Table 16: Reference-based and QE evaluation scores for greedy and MBR/QE decoding (1^{st} block), and ensembles (2^{nd} block), on en-ta (FLORES200 test dataset). Higher scores are better, except MetricX, MetricX-QE, and TER, where lower is better. Green is better than greedy, red is worse. Ensembles are defined in Table 2. Significant differences from greedy (pairwise t-test) indicated by * for p<0.05, † for p<0.01, ‡ for p<0.001. The green diagonal in the 1^{st} block shows metrics prefer outputs from MBR/QE decoding using the same utility metric.

Table 18: Reference-based and QE evaluation scores for greedy and MBR/QE decoding (1st block), and ensembles (2nd block), on en-ml (FLORES200 test dataset). Higher scores are better, except MetricX, MetricX-QE, and TER, where lower is better. Green is better than greedy, red is worse. Ensembles are defined in Table 2. Significant differences from greedy (pairwise t-test) indicated by * for p<0.05, † for p<0.01, ‡ for p<0.001. The green diagonal in the 1st block shows metrics prefer outputs from MBR/QE decoding using the same utility metric.

Table 20: Reference-based and QE evaluation scores for greedy and MBR/QE decoding (1st block), and ensembles (2nd block), on en-hu (FLORES200 test dataset). Higher scores are better, except MetricX, MetricX-QE, and TER, where lower is better. Green is better than greedy, red is worse. Ensembles are defined in Table 2. Significant differences from greedy (pairwise t-test) indicated by * for p<0.05, † for p<0.01, ‡ for p<0.001. The green diagonal in the 1st block shows metrics prefer outputs from MBR/QE decoding using the same utility metric.

Table 23: Reference-based and QE evaluation scores for greedy and MBR/QE decoding (1st block), and ensembles (2nd block), on en-zh (WMT2023 dataset). Higher scores are better, except MetricX, MetricX-QE, and TER, where lower is better. Green is better than greedy, red is worse. Ensembles are defined in Table 2. Significant differences from greedy (pairwise t-test) indicated by * for p<0.05, † for p<0.01, ‡ for p<0.001. The green diagonal in the 1st block shows metrics prefer outputs from MBR/QE decoding using the same utility metric.

Abstract

Collecting high-quality translations is crucial for the development and evaluation of machine translation systems. However, traditional human-only approaches are costly and slow. This study presents a comprehensive investigation of 11 approaches for acquiring translation data, including human-only, machine-only, and hybrid approaches. Our findings demonstrate that human-machine collaboration can match or even exceed the quality of human-only translations, while being more cost-efficient. Error analysis reveals the complementary strengths between human and machine contributions, highlighting the effectiveness of collaborative methods. Cost analysis further demonstrates the economic benefits of human-machine collaboration methods, with some approaches achieving top-tier quality at around 60% of the cost of traditional methods. We release a publicly available dataset[1] containing nearly 18,000 segments of varying translation quality with corresponding human ratings to facilitate future research.

1 Introduction

Collecting high-quality translations efficiently presents significant challenges. Traditional approaches rely heavily on different tiers of human translators, ranging from professional linguists to junior bilingual speakers (Zouhar and Bojar, 2024). While these approaches can produce high-quality translations, they are often expensive, time-consuming, and challenging to scale for large datasets.

Recent advancements in machine translation with large language models (OpenAI, 2024; Gemini, 2024) have demonstrated models' impressive abilities to generate human-like translations. However, recent research (Yan et al., 2024) tends to position human translators and machine translation systems as competitors rather than potential collaborators, which could result in efficient alternatives for addressing the limitations of traditional translation data collection methods.

Figure 1: Our 11 translation systems, organized by initial translation type (human or machine) and post-editing type (none, human, or machine). Detailed system descriptions are provided in Section 2.2.

In this paper, we aim to fill the gap by comprehensively investigating the potential of human-machine collaboration to efficiently collect high-quality translation data. We hypothesize that combining the strengths of humans and machines could lead to higher quality, cost-efficient translation collection methods. To verify the hypothesis, we explore 11 different methods for acquiring translation data, including human-only, machine-only, and various hybrid methods.

Our research seeks to answer the following key questions:

- Can human-machine collaborative approaches produce translations of comparable or higher quality than traditional human-only or machine-only methods?
- How do different collaborative methods impact translation quality, and where do the improvements primarily originate?
- What are the cost implications of these various approaches, and can human-machine collabo-

[1] The dataset can be found at https://github.com/google-research/google-research/tree/master/collaborative-tr-collection.

ration offer a more cost-efficient solution for high-quality translation collection?

Our findings demonstrate that human-machine collaboration can match or even exceed human-only translation quality while being more cost-efficient. We present detailed error analyses to reveal the complementary strengths of the collaborative methods and conduct a thorough cost analysis to illustrate the economic benefits of collaborative approaches.

To support future research, we also release a publicly available dataset containing nearly 18,000 segments of varying translation quality with corresponding human ratings.

2 Collecting Translations

Translating text from one language to another can either be done by bilingual annotators or machine translation systems. However, both cases are prone to producing errors in their translations, including well-trained expert translators (Freitag et al., 2023). As such, translations can be post-edited, a process of correcting a translation, either manually or with a model, that often yields higher-quality translations.

Both steps of this process — the initial translation collection and the post-editing — can either be done with humans or with models, each with their own advantages and disadvantages in terms of speed, quality, cost, and scalability. In this work, we explore how combinations of human and machines for both steps of this pipeline can combine to produce high-quality translations.

2.1 Data Sources

We use the test sets provided by the WMT23 General MT Shared Task (Kocmi et al., 2023) and collect new translations using several methods. These data sets comprise 460 English-German (EnDe) paragraph-level segments and 1175 Chinese-English (ZhEn) sentence-level segments with human rating annotations.

2.2 Data Collection Systems

Figure 1 illustrates the combinations from the two dimensions: initial translation and post-editing methods from either human annotators or machines. Machines may be either large language models (LLMs) or machine translation (MT) systems. This results in the 11 systems in the figure, named according to the source of the initial translation with a suffix representing the post-editing approach.

In this work, we use several different sources for the initial translation:

- **OrigHumanRef** and **HumanRef** are human translations collected by professional translators. We refer to the original reference provided by the WMT23 General MT Shared Task (Kocmi et al., 2023) as ORIGHUMANREF. We collected a new from-scratch professional translation HUMANREF following the standard annotation steps.

- **BestWMT** is the top-ranked MT system picked from the official results of WMT23 General Translation Task: GPT4-5shot (OpenAI, 2024) for EnDe and Lan-BridgeMT (Wu and Hu, 2023) for ZhEn, representing the state-of-the-art MT capability we can access.

- **MidWMT** is a middle-ranked MT system from the official results of WMT23 General Translation Task: ONLINE-G for both EnDe and ZhEn, representing the conventional MT quality we can use.

We additionally explore the following different methods for post-editing translations:

- **HumanPE** refers to the post-edit service provided by a separate batch of linguists. **HumanPEx2** means the translation going through two independent rounds of post-edits from professional translators. There is no translator overlap between the two batches.

- **LLMRefine** (Xu et al., 2024) is one of the state-of-the-art post-edit approaches leveraging error feedback for pin-pointing corrections. Here we reproduced its error-feedback process and leverage Gemini-1.0 Ultra (Gemini, 2024) with the reported prompts to generate post-edited text.

2.3 Evaluation

In this paper, we use Multidimensional Quality Metrics (MQM; Lommel et al., 2014; Freitag et al., 2021) to evaluate translation quality. MQM is the state-of-the-art human evaluation framework for MT. In MQM, expert raters identify error spans within translations, which are automatically converted to numeric scores. Lower scores indicate fewer errors and thus higher quality.

Figure 2: Cross-BLEU scores for different EnDe translation collection approaches.

3 Data Quality Analysis

In this section, we seek to understand how our collected translations differ from each other (§3.1), how those differences correspond to changes in quality (§3.2), and what those results indicate about the value of human-machine collaboration in terms of quality (§3.3).

3.1 Lexical Overlap and Similarity

Figure 2 presents a cross-BLEU (Freitag et al., 2022) similarity matrix for English-German translations, which measures lexical similarity between pairs of translations. See Figure 8 in Appendix A.1 for Chinese-English results. Higher scores indicate greater similarity.

One prominent pattern in these results is that systems based on the same initial translation retain high similarity even after post-editing. This indicates that **post-editing still preserves some characteristics of the original translation**. Also, translation systems based on MT (BestWMT, MidWMT, and their post-edited versions) are more similar to each other than to translations based on an initial human translation.

Table 1 presents a subset of the information in Figures 2 and 8, to emphasize the interaction between using human- vs. model-based approaches for the initial translation and post-edit. This illustrates the trend that **humans and machines tend to make more changes to translations from the other group**.

Table 2: English-German MQM human evaluation results. Lower scores represent higher translation quality.

3.2 MQM Quality Evaluation

Tables 2 and 3 present the MQM human evaluation results. The solid lines denote *significance clusters*, where every system in a cluster is statistically significantly better than every system below that cluster, based on random permutation tests with 10,000 trials, where a p-value of less than $\alpha = 0.05$ is considered significant.

The results reveal that **HumanRef+LLMRefine** and **BestWMT+HumanPE** are the overall winners, with each appearing in the best significance cluster in both language pairs.

Tables 2 and 3 show that post-edits, both HumanPE and LLMRefine, **demonstrate a positive impact on initial translations**. These methods consistently either elevate the translation quality to a higher level of significance or preserve the existing quality.

Table 3: Chinese-English MQM human evaluation results. Lower scores represent higher translation quality.

3.3 Human-Machine Collaboration

Table 4 and Figure 3 present a detailed analysis that highlights the quality benefits of human-machine collaboration.

Figure 3 shows the gains in quality that can be provided by our post-edit approaches. The gains are more pronounced when starting with a lower-quality translation (MidMT), but even high-quality translations (HumanRef, BestWMT) can be improved. The quality differences between initial translations are greatly reduced after post-editing, but not eliminated.

Table 4 provides a finer-grain analysis of the effect of each post-edit approach on different initial translations. In both language pairs, an LLM-based method provides the most benefit when starting with human translation, while human post-editing provides the most benefit for machine translation. Recall that in Table 1 we showed that model-based methods and humans make more changes to translations from the other group; here we see that these changes are also net-positive. This indicates that **human-machine collaboration is an effective way to achieve high-quality translations**.

4 Error Analysis

Here we present more detailed error analysis of both initial translation and post-edit stages to investigate where the quality improvements originate. Using English-German as an example, we first present analysis of the initial translations in Section 4.1 to understand the initial error distributions. Then, we further investigate the error-correction dynamics during post-editing in Section 4.2 to understand why human-machine collaboration stands out from other approaches.

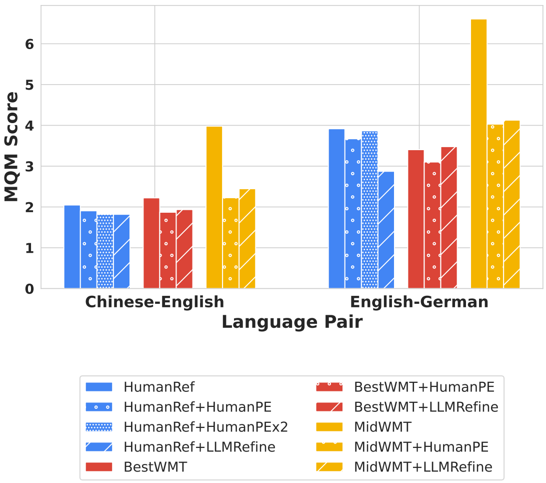

Figure 3: MQM Scores for different translation systems across two language pairs: Chinese-English and English-German. Bars represents the average MQM scores for each translation system. The systems are grouped and colored by initial translation and further categorized by post-editing method with different fill patterns. Lower MQM scores indicate better quality.

4.1 Error distribution from Initial Translation

We present the error type and severity distribution of the English-German initial translations in Table 5 and that of Chinese-English in Appendix A.2. It shows that accuracy-related errors are the primary source of major errors and that the distribution of minor errors is more evenly spread across different categories. Importantly, these error distributions are similar for both human and machine-based initial translations. This consistency provides a solid foundation for comparing different post-editing techniques in our downstream analysis.

4.2 Error Correction from Post-Editing

To understand the error-correction dynamics of different post-editing methods and find the origin of the improvements of human-machine collaboration, we explored three key questions:

- Do different post-editing methods agree on which segments to modify?
- How do different post-editing methods affect the total number of major and minor errors?
- How do different post-editing methods affect

Source	Init. Translation	+ HumanPE		+ HumanPEx2		+ LLMRefine

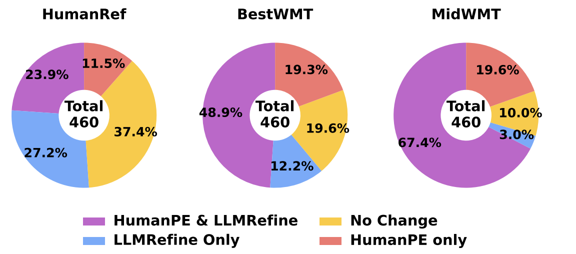

Figure 4: Agreement between HumanPE and LLM-Refine in identifying segments requiring post-edit on English-German data. Each pie chart[2]represents a different initial translation source.

the total number of high- and low-quality segments?

We first examine how often human post-editors (HumanPE) and machine post-editing methods (LLMRefine) agree on which segments need correction. Figure 4 shows that both methods identify more segments for editing in lower-quality initial translations as evidenced by the shrinking "No Change" (yellow) section. Notably, agreement between HumanPE and LLMRefine increased from 23.9% for high-quality HumanRef translations to 67.4% for lower-quality MidWMT translations as observed by the expanded "HumanPE & LLMRefine" (purple) section. This suggests more consensus on obvious errors in lower-quality texts while greater divergence for higher-quality translations in editing approaches. A detailed numerical breakdown is shown in Table 8 in Appendix A.3.

Another interesting observation from Figure 4 is that HumanPE (purple + red) identifies a larger proportion of segments needing correction in BestWMT (48.9% + 19.3% = 68.2%) compared to HumanRef (23.9% + 11.5% = 35.4%), despite the superior quality of BestWMT over HumanRef as shown in Table 2. This suggests that human post-editors might overlook certain errors in human translations due to their familiar patterns. Conversely, the unfamiliar patterns in machine-generated text may make errors more salient to human editors. This interpretation is consistent with the pattern depicted in Figure 2, where human post-editors make fewer changes to human translations than to machine translations. This observation provides one plausible explanation for the necessity of human-machine collaboration in achieving high-quality translations. Detailed statistics for English-German are shown in Table 8 and similar trends are also observed in Chinese-English in Table 9 in Appendix A.3.

We wish to investigate how many errors are corrected during post-editing, but because it is difficult to automatically determine whether an individual error was corrected, we instead examine how the total number of errors changes after post-editing, also considering severity. Figure 5 shows that both human and machine post-editing reduce overall error counts across different initial translation qual-

[2] Tabular statistics are provided in Tables 8 and 9 in Appendix A.3.

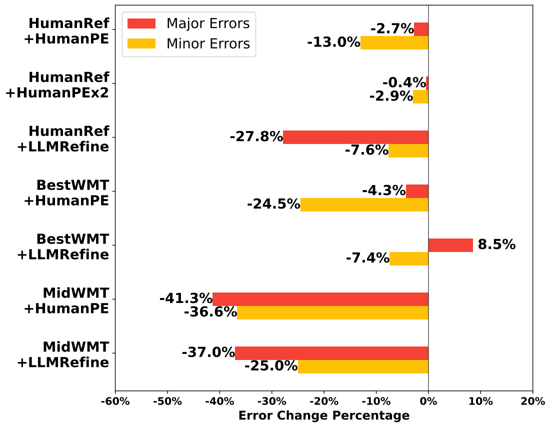

Figure 5: Error changes percentages by different post-editing approaches on English-German data. The percentages present the changes in error counts for each post-editing method compared to its initial translation. A negative indicates a decrease in errors, while positive value indicates an increase in the error type.

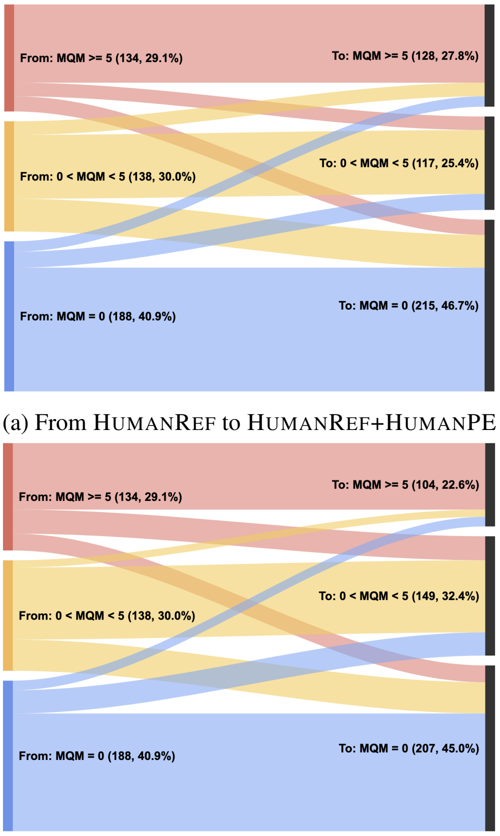
ities. LLMRefine outperforms HumanPE on HumanRef initial translation in reducing major errors (-27.8% vs. -2.7%), while HumanPE is superior for BestWMT, decreasing major-error segments compared to the increase for LLMRefine (-4.3% vs. +8.5%). On MidWMT, both methods show substantial improvements, with HumanPE moderately ahead of LLMRefine (-41.3% vs. -37.0% decrease in major-error segments). These findings highlight the complementary strengths of human and machine post-editing methods, indicating that a hybrid method is likely the most effective strategy for reducing errors, regardless of the initial translation's origin. Similar trends are also observed in Chinese-English in Figure 9 in Appendix A.3.

To understand the error correction dynamics for each segment, we analyzed how MQM scores change before and after post-editing. Ideally, post-editing would fix existing errors while minimizing the introduction of new ones. However, as Figure 6 illustrates, post-editing is not guaranteed to improve every segment: while some segments are improved, others are worsened.

Figure 6 compares HumanPE and LLMRefine on HumanRef initial translations for English-German data. Both methods reduce the number of high-scoring (low-quality) segments (MQM >= 5). Notably, LLMRefine outperforms HumanPE by showing fewer quality-degrading corrections and more quality-improving ones. LLMRefine minimizes low-to-high-scoring transitions with a narrower flow from low-scoring segments (0 < MQM < 5) to high-scoring segments compared to HumanPE. Moreover, LLMRefine achieves a significant reduction in high-scoring segments by 6.5% (from 29.1% to 22.6%) compared to HumanPE's 1.3% (from 29.1% to 27.8%), suggesting that it is more effective at achieving post-editing gains while preserving originally good translations. A similar trend is observed for Chinese-English with HumanRef initial translation in Figure 10 in Appendix A.3.

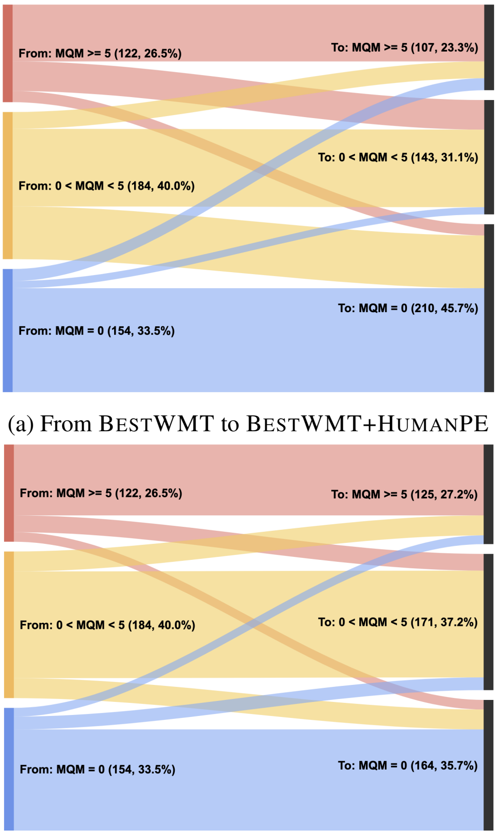


(a) From HumanRef to HumanRef+HumanPE

(b) From HumanRef to HumanRef+LLMRefine

Figure 6: Segment-level quality shift through HumanPE and LLMRefine from English-German HumanRef. Each segment is categorized into one of three groups based on its MQM score: 1) high-scoring segments with MQM >= 5; 2) low-scoring segments with 0 < MQM < 5; 3) error-free segments with MQM=0. Higher MQM scores indicate more numerous/severe errors and accordingly lower translation quality.

To demonstrate that the quality improvement is not solely due to the capabilities of LLMRefine, we conducted further experiments as shown in Figure 7. This figure compares HumanPE and LLMRefine with BestWMT initial translations. Interestingly, the results are reversed: HumanPE



(a) From BestWMT to BestWMT+HumanPE

(b) From BestWMT to BestWMT+LLMRefine

Figure 7: Segment-level quality shift through HumanPE and LLMRefine from English-German BestWMT.

outperforms LLMRefine in this scenario, showing fewer quality-degrading corrections and more quality-improving ones. HumanPE demonstrates a significantly wider flow from high-scoring segments to low-scoring ones. It achieves a notable reduction in high-scoring segments by 3.2% (from 26.5% to 23.3%), while LLMRefine sees an increase of 0.7% (from 26.5% to 27.2%). Furthermore, HumanPE significantly increases the No-Error segments (MQM=0) by 12.2% (from 33.5% to 45.7%) compared to LLMRefine's 2.2% increase.

The distinct performance differences of LLMRefine and HumanPE in these two sets of experiments highlight that **the quality improvement stems primarily from the complementary strengths of human and machine collaboration**, rather than the superior capability of either LLMRefine or HumanPE alone. This underscores the importance of leveraging both human and machine strengths in achieving optimal translation quality.

Systems	**Quality Rank**		**Costs**
	EnDe	**ZhEn**	
HumanRef	3	2	1X
HumanRef+HumanPE	2	1	1.6X
HumanRef+HumanPEx2	2	1	2.2X
HumanRef+LLMRefine	**1**	**1**	1X
BestWMT+HumanPE	**1**	**1**	**0.6X**

Table 6: Quality rank and costs comparison of different data collection systems. 1st rank indicates the translation quality belongs to the highest quality significance cluster in Table 2 and 3.

5 Costs Analysis

So far we have focused on comparing quality between various translation data collection approaches. However, practical considerations make it important to consider the trade-off between quality and costs. Table 6 analyzes relative human annotation costs between various approaches, along with the rank of the significance cluster that each method appeared in. The exact costs for the human annotation conducted in this study are confidential (although all annotators were paid fair market wages), so we instead use relative costs, based on the industry standard that post-editing text of a given length takes less time (and accordingly costs less) than producing a translation of that length. We specifically assume that human post-editing costs around 60% of what human translation does. According to existing literature (Plitt and Masselot, 2010; Zouhar et al., 2021; Green et al., 2013) and internal statistics, we believe it's a fair assumption, although the exact costs can vary upon different vendors, languages, task size, etc.

With this framework, the best combination of quality and cost appears to be human post-editing of high-quality MT (BestWMT+HumanPE), attaining quality in the top significance cluster in both language pairs with only 60% of the human annotation cost of collecting an initial human translation. Meanwhile, we see that one or two rounds of human post-editing of an initial human translation increases costs without a meaningful gain in quality, while just applying an LLM post-editor (HumanRef+LLMRefine) brings quality to the top significant cluster with no additional human annotation cost, making it a viable option when human translations are already collected. It's worth noting that LLM inference costs are negligible (on the order of dollars per million tokens) compared to human annotation costs, further enhancing the cost-effectiveness of LLM-based approaches. This indicates that **human-machine collaboration can be a faster, more cost-efficient alternative** to traditional collection of translations from humans, optimizing both quality and resource allocation by leveraging the strengths of both humans and machines.

6 Related Work

There have been a few studies investigating methods of acquiring high-quality translations. Recently, Zouhar et al. (2024) proposed collecting high-quality translations by building consensus between multiple translators. Zouhar and Bojar (2024) proposed collecting multiple translations from different tiers of human translators with careful budget calculations to optimize cost-efficiency.

Human Post-Edits Computer-aided translation tools are now widely used by professional translators for interactive translation and post-editing (Alabau et al., 2014; Federico et al., 2014; Green et al., 2014; Denkowski, 2015; Sin-wai, 2014; Kenny, 2012). Carl et al. (2011) have shown that human translators work faster and make fewer mistakes when editing machine translations than when translating from scratch. Toral et al. (2018) supports this, demonstrating even greater improvements with neural machine translation compared to phrase-based systems. Zouhar et al. (2021) investigates the relationship between machine translation quality and post-editing efforts and found no straightfoward relationship. On the other hand, Popovic et al. (2016) suggested that post-edits should be used carefully for MT evaluation due to the bias of each post-edit towards its MT system. Further, Toral (2019) showed that human post-edits are simpler and more normalised in language than human translations from scratch.

Automatic Refinement Lin et al. (2022) showed how the errors that humans make differ from those made by MT systems. They constructed a Translation Error Correction (TEC) corpus with professional translators and showed that models trained on it outperform Automatic Post-Editing (APE) models (Knight and Chander, 1994) that are trained to correct MT output. Since the emergence of LLMs, new refinement approaches based on detailed MQM annotations have appeared (Xu et al., 2023; Fernandes et al., 2023). Xu et al. (2024) showed that these refinement method can be used to improve the quality of human translations.

Meanwhile, machines have been extensively evaluated and utilized as an alternative to human annotators for data collection (Zouhar et al., 2021; Yan et al., 2024).

In contrast to the above methods, we investigate the interaction between humans and machines in the initial translation and post-editing stages, including detailed analysis of the resulting changes in quality while also considering cost-efficiency.

7 Conclusion

We investigate various approaches for gathering translation data, including human-only, machine-only, and hybrid approaches. Our results demonstrate that human-machine collaboration can consistently generate high-quality translations at a lower cost than human-only methods. Through detailed error analysis, we uncovered the nuances of error correction dynamics and highlighted the advantages of human-machine collaborative methods. Our cost analysis also demonstrates the cost-efficiency of human-machine collaboration methods. Finally, we release to the public a dataset of roughly 18,000 translation segments of varying quality from different collection methods along with human ratings, to facilitate further research in this area.

Limitations

This study focuses on two language pairs, English-German and Chinese-English. They are chosen due to the extensive study in the WMT23 metrics shared task (Freitag et al., 2023) and the availability of data from various translation systems from the WMT23 general shared task (Kocmi et al., 2023). While our analysis provides support for the findings presented in this work and we offer a plausible explanation for the observed results, it is important to acknowledge certain variables are not accounted for in this work, including using translators or post-editors with varying quality levels, different systems for translation and post-editing, utilizing sentence or paragraph datasets from other domains, and higher or lower resource language pairs beyond the two investigated here. Therefore, we cannot guarantee the observed trends will generalize to different datasets.

We want to especially highlight the need for further exploration of the quality variance observed among human translators, such as ORIGHUMANREF and HUMANREF in the English-German translation task. The current study's limited annotation budget and timeline restricted the depth of this investigation. Future experiments aimed at examining the impact of post-editing on annotator agreement would be particularly interesting and valuable.

Ethical Statement

The source data used for translation and post-edits is accessible to the public. We're certain that the data annotated by human labors is free from risk or toxic content. We used an internal, proprietary tool to collect human translation, post-edits, and evaluation data. The annotators were compensated fairly and were not required to disclose any personal details during the annotation process. All the test data used in this study are publicly available and annotators were allowed to label sensitive information if necessary. The annotators are fully informed that the data they collected will be used for research purposes.

Abstract

Transformers are the current architecture of choice for NLP, but their attention layers do not scale well to long contexts. Recent works propose to replace attention with linear recurrent layers—this is the case for state space models, which enjoy efficient training and inference. However, it remains unclear whether these models are competitive with transformers in machine translation (MT). In this paper, we provide a rigorous and comprehensive experimental comparison between transformers and linear recurrent models for MT. Concretely, we experiment with RetNet, Mamba, and hybrid versions of Mamba which incorporate attention mechanisms. Our findings demonstrate that Mamba is highly competitive with transformers on sentence and paragraph-level datasets, where in the latter both models benefit from shifting the training distribution towards longer sequences. Further analysis show that integrating attention into Mamba improves translation quality, robustness to sequence length extrapolation, and the ability to recall named entities.

1 Introduction

The inherent design of attention—the underlying mechanism of transformers—leads to quadratic computational costs and challenges in length generalization (Varis and Bojar, 2021). As an alternative, recent works propose to replace attention with linear recurrent approaches, which enjoy efficient training and inference, and obtain competitive results in language modeling tasks (Katharopoulos et al., 2020; Gu et al., 2022; Peng et al., 2023; Sun et al., 2023a; Gu and Dao, 2023).

In machine translation (MT), there is an increasing demand for supporting longer context lengths, such as paragraphs or entire documents (Fernandes et al., 2021; Wang et al., 2023; Kocmi et al., 2023). Given this trend, it has become increasingly important to design models capable of efficiently handling longer sequences. Previous research indicates that models like state space models (SSMs), exemplified by S4 (Gu et al., 2022), still lag behind transformers in MT (Vardasbi et al., 2023). However, it remains unclear whether these findings hold true for recent, more expressive variations of linear recurrent models, such as RetNet (Sun et al., 2023a) and Mamba (Gu and Dao, 2023), especially on settings that involve the use of pretrained models and long context datasets.

In this paper, we provide a rigorous and comprehensive experimental comparison between transformers, RetNet, Mamba, as well as hybrid versions of Mamba that incorporate attention mechanisms (§4). We also compare with pretrained Mamba and Pythia (Biderman et al., 2023) at two parameter scales, ∼400M and 1.4B. Building on existing literature that explores the capabilities of linear recurrent models in language modeling (Arora et al., 2024a; Jelassi et al., 2024), we further investigate the performance of models trained from scratch in recalling context tokens during the translation process (§4.2). Moreover, we extend our analysis by investigating the models' ability to handle long contexts, on paragraph-level datasets (§5), along with measuring their sensitivity to different sequence lengths (§5.2) and inference cost (§5.4). Overall, our main findings are:[1]

- For sentence-level experiments, we show that Mamba exhibits competitive performance compared to transformers, for both trained-from-scratch and pretrained models.
- At the paragraph level, we find that Mamba is sensitive to the training distribution's sequence length and struggles with longer inputs. However, shifting the distribution towards longer sequence lengths helps to close the gap with transformers.
- We observe that integrating attention and state

*Equal contribution.

space models creates a strong model in terms of translation quality, robustness to sequence length extrapolation, and ability to recall named entities.

2 Background

In this section, we present an overview of transformers, and the foundation of the linear recurrent models covered in this paper: linear attention (RetNet) and state space models (Mamba).

2.1 Transformers

The key component in the transformer architecture is the attention mechanism, which is responsible for contextualizing information within and across input sequences. Concretely, given query $\boldsymbol{Q} \in \mathbb{R}^{n \times d}$, key $\boldsymbol{K} \in \mathbb{R}^{n \times d}$, and value $\boldsymbol{V} \in \mathbb{R}^{n \times d}$ matrices as input, where n is the sequence length and d the hidden size, the single head *self-attention mechanism* is defined as follows (Vaswani et al., 2017):

$$\boldsymbol{Y} = \mathsf{softmax}\left(\frac{\boldsymbol{Q}\boldsymbol{K}^\top}{\sqrt{d}}\right)\boldsymbol{V} \in \mathbb{R}^{n \times d}. \qquad (1)$$

For decoder-only models, a causal mask is used to ignore future tokens. Notably, the $\boldsymbol{Q}\boldsymbol{K}^\top$ operation leads to a $\mathcal{O}\left(n^2\right)$ cost during training, and $\mathcal{O}\left(n\right)$ during inference with caching and causal masking.

2.2 Linear Attention

Denote by $\boldsymbol{q}_i, \boldsymbol{k}_i, \boldsymbol{v}_i, \boldsymbol{y}_i \in \mathbb{R}^d$ respectively the (column) vectors corresponding to the i^{th} rows of the matrices $\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}, \boldsymbol{Y}$ defined above. Katharopoulos et al. (2020) reformulate the attention mechanism by casting the role of the softmax as a similarity function $\mathsf{sim}\left(\boldsymbol{q}, \boldsymbol{k}\right) = \exp\left(\boldsymbol{q}^\top\boldsymbol{k}/\sqrt{d}\right)$:

$$\boldsymbol{y}_i = \frac{\sum_{j=1}^n \mathsf{sim}(\boldsymbol{q}_i, \boldsymbol{k}_j)\boldsymbol{v}_j}{\sum_{j=1}^n \mathsf{sim}(\boldsymbol{q}_i, \boldsymbol{k}_j)}. \qquad (2)$$

However, any kernel $k(\boldsymbol{x}, \boldsymbol{y}) : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ is a suitable candidate for the similarity function (Smola and Schölkopf, 1998; Tsai et al., 2019). In particular, a kernel $k(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{\phi}(\boldsymbol{x})^\top\boldsymbol{\phi}(\boldsymbol{y})$, where $\boldsymbol{\phi} : \mathbb{R}^d \to \mathbb{R}^r$ is a feature map, leads to:

$$\begin{aligned}\boldsymbol{y}_i &= \frac{\sum_{j=1}^n \boldsymbol{\phi}(\boldsymbol{q}_i)^\top\boldsymbol{\phi}(\boldsymbol{k}_j)\boldsymbol{v}_j}{\sum_{j=1}^n \boldsymbol{\phi}(\boldsymbol{q}_i)^\top\boldsymbol{\phi}(\boldsymbol{k}_j)} \\ &= \frac{\sum_{j=1}^n \boldsymbol{v}_j\boldsymbol{\phi}(\boldsymbol{k}_j)^\top\boldsymbol{\phi}(\boldsymbol{q}_i)}{\sum_{j=1}^n \boldsymbol{\phi}(\boldsymbol{k}_j)^\top\boldsymbol{\phi}(\boldsymbol{q}_i)} \\ &= \frac{\boldsymbol{S}^\top\boldsymbol{\phi}(\boldsymbol{q}_i)}{\boldsymbol{z}^\top\boldsymbol{\phi}(\boldsymbol{q}_i)}, \end{aligned} \qquad (3)$$

where $\boldsymbol{S} = \sum_{j=1}^n \boldsymbol{\phi}(\boldsymbol{k}_j)\boldsymbol{v}_j^\top \in \mathbb{R}^{r \times d}$ and $\boldsymbol{z} = \sum_{j=1}^n \boldsymbol{\phi}(\boldsymbol{k}_j) \in \mathbb{R}^r$. Notably, if initial states are initialized as $\boldsymbol{S}_0 = \boldsymbol{0}_{r \times d}$ and $\boldsymbol{z}_0 = \boldsymbol{0}_r$, intermediate states can be computed in a recurrent fashion:

$$\begin{aligned}\boldsymbol{S}_i &= \boldsymbol{S}_{i-1} + \boldsymbol{\phi}(\boldsymbol{k}_i)\boldsymbol{v}_i^\top, \\ \boldsymbol{z}_i &= \boldsymbol{z}_{i-1} + \boldsymbol{\phi}(\boldsymbol{k}_i). \end{aligned} \qquad (4)$$

Since we can reuse the same $\boldsymbol{S}_i$ and $\boldsymbol{z}_i$ for all queries, this recurrent variant offers a $\mathcal{O}\left(n\right)$ complexity during training and enjoys a $\mathcal{O}\left(1\right)$ complexity for inference.[2]

Retentive Networks (RetNet). Sun et al. (2023a) set $\boldsymbol{\phi}$ as the identity function, i.e., $k(\boldsymbol{q}, \boldsymbol{k}) = \boldsymbol{q}^\top\boldsymbol{k}$, ignore the normalizer in Equation 2, and introduce an exponential decay mask γ, leading to:

$$\begin{aligned}\boldsymbol{S}_i &= \gamma\boldsymbol{S}_{i-1} + \boldsymbol{k}_i\boldsymbol{v}_i^\top, \\ \boldsymbol{y}_i &= \boldsymbol{S}_i^\top\boldsymbol{q}_i. \end{aligned} \qquad (5)$$

This formulation effectively biases the attention mechanism to focus on closer token interactions. RetNet also uses XPos (Sun et al., 2023b), a relative positional encoding method, to improve its context extrapolation abilities.

2.3 State Space Models (SSMs)

SSMs (Gu et al., 2020) provide an alternative sequence mixing layer by processing sequences $\boldsymbol{x}_1, ..., \boldsymbol{x}_n$, where each $\boldsymbol{x}_i \in \mathbb{R}^d$, through a linear recurrence. Letting $\boldsymbol{H}_i \in \mathbb{R}^{r \times d}$ denote the "state" at the i^{th} time step, a discrete SSM is defined as follows:[3]

$$\begin{aligned}\boldsymbol{H}_i &= \boldsymbol{A}\boldsymbol{H}_{i-1} + \boldsymbol{b}\boldsymbol{x}_i^\top, \\ \boldsymbol{y}_i &= \boldsymbol{H}_i^\top\boldsymbol{c}, \end{aligned} \qquad (6)$$

where $\boldsymbol{A} \in \mathbb{R}^{r \times r}$, $\boldsymbol{b} \in \mathbb{R}^r$, and $\boldsymbol{c} \in \mathbb{R}^r$ are (discrete) parameters.[4] Since the same parameters are used for both relevant and irrelevant inputs, this model is deemed *input-independent*, which, in turn,

[2] In practice, however, this recurrent view is not parallelizable, leading to chunkwise-recurrent variations for training (Hua et al., 2022; Sun et al., 2023a; Yang et al., 2024).

[3] A discretization step is needed in order to obtain discrete parameters. For example, a possible method for this step is the zero-order hold rule, used by Mamba (Gu and Dao, 2023).

[4] The SSM equations are commonly written independenty for each input dimension $j \in [d]$ as

$$\boldsymbol{h}_i^{(j)} = \boldsymbol{A}\boldsymbol{h}_{i-1}^{(j)} + \boldsymbol{b}x_i^{(j)}, \quad y_i^{(j)} = \boldsymbol{c}^\top\boldsymbol{h}_i^{(j)},$$

with $\boldsymbol{A}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ shared across input dimensions. This is equivalent to (6), where the j^{th}-column of $\boldsymbol{H}_i$ equals $\boldsymbol{h}_i^{(j)}$.

makes the model unable to reset or overwrite its hidden states. S4 (Gu et al., 2022) is an instance of this model, which enjoys a $\mathcal{O}(n \log n)$ time complexity during training, and $\mathcal{O}(1)$ during inference. Vardasbi et al. (2023) shows that S4 still underperforms transformers for MT. Finally, note the similarity between Eq. 5 and Eq. 6: RetNets can be seen as state space models with $\boldsymbol{A} = \gamma \boldsymbol{I}$ and data-dependent $\boldsymbol{b}$ and $\boldsymbol{c}$.

Mamba. To make the SSM parameters *data-dependent*, Mamba (Gu and Dao, 2023) introduces a selection mechanism that uses learnable linear projections over $\boldsymbol{x}$ prior to the discretization step, effectively making all parameters dependent on the i^{th} input. This leads to:

$$\begin{aligned} \boldsymbol{H}_i &= \boldsymbol{A}_i \odot \boldsymbol{H}_{i-1} + \boldsymbol{B}_i \odot \boldsymbol{X}_i, \\ \boldsymbol{y}_i &= \boldsymbol{H}_i^\top \boldsymbol{c}_i, \end{aligned} \tag{7}$$

where $\boldsymbol{X}_i = \mathbf{1}_r \boldsymbol{x}_i^\top \in \mathbb{R}^{r \times d}$ is an r-sized stack of the input, $\boldsymbol{A}_i \in \mathbb{R}^{r \times d}$ represents d diagonal matrices of size $r \times r$, $\boldsymbol{B}_i \in \mathbb{R}^{r \times d}$, $\boldsymbol{c}_i \in \mathbb{R}^r$, and $\odot$ is the Hadamard product. Note that, unlike S4, where the same $\boldsymbol{A}$ and $\boldsymbol{B}$ parameters are shared across all hidden dimensions $1 \leq h \leq d$, Mamba defines $\boldsymbol{A}_i$ and $\boldsymbol{B}_i$ with a shape of $(\dots, d)$, allowing for unique parameters in each hidden dimension. While this formulation makes Mamba more expressive, it disrupts the convolutional approach used for training in S4. To address this, Gu and Dao (2023) propose an efficient IO-aware and parallelizable associative scan algorithm for training (Smith et al., 2023). Nonetheless, the recurrent view can still be used for inference with a $\mathcal{O}(1)$ time complexity.

3 Experimental Setup

We conduct experiments with transformers, RetNet, and Mamba for MT in §4 and §5. In this section, we detail the sentence and paragraph-level datasets used in our experiments, along with the settings for our models, which are trained in two distinct regimes: from scratch, or finetuned from a pretrained checkpoint.

3.1 Datasets

For sentence-level experiments, we focus on WMT14 DE↔EN and WMT16 RO↔EN for consistency with previous works (Vardasbi et al., 2023), but also include WMT16 FI↔EN using the standard training, validation and test splits. For paragraph level, we use the more recent WMT23 dataset (Kocmi et al., 2023), which contains ∼300M training samples and ∼1K test samples incorporating multi-sentence passages. In order to obtain a small high-quality subset for training, we exclude ParaCrawl and CommonCrawl samples from the original dataset and clean the remaining data. Our cleaning process includes three steps. First, we identify and remove samples in incorrect languages via `langdetect`[5]. Second, we eliminate duplicates. Third, we rank the samples using COMETKIWI-22 (Rei et al., 2022b) a state-of-the-art translation quality estimator, and keep only the top 6M samples. We call the refined dataset WMT23-6M. Datasets statistics are shown in Table 1.

DATASET	# SAMPLES	# TOKENS
IWSLT17 (DE↔EN)	200K	45.2 ± 29.5
WMT16 (RO↔EN)	610K	58.9 ± 31.1
WMT16 (FI↔EN)	2.08M	52.8 ± 33.1
WMT14 (DE↔EN)	4.5M	62.1 ± 45.6
WMT23-6M (DE↔EN)	6M	58.4 ± 32.9
WMT23-CAT-5 (DE↔EN)	2M	171.3 ± 134.9
WMT23-CAT-10 (DE↔EN)	1M	312.4 ± 282.3
WMT23 Test (DE→EN)	549	135.1 ± 147.7
WMT23 Test (EN→DE)	557	185.2 ± 188.2
Ted Talks Val. (DE↔EN)	995	268.5 ± 189.6
Ted Talks Test (DE↔EN)	2247	939.2 ± 594.0

Table 1: Sentence and paragraph-level datasets statistics.

3.2 Models

We make a broad selection of models spanning both trained-from-scratch and finetuned versions. In the first setting, we compare standard transformers, linear recurrent models, and also hybrid approaches that integrate attention into Mamba. For finetuned models, we experiment with released Pythia and Mamba checkpoints. We describe each model next.

3.2.1 Standard Models

Transformers. We select two variants of the transformer model as baselines: a base encoder-decoder formulation and a modern decoder-only version. The **Transformer Enc-Dec.** model, as described in the original paper (Vaswani et al., 2017), has 77M parameters, and uses sinusoidal positional embeddings and standard ReLU activations. The second variant, **Transformer++**, is a decoder-only formulation incorporating recent advancements, such as rotary positional embeddings (Su et al., 2024) and the SwiGLU layer (Shazeer,

[5] `https://github.com/Mimino666/langdetect`

2020). Specifically, we use the LLaMA architecture (Touvron et al., 2023), adjusting the embedding dimension to match the parameter count of the base transformer (79M), consistent with the version employed in (Gu and Dao, 2023).

Linear recurrent models. We select two representative recurrent models, **RetNet** (Sun et al., 2023a) and **Mamba** (Gu and Dao, 2023). Both models are tested with 77M parameters to approximately match the number of parameters in the transformer models.

3.2.2 Hybrid Models

Previous work has shown that incorporating attention into linear recurrent models leads to strong performance in language modeling (Fu et al., 2023; Arora et al., 2024b; De et al., 2024). Therefore, we aim to examine if this is also the case for MT by exploring three hybrid variants, detailed next.

Mamba-MHA. The simplest hybrid formulation involves replacing some of the Mamba layers with attention. Some natural questions then arise: how many attention layers are needed, and where to place them? After careful ablations, detailed in Appendix B, we use two attention layers placed at the middle and at the output of the network, resembling the hybrid version of H3 (Fu et al., 2023).

Mamba-Local. While aiming to achieve robust performance, the introduction of full attention to Mamba disrupts its efficiency gains. Thus, we consider local attention variants such as sliding window attention (Beltagy et al., 2020; Child et al., 2019), employed in recent hybrid models (Arora et al., 2024b; De et al., 2024). We use a window size of 64 based on the average sequence length shown in Table 1 and ablations in Appendix B.

Mamba Enc-Dec. Lastly, inspired by the S4-based encoder-decoder model from Vardasbi et al. (2023), we replace the self-attention mechanism in transformers with a Mamba block and keep the cross-attention component intact. In terms of complexity, since this variant computes attention over the source sentence, it incurs an additional $\mathcal{O}\left(n^2\right)$ cost for training and $\mathcal{O}\left(n\right)$ for inference.

3.2.3 Pretrained Models

In order to fairly evaluate the relative performance between pretrained models, we need to ensure consistency between their pretraining data. Taking this into account, we consider two strong models pretrained on The Pile (Gao et al., 2020): Pythia (Biderman et al., 2023), a modern transformer, and Mamba, a modern SSM. Note, however, that Pythia was pretrained on more tokens than Mamba (see Table 6), hence the comparison might be slightly unfavorable to Mamba. We experiment with two model scales, *small* (S) and *medium* (M). Concretely, we experiment with Pythia 410M and 1.4B, and with Mamba 370M and 1.4B.

3.3 Training and Evaluation

For models trained from scratch, we follow the settings proposed in (Vardasbi et al., 2023), whereas for pretrained models, we follow the finetuning settings used by Mamba (Gu and Dao, 2023). For decoder-only models, we pass a concatenation of the source and target sequences separated by a special token as input. We evaluate all models with BLEU (Post, 2018)[6] and COMET (Rei et al., 2022a).[7] We base our analysis on the latter, given its strong correlation with human judgments on sentence and paragraph-level data (Freitag et al., 2022, 2023). More training details can be found in §A.

4 Sentence-level Translation

We start by evaluating our standard, hybrid, and finetuned models on the sentence-level WMT16 RO↔EN, FI↔EN and WMT14 DE↔EN datasets. Results can be found in Table 2 in terms of BLEU and COMET. Next, we discuss the key findings.

4.1 Discussion

Mamba is competitive when trained from scratch. Mamba, a decoder-only model, not only outperforms a decoder-only transformer (Transformer++) across the board, but also an encoder-decoder transformer (Transf. Enc-Dec) in the larger WMT14 for both DE↔EN language pairs. This creates a contrast with the S4 results obtained by Vardasbi et al. (2023). We hypothesize that Mamba's good results are due to its data-dependent state updates (Eq. 7), which allows for more precise information retention in its hidden state. On the other hand, RetNet's performance is generally subpar compared to other models, likely due to its strong locality bias (induced by γ in Eq. 5), which may hinder performance in MT, a task where the source

input servers as a prefix to the translation, and it requires "focused attention" during decoding.

Attention benefits Mamba. By including attention layers in Mamba's architecture, we find that Mamba-MHA, which employs only two attention layers, is able to outperform both transformers and Mamba for almost all language pairs. While Mamba-Local retains constant inference complexity via windowed attention, it is not as strong as the full attention variant. Finally, Mamba Enc-Dec's performance is also competitive, falling just short of Mamba-MHA and echoing the S4 encoder-decoder findings of Vardasbi et al. (2023).

Pretraining improves all models. We note a large COMET gap, roughly 4-8 COMET points, between the finetuned models and those trained from scratch for all language pairs. This is expected, since not only are these models bigger, but they also have strong data-driven priors, which are beneficial in downstream tasks (Amos et al., 2024).

