

B Meta-prompting phase 1 prompts

This Appendix presents the prompts utilized in the Metaprompting approach, the second text is an extension from the metaprompt, that is appended before the return criteria.

Meta-prompt

You are an expert in educational assessment
→ and prompt design.

Given a question, a rubric, and labeled
→ training answers for one fixed
→ question/rubric group, generate a
→ reusable prompt for scoring a NEW answer
→ for that same group.
The possible labels are Correct and
→ Incorrect (Partially Correct are
→ classified as Incorrect).

The generated prompt must:

- be specific to this question/rubric group,
- reflect the rubric and the training
→ signals,
- use training examples for illustrating the
→ classification instructions,
- instruct the model to output only the
→ final label and nothing else,
- contain exactly these placeholders:
 - {question}
 - {answer_to_classify}

Do not:

- Repeat the rubric as-is: the idea is for
→ you to reflect on the training examples
→ and generate better criteria,
- Add examples as few-shot: use the
→ examples to explain the task and
→ classification criteria, and to
→ illustrate your explanations.

Return only the generated prompt template as
→ plain text.

Do not include any explanation or extra text.

Input:

```
<Question>
{question}
</Question>
```

```
<Rubric>
<Incorrect>
{rubric_incorrect}
</Incorrect>
<PartiallyCorrect>
{rubric_partially_correct}
</PartiallyCorrect>
<Correct>
{rubric_correct}
</Correct>
</Rubric>
```

```
<TrainingExamples>
{training_examples}
</TrainingExamples>
```

Meta-prompt extension

The expected prompt should be sufficiently
→ complex, nuanced, and comprehensive so
→ that, if you were given only your own
→ prompt, you would be fully confident in
→ your ability to correctly classify all
→ training examples, without overfitting
→ to the specific examples provided. Do
→ not optimize for brevity at the expense
→ of completeness. It is perfectly
→ acceptable for the prompt to be long if
→ that is necessary to capture all
→ relevant distinctions, edge cases, and
→ decision criteria required for perfect
→ classification. Ask yourself: does this
→ prompt contain all the information needed
→ to classify every example correctly?

Your task is to generate a three-paragraph
→ discussion on reasons to consider that
→ answer as Correct or Incorrect. In order
→ to provide a framework, you can consider
→ the answer is Correct or Incorrect
→ according to the following criteria:

- The answer is Incorrect if: {incorrect}
- The answer is Correct if: {correct}

In your discussion try to focus on the
→ NEGATIVE aspect of the answer: why would
→ you consider it as Incorrect? Write your
→ review in English.

C Roleplaying prompts

This Appendix presents the prompts used in the *Role-playing prompting* approach, described in Section 3.1.

Positive reviewer

You are a teacher in a distant planet
→ correcting homework in German. You do not
→ have the possibility of communicating
→ with any of your colleagues.
Consider the following question in German
→ written by some teacher in your solar
→ system: '{question}'. A high-school
→ student wrote this answer: '{answer}'.

Your task is to generate a three-paragraph
→ discussion on reasons to consider that
→ answer as Correct or Incorrect. In order
→ to provide a framework, you can consider
→ the answer is Correct or Incorrect
→ according to the following criteria:
- The answer is Incorrect if: {incorrect}
- The answer is Correct if: {correct}

In your discussion try to focus on the
→ POSITIVE aspects of the answer: why
→ would you consider it as Correct? Write
→ your review in English.

Metareviewer

You are a teacher in a distant planet. You
→ have received two opinions from
→ colleagues in your solar system about
→ the following question-answer pair in a
→ high-school test:
- Teacher's question: '{question}'.
- High-school student's answer: '{answer}'.

On one hand, the first colleague says:
→ '{positive_review}'.
On the other hand, the second colleague says:
→ '{negative_review}'.

Your task is to have the final word.
→ Considering that the answer was written
→ by a high-school student, say if it is
→ 'Correct' or 'Incorrect', according to
→ the words of your colleagues and the
→ following criteria:
- The answer is Incorrect if: {incorrect}
- The answer is Correct if: {correct}

Write a brief essay to support your decision,
→ and then end it saying if it is
→ 'Correct' or 'Incorrect' between two #
→ (e.g. #Correct#).