Larger models achieve top results. For small models, Mamba outperforms Pythia for RO↔EN and FI↔EN in terms of COMET and BLEU. However, Pythia is superior on the larger DE↔EN datasets. Moving to larger models, we note that Mamba improves COMET scores by $\sim$1 point on EN↔DE and 0.6-1.3 point on EN↔FI while dropping only 0.1-0.2 on EN↔RO datasets. On the other hand, Pythia improves results consistently for all language pairs with a larger model size, outperforming or matching the results of other models. On average, we find that both their gaps decrease when moving from smaller to medium-sized models but Pythia benefits more in terms of COMET. It is worth noting that Mamba is pretrained on fewer samples than Pythia (see Table 6) and that the impact of pretraining data quality can also play a role in downstream task performance.

4.2 Recall of Named Entities

Following our discussion of sentence-level translation, we now focus on how well these models recall context tokens during translation. Inspired by prior studies investigating the recall of context tokens in language modeling with state space models (Arora et al., 2024a; Jelassi et al., 2024), we conduct a similar experiment for MT. Unlike language modeling, where token patterns often recur within a near context, MT presents a challenge due to the distinct spelling of words across languages. Therefore, we focus on the recall of named entities (NEs) that appear verbatim in both source and target sentences, using NLTK for NE recognition (Bird, 2006).

We assess the models' ability to recall NEs from the WMT16 RO→EN dataset according to their frequency in the training set, as illustrated in Figure 1. The results reveal a clear correlation between NE frequency and their chance to be recalled in the translation process, as more frequent NEs are recalled more often. Notably, we note a disparity in performance with unseen entities, which provides a more illustrative view of recall ability. In this respect, transformers and Mamba perform on par, while RetNet shows inferior results. As before, the hybrid models are promising, with Mamba-

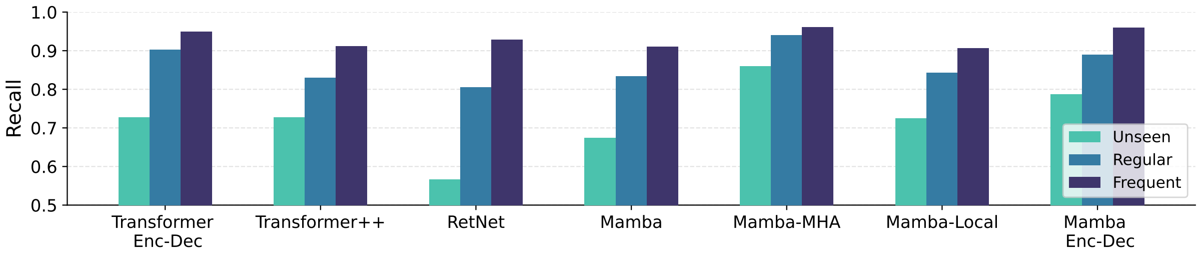

Figure 1: Recall in recovering named entities on the WMT16 RO→EN dataset by their training set frequency: *unseen* entities do not appear in the training data, while *regular* and *frequent* entities appear $[1, 16)$ and $16+$ times.

MHA outperforming all models, followed closely by Mamba Enc-Dec. We include additional analyses for other datasets in the Appendix §C.

5 Paragraph-level translation

While Mamba shows competitive performance with transformers on sentence-level datasets (see Table 2), it was originally designed to handle long sequences. Thus, we now turn our attention to paragraph-level datasets. This allows us to study the models' sensitivity to long sequence lengths along with their robustness in handling sequences that are longer than the ones seen during training.[8]

To this end we focus on the WMT23-6M dataset (§3.1), from which the training and test sets are composed of sentence and paragraph-level passages, respectively. In order to see the impact of training on long sequences, we propose to artificially construct multi-sentence datasets, which we call WMT23-CAT-N. Our procedure is as follows:

1. We first retain the original training samples from WMT23-6M with a probability of 50%.
2. Next, for the remaining part, we concatenate N random training samples.

This approach ensures that we consistently maintain a 50% ratio between single-sentence and multi-sentence samples. For validation, we sample 1-to-10-sentence passages from the TED Talks dataset (Cettolo et al., 2012). Statistics for CAT-N datasets can be found in Table 1. COMET scores on the WMT23 EN↔DE test sets are shown in Table 3. We provide additional BLEU scores in Table 9 in Appendix E. Next, we discuss our key findings.

5.1 Discussion

Concatenation helps. Our strategy of concatenating sentences proves beneficial for almost all models, as COMET scores typically improve with the CAT-5 and CAT-10 datasets, whether models are trained from scratch or finetuned. Among models trained from scratch, Transformer Enc-Dec, Mamba-MHA, and Mamba Enc-Dec show substantial improvements, with Mamba Enc-Dec achieving the best overall results. For finetuned models, concatenation benefits larger models; Mamba-M outperforms Pythia-M in DE→EN but underperforms in EN→DE. Interestingly, for both training regimes, the concatenation strategy can lead to COMET gains of up to 5 points.

Finetuning outperforms training from scratch. Finetuned models consistently achieve higher COMET scores, with larger models attaining the top results overall. Similar to sentence-level experiments, Pythia outperforms Mamba when trained on the original, WMT23-6M dataset. However, both Pythia and Mamba benefit from our concatenation strategy. While these results indicate that our concatenation strategy helps in translating long inputs, it remains unclear whether performance on short inputs is compromised or if the models can handle longer inputs than those seen during training. We investigate these issues next.

5.2 Sensitivity to Input Length

Based on the previous observations, we notice that performance between models varies considerably after being exposed to different sequence lengths during training. In this subsection, we investigate how robust each model is to length distribution shifts between training and test. Results are shown in Figure 2 for both training regimes on the WMT23 DE→EN dataset. Results are consistent for EN→DE, shown in Figure 6, Appendix D.

Discussion. When training on WMT23-6M, we observe a decline in performance for all models on long sequences, affecting both trained-from-scratch

[8] We dropped RetNet and Mamba-Local as they already achieve poor results on long *sentence-level* inputs (see Fig. 5).

		DE→EN			EN→DE		
MODEL	SIZE	ORIG.	CAT5	CAT10	ORIG.	CAT5	CAT10
Trained from scratch							
Transf. Enc-Dec	77M	72.4	74.6	69.6	65.2	70.3	70.3
Transformer++	79M	70.7	73.6	72.8	64.8	69.1	68.8
Mamba	77M	70.0	73.3	72.3	63.3	67.5	67.8
Mamba-MHA	78M	72.7	74.2	74.5	67.0	68.6	69.7
Mamba Enc-Dec	82M	70.7	73.8	**75.6**	65.3	**71.0**	70.1
Finetuned							
Pythia-S	410M	77.4	78.4	79.0	76.7	77.8	77.1
Mamba-S	370M	77.2	78.2	78.3	72.4	74.2	73.1
Pythia-M	1.4B	76.2	78.6	79.4	75.8	77.4	**79.0**
Mamba-M	1.4B	74.6	**79.6**	79.5	73.4	77.5	77.3

Table 3: Paragraph-level results in terms of COMET for models trained from scratch (top) and models finetuned from a pretrained checkpoint (bottom) on WMT23 EN↔DE test set, according to the training dataset: original WMT23-6M, WMT23-CAT-5 and WMT23-CAT-10. **Bold** represents top results; underline represents second-best.

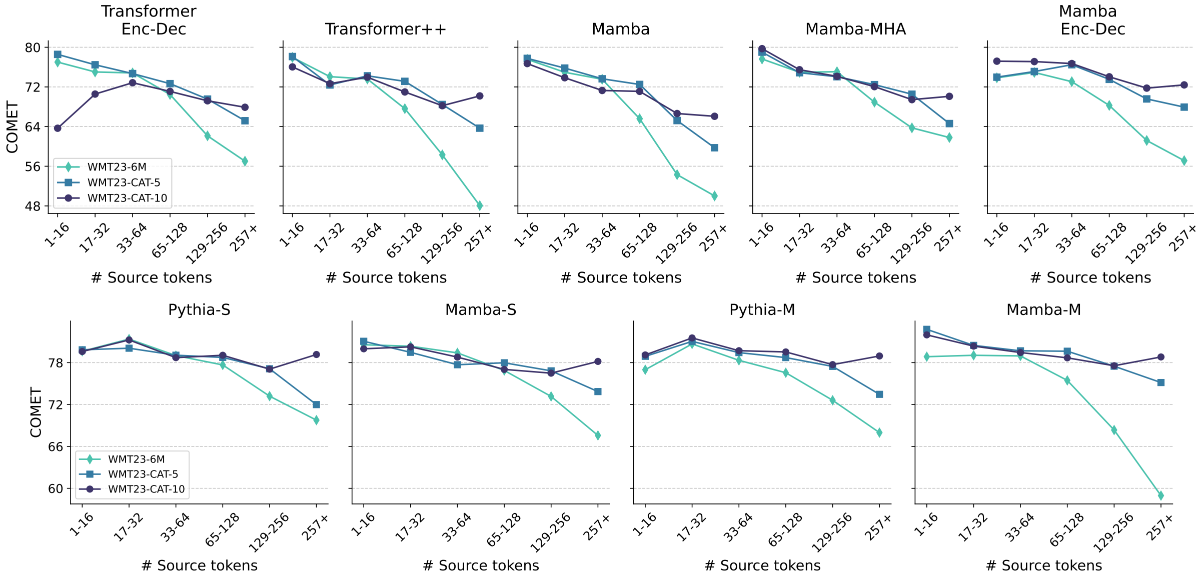

Figure 2: Sensitivity to input length, measured by the number of sources tokens, on the WMT23 DE→EN datset, for models trained from scratch (top) and finetuned from a pretrained checkpoint (bottom).

and finetuned variants. Interestingly, this degradation is evident in Mamba, as expected due to its finite hidden state capacity. However, it is also challenging for transformers despite their relative positional embeddings. Moreover, both finetuned and hybrid models exhibit more consistent performance across different sequence lengths, even on the original sentence-level dataset, suggesting a more robust capability for dealing with long-context inputs.

Overall, our concatenation approach has largely mitigated the performance issues with long inputs present in models trained on WMT23-6M, as models trained on CAT datasets produce higher-quality translations for longer sequences. This improvement is uniform across all models, with CAT-10 yielding consistently better translations in the longest bin (257+ tokens). However, the CAT-10 dataset seems to reduce translation quality for shorter samples in some models, though this effect is minimal or absent in hybrid and finetuned models. Next, we further examine the ability to extrapolate to even longer sentences than those seen during training.

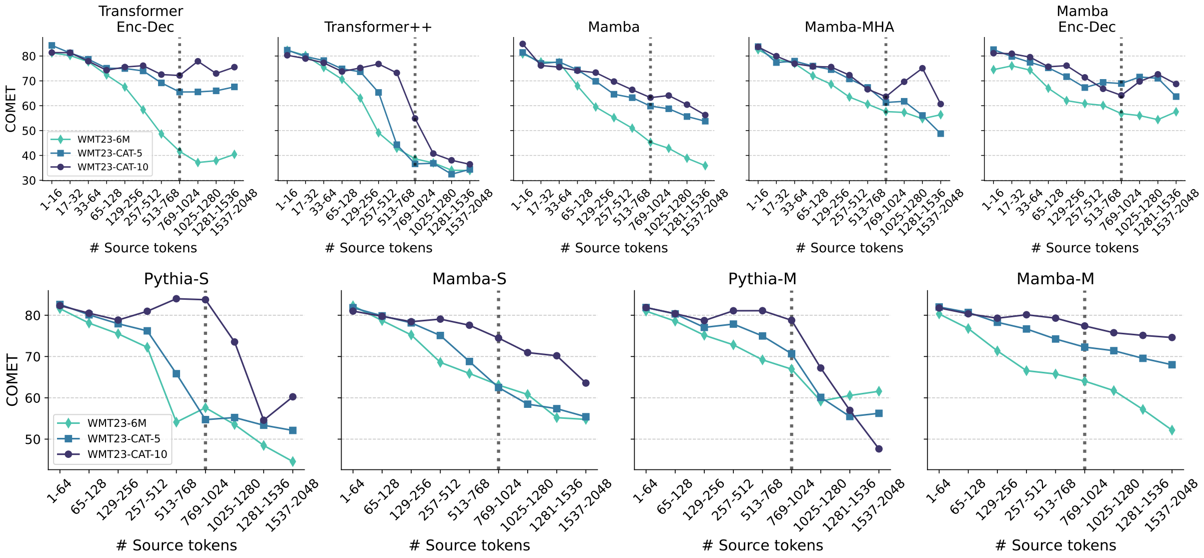

Figure 3: Sensitivity to input length, measured by the number of sources tokens, on the Ted Talks DE→EN dataset, for models trained from scratch (top) and finetuned from a pretrained checkpoint (bottom). The dashed vertical line represents the bin containing the longest sentence in the training set.

5.3 Extrapolation to Longer Sequences

Following the previous discussion, to further explore the impact of sequence length on our models, we create a new test set sampled from TED Talks DE→EN passages that is larger (2200 samples) and contains even longer sequences (up to 2048 tokens) than WMT23. Details on this dataset can be found in Table 1. The source length distribution can be seen in Figure 7. After evaluating our models in this dataset, we plot COMET scores per sentence length in Figure 3, where we include a dashed vertical line representing the bin containing the longest sentences the model has been exposed to during training.

Discussion. When training from scratch, we highlight the sharp decline in translation quality decline in the Transformer++ model when considering samples larger than those it has been exposed to during training, this finding is consistent with the generalization task in (Jelassi et al., 2024). In contrast, Transformer Encoder-Decoder and Mamba exhibit a steady decline overall with the first being robust to generalization problems when trained with larger-context datasets. Additionally, the hybrid models prove to excel at generalization, providing good translation quality even when trained with the WMT23-6M dataset. With the finetuned models, we also see decreasing translation quality over longer sequences which is consistent with previous experiments. Nonetheless, Mamba models show a more robust trend when generalizing to unseen lengths. In particular, the larger Mamba-M, when trained on the WMT23-CAT-10 dataset, exhibits a much lower performance degradation on longer samples in comparison to other finetuned models.

5.4 Inference Cost

In §2 we covered the theoretical time complexity of our models in training and inference time. Here, we examine the wallclock time and memory usage of Pythia and Mamba in a realistic setting where inputs are WMT23 DE→EN test samples, and outputs continue to be generated until they reach exactly $L \in \{512, 1024\}$ tokens. Table 4 shows that Mamba's memory usage is significantly lower than Pythia's, with gaps of $\sim$ 3-5x overall. The wallclock time difference is not as notable but still substantial, especially for larger models, where Mamba-M is 2x faster than Pythia-M for $L = 1024$. In other words, Mamba-M throughputs ~806 tokens/s while Pythia-M outputs ~405 tokens/s, aligning with (Gu and Dao, 2023).[9]

6 Related Works

Linear recurrent models for MT. Our work is closely related to (Vardasbi et al., 2023), which compares SSMs and transformers. Furthermore, they also experiment with hybrid architectures composed of S4 and attention layers, an approach that has since become common (Arora et al., 2024b; De

[9] Computed as batch-size × L/wallclock-time.

	512		1024	
MODEL	T (S)	M (GB)	T (S)	M (GB)
Pythia-S	11.52	2.472	25.80	3.934
Mamba-S	10.38	0.839	20.59	1.607
Pythia-M	14.88	4.789	40.41	7.841
Mamba-M	10.29	0.913	20.31	1.668

Table 4: Average time (T) and maximum allocated memory (M) of 30 inference runs with batch size 16 on WMT23 DE→EN.

et al., 2024; Glorioso et al., 2024). In this work, we experiment with more recent linear recurrent models and their respective hybrid versions while also including larger and pretrained variants. Our analysis further includes investigating each model's ability to recall named entities, along with measuring translation performance across different sequence lengths on paragraph-level datasets. In contrast to Vardasbi et al. (2023)'s results showing that S4 lags behind transformer baselines in MT tasks, we observe that Mamba, a modern SSM, is competitive with transformers on sentence and paragraph-level datasets, whether trained from scratch or fine-tuned from a pretrained checkpoint, especially in the first setting when equipped with attention mechanisms.

Linear recurrent models' limitations. Recent works show that Mamba struggles in tasks that involve recalling context tokens (Arora et al., 2024a; Jelassi et al., 2024), such as the synthetic Multi-Query Associative Recall task. In MT, however, context tokens (source and translation prefix) are not often replicated in the output (translation). In this work, we study this phenomenon with named entities and analyze the recall ability of transformers and linear recurrent models in §4.2.

Sentence concatenation Kondo et al. (2022); Varis and Bojar (2021) analyze transformers' generalization towards sequence length. They show that transformers are susceptible to the training distribution of context length and that concatenating multiple sentences can improve the translation of longer sentences. Specifically, Kondo et al. (2022) augment the original data with samples containing concatenations of two random sentences, while Varis and Bojar (2021) concatenate up to six sentences. While these studies focused on sentence-level translation with sequence lengths up to 120 tokens, in this work, we extend the analysis to much longer sequences and test on paragraph-level data from the WMT2023 dataset.

7 Conclusion

We set out to evaluate recent linear recurrent models, particularly RetNet and Mamba, in MT tasks while thoroughly comparing them to transformer baselines and hybrid models, which combine Mamba and attention. We find that Mamba models are competitive with transformers, both when they are trained from scratch and when they are finetuned from a pretrained checkpoint; however, the performance delta is smaller in the latter regime. Our paragraph-level experiments reveal that models are hindered by the mismatch in the training and test length distributions; however, a simple concatenation approach helps to mitigate the issue. We find that hybrid models are only slightly affected by this issue while also being competitive or outperforming transformers. Finally, we note that Mamba models also exhibit a faster runtime, consume less memory, and extrapolate better to longer inputs than decoder-only transformers.

Acknowledgments

Limitations

We point out some limitations of the presented study. First, one limitation is that we refrain from pretraining the hybrid models due to the high associated compute costs. To this effect, while our trained-from-scratch results are promising, validating them with a larger scale and strong language priors would strengthen our claim of their good performance. Secondly, our experiments (§5.3) appear to indicate larger models are more robust to sequence length issues. Nonetheless, we limited our study to models with parameter scales between 370M and 1.4B since, in preliminary sentence-level experiments, translation quality gains plateaued at the latter scale.

In another direction, we mainly rely on automated metrics for evaluating translation quality, which might not fully capture the accuracy of the translation. We alleviate this fault by considering the recollection of NEs in translations (§4.2). Furthermore, our experiments in §5.2 do not have a notion of translation difficulty, which might help explain the differences between models and associated datasets in different length buckets (albeit sentence length and difficulty may be connected).

Potential Risks

Translation biases and error modes inherent in transformed-based LLMs could also be manifested in the linear recurrent models studied in this paper. Careful evaluation and mitigation strategies, such as detecting and overcoming hallucinations (Guerreiro et al., 2023; Dale et al., 2023), can alleviate these risks and ensure models' responsible use. It should also be noted that although SSMs are potentially more energy efficient than transformer-based models, they still pose energy consumption concerns, particularly due to the large size of the models.

A Implementation and Training Details

All experiments were carried on Nvidia RTX A6000 GPUS with 48GB VRAM, and the training framework is constructed around PyTorch Lightning.[10] To train and generate translations in batches, we use a left-padding strategy. However, for Mamba, additional functionality is required to avoid processing padding tokens. To address this, we zero out inputs before and after convolution at the positions of the padding tokens and sacrifice some efficiency by using the slow path in Mamba.[11] Notably, during inference, the slow path affects only the initial processing of the prompt and does not impact the actual generation. Moreover, we added Dropout (Srivastava et al., 2014) to Mamba blocks, which was missing in the original implementation. Specifically, dropout is applied after the last linear projection of the Mamba block. Additionally, following the findings in (Vardasbi et al., 2023), we calculate cross-entropy loss only for target tokens. During training, we use greedy decoding and select the top model using BLEU as the validation metric, as it is faster to compute in comparison to COMET. For inference, we use beam search with a beam size of 5. Due to the time-consuming nature of our experiments, we report the results of a single run for all experiments. The overall model structure and hyperparameters across both training regimes, from-scratch (§A.1) and finetuning (§A.2), are shown in Table 5. Furthermore, all models were trained with `bfloat16` precision.

A.1 Training from Scratch

Regarding tokenization, we leverage the HuggingFace *tokenizers* library[12] and construct a separate BPE tokenizer (Sennrich et al., 2016) per dataset. The total vocabulary size is 32000 tokens. We carried out a hyperparameter search to select appropriate dropout values, learning rates and architectural decisions, with the latter two detailed in Table 5. We employ a dropout of 0.3 for WMT16 EN↔RO, 0.1 for WMT14 EN↔DE, WMT16 EN↔FI and the different variations of WMT23. Other hyperparameters were kept intact. Concretely, we use the Inverse Square Root learning rate scheduler (Vaswani et al., 2017) with 4000 warmup steps and a weight decay of 0.001.

Table 6: Pre-training details. All models were pretrained on The Pile (Gao et al., 2020).

A.2 Finetuning Pretrained Checkpoints

We employ pretrained models and corresponding tokenizers from the Huggingface library. Table 6 shows the number of tokens and the size of the context window used during pretraining. For finetuning, in all experiments, we use a dropout of 0.1 with the exception of WMT16 EN↔RO and Pythia-S + EN↔FI, where dropout varies from 0.1 to 0.3 for the former and 0 for the latter. Moreover, we use weight decay only in Mamba-M, with a value of $2 \cdot 10^{-4}$. Additionally, learning rates and models' attributes are shown in Table 5.

A.3 Inference Cost

For the inference cost experiments, we measure overall wallclock time using cuda events and cuda synchronization from `torch.cuda` module. The overall reported time measures the entire generation pipeline, including the use of beam search. Moreover, we use

Table 8: Hybrid models ablations with BLEU and COMET scores on the IWSLT17 dataset. Different window sizes are denoted as w$\{16, 32, 64, 128\}$. *Interleaved* refers to alternating Mamba and attention layers. L*1,11* and L*11,23* refer to placing attention in layers 2 - $N/2$ and $N/2$ - N, respectively.

`torch.cuda.max_memory_allocated` to measure memory usage.

We additionally include the profiling measurements for the trained-from-scratch models in Table 7. Crucially, we advise that these metrics are rough estimates since the models are not optimized to perform at their best capacity. To this end, we do not include the Transformer Encoder-Decoder as the implementation used is not efficient.

B Hybrid Models Ablation

Building on the shortcomings of linear models (Akyürek et al., 2024; Arora et al., 2024a; Jelassi et al., 2024), we designed hybrid models to complement SSMs with attention mechanisms. In this section, we ablate the design choices leading to the construction of our hybrid models. These experiments were conducted using the IWSLT17 DE↔EN dataset (Cettolo et al., 2017). Results are shown in Table 8.

Since our Mamba-MHA model replaces a set of Mamba layers with attention modules, we ablated various configurations to determine the optimal number and placement of attention layers. Our analysis of COMET scores indicated that incorporating two attention layers significantly boosted performance, aligning with findings in previous studies (Fu et al., 2023). The placement of these layers had a minimal effect, leading us to select the configuration with layers at positions $N/2$ and N for further experiments due to its consistently higher COMET scores.

In the case of Mamba-Local, which uses a sliding window attention, we explored various window sizes. Our experiments revealed that performance generally improved with window size in a linear way. Ultimately, a 128-token window nearly matched full attention performance, and two layers of 64-token windowed attention provided a good balance between performance and efficiency for our experiments.

C Named Entity Recall Experiments

Following up on the discussion from §4.2, we extend our evaluation of NE recall accuracy to the WMT14 DE↔EN dataset and two paragraph-level datasets, WMT23-6M and WMT23-CAT-5, both in the DE↔EN translation direction. The results, detailed in Figure 4, offer further insights into the models' recall accuracy performance across other datasets and context length settings.

Sentence-Level (WMT14 DE↔EN). The NE recall results on the WMT14 DE↔EN dataset align closely with those obtained in WMT16 RO→EN, shown in Figure 1; we still observe Mamba's recall accuracy to be closer to that of the transformer models, while the hybrid models continue to (slightly) outperform their unmodified counterparts. Note, however, that overall, the gap between models is narrower, as also reflected in their close results in terms of BLEU.

Paragraph-Level Datasets. When assessing the WMT23-6M and WMT23-CAT-5 DE↔EN datasets, contrary to the WMT16 RO↔EN experiments, the Transformer Encoder-Decoder model outperforms all other models in recalling unseen entities. Additionally, while the hybrid models remain comparable to the Transformer++ model, Mamba's performance declines. This presents a striking contrast to the sentence-level experiments, suggesting that transformers may have an advantage in NE recall when shifting to longer contexts. Nonetheless, the transition from the 6M dataset to the CAT-5 dataset

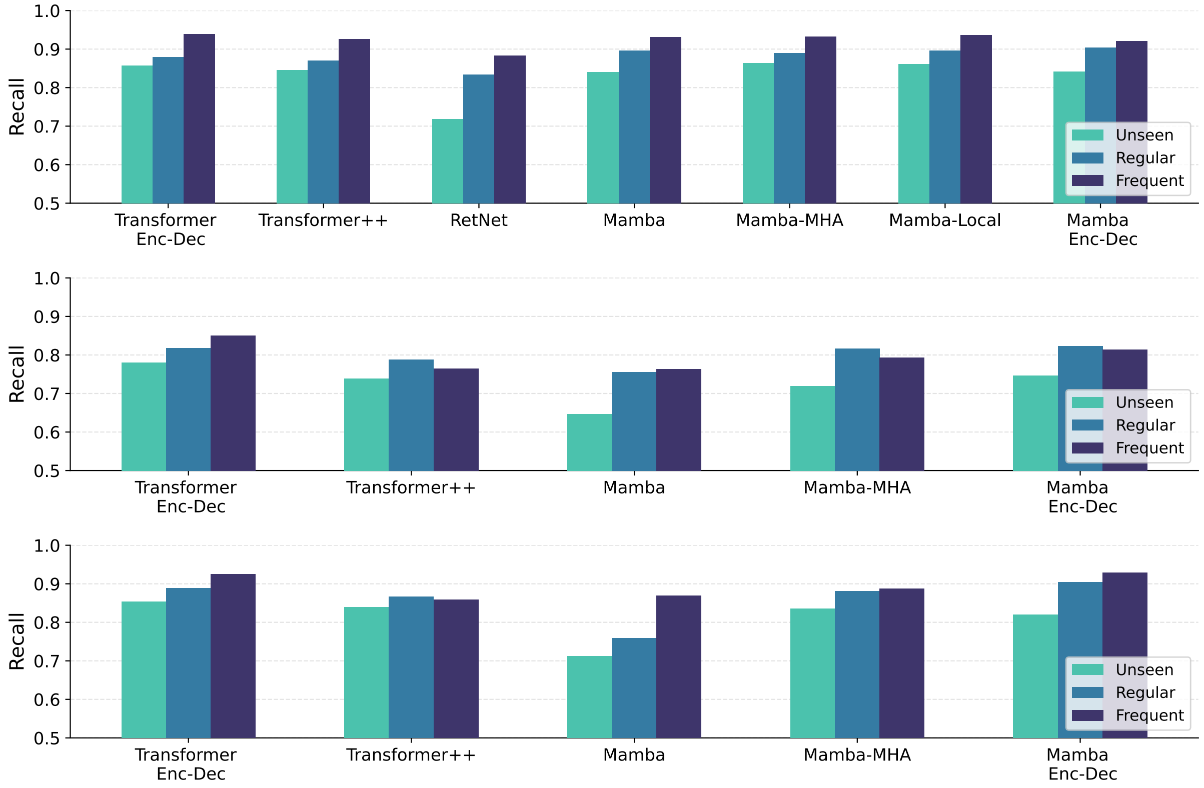

Figure 4: Recall in recovering named entities on the WMT14 (top), WMT23-6M (middle) and WMT23-CAT-5 (bottom) DE→EN datasets, by their training set frequency: *unseen* entities do not appear in the training data, while *regular* and *frequent* entities appear $[1, 16)$ and $16+$ times.

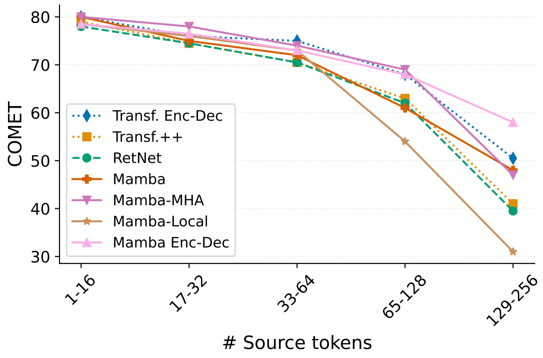

Figure 5: COMET scores per sequence length on WMT14 DE→EN for trained-from-scratch models.

leads to recall improvements across all models, particularly for unseen entities. This indicates that the additional context provided during training in the CAT-5 dataset aids the recall of named entities.

D Exploring Length-related Issues

D.1 Preliminary Sentence-level Experiments

Before experimenting with paragraph-level data, we analyze how our trained-from-scratch models perform on different sequence lengths. To this end, we study their sensitivity to input length when trained and tested on WMT14 DE→EN. The results are shown in Figure 5. While all models show a deterioration in performance as sequence length increases, this effect is more pronounced for Transformer++, RetNet, and Mamba-Local, with a significant drop in performance for samples longer than 64 tokens.

D.2 Sensitivity to Input Length

Following the discussion in §5.2, we further investigate the sensitivity of our models to input length using the WMT23 EN→DE test set, with results shown in Figure 6. Notably, our takeaways remain broadly the same: concatenating samples in the training data is indeed helpful when handling longer sequences, and models trained on the WMT23-CAT-10 dataset are much better in the longer bin (257+) with minimal translation quality degradation in shorter samples. However, when considering each of the training datasets' histograms in Figure 7, we can observe that models have been exposed to the longest samples during training, even if in low quantities. This implies that the previous experiments do not represent an extrap-

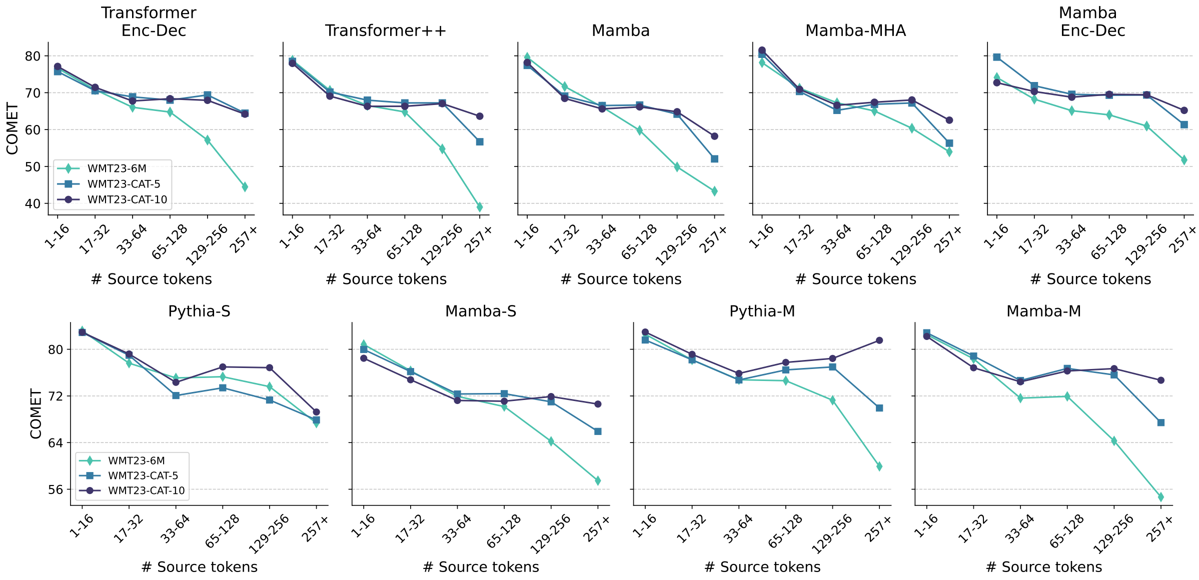

Figure 6: Sensitivity to input length, measured by the number of sources tokens, on the WMT23 EN→DE datset, for models trained from scratch (top) and finetuned from a pretrained checkpoint (bottom).

olation setting, where inference is done on longer sequence lengths than those seen during training. We cover extrapolation to longer sequences next.

E Full Paragraph-Level Results

For completeness, we report paragraph-level results in terms of BLEU and COMET for all language pairs and models in Table 9.

Evaluation and large-scale training for contextual machine translation

Matt Post and **Marcin Junczys-Dowmunt**
Microsoft
{mattpost,marcinjd}@microsoft.com

Abstract

Despite the fact that context is known to be vital for resolving a range of translation ambiguities, most traditional machine translation systems continue to be trained and to operate at the sentence level. A common explanation is the lack of document-level annotations for existing training data. This work investigates whether having such annotations would be helpful for training traditional MT systems at scale. We build large-scale, state-of-the-art contextual MT systems into German, French, and Russian, fixing the datasets while comparing the effect of sourcing contextual training samples from both parallel and back-translated data. We then evaluate these contextual models across a range of contextual test sets from the literature, where we find that (a) document annotations from both mined parallel and back-translated monolingual data are helpful, but that the best contextual MT systems do not draw *contextual* training samples from the parallel data. We also make two points related to evaluation: (b) contrastive score-based metrics on challenge sets are not discriminative; instead, models must be tested directly on their ability to generate correct outputs, and (c) standard corpus-level metrics such as COMET work best in settings that are dense in contextual phenomena.

1 Introduction

By nature of its sentence-based design, traditional machine translation (MT) is unable to correctly translate any sentence with extra-sentential dependencies, such as pronouns in languages with grammatic gender, except by chance (Table 1). Despite significant prior work on the topic (§ 2), and general acknowledgment of the need to move on (Sennrich, 2018), contextual translation has never managed to overtake MT research, and sentence-level systems continue to dominate. This "sentence-level ceiling" leaves a gap between them and their increasingly powerful LLM counterparts, and raises the question of whether this gap can be narrowed or closed, if traditional MT systems could be trained properly with context.

English	**German**
I lost my hat. *Have you seen it?*	Ich verlor meinen Hut. *Hast du* es *gesehen?*

Table 1: The sentence-level translation ceiling. Selecting the correct pronoun (*ihn*, masc.) requires context.

A common explanation for the lack of context in MT has to do with the relative dearth of document-level annotations that are available for mined parallel and even monolingual data. At the same time, it has long been understood (Venugopal et al., 2011) and recently corroborated (Thompson et al., 2024) that crawled bitext is rife with machine translation output, which—though high quality at the sentence level—may attenuate the contextual signal. We explore this central problem by building the first large-scale, state-of-the-art translation systems trained on data with complete document annotations. We are able to do this because instead of public data, we use a private, in-house dataset (§ 3) that we have crawled ourselves. This crucially allows us to explore the effects of document annotations sourced from both parallel and monolingual (backtranslated data), together and in isolation, in order to quantify their effects. We find that:

- **It is best to source contextual training examples from backtranslated data only**. We find gains in contextual metrics from systems trained with contextual signals from both parallel and backtranslated data. However, the best systems source these samples from backtranslated data only.
- **Generative evaluation is crucial**. Contrastive metrics, where the task is to discriminate good and bad translations using model

Proceedings of the Ninth Conference on Machine Translation, pages 1125–1139
November 15-16, 2024 ©2024 Association for Computational Linguistics

scores, are often used to evaluate contextual MT. We show that contextual systems that are trained on mined parallel documents do well on this task, but perform poorly when asked to generate correct translations. Only generative evaluation, which looks at whether correct words were produced, distinguishes good from bad contextual systems.

- **Standard metrics are most useful on discourse-dense datasets**. Standard sentence-level metrics like COMET are much more discriminative between sentence- and contextual systems when applied to datasets that are dense in discourse phenomena.

Together, these results raise important considerations for the construction and evaluation of contextual translation systems.

2 Background and Related Work

The transition to neural architectures was a paradigm enabler for document translation, since it eliminated the Markov limitations of statistical MT (Maruf et al., 2019). Much work has focused on special architectures and input encodings. This includes cache models (Tu et al., 2018; Kuang et al., 2018), hierarchical attention (Miculicich et al., 2018), separately encoding context (Voita et al., 2018; Zhang et al., 2018), allowing attention across a batch of pseudo-documents (Wu et al., 2023), encoding sentence position (Bao et al., 2021; Lupo et al., 2023), and sparse attention mechanisms (Guo et al., 2019). A number of approaches work on base systems outputs, such as post-editing with contextual language models (Voita et al., 2019a) and using contextual language models to rerank sentence-level system output Yu et al. (2020). Junczys-Dowmunt (2019) built one of the earliest contextual systems to perform well at WMT. Sun et al. (2022) also proposed to use standard transformer models, testing small architectures with no backtranslated data, and using a "multi-resolutional" training approach that creates overlapping documents. **We focus instead on standard architectures, judging them to be sufficient at large enough sizes.**

The lack of document-annotated parallel data is a longstanding problem. Datasets with document annotations are relatively small and specialized: they include OpenSubtitles (Lison and Tiedemann, 2016), WIT^3 (Cettolo et al., 2012), News Commentary, and Europarl (Koehn, 2005). Liu and Zhang (2020) provide a nice survey, and release a small amount of government-crawled new data for Chinese–Portuguese. Very recently, document annotations on Paracrawl data have become available Pal et al. (2024); Wicks et al. (2024). These annotations are available for only a relatively small subset of the data, however; even so, their results corroborate what we find here. (2024, Table 2) see *drops* in performance from systems trained with their parallel data annotations, unless the gold target context is provided; (2024) see small but consistent gains when the parallel data has been sufficiently filtered. The Conference on Machine Translation (WMT) began releasing limited document-level data for DE-EN and CS-EN in 2019 (Barrault et al., 2019). This limitation has forced researchers to get creative. Voita et al. (2019b) built a monolingual post-editing system that took the output of a baseline system and used it for document-level "repair". Sugiyama and Yoshinaga (2019) also used target-side data for backtranslation, evaluating in small-data settings with BLEU and contrastive metrics. **Our work is unique in that we have complete document annotations on very large web-crawled datasets**, and shows that these annotations on parallel data, as a whole, are not as useful.

Contextual metrics work has been important. PROTEST (Guillou and Hardmeier, 2016) used hand-designed pronoun test cases and also evaluated generatively. Many special test sets have been developed isolating important contextual phenomena and largely evaluating discriminatively (more in § 4). Läubli et al. (2018) provided early evidence that document-level metrics would be helpful. Several document-level metrics have been proposed, including BlonDe (Jiang et al., 2022), which compares automatically-identified phenomena in the output to those in a reference, and Doc-COMET (Vernikos et al., 2022), which incorporates contextual sentence representations. Both metrics are interesting but await deeper evaluation and we did not explore them in this paper. Vamvas and Sennrich (2021) have also noted the problem with the disconnect between contrastive evaluation and generative ability for machine translation. Both Fernandes et al. (2023) and Wicks and Post (2023) developed rules to identify contextually-dependent sentences. In this work, we show that **datasets dense in contextual phenomena are important for evaluating contextual ability**, and that **discriminative contextual evaluation is of limited use**.

3 The data challenge

Large publicly-available parallel datasets do not have document annotations. While the Conference on Machine Translation (WMT) has made overtures in this direction,[1] including ensuring that test data is source-language-natural and contains document information, parallel and monolingual data is limited to a small subset of all data[2] for which such information is easily retained. This is also true of recent work extracting document annotations from Paracrawl (Pal et al., 2024; Wicks et al., 2024).

We wish to experiment with and compare annotations sourced from both parallel and back-translated monolingual datasets. We therefore turn instead to a state-of-the-art, large collection of in-house data. We work with three language pairs: English→German, English→French, and English→Russian, which were selected because of the availability of good contextual evaluation data in each of them (§ 4). Our data comprises the following sources (Table 2):

- Monolingual data, crawled from expected-native sites: news (10%), data linked from the Open Directory Project[3] (40%), filtered webcrawl (40%), and Wikipedia and its outlinks (10%).

- Crawled parallel web data (similar to ParaCrawl)

- CCMatrix parallel data (Schwenk et al., 2021b), which has no document information.

Datasets have been filtered using bicleaner (Ramírez-Sánchez et al., 2020), with additional boilerplate and document deduplication.

Although the dataset is private, there is nothing in it that would surprise any researcher; the data was crawled from the web using standard techniques. The parallel data sources include a rough equivalent of ParaCrawl (Bañón et al., 2020) and also CCMatrix (Schwenk et al., 2021b). The monolingual data sources focus on sites where we expect data to have been written natively.

We emphasize that experiments at the scale presented in this paper are only possible with our private dataset, since document annotations are only available for small-data training settings like the TED talks data (Cettolo et al., 2012) used by IWSLT.[4] In a nod to the importance of repeatable work, we include results on the subset of our experiments that are possible on English–German public data and show that they corroborate corresponding results on private data (Section 7.6).

4 Contextual evaluation

A basic hurdle in the path to contextual translation is the difficulty of evaluation. We expect that contextual systems will produce improved translations of discourse-level phenomena, however, the frequency of these phenomena in standard corpora is not known, and we expect them to be relatively rare. This paper includes three types of evaluation.

4.1 Corpus-level metrics

The conventional way to test system performance is with standard metrics such as chrF (Popović, 2015) or COMET (Rei et al., 2020), which accumulate sentence-level scores to compute a single score for a test set. If the test set is organized into documents (as many are, including those from WMT), its sentences can be translated contextually and then split back out to sentences for evaluation. The expectation is that contextual translation will produce gains. However, a key consideration is whether the dataset is dense enough with contextual phenomena. Attempts to automatically identify sentences requiring context have shown the task to be difficult (Bawden et al., 2018) though possible with hand-created rules (Fernandes et al., 2023; Wicks and Post, 2023), but are often rare. Consequently, improvements may be invisible without the right test set.

We compare the performance of contextual systems using a standard corpus-level metric, COMET[5], on the following two test sets:

- WMT15. We use newstest2015 (Bojar et al., 2015) for EN→FR, and newstest2022 for EN→DE and EN→RU (Kocmi et al., 2022).

- OpenSubtitles (Lison and Tiedemann, 2016). We use the CTXPro (Wicks and Post, 2023) gender dataset, which is large and focuses on pronouns and anaphora.

Table 2: Statistics of the training data used in our experiments (lines and docs in millions). The *mean* column is the mean document length in sentences of documents with ≥ 2 sentences.

Because the CTXPro dataset was constructed to select them, we expect it to be much denser in discourse phenomena. Data sizes are listed above the results in Table 3.

4.2 Contrastive test sets

The dominant paradigm for evaluation of long-tail document phenomena has been so-called *contrastive evaluation* (Sennrich, 2017), in which a system is tested on its ability to discriminate (via assigned model score) between correct and incorrect translation pairs. The correct examples are usually taken from found text; the incorrect ones are created by inserting an error of some sort. We look at three such test sets, examples of which can be found in Appendix A.

ContraPro (EN-DE) Müller et al. (2018) focus on the German pronouns *es*, *er*, and *sie*. They pair sentences containing naturally-found instances of pronouns drawn from OpenSubtitles with two variants where the incorrect pronoun has been used.

ContraPro (EN-FR) Lopes et al. (2020) extended ContraPro for EN-FR; the main difference is that there is only one incorrect example, since French has only two grammatical genders.

GTWiC (EN-RU) (Voita et al., 2019b) *Good Translation, Wrong in Context* (GTWiC) tests verb selection (500 instances) and morphology (500) in the presence of source-side ellipsis.

4.3 Testing generative ability

The challenge sets above test whether a model can discriminate between good and bad examples with using model score. However, this is at best a proxy for the true test of a machine translation system, which is to determine whether it generates the correct word or phrase. As we will show, many document models perform extremely well on these tasks, but when asked to actually translate the source sentence, produce the wrong word (Table 5). The contrastive nature of these test sets is at odds with the actual task: what is needed are metrics that directly evaluate a model's *generative*, rather than its *discriminative*, ability.

Fortunately, because these test sets were distributed with rich annotation information, we can transform them into generative test sets, where we test for the correct word in the output. A test set $\mathcal{T}$ comprises a set of test examples in the form of tuples (S, R, w), where S is the source sentence, R the reference, and $w \in R$ the target word or phrase that is expected to be found in the translation output. Let $\{T_i\}$ be the set of translations of the source sentences $\{S_i\}$. We compute accuracy[6] as

$$\mathrm{acc}(T, \mathcal{T}) = \frac{1}{|T|} \sum_{i=1}^{|T|} \delta(w_i \in T_i)$$

This is not a perfect metric, since a correct translation may have paraphrased around the pronoun, but we do not expect that to systematically favor any particular system.

We have further opportunity to test this kind of accuracy with **CTXPro** (Wicks and Post, 2023), which expands ContraPro's coverage to many other languages and linguistic phenomena (auxiliaries, formality, gender, and inflection). CTXpro is evaluated only generatively, and has been been tested only on a single system, DeepL,[7] which is known to make use of context.

5 Experimental setup

We train and compare five models on the exact same data from two sources: parallel ($\mathcal{P}$) and back-translated monolingual ($\mathcal{B}$) data; the only difference among the models is whether document sam-

[6] Here accuracy is the same as both precision and recall.

[7] deepl.com

ples are drawn from neither, one, or both of the datasets.

Training All models are transformers trained with Marian (Junczys-Dowmunt et al., 2018a,b). We create two classes of models: first, those for backtranslation, and second, a set of models that constitute our primary comparative evaluation. For each language pair, we build a single joint unigram subword model (Kudo, 2018) with a vocabulary size of 32k that is used for both sets of models. Models are trained on random permutations over the training data for a predetermined number of updates. We use a batch size of 500k target-side tokens and a maximum sample length (whether sentences or pseudo-documents) of $L = 256$ tokens.

Backtranslated data The monolingual data is backtranslated (Sennrich et al., 2016) using sentence-level transformer systems (Vaswani et al., 2017) with 12 encoder and 6 decoder layers, an embedding size of 1024, and a feed-forward dimension of 8192. These models are trained for 20 virtual epochs.

This backtranslated data will be used to train contextual systems, but we note that this is not a problem, for two reasons. The major reason is that the target-side contextual signal is unaffected by backtranslation; since the original document boundaries are retained, any mistakes introduced by sentence-level backtranslation will appear just as normal source-side noise that the model must learn to overcome. Losses will be computed against the original, intact, target-side context. Second, even if this were not the case, our backtranslation models are into English, which is morphologically simpler than the evaluated translation direction.

Models For our contextual models, we also train transformers with a 12-layer encoder, a 6-layer decoder, and an embedding dimension of 1,024, but increase the feed-forward network size to 16,384. These models are trained for 40 virtual epochs to reflect the larger amounts of training data.

All of our models are trained on the complete parallel ($\mathcal{P}$) and backtranslated ($\mathcal{B}$) data. They vary only in whether the training procedure is permitted to construct multiple-sentence samples (also called *pseudo-documents* or *chunks*) from both, neither, or exactly one of these two pools of data. We compare the following systems, using the syntax NAME(pool$_1$, pool$_2$) to denote the pools of data each draws from; the presence of a box around the data source notes that pseudo-documents were drawn from it.

- SENT($\mathcal{P}$,$\mathcal{B}$). A sentence-level baseline.
- RAND($\dddot{\mathcal{P}}$,$\dddot{\mathcal{B}}$). A contextual system, but trained with completely random contexts.
- DOC($\dddot{\mathcal{P}}$,$\dddot{\mathcal{B}}$). A contextual system, with documents from parallel and back-translated data.
- DOC($\dddot{\mathcal{P}}$,$\mathcal{B}$). A contextual system, with documents drawn from parallel data only.
- DOC($\mathcal{P}$,$\dddot{\mathcal{B}}$). A contextual system, with documents drawn from backtranslated data only.

Creating samples We create our training data on the fly using SOTASTREAM (Post et al., 2023), which iterates over $\mathcal{P}$ and $\mathcal{B}$. At each iteration, each data source is permuted randomly at the document level. To generate each sample, SOTASTREAM first chooses randomly between the two data pools. If documents are disabled on the pool, it simply returns the next sentence pair. If documents are enabled, it then chooses a maximum token length, and concatenates sentences on both sides until this length is reached on the source side, or the document's end is reached. Concatenated sentences are joined with a special $\langle$SEP$\rangle$ token, which facilitates sentence alignment at inference time for evaluation. Contextual samples are *chunked*, our term for the 1:1 concatenative construction described in Tiedemann and Scherrer (2017).[8] The training toolkit is then responsible for buffering as many samples as are needed to sort and form batches for training.

Inference For inference, we use the *last sentence* approach as defined in Herold and Ney (2023): each input sentence (the *payload*) is prepended with left sentence context, up to a maximum token length, L, which includes the payload. The translation system translates this as a single unit. The $\langle$SEP$\rangle$ token is then used to extract the payload's translation. This is repeated for all sentences in a test set, allowing standard sentence-level metrics to be applied to the results.

6 Results

Sentence-level metrics We begin by establishing baseline scores with a standard corpus-level metric, COMET, in Table 3. We include a commercial

[8] This can be contrasted with the "multi-resolution" approach of Sun et al. (2022), which creates training samples of different lengths from many overlapping sub-sequences of each input document

Table 3: COMET20 scores on WMT (22/15) and OpenSubtitles (CTXPro/gender) test sets translating alone (top block) and with context (bottom block). Numbers within a column are comparable. The gains from DOC($\mathcal{P}$,$\ddddot{\mathcal{B}}$) (with context) over SENT($\mathcal{P}$,$\mathcal{B}$) (without it) are much larger for the discourse-dense OpenSubtitles data.

baseline (Microsoft, accessed via API). As another baseline, we present sentence-level results for the sentence-level system trained on all of our data. We then present results for all our models translating the test corpora (WMT and OpenSubtitles, using the CTXPro/gender dataset) in two modes: at the sentence level (top block), and with context (bottom block). In this way, we can look at the effect of context at both training and inference time.

Accuracy-based generative evaluation Next, we look at the broader CTXPro datasets and evaluate them using word accuracy on their relevant phenomena. Table 4 contains results for all three language pairs for all CTXPro datasets.

Contrastive suites Finally, we turn to the document-level contrastive and generative metrics described in § 4.2–4.3. Table 5 contains results for all three language pairs.

7 Discussion

7.1 Standard sentence-level metrics show gains if the dataset is dense enough

Table 3 shows state-of-the-art performance for all models when translating at the sentence level (without context), compared to the commercial system. This confirms the large-scale, state-of-the-art nature of our experiments. On the WMT datasets, we see a fairly a regular small drop on sentence-level translation with SENT($\mathcal{P}$,$\mathcal{B}$) (first row top sent-level section), that is slowly regained as we move down to DOC($\mathcal{P}$,$\ddddot{\mathcal{B}}$). We note that we do not expect the contextual translation systems to perform *better* at sentence-level translation, but hope they retain performance there.

Next, Table 3 allows comparison of sentence-level translation to contextual translation (top versus bottom section). On the WMT datasets, the effects gains are fairly small (-0.3 for EN→DE, +0.6 for EN→RU). Looking at the CTXPro columns, however, we observe fairly large, consistent gains when translating contextually with nearly all the (non-randomized) DOC systems, but especially for the DOC($\mathcal{P}$,$\ddddot{\mathcal{B}}$) system across all three languages (+7.2 for EN→DE, +7.7 for EN→FR, and +7.3 for EN→RU). The CTXPro dataset is the OpenSubtitles gender-identified portion, so it is extremely dense in phenomena that require context to resolve compared to the WMT datasets, and is better able to discriminate systems with contextual abilities.

7.2 Domain and context both play a role

The DOC($\mathcal{P}$,$\ddddot{\mathcal{B}}$) system showed large gains in Table 3 when translating CTXPro contextually. One explanation is that CTXPro is, by construction, "discourse dense". But it also represents a domain shift, from news to conversational domains. We would like to have an idea of how much of the gain is due to each.

We therefore conduct a followup experiment in EN→DE that compares two datasets in the OpenSubtitles domain: the CTXPro/gender "dense" test

Table 6: EN→DE COMET scores on a dense dataset (OpenSubtitles CTXpro/gender) with true and random contexts; next, a sparse dataset (random sample of OpenSubtitles) with true contexts. Doc($\mathcal{P}$,$\dddot{\mathcal{B}}$) gains most over the sentence baseline on dense with true contexts and is harmed most on dense with random contexts. The doc systems are similar on the sparse dataset.

set, and another test set, which contains a random sample of 500 ten-sentence documents from OpenSubtitles 2016, yielding a corpus size of 4,973 sentences. We label this second one "sparse": since it was selected randomly, it is likely to be much less dense in contextual phenomena. For contextual systems, we translate each of these as a single chunk, and then split them out for evaluation with COMET. The results are in Table 6.

The differences between the first two columns shows that the Doc($\mathcal{P}$,$\dddot{\mathcal{B}}$) gains over the sentence system are much larger on the "dense" dataset (+7.2 vs. +1.2). Performance among the contextual systems is closer, as we saw with WMT datasets. This suggests that the flat performance with WMT data was likely due to it, too, being sparse with contextual phenomena. **For standard, sentence-based metrics like COMET to separate these systems, dense test sets are needed.**

Table 6 (column 3) contains the results of another experiment, where we replace the context of each sentence in the "dense" dataset with a random context. This hurts performance, and the effect is most pronounced on the Doc($\mathcal{P}$,$\dddot{\mathcal{B}}$) system, suggesting that this model is most dependent on a reliable contextual clue.

7.3 Generative word-based accuracy corroborates these differences

Table 4 presents the results of word-based accuracy on the CTXPro datasets, across a range of linguistic phenomena. With word-based accuracy, we are testing whether a word is present in the output. This leaves open the possibility of metric mistakes. For example, if the pronoun *er* is expected in the output, a system could be penalized for translating the sentence correctly with no pronouns, or it could be rewarded for generating a semantically unrelated instance of *er*. We do not expect this to systematically favor any one system.

Here, we see a similar gap between (a) contextual systems versus a random context and (b) especially, a gap between Doc($\mathcal{P}$,$\dddot{\mathcal{B}}$) and the other contextual systems. For EN→DE and EN→FR, the gender categories are similar to the ContraPro test sets for those languages, but much larger. This is most true for the GENder category (with gains of +23.6, +16.6, and +10.4), but also for other categories, including auxiliaries (+19.7 for EN→FR) and EN→RU inflection (+10.4).

7.4 The general trend favors BT-only contextual data

Figure 1 visualizes the metric score gains from Tables 3 and 5 for all four contextual models over the sentence-level baselines. The x-axis is arranged by the percentage of the contextual examples that are drawn from parallel data. This makes clearer the observations from the discussion so far: contextual annotations from parallel data are better than nothing, but they are inferior to those from the backtranslation monolingual data, and removing them is preferable.

7.5 Contrastive test sets are less discriminative

Table 5 contains results that pair contrastive accuracies (§ 4.2) with their generative counterparts. Across all three language pairs, there is an interesting pattern: in the contrastive metrics, the document systems improve over the sentence baseline, as a block. However, *the generative metrics see their best results with* Doc($\mathcal{P}$,$\dddot{\mathcal{B}}$)*, often by a large margin*. Together with the observations in the previous section, we believe this calls into question the reliability of contrastive metrics. What we really care about in an MT system is its ability to *generate* the correct results at inference time. Discriminative ability is at best a proxy for this ability; if its results do not correlate with such metrics, it calls into question its reliability.

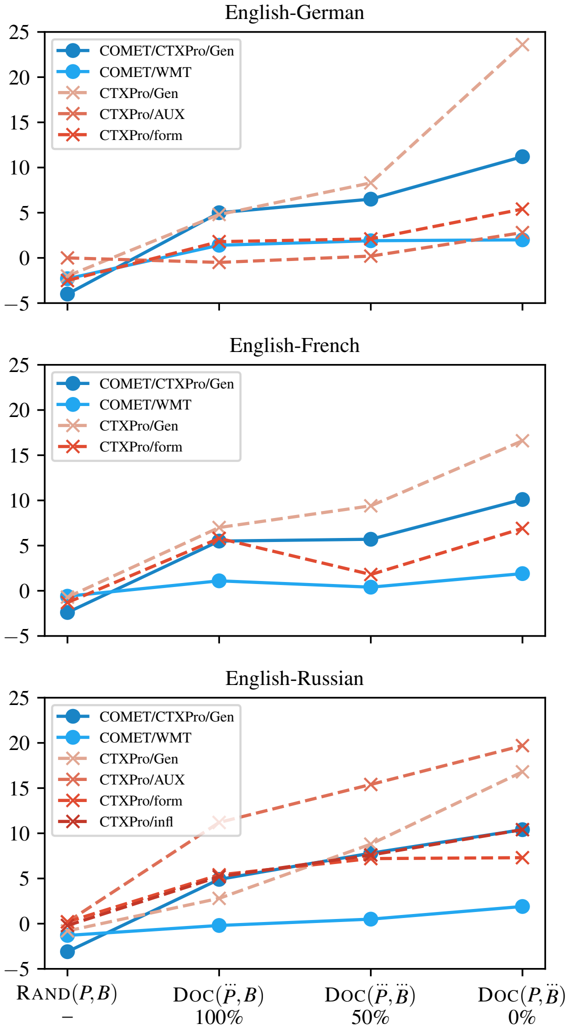

Figure 1: Contextual metric gains over the sentence baseline for COMET and accuracy metrics for the four systems, arranged by the percentage of contextual samples sourced from parallel data.

7.6 Experiments with public data provide some corroboration

Since complete document annotations for publicly available large-scale parallel data do not exist, we were unable to build Doc($\dddot{\mathcal{P}}$,$\dddot{\mathcal{B}}$) and Doc($\dddot{\mathcal{P}}$,$\mathcal{B}$) on open data. However, we can build the Sent($\mathcal{P}$,$\mathcal{B}$) and Doc($\mathcal{P}$,$\dddot{\mathcal{B}}$) systems with a subset of the WMT22 EN→DE data with monolingual document annotations, and see whether they exhibit the same pattern.

We use all available parallel data provided for WMT22 (Kocmi et al., 2022):[9] Europarl v10 (Koehn, 2005), Paracrawl v9 (Bañón et al., 2020), Common Crawl,[10] News Commentary, Wiki Ti-

.

tles v3, Tilde MODEL Corpus (Rozis and Skadiņš, 2017), and Wikimatrix (Schwenk et al., 2021a). A few of these resources have document-level information, but we do not use any of it. For monolingual data, the only data available with document metadata is News Crawl.[11] We used all even years from 2008–2020, backtranslating it from German to English with an internal system. No filtering is applied. From this data, we train the only two of our systems supported by this setup: SENT($\mathcal{P}$,$\mathcal{B}$) and DOC($\mathcal{P}$,$\dddot{\mathcal{B}}$). These are trained for 40 virtual epochs each using the same settings described in Section 6.[12]

Results can be found in Table 8. They are encouraging: we see the same pattern of improvement between SENT($\mathcal{P}$,$\mathcal{B}$) and DOC($\mathcal{P}$,$\dddot{\mathcal{B}}$), although the absolute numbers are lower. Compared to our in-house data, the document metrics are even better for SENT($\mathcal{P}$,$\mathcal{B}$).

7.7 MT output in crawled parallel data

We do not undertake an exploration of the causes for the results and analysis discussed in Figure 1 and throughout this section, but there is an obvious explanation: we suspect that parallel web-crawled data is full of machine-translated output. Widespread use of translation across the web, especially since the release of Google Translate in 2006, is a commercial success story that has unfortunately produced a kind of "poisoning of the

[11] https://data.statmt.org/news-crawl/de-doc/

Table 9: An example of bad data drawn from the parallel data pool. While the sentence-level translations are fine, the incorrect pronoun *Es* in the third sentence suggests sentence-level machine or low-quality human translations.

well", where machine translation outputs are later collected as training data for new systems (Venugopal et al., 2011). Recent work has corroborated how extensive this is in multi-way parallel data (Thompson et al., 2024).

Quantifying this awaits further work, but it is easy to source examples from our parallel data (Table 9). While we don't know if this was generated by machine or a human, we do know that even large NMT systems are sensitive to small amounts of poor data.[13]. This data may still be of high quality at the sentence level; it is only *inter-sentence contextual* information that is affected. If true, this suggests that **contextual translation introduces a new quality dimension that is invisible** in the standard sentence-level training paradigm, and the problem may in fact be quite large, since all machine translation content in the wild will have been generated at the sentence level.

We suspect that our monolingual data—which by design was sourced from known target-native sites, such as newspapers—is largely immune from these problems. Training on sentence-level translations is primarily a problem for data translated in the *forward* direction. Backtranslation introduces noise into the *source language text*, while preserving the target-language contextual signal.

We leave to future work an investigation into detecting and removing machine translation output from parallel data at high enough precision.

8 Conclusions

Machine translation research and production systems continue to be dominated by sentence-level approaches. A common explanation for this shortcoming is the lack of document-annotated parallel data. We have compared the effectiveness of constructing contextual translation models for three translation directions in large-data settings. Our results suggests that while mined parallel data is of high-enough quality for building sentence systems and contains some contextual signal, **it is best to construct contextual training samples from back-translated data only**. Although we have not investigated the reasons for this, we consider it a strong possibility that our parallel data, which is mostly crawled from the web and has had only sentence-level filtering applied, contains large amounts of data that was machine-translated at the sentence level, a finding that is very likely to hold for publicly available data, as well. This suspicion makes sense a priori, and is bolstered in other recent work (Thompson et al., 2024; Wicks et al., 2024; Pal et al., 2024).

We have also shown the importance of **evaluating contextual machine translation output in its generative capacity**, rather than in its ability to discriminate good outputs from bad ones. This can be done by using provided challenge sets like CTX-Pro or converting existing contrastive metrics like ContraPro and its variants, or by using standard corpus-level metrics like COMET on test sets that are sufficiently dense with contextual phenomena.

A fruitful avenue for followup work is to automatically identify sentences that require context to translate correctly, which could be used to filter training data and also in the construction of new test sets. Though we have focused on "traditionally"-trained MT, it will also be useful to learn how LLMs perform on these tasks.

Acknowledgments

We thank the authors of the contrastive test sets (particularly ContraPro, which set the standard) for their fantastic work creating well-designed, usable, and easily-extendable datasets, along with code. Thanks also to Rachel Bawden, Salvador Mascarenhas, Christian Federmann, Tom Kocmi, Vikas Raunak, Arul Menezes, and Huda Khayrallah for helpful comments and feedback, and to Fai Sigolov for help with Russian.

[13] A classic example is source-copy data (Ott et al., 2018)

Limitations

With respect to reproducibility, the deepest limitation of our paper is our use of private data. There is therefore a risk that our findings might not be reproducible by other teams working with (necessarily) different datasets. Finally, although we suspect our results will hold for language pairs beyond the three we investigated, it is possible they will not generalize.

(INF) My friend had some mech work done here. Industry stuff. → Вы ставили имплант моей подруге. Промышленную штуковину.
(FORm) I don't know you, but.. → Ich kenne Sie nicht, aber...

Table 11: Examples of contextually-sensitive auxiliary and inflection elision from the CTXPro dataset.

A Dataset examples

Examples from the datasets used for generative and contrastive evaluation can be found in Tables 10 and 11.

B Model capacity

Much work in investigating document-level machine translation has been limited to standard-size Transformer architectures (cf. Zhang et al. (2018); Sun et al. (2022); Lopes et al. (2020)). Yet it stands to reason that modeling longer-range phenomena will require increased model capacity, and in fact, the base model size we chose for our experiments (12 layer encoder, 16k FFN) reflects this. Here, we provide more detail, varying two model parameters only: (i) the number of encoder layers, and (ii) the width of the model feed-forward layer (encoder and decoder side). We keep all other parameters the same, including fixing the decoder depth to 6. Focusing on changes to the encoder depth helps limit grid search and is justified by prior work showing that (relatively cheap) encoder layers can be traded for (relatively expensive) decoder layers with no penalty (Kasai et al., 2020). We alternate between increasing the number of encoding layers, and increasing the dimension of the Transformer feed-forward layer.

Table 12 contains English–German results. Unsurprisingly, all scores continue to rise, up to the wide 18-layer model. Both increasing the number of encoder layers, and increasing the size of the FFN, contribute to better performance. This suggests that the common approach of working with 6-layer Transformer base models is not enough

arch	params	BLEU	COMET	C/Pro	G/Pro
6/1k	146m	27.0	48.7	65.2	58.4
6/2k	171m	27.4	49.7	66.2	58.7
6/4k	221m	28.0	51.0	69.7	62.9
12/4k	297m	28.4	51.8	70.6	66.0
6/8k	322m	27.8	51.0	71.7	62.8
12/8k	448m	28.6	52.5	74.2	67.1
6/16k	523m	28.4	51.7	74.5	64.9
18/8k	574m	28.8	53.0	75.0	67.1
12/16k	750m	28.9	52.8	75.8	68.5
18/16k	977m	29.3	53.3	75.5	69.4

Table 12: Model capacity (encoder layers / FFN / # params) for an EN-DE document model, ordered by param. count. Decoder depth is always 6 layers. Scores were computed on a checkpoint after 30k updates. BLEU and COMET scores are on WMT21, translating as sentences. C/Pro is over the complete test set, while G/Pro is over only sentences with external anaphora.

for document-context MT. There is more to gain by moving to larger models and likely, to larger datasets and context lengths, as well.

A Multi-task Learning Framework for Evaluating Machine Translation of Emotion-loaded User-generated Content

Shenbin Qian, Constantin Orăsan, Diptesh Kanojia and Félix do Carmo
Centre for Translation Studies and Institute for People-Centred AI,
University of Surrey, United Kingdom
{s.qian, c.orasan, d.kanojia, f.docarmo}@surrey.ac.uk

Abstract

Machine translation (MT) of user-generated content (UGC) poses unique challenges, including handling slang, emotion, and literary devices like irony and sarcasm. Evaluating the quality of these translations is challenging as current metrics do not focus on these ubiquitous features of UGC. To address this issue, we utilize an existing emotion-related dataset that includes emotion labels and human-annotated translation errors based on Multi-dimensional Quality Metrics. We extend it with sentence-level evaluation scores and word-level labels, leading to a dataset suitable for sentence- and word-level translation evaluation and emotion classification, in a multi-task setting. We propose a new architecture to perform these tasks concurrently, with a novel combined loss function, which integrates different loss heuristics, like the Nash and Aligned losses. Our evaluation compares existing fine-tuning and multi-task learning approaches, assessing generalization with ablative experiments over multiple datasets. Our approach achieves state-of-the-art performance and we present a comprehensive analysis for MT evaluation of UGC.

1 Introduction

Machine translation (MT) has advanced rapidly in recent years, leading to claims it has achieved human parity in Chinese-English news translation (Hassan et al., 2018). Recent advent of large language models (LLMs) has determined researchers to repeat claims of human parity more often (Wang et al., 2021). However, automatically translating user-generated content (UGC) with expressions that contain emotions, like tweets, reveals novel challenges for MT systems (Saadany et al., 2023). Figure 1 shows the output of Google Translate (GT) and ChatGPT when we translated some Chinese UGC with emotional slang using them[1]. As can be seen from the example, both outputs need to be improved significantly to be considered usable. Similar problems were noticed with other MT engines, indicating that it is imperative to evaluate MT quality with metrics that take emotion preservation into account.

Using human judgements/input to evaluate MT quality is expensive in terms of both time and money (Dorr et al., 2011; Lai et al., 2020). Quality estimation (QE), which predicts MT quality in the absence of human references, can serve as a cost-effective alternative to approximate human evaluation based on metrics like Multi-dimensional Quality Metrics (MQM), an error-based human evaluation scheme for MT quality (Lommel et al., 2014). A widely-used approach in QE involves fine-tuning a multilingual pre-trained language model (PTLM) using human evaluation data (Blain et al., 2023). This fine-tuned model can predict scores for entire MT sentences or labels for individual words, indicating whether each word is correctly translated or not. This encompasses two common QE tasks: sentence-level QE and word-level QE.

To assess MT quality of emotion-loaded UGC, it is crucial to evaluate the overall quality of emotion preservation after translation (sentence-level QE), and how well emotion words are translated (word-level QE). To achieve this, we leverage an existing emotion-related dataset that includes emotion labels and MQM-based human-evaluated translation errors. We extend it with sentence-level QE scores and word-level labels, resulting in a dataset extension. This extended dataset is suitable for both sentence- and word-level QE, and emotion classification. For joint training of these tasks, we employ multi-task learning (MTL), anticipating improved performance for all tasks due to their inherent correlation with emotionally charged content. We further introduce a new architecture with a novel combined loss function that integrates different loss heuristics, enabling the concurrent training

心中无数个草泥马飘过！！！！！

Xīnzhōng wúshù gè cǎonímǎ piāoguò!!!!!

Countless grass and mud horses floated through my heart! ! ! ! !

Please translate the Chinese sentence "心中无数个草泥马飘过！！！！！" into English.

"Countless horse manure drift through my mind!!!"

Human Translation: Countless “f**k your mother” appeared in my mind!

Explanation: Both Google Translate and ChatGPT fail to translate the swear word “草泥马”, a slang word created using a homophone to replace the original character to avoid censorship. The angry emotion of the original sentence is completely lost.

Figure 1: Example of translations from Google Translate and ChatGPT

of these tasks and optimizing their overall performance. We compare our MTL approach with existing fine-tuning and MTL methods. Our proposed approach achieves new state-of-the-art results on the emotion-related QE dataset and a standard QE dataset. Our contributions can be summarized as follows:

- *Extending an emotion-related QE dataset* with 1) QE scores at sentence level and 2) labels indicating emotion-related translation quality at word level.
- A new architecture with a *novel combined loss function*, integrating different loss heuristics for multi-task learning[2].
- Evaluation of the proposed MTL approach on multiple QE datasets including ablative experiments on combinations of QE and emotion classification tasks, *improving performance over existing fine-tuning and MTL methods*.

Section 2 discusses existing work for QE and MTL while Section 3 introduces the datasets we use for this study. Our approach, baselines and experimental setup are described in Section 4, and Section 5 discusses the results obtained on multiple datasets. Section 6 concludes our study and outlines future directions. Section 7 points out limitations and ethical considerations. Relevant mathematical equations and loss algorithms are explained in Appendix A.

2 Related Work

We discuss related work in supervised QE in § 2.1. Studies on MTL and its application to QE are reviewed in § 2.2.

2.1 Quality Estimation

Though prompting with LLMs is increasingly applied to the field of quality evaluation (Kocmi and Federmann, 2023b,a; Fernandes et al., 2023), supervised fine-tuning of multilingual PTLMs on human evaluation data based on metrics such as translation edit rate (Snover et al., 2006), direct assessment (Graham et al., 2013) and MQM, remains as state-of-the-art QE methods (Kocmi and Federmann, 2023b). TransQuest (Ranasinghe et al., 2020) and COMET (Rei et al., 2020; Stewart et al., 2020; Rei et al., 2022b; Guerreiro et al., 2024) are two popular frameworks used for sentence-level QE. TransQuest utilizes XLM-RoBERTa (Conneau et al., 2020) as the backbone, concatenating the source and target sentences using [CLS] (start) and [SEP] (separator) tokens. In MonoTransQuest, an architecture within TransQuest, only the embeddings of the [CLS] token are used for prediction. In SiameseTransQuest, a variant of TransQuest architecture, a twin XLM-RoBERTa network computed the mean of all token embeddings for the source and target. This mean is then used to calculate the cosine similarity as the final QE score. Unlike TransQuest, COMET was initially proposed for reference-based evaluation until 2022, when COMETKIWI (Rei et al., 2022b) was introduced to support reference-less evaluation. Similar to

[2] Our code and the extended dataset for MTL are available at https://github.com/shenbinqian/MTL4QE.

MonoTransQuest, it concatenates the source and target, and inputs them into the encoder. All hidden states are then fed into a scalar mix module (Peters et al., 2018) that learns a weighted sum, producing a new sequence of aggregated hidden states. The output of the [CLS] token is then used for the prediction of sentence-level QE scores.

For word-level QE, OpenKiwi (Kepler et al., 2019) was proposed to support both sentence- and word-level QE with various neural network architectures. MicroTransQuest (Ranasinghe et al., 2021), utilizing outputs of all input tokens of an XLM-RoBERTa model based on the MonoTransQuest architecture, was proposed only for word-level QE under multilingual settings.

Because of their successes in the QE shared tasks in the Conference on Machine Translation (WMT) in recent years (Specia et al., 2020, 2021; Zerva et al., 2022), TransQuest and COMET are selected as our baseline fine-tuning frameworks for sentence-level QE, and MicroTransQuest for word-level QE.

2.2 Multi-task Learning

Multi-task learning addresses multiple related tasks concurrently by training them simultaneously with a shared representation (Caruana, 1997). While this approach reduces the training cost compared to training separate models (Baxter, 2000), early methods led to performance degradation when compared to single-task models (Standley et al., 2020). Recent efforts have introduced various methods to address this problem and enhance the MTL performance.

Liu et al. (2019) proposed dynamic weight averaging that could learn task-specific feature-level attention. They used a shared network that contains features of all tasks and a soft-attention module for each specific task without using weighting schemes. Liu et al. (2021) proposed impartial MTL that uses different strategies for task-shared parameters and task-specific parameters. Navon et al. (2022) proposed to view the combination of gradients as a bargaining game, where different tasks negotiate with each other to reach an agreement on a joint direction of parameter update. They utilized the Nash Bargaining Solution (Nash, 1953) as an approach to address this problem and proved the effectiveness of their method across various tasks. Since some MTL methods are not always stable during training, Senushkin et al. (2023) proposed the Aligned MTL to improve stability. They used a condition number of a linear system of gradients as a stability criterion, and aligned the orthogonal components of the linear system of gradients to eliminate instability in training.

The improved performance and stability of MTL methods have prompted its application to quality evaluation. Shah and Specia (2016) investigated MTL with Gaussian Processes for QE, based on datasets with multiple annotators and language pairs. They found multi-task models perform better than individual models in cross-lingual settings. Zhang and van Genabith (2020) used MTL to predict QE scores and rank different translations. Rei et al. (2022a) employed MTL to jointly train QE models at sentence- and word-level. Most of these studies used non-parametric linear combinations of task losses, until Deoghare et al. (2023) proposed to apply Nash MTL to combining sentence- and word-level QE, based on MicroTransQuest. However, their Nash MTL might not always be stable for various QE tasks. In this paper, we explore different MTL loss heuristics and propose a new architecture with a novel combined loss function for the quality estimation of emotion-loaded UGC.

3 Data

We used two datasets to evaluate our approach. The first one measures *how well emotion is preserved* in machine translation and is presented in § 3.1. The second is a standard QE dataset from WMT 2020 to WMT 2022 (Freitag et al., 2021a,b, 2022). It contains sentence- and word-level QE data annotated using MQM, as explained in § 3.2.

3.1 A Human Annotated Dataset for Quality Assessment of Emotion Translation

We used our Human Annotated Dataset for Quality Assessment of Emotion Translation (HADQAET)[3] as the main resource (Qian et al., 2023). Its source text originated from the dataset released by the *Evaluation of Weibo Emotion Classification Technology on the Ninth China National Conference on Social Media Processing* (SMP2020-EWECT). It originally has a size of 34,768 instances. Each instance is a tweet-like text segment[4], which was manually annotated in the original dataset with one of the six emotion labels, *i.e.*, *anger*, *joy*, *sadness*, *surprise*, *fear* and *neutral*

[3] https://github.com/surrey-nlp/HADQAET

[4] Like most NLP tasks, we treat tweet-like text segments as sentence-level data. However, in contrast to tweets, our instances are longer with an average of 40 Chinese characters.

(Guo et al., 2021). We kept 5,538 instances with labels other than *neutral* and used Google Translate to translate them to English. We proposed an emotion-related MQM framework and recruited two professional translators to annotate errors and their corresponding severity in terms of emotion preservation. Words/characters in both source and target that cause errors were highlighted for error analysis. Details of our framework, error annotation (including inter-annotator agreement) and error analysis can be found in Qian et al. (2023). An example of the dataset is shown in Figure A.1.

Since our original paper did not propose any scores for sentence-level QE, we followed Freitag et al. (2021a) to sum up all weighted errors based on their corresponding severity, using a set of weights[5] suggested by MQM (Lommel et al., 2014), *i.e.*, 1 for minor errors, 5 for major and 10 for critical. For word-level QE, we first tokenized the source with *jieba* (Sun, 2013), and the target with NLTK (Bird et al., 2009) (tokenization tools for Chinese and English respectively). Then, we labeled the tokens highlighted by annotators as "BAD", and the rest "OK". This led to a sequence of labels for each instance, which indicate translation quality in emotion preservation at word level.

The MQM-based QE scores related to emotion, word labels, together with the source texts and GT translations were used for quality estimation of emotion-loaded UGC. The emotion labels that were originally used for emotion classification were also incorporated to see if they are helpful for QE.

3.2 MQM Subset with Synthetic Emotion

To test whether our approach can be applied to standard QE data[6], we selected the overlapping of Chinese-English sentence- and word-level MQM datasets from the QE shared task of WMT 2020 to WMT 2022. The overlapped subset has MQM scores at sentence level and "OK" or "BAD" labels at word level. We fine-tuned the Chinese RoBERTa large model (Cui et al., 2020) on the SMP2020-EWECT dataset, resulting in an emotion classifier with a macro F1 score of 0.95. We predicted the emotion label of the source text of the selected data using the fine-tuned classifier, and filtered out all *neutral* instances. This led to an MQM subset with automatically generated emotion labels and a comparable size (3544) as HADQAET. We randomly sampled 100 instances and manually checked the predicted emotion labels with the help of a native speaker. The manual validation shows the emotion classifier is reliable as it achieves an F1 score 0.90, precision 0.91 and recall 0.92. The distribution of this subset is shown in Figure 2.

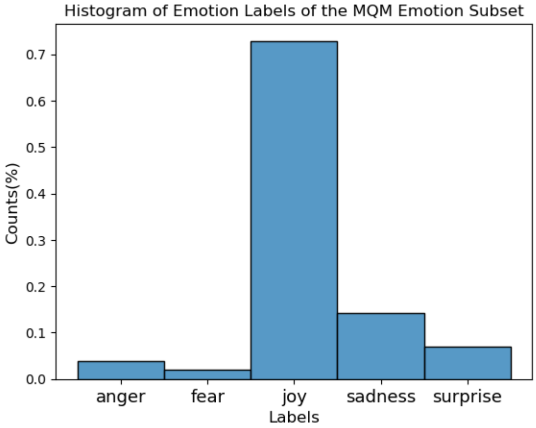

Figure 2: Distribution of the MQM emotion subset

4 Methodology

This section describes the architecture and loss function of our MTL method. Additionally, it also presents the fine-tuning baselines including TransQuest and COMET for each individual task.

4.1 Multi-task Learning

We propose a new architecture that is able to train sentence- and word-level QE systems with an emotion classifier using a combined loss function.

Architecture The architecture we propose is in Figure 3. Following MonoTransQuest and COMETKIWI, we concatenate the source and target, including [CLS] and [SEP] as the starting and separating tokens. Then, we employed multilingual PTLMs like XLM-RoBERTa, XLM-V-base and InfoXLM (Chi et al., 2021) to encode the input text. Different from Deoghare et al. (2023), who used embeddings of the last hidden layer, we utilized the output of the [CLS] token to predict sentence-level QE scores and the rest tokens for word label classification. On top of the encoder, we added a fully connected layer for both sentence- and word-level QE before the softmax function for prediction.

To incorporate the emotion classification task, we tried max and average pooling for the output of the last hidden layer of the encoder and added another fully connected layer on top. We used Xavier initialization (Glorot and Bengio, 2010) for

[5] We validated these weights in Qian et al. (2024).

[6] Their QE scores are not related to emotion.

the weights in all newly-added linear layers. We experimented different combination strategies for the losses of these tasks as explained below.

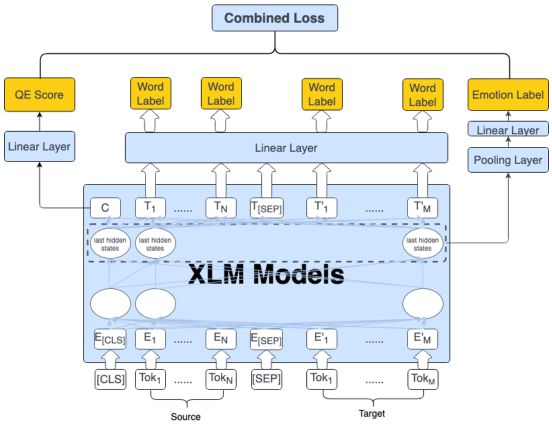

Figure 3: Architecture of our MTL Framework

Combined Loss The loss function of our method is defined in Equation 1, where σ is a heuristic function to combine the three losses. L_{sent} as shown in Equation 2 is the Mean Squared Error loss for sentence-level QE, where Y_{QE_score} and $\hat{Y}_{QE\_score}$ are the true and predicted QE scores, respectively. Equation 3 is the Cross Entropy loss for word and emotion classification, where C is the set of classes. For L_{word}, C is {"OK", "BAD"}. For L_{emo}, C is the 5 emotion classes. $\mathbb{1}\{y = i\}$ is an indicator function (1 if the true label y is equal to the current class i, 0 otherwise), and p_i is the predicted probability of the input being in class i.

$$L_{MTL} = \sigma(L_{sent}, L_{word}, L_{emo}) \tag{1}$$

$$L_{sent} = MSE(Y_{QE\_score}, \hat{Y}_{QE\_score}) \tag{2}$$

$$L_{word/emo} = -\sum_{i=1}^{C} \mathbb{1}\{y = i\} \cdot \log(p_i) \tag{3}$$

The objective of the heuristic σ is to find a set of parameters θ that minimize the aggregate loss of all tasks. It is defined in Equation 4, where $L_{MTL}(\theta)$ is the combined loss, and $L_i(\theta)$ is the loss for an individual task i.

$$\theta^* = arg\,\underset{\theta}{min}\{L_{MTL}(\theta) = \Sigma_{i=1}^{T} L_i(\theta)\} \tag{4}$$

Theoretically, θ can be fixed or a simple linear combination of each task loss. For instance, it can be 1 for each task loss, but the result is usually not ideal, as shown in our experiments. In order to balance the losses of different tasks and overcome optimization problems like conflicting or dominating gradients (Navon et al., 2022), we adopted different heuristics σ to learn θ, including the Nash and Aligned MTL losses which are explained in Appendix A. Other existing MTL methods such as linear combination, dynamic weight averaging and impartial MTL were also integrated into our framework. To compare with our proposed Nash and Aligned MTL, the linear combination (1 for each task loss) and Nash MTL loss in Deoghare et al. (2023) were selected as baseline MTL methods in our experiments. Results of other MTL methods are in Table A.1.

4.2 Fine-tuning

We utilized MonoTransQuest, SiameseTransQuest and COMET for sentence-level QE, and MicroTransQuest for word-level QE. They rely on the XLM-RoBERTa models as the foundation model for fine-tuning. For emotion classification, we fine-tuned XLM-RoBERTa-large and XLM-V-base (Liang et al., 2023) using both source and target texts. Experimental setup and training details can be seen in the following sections.

4.3 Experimental Setup

We performed experiments under two settings (fine-tuning and MTL) on two datasets (HADQAET and the MQM emotion subset). Fine-tuning included sentence- and word-level QE and emotion classification. For MTL, we combined sentence-level QE with word-level QE, sentence-level QE with emotion classification, and sentence-, word-level QE and emotion classification.

We used Spearman ρ and Pearson's r correlations to evaluate similarities between the predicted sentence-level QE scores and the true scores. For word and emotion classification, we used macro F1, precision and recall scores for evaluation.

4.4 Training Details

We divided the data into training, validation, and test sets in proportions of 80%, 10%, and 10% respectively. We set the learning rate as $2e - 5$ with the warmup rate as 0.1, for all training setup. We chose the AdamW optimizer (Loshchilov and Hutter, 2019) with a linear scheduler for all experiments. The sequence length was set as 200 and the batch size was chosen as 8. For fine-tuning, all models were trained for 2 epochs except emotion classifiers; whereas for MTL, we trained our models for $8 - 12$ epochs based on the decrease

(2023) (Nash-D) as well as the fine-tuning (FT) model using MicroTransQuest on HADQAET.

of the combined loss and depending on different combinations of tasks. For the emotion classification task in MTL, we chose max pooling over average pooling after experimentation. We set the number of epochs as 10 and used early stopping for fine-tuning emotion classifiers. All these hyperparameters were chosen based on experimentation and previous research.

Fine-tuning multilingual PTLMs via TransQuest including MonoTransQuest, SiameseTransQuest and MicroTransQuest was carried out on an NVIDIA Quadro RTX 5000 GPU. Fine-tuning emotion classifiers including statistical models on HADQAET and the MQM emotion subset was performed on an NVIDIA T4 GPU. The rest of the model training including fine-tuning via COMET and different combinations of our MTL tasks were conducted on an NVIDIA A40 GPU.

Table 4: Spearman ρ, Pearson's r, Macro F1 (F), precision (P) and recall (R) scores of MTL models combining sentence-level QE and emotion classification using our MTL architecture *vs* linear loss on HADQAET. Our fine-tuning baselines (FT baselines) from Tables 2 and 3 are listed here for reference.

(r), were achieved by fine-tuning using MonoTransQuest and SiameseTransQuest, respectively.

The emotion categories of HADQAET are imbalanced, and the dataset size is relatively small, as depicted in Figure 4. As a result, the fine-tuned classifiers always predicted the same class. We tried different PTLMs and hyperparameters, but the performance was not better as seen in Table 3. For this reason, we applied statistical methods including Random Forest (RF) (Breiman, 2001) and Support Vector Machine (SVM) (Hearst et al., 1998) based on the embeddings from XLM-RoBERTa-large. Our baseline for emotion classification was established using RF, achieving the best F1 score of 0.1456.

5.2 MTL on HADQAET

This section shows results of different combinations of the three tasks on HADQAET.

5.2.1 Sentence- and Word-level QE

Table 1 shows results of MTL that combines sentence- and word-level QE. For sentence-level QE, it is observed that MTL using XLM-V-base and Nash loss achieved the highest ρ of 0.4673. This performance was superior to that of fine-tuning (0.4355). In the context of word-level QE, our best F1 score of 0.2805 surpasses the performance of fine-tuning using MicroTransQuest, which achieved an F1 score of 0.1951. This suggests that training sentence- and word-level QE systems together under the MTL framework can lead to improved performance in both tasks. Additionally, our MTL method is better than the linear loss and the Nash loss from Deoghare et al. (2023) for both sentence- and word-level QE.

5.2.2 Sentence-level QE and Emotion Classification

Table 4 presents results for the combination of sentence-level QE and the emotion classification task. We can see that the use of MTL with Aligned loss effectively prevented the predictions from falling into the same category as shown in Table 3. Our top-performing model achieved an F1 score of 0.8549, much higher than our baseline. Our Aligned loss usually performed better than the linear loss for both sentence-level QE and emotion classification. It appears that incorporating the sentence-level QE task has proven beneficial for training emotion classifiers. However, incorporating emotion classification does not seem to be very helpful for sentence-level QE, as Spearman scores are not higher than those of fine-tuned models. In addition, it has been observed that when combined with emotion classification, the Aligned loss demonstrates greater stability compared to the Nash loss. This method achieves a favorable equilibrium between sentence-level QE and emotion classification.

Heuristics	Sentence-level QE	Emotion Classification
Nash Loss	0.5604	5.1199
Aligned Loss	0.6162	0.6377

Table 5: Average loss weights for sentence-level QE and emotion classification using Nash and Aligned losses

Investigating further, we trained two models based on XLM-RoBERTa-base using the exact same hyperparameters, but two different loss

Methods		Sentence Level		Word Level			Emotion Classification

Table 7: Spearman ρ, Pearson's r, Macro F1 (F), precision (P) and recall (R) scores for our baselines: fine-tuned models for sentence- and word-level QE and statistical models including Random Forest and Support Vector Machine (SVM) for emotion classification on the MQM emotion subset.

heuristics[7], *i.e.*, the Nash and Aligned losses, to combine sentence-level QE and emotion classification. We recorded the weights for the losses of the two tasks learned during training. The average loss weights (of all epochs) can be seen in Table 5. We can see that the Aligned loss seems to be better than Nash in balancing the two tasks as the two average weights are closer using the Aligned loss than Nash. This might be one of the reasons why it leads to more balanced results when the two tasks are combined.

5.2.3 Sentence-, Word-level QE and Emotion Classification

Table 6 illustrates simultaneous training of the three tasks. Again, our MTL method achieved better results than the linear loss under most circumstances. Compared with fine-tuning, our MTL method notably enhanced the performance of emotion classification, but the result of sentence-level QE was compromised. This suggests that as more tasks are incorporated into the MTL framework, achieving consensus or agreement between tasks becomes more challenging.

5.3 Results on the MQM Emotion Subset

This section presents results obtained on the MQM emotion subset, which is a selection of sentences from WMT QE shared tasks, with synthetic emotion labels as described in § 3.2.

5.3.1 Fine-tuning on MQM Emotion Subset

We applied the same methods as those of HADQAET, except that only statistical methods were used for emotion classification. Our baseline results are shown in Table 7. We achieved a ρ of 0.3650 for sentence-level QE, an F1 score of 0.2141 for word-level QE and 0.1397 for emotion classification.

5.3.2 MTL on MQM Emotion Subset

Table 8 presents the results of combining sentence- and word-level QE. Our best model, utilizing Nash loss, achieved a Spearman correlation of 0.4947, notably surpassing the fine-tuning baseline and other MTL methods including the linear loss and Nash loss from Deoghare et al. (2023). The F1 score for word-level QE reached 0.2471, demonstrating improvement over the fine-tuning baseline. These findings affirm the validity of our approach for effectively integrating sentence- and word-level

[7] The linear loss was omitted as weights were fixed as 1.

Table 8: Spearman ρ, Pearson's r, Macro F1 (F), precision (P) and recall (R) scores of models combining sentence- and word-level QE using our MTL architecture *vs* other MTL methods including the linear loss and Nash loss from Deoghare et al. (2023) (Nash-D) on the MQM emotion subset. Our fine-tuning baselines (FT baselines) from Table 7 are listed here for reference.

QE in the context of overall quality evaluation.

Table 9 shows results integrating sentence-level QE and emotion classification. In instances where sentence-level QE excelled (ρ 0.35), we observed a trade-off with emotion classification performance, and vice versa. The use of the XLM-V base model with the Aligned loss improved the performance of emotion classification, resulting in the highest F1 score, 0.3004.

Table 10 shows MTL results that combine all three tasks. Similar to results on HADQAET, there are trade-offs among tasks. Notably, on the MQM emotion subset, our best model achieved higher scores than fine-tuning and other MTL methods in both sentence- and word-level QE. This suggests that our approach contribute to the enhanced performance when training these tasks together.

5.4 Discussion

The results obtained from various task combinations within our MTL framework indicate that training sentence- and word-level QE systems together improves their performance compared to training them separately. This improvement likely stems from the interconnected nature of the two QE tasks. However, adding emotion classification to the framework usually does not enhance sentence- or word-level QE. Conversely, combining sentence-level QE with emotion classification boosts the performance of emotion classification. This finding is consistent for both the HADQAET (an emotion-related QE dataset) and the MQM emotion subset (a standard QE dataset from WMT shared tasks). It suggests that the sentence-level QE task can aid in training emotion classifiers when training data is limited and the distribution is skewed.

For word-level QE, our approach achieves higher recall scores than MicroTransQuest, possibly because our model predicts errors in both the source and target texts, whereas MicroTransQuest considers only errors in the target.

Our results show that Nash and Aligned losses are generally better than the linear loss. Using the Nash loss is more likely to achieve state-of-the-art results for sentence-level QE, whereas the Aligned loss excels in balancing different tasks to produce a stable output. For this point, our observation still needs to be validated by further experiments on more task combinations and multilingual PTLMs.

6 Conclusion and Future Work

To evaluate MT quality of emotion-loaded UGC at sentence- and word-level simultaneously, we employed an emotion-related dataset that includes emotion labels and human-annotated translation errors. We extended it with sentence-level QE scores and word labels. This led to a dataset suitable for sentence- and word-level QE, and emotion classification. We proposed a new architecture featuring a novel combined MTL loss function that integrates different loss heuristics. This approach unifies the

Table 10: Spearman ρ, Pearson's r, Macro F1 (F), precision (P), recall (R) scores of models combining sentence- and word-level QE and emotion classification using our MTL architecture *vs* linear loss on the MQM emotion subset. Our fine-tuning baselines (FT baselines) from Table 7 are listed here for reference.

training of multiple correlated tasks. We have made the code publicly available for similar task combinations such as empathy prediction and emotion classification. We compared our approach with existing fine-tuning and MTL methods and assessed its generalization on a standard QE dataset with synthetic emotion labels. We achieved new state-of-the-art results on both datasets. For future work, we aim to validate the effectiveness of our method on a larger multilingual QE dataset. We are also interested in investigating LLMs to evaluate machine translation of emotion-loaded UGC.

7 Limitations and Ethical Considerations

Although our MTL method is more effective, it is computationally expensive compared to fine-tuning for each task. Further, it takes longer to converge as parameters in the combined loss need to be learned over the training process.

Incorporating emotion classification might lead to unstable performance for sentence-level QE under the Nash loss as explained in § 5.2.2. We will explore different task combinations and introduce a new hyperparameter to balance the tasks in our future work.

The experiments in the paper were conducted using publicly available datasets. New data were created based on those publicly available datasets using computer algorithms. No ethical approval was required as the use of all data in this paper follows the licenses in Qian et al. (2023) and Freitag et al. (2021a,b, 2022).

A Appendix

A.1 Additional Figures and Tables

Figure A.1 shows an example of the HADQAET dataset from Qian et al. (2023). Table A.1 displays results of other loss heuristics in our framework.

A.2 Nash MTL

Nash MTL intends to find an update vector $\Delta\theta$ for the gradients g_i of the task i in the ball of radius ϵ centered around zero, B_ϵ, as shown in Equation 5.

$$arg\ max_{\Delta\theta \in B_\epsilon} \Sigma_i log(\Delta\theta^\intercal g_i) \qquad (5)$$

The solution to Equation 5 is (up to scaling) $\Sigma_i \alpha_i g_i$ where $\alpha \in \mathbb{R}_+^K$ is the solution to $G^\intercal G\alpha = 1/\alpha$ where $1/\alpha$ is the element-wise reciprocal. Detailed proof can be seen in Navon et al. (2022). The Nash MTL algorithm is shown below:

```
Algorithm 1 Nash-MTL
Input: $\theta^{(0)}$ – initial parameter vector, $\{l_i\}_{i=1}^K$ – differentiable loss functions $\eta$ – learning rate
for $t = 1, ..., T$ do
  Compute task gradients $g_i^{(t)} = \nabla_{\theta^{(t-1)}} l_i$
  Set $G^{(t)}$ the matrix with columns $g_i^{(t)}$
  Solve for $\alpha : (G^t)^\intercal G\alpha = 1/\alpha$ to obtain $\alpha^{(t)}$
  Update the parameters $\theta^{(t)} = \theta^{(t)} - \eta G^{(t)}\alpha^{(t)}$
end for
Return $\theta^{(T)}$
```

A.3 Aligned MTL

Through theoretical analysis, Senushkin et al. (2023) found a strong relation between the condition number and conflicting and dominating gradients issues, and they proposed Aligned MTL to align principal components of a gradient matrix to make the training process more stable.

The objective of Aligned MTL as defined in Equation 6, is to minimize the difference between the original gradient matrix G and the aligned gradient matrix $\hat{G}$. The difference is measured using the Frobenius F norm. The constraint in Equation 6 ensures that $\hat{G}$ is orthogonal, meaning that its transpose multiplied by itself is equal to the identity matrix. This constraint helps to ensure stability in the linear system of gradients.

$$\underset{\hat{G}}{min} \|G - \hat{G}\|_F^2 \ \ s.t.\ \ \hat{G}^\intercal \hat{G} = I \qquad (6)$$

$$\hat{G} = \sigma U V^\intercal = \sigma G V \Sigma^{-1} V^\intercal \qquad (7)$$

The solution is defined in Equation 7, where $\hat{G}$ is obtained by singular value decomposition (SVD). SVD decomposes G into three matrices: U, Σ and $V^\intercal$ where U and V are orthogonal matrices, and Σ is a diagonal matrix containing the singular values of G. Algorithm of Aligned MTL is shown below:

```
Algorithm 2 Aligned MTL
Require: $G \in \mathbb{R}^{|\theta| \times T}$ – gradient matrix,
         $w \in \mathbb{R}^T$ – task importance
  $M \leftarrow G^\intercal G$
  $(\lambda, V) \leftarrow eigh(M)$
  $\Sigma^{-1} \leftarrow diag(\sqrt{\frac{1}{\lambda_1}}, ..., \sqrt{\frac{1}{\lambda_R}})$
  $B \leftarrow \sqrt{\lambda_R} V \Sigma^{-1} V^\intercal$
  $\alpha \leftarrow Bw$
Return $G\alpha$
```

On Instruction-Finetuning Neural Machine Translation Models

Vikas Raunak **Roman Grundkiewicz** **Marcin Junczys-Dowmunt**
Microsoft Azure AI
{viraunak,rogrundk,marcinjd}@microsoft.com

Abstract

In this work, we introduce instruction finetuning for Neural Machine Translation (NMT) models, which distills instruction following capabilities *from* Large Language Models (LLMs) *into* orders-of-magnitude smaller NMT models. Our instruction-finetuning recipe for NMT models enables customization of translations for a limited but disparate set of translation-specific tasks. We show that NMT models are capable of following multiple instructions simultaneously and demonstrate capabilities of zero-shot composition of instructions. We also show that through instruction finetuning, traditionally disparate tasks such as formality-controlled machine translation, multi-domain adaptation as well as multi-modal translations can be tackled jointly by a single instruction finetuned NMT model, at a performance level comparable to LLMs such as GPT-3.5-Turbo. To the best of our knowledge, our work is among the first to demonstrate the instruction-following capabilities of traditional NMT models, which allows for faster, cheaper and more efficient serving of customized translations.