Negative reviewer

You are a teacher in a distant planet
→ correcting homeworks in German. You do
→ not have the possibility of communicating
→ with any of your colleagues.
Consider the following question in German
→ written by some teacher in your solar
→ system: '{question}'. A high-school
→ student wrote this answer: '{answer}'.

SDPA at BEA 2026 Shared Task 2: Efficient LLM Fine-Tuning for Rubric-based Short Answer Scoring

Zhexiong Liu^{1*}, Jing Zhang^{2*}

¹University of Pittsburgh, Pittsburgh, Pennsylvania 15260 USA

²Emory University, Atlanta, Georgia 30322 USA

zhexiong@cs.pitt.edu, jingz1@alumni.emory.edu

Abstract

Automated short-answer scoring (ASA) is an important yet challenging task in educational assessment as it aims to evaluate open-ended student responses against predefined scoring rubrics that are often interrelated. Although large language models (LLMs) have demonstrated impressive capabilities in text understanding and reasoning, their application to ASA has primarily focused on prompt-based inference, largely due to the limited availability of annotated data required for effective model training. In this work, we investigate parameter-efficient fine-tuning strategies for LLMs using ASA annotations in German. Our experiments show that fine-tuned LLMs consistently outperform both prompt-based and ensemble-based language models, suggesting domain-adaptive LLM fine-tuning is more effective than prompting alone for ASA.

1 Introduction

Student responses to open-ended domain-specific questions are often regarded as important indicators of their acquaintance with teacher-instructed content (Berliner and Rosenshine, 2017). Faithful assessment of their responses is essential for determining how well students have internalized curricular materials. In practice, however, manually evaluating short-answer responses remains dominant in classrooms, and it is both time-consuming and cognitively intensive since the responses are often diverse and a single question may accept multiple answers from different conceptual perspectives, which makes the manual scoring exceedingly difficult to scale. For example, Figure 1 shows three student answers scored as correct, partially correct, and incorrect based on highly interrelated rubrics. These challenges have thus motivated growing interest in the development of automated short-answer scoring (ASA) systems that can provide

Question: Assess the rate of spoilage when the apples are cut
(Note: if you would like to include technical information on the chemical processes of spoilage, you can research and include it, citing your sources).

- I. Correct Answer:** The smaller the apples are cut, the larger their surface area that can react. The larger the surface area, the more collisions and therefore more effective collisions can occur, and the faster the reaction proceeds.
- II. Partially Correct Answer:** The larger the surface area of the apple, the more substances can react on the surface, e.g., oxidize (i.e., turn brown).
- III. Incorrect Answer:** Apples spoil faster at higher temperatures because the reaction rate is increased.

- I. Correct Rubric:** The students comprehensively assess the perishability of the apples based on the collision model.
- II. Partially Correct Rubric:** The students partially assess the perishability of the apples based on the collision model.
- III. Incorrect Rubric:** The students do not assess the perishability of the apples based on the collision model.

Figure 1: A short-answer scoring example where a single question could receive correct, partially correct, and incorrect answers based on the given rubrics. The original example is in German (Gombert et al., 2026).

rubric-aligned assessments with minimal human burdens. Early automated methods focused on either lexical and semantic text matches (Ramachandran et al., 2015), or training Transformer-based S-BERT (Bexte et al., 2022). Although these models achieve reasonable performance, they have limited capability to align complex student responses with nuanced rubrics, particularly when training data are scarce. Recent large language models (LLMs) have been used to solve several challenging problems in the educational domain, e.g., essay revision (Li et al., 2024), propositional logic (Liu et al., 2024b), and mathematical geometry (Zhang et al., 2024). However, existing LLM approaches to ASA have predominantly relied on prompt methods (Henkel et al., 2024; Ferreira Mello et al., 2025), which tend to underperform when several rubrics are interrelated, e.g., partially correct versus correct rubrics. The potential of fine-tuned LLMs for ASA, particularly under low-resource conditions, therefore

*These authors contributed equally to this work

warrants further exploration. In this study in particular, we investigate parameter-efficient fine-tuning (PEFT) strategies to align LLMs with the linguistic features and rubric-matching requirements of short-answer scoring tasks.