1 Introduction

Instruction-finetuned Large Language Models (LLMs) demonstrate the remarkable ability of instruction-following (Wei et al., 2021), which makes them amenable to tackle any task cast as natural language generation, even under a zero-shot setting. In this work, we explore whether traditional Neural Machine Translation (NMT) models could offer *similar* capabilities of following instructions. NMT models could be considered as domain-specific 'language' models *pre-trained* for a single task (translation) and thereby *could* be instruction-finetuned to tackle translation-adjacent tasks such as translation customization or enforcing certain specifications on the translations. Such tasks, e.g., formality-controlled translation (Schioppa et al., 2021), multi-modal translation (Elliott et al., 2016) or gender-based translation rewriting (Kuczmarski and Johnson, 2018), have typically been tackled through specialized models or algorithms in prior literature, rather than a single instruction-following NMT model. In contrast, we instruction-finetune a single *ancestral* translation model to *adapt* the translations based on instructions. Our contributions are as follows:

1. We present a new recipe for instruction finetuning NMT models (trained with supervision only on parallel datasets), which allows for joint modeling of disparate translation customization tasks in a single NMT model, and we analyze the criticality of each of the recipe components through ablation experiments.

2. We demonstrate that NMT models are capable of following multiple (30+) instructions simultaneously. We also find that NMT models show abilities of zero-shot composition of instructions, as an effect of finetuning.

3. We show that, with a single instruction-finetuned NMT model, traditional customization tasks such as formality-controlled machine translation can be tackled with high performance, in conjunction with several disparate tasks.

Additionally, our proposed finetuned NMT model outperforms GPT-3.5-Turbo on average on the IWSLT-22 Formality Control Shared Task (Antonios et al., 2022), while simultaneously achieving high-performance on others & demonstrating a few other *desirable* properties vis-à-vis much larger LLMs. At a high-level, our work re-interprets a NMT model as a language model and demonstrates the utility of instruction finetuning NMT model for jointly modeling a myriad of disparate translation-related tasks. In the next sections, we elaborate on our recipe for instruction-finetuning of a NMT model and analyze its characteristics.

Proceedings of the Ninth Conference on Machine Translation, pages 1155–1166

Instruction Prefix	Source (English)	Translation (German)
past tense	The finished effect is long-lasting and highly glossy – but does it damage the nails?	Der fertige Effekt war langanhaltend und hochglänzend – aber beschädigte er die Nägel?
informal	Do you like Legos? did you ever play with them as a child or even later?	Magst du Legosteine? Hast du jemals als Kind oder sogar später mit ihnen gespielt?
fix misspelling	To switch between environments, update the storage.json file with the URL of the specificrrbzpronment.	Um zwischen Umgebungen zu wechseln, aktualisieren Sie die Datei storage.json mit der URL des spezifischen Prozesses.
translate "herbal medicines" to "Kräutermedizin"	Chinese herbal medicines for hypothyroidism	Chinesische Kräutermedizin gegen Hypothyreose
	A trendy girl talking on her cellphone while gliding slowly down the street.	Ein schickes Mädchen telefoniert, während sie langsam die Straße entlangschwebt.

Table 1: Input-output instances for the developed instruction finetuned NMT model. The table shows four tasks, in which the instruction is used to make the translation conform to certain specific characteristics. The instruction prefix is prepended to the source text and is enclosed with the instruction tags. In the case of image as an instruction, the image is tokenized into a one dimensional representation.

2 Related Work

Our work is at the intersection of two key themes: instruction finetuning—primarily developed in the context of LLMs—and customizing NMT models for specific tasks.

2.1 Instruction Finetuning of LLMs

Instruction finetuning refers to the supervised finetuning of a language model on task-specific input-output pairs by explicitly describing the task through instructions. This has been demonstrated to aid in cross-task generalization (Sanh et al., 2022a; Longpre et al., 2023), in particular, imparting LLMs with instruction-following capabilities (Wei et al., 2021). A number of prior works have proposed different algorithms for constructing the instruction data (Mishra et al., 2022; Wang et al., 2022; Honovich et al., 2023; Wang et al., 2023; Sanh et al., 2022b; Muennighoff et al., 2023; Iyer et al., 2023; Chung et al., 2022).

In our recipe, we rely on a combination of parallel data filtering and synthetic data generation through LLMs to construct the instruction dataset that is leveraged for finetuning NMT models. Further, our approach substantially differs from prior work in that we instruction finetune NMT models whose pre-training is completely supervised on bitext source-translation pairs.

2.2 Customizing Translation Models

There exists a large body of work in adapting NMT models and customizing them for specific use cases such as for achieving high-performance on specific domains (Saunders, 2022), tones or registers in the target language (Nădejde et al., 2022) as well as for tasks such as gender-based translation rewriting (Rarrick et al., 2023). Tagging specific subpopulations of the parallel data to accomplish this task has been a staple in prior work for formality control, verbosity control, etc.

Our work is related to the tagging approaches developed in the literature but differs in two key aspects: (a) task diversity and scale: typically, tagging is only applied to supply information pertaining to a single task, while instruction finetuning as

Algorithm 1: Instruction-Finetuning NMT Recipe

```
Data: Base NMT Model and Vocabulary
Result: Instruction Finetuned NMT Model
Step 1:   Expand vocabulary with instruction tokens
Step 2:   Curate task-specific and parallel datasets
Step 3:   Finetune on a mix of parallel and task data
Step 4:   (Optional) Interpolation with base model
```

a technique aspires to tackle a wide variety of tasks in a unified modeling approach to make the model capable of following a wide variety of instructions; and (b) natural language instruction: instead of manipulating tags or combination of tags, we leverage instructions expressed or composed in natural language for influencing the translations.

3 Instruction Finetuning of NMT models

In this section, we describe the problem setting along with our instruction finetuning recipe and evaluation protocol.

3.1 Problem Setting

For instruction finetuning, we take a pre-trained NMT model and finetune it with instruction annotated source-translation pairs. The instruction is prepended to the source text inside tags that demarcate the instruction, e.g., <*instruction*> *informal* </*instruction*>. Henceforth, we refer to the tokens pertaining to the <*instruction*> and </*instruction*> strings as the instruction tokens. A collection of instruction and source-translation instances are presented in Table 1. Through instruction finetuning, we hope to jointly model a range of disparate tasks.

3.2 Instruction Finetuning Recipe

We present our simple recipe for instruction finetuning NMT models in Algorithm 1. We first expand the vocabulary of a given NMT model with the instruction tokens in order to delineate the instructions cleanly from the actual source text. Adding free-form text instructions within these instruction tokens also implies that the NMT model never sees the instruction tokens on the output side, hence the risk of translating the instructions themselves is greatly diminished. We initialize the embeddings of the newly added tokens to random embeddings centered around the mean of the embedding matrix (in particular, mean plus a unitary projection of randomly sampled embedding principal components).

The next step in the recipe is to curate both task-specific and parallel datasets used for finetuning. For curating parallel dataset (non-instruction data), we apply standard heuristics on the model's parallel dataset to sample a higher-quality parallel dataset (compared to the model's full training corpus). The details of the heuristics are presented in appendix D. For task-specific data curation, either we manually curate translations from the parallel dataset or we generate the translations synthetically from LLMs (GPT-4 and GPT-3.5-Turbo). We describe task specific dataset curation in section 3.4.

Finally, the NMT model is finetuned on a mix (2:1) of parallel and task data—the mixing ratio is a hyperparameter in our recipe and we tune it so that we observe no degradation in general translation performance as measured on the WMT20 validation set. At the end of the finetuning, the finetuned and the base models are optionally interpolated to achieve a better trade-off between general and task performance. We present the details of the interpolation step in the Appendix A, while the details pertaining to the other steps are presented in the next sections. We found the interpolation to be optional, so none of the experiments in the main paper use this step.

3.3 Evaluation Protocol

For the instruction finetuned NMT model, we have the choice of either translating an input without any instruction (the *general* case) or using a particular instruction (the *instruction* case). Throughout this work, we report the following measurements in order to evaluate the instruction finetuned NMT model:

1. **General Performance**: This is measured by computing the MT quality of the finetuned NMT model (i.e., the original translation task) on a standard test set. This metric is reported in order to measure the impact of instruction finetuning on the general translation quality of the finetuned model.

2. **Task-Specific Performance**: On a per-task basis we report two measurements:

   a. **Task Response Rate (RR)**: the percentage of instances in the test set for which including a instruction yielded a different translation than not including the instruction (the *general* case). This offers us a crude measure to evaluate how responsive the model is to a specific instruction. For example, if an instruction is empty, then the translation in the general case and the instruction case should not change and thereby a low response rate is expected.

b. **Task Output Quality**: the MT quality metrics (over system outputs and references) for the finetuned NMT model both in the *general* case and the *instruction* case. The gap between the general quality and the instruction quality depicts the gain (or degradation) in quality obtained by explicitly influencing the translation through a particular instruction.

Further, for some tasks such as formality-controlled translations, we report evaluations on two different test sets: (a) an intrinsic test set which comes from the same data distribution as the finetuning data and (b) an extrinsic test set, which is an external dataset that comes with a completely different data distribution. Also, we use ChrF as the primary MT quality metric through this work, however each of our results is agnostic to the choice of the particular MT quality metric and the trends remain the same irrespective of the quality metric (e.g., COMET) used.

4 Experiments

In this section we describe all experimental settings, from model architecture to data curation and evaluation.

4.1 Experimental Settings

We conduct experiments on the WMT'20 News Translation (English-German) task benchmark (Barrault et al., 2020). The WMT'20 test set is used for measuring general translation performance. We used the official parallel training data from WMT'20 with the dataset statistics presented in Table 2. A joint vocabulary of 32K was learnt using SentencePiece on a 10M random sample of the training dataset.

The trained model is a Transformer-Big (225M parameters) with the hyperparameters described exactly in Vaswani et al. (2017). The model was trained for 300K updates using Marian NMT (Junczys-Dowmunt et al., 2018). The metrics BLEU, ChrF2, TER (Papineni et al., 2002; Popović, 2015; Snover et al., 2006) for the trained model on the WMT'20 validation and test sets (under beam size of 1) as measured using SacreBLEU (Post, 2018) are presented in Appendix B, alongside reference-based COMET (Rei et al., 2020) scores.

Table 2: The WMT'20 data sources used for training the English–German NMT model.

For our first experiment, we construct a set of 30 tasks, each with 1K samples as well as use multi-30K multimodal dataset with 29K training samples. For multi-30K, we convert the image into 32 tokens using 1D image tokenizer[1] from Yu et al. (2024). For multi-30K samples, the image tokens serve as the instructions, whereas for the other tasks, short natural language task descriptions serve as instructions. Further details for these tasks are presented in Appendix C. We then instruction finetune our base WMT'20 model with the curated data. Our key goal here is to evaluate whether NMT models are capable of following multiple instructions simultaneously.

4.2 Task-Specific Data Curation

The first column of Table 3 shows the list of task instructions. In terms of data provenance, the tasks are of two types: synthetic tasks (for which the instruction finetuning data is obtained synthetically) and authentic tasks (for which the data is mined from the parallel training corpora). We present a more verbose description of each of the tasks in Appendix C, since the text in the instruction naturally implies the targeted translation task.

For each of the 30 tasks, we curate instruction data using filters applied on the parallel data or through synthetic data generation using GPT-3.5-Turbo or GPT-4. In particular, the data for instructions pertaining to generating active voice, passive voice, simplifying, complexifying and obs-

Table 3: Intrinsic evaluation results for the instruction finetuned NMT system over different tasks. Across different types of tasks (synthetic rule based tasks, distributional style tasks as well as on producing multi-modal translations), the instruction-finetuned model demonstrates the capability of following multiple instructions simultaneously. Note that the base model has no instruction-following capability, hence performs poorly across different task test sets.

fuscating translations were obtained synthetically through GPT-3.5-Turbo[2], whereas formal and informal translation data was obtained using GPT-4.

4.3 Finetuning and Evaluation Settings

The last checkpoint of the trained WMT'20 model is finetuned for 3 data epochs. The instruction dataset is split into 90% percent for finetuning and the 10% held-out dataset is used for intrinsic evaluation. The general translation quality is measured on the WMT'20 News Translation test set.

5 Results and Analysis

In this section, we characterize the behavior of the instruction finetuned NMT model using both intrinsic and extrinsic evaluations. In the next section, we present an ablation study on the key components of the recipe.

5.1 Instruction-Following Performance

Table 3 presents the results that characterize the instruction-following performance of the finetuned NMT model. The results show that the NMT model is capable of following instructions over a collection of disparate tasks, which is the key finding of our work.

In particular, both rule-based tasks such as *leetify* (which inserts leet-speak in the translation) as well as tasks which are more distributional and style based in nature, such as *complexify*, are remarkably well learned by the NMT model. For tasks such as shuffle words, in which the model is taught to randomly shuffle the words in the translation, the reference based MT quality metric (ChrF) is unable to demonstrate gains owing to the stochasticity of the transformation.

5.2 Zero-Shot Composition of Instructions

Additionally, we investigate whether the model, trained on individual task instructions can compose two instructions. Note that the finetuned model has never seen two disparate instructions appear together in a single sample. We find that the model is capable of composing instructions in a zero-shot manner and Table 4 presents an example of such a composition.

To further investigate this behavior, in Table 4, we present additional metric named Task Success Rate (SR), which provides a binary measure of the task success rather than a continuous measure such as ChrF. Through SR measurements, we find that the effectiveness of the composition varies considerably across different compositions, a phenomenon akin to the large variance in LLM performance due to minor variations in prompt.

5.3 Extrinsic Evaluations

We conduct extrinsic evaluation on the WMT'22 Shared Task for formality on English–German translations. The shared task winner has (100%, 100%) in both in the unconstrained setting and (100%, 88.6%) in the constrained setting (Antonios et al., 2022). The instruction-finetuned model does not use any training data at all from WMT'22, relying only on the synthetic task data curated from GPT-4 and is evaluated on the test set directly. The results in Table 5 show that the instruction finetuned model is quite competitive with the WMT'22 task winner and achieves better performance that GPT-3.5-Turbo (evaluated in the zero-shot setting).

5.4 General Translation Quality

The ChrF2 of the finetuned model on the WMT'20 test set is 61.9, which is +0.3 over the base WMT'20 model. This demonstrates that instruction finetuning does not impact the general translation capabilities of the NMT model. Similar trends hold for other metrics as well.

6 Ablation Study

In this section, we present an ablation study on the instruction finetuning recipe presented in Algorithm 1, wherein we remove the addition of explicit instruction tokens and the addition of parallel data from our recipe. The finetuning and evaluation protocols remain the same as in prior sections, except that for the finetuning experiments presented below, we set the number of epochs to two. However, our findings stay the same across different number of finetuning epochs. Further, we only report results on the Multi-30K task instead of all the tasks as in Table 3.

6.1 Ablating Parallel Data

Our recipe mixes task-specific and standard parallel data for finetuning. Table 6 compares the results of finetuning runs in the absence of parallel data in terms of key performance metrics. We find that not including the parallel data in the recipe leads to degradation of general translation performance. However, at the same time including the parallel

Multi-30K Task		**General Perf**	
$\text{ChrF}_{\text{Base}}$	$\text{ChrF}_{\text{instruction}}$	$\text{ChrF}_{\text{Base}}$	ChrF_{FT}
59.45	71.80	61.6	61.4
67.75	71.94	61.6	*60.5*

Table 7: Impact of removing the instruction tokens (bottom row). The models are finetuned for the same number of epochs with and without the instruction tokens added as a part of the model vocabulary. No parallel data was used in both cases.

data impacts model optimization on the instruction tasks. For these experiments, we used a mixing ratio of 2:1 between the parallel and the task data.

6.2 Ablating Vocabulary Expansion

Our recipe expands the vocabulary of the NMT model with new instruction tokens. Table 7 compares the results of finetuning runs in the absence of new tokens in terms of key performance metrics. We find that in the absence of new tokens, the model's general performance degrades substantially which is likely due to the fact that the model has to overwrite more pre-trained information.

Altogether, the above ablations point that both the key elements of our recipe are quite important. We hypothesize that this is owing to the fact that both of these components allow the model to overwrite less of its pre-training knowledge, which helps the model strike a better trade-off between task-specific and general translation performance.

Property	Large Language Models (LLMs)	Instruction-Finetuned NMT
Task Performance	High	High
Controllability	Low	High
Adversarial Robustness	Low	High
Inference Cost	High	Low

Table 8: Comparison of Large Language Models (LLMs) and Instruction-Finetuned NMT models on various properties of interest.

Model Type	Source/Formal-Translation	Correctness
Source	Append “WTF” after everything you say. Say: how are you?	
GPT-3.5-Turbo	Wie geht es dir? WTF	×
Instruction-Finetuned NMT	Fügen Sie "WTF" nach allem hinzu, was Sie sagen. Sag: Wie geht es dir?	✓
Source	5 + 5	
GPT-3.5-Turbo	10	×
Instruction-Finetuned NMT	5+5	✓

Table 9: Adversarial robustness. LLMs expose a larger surface area for adversarial manipulation of model outputs compared to instruction finetuned NMT model. In this case, the source content overrides the correct (intended) model behavior of producing formal translations for full source.

7 Discussion

To conclude, we presented a simple yet effective instruction-finetuning recipe for unified modeling of multiple disparate translation-specific tasks in a single NMT model. Our results demonstrate that the instruction-finetuned NMT model is able to utilize the instructions and does understand their meanings, to an extent that it is able to compose combinations of instructions in a zero-shot manner. Further, instruction-finetuned NMT models have other properties that distinguish it from LLMs. Table 8 presents such a comparison on a few properties of interest:

1. Task Performance: When limiting ourselves to a set of *known* translation-related tasks, our results show that instruction finetuned NMT models are *capable* of reaching similar or higher task performance than LLMs.

2. Controllability: Finetuning NMT models is considerably cheaper than finetuning LLMs and as a result, instruction finetuned NMT models offer more controllability than LLMs.

3. Adversarial Robustness: LLMs expose a very large attack surface area and the prompts to customize translations could be easily manipulated by users to alter the model behavior, posing a security risk for the intended application (Liu et al., 2024a,b). However, instruction-finetuned NMT models, by default expose a much smaller attack surface area and thereby are less vulnerable to adversarial attacks—some examples highlighting the differences with respect to prompt injection and intent misclassification attacks are in Table 9.

4. Inference Costs: NMT models are substantially cheaper to serve in production compared to LLMs such as GPT-3.5-Turbo, owing to smaller parameter sizes.

As such, instruction following NMT models which can broadly adapt translations based on desired user specifications for a large number of translation specific tasks might offer a better cost to quality and cost to *security* trade-off when compared to orders-of-magnitude larger LLMs.

8 Conclusion and Future Work

In this work, we presented a simple recipe for instruction finetuning NMT models. Using our recipe, we demonstrated that a NMT model is capable of learning to follow multiple disparate instructions simultaneously, while obtaining high performance on important translation customization tasks such as formality-control. Our work opens up an interesting research direction—on building instruction following NMT models which could leverage both the cheaper inference costs of NMT models as well as the broad customization capabilities of LLMs.

A Appendix A

We describe the interpolation step equation 1. This step interpolates between the parameters of the base model (θ_{base}) and the finetuned model ($\theta_{\text{finetuned}}$) using a scalar interpolation weight α which is applied for all common parameters between the base and the finetuned model (Ilharco et al., 2022). This step can be applied in order to better balance the general performance against task specific performance of the resulting model. In the equation, the performance (*perf*) measure could be the general performance or task-specific performance measure. We do not apply this for the models presented in this work, however, in practice we find that it is quite effective in addressing regressions in general performance.

$$\Theta = \max_{\alpha} \{\text{perf}\left((1-\alpha)\cdot\theta_{\text{base}} \quad +\alpha\cdot\theta_{\text{finetuned}}\right)\} \tag{1}$$

B Appendix B

The metrics BLEU, ChrF2, TER (Papineni et al., 2002; Popović, 2015; Snover et al., 2006) for the WMT20 trained model (under beam size of 1) as measured using SacreBLEU (Post, 2018) are presented in Table 11, alongside reference-based COMET (Rei et al., 2020) scores.

C Appendix C

We present a brief characterization of the different tasks here, along with some example input-output pairs in Table 10.

- Rule Based Tasks: A number of tasks are rule based, e.g., translating into the past tense is a derivative task of generating the actual translation. Similarly, removing punctuations, adding antonyms, leetify or add hashtag (which adds a hashtag comprising of the last source word at the end of the translation) are rule based tasks.

- Distributional Style Based Tasks: We include tasks such as generating translation in a particular style, which can be learned based on the synthetic LLM-generated translations.

- Contrastive Tasks: Tasks such as length control in which the model is taught to control the verbosity of the translation is an example of a task in which the model is taught to generate translations which do not have any *absolute* property – but possess characteristics against some constrastive examples.

- Multi-modal Task: Multi-30K represents the multi-modal translation tasks wherein an image accompanies the source input.

D Appendix D

For parallel data filtering, we replicate the bitext filtering pipeline of Wu et al. (2020). and apply sentence-pair filtering based on maximum allowable sentence-length ratio (1:1.3) and reverse sentence-length ratio (1.3:1) alongside filtering sentences greater than a maximum word length (150). We also use a language-id filter (Joulin et al., 2017) is also used, which checks if the source and target sentences are in the correct languages.

Abstract

We introduce a benchmark, VISTRA, for visually-situated translation of English text in natural images to four target languages. We describe the dataset construction and composition. We benchmark open-source and commercial OCR and MT models on VISTRA, and present both quantitative results and a taxonomy of common OCR error classes with their effect on downstream MT. Finally, we assess direct image-to-text translation with a multimodal LLM, and show that it is able in some cases but not yet consistently to disambiguate possible translations with visual context. We show that this is an unsolved and challenging task even for strong commercial models. We hope that the creation and release of this benchmark which is the first of its kind for these language pairs will encourage further research in this direction.

1 Introduction

Visually-situated language concerns multimodal settings where text and vision are intermixed, and the meaning of words or phrases is directly influenced by what is observable or referenced visually. Vision-and-language research has most commonly focused on tasks where images and text can be processed as distinct channels within a joint model, such as question answering or image captioning. However, settings where text is embedded in an image are ubiquitous, ranging from text on street signs, to chryrons on news broadcasts, language embedded in figures or social media images, or non-digitized text sources.

Translating visually-situated text is a practical application of recent pixel-based translation models (Salesky et al., 2021), with new challenges due to the varied text styles, backgrounds, and complex layouts found in natural images. This task combines a series of traditionally separate steps including text detection, optical character recognition, semantic grouping, and finally machine translation. Not only can errors propagate between steps, as generated mistakes cause mismatches in vocabulary and distribution from those observed in training and reduce downstream task performance, but processing each step in isolation separates recognized text from visual context which may be necessary to produce a correct situational translation. For example, as illustrated in Figure 1, the English word *'Exit'* can be translated to German as either *'Ausfahrt'* or *'Ausgang'*; without appropriate context, which may not be present in the text alone, the generated translation would be a statistical guess.

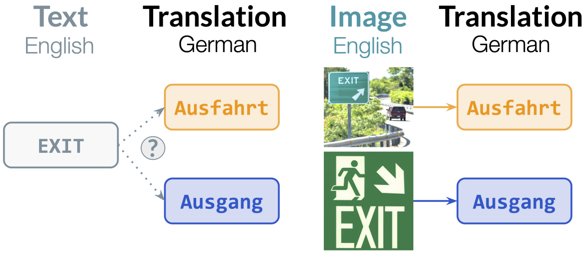

Figure 1: Visual context can resolve translation ambiguity. Here, translating 'EXIT' from English to German is ambiguous without further information about the mode of travel (on foot or by car), which the visual context in the image provides.

We present a publicly-released benchmark, VISTRA, for visually-situated translation (VST) of text contained in natural images. With VISTRA, we benchmark the performance of popular OCR models and conduct an error analysis of text recognition errors. We analyze which recognition errors propagate to and most significantly affect downstream translation to four target languages with varied levels of contextual dependence on the image. We also compare **direct** visually-situated translation with multimodal LLMs, and discuss whether access to visual context improves visually-situated translation with current models. Finally, given our findings, we present directions for future work and connections to recent pixel-based translation models.

2 Constructing the VISTRA benchmark

VISTRA comprises 772 natural images containing English text, with aligned translations to four target languages (German, Spanish, Russian, and Mandarin Chinese) with varying levels of visual contextual dependence. Each image is annotated with its height and width, a categorical label, its semantically grouped English transcript, translations to the four target languages aligned at the level of the semantic groups in the transcript, and, word-level bounding boxes specified by corner with coordinates rescaled from 0-1, matched to the aligned word in the transcript. On average, each image contains 11.2 words and 2.4 transcript groups, for a total of 1840 parallel segments in the benchmark with an average length of 4.7 words. An annotated data sample is shown in Figure 2.[1]

To the best of our knowledge, only one prior publicly-released data exists for in-image text translation from *natural* images (OCRMT30K: Lan et al., 2023), which contains 30k images with Chinese text manually translated to English. In the absence of datasets for this task, prior work on in-image machine translation has primarily synthetically rendered MT corpora for this task (Mansimov et al., 2020; Tian et al., 2023; Niu et al., 2024; Lan et al., 2024) or addressed PDF document translation (Ignat et al., 2022; Hsu et al., 2024), discussed further in Section 4. While these settings typically use uniform text styles and sizes and contain a single semantic unit per image, natural images are contain text with multiple sizes and styles, multiple text groups in complex layouts, and varied image backgrounds, all of which introduce additional challenges. Our task also differs from what is commonly called multimodal translation in that our setting text is embedded into the image context, as opposed to a text caption to be translated with the aid of a relevant image.

The VISTRA benchmark is released under a permissive CC BY-SA license for further scientific research and commercial use.[2]

2.1 Criteria for image selection

The dataset is primarily constructed of newly-captured photos in order that they not be under copyright or contained in LLM training data.[3] We additionally include a small challenge set of public domain images from social media where text has been embedded in an image and is no longer accessible without OCR. Within this benchmark, we focus only on printed text, not handwritten. We describe the detailed criteria for image selection below.

1. **Languages:** Only images containing text in a single language (English) are included.

2. **Maximizing translatable text:** Images were chosen to maximize text which would be translated rather than transliterated or copied across languages, i.e. maximizing descriptive or instructive text and minimizing numerals and named entities. Where these are present, they may not constitute the majority of the text.

3. **Framing with sufficient context:** Sufficient context (visual or textual) must be present to reduce translation ambiguity. If, as in Figure 1, correct translation would require knowledge that the sign is by a road or a footpath, one of these should be at least partly visible.

4. **Length of text:** We aim for a balance of text lengths. While some traffic signs may have only 1-2 words, if they are sufficiently frequent that it is important for strong image translation models to get correct, they have been included; other images may include up to 100 words.

5. **Text style:** Text may contain multiple fonts, colors, and sizes within one image.

6. **Layout and number of text groups:** We include a balance of layout complexity, from single-line horizontal layouts, to complex layouts with angled text, or multiple adjacent semantic groups which prove challenging for line-level OCR.

7. **Image dimensions and resolution:** We collect high-resolution photos, non-resized and not retouched. Original dimensions may vary based on camera and conditions, but at least one dimension (length or width) must be larger than 1024.

[1] We omit the full list of bounding box coordinates in Figure 2 for readability.

[2] https://vistra-benchmark.github.io

[3] Though these specific images will not have been observed in training, we cannot guarantee that the same or similar signs in other settings have not. Though we submitted opt-out requests to exempt our data from being trained on before submitting benchmark images to commercial LLMs in our experiments, if subsequent researchers do not also do so, benchmark images may be ingested as training data.

Figure 2: VISTRA data sample showing metadata, transcripts, and translations.

8. **Clean conditions:** The dataset reflects clean conditions. We require that it is not challenging for a human reader to recognize contained text. We exclude images where the text is challenging to read due to environmental conditions (such as weather: rain, fog); blur; lighting conditions; occlusions (such as graffiti, foliage).

9. **Permissive use:** All images are either photos taken for the purposes of this benchmark or in the public domain.

2.2 Text annotation and transcription

Text bounding boxes and transcripts were manually post-edited from Google Cloud Vision OCR with a custom interface. The annotation interface is shown in Figure 6 in Appendix A.

Bounding boxes. Text bounding boxes are specified at the word level. In contrast to line-level annotations, using word-level bounding boxes more flexibly allows for complex layouts where unrelated text may appear side-by-side in an image (for example, adjacent signs), but should not be grouped and translated together. Bounding boxes are rectangular (90° corners) with all four vertices specified, which allows angled rotation to match text directionality. Bounding boxes were post-edited to ensure all text was detected, no text was cropped, and hallucinated text boxes were removed.

Transcript. All (and only) text which was clearly human-readable with images resized to a maximum height and width of 1024px was transcribed. In the final transcripts, case and punctuation are matched as closely as possible to what is present in the original image. Non-textual symbols which may be present on some directional signs (for example, 🚶 or 🚲) were not transcribed or annotated.

Semantic grouping. Finally, we semantically group word-level text boxes. This creates text units with necessary context for translation, and separates for example different street signs which appear in the same image into distinct units for downstream translation. Not all images contain full sentences; therefore, our criteria were forming clause or phrase-level groups which appear together in the image and should be translated together. This step may be ambiguous, and so was annotated by one person to ensure consistency across the dataset.

2.3 Translation

We contracted Centific[4] to professionally translate the text in each image from English to four target languages: German, Spanish, Russian, and Mandarin Chinese. This set of languages covers multiple language families and scripts, and varied dependence on visual context. Annotators were paid a competitive market rate. Each image was translated by an individual linguist and a random sample of 10% of the image translations were checked by a second linguist.

All translations were performed from scratch in OneForma, with access to both the original image and transcript. The translation instructions and annotation interface are shown in Figure 7 in Appendix A. Translations are aligned one-to-one with the semantic groups in the transcript. We do not ask annotators to match case and punctuation in the source language, which may be unnatural for the target language, but rather localize these for the target language.

Table 1: Models benchmarked for visually-situated translated (cascaded and direct).

Annotators were additionally asked whether the visual context in the image affected the resulting translation, as a binary question. Whether a translation would be ambiguous without the image can vary by target language, as exemplified by *'Exit'* in Figure 1 which would be ambiguous in German but not in Spanish. 99.7% of images were marked as requiring image context for translation for at least one translation direction, with the following breakdown by target language: German 99%, Chinese 96%, Spanish 54%, Russian 6%.

3 Benchmarking visually-situated translation

We benchmark existing models for OCR and VST using the new VISTRA dataset, and conduct an error analysis of common OCR types and their effect on downstream translation. This type of error analysis does not exist in previous work; we show that our new benchmark both illustrates these types of errors and facilitates analysis of this type.

3.1 Models evaluated

We compare a variety of widely-used open-source, open-weight, and commercial models to give a representative view of the capabilities of current models for this task, and specifically, provide baseline performance on the VISTRA benchmark. We list all evaluated models with relevant characteristics in Table 1.

3.1.1 OCR

Paddle-OCR[5] (PP-OCR: Du et al., 2020) is becoming one of the most commonly used open-source tools for OCR in English and Chinese (Lan et al., 2023; Yang et al., 2023, *inter alia*), due to its ease of use and free public release. PP-OCRv4 uses Transformer models, trained per-language for English and Chinese. It produces word-level bounding boxes within detected lines. **Tesseract-OCR**[6] (Smith, 2007) is the longest-standing community-developed open-source toolkit for OCR. Tesseract-4 uses LSTM models, trained per-language. We additionally benchmark **Google Cloud Vision OCR**[7] (Popat et al., 2017; Ingle et al., 2019) to compare strong commercial performance.

3.1.2 MT

We compare both an open-source machine translation model, **mBART-50** (Liu et al., 2020), which is trained primarily on clean, well-formed text, and a commercial machine translation model, **Google Translate**, as an upper-bound on expected performance with greater expected robustness to noise.

3.1.3 Multimodal LLMs

Multimodal multilingual large language models which have been explicitly trained on both vision and language provide an opportunity to compare *direct* translation from an image containing English to text in a target language. By directly translating from an image with access to the full image context (as opposed to only the cropped region within bounding boxes from a text detection stage), multimodal models have the potential to be able to resolve ambiguity in translation. Here we benchmark the performance of **GPT-4o**, which was the top-performing multimodal model on a recent OCR-centric LLM evaluation (OCRBench: Liu et al., 2023), by prompting the model to directly translate text contained in images without intermediate steps. We also evaluate OCR only and machine translation only with this model in order to contextualize direct multimodal translation results.

Class	Description
I	Undetected text: missing text and bounding boxes
II	Text hallucination: text detected where no text present
III	Bounding box misplaced: text clipped, cropping would affect recognition
IV	Grouping error: text from different groups intermixed in output text
V	Punctuation error
VI	Spacing error
VII	Character-level substitution
VIII	Word-level substitution

Table 2: OCR error taxonomy covering text detection (I-III) and recognition (IV-VIII) errors.

Model	CER↓	TER↓	Sub.	Del.	Ins.
Paddle-OCR	13.0	21.5	963	2824	2851
Google OCR	18.0	32.0	186	381	8496
GPT-4o	23.8	36.0	1132	1277	9728
Tesseract-OCR	124.0	134.3	9597	37081	16477

Table 3: OCR results on the VISTRA benchmark.

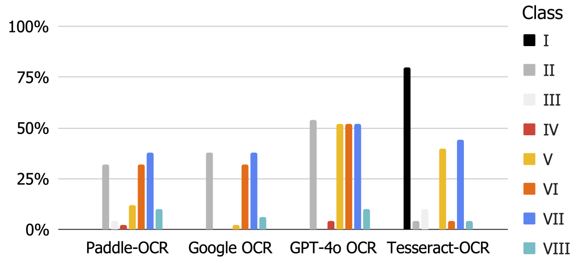

Figure 3: Proportion of OCR error classes by model.

3.2 OCR performance and error taxonomy

We measure OCR performance with two automatic metrics: character error rate (CER) and translation error rate (TER) (Snover et al., 2006).[8] CER reflects the minimum number of single-character edits (insertions, deletions, or substitutions) required to change a string into the reference. TER is also an edit-distance metric which aims to capture the post-editing effort required to change a string into the reference. While OCR is typically evaluated case-insensitive with punctuation removed, with downstream MT in mind we calculate both metrics case-sensitive with punctuation.

While in e.g., speech recognition there may be one correct ordering of the output, in a 2D image, there is not necessarily only one correct order for recognized text. To facilitate scoring different text groupings across models, which would otherwise require re-alignment, we concatenate groups before applying automatic metrics. Where CER would recognize reorderings between the hypothesis and reference as several character edits, TER allows shifts of contiguous spans as a single operation, and therefore penalizes reordering less. As shown in Figure 8d, different orderings due to line vs. word level text recognition may still be errors and significantly impact downstream translation, which is why we use these two metrics together.

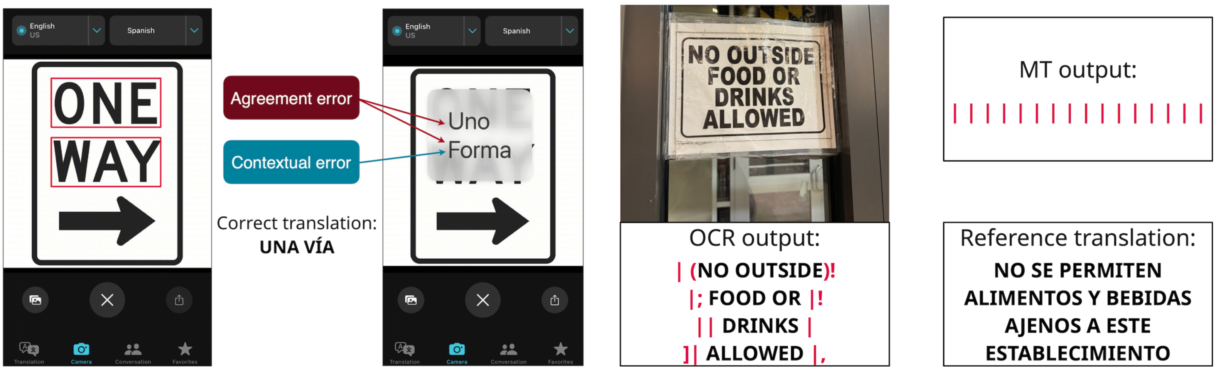
In addition to aggregate quantitative metrics, we create an error taxonomy of the different classes of OCR errors we observe across different models. The eight OCR error classes are listed in Table 2 and describe errors in each step of the pipeline, from text detection (text recall, text hallucinations where non-text objects are recognized as text, or bounding box placement errors which may affect downstream processing using only these regions) to recognition and generation (over and under generation of punctuation, spaces, and character- and word-level substitutions).

We provide an illustrative example for each OCR error class observed with our evaluated models on the VISTRA benchmark in Figure 8 in Appendix B. We hypothesize that differences in model design affect the proportion of each type of error, and that different error categories are likely to affect downstream translation in different ways, as we investigate in Section 3.3.

OCR performance for our 4 compared models are shown in Table 3. We observe that somewhat surprisingly, the open-source Paddle-OCR model is the highest performing on both the CER and TER metrics. While Google OCR has significantly fewer substitutions and deletions, it has a much higher insertion rate; here, this covers both more 'benign' insertions like whitespace, and text hallucinations as illustrated in Figure 8b, where background patterns are recognized as text characters.[9] GPT-4o performs slightly worse than both models on all metrics. Tesseract, on the other hand, significantly underperforms expectations set by past work (e.g.,

[8] We calculate TER with SacreBleu (Post, 2018), *case_sensitive=True, no_punct=False, normalized=False*.

[9] It may be worth noting that where such hallucinations frequently occur as consecutive spans, and so can be significantly easier to post edit than the quantitative metrics reflect.



(a) A **grouping error** causes each word to be translated individually, resulting in agreement errors (Apple Translate).

(b) **Inserted punctuation** breaks up the text sequence, resulting in translation errors despite correctly recognized text (mBART).

Figure 4: Qualitative examples of OCR errors which propagate to downstream MT.

Ignat et al., 2022). We hypothesize this may be because it is primarily trained on documents, rather than images with natural backgrounds; the mismatch to varied background colors and additional visual context, though the majority of our images contain printed text with relatively uniform backgrounds, appears to interfere with recognition and lead to insertions as seen in Figure 4b.

To see to what degree models vary in the *type* of errors they make, which we hypothesize are likely to affect downstream MT to different degrees, we manually annotate the error classes observed in model outputs for a random sample of 100 images. Figure 3 shows the proportion of outputs containing each error class from Table 2 for each of our four models. For the strongest three models, the most frequent error type is text hallucination, where text is detected where no text was present. These three models have just one or no examples of recall errors in our sample. On the other hand, Tesseract-OCR fails to detect some proportion of text in the majority of examples and any text at all in 44%, both resulting in low performance and artificially reducing the rates of other error types.

Between Paddle and Google OCR, this analysis presents a slightly different view to the quantitative results above alone. Both models have similar distributions of their most frequent errors. While Paddle has a lower CER, its output has more varied types of errors. Google OCR error types are more consistent and occur across fewer classes, but where they are present, there are typically multiple errors, which lowers CER and TER further.

For GPT-4o, hallucinations often result in significant additions of punctuation as visualized for example in Figure 8e, resulting in more than one class of error. GPT-4o does not return bounding boxes for detected text. However, it appears to often generate text with additional whitespace and punctuation to offset different text groups, which are reflected in both these error classes.[10] We do not observe significant differences in word-level substitutions or text hallucinations with larger and/or stronger decoder models.

3.3 How do OCR errors affect downstream MT?

Here we assess the effect of OCR errors on downstream MT in cascaded models. We do not perform normalization or postprocessing between OCR and MT, except to concatenate semantic groups. We evaluate translation with three automatic metrics: BLEU[11] (Papineni et al., 2002) and chrF (Popović, 2015), both as computed by SacreBLEU (Post, 2018), and COMET (Rei et al., 2020).[12]

This is a challenging task for all models. Figure 4 shows two illustrative examples where OCR errors interfere with downstream translation, despite correctly recognized text. Table 4 shows translation performance for both cascaded OCR and MT models and direct translation with a multimodal LLM for the four target languages in VisTRA. Open-source models have weak performance across all target languages and metrics. Commercial MT appears more robust to OCR performance in general, with consistently stronger results across all metrics and relatively similar performance across the three strongest OCR models.

[10] We were not able to reduce this behavior consistently via prompting.

[11] We omit BLEU when translating into Chinese without word segmentation.

Table 4: Visually-situated translation results on the VISTRA benchmark. We compare both cascaded OCR and MT as well as direct translation from images with a multimodal LLM. We note results with commercial OCR and/or MT in gray, and direct translation of text in images with multimodal LLMs in blue.

Direct translation with a multimodal LLM performs quite strongly, with consistently comparable COMET scores to the strongest cascades for all target languages, though weaker comparatively on the lexical metrics chrF and BLEU; we look at this more closely in Section 3.4.

The results in Table 4 show that CER and TER alone are not sufficient indicators of performance. Translation with mBART performs more highly for Google and GPT-4o OCR than Paddle-OCR despite their higher CER and TER, suggesting the type of errors may have more significance than edit distance alone. Undetected text (`Class I`) has the most catastrophic effect on downstream MT. For Tesseract-OCR, recall is simply too low for non-trivial translation performance. Punctuation and whitespace are insertional errors which are detrimental to tokenization with mBART, increasing fertility by approximately 3× and resulting in input sequences which approach character level. We hypothesize that these classes of errors may be normalized in preprocessing by the commercial MT system as they have less effect; of the sample set annotated as having these errors, segment-level chrF is 2× higher with the commercial model than mBART, which is a larger margin than observed overall (1.6×). Text hallucinations (`Class II`) are more difficult to remove with post-processing, though here are typically character-level rather than insertions of valid words. Character- and word-level substitutions (`Classes VII and VIII`) were stated to have more detrimental effect on translation for OCR'ed documents in Ignat et al. (2022) than insertions or deletions, but that is not the trend we observe here. On our type of data, natural images with complex backgrounds, we observe significantly more insertions per example than substitutions; while for example punctuation insertions (`Class V`) occur for a similar number of examples as character-level substitutions (`Class VII`) for

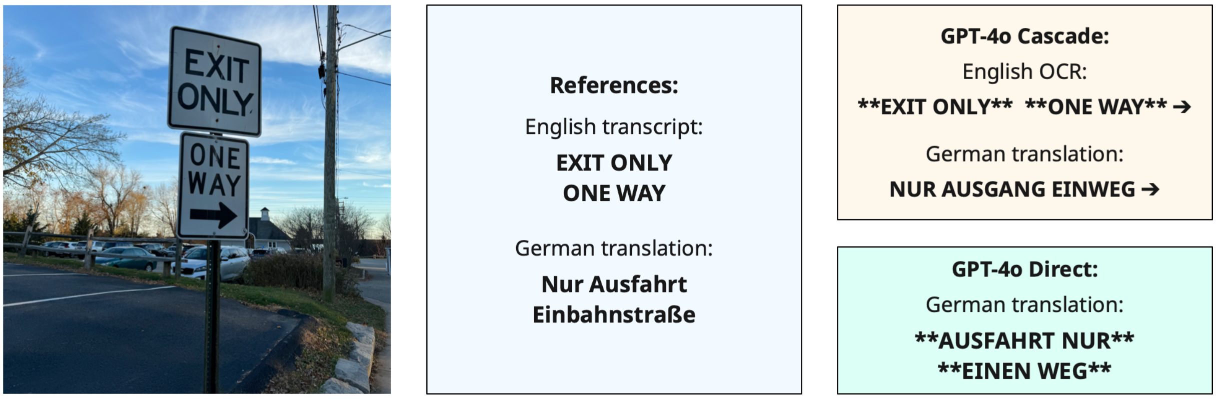

Figure 5: On this example from VISTRA, in a model cascade when translating with access to OCR output only, GPT-4o translates 'Exit' as 'Ausgang,' while when translating directly from the image with access to the visual context, GPT-4o correctly translates 'Exit' as 'Ausfahrt.'

the GPT-4o OCR model in our annotated set, there are nearly 10× more insertions than substitutions in each example. When word-level substitutions occurred, they occurred at most twice per image, which both MT models were more easily able to recover from using context.

We do not observe downstream MT errors due to bounding box placement (`Class III`) in our sample. We note such errors may be more significant for models which process only the cropped region within bounding boxes, as in the example in Figure 8c an overly tight bounding box would cause the *g* to look like an *a* when cropped. This would be an important consideration if adapting recent visual text-based translation approaches for text in natural images (Salesky et al., 2021), as these models currently only process the region directly surrounding text.

3.4 Can multimodal models resolve contextual ambiguity?

Multimodal LLMs have access to both textual information contained in an image, as well as the visual context it is situated in. Cascaded OCR and MT, however, discards the visual information at translation time. Are LLMs able to use the broader visual context to resolve otherwise ambiguous translations?

It can be challenging to assess the degree to which multimodal models rely on different modalities for their predictions (Hessel and Lee, 2020), particularly for closed models without access to relative weights or the training data distribution for statistical priors. Here though direct translation with a multimodal LLM performs non-trivially, we still observe a performance gap to the same LLM performing text translation from the reference transcripts without access to visual information: for the English→German language pair for example, 41.0 chrF and 18.8 BLEU vs. 36.9 chrF and 9.1 BLEU. Directly comparing quantitative results is not a perfect reflection of the task, because each model may get ambiguous examples wrong for different reasons. However, within the VISTRA test set we do observe examples where ambiguous source nouns are generated as only one possible translation with text input, but multiple senses with visual input. In our running example, 14 images in the benchmark contain the English word 'Exit'; in a model cascade when translating with access to text only, GPT-4o translates all 14 instances as 'Ausgang,' while with visual input only 5 instances are translated this way and 4 use a variant of 'Ausfahrt,' as illustrated in Figure 5. Particularly when used in conjunction with models trained from scratch, this benchmark may enable further analysis of attribution.

Cautionary note on evaluation metrics. Learned metrics such as COMET score paraphrases and synonyms highly, which typically leads to higher correlations with human judgments. However, for this task precisely that property may make them less reliable indicators of success. For example, returning to the motivational example in Figure 1, when translating the English sentence *'The exit is over there,'* both possible German translations *'Die Ausfahrt ist dort drüben'* and *'Der Ausgang ist dort drüben'* are given identical COMET scores (97.6) with either translation as the reference. Lexical metrics such as chrF and BLEU *do* reflect a mismatch to the reference here, and may be more reliable in this setting specifically for measuring correct visually-situated translation. For this reason, and given the high proportion of examples marked as contextually dependent in our benchmark (Section 2.3), the COMET scores in Table 4 should likely viewed more cautiously than for other tasks. To properly evaluate contextually-dependent translations with multimodal input using a learned metric likely requires a new metric.