We present our system submissions to the ASA shared task co-located at the Building Educational Applications (BEA) workshop (Gombert et al., 2026). The shared task aims to contribute to non-English benchmark datasets with four submission tracks described by two dimensions: whether the answers or questions are unseen at test time, and whether scoring follows a three-way (correct, partially correct, incorrect) or two-way (correct, incorrect) scheme. The two-way tracks collapse partially correct responses into the incorrect class, thereby posing an additional challenge for interpreting interrelated rubrics. We first establish a strong baseline using small pre-trained language models (Liu et al., 2019; Devlin et al., 2019; Chan et al., 2020), and then investigate an ensemble strategy that integrates small language models with LLMs to exploit their complementary strengths. In addition, we investigate PEFT (Hu et al., 2022; Liu et al., 2024a) strategies for LLM fine-tuning to assess their task-specific adaptation under low-resource conditions. Our system achieves second place on the binary unseen-question track and third place on the remaining three tracks. These findings demonstrate that LLMs can be effectively fine-tuned for ASA even with limited labels, providing a practical solution for low-resource educational assessment.

2 Related Work

Small Language Models. In the literature, ASA mostly relied on hand-crafted features for similarity measurement between answers and rubrics, e.g., semantic-based dependency graph alignment (Mohler et al., 2011), machine learning-based methods (Burrows et al., 2015), and several scoring systems described in the SemEval-2013 Task 7 shared task (Dzikovska et al., 2013). In addition, pre-trained Transformer encoders have substantially advanced ASA tasks (Haller et al., 2022), e.g., domain-adaptive BERT (Devlin et al., 2019) trained with augmenting data from the domain-specific textbooks (Sung et al., 2019), SBERT (Reimers and Gurevych, 2019) based on transfer learning and data augmentation (Bonthu et al., 2023). Despite these advances, small encoder models have limited capacity to handle nu-

anced open-ended responses and often struggle to distinguish between incorrect and partially correct answers. This limitation has motivated increasing interest in leveraging LLMs, which offer stronger semantic understanding and reasoning capabilities.

Large Language Models. Recent work has applied large language models (LLMs) to ASA scoring. Henkel et al. (2024) suggest that LLMs with few-shot prompts achieve human scoring in K-12 education, while Chamieh et al. (2024) and Ferreira Mello et al. (2025) indicate that prompt-based LLMs are, in contrast, less competitive than fine-tuned BERT approaches, but LLMs show promising capabilities when configured with optimized prompts such as few-shot examples and clear instructions. These observations are also presented while assessing student explanations, where fine-tuned FLAN-T5 (Chung et al., 2024) outperforms LLMs in-context learning (Carpenter et al., 2024) as well as reasoning propositional logic, where a BERT-based model outperforms Llama-based LLMs (Liu et al., 2024b). Thus, these findings reveal the limited domain generalizability of LLM prompting methods and have thus motivated the development of more task-adaptive LLM solutions. More recent ASA work investigates a QLoRA-based cross-prompt fine-tuning method (Funayama et al., 2025) and a LLM fine-tuned framework with generated feedback (Aggarwal et al., 2025). However, rubric-aware LLM fine-tuning with limited data, particularly in non-English settings (Padó et al., 2024), remains underexplored, which motivates our study.

3 Dataset

The ASA scoring task is based on a novel dataset, ALICE-LP-1.0 (Gombert et al., 2026), which contains a German-language corpus of mid- and high-school level answers to questions across four STEM domains: physics, mathematics, biology, and chemistry. Students answered short-answer items embedded in synchronous Moodle-based learning activities under teacher supervision. Each instance consists of a question, a student response, a textual rubric defining the scoring rubrics, and a label on a three-way scale (*incorrect*, *partially correct*, *correct*), as well as a binary version that collapses *partially correct* into *incorrect* label (see Figure 1). The training set contains 7,899 responses, the trial set used for validating the models contains 827 responses, and the evaluation set used for

leaderboard ranking is split into two subsets: 2,008 *unseen answers* responses obtained during training and 3,168 *unseen questions* responses held out from training. The evaluation design follows the protocol established by SemEval-2013 (Dzikovska et al., 2013) and SAF (Filighera et al., 2022). An example of the ASA data is shown in Figure 1.

4 Method

We address the ASA task with a batch of small and large language models from two perspectives. **Ensemble LLMs**, as described in Section 4.1, first employ small language model encoders to learn task-specific representations from labeled responses and produce calibrated predictive probability distributions of the candidate labels. Afterward, we ensemble multiple fine-tuned models, including few-shot predictions from LLMs, i.e., Claude-Opus-4.6 (Anthropic, 2026), to provide complementary scoring predictions. The final results are based on ensemble probabilities across candidate models. In addition, **Finetuned LLMs**, as described in Section 4.2, leverage LLM layers and a classifier head for fine-tuning using parameter-efficient methods, e.g., LoRA (Hu et al., 2022) and DoRA (Liu et al., 2024a). Unlike most generative LLMs that aim to generate predictive labels by learning the next-token probabilities, our fine-tuned LLMs instead learn to directly predict probabilities over the scoring labels. The two approaches are complementary as the encoder ensembles excel when training questions overlap with test questions (unseen answers), while the instruction-tuned LLM generalizes better to novel questions (unseen questions) by leveraging its strong linguistic capabilities.

4.1 Encoder-Ensemble LLMs

We preprocess the input text by concatenating the question, student answer, and rubric into a single sequence, i.e., *Question: {question} [SEP] Answer: {answer} [SEP] Rubric: {label₁}: {desc₁} | {label₂}: {desc₂} | {label₃}: {desc₃}*. This format provides the model with the full context needed to assess the answer against the rubric criteria, inspired by prior ASA scoring approaches (Sung et al., 2019). We train three Transformer-based models, ranging from monolingual German to multilingual language models:

- **GELECTRA-large** (Chan et al., 2020): A German ELECTRA model pre-trained on a large German corpus using the replaced token detec-

tion objective. It has demonstrated strong performance on GermEval14 (Benikova et al., 2014) and GermEval18 (Wiegand et al., 2018).

- **XLM-RoBERTa-large** (Conneau et al., 2020): A multilingual model pre-trained on 100 languages using masked language modeling on 2.5TB of clean CommonCrawl data.
- **BERT-base-german-cased** (Chan et al., 2020): A German BERT model pre-trained on German Wikipedia and news corpora.

We combine predictions from the trained encoder models with few-shot predictions from Claude-Opus-4.6 (Anthropic, 2026), without fine-tuning. Claude-Opus-4.6 uses a small number of training examples as demonstrations, of which the same questions are excluded for unseen answer tracks. It returns a score label based on its rubric interpretation and reasoning capabilities. The final ensemble uses soft voting with optimized weights. Each fine-tuned encoder produces a softmax probability distribution over labels, while Claude-Opus-4.6’s predictions are regarded as hard labels (one-hot). The ensemble prediction is:

$$\hat{y} = \arg \max_c \sum_{i=1}^n w_i \cdot p_i(c | x) \quad (1)$$

where w_i are model weights optimized via the Nelder-Mead simplex algorithm (Nelder and Mead, 1965) to maximize QWK on the trial set, p_i is the predicted probability for label c , and n is the number of ensembled models. Note that models that fail to learn (QWK = 0 on the trial set) are excluded from the ensemble for that track. We also explore multiple fusion ratios between the encoder ensemble and Claude-Opus-4.6 predictions (e.g., 70% encoder and 30% Claude-Opus-4.6), as well as a confidence-based selection strategy in which the encoder ensemble is applied when its maximum softmax probability exceeds a confidence threshold (e.g., 0.7), and Claude-Opus-4.6 is used for the remaining uncertain cases.