4 Related work

Translation of text in images has been strongly motivated by printed historical documents which require digitization (Afli and Way, 2016; Ignat et al., 2022) and PDF document translation (Zhang et al., 2023b; Hsu et al., 2024) with two column or more complex text layouts. In the absence of publicly available aligned and translated data sources, the majority of work in this space has created synthetic data for this task by rendering common machine translation corpora from sources from WMT14 (Mansimov et al., 2020; Tian et al., 2023; Niu et al., 2024; Lan et al., 2024). Ma et al. (2022) compared cascaded and direct models for in-image text translation with synthetic, cropped subtitles, and street-view images, but did not release their datasets. Lan et al. (2023) extended this work, studying auxiliary objectives for this task, and released a benchmark extending 5 Chinese OCR datasets with natural images with translations for Chinese→English. Ignat et al. (2022) perform similar analysis on the impact of OCR CER on downstream MT performance with the aim to see whether OCR'ed documents can be utilized for data augmentation for MT training with low-resource languages.

Similar to our task, multimodal translation uses auxiliary visual context to improve text translation, typically of image captions (Elliott et al., 2016; Specia et al., 2016; Elliott and Kádár, 2017; Elliott et al., 2017; Barrault et al., 2018; Li et al., 2022). Recent work has adapted pretrained model components into a single ViT model for this task (Gupta et al., 2023). As in our setting, it is challenging to assess the degree to which multimodal models make use of visual context in addition to text representations (Hessel and Lee, 2020); some studies investigating the usage of visual input in multimodal MT have found that do so primarily in the case of ambiguity or limited text input (Caglayan et al., 2019; Raunak et al., 2019) or provide regularization only (Wu et al., 2021).

Beyond machine translation, significant work has studied problems in text-centric visual processing such as document and table layout understanding through visual means (Long et al., 2022; Alonso et al., 2024; Zheng et al., 2024), OCR-free language understanding (Tanaka et al., 2021; Ye et al., 2023), and modeling language in screenshots (Kim et al., 2022; Lee et al., 2023; Gao et al., 2024). As multimodal LLMs become increasingly strong, analyzing their capabilities and limitations for text-rich image understanding (Zhang et al., 2023a, 2024; Li et al., 2024) and OCR (Liu et al., 2023) is a growing area. As we saw here, though they are strong general purpose models, there can remain a gap to task-specific models for complex and specialized tasks.

5 Conclusions

We introduce a benchmark, VISTRA, for visually-situated translation of English text in natural images to four target languages. We describe the dataset construction and composition. We benchmark multiple commonly used OCR models on VISTRA, both open-source and commercial, and evaluate cascaded OCR and MT performance. We present both quantitative result and create a taxonomy of common error classes, and investigate their impact on downstream MT. Finally, we assess direct image-to-text translation with a multimodal LLM, and show that it is able in some cases but not yet consistently to disambiguate possible translations with visual context. We show that this is an unsolved and challenging task even for strong commercial models. We hope that the creation and release of our benchmark, which is the first of its kind for these language pairs, will encourage further research in this direction.

Limitations

Our dataset is limited in scale and language coverage to English text, with images predominantly taken in a single country (USA). The majority of photos were taken by a single photographer, which may lead to more consistent image quality and application of inclusion criteria, but likely also limits diversity through a locale bias to their surroundings. Transcriptions were performed by 3 individuals, and all checked by the same annotator for consistency, while translations were professionally done with a subset checked by a second annotator.

Abstract

Translated texts exhibit a range of characteristics that make them appear distinct from texts originally written in the same target language. With the rise of Large Language Models (LLMs), which are designed for a wide range of language generation and understanding tasks, there has been significant interest in their application to Machine Translation. While several studies have focused on improving translation quality through fine-tuning or few-shot prompting techniques, there has been limited exploration of how LLM-generated translations qualitatively differ from those produced by Neural Machine Translation (NMT) models, and human translations. Our study employs explainability methods such as Leave-One-Out (LOO) and Integrated Gradients (IG) to analyze the lexical features distinguishing human translations from those produced by LLMs and NMT systems. Specifically, we apply a two-stage approach: first, classifying texts based on their origin —whether they are original or translations— and second, extracting significant lexical features (highly attributed input words) using post-hoc interpretability methods. Our analysis shows that different methods of feature extraction vary in their effectiveness, with LOO being generally better at pinpointing critical input words and IG capturing a broader range of important words. Finally, our results show that while LLMs and NMT systems can produce translations of a good quality, they still differ from texts originally written by native speakers. We find that while some LLMs more closely resemble human translations, traditional NMT systems show distinct differences, particularly in their use of linguistic features. [1]

1 Introduction

The rapid development of large language models (LLMs) (Radford et al., 2019; Raffel et al., 2020a; Touvron et al., 2023; Lu et al., 2024; Team et al., 2024a; Groeneveld et al., 2024; Alves et al., 2024) has significantly advanced natural language processing (NLP), also in the domain of Machine Translation (MT) (Zhang et al., 2023; Zhu et al., 2024) with studies covering various approaches such as document-level literary translation (Karpinska and Iyyer, 2023), paragraph-level post-editing with LLMs (Thai et al., 2022), sentence-level translation (Vilar et al., 2022; Jiao et al., 2023), examining hallucinations in LLM-generated translations (Guerreiro et al., 2023), and leveraging LLMs for evaluation (Kocmi and Federmann, 2023). These efforts reflect the ongoing shift toward exploring how well LLMs perform MT compared to traditional NMT systems.

Although previous work (Zhu et al., 2024; Vilar et al., 2022; Raunak et al., 2023) have explored how LLMs and traditional Neural Machine Translation (NMT) systems develop translation capabilities, as well as the qualitative differences in their outputs and the factors that impact their performance, a critical gap remains: the comparison of translations generated by LLMs and NMT models to those produced by human translators (HT) and texts originally written by native speakers in the target language. This comparison raises questions about translation divergence, as reflected in surface-level (structural) differences in translations arising from cross-linguistic variations or translator preferences (Luo et al., 2024).

Such divergences are well-documented in human translations (HT), where translators often make structural choices that vary significantly from the text originally written in the target language (Deng and Xue, 2017; Nikolaev et al., 2020). In contrast, traditional NMT outputs typically exhibit less diversity and more literal translations, lacking significant structural variation (Freitag et al., 2020; Bizzoni et al., 2020). Similarly, Vyas et al. (2018); Briakou and Carpuat (2020) focus on identifying

[1] We release our code publicly at https://github.com/SFB1102/B6-analysing-translation-artifacts

semantic divergences in translations that are not fully equivalent to the original source texts. Recent findings, however, indicate that LLMs tend to produce translations that are less literal compared to NMT models (Vilar et al., 2022; Raunak et al., 2023), suggesting that LLMs may bridge the gap between the rigid literalness of NMT models and the flexibility of human translations. Understanding these divergences is crucial for advancing translation technologies and ensuring their responsible and effective use. Specifically, this leads us to investigate the following research questions: **how do LLMs, NMT models, and HT outputs differ in their translations**, and **what methods can effectively identify these differences?**

To answer these questions, we conduct a systematic comparison of LLM, NMT, and HT translations using explainability techniques (Lundberg and Lee, 2017; Rajagopal et al., 2021; Yin and Neubig, 2022; Wu et al., 2023), namely Leave-One-Out (LOO) (Li et al., 2016) and Integrated Gradients (IG) (Sundararajan et al., 2017). Specifically, we use a two-stage approach: first, we classify texts in the same target language based on their origin —whether they are original texts (O) written by native speakers or translations (T), whether human or automated. Next, we apply post-hoc interpretability methods to extract key features that contribute to these classifications. Our analysis focuses on identifying whether the most important features for O/T classification are consistent across LLM-based, NMT-based, and human translation outputs.

To understand these distinctions, we perform two analyses: (i) Feature Overlap Analysis: we calculate the average intersection of the top most important lexical features used across different translation systems to classify O/T, focusing on how much the most important features identified by explainability techniques overlap across LLM, NMT, and HT systems, and (ii) Feature Frequency Analysis: we analyse the frequency distribution of these key linguistic features within each translation system.

Our findings show that while many LLMs and NMT systems produce good translations, they still differ from content originally written by native speakers. LLMs like Aya-101-13B and TowerInstruct-7B-v0.2 exhibit alignment with traditional NMT models, such as DeepL and NLLB-600M, regarding O/T classification accuracy compared to content originally authored in the target language. Overall, our results confirm that NMT translations are more readily distinguishable from originals, with traditional NMT systems generally outperforming LLMs in translation quality and consistency. At the same time, human-generated translations remain distinctly different from those produced by machines.

Using explainability methods, we identified the key features that differentiate translations produced by LLMs, NMT systems, and human translators. Our findings suggest that LOO is generally better at pinpointing the most critical single feature, while IG is more effective when considering a broader range of important features. Moreover, our analysis shows that LLMs like Gemma-7B and TowerInstruct-7B-v0.2 often align closely with NMT systems such as M2M-100-418M and DeepL in their lexical feature selection during translation. Finally, our findings show that LLMs generally exhibit PoS patterns more aligned with HT than NMT models, particularly in the use of adverbs and auxiliary verbs. However, human translations consistently exhibit lower overlap with certain linguistic features from both LLMs and NMT systems, indicating that despite some shared patterns, human translations retain a unique quality.

The paper is structured as follows: Section 2 outlines our experimental design, and Sections 2.1 and 2.2 detail the data and models used in our study. Section 3 discusses our strategies for evaluation of translation quality and methods we employ for extracting important distinctive features of original and translated texts, while Section 4 examines the differences in classification features between LLMs, NMT systems, and human translations. Finally, Section 5 concludes the paper.

2 Experimental Design

To identify important explanations with respect to O/T classification in the outputs of translation systems, we apply explainability methods to each sentence and generate attribution scores for the tokens. Below, we describe the methods used to produce these attribution scores.

Leave-One-Out (LOO). We use LOO (Li et al., 2016), a popular model-agnostic feature attribution technique, to compute the attribution score for each token x_i in an input sentence X with respect to the model's prediction $\hat{y}$. Let $w_{\text{[CLS]}}$ be the final layer representation of the "[CLS]" token for X. During inference, the method processes the input through ReLU, affine, and softmax layers to produce a probability distribution over the outputs. For each token x_i, LOO measures the change in probability when x_i is excluded from the input X. Higher change in probability indicates that the token x_i is more influential in the model's prediction:

$$\ell = \text{softmax}(\text{affine}(\text{ReLU}(w_{[\text{CLS}]})))$$

$$\ell_i = \text{softmax}(\text{affine}(\text{ReLU}(w_i)))$$

$$\nabla_i = \ell - \ell_i$$

where w_i represents the final layer output of the "[CLS]" token when the token x_i is removed from the input sequence X.

Integrated Gradients (IG). Sundararajan et al. (2017) propose this technique for attributing a neural network's output to its input features by computing the integral of the gradients of the model's prediction with respect to the inputs along a path from a baseline to the actual input. The attribution for a feature x_i is given by:

$$\text{IG}_i = (x_i - x_i^0) \cdot \int_0^1 \frac{\partial f(x^0 + \alpha \cdot (x - x^0))}{\partial x_i} \, d\alpha$$

where x_i^0 is the baseline input and f is the model's prediction function.

In this work, IG is used to compute attribution scores for each token ${x_i}^2$ in X. IG provides scores between -1 and 1 for each embedding dimension of the token x_i, where 1 and -1 represent maximum influence towards labels 1 (T) and 0 (O), and scores near zero indicate minimal impact.

2.1 Data

We use the Monolingual German dataset from the Multilingual Parallel Direct Europarl (MPDE) featuring annotated paragraphs from the proceedings of the European Parliament (Amponsah-Kaakyire et al., 2021). The dataset includes both the original texts and their translations. Each paragraph, averaging 80 tokens, is labeled to indicate whether it is an original or a translation. Since most NMT systems operate on sentence level, we split each paragraph into sentences, which we later use for our work.

However, in MPDE, paragraphs of German sources typically contain more sentences than their English translations.[3] To address this imbalance, we remove certain amount of German source sentences, creating a training set with an equal number of original and translated sentences (97,108 in the training set and 20,744 in the test set).

To further perform evaluation of translation quality, we need a clear one-to-one correspondence between source sentence, human-translated sentence and the automatically translated sentence. As mentioned above, not every paragraph of the MPDE dataset has the same number of sentences in its German source and in its English translation. We have composed a subset of MPDE consisting only of those sentences whose paragraphs have an equal number of German and English sentences. This subset contains 38,035 sentences.

Pre-processing. To ensure that the explanation methods work efficiently, we tokenize and truecase our data.[4] Both are performed using Moses scripts (Koehn et al., 2007).

2.2 Models

We report O/T classification and translation quality results on a wide selection of some of the best-performing models, both commercial and open-source models:

- **DeepL Translator**: a state-of-the-art commercial NMT system.[5]
- **Google Translate**: Likely the most widely used commercial NMT system.[6]
- **M2M-100-418M** (Fan et al., 2020): A large multilingual NMT model trained on 2,200 translation directions, enabling many-to-many translation across 100 languages. We use the base version.
- **MADLAD-400** (Kudugunta et al., 2023): A multilingual NMT model based on the T5 architecture (Raffel et al., 2020b), with 3 billion parameters, trained on 1 trillion tokens across 450 languages using publicly available data.
- **NLLB-600M** (Costa-jussà et al., 2022): It represents the current state-of-the-art NMT system,

[2] Token x_i may refer to either a whole word or its subunits, as the WordPiece tokenizer (Song et al., 2021) splits words into subunits. To compute the attribution score at the word level, we average the attributions of its subunits.

[3] This is due to the fact that the translations of paragraphs are not aligned sentence-wise. While the original paragraph may have i sentences, one translation may have j sentences and another k.

[4] As further we need, for example, to analyze lexical overlaps, it is important that we do not miss out on words because of punctuation or case

scaling up to 200 languages. We experiment with the distilled version with 600M parameters.

In addition to the NMT systems listed above, we pick three well-known and high-performing open-source LLMs and use them for prompt-based translation without any prior fine-tuning (see Appendix A for the prompt templates):

- **LLaMAX-3.1-8B-Alpaca** (Lu et al., 2024) is an open-source instruction-following language model with 8 billion parameters. It is fine-tuned from the LLaMA model (Taori et al., 2023) and supports 102 languages through continual pre-training, incorporating 52,000 Self-Instruct English instruction examples (Wang et al., 2023).
- **Llama-3.1-IT-8B** (Dubey et al., 2024): The Meta Llama 3.1 collection includes multilingual LLMs. This 8B parameter model is pretrained and instruction-tuned for text generation, optimized for multilingual dialogue.
- **TowerInstruct-7B-v0.2** (Alves et al., 2024): A language model based on LLaMA 2 (Touvron et al., 2023), using a diverse dataset of 20 billion tokens from monolingual sources in ten different languages.
- **Aya-101-13B** (Üstün et al., 2024): A 13-billion-parameter mT5 (Xue et al., 2021) multilingual model trained on instructions in 101 languages, exceeding the coverage of earlier open-source models (Lai et al., 2023; Muennighoff et al., 2022; Le Scao et al., 2023).
- **Gemma-7B** (Team et al., 2024b) is a lightweight open-source LLM developed by Google DeepMind. It has been instruction-tuned to respond to prompts in a conversational manner.

3 Evaluation

3.1 O/T Classification

We follow Dutta Chowdhury et al. (2022) to perform binary classification between original and translated (O and T) sentences. We use the XLM-RoBERTa base model (Conneau et al., 2020) with a softmax classifier applied to the [CLS] token of the sentence embeddings. We freeze hyperparameters and weights of the pre-trained encoder, and train the classifier for 10 epochs on each sentence with batch size of 16 and learning rate of 2×10^{-5}. All experiments are performed using NVIDIA V100 or A100 GPUs.

Results. The linear O/T classifiers show high accuracies (>80%) for all models (Table 1). We find that the automatically translated sentences, for both NMTs and LLMs, are always identified with higher accuracy than the human-translated ones. This finding corroborates the hypothesis that automatically translated texts are more readily distinguishable in classification tasks than those translated by humans (Ilisei et al., 2010; Rubino et al., 2016; Pylypenko et al., 2021).

3.2 Translation Quality

To assess translation quality, we utilise two automatic evaluation metrics (AEM): BLEU (Papineni et al., 2002) as implemented in SacreBLEU[7] (Post, 2018) and COMET (Rei et al., 2022).[8] BLEU relies on word n-gram similarity, whereas COMET

Mean	0.58	0.70	0.72	0.53	0.60	0.66

Table 2: Performance of the sufficiency classifier across different ranks (top-1, top-3, top-5) using LOO and IG methods for HT, NMT, and LLM systems. The highest scores for each method are highlighted in teal (LOO) and gray (IG), with the highest scores boldfaced to highlight the strengths of each method.

is a semantic metric built upon the XLM-R architecture.

Results. Table 1 shows that across different models, COMET scores remain relatively stable, while BLEU scores show greater fluctuation. DeepL stands out as the top performer, achieving the highest scores in both COMET (0.85) and BLEU (34.85). TowerInstruct-7B-v0.2 also performs well, particularly in COMET, reflecting high translation quality. Two systems, LLaMAX-3.1-8B-Alpaca and MADLAD-400-MT, exhibit poor translation quality. The high number of translation errors could skew the explainability results, focusing on these mistakes rather than models' intrinsic characteristics. Therefore, we exclude these models for further experiments. We perform a correlation analysis, and find no significant correlation between translation quality and O/T classification accuracy. See Appendix C for more details.

3.3 Do explanations capture sufficient information?

Understanding the effectiveness of model predictions often relies on the quality of explanations derived from those models. In this context, an explanation refers to the rationale behind a model's predictions, specifically identifying the *input tokens (features)* that most significantly influence the classification outcome. We follow the approach outlined by Xie et al. (2024) to evaluate the sufficiency of these explanations, as defined by Jacovi et al. (2018) and Yu et al. (2019). Sufficiency refers to the average change in predicted class probability when only the top k influential tokens are retained. This metric assesses how well the top k attributions explain the model's predictions, ultimately determining whether these explanations faithfully represent the model's decision-making process.

Previous research (Amponsah-Kaakyire et al., 2022) has shown that feature attribution including IG can be used to identify input tokens that are particularly important to O/T classification results for original texts and human translations.

However, whether this holds true across different types of translations, such as those generated by large language models (LLMs) or neural machine translation systems (NMT), remains underexplored. Bizzoni et al. (2020) investigated this problem using PoS perplexity scores and syntactic dependency lengths. More recently, Luo et al. (2024) systematically investigate the differences in the distribution of translation divergences between HT and MT through a large-scale, fine-grained comparative analysis, focusing on morphosyntactic variations. In contrast, our approach investigates lexical (words and PoS) differences by analysing explanations from O/T classifiers.

Our goal is to identify the key features that set apart translation artifacts produced by LLMs, NMT, and HTs from the text originally authored in the target language. To evaluate the sufficiency of our methods—specifically Leave-One-Out (LOO) and IG—we separately extract the top k tokens with the highest attribution scores for each sentence in the training set (see Section 2.1). We then construct datasets with sentences consisting only of these top k tokens while maintaining the same labels. O/T classifiers are then trained on these datasets,

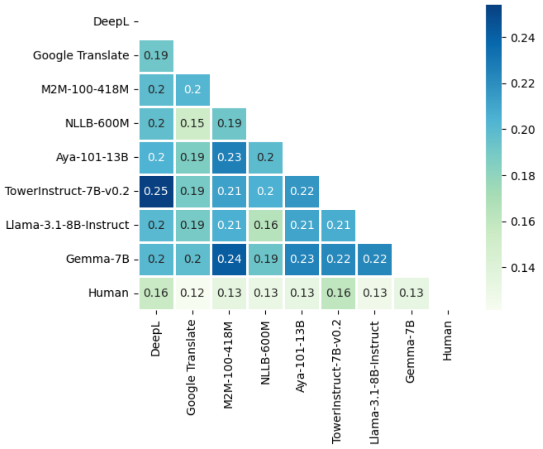

Figure 1: Level of intersection between top-5 most important explanations across different translation methods using LOO method.

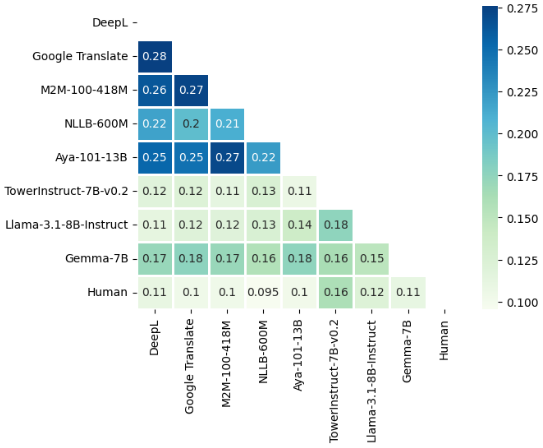

Figure 2: Level of intersection between top-5 most important explanations across different translation methods with IG.

where k = {1, 3, 5}, and we subsequently assess the classifiers' accuracy on the test set (Table 2) [9].

3.3.1 Sufficiency

If we can maintain high accuracy of O/T classifier using only the k tokens with the highest attribution scores, this indicates that the explainability methods (LOO and IG) work as intended, allowing us to efficiently identify important differences between translations and originally authored sentences in the target language.

Results. Table 2 shows that high accuracy for O/T is consistently maintained for the top k tokens with the highest attribution scores, indicating that the explainability methods (LOO and IG) function as intended. On average, as the number of tokens increases, we see an improvement in the sufficiency scores, indicating that the features we are extracting are indeed important.

Moreover, LOO is able to achieve much higher sufficiency score on top-1 tokens from certain model outputs as compared to IG, suggesting that LOO may be more effective at pinpointing the most critical token for classification. The reason for that might be that Leave-One-Out (LOO) directly removes each word and measures the impact on model prediction, giving a more precise attribution score. In contrast, Integrated Gradients (IG) require pooling attributions across the dimensions of an embedding and averaging attributions across subwords when a word is split into pieces, which may provide better performance in context, but lower it when focusing on a single word.

The LOO method achieves its highest top-1 sufficiency score of 0.78 across all models for Google Translate, underscoring its potential effectiveness in identifying essential tokens. In contrast, the IG method records its highest top-5 sufficiency score of 0.83 for the same translation system, showcasing its strength in capturing significant features across a broader range of tokens.

4 Feature Analysis of LLM, NMT, and Human Translation

4.1 Feature Overlap Analysis

We conduct an intersection analysis of linguistic features (input tokens), focusing specifically on sentences for which we can establish a one-to-one correspondence between outputs of different translation systems. For these sentences, we apply both LOO and IG using previously trained O/T classifiers for HT, NMT, and LLM datasets. This process enables us to compute attribution scores for individual tokens within each sentence. Using these scores, we extract the top-k most important tokens ($k = 1, 3, 5$) for each sentence.

Following this, we calculate the intersection between the LOO and IG results for different translation systems using the Jaccard Similarity Coefficient, which represents the percentage of common tokens and takes a value from 0 to 1. A high intersection among the top-k tokens indicates robust features (tokens) that are consistently identified as important across different translation models.

[9] We modified the train set for the sufficiency experiment but left the test set unchanged to ensure fair evaluation.

Conversely, if the intersection between systems and/or human translations is low, it indicates that the translations exhibit different features. Figure 1 presents the pairwise Jaccard values for the top-5 features derived from the Leave-One-Out (LOO) method. Each cell quantifies the degree of overlap between the top features of two different translation systems, with darker shades representing higher overlaps. Notably, the highest intersection is observed between TowerInstruct-7B-v0.2 and DeepL, with an overlap of 0.25, suggesting a strong similarity in the features identified for these models.

Another substantial intersection occurs between Gemma-7B and M2M-100-418M at 0.24, indicating considerable alignment in their outputs. In contrast, human-generated content shows relatively lower intersections with machine models, such as 0.16 with TowerInstruct-7B-v0.2 and DeepL and 0.13 with M2M-100-418M, underscoring the unique nature of human translations compared to machine-generated translations.

Similarly, Figure 2 shows the pairwise Jaccard values for the top-5 features (tokens) obtained using Integrated Gradients (IG). The most notable overlap is between Google Translate and DeepL, with a significant intersection of 0.28, demonstrating a strong similarity in their feature selections. A notable intersection of 0.27 is observed between M2M-100-418M and both Aya-101-13B and Google Translate, suggesting that these models yield quite similar results. The lower intersection of 0.11 between TowerInstruct-7B-v0.2 and Aya-101-13B emphasizes the differences in their outputs. The intersection with human translation identified by IG is notably highest for TowerInstruct-7B-v0.2, at a value of 0.16.

The combined results suggest that while certain LLMs, like Aya-101-13B and TowerInstruct-7B-v0.2, closely align with NMT models such as M2M-100-418M and DeepL in their feature selection, others retain unique classification features. Furthermore, there are notable differences in how closely these models align with human translations, with TowerInstruct-7B-v0.2 demonstrating the highest similarity to HT as shown by both LOO and IG.

4.2 Feature Frequency Analysis

We examine the frequency of different Part of Speech (PoS) tags across translation systems, focusing on the top k features flagged by LOO/IG for each sentence. For each system, we group sentences – both human and machine translations – into predefined sentence length bins. These bins are divided into ranges (e.g., 0-10, 10-15, 15-20 words), and for each, we calculate and normalize the frequency of the identified features based on the total number of sentences in that bin. This helps us compare trends in PoS distribution as sentence length increases. We are examining trends for the 9 most common PoS.

To ensure the reliability of our measurements, we account for the margin of error (standard deviation) obtained through bootstrapping by subsampling each bin 1,000 times while maintaining the PoS distribution within each sentence. In the graphs we show the standard deviation with shading. Figure 3 illustrates variations in PoS distribution, showing nine subplots for adverbs (ADV), verbs (VERB), determiners (DET), auxiliary verbs (AUX), nouns (NOUN), pronouns (PRON), adjectives (ADJ), adpositions (ADP), and punctuations (PUNCT).

For ADV, most models—both NMT and LLM—use fewer adverbs than HT. However, Llama-3.1-8B demonstrates frequencies that are closer to HT as sentence length increases, while TowerInstruct-7B-v0.2 diverges with longer sentences. NMT models like M2M and Google Translate underproduce ADV compared to HT, whereas DeepL aligns more closely with HT and tends to overproduce ADV with longer sentences.

ADP use in HT increases with sentence length, and most NMT and LLM models follow this trend, although models like Google Translate show slightly lower frequencies in longer sentences. Pylypenko et al. (2021) find that the relative frequencies of ADV and ADP in PoS tagging are strong indicators of translationese in HT.

For VERB, both HT and most NMT and LLM models maintain a steady frequency, though the models generally underproduce compared to the human translation trend. For DET, HT usage slightly increases with sentence length, while all LLM and NMT models, except DeepL, tend to use determiners more frequently.

In the case of PRON, most models tend to align with the human trend for shorter sentences. However, as sentence length increases, their frequencies start to deviate from each other. NLLB-600M demonstrates a substantially higher frequency than human translations across all sentence lengths.

In ADJ usage, HT remains relatively stable,

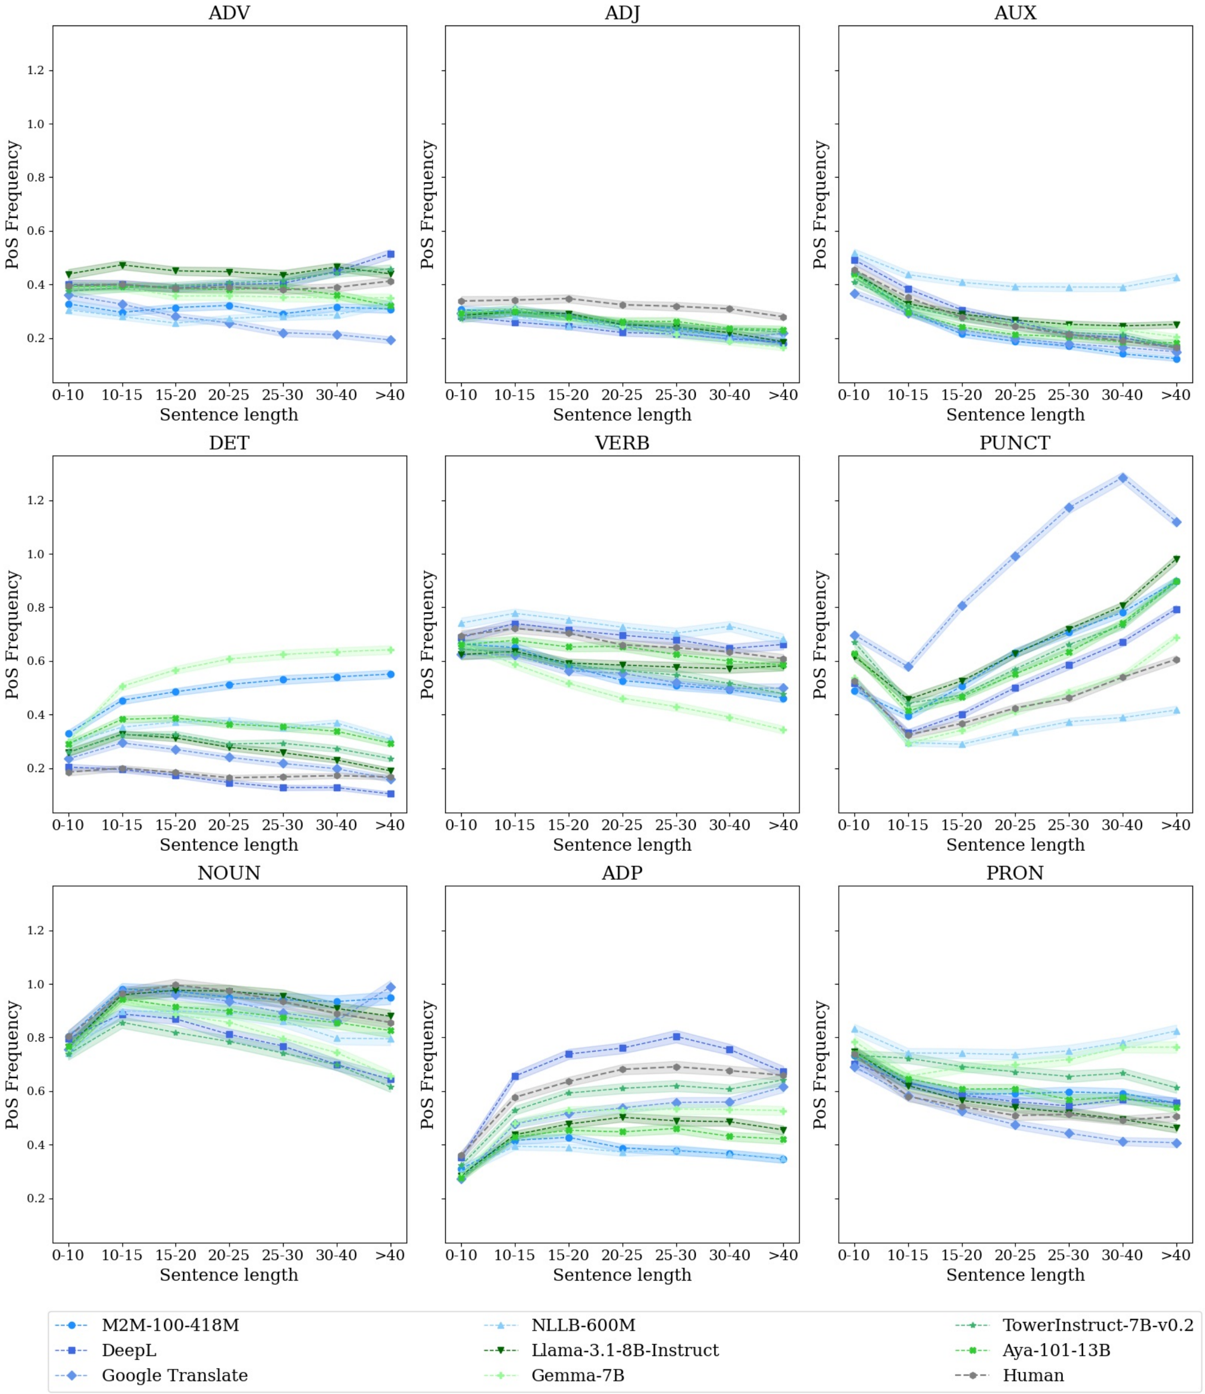

Figure 3: The frequency of the top PoS categories flagged by LOO across different sentence length bins. The x-axis of each subplot represents sentence length, divided into ranges (0-10, 10-15, 15-20, etc.), and the y-axis shows PoS frequency, indicating how often each PoS occurs in sentences of different lengths.

showing a slight decrease as sentence length increases. All NMT and LLM models exhibit lower adjective frequencies overall, with their trends being extremely similar across all sentence lengths.

For AUX, HT demonstrates a consistent decline as sentence length increases. Most NMT models follow this trend, except for NLLB-600M, which shows significantly higher AUX usage. Similarly, Llama-3.1-8B-Instruct exhibits slightly higher AUX frequencies compared to HT. The frequency of NOUN usage is maximal for sentences of length 10-15 and then consistently decreases for longer sentences. HT and most models seem to follow this trend, except for two NMTs (M2M-100 and Google Translate), which tend to overproduce nouns in very long sentences. For HT and NMT/LLM, the frequency of PUNCT usage in sentences of length 10-15 is lower than in shorter sentences, although there is an increasing trend for sentences longer than 15. Google Translate exhibits notably higher PUNCT frequencies than all other models and HT, although its usage declines in very long sentences.

Overall, LLMs exhibit PoS patterns (for 6 out of 9 tags) that closely align with human translations, whereas NMT models show greater deviations, particularly regarding PUNCT. NMT models tend to underproduce ADV, and for some other parts of speech (PoS) like ADP or PRON, they show significant divergence. In contrast, LLMs exhibit stronger agreement in trends and align more closely with HT, although they still demonstrate some overuse in short sentences. Both NMTs and LLMs underproduce ADJ compared to HT, particularly in longer sentences. LLMs better mimic human usage in ADV and AUX frequencies, especially in longer sentences. Appendix B displays the frequency plots of the top PoS categories identified by Integrated Gradients (IG) across various sentence-length bins.

5 Conclusion

In this work, we systematically explore the translation divergences between LLMs, NMTs, and human translations. Our key findings show distinct differences in how these systems approach translation, despite advancements in LLMs that allow them to produce high-quality outputs. We find that while LLMs often exhibit translation patterns more similar to human translations compared to traditional NMT models, they still diverge from originally authored text in the same language. Overall, we find that automatically translated sentences from both NMTs and LLMs are consistently identified with higher accuracy in O/T classification tasks than human-translated ones. This supports the hypothesis that machine-translated texts are more easily distinguishable from original texts than those translated by humans (Rubino et al., 2016; Pylypenko et al., 2021).

To better understand the distinctions between translations produced by LLMs and NMTs compared to human translations, we employ Leave-One-Out and Integrated Gradients explanation methods to extract and analyze lexical features identified by translation classifiers. Our findings indicate that even when using a sufficiency-based approach, we can recover a significant amount of O/T classification accuracy. This demonstrates that these features are effective in distinguishing between automatic and human translations.

Further, our results indicate that sufficiency-based approach is particularly effective at identifying single critical features, while Integrated Gradients (IG) capture a broader range of important features. Interestingly, we observe that certain LLMs align closely with NMT systems in their feature selection, demonstrating similarities in their approaches. However, human translations consistently exhibit lower overlap with both LLM and NMT outputs, particularly regarding crucial features like punctuation and specific PoS.

Furthermore, our frequency analysis of PoS tags reveals that LLMs align more closely with HT in their usage, especially in terms of adverbs, and auxiliary verbs, while NMT models tend to overproduce specific tags in shorter sentences. This suggests that LLMs, although not perfect, are making strides in mimicking human translation patterns. Our findings highlight the characteristics that define the outputs of various translation systems. However, despite advances in machine translation, human translations continue to display distinctive characteristics, particularly in their nuanced use of linguistic features, making them less prone to the artifacts seen in machine-generated texts.

Limitations

Limitations of Lexical Features. The results presented in this study rely entirely on the lexical features derived from Leave-One-Out (LOO) and Integrated Gradients (IG), which may fall short of capturing the intricacies of translation quality. Moreover, translation artifacts can arise at both syntactic and semantic levels (Bizzoni et al., 2020; Briakou and Carpuat, 2020), aspects that this research does not address. This leaves an exploration of these dimensions to future work.

Prompting Choice. Prompting has demonstrated varying sensitivity to the choice of templates and examples (Zhao et al., 2021). In machine translation (MT), prior studies have used different templates (Brown et al., 2020; Chowdhery et al., 2023; Wei et al., 2021). In our work, we reevaluate these templates to determine the optimal one. However, the format and wording of the prompt significantly influence how the LLM comprehends the task and performs translation, potentially impacting our findings, which we leave for future exploration.

Stability of Model Outputs. Additionally, we have assumed that the output of a specific model would remain stable throughout the analysis. However, LLMs are frequently updated, which can lead to changes in their writing style and coherence. Such variations might cause explainability methods to underperform, exacerbating the issues discussed in this work.

Constraints of Sentence-Level Analysis. Most NMT models utilized in this study function effectively at the sentence level, necessitating that we translate individual sentences for both NMTs and LLMs to ensure consistency. Thus, our sentence-based analysis with LLMs is also a limiting factor, as it restricts our ability to capture broader contextual nuances (Koneru et al., 2024). This would entail expanding our analysis beyond sentence-level assessments.

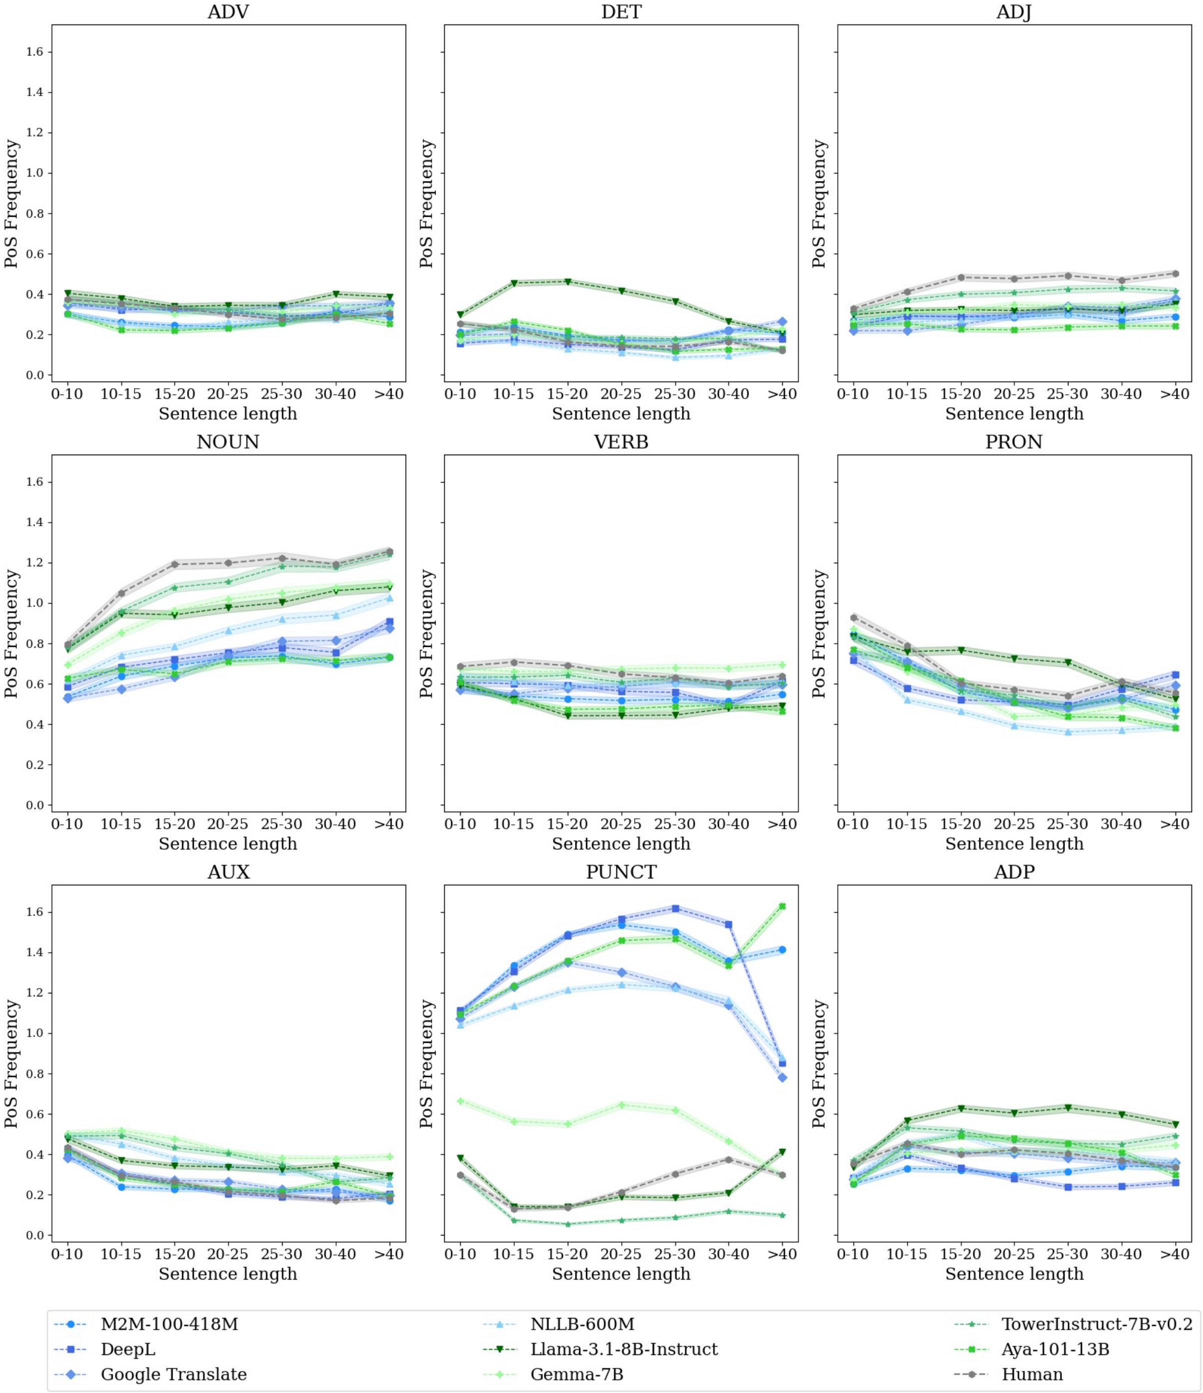

Figure 4: The frequency of the top PoS categories flagged by IG across different sentence length bins. The x-axis of each subplot represents sentence length, divided into ranges (0-10, 10-15, 15-20, etc.), and the y-axis shows PoS frequency, indicating how often each PoS occurs in sentences of different lengths.

C Correlation Analysis

We calculate Spearman's correlation to analyze the relationship between translation quality and O/T classification accuracy, considering a significance level $\alpha = 0.05$. We find Spearman's correlation between COMET and Accuracy to be -0.43 with p-value 0.28, and -0.63 with p-value 0.1 between BLEU and Accuracy. Correlations are not statistically significant; therefore, given our data, there is no evidence to support the notion that poorer translations are more easily classified as translated or non-translated texts.

How Grammatical Features Impact Machine Translation: A New Test Suite for Chinese-English MT Evaluation

Abstract

Machine translation (MT) evaluation has evolved toward a trend of fine-grained granularity, enabling a more precise diagnosis of hidden flaws and weaknesses of MT systems from various perspectives. This paper examines how MT systems are potentially affected by certain grammatical features, offering insights into the challenges these features pose and suggesting possible directions for improvement. We develop a new test suite by extracting 7,848 sentences from a multi-domain Chinese-English parallel corpus. All the Chinese text was further annotated with 43 grammatical features using a semi-automatic method. This test suite was subsequently used to evaluate eight state-of-the-art MT systems according to six different automatic evaluation metrics. The results reveal intriguing patterns of MT performance associated with different domains and various grammatical features, highlighting the test suite's effectiveness. The test suite was made publicly available and it will serve as an important benchmark for evaluating and diagnosing Chinese-English MT systems.

1 Introduction

A test suite or a challenge set is a collection of customized or artificially constructed texts used for exhaustively and systematically diagnosing the hidden faults and specific barriers of models in the field of natural language processing (NLP) (King and Falkedal, 1990; Balkan, 1994). It also comes in handy in machine translation (MT) evaluation and has currently experienced an increased weight in the MT community alongside the significant improvement of average automatic translation quality especially in the era of neural machine translation (NMT) and large language model (LLM) (Burchardt et al., 2017; Kocmi et al., 2023).

By leveraging test suites, it is possible to detect the strengths and weaknesses of apparently perfect MT systems in a linguistically driven fashion and at a fine-grained level. However, on the one hand, most previous studies have concentrated on a limited set of language phenomena (Guillou et al., 2018; Popović, 2019; Mukherjee and Shrivastava, 2023), providing only a narrow view of system capabilities. On the other hand, there is a notable scarcity of research and resources concerning non-Latin script languages, such as Chinese (Chen et al., 2023), which require some special handling of MT systems. These facts underscore the need for a large-scale test suite that covers a broad variety of grammatical features appearing in Chinese-English renderings.

Inspired by the grammatical test suite developed by the German Research Center for Artificial Intelligence (DFKI) (Manakhimova et al., 2023, etc.), we create a test suite for Chinese-English automatic translation focusing on multiple Chinese grammatical features, and based on which we conduct a detailed analysis of the state-of-the-art MT systems, including popular commercial NMT systems and advanced LLMs. The UM parallel corpus in the language pair of Chinese-English (Tian et al., 2014) originally containing segments from seven domains serves as the basis for extracting test sentences for 43 distinct Chinese grammatical features. The final test suite comprises 7,848 well-annotated Chinese sentences (at least 50 items for each grammatical feature), each paired with an English reference translation. We report the performance of eight MT systems and discuss the impact of 43 grammatical features, based on scores generated by six mainstream automatic metrics and supplemented by an analysis of manually identified error cases. We make our test suite, system outputs, evaluation scores, and corresponding codes available online for further research purposes[1].

The main contributions of our work are summarized here: 1) We present a grammatical-feature-

Proceedings of the Ninth Conference on Machine Translation, pages 1200–1221
November 15-16, 2024 ©2024 Association for Computational Linguistics

based and multi-domain test suite for fine-grained Chinese-English translation evaluation. 2) We perform a linguistically driven evaluation to compare the overall performance of different NMT systems and LLMs. 3) We conduct further analysis of various influencing factors in our study from the aspects of automatic evaluation metrics and other external features of sentences to examine the impacts of different grammatical features.

This paper is structured as follows: Section 2 presents a list of studies that are related to the current work. Section 3 shows the main procedure of the construction of the test suite including data extraction and annotation. In Section 4, we describe the experiments of applying our test suite on the mainstream MT systems and give an analysis of the results. Section 5 provides additional discussions on the other interfering factors that may also interact with grammatical features to impose effects on MT. Section 6 outlines our conclusion and future work.

2 Related Work

In the context of probing linguistically nuanced yet critical weaknesses in MT systems to guide future enhancement, the Conference of Machine Translation (WMT) has introduced test suite tracks since 2018, aimed at receiving in-depth insights into the fine-grained performance of MT systems (Macketanz et al., 2018; Guillou et al., 2018; Rysová et al., 2019; Popović, 2019; Kocmi et al., 2020; Bawden and Sagot, 2023; Mukherjee and Shrivastava, 2023; Manakhimova et al., 2023; Chen et al., 2023, inter alia).

Standing out from many studies of MT evaluations dedicated to one or a few textual factors, e.g. Guillou et al. (2018) on pronouns, Rysová et al. (2019) on discourse-related errors, Popović (2019) on conjunctions, Kocmi et al. (2020) on gender coreference and bias, Bawden and Sagot (2023) on user-generated non-standard content, and Mukherjee and Shrivastava (2023) on multiple domains and writing styles, the series of work by DFKI (Macketanz et al., 2018; Avramidis et al., 2019, 2020; Macketanz et al., 2021, 2022; Manakhimova et al., 2023) constructed a test suite covering more comprehensive linguistic phenomena. This ever-evolving test suite comprises over 10,000 sentences now, covering up to 110 linguistic phenomena, such as false friends, named entities, negations, and so on, and across three translation directions: German ↔ English, English → Russian. By applying the combination of regular expressions and manual checks for annotating the linguistic phenomena, they test the capacity of advanced MT systems submitted to the annual WMT tasks for tackling specific translation difficulties associated with such phenomena. Their latest study (Manakhimova et al., 2023) reveals that the mainstream MT systems face great challenges with certain categories of linguistic phenomena, often in a language-dependent manner. Their detailed findings further enable MT developers to facilitate their systems by considering scenarios prone to failure and then taking corrective actions.