Implementation Each model is trained with random seeds to improve robustness through diversity, yielding up to 6 model variants per track. Also, all models are trained using the HuggingFace¹ with a linear classification head. The Claude-Opus-4.6 uses 0 temperature, and a maximum token of 50. BERT-based model training hyperparameters

¹<https://huggingface.co/>

Hyperparameter	Value
Batch size	16
Learning rate (encoder)	2×10^{-5}
Optimizer	AdamW
Max epochs	8
Max sequence length	512
LR scheduler	warmup (200 steps)
Loss function	CE with class weights

Table 1: Training hyperparameters for encoder models.

are summarized in Table 1. We also employ differential learning rates (Cazé and van der Meer, 2013), applying a $5\times$ multiplier to the classification head compared to the pre-trained encoder layers. The inverse-frequency class weights in the cross-entropy loss are used to address label imbalance, which is particularly important for the 2-way track where the Incorrect class comprises 71% of samples in the training set.

4.2 Instruction-Finetuned LLMs

While encoder models are effective for classification, they take ASA scoring as pattern matching rather than explicitly rubric-based reasoning. While full fine-tuning of LLMs can address this limitation, it is prohibitively expensive and requires large-scale annotated data. We thus leverage PEFT methods (Hu et al., 2023) to adapt low-resource fine-tuning while preserving their strong linguistic capabilities. Unlike ensemble-LLMs (Sec. 4.1), which are built from multiple models, fine-tuned LLMs produce a standalone scorer directly for inference. Specifically, we use Llama-3.1-8B (Grattafiori et al., 2024) as our base model, as it has strong multilingual capabilities and instruction-following performance. The model is instruction-tuned on the scoring task, using the instruction formatted following the prior Alpaca instruction template² (Taori et al., 2023).

```

### Instruction:
Score the following student response based on
the given rubric.
### Input:
Question: {question}
Student Response: {answer}
Rubric:
- Correct: {rubric_correct}
- Partially correct: {rubric_partial}
- Incorrect: {rubric_incorrect}

```

Inspired by previous PEFT work on text classification (Liu, 2025; Liu and Litman, 2025), we employ adapter-based methods for efficient LLM fine-

²The instructions used in the experiment were in German, but are translated into English for visualization.

Hyperparameter	Value
Quantization	8-bit
LoRA/DoRA rank r	32
Alpha α	64
Target modules	q, k, v, o projections
Dropout	0.05
Learning rate	1×10^{-4}
Batch size	16
Max epochs	5
Max sequence length	512
LR scheduler	warmup (100 steps)

Table 2: Hyperparameters for LLMs with LoRA/DoRA.

tuning, i.e., LoRA (Hu et al., 2022), which freezes the pre-trained model weights and injects trainable low-rank decomposition matrices into each transformer layer. For a pre-trained weight matrix $W_0 \in \mathbb{R}^{d \times k}$, the modified forward pass is:

$$h = W_0x + \Delta Wx = W_0x + BAx \quad (2)$$

where $B \in \mathbb{R}^{d \times r}$, $A \in \mathbb{R}^{r \times k}$, and the rank $r \ll \min(d, k)$. This reduces trainable parameters by orders of magnitude while preserving the model’s pre-trained knowledge. In addition, we also used the recent DoRA (Liu et al., 2024a), which extends LoRA by decomposing the pre-trained weight into magnitude and direction components:

$$W' = m \cdot \frac{W_0 + BA}{\|W_0 + BA\|_c} \quad (3)$$

where $m \in \mathbb{R}^{1 \times k}$ is a learnable magnitude vector and $\|\cdot\|_c$ denotes the column-wise norm. This decomposition enables independent adaptation of weight magnitude and direction, closely approximating full fine-tuning dynamics while maintaining the parameter efficiency of LoRA. DoRA has been shown to outperform LoRA on several NLP tasks (Liu et al., 2024a).