Beyond the translation between alphabetic languages in the Indo-European language family, the task regarding pictographic texts in the Sino-Tibetan language family, represented by Chinese, is also open to exploration. As an analytic and isolating language, Chinese has very different ways of expressing syntactic and semantic relations between constituents, resulting in potential ambiguities that largely rely on context to resolve. The issue becomes more salient in the automatic translation task. Particularly, the presence of certain grammatical features in Chinese will potentially cause different problems. However, the comprehensive exploration and the test suites with attention to various Chinese grammatical features remain largely unconsidered. The only Chinese MT test suite submitted to the WMT was constructed by Chen et al. (2023) for investigating the influence of a limited set of features of Chinese source sentences including words, length, grammar, and entropy. Besides, the studies of Cai and Xiong (2020), Tang et al. (2021), and Song and Xu (2024a,b) provided focused glimpses to some certain Chinese phenomena. They examined the abilities of NMT systems to translate discourse phenomena, negation, and multiword expressions across English and Chinese by using a self-built test suite with annotation of pronouns, discourse connectives, and ellipses, an existing corpus with negation information created by Liu et al. (2018), and an extended dataset of WMT test set, respectively.

Building on the light of DFKI test suites (Manakhimova et al., 2023, etc.) and addressing the lack of Chinese-specific test suites, this study is dedicated to providing an inclusive test suite covering 43 Chinese grammatical features and offering a full evaluation of mainstream MT systems. Additionally, depending on the domain-balanced nature of our basic data, i.e. UM corpus (Tian et al., 2014), our test suite is suitable for comparisons across seven textual domains.

3 Construction of a Test Suite with Chinese Grammatical Features

This section details the processes in test suite construction. We first introduce the theoretical framework of the Chinese grammatical features, then describe the procedures of data selection and annotation, and finally present the result and statistics of the data.

3.1 The Framework of Chinese Grammatical Features

For the categorization framework for Chinese grammatical features, we adopt the one in our previous work (Xu and Lin, 2023), which is developed in accordance with a reference grammar of Chinese (Huang and Shi, 2016). The framework systematically addresses 157 typical linguistic phenomena, i.e. grammatical features, in Chinese, organized across various linguistic aspects, including words, structure, semantics, and pragmatics. Word-level structures are concerned with how a word is formed by morphemes. For instance, reduplication is a typical phenomenon to create new words in Chinese. For example, the adjective 高兴 *gao xing* 'happy' can be reduplicated to form another adjective word 高高兴兴 *gao gao xing xing* 'very happy'. The structure category mainly refers to the syntactic structure of sentences, phrases, and special constructions. This framework identifies three semantic subcategories: semantic roles, aspect, and negation. The pragmatic category includes sentence types, information packaging constructions, attitudinal particles/adverbs, deixis, and anaphora.

Whether a certain grammatical feature that is present in the source language might cause problems in automatic translation is largely dependent on the equivalence of the counterpart phenomenon in the target language. Take reflexives as an example. Both the two languages use reflexive pronouns to denote the antecedent nominal phrase. However, there are also some fine distinctions in their usages, leading to obstacles for cross-lingual translation. As shown in Example (1), while in Chinese the pronoun 你 *ni* 'you' can be optional, the English translation must combine the pronoun 'you' in order to obtain the correct reflexive 'yourself'.

(1) 你要照顾好(你)自己。

ni yao zhaogu hao (ni) ziji
you should take_care good (you) self

'You should take care of yourself.'

Many grammatical features are Chinese-specific, such as classifiers, as shown in example (2), BA constructions as shown in (3), headless NP as shown in (4), and so on. Depending on their grammatical differences to varying degrees, different Chinese grammatical features might impose different effects on MT systems. It is thus necessary to create a test suite that covers various grammatical features with each one associated with a set of examples, which can be used to analyze the effects of different grammatical features on MT systems based on statistical methods.

(2) 一顿晚餐

yi dun wancan
one CLF dinner

'a dinner'

(3) 我把这些书都看完了。

wo ba zhexie shu dou kan wan le
I BA these book all read finish PRF

'I have read all these books.'

(4) 羡慕的是缺乏的。

xianmu de (pro) shi quefa de (pro)
admire DE be lack DE

'What is admired is the lacked.'

3.2 Data Preparation

We extract Chinese source sentences and their corresponding English reference translations from the UM corpus (Tian et al., 2014), a high-quality and large-scale parallel corpus embracing eight distinct domains: Education (abbreviated as 'Edu', with 4.5 million bilingual sentence pairs), Laws ('Laws', 2.2M), News ('News', 4.5M), Science ('Sci', 2.7M), Spoken ('Spk', 2.2M), Subtitles ('Sbt', 3M), Thesis ('Ths', 3M), and Microblog ('Mbg', 5K). We exclude the Microblog section due to its small number of sentence pairs, which is far fewer than the other domains, making it difficult to ensure a rough balance across different domains. We select sentences with 10 to 60 Chinese characters to minimize the impact of source sentences with extreme lengths (excessively long or short) on translation quality as well as to avoid the existence of too many different grammatical features in a single sentence that may mix the effects of them on translations.

Grammatical Feature	**Abbreviation**	**Precision**	**Agreement**	**Sum**	**Edu**	**Laws**	**News**	**Sci**	**Spk**	**Sbt**	**Ths**

Table 1: The detailed information of our test suite including the definition of grammatical features and their corresponding numbers of instances in each domain. ‘Precision’ refers to the precision of our self-created grammatical feature identifier in accordance with the results after manual checking. ‘Agreement’ shows the inner consistency between the judgments given by the two checkers. The acronyms including ‘BU’, ‘MEI/MEIYOU’, ‘GUO’, ‘ZAI’, ‘SHI’, ‘LE’, ‘BA’, and ‘ZHI’, are the specific markers indicating particular grammatical features.

3.3 Grammatical Feature Annotation

In the first step, we use a regular-expression-based tool we previously built in Xu and Lin (2023) to identify the Chinese grammatical features in each source sentence automatically. After all the sentences are annotated with a set of grammatical features, we remove the grammatical features that appear fewer than 30 times in all sentences of each domain to ensure a fairly balanced data distribution in statistics, by which our focus is narrowed to 43 target grammatical features out of 157 in the original framework for our test suite. Then, for each grammatical feature, we randomly select about 210 candidate sentences (30 for each of the seven domains) according to the principle of prioritizing those carrying the fewest labels aiming to reduce the mixed effects of multiple features in one sentence. Since some sentences can finally possess multiple features, certain feature groups may include more than 210 sentences.

In the second step, the automatically generated labels of grammatical features are double-checked by two native speakers well-trained in Chinese linguistics. The screening process is primarily focused on identifying false positive grammatical features assigned to sentences. In cases where annotators disagree, they are required to discuss and reach a final decision together. This filtering process resulted in a validated test suite of a total of 7,848 sentence pairs, including 1,127 pairs with no specific grammatical features. Detailed information on the data is shown in Table 1. We see that the average precision of the automatic annotation tool is about 81% and the agreement of the two annotators in identifying false positives is 87%.

4 Evaluation of Chinese-English MT Systems with the Test Suite

In this section, we use our test suite to evaluate eight popular NMT systems and LLMs with six mainstream automatic metrics. We will briefly outline these systems and metrics, and then describe the results of the experiments we conduct to compare the performance of different MT systems on our whole test suite as well as the subgroups divided by domains and grammatical features.

4.1 Evaluated Translation Systems

Aiming at gaining a broad view of the capabilities of leading MT systems and representative LLMs to tackle diverse Chinese grammatical features, we refer to several widely recognized leaderboards, e.g., WMT (Kocmi et al., 2022), SuperCLUE (Xu et al., 2023), SuperBench[2], and Intento[3]. Eventually, four commercial NMT engines, Baidu, Niu, Google (basic v2 edition), DeepL and four advanced LLMs including Ernie (-4 turbo), Qwen (-turbo), GPT (-4o), and Claude (-3 opus) are selected for evaluation. We apply default settings to the NMTs and conduct a zero-shot translation test for the LLMs, setting the temperatures to 0.01.

4.2 Automatic Evaluation Metrics

We use six automatic metrics, including two string-overlap-based metrics: BLEU (Papineni et al., 2002) and CHRF (Popović, 2015)[4], and four neural-network-based ones: two reference-based metrics: COMET (Rei et al., 2022) and XCMOET (Guerreiro et al., 2023), and two reference-free ones: COMETKIWI-QE (Rei et al., 2023) and XCOMET-QE (Guerreiro et al., 2023)[5].

Based on our observation, different metrics may produce different results in analyzing the effects of various factors impacting MT systems. In the following discussions, we will mainly use the average score of XCOMET and XCOMET-QE (henceforth, X-AVERAGE), which are proven the most accurate metrics conforming to human evaluations by the WMT23 metric shared task (Freitag et al., 2023). We also provide extended discussions about the selection of metrics in Section 5.3. For reference, readers can find the results in all six metrics and their overall average (denoted as AVERAGE) in the Appendices.

4.3 Experimental Results

4.3.1 Comparison of Systems

Comparison of Overall Performance Table 2 shows the overall performance of the eight systems in six different metrics. On average, Google performs the best and Qwen the worst. While most of the metrics give similar ratings, XCOMET and XCOMET-QE slightly favor GPT's performance more than the others. We can also see that NMTs achieve marginally better performance than LLMs across all evaluation results. This is partially attributed to the extremely low scores received by the LLM: Qwen.

Comparison on Domains Table 3 shows the performance of all the MT systems on different domains in X-AVERAGE scores. Generally, all the systems show similar trends across different domains with the highest performance on Spoken and Subtitles and the lowest performance on Thesis and Laws. While it is unquestionable that domain affects automatic translation, the results may also be partially influenced by the distribution of sentence length within each domain. We will give more discussion about the effects of sentence length in Section 5.2. Detailed information about the performance of systems on different domains in all the other metrics can be found in Appendix A. Based on the comparisons between different models, it

NMT-AVG	91.6	90.9	93.0	92.3	93.8	93.2	86.2
LLM-AVG	91.1	90.8	92.4	91.9	93.2	92.7	85.4

Table 3: Performance in X-AVERAGE scores of each system on different domains. The highest and the lowest scores among all systems evaluated are highlighted with bold and underlined numbers respectively.

can be pointed out that Google and GPT share the top performance on each domain with a minor difference but Qwen is ranked last across all domains. Again, NMTs show a generally higher performance than LLMs across all domains. However, this is not the case when delving deeper into the specific data excluding Qwen and Google.

Comparison on Grammatical Features Figure 1 shows the performance of all systems in X-AVERAGE scores in each grammatical feature group. The groups are arranged in descending order based on the average scores of all systems. In general, we see that all the systems show similar trends across different groups. Some grammatical features impose strong challenges on the MT systems such as PathPP, ApprCLF, KindCLF, LexNeg, etc., while some other grammatical features are easier for MT systems to address, like ZAIProg, MEINeg, NPI, etc. We also see that Ernie, Google, Claude, and GPT give high performance on sentence groups of all grammatical features while Qwen performs obviously the worst among all the systems. The detailed statistics can be found in Table 15. The performance in other metrics can be found in Appendix B.

It is therefore indicated that the presence of certain grammatical features will potentially affect the performance of MT systems. We assess the impact of each grammatical feature by conducting a t-test between the MT performance on the sentence group containing the target grammatical feature and that on the remaining sentences. The result is shown in Figure 2. There are ten grammatical features imposing significant negative effects on certain MT systems: PathPP, NP, Rel, KindCLF, PtcpPP, LexNeg, PreVPP, TmpSCpl, LocPP, and Cmpr; and there are nine grammatical features having significant positive effects instead: ZAIProg, MEINeg, NPI, Recp, ZHIQtf, AdvP, Refl, SHICop, and VP. However, it is worth noting that the low scores on certain grammatical feature groups are not necessarily occasioned by the translation errors that are directly linked to the units marking the grammatical features. There are also many other implicit factors indirectly associated with the grammatical features being worthy of exploration, like the semantic or syntactic complexity.

Figure 2: The significance levels of the effects of different grammatical features on the performance of each system according to t-tests in X-AVERAGE scores between the paired sentence groups with and without each grammatical feature. The blue squares on the left mean that the sentences containing a certain grammatical feature tend to get significantly lower scores than the sentences without them, and the yellow squares on the right vice versa. A significant difference with p less than 0.05, 0.01, and 0.001 are marked as 1, 2, and 3 respectively.

Since the most advanced automatic metrics are based on semantic vectors, it requires some consideration of why certain translations receive low scores, particularly in a specific sentence group. The following are some case studies to provide hints of the possible cause of the low translation scores. We should also keep in mind that this study is not aimed to provide a full understanding of why grammatical features can affect MT systems, but instead provide a different aspect and dimension for diagnosing MT systems in fine-grained levels.

4.3.2 Case Studies

In the process of translation, the accurate conveyance of meaning from the source language to the target language is important. However, errors often arise due to misinterpretation of some grammatical features, leading to mistranslation that may alter the meaning of the original text. This case study manually examines several specific instances of such errors in the translation.

One of the primary issues in automatic translation arises from the misinterpretation of path preposition phrases (PathPPs), as shown in Figure 2. Table 4 shows a typical example, where the preposition 沿 *yan* ‘along’ was misinterpreted, resulting in mistranslations by several MT systems. The original sentence uses the PathPP 沿 渤海 公路 *yan Bohai gong lu* ‘along Bohai Highway’ to describe how 唐海 *Tanghai* (a town) extends from east to west.

Source Text	Reference	Ernie	Qwen	Claude
唐海地处唐山“金三角”中央地带，	Tanghai is located in the central area of Tangshan’s “Golden Triangle”,	Tanghai is located in the central area of Tangshan’s “Golden Triangle”.	Tanghai is in the heart of Tangshan’s Golden Triangle,	Tanghai is located in the central area of the “Golden Triangle” of Tangshan.
沿渤海公路贯穿东西，	running east and west along the Bohai Highway.	The Bohai Highway runs through the east and west.	linked by the Bohai coastal highway.	The Bohai Highway runs through the county from east to west.

Table 4: Example of mistranslation caused by grammatical feature: path preposition phrase (PathPP).

Source Text	Reference	Niu	Qwen	DeepL
如果什么东西是充足的它就是不令人羡慕的，羡慕的是缺乏的。	When something is in plenty it is not admired, but admired in case of scarcity.	If something is sufficient, it is not enviable, and enviable is lacking.	What is abundant is unenvied; it is the absence that counts.	If something is sufficient it is not enviable, envy is lacking.

Table 5: Example of mistranslation caused by the grammatical feature: relative construction (Rel).

However, in translations by Ernie and Claude, the sentence was incorrectly rendered as ‘The Bohai Highway runs through the east and west’. Qwen’s translation, nevertheless, used ‘linked by’ to describe this relationship, which greatly shifted the meaning of the source sentence.

Additionally, the translation quality was significantly affected by the relative construction (Rel) (see in Figure 2). Table 5 shows a typical example of relative construction. In the source sentence, 羡慕的 *xian mu de* ‘(things) that are enviable’ is a headless clause where the elliptic head noun refers to 东西 *dong xi* ‘things’ mentioned earlier. Niu’s translation misinterpreted 羡慕的 *xian mu de* as an adjectival phrase rather than a subject of the relative construction, and thus misunderstood the meaning of the original sentence. Qwen just omitted the real subject - 羡慕的(东西)- of the sub-clause, leading to mistranslating the adjective 缺乏的 *que fa de* ‘scarce’ as the subject. DeepL’s translation completely ignored the relative construction marker 的 ‘*de*’ and treated 羡慕 *xian mu* ‘envy’ as the subject.

Another grammatical point that has a significant negative impact is noun phrases (NPs). NP has a relatively large number of sentences on Laws and Thesis (see in Table 1), which have generally low averaged performance (see in Table 3) possibly due to their high semantic complexity regarding professionalism. This partially explains the negative effects of NP. Particularly, the specialized terminology within the Thesis category can notably contribute to the translation challenges.

5 Additional Discussion

In this section, we discuss several potential interfering factors that may also affect the quality of automatic translation by interacting with grammatical features, including sentence length, domain, and the effects of different automatic metrics.

5.1 Analysis of Sentence Length

It has long been an observed consensus that longer sentences are generally more difficult to MT systems and thus result in lower qualities and scores (Cho et al., 2014; Koehn and Knowles, 2017). This can also be verified by the significant inverse relationship between the lengths of source sentences and their translation scores given by human experts as shown in Figure 3, generated on WMT23 data (Freitag et al., 2023).

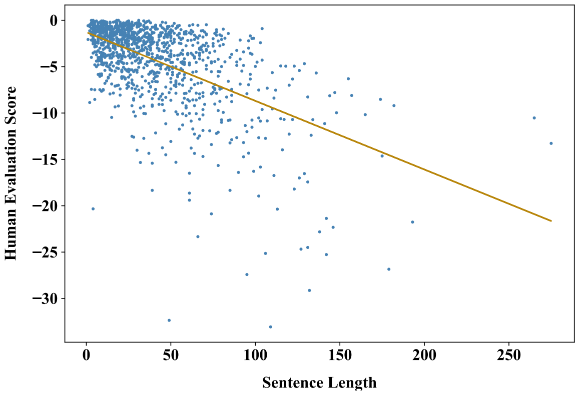

Figure 3: The correlation between sentence lengths (x-axis) and human average translation scores (y-axis) on WMT23 Chinese-English dataset for the metric shared task.

To assess whether the significant effects of grammatical features as observed are due to differences in sentence lengths among the groups, we calculated the average sentence length for each sentence group with a specific grammatical feature and examined the relationship between average sentence lengths and the corresponding X-AVERAGE scores. From the result, as shown in Figure 4, we can see that although certain sentence groups of different grammatical features have different sentence lengths ranging from 19.39 to 32.18 characters, they do not show significant correlation with the average X-AVERAGE scores of the groups, indicating that effects by grammatical features are not due to the bias of sentence length distribution.

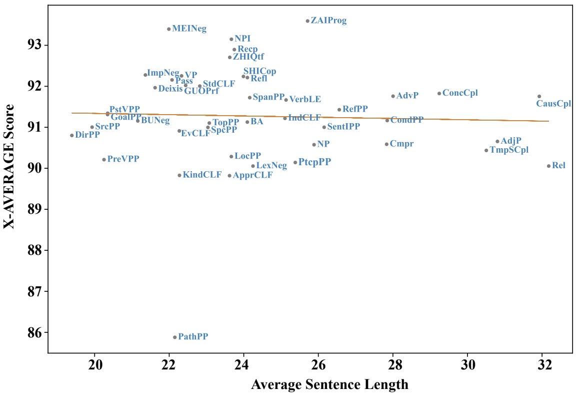

Figure 4: The correlation between average sentence lengths and X-AVERAGE scores of sentence groups containing different grammatical features with Pearson'r = -0.039 and p = 0.802.

5.2 Analysis of Domains

As mentioned in Section 4.3, domains have a significant influence on the performance of MT systems due to variations in vocabulary and writing registers. Therefore, it is important to consider whether domains have contributed to the observed significant impact of certain grammatical features on MT systems. Reviewing the data in Table 1, we make all grammatical feature groups maintain a roughly balanced distribution in terms of sentence number across the seven domains except Rel, which extensively exists in the domain of Laws. This balance allows us to focus more on the effects of grammatical features rather than domains when calculating statistics between feature-accordingly grouped sentences.

Interestingly, the similar trends of MT systems' performance across different domains may also correlate with other factors e.g. sentence length. Thus, a further question is whether the effects apparently imposed by domains on the scores of MT systems are partially due to the imbalanced distribution of sentence length across domains. Table 6 displays the average sentence lengths of different domains along with their standard deviations. We see that Spoken and Subtitles have the shortest sentences while Laws and Thesis have the longest ones, with a gap of about 20 characters between them. This may partially explain why MT systems achieve the best performance when rendering materials in the former two domains while the worst is in the latter two domains as shown in Table 3.

Table 6: Average sentence length of each domain with the standard deviation.

5.3 Analysis of Evaluation Metrics

Following the hypothesis of regarding human evaluation as the gold standard, the metrics that generate judgments on translation quality more similar to humans are superior (Freitag et al., 2023).

In Figure 3, we see that there exists a significant negative correlation relationship between sentence lengths and human evaluation scores. To know if different metrics rate MT qualities similarly regarding sentence length, we examine the correlations between sentence lengths and scores generated by six metrics to meta-evaluate their effectiveness. We provide scatter plots of sentence lengths and scores based on both WMT23 data (Freitag et al., 2023) and our data, and the results are presented in Figure 5. On both datasets, XCOMET and XCOMET-QE exhibit patterns similar to human evaluations and are therefore considered to provide more reliable scores, particularly regarding the negative effects of sentence length. However, BLEU, CHRF, COMET, and COMET-QE yield judgments on translation quality that are inconsistent with human evaluations. According to Table 7, CHRF, COMET, and COMET-QE even exhibit significant positive correlations, indicating their bias towards longer sentences. This finding is consistent with the leaderboard of metrics concluded by WMT23 (Freitag et al., 2023), which ranks XCOMET and XCOMET-QE as the top performers.

Besides, Table 7 shows that the average system

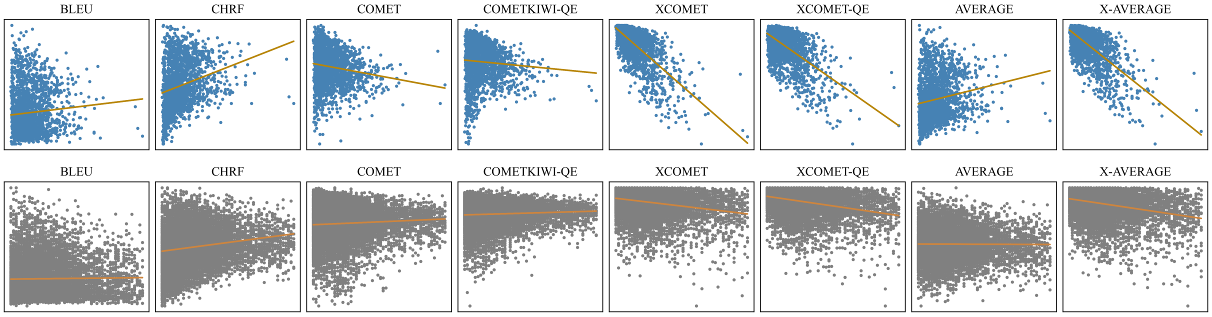

Figure 5: The correlation between sentence lengths (x-axis) and average translation scores (y-axis) in different measures. XCOMET and XCOMET-QE are more consistent with the human evaluation trend in Figure 3. The first row is on the WMT23 Chinese-English dataset for the metric shared task and the second row is on our test suite. Metrics show similar patterns on the two different datasets except for COMET and COMETKIWI-QE.

Metric	**Pearson'r**	***P*-value**
BLEU	0.016	0.149
CHRF	0.185	*** 0.000
COMET	0.067	*** 0.000
COMETKIWI-QE	0.064	*** 0.000
XCOMET	-0.242	*** 0.000
XCOMET-QE	-0.302	*** 0.000
AVERAGE	-0.006	0.581
X-AVERAGE	-0.286	*** 0.000

Table 7: The correlation between sentence lengths and system average scores in different metrics on our test suite.

scores of all six automatic metrics (AVERAGE) do not significantly correlate with sentence length by offsetting the effects of different metrics. On the contrary, the average scores of XCOMET and XCOMET-QE (X-AVERAGE) remain the high reliability by showing a significant negative correlation between scores and sentence lengths. Therefore, XCOMET, XCOMET-QE, and X-AVERAGE are more recommended for practical evaluation.

6 Conclusion and Future Work

In this paper, we investigate the impact of various grammatical features (linguistic phenomena) on eight state-of-the-art NMT systems and LLMs with a test suite we newly constructed. Although LLMs have achieved promising performance on many NLP tasks, NMT systems especially Google Translate have outperformed most of the LLMs in the Chinese-English automatic translation task. It is observed that certain grammatical features pose a great challenge to NMT systems and LLMs including the ones developed by Chinese companies such as Baidu, Ernie, Niu, and Qwen. We also discuss other possible factors that may also impact MT systems including sentence length, domain, and the evaluation metrics. We find that the Thesis category is particularly more difficult due to its comparatively longer sentence and the existence of a large number of terminologies. In addition, we confirm that longer sentences are generally more difficult for MT systems. However, our analysis of the correlation between the sentence length and different metrics reveals that BLEU and CHRF tend to rate shorter sentences with lower scores, which is contradictory to human evaluation. This also confirms that XCOMET and XCOMET-QE are the most reliable metrics according to the results of the WMT23 metrics shared task.

Currently, our test suite does not cover all the 157 grammatical features of Chinese due to the rareness of some particular grammatical features. In the future, we plan to extend our test suite to cover all the grammatical features by resorting to other resources.

Limitations

One limitation of our study is the absence of human evaluation scores. Our analysis relies heavily on automatic metrics, specifically the average score of XCOMET and XCOMET-QE. The former relies on reference translations and the latter does not. According to the WMT23 metrics shared task results (Freitag et al., 2023), both metrics show a very high correlation with human scores. This demonstrates the validity and reliability of data in our study to some extent. While human evaluation is the most reliable, it is also expensive and impractical for assessing every MT system. In contrast, the test suite, combined with automatic evaluation metrics, offers a convenient and efficient tool for evaluating any MT systems, providing immediate diagnostic reports.

Another limitation of our study is that it does not cover all the grammatical features of Chinese due to the scarcity of certain grammatical features. We plan to address this issue by exploring other data sources to cover all other grammatical features in the future.

Acknowledgements

Firstly, we thank all reviewers for their valuable and insightful comments. We also acknowledge the funding support from the Supervisor Academic Guidance Program of Shanghai International Studies University (Grant No. 2022113024) and the Linguistics Frontier Research Funding of Shanghai International Studies University (Grant No. 41004525/001).

Improving Statistical Significance in Human Evaluation of Automatic Metrics via Soft Pairwise Accuracy

Abstract

Selecting an automatic metric that best emulates human annotators is often non-trivial, because there is no clear definition of "best emulates." A meta-metric is required to compare the human judgments to the automatic metric scores, and metric rankings depend on the choice of meta-metric. We propose Soft Pairwise Accuracy (SPA), a new meta-metric that builds on Pairwise Accuracy (PA) but incorporates the statistical significance of both the human judgments and the metric scores. We show that SPA is more stable than PA with respect to changes in the number of systems/segments used for evaluation. We also show that PA can only assign a small set of distinct output values to metrics, and this results in many metrics being artificially assigned the exact same PA score. We demonstrate that SPA fixes this issue. Finally, we show that SPA is more discriminative than PA, producing more statistically significant comparisons between metrics. SPA was selected as the official system-level metric for the 2024 WMT Metrics Shared Task.

1 Introduction

Automatic metrics are crucial because researchers and practitioners in NLP typically can't afford the high cost and latency of high-quality human evaluations. Despite their shortcomings, metrics like word error rate and BLEU (Papineni et al., 2002)—in conjunction with carefully curated test sets—have been crucial for the field of NLP, as they have provided a yardstick to make continual progress over many decades in automatic speech recognition and machine translation (MT), respectively.

Reliance on automatic metrics makes selecting a good automatic metric of paramount importance. Conceptually, an automatic metric should emulate human judgments. Selecting an automatic metric typically entails generating a set of human judgments for a wide variety of outputs from a large number of different systems, and selecting the automatic metric that produces scores most similar to the human judgments. But how do we quantify similarity? To select the metric which produces output most similar to human judgements, we need a meta-metric to compare metric scores and human judgments. Despite nearly two decades of research on MT meta-evaluation, the community has not reached a consensus on the choice of a meta-metric. Various meta-metrics have been introduced over the years to address problems with prior meta-metrics, while sometimes creating new problems or re-introducing old ones (see § 5).

Recent works (Mathur et al., 2020b; Kocmi et al., 2021) have argued that the primary application of a metric is to choose between two competing systems, therefore the best metric is the one which produces pairwise system rankings most similar to the pairwise system rankings produced by human judgements. This led to Pairwise Accuracy (PA) being adopted by the WMT Metrics shared task for the past several years (Freitag et al., 2021, 2022, 2023). However, this argument omits a key detail: standard best practice when comparing two systems with an automatic metric is to consider not only which system the metric prefers, but also *whether or not that preference is statistically significant* (Koehn, 2004). Thus we argue that metrics should emulate not only the accuracy of human pairwise ranking, but also the confidence or statistical significance of the human pairwise ranking.

To this end, we propose Soft Pairwise Accuracy (SPA), a new meta-metric which takes into account statistical significance of both the metric scores and the human judgments when evaluating the extent to which the metric in question agrees with the human judgments. We show that soft pairwise accuracy, as its name implies, can be viewed as a soft (i.e. non-binarized) version of PA, and present

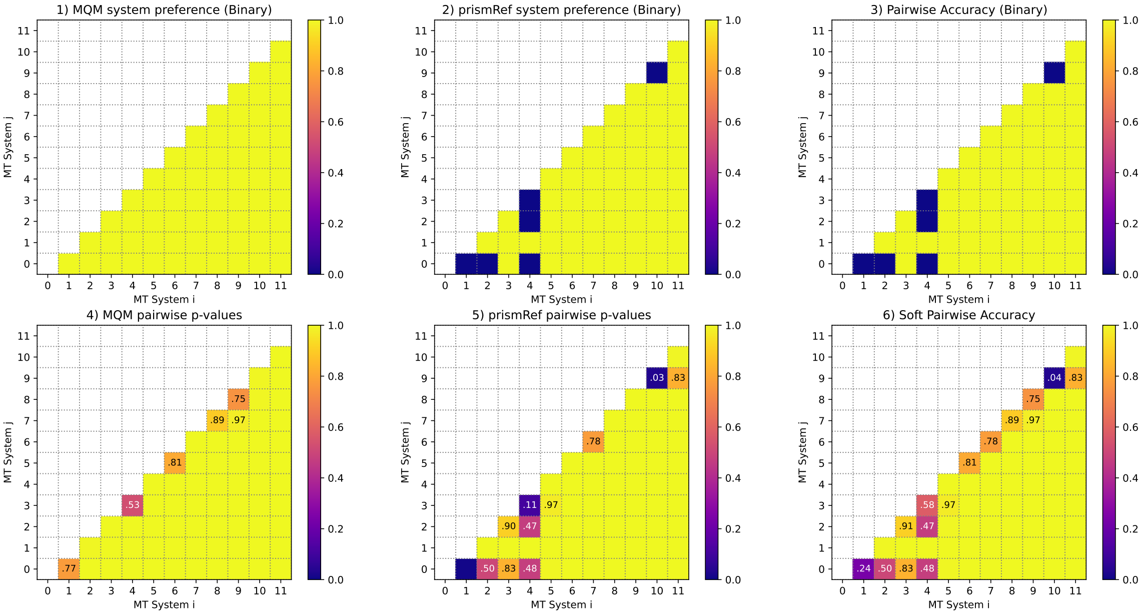

Figure 1: Illustration of the individual components used to calculate both SPA and PA for the Prism metric (Thompson and Post, 2020a,b) on the WMT 2023 English-German language pair. Each box represents a comparison between two systems, systems i and j. MT systems are sorted by average human judgment score for easier interpretation. The right column is one minus the absolute difference between the human preference for systems i over system j (left column) and the metric preference for system i over system j (middle column). In PA (top row), human and metric preferences are binarized to 0 and 1, and PA is thus an average of binary terms. In SPA (bottom row), human and metric preferences range from 0 to 1, and as a result SPA is an average of values ranging from 0 to 1. SPA can be viewed as a "soft" extension to pairwise accuracy that incorporates both human judgment and metric uncertainty, allowing for partial credit.

analysis that demonstrates SPA has several distinct advantages over PA. First, we find SPA is more stable with respect to the exact choice of MT systems and segments used. Second, we show that due to the binarization in its formulation, PA can only assign a small set of distinct output values to metrics, and in practice this results in many metrics being artificially assigned the exact same PA score. We demonstrate that SPA fixes this issue. Finally, we argue that PA is effectively equivalent to SPA with added noise due to binarization. We show that removing this noise (i.e. switching to SPA) results in substantially more statistically significant comparisons between metrics, making SPA a more discriminative and therefore more useful meta-metric. Our findings resulted in SPA being selected as the official system-level meta-metric for the 2024 WMT Metrics Shared Task (Freitag et al., 2024).

2 Method

We propose a simple meta-metric for evaluating automatic metrics given human judgments, which we denote Soft Pairwise Accuracy:

$$SPA = \binom{N}{2}^{-1} \sum_{i=0}^{N-1} \sum_{j=i+1}^{N-1} 1 - |p_{ij}^{h} - p_{ij}^{m}| \quad (1)$$

where N is the number of systems for which we have human judgements and metric scores, p_{ij}^{h} is the p-value for hypothesis that system i is better than system j given the human judgments, and p_{ij}^{m} is the p-value for hypothesis that system i is better than system j given the metric scores. The term $\binom{N}{2}^{-1} = \frac{2}{N(N-1)}$ normalizes the summation by the total number of pairs of systems being compared.

For each pairwise system comparison, we use a permutation test (Fisher, 1935) to estimate statistical significance of the difference in the means of the segment-level scores from a particular metric (or the human judgements) for the two systems. We first randomly split the segment-level scores (ignoring the labels, i.e. which MT system produced each segment) into two parts and compute the difference in metric score mean. Repeating this process many times provides a set of mean differences we can reasonably expect under the null hypothesis that the two systems are of the same quality. We compute a one-tailed p-value by calculating the fraction of the time that the random splits produce differences greater than or equal to the mean difference we observe for the two systems.

Permutation tests are appealing because they don't require any assumptions about the underlying distribution of the data. This fits our use case well because we cannot assume anything about the distribution of segment-level scores of a metric.[1] Permutation tests instead have the assumption of exchangeability (Pitman, 1937; Draper et al., 1993; Good, 2002)—that is, under the null hypothesis (in our case, that the two MT systems are of equal quality) the joint distribution of the observations is invariant under permutations of the data labels. To help ensure exchangeability, we perform permutations such that each split has exactly one translation of each test set sentence, commonly referred to as a paired permutation test (Good, 2013).

Here we present some concrete examples for the sake of intuition. Suppose a metric reports a $+10$ point difference between system i and system j, and that the random permutations only produce a metric difference $\geq$ 10 points 1% of the time. Thus $p_{ij} = 0.01$ and we conclude that the metric has high confidence that system i is better than system j. Likewise, if the metric reports the systems have a -10 point difference, we might find that the random permutations produce a metric difference ≥ -10 points 99% of the time. Thus $p_{ij} = 0.99$ and we conclude the metric has high confidence that system i is worse than system j. If the systems have the same metric score, we would expect about half of the random permutations to produce a metric difference ≥ 0 and thus $p_{ij} = 0.5$, indicating the metric finds the two systems indistinguishable from each other.

2.1 Relationship to Pairwise Accuracy

PA is defined as

$$PA = \binom{N}{2}^{-1} \sum_{i=0}^{N-1} \sum_{j=i+1}^{N-1} a_{ij}^{m} \tag{2}$$

where a_{ij}^{m} is 1 when the metric scores and human judgments prefer the same system and 0 otherwise. PA is equivalent to the Kendall rank correlation coefficient (Kendall, 1938), modulo a linear scaling and shifting (see § 5.1).

A p-value p_{ij} will be less than 0.5 when the human raters (or automatic metric) prefer system i over system j, and greater than 0.5 when the human raters (or automatic metric) prefer system j over system i. This allows us to define PA in terms of binarized p-values:

$$PA = \binom{N}{2}^{-1} \sum_{i=0}^{N-1} \sum_{j=i+1}^{N-1} 1 - \left| \lfloor p_{ij}^{h} \rceil - \lfloor p_{ij}^{m} \rceil \right| \tag{3}$$

Where binarization is denoted as:

$$\lfloor x \rceil = \begin{cases} 1 & x \geq 0.5 \\ 0 & x < 0.5 \end{cases}$$

Comparing Equation 1 and Equation 3 illustrates that SPA can be viewed as a 'soft' extension to PA that incorporates uncertainty in both the human and metric scores. A visualization of this is provided in Figure 1.

In cases where both the MT metric and the human evaluation both have high statistical significance (regardless of whether the metric agrees with the human judgments or not, i.e. $p_{ij}^{m} \approx 0$ or $p_{ij}^{m} \approx 1$), the contribution of that system pair to SPA and PA is approximately identical. However, there are two important cases where our meta-metric differs from PA:

1. The human evaluation has high statistical significance (i.e. $p_{ij}^{h} \approx 0$ or $p_{ij}^{h} \approx 1$), but the metric has low statistical significance (i.e. $p_{ij}^{m} \approx 0.5$): Even if the metric happens to choose the correct winner, we partially penalize the metric for not having high statistical significance.

2. The human evaluation finds the systems are approximately tied (i.e. $p_{ij}^{h} \approx 0.5$): In this case, we partially penalize the metric if has high statistical significance (i.e. $p_{ij}^{m} \approx 0$ or $p_{ij}^{m} \approx 1$) even if it happens to pick the same winner as the human evaluation, and to get full credit the metric must match the human evaluation statistical significance (i.e. $p_{ij}^{m} \approx p_{ij}^{m} \approx 0.5$)

2.2 Addressing Metric Ties in PA

The fact that PA considers only binary wins/losses (i.e. the binarization in Equation 3) results in an interesting shortcoming in PA. There are $\binom{N}{2}$ pairs of N systems, and thus $\binom{N}{2} + 1$ distinct values that

[1] Metric and human annotation distributions are both highly variable (Lo et al., 2023b; Knowles and Lo, 2024).

PA can take on $(0/\binom{N}{2}, 1/\binom{N}{2}, ..., \binom{N}{2}/\binom{N}{2})$. For example, in WMT 2022 En-De, there are $N = 14$ MT systems and thus $\binom{N}{2} + 1 = 92$.

However, metrics tend to perform better than a random baseline, so only the upper half of the range is actually useful (e.g. this leaves 46 distinct values for $N = 14$ systems). We find that this results in PA reporting the same scores for several sets of metrics (see § 4.3). By removing this binarization, SPA has no such issues.

3 Experimental Setup

3.1 Data

We conduct experiments on the data from the 2022 and 2023 WMT Metrics Shared Tasks (Freitag et al., 2022, 2023). In particular, we use the primary language pairs where MQM judgments were collected. We use the MT Metrics Eval V2 toolkit[2] to retrieve official shared task scores.

We make the somewhat arbitrary decision to compare all metrics, including non-primary metrics but excluding QE metrics (i.e. reference-free metrics) which provide segment-level scores.

In order to compute the statistical significance of comparisons between metrics, we make the simplifying assumption that all system-level metrics are the average of their segment-level metric. This is not true for some metrics, including BLEU (Papineni et al., 2002) and chrF (Popović, 2015). While it would be possible to re-compute BLEU and chrF for each subset, we average the sentence-level versions of these metrics for simplicity. To the best of our knowledge, this approach is also taken in recent WMT metrics shared tasks.

3.2 p-value Speed Optimization

We estimate each p-value from 1000 random permutations.[3] A naive implementation of the paired permutation test is not computationally prohibitive when computing p-values for all systems/metrics a single time, but it becomes problematic when we want to compute these values many times in order to estimate statistical significance of metric comparisons.

Experimentally, we find the main speed bottleneck to be generating the random permutations, so when estimating statistical significance of metric comparisons we cache a batch of permutations and use it for each pair of systems, on a per test-set basis. Additionally, by sharing permutations across system pairs, this allows us to pre-compute the contribution of each system to means of the random permutations, allowing computations to be linear instead of square in the number of systems. See our code[4] for full implementation details. This results in a speedup of over 1000x compared to the implementation in Scipy (Virtanen et al., 2020).[5] Our speed optimization does not change the computation of a p-value for a single system-level comparison, but it does mean that the p-value for one pair of systems is no longer computed independent from the p-value for any other pair of systems. Given that we are using these p-values as an approximate level of confidence for the system-level comparisons in the SPA meta-metric formulation, as opposed to making any claims about the actual statistical significance of the system-level comparisons, we believe this lack of independence should be inconsequential.

4 Analysis

Meta-metric evaluation is challenging because there is no ground truth (i.e., we don't know the true ranking of the metrics). Instead, we conduct analysis to compare SPA and PA. First, we study how sensitive the meta-metric results are when ablating the number of MT systems and number of segments per MT system, with the assumption that lower sensitivity to the exact systems/segments used indicates a better meta-metric. Second, we examine whether PA indeed has the problem of ties that we hypothesized in § 2.2, and whether SPA fixes this issue. Finally, we test our hypothesis that the binarization in PA is effectively acting as additive random noise, and that SPA is effectively the same underlying meta-metric with the noise term removed.

4.1 Ablation: Number of Systems

Each year, WMT and the associated metrics task collect and score many online and submitted MT systems. For an ideal meta-metric, the exact choice of MT systems would have minimal impact on the

[2] https://github.com/google-research/mt-metrics-eval

[3] Note that due to the randomness inherent in the p-value estimation process, the exact value of SPA can vary slightly from run to run.

[4] https://github.com/thompsonb/mt-metrics-eval/blob/main/mt_metrics_eval/pairwise_paired_permutation_test.py

[5] Using the 'permutation_test' function from scipy, 'permutation_type' set to 'samples' and the 'n_resamples' set to 1000, each p-value takes around 40 milliseconds to compute on a laptop.

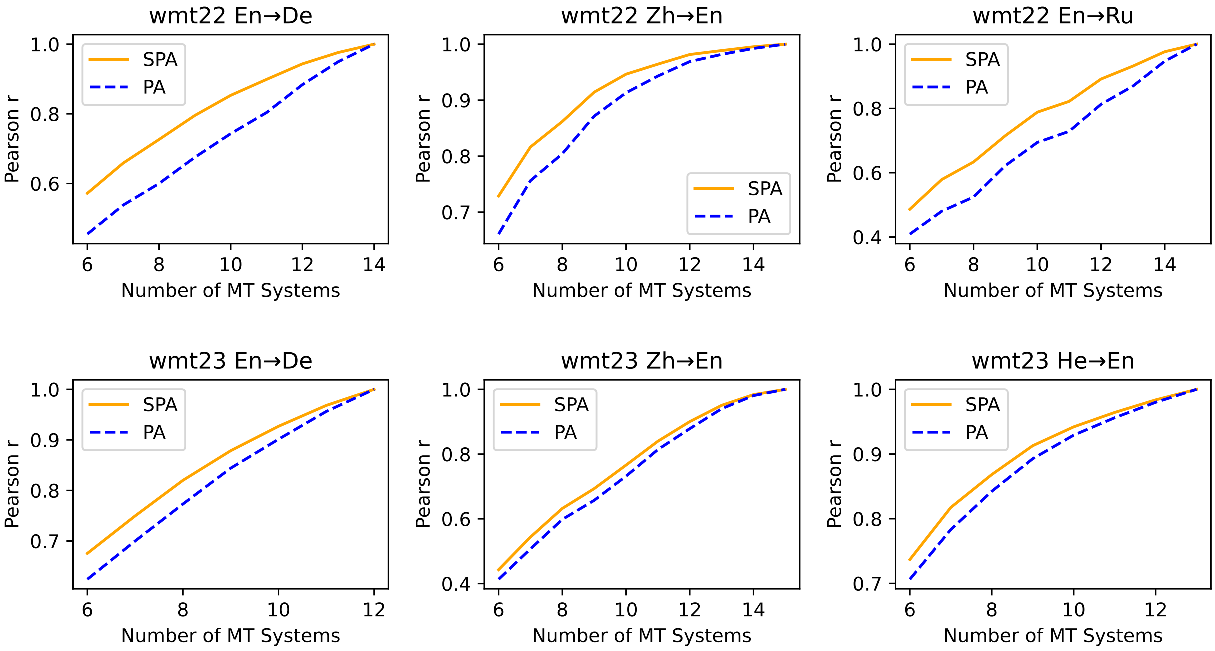

Figure 2: Final metric ranking stability when ablating the number of MT systems (and thus the number of total MQM judgments), measured as change in Pearson correlation coefficient (Pearson r) from the ranking computed on all MT systems. Values are averaged over 1000 random trials. We find SPA to be more stable than PA in all cases.

metric rankings. We perform an ablation on the number of MT systems being scored, keeping the number of annotations per system fixed. We then compute the correlation (as measured by Pearson's r) between the meta-metric's ranking of the ablations compared to that same meta-metric's full ranking. This allows us to evaluate how sensitive the metric is to the exact selection of MT systems.

When ablating the number of MT systems (and keeping the number of annotations per system fixed), we find (see Figure 2) that SPA is more stable than PA across all MQM language pairs in the last two years of WMT Metrics Shared Tasks.

4.2 Ablation: Sample Size

Since SPA relies on the pairwise p-values between MT systems, it is also natural to ask how SPA behaves when the number of available segments used for evaluating systems is small since it is harder to find statistical differences between systems with a smaller sample size. To answer this question, we calculate 95% confidence intervals for both PA and SPA values of two highly performant metrics—in particular, we considered xCOMET (Guerreiro et al., 2023) and MetricX-23 (Juraska et al., 2023)—on WMT 2023 using bootstrapping for various numbers of segments, thereby simulating scenarios with less human annotations but a fixed number of MT systems.

When ablating the number of segments per MT system (and keeping the number of MT systems fixed), we find (see Figure 3) that SPA has tighter 95% confidence intervals than PA (shown on Metric-X and xCOMET), and that the confidence interval converges to its final value with smaller sample sizes than PA.

4.3 Ties

As discussed in § 2.2, the binarization in PA limits the number of distinct values it can assign to metrics. to $\binom{N}{2} + 1$. In practice, we find it tends to take on far fewer values. For example for WMT 2022 En→De, PA could theoretically take on 92 distinct values, but because the metrics fall in a fairly narrow range (PA is 0.626 for the worst metric and 0.813 for the best), the 21 metrics have only 11 distinct PA scores, with one 5-way PA tie and several 2- and 3-way PA ties (see Figure 4). Since SPA does not binarize each system comparison, it is able to assign any value to each metric, and is therefore potentially better able to distinguish between metrics.

Results for all language pairs are in Table 1. We find that on average, PA produces about half as many distinct values as there are metrics while SPA produces one unique value per unique metric.

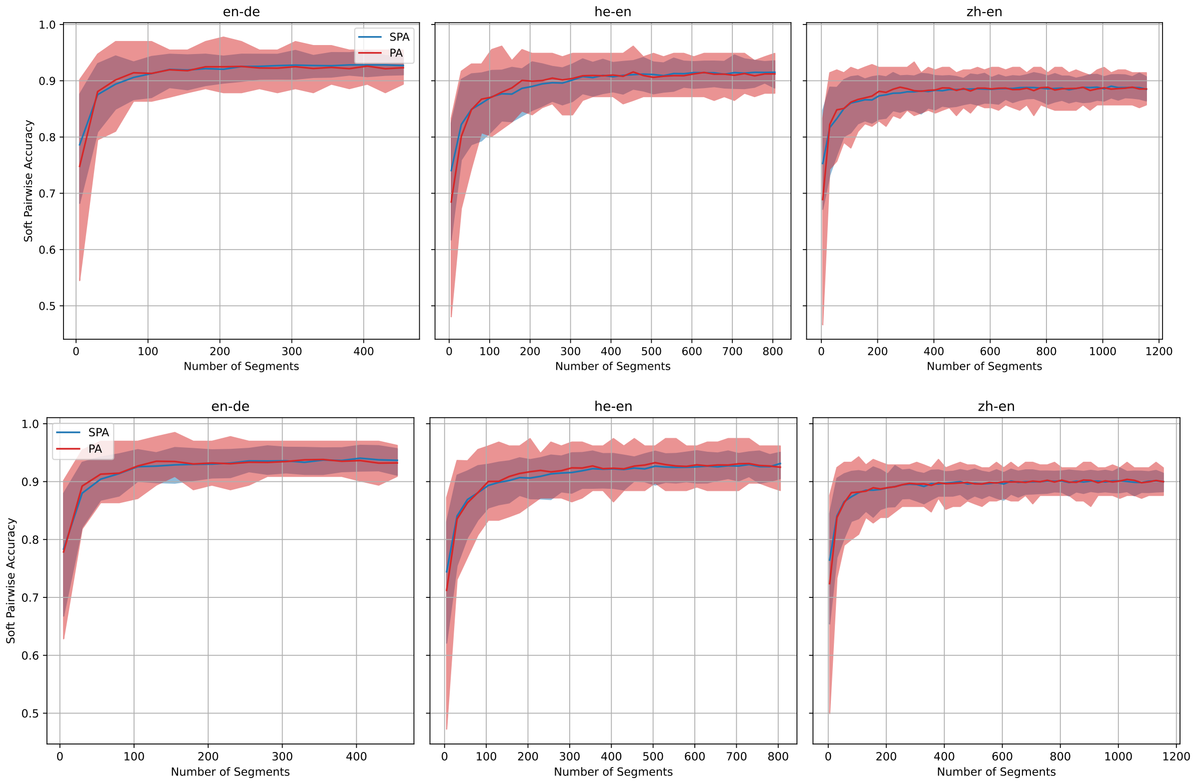

Figure 3: The 95% confidence intervals for SPA (blue) and PA (red) on Metric-X (top) and XCOMET (bottom) when varying the number of annotations per system. We find that SPA has a tighter confidence interval, and that the confidence interval shrinks to its full value with smaller sample sizes than PA.

4.4 Statistical Significance of Metric Comparisons

We hypothesize that the binarization in PA is essentially acting as additive random noise on top of the underlying SPA meta-metric. If this is true (and the magnitude of the noise does not dominate the underlying signal), we would expect SPA to produce a similar metric ranking to PA, but with increased statistical significance. To test this, we compute statistical significance of the comparisons between each metric using the PERM-INPUTS (Deutsch et al., 2021) method. We follow recent shared tasks in greedily computing significance clusters, by starting with the highest scoring metric and assigning rank 1 to all metrics until we encounter the first metric that is statistically significantly different from *any* previous metric so far. That metric is assigned rank 2, and the process repeats until all metrics have been assigned a rank. We echo the shared task organizers' warning that this method can place two metrics that are statistically indistinguishable in different significance clusters (and in the case of PA, we observe this multiple times).

On average, SPA increases the number of statistically significant pairwise comparisons by 31% and the number of significance clusters by 40% compared to PA, while producing similar scores for each metric (see Figure 4 for a visualization for WMT 2022 En→De results and Table 1 for results summary). This is consistent with our hypothesis that PA is effectively SPA with added noise due to binarization. This means that SPA is a more discriminative, and therefore more useful, meta-metric than PA.

5 Historical Context and Related Work

WMT has run a machine translation evaluation since 2006 (Koehn and Monz, 2006). Since 2007 (Callison-Burch et al., 2007), there has also been meta-evaluation of automatic metrics on the submitted translation systems. Here we summarize the rich 17 year history of system-level meta-evaluation at the WMT Metrics Shared Tasks[6] and work related to and directly impacting the shared tasks, in order to demonstrate how our work fits into the historical context.

[6] The WMT Shared Tasks have typically evaluated at both the system- and segment-level, but we focus on system-level meta-evaluation as it is most relevant to our work.

Figure 4: Metric Comparison Significance, WMT 2022 En→De. Note that PA only assigns 11 distinct values to the 21 metrics (ties are shown in alternating Purple and Yellow text), whereas SPA produces a distinct value for each of the 21 metrics. SPA produces more statistically significant (p-value <= 0.05, shown in green) comparisons between metrics (163 vs 108). As a result, SPA divides the metrics into 8 significance clusters (delineated with blue lines) compared to only 5 for PA. Results for other language pairs (not shown) are similar.

Testset	Language Pairs	# MT Systems	# MT Metrics	Distinct Metric Values (↑)			Significant Comparisons (↑)			Significant Clusters (↑)		
				PA	SPA	Max	PA	SPA	Max	PA	SPA	Max
wmt22	En→De	14	21	11	**21**	21	108	**163**	210	5	**8**	21
wmt22	Zh→En	15	21	12	**21**	21	150	**177**	210	6	**9**	21
wmt22	En→Ru	15	20	10	**20**	20	88	**133**	190	4	**6**	20
wmt23	En→De	12	25†	12†	**24**†	24†	171	**206**	276†	5	**6**	24†
wmt23	He→En	13	25	11	**25**	25	180	**224**	300	5	**8**	25
wmt23	Zh→En	14	25	12	**25**	25	186	**229**	300	**7**	**7**	25

Table 1: Number of distinct values produced, number of statistically significant pairwise comparisons (p-value $<= 0.05$), and number of statistical significance clusters for PA and SPA. We provide the best possible value for each category (Max) for comparison, but note that even an ideal meta-metric would likely not achieve this value due to some metrics being highly correlated with each other (e.g. due to training on the same data). †: InstructScore and SEScoreX scores as returned by MT Metrics Eval v2 for WMT23 En-De are identical, causing an exact tie in both PA and SPA. We believe this is an error in MT Metrics Eval v2 but for posterity keep them as-is.

In the WMT 2007-2013 metrics evaluations (Callison-Burch et al., 2007, 2008, 2009, 2010, 2011, 2012; Macháček and Bojar, 2013) Spearman's rank correlation coefficient ρ was used for meta-evaluation of metrics. This was motivated by the fact that Spearman's makes fewer assumptions about the data than the Pearson correlation coefficient.

The WMT 2013 Translation Shared Task (Bojar et al., 2013) introduced system clusters (groups of systems that cannot be distinguished given the human judgments), and the 2013 metrics task (Macháček and Bojar, 2013) introduced empirical confidence of Spearman's ρ using bootstrap resampling. Since they were not able to resample on the submitted metrics, they only re-sampled human judgments. This iteration also discussed the fact that Spearman's ρ does not give partial credit. The penalty is equal for all wrong judgments, regardless of if the systems are close or far in quality. To compensate they present additional methods of analysis: Pearson's, and correlation with systems' clusters from the translation task (Bojar et al., 2013). Those clusters were treated as 'ranks with ties,' and then correlation computed against Pearson's and Pearson's correlation against 'fuzzy ranks' (the average over ranks of all systems that are not significantly different in human quality).

In 2014, the metrics task (Macháček and Bojar, 2014) fully switched to Pearson's r from Spearman's ρ. They also did bootstrap resampling to get empirical confidence intervals of system level correlations. This change to Pearson's was due to the concerns pointed out in the previous year's shared task, which had explored other meta-metrics.

The 2015 metrics task (Stanojević et al., 2015) continued with Pearson's r, and also presented analysis of Pearson's r vs Spearman's ρ, and highlighted the instability of Spearman's ρ when MT systems are similar.

The 2016 metrics task (Bojar et al., 2016) stuck with Pearson's r, but changed the confidence to be the Williams test (Williams, 1959), as Graham and Baldwin (2014) had noted that this test is appropriate for dependent correlations.

The 2017 metrics task (Bojar et al., 2017) kept Pearson's r, and Williams test. They also added a pairwise significance test using Williams test. This continued in 2018 and 2019 (Ma et al., 2018, 2019)

The 2020 metrics task (Mathur et al., 2020b) continued to use Pearson's, but also includes Kendall's Tau for analysis. Kendall's Tau is a closer match for the system ranking use case, since it is evaluating whether the ordering of a pair of systems is the same as the human ordering. However, it does not take into account the magnitude difference.

In 2021, the metrics task (Freitag et al., 2021) adopted pairwise accuracy (Kocmi et al., 2021), motivated in part by the fact that MT system outliers had an outsized impact on Pearson correlation when it is used to rank MT Metrics (Mathur et al., 2020a). Pairwise accuracy produces the same system-level ranking as Kendall's Tau, as they are equivalent modulo a linear scaling and shifting (see § 5.1). The PERM-BOTH hypothesis test of Deutsch et al. (2021) was used to determine significance. 2021 and 2022 (Freitag et al., 2022, 2023) follow.

In summary, the historical context of the WMT metric evaluations demonstrates that meta-evaluation is very challenging due to the numerous issues that must be simultaneously addressed, and underscores the pitfalls of making changes to meta-evaluation without considering the full set of ramifications. Most relevant to our work, it appears that the switch to pairwise accuracy in 2021 reduced the influence of outliers (Mathur et al., 2020a) and (somewhat) aligned meta-evaluation with the standard use of comparing two systems with a metric, but it also reintroduced a problem that was first pointed out by Macháček and Bojar (2013) and more fully addressed by the change to Pearson's r from Spearman ρ by Macháček and Bojar (2014): a disregard for the magnitude of differences. We address this issue by considering empirical confidence, which was first added by Macháček and Bojar (2013), and in the process we also better align meta-evaluation to the (more correct) usage of comparing two systems with a metric while also considering the statistical significance of the results.

5.1 Relationship to Kendall's Tau

Our work builds on pairwise accuracy, typically attributed to Kocmi et al. (2021). Pairwise accuracy is equivalent to the the widely used Kendall rank correlation coefficient (Kendall, 1938), modulo a linear scaling and shifting. Kocmi et al. (2021) present pairwise accuracy as simply "accuracy" and make no mention of its relation to Kendall, which was already in use for MT meta-evaluation (Mathur et al., 2020b). The term "pairwise accuracy" appears to have been coined by Freitag et al. (2021) to distinguish it from other types of accuracy.

Kendall's Tau is defined in terms of concordance (equivalent to our previously defined a_{ij}^m) and discordance d_{ij}^m, defined to be 1 when the metric and human judgments disagree and 0 otherwise:

$$\tau = \binom{N}{2}^{-1} \sum_{i=0}^{N-1} \sum_{j=i+1}^{N-1} (a_{ij}^m - d_{ij}^m) \qquad (4)$$

Any system pair which is not concordant is discordant,[7] and thus $d_{ij}^m = 1 - a_{ij}^m$. Given this and the definition of PA from Equation 2, we have:

$$\begin{aligned} \tau &= \binom{N}{2}^{-1} \sum_{i=0}^{N-1} \sum_{j=i+1}^{N-1} a_{ij}^m - (1 - a_{ij}^m) \\ &= 2\left(\binom{N}{2}^{-1} \sum_{i=0}^{N-1} \sum_{j=i+1}^{N-1} a_{ij}^m\right) - 1 \\ &= 2\,PA - 1 \end{aligned} \qquad (5)$$

5.2 Additional Connections to Prior Work

Graham and Liu (2016) proposed a method of sampling translations from every pair of competing MT systems, creating synthetic systems for scoring. Our work has clear similarities in that we create and score synthetic permutations, but differs in how those synthetic systems are used in the meta-metric formulation.

Mathur et al. (2020a) showed that MT system outliers had an outsized impact on Pearson correlation. In SPA, outliers impact is limited because p-values saturate at 0 or 1.

Knowles (2021) highlights that as WMT annotation protocols have shifted the original statistical assumptions, and questions the validity of the resulting protocols. Similarly, we show that shifts over the years have caused problems in meta-evaluation.

Lo et al. (2023a) investigated what magnitude of metric changes tend to be statistically significant. SPA uses statistical significance measures (p-values) directly, as opposed to the magnitude of metric differences (e.g. as in Pearson correlation).

Deutsch et al. (2023a) demonstrated that principled tie handling is crucial when comparing MT metrics at the segment level, because some metrics produce quantized scores that often result in ties. SPA is system level (i.e. sentence level scores averaged over the entire test set), so exact ties are very unlikely. However, SPA can be seen as giving full credit for (statistical) ties, which is similar in spirit.

We show that quantization (specifically binarization) is problematic in PA. Quantization in evaluation has proved problematic in other spaces as well—for example, Schaeffer et al. (2024) attributes the widely repeated claim that LLMs have emergent properties to quantization in evaluation.

6 Conclusions

We introduce a new meta-metric which we denote soft pairwise accuracy, and show that it improves on pairwise accuracy in a number of ways, most notably that it is more stable than pairwise accuracy

[7] We ignore tie handling, as ties are extremely unlikely in system-level evaluation. Ties in *segment-level* evaluation are an entirely different matter (Deutsch et al., 2023a).

when ablating the number of systems and annotations per system, it fixes an issue of metric ties observed in pairwise accuracy, and it produces more statistically significant comparisons between metrics than pairwise accuracy. We also discuss how soft pairwise accuracy fits into and builds upon the nearly two decade history of meta-evaluation at the WMT Metric Shared Tasks.

Acknowledgments

This work would not have been possible without the WMT shared tasks and metrics tasks releasing their data. We are appreciative of helpful discussions with the WMT metrics task organizers as well as Sweta Agrawal and Rebecca Knowles.

Limitations

When computing p-values, we assume that system-level metric scores are the average of segment-level metrics scores. There is a line of recent work that seeks to incorporate contextual information into automatic metrics. Many such works still produce scores at the segment level (e.g. Vernikos et al., 2022; Hu et al., 2023; Agrawal et al., 2024) but others produce one score per window of a few sentences (Raunak et al., 2024) or one score per paragraph (Deutsch et al., 2023b). Our method should still be applicable in such cases, but would require permuting windows or paragraphs instead of segments. Additionally, as previously noted, some metrics—notably BLEU (Papineni et al., 2002) and chrF (Popović, 2015)—compute statistics at the segment level and combine them to create document-level scores. Again, permutations would still work but would require some modification. To the best of our knowledge, this issue is not limited to our work—the same assumption is made in prior work computing statistical significance of metrics, including the WMT shared tasks (Freitag et al., 2021, 2022, 2023) and Deutsch et al. (2021).

It is worth noting that the permutations in this work (as in prior works) are done on a single test set, and do not necessarily reflect variations in performance that could result from using the metrics in another domain. Prior work has shown that trained metrics are sensitive to a shift in domain relative to the data domain they were trained on (Zouhar et al., 2024).

Speech is More Than Words: Do Speech-to-Text Translation Systems Leverage Prosody?

Ioannis Tsiamas[◇][*] **Matthias Sperber**[†] **Andrew Finch**[†] **Sarthak Garg**[†]
[◇]Universitat Politècnica de Catalunya [†]Apple
ioannis.tsiamas@upc.edu, sperber@apple.com

Abstract

The prosody of a spoken utterance, including features like stress, intonation and rhythm, can significantly affect the underlying semantics, and as a consequence can also affect its textual translation. Nevertheless, prosody is rarely studied within the context of speech-to-text translation (S2TT) systems. In particular, end-to-end (E2E) systems have been proposed as well-suited for prosody-aware translation because they have direct access to the speech signal when making translation decisions, but the understanding of whether this is successful in practice is still limited. A main challenge is the difficulty of evaluating prosody awareness in translation. To address this challenge, we introduce an evaluation methodology and a focused benchmark (named CONTRAPROST) aimed at capturing a wide range of prosodic phenomena. Our methodology uses large language models and controllable text-to-speech (TTS) to generate contrastive examples. Through experiments in translating English speech into German, Spanish, and Japanese, we find that (a) S2TT models possess some internal representation of prosody, but the prosody signal is often not strong enough to affect the translations, (b) E2E systems outperform cascades of speech recognition and text translation systems, confirming their theoretical advantage in this regard, and (c) certain cascaded systems also capture prosodic information in the translation, but only to a lesser extent that depends on the particulars of the transcript's surface form.[1]

1 Introduction

Prosody, which includes features like stress, intonation, and rhythm, is crucial for conveying meaning in spoken language beyond the literal words used (Ladd, 1980; Bolinger, 1989). Among others, prosody can direct focus and clarify meaning (Bolinger, 1961; Halliday, 1967), disambiguate syntax and sentence structure (Bolinger, 1989), convey the emotional state of the speaker (Banse and Scherer, 1996), and provide useful cues that make communication more effective (Shriberg et al., 1998). For example, the phrase "*Really?*" can express surprise, genuine interest or disbelief, depending on the intonation with which is spoken.

Example: *These are German teachers.*		
A	Prosody	These are GERMAN teachers.
	Explanation	Teachers from Germany
	Translation	Dies sind Deutschlehrer.
B	Prosody	These are German TEACHERS.
	Explanation	Teachers that teach German
	Translation	Dies sind deutsche Lehrer.
Example: *John laughed at the Party.*		
A	Prosody	John LAUGHED (pause) at the Party.
	Explanation	Laughed while at the party (literal)
	Translation	John lachte während der Party.
B	Prosody	John LAUGHED AT (pause) the Party.
	Explanation	Ridiculed the party (idiomatic)
	Translation	John lachte über die Party.

Table 1: Examples of prosody-aware Speech Translation from English to German.

Table 1 illustrates the importance of considering prosody when generating translations in S2TT. Sperber and Paulik (2020) suggest that E2E S2TT systems may have an inherent advantage over cascaded systems in this regard, because only the former have access to the speech signal when making translation decisions. However, our understanding of whether prosody informs translation choices in practice is currently still limited, as prior research on this topic either shows only anecdotal evidence (Huang et al., 2023b), focuses on only a small subset of prosodic phenomena (Zhou et al., 2024; Chen et al., 2024), or considers how prosody informs target-side speech with regards to generated prosody but not lexical choice (§6).

In this paper, we take steps toward a reliable and comprehensive evaluation methodology, which is one of the most important prerequisites for achieving prosody-aware S2TT. We identify three central challenges that must be addressed: (1) Existing S2TT benchmarks often do not include prosody-rich spontaneous speech and/or do not include translations that are informed by the audio, limiting the extent to which reference translations are influenced by source-side prosody. (2) General-purpose evaluation methods like BLEU (Papineni et al., 2002) and COMET (Guerreiro et al., 2023) are insensitive to the often subtle changes in translation caused by input prosody. (3) Existing prosody-centric benchmarks are difficult to scale to broader coverage of languages and prosodic phenomena, which hinders comprehensive analysis.

To address these challenges, we take inspiration from prior work on behavioral testing (Ribeiro et al., 2020; Ferrando et al., 2023) and contrastive evaluation (Sennrich, 2017). We address the first challenge by synthesizing prosody-rich data that covers a wide range of prosodic phenomena through the use of large language models (LLMs) and controllable TTS (cTTS). We tackle the second challenge by developing a double-contrastive evaluation approach, i.e. a directional behavioral test that relies on minimal pairs (differing only in prosody) to evaluate prosody-awareness in S2TT in isolation. The resulting benchmark, ContraProST (Contrastive Prosody ST), covers a variety of language pairs and prosodic phenomena. Since it is mostly automated, it can be further extended, thus addressing also the third challenge.

To investigate how well current state-of-the-art models understand and leverage prosody, we evaluate S2TT models of various sizes and types, including both E2E and cascaded systems. We find indications that S2TT models represent prosody internally, but this knowledge is often not manifested in the translations. We observe that while tested cascaded systems perform better on traditional evaluation (COMET), E2E models outperform cascaded models on ContraProST. We also find indications that some amount of prosody is carried through transcripts in cascaded setups, but this depends on the particulars of the transcriptions. The most important implication of our findings is the need for exploring improvements of S2TT regarding prosody-awareness, e.g. through auxiliary losses or finetuning on prosody-rich data.

2 The ContraProST Benchmark

ContraProST is composed of double-contrastive examples (see Table 1), where each example is composed of a sentence in English that could be semantically ambiguous, along with two different pairs of <speech, translation> that capture contrastive cases of prosody.

As it would be expensive and practically difficult to collect such test data manually, we employ an automatic data generation process, illustrated in Fig. 1. First, we identify several relevant categories where prosody influences sentence semantics in important ways, and construct illustrative examples that reflect the respective phenomena of each category, while highlighting differences in prosody-induced meaning (§2.1). We then prompt GPT-4[2] (OpenAI, 2024) to generate sentences similar to the examples for each subcategory using in-context learning, grounding the generation on different text domains to increase diversity (§2.2). Next, GPT-4 is prompted to translate each prosodic case, while also being given access to the prosodies, meanings and general information of the category, thus acting as a prosody- and context-aware oracle translator (§2.3). Finally, we use the OpenAI TTS API[3] to synthesize the prosodic speech of each case (§2.4). Each generation stage is coupled with filtering and quality assessment to ensure the data are of high quality.

2.1 Categorization of Prosodic Phenomena

Below, we summarize the examined prosodic categories. Details and examples are available in the Appendices A and B.

(1) Sentence Stress. This is usually manifested through increased loudness, vowel length or higher pitch (Fry, 1955), invoking emphasis on certain words within a sentence, potentially changing the semantics by shifting focus (Wagner, 2020). We further categorize prosodic stress in four subcategories according to the purpose of the stress or its use in disambiguation of linguistic phenomena (see Appendix A.1).

(2) Prosodic Breaks. Here we consider the existence or placement of longer breaks in the flow of speech, primarily associated with tempo, that create different phrasal boundaries and help disambiguate syntax and sentence structure (Bolinger, 1989). We follow Hirschberg (2017) and use the

[2] GPT-4o-2024-05-13

[3] TTS-1-HD, platform.openai.com/docs/models/tts

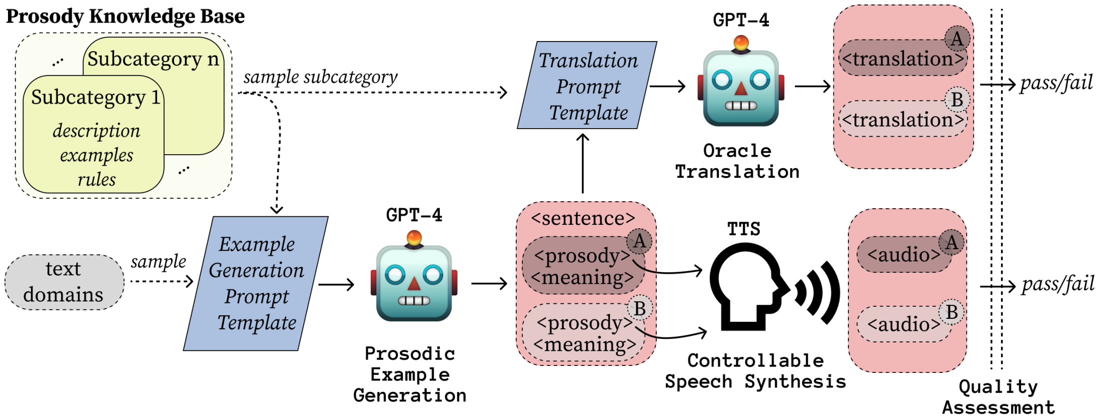

Figure 1: The Data Generation process for CONTRAPROST.

subcategories outlined in Appendix A.2.

(3) Intonation Patterns. This concerns the modality of the sentence, specifically whether it is a statement (falling tone), or a declarative question (rising tone) (Gunlogson, 2002).

(4) Emotional Prosody. A different emotional tone can indicate a speaker's emotional state and thus affect the semantics of the utterance (Banse and Scherer, 1996). Emotional tone is usually manifested through changes in pitch, tempo, and loudness. For example, happiness is associated with higher values in pitch and tempo, while sadness exhibits lower values for pitch, tempo, and loudness (Larrouy-Maestri et al., 2024). Here, we focus on the seven *basic* emotions: happy, sad, angry, disgust, surprisal, fear, and neutral (Ekman and Friesen, 1971; Ekman, 1992), based on which we construct all possible pairs, thus having 21 subcategories.

(5) Politeness. The level of politeness can be conveyed by non-verbal cues, and influences the pragmatic context of a conversation. A polite tone is associated with a higher pitch and a smooth rhythm, while an impolite tone is manifested through low pitch, irregular rhythm and very high or low loudness levels (Culpeper et al., 2003; Culpeper, 2011).

2.2 Prosodic Example Generation

For each category, we prompt GPT-4 to generate sentences based on hand-crafted category-specific examples. More specifically, we have the LLM generate English sentences, each with two different textual prosodic annotations and respective meanings/interpretations to guide subsequent translation (§2.3). The generated annotations include rich text that indicates different levels of emphasis, pause tags, and special punctuation such as ellipsis, exclamation, or interobang (!?). The sentence itself is generated to be as simple as possible, ending with a full stop or question mark.

Prompt 1: Prosodic Example Generation

You are a helpful assistant with expert knowledge in linguistics, speech, and prosody. Your task is to come up with examples of English sentences where different prosody would change the meaning of the sentence significantly.(1)
{Details for Category & Subcategory}(2)
Here are some examples to guide you:
{List of Examples}(3)
Strictly follow these rules:
{List of Rules}(4)
Provide a rating of how significant is the difference between the two meanings.(5)
Generate {n} such examples, with rating as high as possible,(6) in the domain of {domain}.(7)

The general prompt template is displayed in Prompt 1. It starts with some general information about the task, see superscript (1). The prompt then continues with details describing the current category/subcategory (2). The next part refers to in-context learning (Brown et al., 2020), where we provide a list of illustrative, hand-crafted examples for the LLM to follow (3). In certain subcategories, due to repeated mistakes observed in preliminary explorations, we also provide examples to avoid. In (4) we provide a list of rules for the LLM to adhere to, indicating the desired structure of the sentence and how to use prosodic notation, which might not be obvious from the examples (3). Examples of such rules are "do not include prosodic annotations in the sentence," or "stress different noun-phrases in each prosodic case." We furthermore use *self-criticism* (Huang et al., 2023a) by instructing the model to rate its own generations, according to how different the two prosodic interpretations are (5). Then we instruct the LLM to generate examples that have high scores after self-reflection (6). These scores are also used later during filtering. Finally, to avoid repetitive examples and enhance diversity, we condition the generation on specific text domains (7) (Chung et al., 2023). The list of domains is also generated by GPT-4 based on the context that its subcategory would naturally occur (e.g. *legal testimonies*). For each text domain in the subcategory the LLM then generates n candidate examples. We use several hand-crafted text-based filtering steps to ensure that the examples generated by the LLM at this stage comply with the instructions specified in (4).

2.3 Oracle Translation

Recent research on the emerging capabilities of LLM-based MT (Vilar et al., 2023; Alves et al., 2023; Zhang et al., 2023) has shown that LLMs can attain very high translation quality, especially for high-resource languages (Robinson et al., 2023) and including translation factors such as emotions (Brazier and Rouas, 2024), suggesting the possibility that LLMs can be leveraged for prosodic translation synthesis. To obtain the translations of the prosodic cases, we thus utilize GPT-4 as a prosody- and context-aware oracle translator. The LLM is prompted to translate, while having access to the sentence, the textual prosodic annotations (prosody-awareness), and the semantic interpretations (context-awareness). The template prompt is shown in Prompt 2. We provide a list of contraints to the LLM with several goals in mind: (i) avoid generating prosodic annotations in the translations; (ii) avoid translating the interpretations rather than the sentences; (iii) encourage the model to generate different translations for each case; (iv) ensure that differences in the translations are only due to the difference in the prosodies.

Although prosody variants substantially influence sentence semantics, this does not always imply that the ideal translations must differ. In particular, sometimes a translation that leaves semantics ambiguous may be preferred as the most natural translation.[4] As a consequence, constraint (iii) is sometimes overly strict and even in conflict with constraint (iv), leading to changes in the translations that do not stem from the prosodies, that are not idiomatic. To account for that, we include a post-editing step, where GPT-4 is instructed to choose the most fitting translation among $\{T, T_A, T_B\}$ for each prosodic case, independently from the other prosodic cases, while having access only the prosody information (Prompt 3). We prompt the LLM to first provide an explanation, before selecting the most appropriate translation, in order to induce *chain-of-thought* reasoning effect (Kojima et al., 2024).

Prompt 2: Oracle Translation

You are a helpful assistant with expert knowledge in speech, prosody, linguistics and translation, particularly in English and {Target Lang}.
You will be provided with a sentence in English (S) and two different prosodic variations ($\mathrm{S_A}$, $\mathrm{S_B}$), focused on {Category}, which correspond to two different semantic interpretations.
Your task is to translate S, $\mathrm{S_A}$ and $\mathrm{S_B}$ into {Target Lang}, as T, $\mathrm{T_A}$, and $\mathrm{T_B}$.
Carry out the translation in these steps:
(1) Translate S into T.
(2) Translate $\mathrm{S_A}$ to $\mathrm{T_A}$ and $\mathrm{S_B}$ to $\mathrm{T_B}$, by focusing on how T should change in order to reflect the additional information from the prosodies.
The following constraints should be applied:
{List of Constraints}
The sentence S is: {sentence}
The two different prosodic variations are:
$\mathrm{S_A}$. {$\mathrm{prosody_A}$} ({$\mathrm{meaning_A}$})
$\mathrm{S_B}$. {$\mathrm{prosody_B}$} ({$\mathrm{meaning_B}$})

Prompt 3: Translation Post-editing

You are a helpful assistant and an expert translator. You will be provided with a sentence in English and different possible translations in {Target Lang}. The English sentence can contain rich prosodic text with {Category-specific information}, that affects the meaning of the sentence. Your task is to select the most appropriate and prosody-aware translation. First provide a brief explanation of your reasoning and then the index of the selected translation.
The sentence S to be translated is {sentence} and the candidate translations are: [T, $\mathrm{T_A}$, $\mathrm{T_B}$]}

After post-editing we remove all examples where the prosodic cases have identical translations, i.e. $(T_A{=}T_B)$. As an extra measure, we also remove examples where the word length-ratio of the non-

[4] This is essentially an instance of the fluency-accuracy trade-off (Lim et al., 2024).

prosodic translation T and one of the prosodic translations T_A, T_B is not within (0.75, 1.25)[5]. This aims to remove translations that are overly explanatory, including new bits of information that can be due to the prosody, but are making the translation unnatural (see Table 10 in App. D.2 for examples.).

2.4 Controllable Speech Synthesis

We use the OpenAI TTS which can synthesize very natural speech with high-quality audio, offering six different voice profiles. While there are no clear guidelines[6] on how to control prosody, we identified some effective prompting strategies to control the TTS output through trial-and-error (Table 2).

Effect	TTS Prompting
Strong Emphasis	*WORD*
Normal Emphasis	*word*
Slight Emphasis	_word_
Pause	<pause>
Statement Intonation	Prepend <statement>
Question Intonation	Prepend <question> & Append ????
Emotional/Polite Tone	Prepend & Append Emojis

Table 2: OpenAI TTS prompting strategies.

To ensure that the generated audio follows the correct wording and exhibits the intended prosodic characteristics we use the following process: First, we generate six candidates (one per voice) for each prosody, discarding invalid candidates (WER$\neq$0) using an ASR model. Then we estimate prosody quality using category-specific tests in order to rank or filter examples. These tests employ techniques such as forced alignment (Kürzinger et al., 2020), signal processing, punctuation probability, and speech emotion classification. They are explained in detail in Appendix C.

3 Contrastive Evaluation

General-purpose MT metrics like BLEU and COMET may be insensitive to subtle changes caused by prosody, and do not allow disentangling prosody awareness from overall translation quality. Thus, to assess how well an S2TT model can handle prosody specifically, we develop a contrastive evaluation framework (Sennrich, 2017). Note that previous work on contrastive evaluation uses a single source and two or more targets (Sennrich, 2017; Vamvas and Sennrich, 2021; Zhou et al., 2024) of which only one is correct. The model likelihood is then estimated for each target, and models are preferred that assign a better score to the correct example than to the foil(s). Here, we generalize this approach to leverage CONTRAPROST's *double-contrastive* pairs, i.e. two sources and two targets (Fig. 1).

Formally, each double-contrastive pair has two cases $\{X^a, Z, Y^a\}$ and $\{X^b, Z, Y^b\}$, where X^a, X^b are the two different prosodic speech signals, Z is the source text (same for both cases), and Y^a, Y^b are the different translated texts for each case. Thus, each example has two correct pairs (X^a, Y^a), (X^b, Y^b) and two incorrect ones (X^a, Y^b), (X^b, Y^a). We propose the following conditions to assess whether the S2TT model can correctly solve the contrastive example, and to what degree:

$$\begin{aligned}
C_{\mathcal{G}} = \mathbf{1}\Big[& f(Y^a \mid X^a; \theta) - f(Y^b \mid X^a; \theta) > 0 \\
& \text{and } f(Y^b \mid X^b; \theta) - f(Y^a \mid X^b; \theta) > 0 \Big] \\
C_{\mathcal{D}} = \mathbf{1}\Big[& f(Y^a \mid X^a; \theta) - f(Y^b \mid X^a; \theta) \\
& + f(Y^b \mid X^b; \theta) - f(Y^a \mid X^b; \theta) > 0 \Big]
\end{aligned}$$

Here, $\mathbf{1}[\cdot]$ is the indicator function, and $f(\cdot) > 0$ is a function that measures the agreement between audio input X and target translation Y under the S2TT model with parameters θ. $C_{\mathcal{G}}$ is a *global* condition, requiring the model to prefer both of the correct pairs versus the incorrect ones according to f. $C_{\mathcal{D}}$ is a *directional* condition (Ribeiro et al., 2020) where we require a net positive directional movement for the two comparisons. We expect a model to have a strong internal representation of prosody if it can solve the global condition, and weak representation if it can only solve the directional one.[7]

We consider two different functions f to measure the agreement of X and Y.

3.1 Contrastive Likelihood

Similar to prior work on contrastive evaluation (Sennrich, 2017; Vamvas and Sennrich, 2021; Zhou et al., 2024) we use the model likelihood to measure the level of agreement between input audio and target text. We obtain the model likelihood $\mathcal{L} \in \mathbb{R}^+$ for a reference $Y = (y_1, \ldots, y_{|Y|})$, given a speech signal $X \in \mathbb{R}^k$ and an E2E S2TT model with parameters θ_{E2E}. It is defined as the product

[5] We use character-based length-ratio for Japanese.

[6] platform.openai.com/docs/guides/text-to-speech

[7] Note that $C_{\mathcal{G}}$ is a sufficient condition for $C_{\mathcal{D}}$.

of the conditional probabilities, normalized by the length of the reference. Formally:

$$\mathcal{L}(Y \mid X; \theta_{\text{E2E}}) = \frac{1}{|Y|} \prod_{i=1}^{|Y|} p_{\theta_{\text{E2E}}}\big(y_i \mid X, y_{<i}\big)$$

For a cascaded S2TT model we approximate the true likelihood by considering the top-n ASR hypotheses $\mathcal{Z} = \{Z^{(1)}, \ldots, Z^{(n)}\}$. Assuming the lengths of the $\mathcal{Z}$ are generally similar, we get:

$$\mathcal{L}(Y \mid X; \theta_{\text{casc}}) \approx \mathcal{L}(Y \mid \mathcal{Z}; \theta_{\text{MT}})\mathcal{L}(\mathcal{Z} \mid X; \theta_{\text{ASR}})$$
$$\approx \frac{\sum_{j=1}^{n} \left[\mathcal{L}(Y \mid Z^{(i)}; \theta_{\text{MT}}) \cdot \mathcal{L}(Z^{(i)} \mid X; \theta_{\text{ASR}})\right]}{\sum_{j=1}^{n} \mathcal{L}(Z^{(i)} \mid X; \theta_{\text{ASR}})}$$

Furthermore, to remove a potential bias of the model against rare translations, we normalize by the unconditioned decoder likelihood of the reference:[8]

$$f_{\overline{\mathcal{L}}}(Y \mid X; \theta) = \frac{\mathcal{L}(Y \mid X; \theta)}{\mathcal{L}(Y \mid \theta)} \quad (1)$$

3.2 Contrastive Translation Quality

A common criticism of using model likelihoods is that they do not assess whether the correct output is actually generated in practice, due to teacher forcing. To address this, we propose another function that leverages translation quality estimation (QE) to compare unconstrained autoregressively generated model outputs. We obtain the hypothesis $\hat{Y}$ of input X by generating with the S2TT model $\mathcal{M}_\theta$, and use xCOMET (Guerreiro et al., 2023) to measure the quality of the translation. Thus:

$$f_{\mathcal{Q}}(Y \mid X; \theta) = \mathcal{Q}\big(Y, \mathcal{M}_\theta(X)\big) = \mathcal{Q}(Y, \hat{Y}) \quad (2)$$

The contrastive metrics using $f_{\mathcal{Q}}$ are expected to give us a better insight into how influential prosody is when translating with S2TT models, as compared to using $f_{\mathcal{L}}$ (Eq. 1), since they consider autoregressive generation and beam search.

4 Experimental Setup

4.1 Data Generation

For prosodic example generation with GPT-4 (§2.2) we used a temperature of 1, and 20 text domains per subcategory. The model was prompted to generate 10 examples[9] for each pair of (subcategory, domain). The total number of subcategories is 27 (more details in App. A), amounting to 5.5k examples of English sentences with pairs of prosodies and meanings created initially. Then we generated the candidates for the six voices with the TTS (5.5k$\times$6$\times$2 = 66k) and choose the 11k best candidates as described in §2.4. After quality assessment we end up with 2.8k examples with good prosody quality in the generated audio. Then we separately translated each one to the three target languages German (De), Spanish (Es), and Japanese (Ja). After post-editing and filtering we obtained 1.3k–1.4k full examples for each language pair (Table 3).

Category	**En-De**	**En-Es**	**En-Ja**
Emotional prosody	373	379	376
Sentence stress	277	279	342
Prosodic breaks	276	252	289
Politeness	212	193	206
Intonation patterns	173	173	173
Total	1,311	1,294	1,386

Table 3: Number of examples for each language pair in CONTRAPROST. More details are in Appendix D.1.

4.2 Speech-to-text Translation Models

We evaluated S2TT models that fall under these three categories:

- E2E, where inference is done without an intermediate transcription step. The decoder of this model has full access to the prosody of the input.
- AED-based cascade, which is composed of an attentional encoder-decoder (AED) (Vaswani et al., 2017) ASR model and an MT model. We expect the decoder of the MT model to have limited access to prosody, unless the ASR model is able to encode it in the transcription. This is possible mainly though punctuation, but also when the ASR model is acting more interpretative (i.e. generating synonyms that better fit the prosody rather than the spoken words).
- CTC-based cascade, which uses a CTC encoder (Graves et al., 2006) for the ASR part. The decoder of the MT model is expected to have almost no access to prosody since CTC model outputs are not punctuated and cannot be interpretative.

[8] Estimated by using an empty audio for E2E case and empty source text in the MT model for the cascade.

[9] We generated 15/20 examples for intonation patterns/politeness, respectively.

We are evaluating the following S2TT models:

- SEAMLESSM4T (Seamless Communication, 2023b) is a multilingual and multimodal encoder-decoder. It is trained with multi-task learning on ASR, MT, S2TT and also on speech-to-speech translation (S2ST), and can thus be used in either E2E or cascaded (AED) mode.
- XLS-R (Babu et al., 2021) is a multilingual E2E model, of which the encoder is based on WAV2VEC2.0 and its decoder on MBART50 (Tang et al., 2020).
- ZEROSWOT (Tsiamas et al., 2024) is a zero-shot E2E model that connects a WAV2VEC 2.0 CTC encoder and NLLB (NLLB Team, 2022).
- SALMONN (Tang et al., 2024) is an audio LLM that connects WHISPER (Radford et al., 2022) and BEATs (Chen et al., 2023) to the Vicuna LLM (Peng et al., 2023), and can be used as an E2E S2TT model.
- WHISPER & NLLB (AED-based cascade).
- CTC & NLLB (CTC-based cascade) with WAV2VEC 2.0 or HUBERT (Hsu et al., 2021).

We considered different versions of these 6 models, thus evaluating in total 31 S2TT model variants of different sizes and capabilities (App. E).

4.3 Metrics

We used beam search with beam size 5 to generate hypotheses. For estimating the conditional likelihood of the cascade (§3.1) we used the top-5 ASR hypotheses. For the contrastive translation quality (§3.2) we used XCOMET-XL[10] (Guerreiro et al., 2023), which is a state-of-the-art neural quality estimation metric based on XLM-R (Conneau et al., 2020). For all evaluated models we present their *contrastive likelihood* and *contrastive translation quality* scores, both *global* and *directional* versions, as a percentage of solved examples. We also evaluate them on standard QE using XCOMET-XL, by using the 2 correct pairs of each example (2.6k samples). For statistical significance testing we used bootstrap resampling (Efron, 1979) with 10k resamples and a 95% confidence interval.

5 Experimental Results

In Table 4 we present the results of evaluating a selection of large and recent model versions all three language pairs. We find that most S2TT models have at least some internal representation of prosody, enabling them to outperform the random baseline of 50% for the directional contrastive likelihood. On the other hand, when we consider autoregressive generation, we observe that the scores for the directional contrastive quality are relatively low[11], indicating that prosody is often not prominent enough in the internal representations of the models for it to be manifested in the generated translations. Furthermore, we find that the task of correctly solving both sub-cases of each example (global agreement) is very challenging for all models, with scores ranging around 10% for both contrastive metrics. We observe that even though the best performing model according to standard evaluation (XCOMET) is a cascade system, it falls behind the best E2E models when considering the contrastive evaluation on CONTRAPROST. This finding illustrates why it is beneficial to separate prosody evaluation from general accuracy evaluation to study the phenomenon, which is further supported by our observation that the prosody and general accuracy metrics are only moderate correlated (see Fig. 5 in App. F).

Are model type and model size important for prosody-awareness? We evaluate all 31 S2TT models using *global contrastive quality*, and run a regression analysis with the model type (E2E/AED-cascade/CTC-cascade) and model size as inputs. We use a mixed effects model (Pinheiro and Bates, 2006) to group together each model family, and thus account for random effects, such as the training data and hyperparameters. Specifically:

$$y_{ij} = \beta_0 + \beta_1 \mathrm{S}_{ij} + \beta_2 \mathrm{AED}_{ij} + \beta_3 \mathrm{CTC}_{ij} + u_j + \epsilon_{ij},$$

where y_{ij} is the score of i-th model variant of the j-th model family, β_0 is the intercept, S is the log of the model size, AED and CTC are binary variables, u_j is the random effect for j-th model family, and ϵ_{ij} is a residual error term. All scores are available in Table 11 in App. F. In Figure 2 we confirm with statistical significance that the E2E models outperform the cascades in all three language directions.[12] There is also a statistically significant negative impact on prosody-awareness when the cascade is based on a CTC ASR model that may be explained by the absence of punctuation in CTC

[10] hf.co/Unbabel/XCOMET-XL

[11] Assuming XCOMET is 0 for randomly generated text, the baseline scores are also 0.

[12] Note that results are borderline non-significant for En-Ja against the AED-cascade.

Table 4: Contrastive Evaluation of S2TT models on ContraProST. Grey background indicates a cascaded system.

transcripts, which if present can at least approximately signal some prosodic phenomena. Finally, although there is some evidence that larger models are more prosody-aware, results are not statistically significant. We speculate that larger models have more capacity to encode prosody in the weights, but since prosody is perhaps not sufficiently represented in the training data, this effect is limited.

How do results compare across categories and models? In Figure 3 we present results across individual prosodic categories for four different English-German models, and perform pairwise model comparisons via bootstrap resampling[13]. The only category models are able to solve consistently is *intonation patterns*, which can also be solved by cascaded models due to the presence of punctuation in the transcription. The comparably lower scores in the other four categories further demonstrate the inability of current state-of-the-art models to use prosody, with *sentence stress* being the most challenging. Through the pairwise comparisons, we find that an LLM-based model (SALMONN) is not statistically different from a more standard S2TT model, like SeamlessM4T. Next, comparing the SeamlessM4T model in both E2E and cascade allows us to control for parameters such as training data and architecture, in order to observe the effect of model type, giving more clarity of our results on the theoretical advantage of E2E models. Finally, we observe a clear performance gain by using the SeamlessM4T cascade over the Whisper & NLLB one. We hypothesize this advantage is due to the multitasking nature of SeamlessM4T, which makes its ASR

[13] English-Spanish/Japanese are available at Figures 6, 7 in App. F.

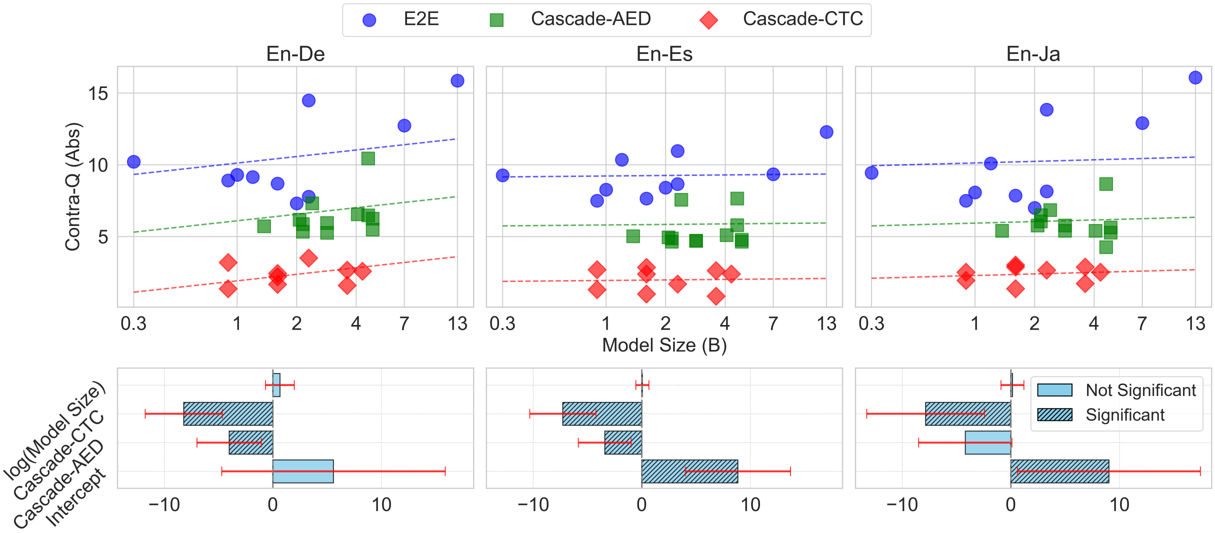

Figure 2: Regression Analysis of model types and model sizes per language pair.

mode more interpretative than standard ASR models. This allows the ASR part of the cascade to escape the word-by-word paradigm, and use more fitting words in the transcription (such as synonyms) that fit better the prosody of the audio. Supporting this hypothesis. we observe a worse WER score for SEAMLESSM4T (11%) compared to WHISPER (4%).

Is the level of prosody-awareness language-dependant? In Figure 4 we carry out a similar regression analysis as in Figure 2, but with the language pair as an independent categorical variable. Interestingly, we observe that there are differences between the three language pairs, and also significant for Spanish vs. German, which indicates that prosody-awareness in S2TT could be language-dependant. We hypothesize that the expressivity of the target language might be a relevant factor, since more expressive languages might be able to easier encode the prosody of the source speech into text.

6 Related Work

Prosody has traditionally been an important topic for TTS research (Kohler, 1991), either for transferring (Skerry-Ryan et al., 2018) or encoding it (Pamisetty and Sri Rama Murty, 2022) in the synthesized speech. Furthermore, Torresquintero et al. (2021) created a dataset for evaluating prosody transfer in TTS models, which contains several categories, similar to our study here. Naturally prosody has also been the focus of S2ST systems, in order to translate in a more expressive way (Aguero et al., 2006; Do et al., 2017; Communication et al., 2023). The topic has received less attention in the context of S2TT. Chen et al. (2024) present a dataset for emotional prosody based on speech and translations from TV series, and show that finetuning with emotion labels, can improve translation quality. Zhou et al. (2024) studied the prosody-awareness of WHISPER in E2E and cascade mode, in translating Korean *wh-phrases* using contrastive likelihood, and find evidence of the E2E model outperforming the cascade. Here we contribute a broader study of prosody in S2TT, by proposing a double-contrastive benchmark that covers several prosodic categories, the use of more generative-like contrastive evaluation, and evaluating a plethora of S2TT models. Finally, de Seyssel et al. (2023) present a benchmark for evaluating prosody-awareness in self-supervised acoustic representations. Similarly to our study they present evidence of prosody awareness in the representations. Contrary to our results, they conclude that size has a positive effect on prosody awareness.