4.2.1 Implementation

Specifically, we apply 8-bit quantization, following prior work (Liu and Litman, 2026), to reduce memory consumption. We build the framework using PyTorch³ and HuggingFace, and optimize task losses using the Adam optimizer on an Nvidia A100. We fine-tune LLMs on the training set and tune hyperparameters on the trail set. At inference time, the fine-tuned Llama3.1-8B model outputs label probabilities given the instruction-formatted input. A softmax is applied to return the predicted label. The detailed hyperparameter settings are shown in Table 2.

Table 4: The 3-way track test results for Unseen Answers (UA) and Unseen Questions (UQ).

4.3 Results

Regarding ensemble-LLMs for the two-way and three-way track performance in Table 3 and Table 4, GELECTRA-large consistently achieves the strongest individual performance, benefiting from German-specific pre-training. In terms of XLM-RoBERTa-large, it exhibits training fluctuation, with some seeds failing to converge (e.g., QWK = 0), particularly on the 2-way track, thus we did not submit its performance. In contrast, GELECTRA-large outperforms the larger multilingual XLM-RoBERTa-large in three-way track. This demonstrates that monolingual pre-training yields more useful representations than model size for language-specific classification tasks, whereas XLM-RoBERTa-large exhibits high sensitivity to experimental configuration, as some runs fail to learn in our pilot study. This might be caused by a linguistic adaption from its multilingual pre-training to the German classification objective, given the relatively small training set.

Regarding LLMs for the two-way and three-way scoring, ensemble Claude-Opus-4.6’s few-shot predictions without fine-tuning on the task consistently provide a complementary strength by leveraging rubric-level reasoning. In other words, incorporating Claude-Opus-4.6’s predictions into the encoder ensemble is particularly beneficial for ambiguous cases where discriminative models produce low-confidence outputs. In contrast, the instruction fine-tuned Llama3.1-8B models substantially outperform the ensemble-based method on both the

unseen answer and unseen question tracks. Specifically, fine-tuning yields relatively larger gains on the 2-way track than on the 3-way track, suggesting that 3-way ASA scoring, which requires distinguishing partially correct from incorrect responses, is inherently more challenging. Although LoRA generally outperforms DoRA in terms of QWK, their weighted F1 scores remain comparable. Given that LoRA is also more computationally efficient, it is regarded as the preferred PEFT method. Notably, the fine-tuning approaches offer the advantage of a single scorer that evaluates responses against rubrics without relying on an ensemble of multiple models. This is particularly beneficial for the unseen questions track, where generalization to novel questions and rubrics is critical.

5 Conclusion

We presented a set of novel ensemble-based and fine-tuned LLM methods for ASA scoring in German. The encoder ensemble augmented with few-shot Claude-Opus-4.6 predictions demonstrates advantages over small language models, while the instruction-tuned Llama3.1-8B scorer exhibits superior performance in learning complex scoring patterns. Our results suggest that parameter-efficient fine-tuning enables LLMs to score diverse student responses even with limited training data. These findings offer a practical solution for deploying LLM-based ASA scoring systems in low-resource educational assessment.

Limitations

Our encoder ensemble optimization relies on the trial set for weight tuning, which may lead to overfitting on the evaluation set. In addition, the ensemble approach increases system complexity, requiring training multiple models and careful ensemble-based strategies. While fine-tuned LLMs with PEFT achieve substantial improvement, they require GPU resources, potentially limiting deployment in low-resource educational contexts. Furthermore, our experiments are conducted exclusively on German short-answer data, and the effectiveness of the proposed methods on other languages or domains remains unverified.

Ethics Statement

This work uses the ALICE-LP-1.0 dataset, which was collected and annotated for academic research purposes with appropriate institutional oversight. As the dataset contains student responses from minors in German secondary schools, we do not attempt to re-identify individual students. Our automated scoring systems are intended to assist, not replace, human graders; deployment in high-stakes assessment settings would require thorough validation and human oversight to ensure fairness across student populations. We acknowledge that both encoder models and LLMs may introduce biases during pretraining that could affect scoring equity. Additionally, LLM-generated scores may exhibit inconsistencies or errors that require careful human review prior to educational deployment. Lastly, the use of LLMs may raise practical concerns regarding cost, accessibility, and reproducibility.