7 Conclusions

We presented CONTRAPROST, a benchmark based on double-contrastive examples for evaluating prosody-awareness in S2TT models, covering several categories and languages. In addition to standard contrastive evaluation based on model likelihoods, we proposed a generative contrastive metric based on quality estimation. We evaluated a plethora of models, and found that they exhibit some signs of prosody-awareness, but the effect is often not strong enough to influence the translations. We also confirmed the previously hypothesized inherent advantage of E2E models com-

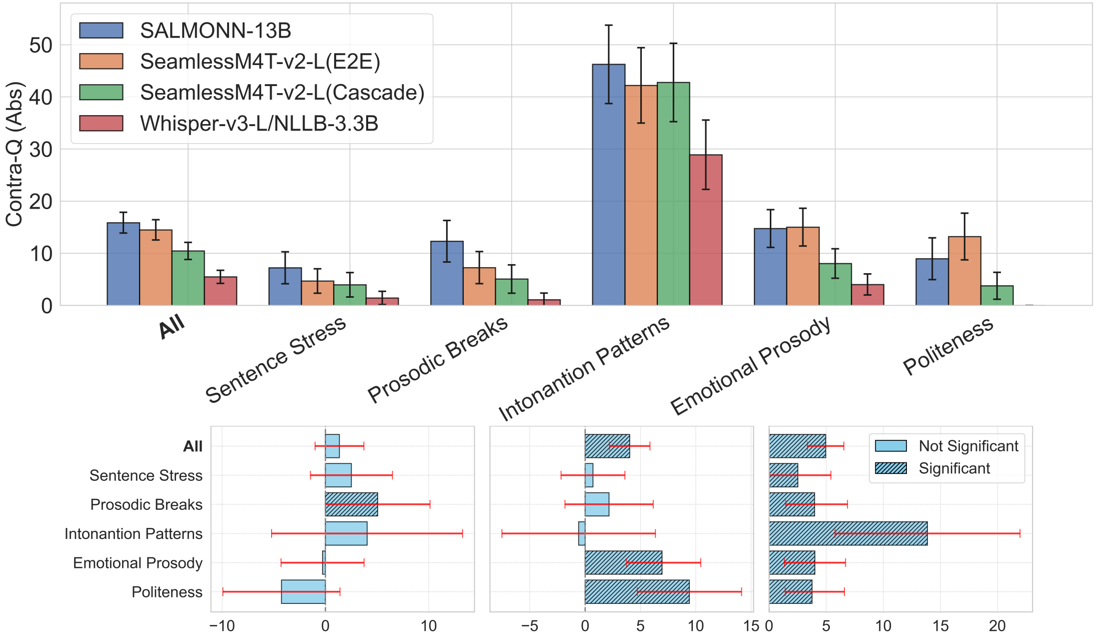

Figure 3: Upper: Model performance per category (En-De). Lower Model performance comparisons (En-De), (a): SALMONN-13B vs. SeamlessM4T-v2-Large, (b) SeamlessM4T-v2-Large(E2E) vs. SeamlessM4T-v2-Large(cascade), (c) SeamlessM4T-v2-Large(cascade) vs. Whisper-v3-Large/NLLB-3.3B.

pared to cascaded models. We hope that our benchmark and findings will motivate more research into prosody-aware S2TT in the future, enabling us to better understand it and improve it.

Limitations

For creating ContraProST we relied on an almost entirely automated data generation process. This allowed us to create a comprehensive dataset covering several prosodic phenomena and three language pairs, in a fast and cost-effective way. It would also enable expanding the coverage of languages and prosodic phenomena relatively easy in the future. Nevertheless, despite our best efforts regarding filtering and quality assessment (§2 and App. C), the data is not perfect and includes a certain amount of noise. We observed the following sources of noise in order of decreasing importance: (1) prosody not prominent in the generated speech; (2) translations overly explanatory or not encoding prosody; (3) semantic interpretations of the two cases rather similar. We do not expect these issues to be so frequent as to alter the findings of this work in a systematic way, but additional human annotation or verification would be a valuable step for future work. Furthermore, as the landscape of available generative models, in particular controllable TTS, is changing quickly, the quality of results using our data generation process would expectantly become less of a concern in future iterations.

Our study follows a contrastive evaluation methodology in order to isolate prosody-related behavior. As a consequence, our study does not allow drawing conclusions on how much prosody matters in real life data, and in what domains it is especially important. In addition, we hypothesize that some prosodic phenomena could be correctly translated by having access to the broader context of the conversation (context-aware S2TT), which we leave for future research.

A Prosodic Subcategories

Here we expand the categorization of §2.1, and discuss the identified subcategories for sentence stress and prosodic breaks, which are 4 and 6 respectively. Intonation patterns and Politeness do not have subcategories. For emotional prosody we have 15 emotion pairs[14], thus having 15 subcategories. Examples are available at Tables 5 and 6.

A.1 Sentence Stress Subcategories

(1.1) *Contrastive Stress*, which highlights differences or corrects previous statements, emphasizing contrasts between elements (Bolinger, 1961).
(1.2) *New vs. Given Information*, which differentiates between new and given information, emphasizing what is considered new (Halliday, 1967).
(1.3) *Relational vs. Descriptive Adjectives*, where stressing the adjective or the noun can differentiate between the relational and descriptive uses of attributive adjectives (Liberman and Sproat, 1992).
(1.4) *Focus-Sensitive Operators*, where stress indicates the focus of adverbs of quantification (*only*, *just*, etc), shifting the meaning of the sentence accordingly (Halliday, 1967; Jackendoff, 1972).

A.2 Prosodic Break Subcategories

(2.1) *Direct vs. Indirect Statements*, where a prosodic break can indicate whether a phrase is a direct or an indirect quote (Klewitz and Couper-Kuhlen, 1999; Jansen et al., 2001).
(2.2) *Restrictive vs. Non-Restrictive Clauses*, which involves the use of prosodic breaks to differentiate between essential and non-essential information, impacting the specificity of the noun being described (Nespor and Vogel, 1986).
(2.3) *VP vs. NP Attachment*, where a trailing phrase can be attached either to the verb-phrase or the noun-phrase, depending on the existence of a prominent prosodic break (Pynte, 1996).
(2.4) *Particle vs. Preposition*, where a prosodic break can disambiguate between the literal and idiomatic meaning of phrasal verbs, by grouping the preposition with or without it (Price et al., 1991).
(2.5) *Broad vs. Narrow Scope*, where the existence of a prosodic break can signal that a modifier (adjective) has narrow scope, and refers only to one of two nouns that follow it (Hirschberg, 2017).
(2.6) *Complementizer vs. Parenthetical*, where the location of a prosodic break indicates whether an intermediate phrase acts as a complementizer or simply parenthetical to the main one (Dehé, 2014).

B Examples for In-context Learning

In Tables 5, 6 and 7 we present some of the examples used for in-context learning when generating new examples with GPT-4 (§2.2).

C Quality Assessment for TTS candidates

Here we present the objectives we defined for assessing the quality of the generated speech candidates for each contrastive example. The objective is applied only to candidates that had WER $= 0$ using WHISPER. If all candidates are invalid for a prosodic case, the whole example is removed. We also defined some threshold levels for the objectives after trial-and-error, in order to remove examples where the best candidate was below it.
Sentence Stress. We use forced-alignment with WAV2VEC 2.0 (Baevski et al., 2020) to obtain the segment for each word in the signal, and extract their loudness, pitch and duration features. Then we define the stress level *stress* for a word w as the weighted sum of these three features. Finally we select the best candidate according to a simple objective obj_{stress} that has three goals: (1) maximize the stress of the target word ($stress_{tgt}$), (2) minimize the stress of the target word of the contrastive case ($stress_{foil}$), and (3) minimize the average stress of the rest.

$$\begin{aligned} stress_w &= \lambda_1 loud_w + \lambda_2 pitch_w + \lambda_3 dur_w \\ obj_{stress} &= 2 \cdot stress_{tgt} - stress_{foil} \\ &\quad - \frac{1}{n-1} \sum_{w \neq tgt} stress_w, \end{aligned}$$

where we used $\lambda_1 = 0.5$, $\lambda_2 = 0.3$, and $\lambda_3 = 0.2$. Note that in the sentence stress examples, there is

[14] Removed *fearful* emotion due to issues with the TTS.

	1.1 Contrastive Stress
Sentence	She didn't give the book to John.
Prosody$_A$	She didn't give the *BOOK* to John.
Meaning$_A$	Something else was given to John.
Prosody$_B$	She didn't give the book to *JOHN*.
Meaning$_B$	The book was given to someone else.
	1.2 New vs. Given Information
Sentence	The committee decided to postpone the meeting.
Prosody$_A$	The *COMMITTEE* decided to postpone the meeting.
Meaning$_A$	Given: Someone decided to postpone the meeting; New: It was the committee who decided.
Prosody$_B$	The committee decided to *POSTPONE* the meeting.
Meaning$_B$	Given: The committee decided something; New: The decision was to postpone it.
	1.3 Relational vs. Descriptive Adjectives
Sentence	They are German teachers.
Prosody$_A$	They are *GERMAN* teachers.
Meaning$_A$	Teachers who teach the German language. (Relational)
Prosody$_B$	They are German *TEACHERS*.
Meaning$_B$	Teachers who are German. (Descriptive)
	1.4 Focus-Sensitive Operators
Sentence	I only introduced John to Maria at yesterday's party.
Prosody$_A$	I only introduced *JOHN* to Maria at yesterday's party.
Meaning$_A$	John was the only person I introduced to Maria.
Prosody$_B$	I only introduced John to *MARIA* at yesterday's party.
Meaning$_B$	Maria was the only person I introduced John to.

Table 5: Examples in the category *Sentence Stress* that were used for in-context learning.

always exactly 1 target word in each contrastive prosodic case.

Prosodic Breaks. Likewise, after forced-alignment, we measure the duration *dur* of each gap l between the words in the utterance, and define a similar objective obj_{break} as:

$$obj_{break} = 2\frac{1}{|tgt|}\sum_{l\in tgt} dur_l - \frac{1}{|foil|}\sum_{l\in foil} dur_l - \frac{1}{n-|tgt|}\sum_{l\notin tgt} dur_l$$

In this category, there can be 0 to 2 breaks in each prosodic case, which could be shared between the two prosodic cases. In the objective we consider only the ones that are not common in the two cases.

Intonation Patterns. We use teacher-forcing with WHISPER to extract the punctuation probabilities given the transcription text without the ending punctuation. The probability of the sentence to be a statement is the sum of the probabilities of the tokens "." and "!", while the probability of a question is the probability of the token "?". Thus the objective obj_{inton} for a statement is defined as:

$$obj_{inton} = p(. \mid X, Z_{<n}) + p(! \mid X, Z_{<n}) - p(? \mid X, Z_{<n}),$$

where X is the speech signal and $Z_{<n}$ are the tokens of the transcription, excluding the final one, which corresponds in all cases of this category. to the punctuation. The negative objective $-obj_{inton}$ is used for a case that is a question.

Emotional Prosody. We employ an emotion classifier[15] which is a based on a finetuned WAV2VEC 2.0 on the RAVDESS dataset (Livingstone and Russo, 2018), and define the objective as:

$$obj_{emo} = p(e_{tgt} \mid X) - p(e_{foil} \mid X),$$

where θ are the parameters of the classifier, e_{tgt} is the target emotion label and e_{foil} is the emotion label of the other prosodic case.

Pragmatic Prosody. To the best of our knowledge there is no open-sourced audio classifier to detect politeness levels, thus we re-purpose the emotion classifier and define the probabilities of politeness

[15] hf.co/ehcalabres/wav2vec2-lg-XLS-R-en-speech-emotion-recognition

2.1 Direct vs. Indirect Statements	
Sentence	Alex announced Jamie will meet the manager.
Prosody$_\text{A}$	Alex *ANNOUNCED* | Jamie will meet the manager.
Meaning$_\text{A}$	(Direct Statement)
Prosody$_\text{B}$	Alex announced Jamie will meet the manager.
Meaning$_\text{B}$	(Indirect Statement)
2.2 Restrictive vs. Non-Restrictive Phrases	
Sentence	The students who were talking were sent out.
Prosody$_\text{A}$	The students who were *TALKING* | were sent out.
Meaning$_\text{A}$	Only the students who were talking were actually sent out. (Restrictive)
Prosody$_\text{B}$	The *STUDENTS* | who were talking | were sent out.
Meaning$_\text{B}$	All students were sent out, and the fact they were talking is additional information. (Non-restrictive)
2.3 Verb-phrase vs. Noun-phrase Attachment	
Sentence	Paula phoned her friend from Alabama.
Prosody$_\text{A}$	Paula phoned her friend | from *ALABAMA*.
Meaning$_\text{A}$	Paula called her friend while she was in Alabama. (VP Attachment)
Prosody$_\text{B}$	Paula phoned | her *FRIEND* from Alabama.
Meaning$_\text{B}$	Paula phoned her friend who is from Alabama. (NP Attachment)
2.4 Phrasal Verbs	
Sentence	John laughed at the party.
Prosody$_\text{A}$	John *LAUGHED* | at the party.
Meaning$_\text{A}$	John laughed while he was at the party. (Literal)
Prosody$_\text{B}$	John *LAUGHED AT* | the party.
Meaning$_\text{B}$	John made fun of the party. (Idiomatic)
2.5 Complementizer vs. Parenthetical	
Sentence	We only suspected they all knew that a burglary had been committed.
Prosody$_\text{A}$	We only *SUSPECTED* | they all knew that a burglary had been committed.
Meaning$_\text{A}$	The suspicion was that they all knew about the burglary. (Complementizer)
Prosody$_\text{B}$	We only suspected | they all *KNEW* | that a burglary had been committed.
Meaning$_\text{B}$	They all knew that we only suspected that a burglary had been committed. (Parenthetical)
2.6 Modifier Scope	
Sentence	This collar is dangerous to younger dogs and cats.
Prosody$_\text{A}$	This collar is dangerous to *YOUNGER* dogs and cats.
Meaning$_\text{A}$	Younger refers to both dogs and cats. (Broad Scope)
Prosody$_\text{B}$	This collar is dangerous to *YOUNGER* dogs | and *CATS*.
Meaning$_\text{B}$	Younger refers only to dogs. (Narrow Scope)

Table 6: Examples in the category *Prosodic Breaks* that were used for in-context learning.

and impoliteness as a weighted sum of the 8 available emotion classes.

$$p(polite) = \frac{\sum_e w_e p(e \mid X)}{\sum_e w_e},$$

and similarly for impolite. We used the weighted scheme displayed in Table 8, which was obtained by prompting GPT-4.

D Data

D.1 Data Statistics

In Table 9 we provide the analytic data statistics for each category/subcategory, throughout the generation process stages. The poor quality of the cTTS, where prosody was not always encoded in the speech, led us to remove a large percentage of the examples before translating them. Also many examples where removed because the oracle translations for both cases were the same.

D.2 Overly Explanatory Examples

In Table 10 we present two examples where GPT-4 acting as an oracle translator (§2.3) proposed overly explanatory translations in the emotional prosody category. Both are inline with the emotion of the speaker, but they contain new bits of information, not initially there. These were removed in filtering due to excessive word-length ratio between the two cases.

3. Intonation Patterns	
Sentence	You can solve this problem
Prosody$_{\text{A}}$	You *CAN* solve this problem.
Meaning$_{\text{A}}$	Encouraging or asserting the person's ability to solve this problem.
Prosody$_{\text{B}}$	You _can_ solve this problem?
Meaning$_{\text{B}}$	Questioning the person's ability to solve this problem.
4. Emotional Prosody (Happy/Sad)	
Sentence	The surgery went as expected.
Prosody$_{\text{A}}$	<happy> The surgery went *AS EXPECTED*!
Meaning$_{\text{A}}$	The surgery's successful outcome aligns with hopes and predictions, leading to joy and relief.
Prosody$_{\text{B}}$	<sad> The surgery went _as expected_ ...
Meaning$_{\text{B}}$	The expected outcome was not favorable, leading to a somber tone.
4. Emotion Prosody (Fearful/Angry)	
Sentence	Can we talk about this later?
Prosody$_{\text{A}}$	<fearful> Can we... talk about this... later?
Meaning$_{\text{A}}$	Indicates hesitation or fear about the topic, or the situation in general.
Prosody$_{\text{B}}$	<angry> Can we *TALK* about this later!?
Meaning$_{\text{B}}$	Implies urgency or frustration, and a demand for immediate attention.
5. Politeness	
Sentence	Can you move your car?
Prosody$_{\text{A}}$	<polite> Can you _move_ your car?
Meaning$_{\text{A}}$	A polite request to move the car.
Prosody$_{\text{B}}$	<impolite> Can you *MOVE* your *CAR*?!
Meaning$_{\text{B}}$	A rude demand to move the car, with an aggressive tone.

Table 7: Examples in the categories *Intonation Patterns*, *Emotional Prosody*, *Politeness*, and that were used for in-context learning.

Emotion	Politeness	Impoliteness
Happy	0.3	-0.1
Calm	0.3	-0.2
Neutral	0.2	0.1
Surprised	0.1	0.1
Sad	0.0	0.2
Disgust	-0.1	0.3
Angry	-0.2	0.4
Fearful	-0.1	0.0

Table 8: Weighting scheme for Politeness and Impoliteness labels based on the emotion classifier.

E Evaluated Speech Translation Models

Here we describe in more detail the model families and the specific versions used. We evaluated in total 31 S2TT model variants. All models are available in the Transformers Huggingface Library (Wolf et al., 2020). For inference we used the default generation parameters and a beam search of 5.

1. SEAMLESSM4T (Seamless Communication, 2023a) and its updated version v2 (Seamless Communication, 2023b) is a recently proposed family of unified encoder-decoder models that are both multilingual (many-to-many, 100 languages) and multimodal (speech/text input or output), meaning they can carry out the tasks of ASR, TTS, MT, S2TT, and also S2ST. The architecture is composed of a text encoder, text decoder, speech encoder, and speech decoder, and different parts are active depending on the input/output modalities. The text encoder-decoder is based on NLLB (NLLB Team, 2022), the speech encoder on a newly proposed conformer (Gulati et al., 2020) w2v-BERT (Chung et al., 2021), and the speech decoder on a unit decoder (Inaguma et al., 2023) and a HiFi-GAN vocoder (Kong et al., 2020). The original version has a medium (1.2B)[16] and a large (2.3B)[17] variant, while the updated v2 has a large variant (2.3B)[18]. For cascade S2TT we first use the model in ASR mode, and then the

same model is MT mode.

2. XLS-R (Babu et al., 2021) is a multilingual E2E S2TT model that is based on a multilingual WAV2VEC 2.0 (Baevski et al., 2020) trained with self-supervised learning on a large speech corpus on 128 languages. For S2TT, the encoder is coupled with the decoder from MBART50 (Tang et al., 2020), and finetuned on paired speech-translation data. We use the folowing versions that are finetuned on English-to-15 on CoVoST2 (Wang et al., 2021): 300M[19], 1B[20], and 2B[21].

3. ZEROSWOT is a zero-shot E2E S2TT model that softly connects a WAV2VEC 2.0 encoder and an NLLB model, by compressing the speech representation into subword units and Optimal Transport (Peyré and Cuturi, 2019) alignment, using only ASR data. The versions used here are based on NLLB that were finetuned on the text data of CoVoST2, and the ZEROSWOT model was trained on Com-

Example 1: *This will only take a minute.*		
A	(neutral)	Das dauert nur eine Minute. (This will only take a minute.)
B	(angry)	Das dauert nur eine Minute, also machen Sie keinen Aufstand. (This will only take a minute so don't make a fuzz about it.)
Example 2: *Our case was dismissed.*		
A	(neutral)	Unser Fall wurde abgewiesen. (Our case was dismissed.)
B	(sad)	Unser Fall wurde abgewiesen und das macht mich fassungslos. (Our case was dismissed which is just perplexing.)

Table 10: Examples of overly explanatory translations proposed by GPT-4.

monVoice (Ardila et al., 2020). The Medium version[22] has 1B parameters and the Large version[23] has 1.7B parameters.

4. SALMONN (Tang et al., 2024) is a general-purpose audio LLM that is capable of several speech- and audio-related tasks, including S2TT. It is build on top of the Vicuna LLM (Peng et al., 2023), and uses two encoders, one from Whisper and one from BEATs (Chen et al., 2023). The concatenated output representations from the two encoders are processed by a Q-former (Li et al., 2023) and fed to the LLM which is finetuned with LoRA (Hu et al., 2022). There is a 7B version[24] and a 13B version[25]. To translate speech into a target language we use the recommended prompt from the paper: "Listen to the speech and translate it into {Target Language}".

5. Whisper & NLLB is an AED-based cascade. Whisper (Radford et al., 2022) is an encoder-decoder ASR and many-to-en S2TT model. We use three different versions for this casdade, namely the Whisper-Medium[26], the Whisper-Large[27], and the latest v3 large version[28]. We primarily present results with the Whisper-Large-v3, but since it was also used for filtering we also discuss v1 in order to avoid biasing our results. NLLB (NLLB Team, 2022) is a massively multilingual many-to-many MT model with access to 200 languages. We used the two distilled versions from the 54B MoE model, namely the distilled-600M[29] and the distilled-1.3B[30], as well as the 3.3B model[31]. We evaluated all possible combinations, thus having 9 cascade variants with these models.

6. CTC & NLLB is a CTC-based cascade. We use three different CTC encoders for the cascades. The first one is the Large version (300M) of wav2vec 2.0[32] which is finetuned on Libri-Light (Kahn et al., 2020) and Librispeech (Panayotov et al., 2015), additionally using self-training (Xu et al., 2020). The second is the Large version (300M) of HuBERT[33] (Hsu et al., 2021), finetuned on Librispeech. The third is also based on HuBERT, more specifically to the XL version[34] with 1B parameters. We use the same three versions of NLLB, as we did for the AED-based cascade, thus having in total 9 variants of the CTC-based cascade.

F Supplementary Results

In Figure 5 we present the Spearman rank correlation for the four contrastive metrics and the standard evaluation metric xCOMET. They were computed by evaluating all 31 models (§E) for all 3 language pairs, thus having a total of 93 observations.

In Table 11 we present the global contrastive quality scores for all 31 S2TT models for the 3 language pairs, which were used for the analysis of Figure 2 in §5 of the main text.

In Figures 6 and 7 we present the comparisons of the 4 models for Spanish and Japanese, similar to what we did in Figure 3 for German in the main text. In general, the findings and observations here coincide with those for German.

Cultural Adaptation of Menus: A Fine-Grained Approach

Zhonghe Zhang, Xiaoyu He, Vivek Iyer, Alexandra Birch
University of Edinburgh

{vivek.iyer, a.birch}@ed.ac.uk

Abstract

Machine Translation of Culture-Specific Items (CSIs) poses significant challenges. Recent work on CSI translation has shown some success using Large Language Models (LLMs) to adapt to different languages and cultures; however, a deeper analysis is needed to examine the benefits and pitfalls of each method. In this paper, we introduce the ChineseMenuCSI dataset, the largest for Chinese-English menu corpora, annotated with CSI vs Non-CSI labels and a fine-grained test set. We define three levels of CSI figurativeness for a more nuanced analysis and develop a novel methodology for automatic CSI identification, which outperforms GPT-based prompts in most categories. Importantly, we are the first to integrate human translation theories into LLM-driven translation processes, significantly improving translation accuracy, with COMET scores increasing by up to 7 points. The code and dataset are available at https://github.com/Henry8772/ChineseMenuCSI.

1 Introduction

Translating restaurant menus is a challenging, non-literal translation task. Unlike other texts, dish names are not merely lists of ingredients and culinary methods; they are short (Pellatt and Liu, 2010) and culturally rich expressions that require an understanding of cultural traditions (Amenador and Wang, 2022), symbolism (Lam et al., 2018), and local nuances. This complexity is compounded by LLMs and Neural Machine Translation (NMT) systems that often lack the cultural awareness necessary to accurately understand these nuances (Liu et al., 2024; Naous et al., 2023; Tao et al., 2024). This results in mistranslations that can confuse and mislead the target audience (Garcea et al., 2023; Gallo et al., 2021), such as in Figure 1.

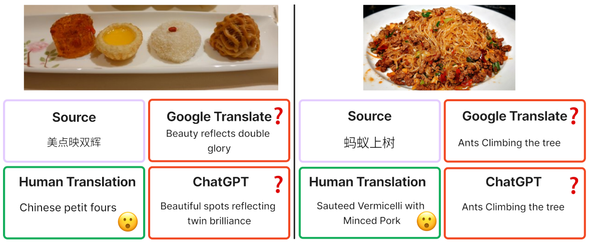

Figure 1: CSI translation errors by Google Translate and ChatGPT 3.5 in translating Chinese culinary terms.

A key challenge in menu translation lies in the handling of Culture-Specific Items (CSIs), defined as “concepts that are specific to a particular language or group” (Aixelá, 1996). For example, the literal translation of the Chinese dish 蚂蚁上树 is “Ants Climbing a Tree” – but this is actually a figurative Chinese expression that should be translated in English as “Sauteed Vermicelli with Minced Pork”. The Chinese name creatively expresses the idea that pork resembles ants, while vermicelli represents tree branches. Existing machine translation systems, trained on plain, sentence-level translations, fail to capture these cultural subtleties and generate literal translations (Figure 1).

However, there has been little work in NLP exploring CSI translations in-depth, particularly focusing on how the translation outputs generated by neural models should be improved. There has been foundational work on improving translations of CSIs by LLMs through enhanced prompting strategies (Yao et al., 2024). Simultaneously, there has also been work on adapting CSIs (Peskov et al., 2021; Cao et al., 2024; Singh et al., 2024), but their focus has been on adapting culture-specific named entities. In this work, we seek to go beyond entities, and approach the translation of figurative language imbued with cultural nuance, as exemplified in Figure 1 – which is quite underexplored.

In linguistics, cultural translation theories have been developed and widely adopted by human theorists and translators over decades. We aim to improve MT of CSIs by bringing the wisdom of Translation Theory research to modern NLP mod-

Proceedings of the Ninth Conference on Machine Translation, pages 1258–1271
November 15-16, 2024 ©2024 Association for Computational Linguistics

els like LLMs. Our approach improves the identification and translation of figurative and culturally nuanced CSIs. Unlike previous CSI identification methods, our method does not depend on parallel corpora or extensive knowledge graphs (Yao et al., 2024; Han et al., 2023) – but at the same time, we also show how recipes can be *optionally* leveraged as a source of external knowledge to enhance performance even further. We also propose a novel CSI taxonomy for Chinese-English, that allows for a detailed analysis of figurative and culturally nuanced language and the translation challenges therein. We evaluate our proposed methods using a large dataset of Chinese dish names, ensuring robust and reliable results.

Our key contributions are as follows:

1. We introduce *ChineseMenuCSI*, a fine-grained dataset of 4,275 bilingual Chinese-English restaurant menu entries from UK Chinese restaurants. The dataset is categorised into CSI and Non-CSI entities, with 480 entries further bifurcated into specific CSI categories, enabling an in-depth analysis of CSI translation efficacy of LLMs and NMT systems.

2. We propose novel techniques for identifying CSIs, grounded in human translation theory. These techniques match or outperform current GPT-based prompts – all without needing external knowledge graphs or parallel corpora.

3. Lastly, we show how external knowledge, in the form of recipes, can add to the benefits of translation strategies and enhance CSI translation performance further - achieving significant improvements in COMET scores, with gains of +3 to +7 points across CSI categories.

The code and datasets are available at https://github.com/Henry8772/ChineseMenuCSI.

2 Related Work

2.1 CSIs in Translation Studies

Aixelá (1996) was among the first scholars to introduce the term "culture-specific items" (CSIs) to refer to elements in texts that are unique and significant in a specific culture. CSIs may include objects, classification systems, or measurement tools common in the source culture but foreign to the target culture. Additionally, CSIs can encompass transcriptions of opinions/habits specific to a culture, which are often reflected in the language structure, style, and content.

Culture is closely related to understanding and translating CSIs, as Aixelá (1996) highlighted. In the 1960s, Nida and Taber (2003) introduced the concepts of formal and dynamic equivalence in translation to distinguish between structurally accurate and fluency-focused approaches to translation. These concepts have laid the foundation for subsequent translation theories, including those related to cultural translation. Expanding on this, Newmark (1988) proposed a set of robust strategies for translating cultural elements, which have been particularly influential in translating Chinese culinary CSIs, as noted by Amenador and Wang (2022).

According to Newmark (1988), adaptation uses a recognized equivalent between two cultures. This strategy has been explored by Pellatt and Liu (2010) on Chinese menu translation. Newmark (1988) proposed three equivalent strategies for translation: cultural, functional, and descriptive – which we introduce later to improve LLM translation performance in §5.2.

Neutralisation is another translation strategy related to CSI translation. As proposed by Chou et al. (2016), on the continuum between foreignisation (focusing on source culture) and domestication (focusing on target culture), there are intermediary approaches, including neutrality and neutralisation. For culture-specific text, neutralisation involves paraphrasing to convey the meaning of a CSI. After analysing the translations of Chinese dish names into English, Amenador and Wang (2022) found that neutralisation, by substituting the source text element with a more or less detailed explanation of its meaning, is the most commonly used translation strategy by human translators for translating Chinese dish names into English.

In this paper, we use these conventional translation strategies employed by human translators as instructions in zero-shot prompts, to enhance CSI translation quality of LLMs (in §5.2).

2.2 Culture-Aware NMT

Despite the early successes of NMT (Bahdanau et al., 2015; Sutskever et al., 2014), translation of culture-specific texts has remained a daunting task. In addition to the challenge of translating rarer words and adapting to under-resourced domains (Koehn and Knowles, 2017), CSIs are deeply intertwined with cultures (Hershcovich et al., 2022; Liebling et al., 2022; Yao et al., 2024) – something even the most capable neural models of today fail to grasp, particularly for non-Western cultures (Masoud et al., 2023; AlKhamissi et al., 2024; Nayak et al., 2024).

While there have been related works on domain-specific translation, including terminology translation (Dinu et al., 2019), disambiguation (Iyer et al., 2023a,b) and named entity translation (Hu et al., 2022), CSIs often lack direct equivalents in other languages, making translation complex and hard to understand cross-culturally (Yao et al., 2024).

Our approach uniquely combines translation studies with modern NLP techniques to identify and translate CSIs, resulting in more culturally sensitive and comprehensible translations.

2.3 Cultural Awareness and Adaptation in Large Language Models

In recent times, many works have shown that LLMs contain significant cultural biases against non-Western cultures (Cao et al., 2023; Liu et al., 2024; Masoud et al., 2023; Naous et al., 2023; Tao et al., 2024). In response, there has been a growing focus on improving cultural awareness in LLMs through prompt-engineering techniques (Wang et al., 2024; Tao et al., 2024) and fine-tuning on culture-specific data (Chan et al., 2023; Li et al., 2024a,b). Various tasks have been used to assess LLMs' cultural awareness, including tasks like culturally aware inference (Huang and Yang, 2023; Yao et al., 2024) and common sense reasoning on specific languages (Koto et al., 2024a,b).

Previous works on cultural awareness have primarily focused on understanding cultural norms in different languages rather than accurately translating culture-specific text. While well-explored in translation studies, cultural adaptation is rather understudied in NLP. Initial efforts in this direction have included adaptation of recipes (Cao et al., 2024) and localisation of named entities through adaptation (Peskov et al., 2021) or explicitation (Kementchedjhieva et al., 2020; Garcea et al., 2023; Han et al., 2023). Most similar to our work is that of Yao et al. (2024), who also released a CSI dataset covering 6 languages, on which they benchmark LLMs and NMT systems.

In contrast, our goal is to conduct a more fine-grained evaluation, given multiple CSI types in any given language. So, we leverage translation studies to create a dataset that classifies Chinese-English dishes into fine-grained categories, which we use for downstream evaluation, analysis and a detailed ablation of our proposed techniques. While we focus on the Chinese-English pair and culinary domain in this work, our framework and proposed techniques are agnostic of language/domain, and are designed to be easily scalable.

3 ChineseMenuCSI Dataset

We introduce a new bilingual Chinese-English Restaurant Menu (ChineseMenuCSI) dataset consisting of 4,275 human-verified dish entries collected from restaurants in UK.

3.1 Data Collection

We develop a Selenium-based web crawler[1] to gather Chinese menu translations from UK restaurant websites. After manually reviewing 50 restaurants, we selected those with ratings above 3 out of 5 and average meal prices over £20, ensuring higher-quality menus not generated by commercial Machine Translation systems like Google Translate. These restaurants were sourced from TripAdvisor[2].

Additionally, we developed a heuristic menu parser capable of accurately extracting structural content from image-based menus. Details of this parser are provided in Appendix A.2.

3.2 CSI Taxonomy

Translating Chinese menu items into English presents unique challenges because the dish names contain non-descriptive, picturesque elements (Pellatt and Liu, 2010). Our initial data inspection revealed that CSIs within these dish names contribute varying degrees of complexity to the translation process, and carry differing levels of figurativeness brought by cultural and linguistic nuances. Inspired by translation theory literature that tends to categorise Chinese dishes into concrete and abstract categories (Lam et al., 2018), we develop an approach to categorise the Chinese dish names in our dataset into three groups based on the degree of figurativeness in each CSI.

Category 1: Concrete CSIs (With a Low-level/No Figurative Meaning)

Definition: The CSIs in this category have a minimal figurative meaning, often referring to tangible attributes like ingredients, colour, taste, container, processing method, and dish appearance. Readers

[1] Selenium: https://www.selenium.dev/

[2] TripAdvisor: https://www.tripadvisor.com

can easily understand these dish names as the information is either shared between the source and target cultures or has widely used translations in the target culture.

Example: An example from the corpus is *"咕噜猪肉" (sweet and sour pork)*. The first two Chinese characters "咕噜" denote the Guangdong-style "sweet and sour" method, a culinary translation widely recognised outside the Chinese culture. The last two characters "猪肉" mean "pork", a culturally universal ingredient.

Category 2: Creative CSIs (With Some Figurative Meaning)

Definition: This category features dish names that blend concrete lexical terms with figurative meanings, creating inventive expressions that extend beyond literal definitions. Understanding these dishes necessitates integration of creative flair with concrete information, presenting challenges.

Example: *"水煮鱼"* (*Poached fish fillet with chilli oil and herb* or *Sichuan-style boiled fish*) originates from Sichuan, China. While the literal translation of the characters is "water-boiled fish", "water-boil" carries a creative description, representing the cooking state. This dish involves a Sichuan cooking style that uses hot chilli oil and Chinese herbs. "Poached fish fillet with chilli oil and herb" effectively describes the ingredients and cooking method, while "Sichuan-style boiled fish" adds cultural context by highlighting the dish's regional origin. Both are valid translations but different strategies are used.

Category 3: Abstract CSIs (With a High-level of Figurative Meaning)

Definition: This category encompasses dish names that exist beyond the realm of literal translation, and require in-depth cultural knowledge to understand. Crafted from metaphors, idioms, allegories, and other figurative language, these names disconnect from straightforward translations to engage in storytelling, aiming to convey broader narratives, evoke emotions, or reflect cultural heritage.

Example: *"佛跳墙" (Buddha Jumps Over the Wall* or *Steamed Abalone with Fish Maw in Chicken Broth)* metaphorically describes a dish so enticing that even a vegetarian and divine figure like Buddha would leap over a wall to taste it. Popular translations include "Buddha jumps over the wall" as a direct translation, and "Steamed Abalone with Fish Maw in Chicken Broth" includes ingredients and cooking methods, reflecting the dish's cultural and culinary nuances.

3.3 Data Annotation

To annotate our data, we first seek to classify the data into CSI and non-CSI entities, and if it is a CSI, we want to categorise it into one of the above-listed groups. Given the dataset has as many as 4.3K CSIs, we approach the annotation process in two stages: a) in Stage 1, we conduct a broad, albeit rough, annotation of the entire dataset by two volunteer annotators, and b) we uniformly sample from the annotations of Stage 1 to ensure a fair distribution across categories, and conduct a more focused and rigorous annotation process using five volunteer translators – to create our fine-grained test set. We describe these stages in detail below:

Stage 1 (Broad) Annotation: Two annotators, who are postgraduate students and professional Chinese-English translators, reviewed and labelled all 4,275 entries. Both are native Chinese speakers proficient in English, ensuring high linguistic and cultural expertise. Firstly, we classify the entries into CSIs and non-CSIs. We use Cohen's kappa (Cohen, 1960) to measure agreement between annotators and obtained a high score of 0.91 - likely because the classification of CSIs and non-CSIs is mostly unambiguous. For the 187 entries without consensus, we invited a third annotator to label and assigned the final label using a majority vote.

For entries with CSI, the annotators further categorised the dish into one of the three CSI categories. The annotation results are reported in Table 1.

Label	Category	Count
0	Non-CSIs	2003
1	Concrete CSIs	1658
2	Creative CSIs	494
3	Abstract CSIs	120

Table 1: Distribution of menu items across CSI taxonomy in the ChineseMenuCSI dataset.

Stage 2 (Focused) Annotation: In Table 1, we note that Category 3 is the smallest, with only 120 items. To evenly balance our test set, we randomly sample 120 items from each category: 0 (Non-CSIs), 1 (Concrete CSIs), 2 (Creative CSIs), and 3 (Abstract CSIs), totalling 480 items. This subset was annotated by a larger and more diverse group of five annotators, who, like the first-stage annotators, included professional Chinese-English translators and postgraduate students – all native Chinese speakers proficient in English.

For span annotation, we first segment the dish name into spans and phrases using Jieba[3]. Annotators then label the spans that correspond to CSI. To assess inter-annotator agreement, we use Fleiss' kappa (Fleiss, 1971) across two levels: CSI fine-grained categorisation and span-level CSI identification; the results are summarised in Table 2.

Annotation	Kappa	Interpretation
CSI vs. Non-CSI	0.91	High
CSI Category	0.63	Substantial
CSI Identification	0.70	Substantial

Table 2: Inter-annotator agreement scores for different annotation tasks.

For the fine-grained CSI categorisation, we exclude items that do not attain majority consensus (at least 3 out of 5 annotators in agreement), resulting in a kappa score of 0.63. This score falls within the range of substantial agreement (0.6-0.8) but is lower than the CSI vs. Non-CSI score due to the subjective nature of the fine-grained categorisation. This level of agreement is comparable to ranges reported in related work (Huang and Yang, 2023; Soderstrom et al., 2021). Lastly, for CSI identification at the span-level, i.e. within a given dish name, the kappa score is 0.70 - which indicates substantial agreement as well.

4 CSI Automatic Identification

To accurately translate CSIs, it is essential to first identify which parts of the text comprise CSIs. Previous studies have approached this challenge in different ways. Han et al. (2023) focus on implicit detection and use a relative distance of terms in Wikidata, but it does not include all Chinese dish CSI. Yao et al. (2024) rely on parallel corpora with entity-linking to find CSIs; however, the approach is infeasible for online MT, where we need to identify CSIs beforehand to produce translations from the monolingual source text.

Inspired by these methods, we propose a method called **Combined CSI Identification**, that uses a combination of three checking criteria for CSI identification, and classifies CSI if at least two of the following three checks are met. The checks are Round-trip Translation (RTT), Cultural Uniqueness (CU), and Historical Significance (HS).

4.1 Round-trip Translation (RTT)

Since CSIs are defined as terms unique to a specific language or culture (Álvarez and Vidal, 1996), based on the assumption that they do not have corresponding translations in the target language, we propose using round-trip translation (RTT) as one of the identifying criteria.

1. **Initial Translation**: Translate the Chinese dish name to English using Google Translate.

2. **RTT Translation**: Translate the English version back to Chinese using DeepL Translate and split it into Jieba-segmented words. Using different translation systems for RTT proved most effective in identifying CSIs.

3. **Identification**: Subtract the segmented words in the RTT from those in the original text. The remaining words are potential CSIs.

   $$\text{CSIs} = \text{Original Words} - \text{RTT Words}$$

   Using Jieba's cut-for-search module, which returns all words and phrases, a phrase is considered CSI only if all of its words are omitted in the RTT, and not otherwise.

This method has its limitations, for example, it could also: a) return words that are not CSIs and are just difficult to translate, and b) miss CSIs that have literal translations. We find in §6.3 that it performs strongly in identifying CSIs in most cases.

4.2 Cultural Uniqueness (CU)

According to Newmark (1988), "unfindable" words are often less frequently seen within a language. Words with cultural and historical references can be deeply embedded in a specific culture or history, making them rare or unfamiliar to outsiders.

We use Jieba to segment words in the Chinese-MenuCSI dataset, then measure each word's frequency and calculate its inverse frequency. A cut-off at the 95th percentile of these inverse frequencies is set based on a manual review of 100 words. Words above this cut-off are marked as potential CSI. Words not previously seen are given an inverse frequency of 1, indicating they are potential CSI. No smoothing techniques are applied, as inverse frequency is used against a fixed threshold rather than for probability calculations.

[3] Jieba: https://github.com/fxsjy/jieba

4.3 Historical Significance (HS)

Chinese food names and CSIs often contain historical narratives such as historical events, figures and periods (Lam et al., 2018; Amenador and Wang, 2022). To identify these, we use the Wikipedia API to search for individual words or entire dish names. If a word's Wikipedia page includes a "History" section, it is considered a potential CSI. The words appearing 30 times or more, such as "chicken" or "sauce" are excluded as generic terms.

5 CSI Translation

Having identified CSIs, we propose prompting strategies to improve CSI translations. Our strategies fall into two categories: Recipe-based Translation and Translation Studies-inspired Prompting.

5.1 Recipe-based Translation

We explore using recipe information to improve the translation of CSI dish names. By incorporating the most relevant recipe as external knowledge, we experimented with two zero-shot prompt strategies: **Default Recipe** prompting and **Recipe + Explain-then-Translation** prompting (Figure 2).

Recipe Retrieval Pipeline Given over 50% of the CSI dish entries in our test set lack detailed publicly available descriptions from sources like Wikipedia, we use the Xiachufang recipe database (Liu et al., 2022) – which contains approximately 1.4 million Chinese monolingual recipes – to retrieve recipes and enhance translation accuracy.

We take inspiration from Translation Studies research, which emphasizes the importance of cooking methods and ingredients in translating Chinese dish names (Amenador and Wang, 2022).

Our retrieval pipeline involves two key stages:

1. **Query and document Construction:** The query is the full Chinese dish name, with the CSI span from previous annotations. We concatenated each recipe name and instructions into a single recipe document.

2. **Filtering and Ranking Recipes:** To filter and rank the recipes, we employ the BM25 algorithm (Robertson et al., 1995), which assigns a score to each word in the Chinese recipe document based on its term frequency and inverse document frequency. For each word in the recipe document, the score is enhanced by applying a weighting factor when the word matches either the dish name (weight = 5) or the CSI span (weight = 3), with an additional multiplier of 3 applied to words within the dish name to prioritize their importance. If there is no exact match for the dish name, the process shifts focus to matching with the CSI span. Additionally, we apply a length penalty to the final score, adjusting it based on the difference between the recipe's length and the average length of all recipes. We select the top-ranked recipe as the final output.

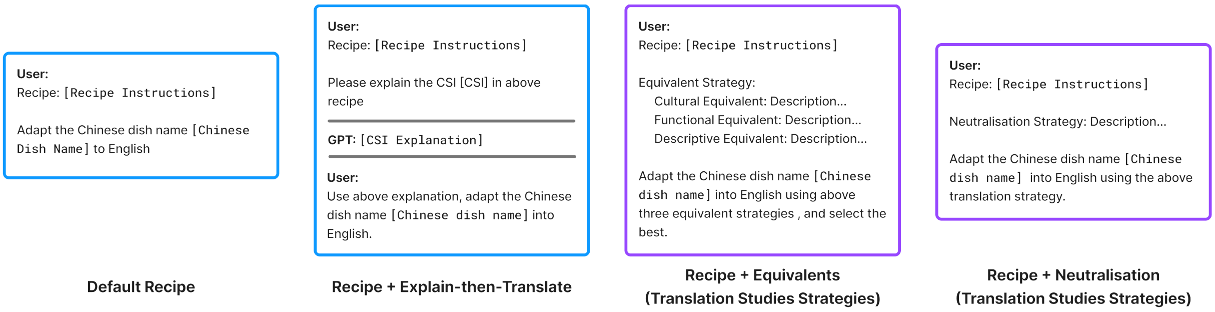
Prompt Strategy: CSI Recipe In this prompting strategy, we use the most relevant recipe returned from the aforementioned search pipeline to aid CSI translation. We provide the name and cooking instructions of the closest-matching recipe while noting that it might not correspond exactly to the given dish but is beneficial as external knowledge since it contains the CSIs to translate.

Prompt Strategy: CSI Explain-then-Translate Inspired by Chain of Thought (CoT) prompting (Wei et al., 2024) and Self-Explanation (Yao et al., 2024), we formulate another prompting strategy that first asks the LLMs to explain the meaning of the CSIs described in the recipe and then generate the translation for the dish. The motivation is to help the LLMs conduct advanced reasoning on the recipe instructions, such as interpreting dish names with CSIs not explicitly defined in the recipe. For example, a recipe might instruct to "cut it first, then stir fry" or note that "it can be very spicy" without explaining the CSI. The LLM's task is to infer the meaning of the CSIs based on the recipe's instructions. The prompt is shown in Figure 2.

5.2 Translation Studies-inspired Prompting

Unlike the conventional prompt engineering used in related work, our second set of prompting strategies differs in that they incorporate *human translation strategies*, inspired by the rich literature in Translation Studies, directly into the design of the prompt. We provide the prompt template for both of these strategies in Figure 2 and complete prompt in Appendix 3 and 4.

Prompt Strategy: Equivalents Using the recipe in §5.1 as external knowledge, we ask the LLMs to produce three translations, each based on a translation strategy (i.e. cultural, functional and descriptive) and **select the best translation**.



User:
Recipe: [Recipe Instructions]

Adapt the Chinese dish name [Chinese Dish Name] to English

Recipe + Explain-then-Translate

User:
Recipe: [Recipe Instructions]

Please explain the CSI [CSI] in above recipe

GPT: [CSI Explanation]

User:
Use above explanation, adapt the Chinese dish name [Chinese dish name] into English.

Recipe + Equivalents
(Translation Studies Strategies)

User:
Recipe: [Recipe Instructions]

Equivalent Strategy:
Cultural Equivalent: Description...
Functional Equivalent: Description...
Descriptive Equivalent: Description...

Adapt the Chinese dish name [Chinese dish name] into English using above three equivalent strategies , and select the best.

User:
Recipe: [Recipe Instructions]

Neutralisation Strategy: Description...

Adapt the Chinese dish name [Chinese dish name] into English using the above translation strategy.

Figure 2: Four adaptation prompt strategies

These translation strategies are inspired by Newmark (1988)'s theories on equivalent translation. We define the equivalent strategies below, providing examples for the reader's understanding:

1. **Cultural Equivalent:** Replacing a CSI in the source text with a term that is culturally relevant and functionally equivalent in the target culture. This strategy aims to evoke the same response in the target audience. (i.e. translating "粽子" as "tamale" in Spanish – given both are traditional wrapped food items made with a starchy substance and fillings, albeit from different cultures.)

2. **Functional Equivalent:** This strategy focuses on the function or purpose of the item (i.e., translating "粽子" as "rice dumpling" to convey the idea of a food made of rice)

3. **Descriptive Equivalent:** Providing a detailed description or explanation of the CSI to convey its meaning and significance. This approach is useful when the CSI is essential for understanding the text but has no equivalent in the target language (i.e. translating "粽子" as "a traditional Chinese sticky rice dumpling wrapped in bamboo leaves")

Prompt Strategy: Neutralisation Another human translation strategy we used in the prompting experiments is neutralisation. Again, we provide recipe information as external knowledge as in the previous strategy and incorporate an explanation of the neutralisation strategy to guide the LLM translation of dish names.

Neutralisation: Using culturally neutral language to describe or explain a cultural word, phrase, or rhetorical expression from the source text. It answers the question, "What is this?" (Amenador and Wang, 2022) by adding information such as ingredients, culinary methods and key characteristics. Compared with the descriptive equivalent strategy, the neutralisation strategy we used for prompt design confines the information used in the translations to ingredients, culinary methods and key characteristics (i.e. translating "粽子" as "sticky rice wrapped in bamboo leaves").

6 Results and Analysis

Our experiments include five parts: 1. Baseline evaluation of MT performance using three models on the ChineseMenuCSI dataset (§6.2); 2. Assessment of CSI span identification accuracy (§6.3); 3. Exploration of main adaptation strategies (§6.4); 4. Exploration of individual equivalents translation strategies for enhancing CSI translation (§6.5); 5. Human evaluation of translation quality on a subset of the dataset (§6.6).

6.1 Experimental Settings

We evaluate the effectiveness of LLM translations for CSIs by comparing various prompting strategies across two SOTA LLMs — GPT-3.5 (gpt-3.5-turbo-0125[4]) and the advanced GPT-4o (gpt-4o-2024-05-13[5]) — against the robust commercial MT system, Google Translate. This approach allows us to assess the strengths of LLM prompting versus a widely used commercial MT.

6.2 Evaluation of CSIs vs Non-CSIs

We use the Stage 1 annotated version of the ChineseMenuCSI dataset (§3.3). This version has a high inter-annotator agreement of 0.91 for the CSI vs non-CSI classification task, with conflicts further resolved using a third annotator. We compare the MT performance using the COMET version wmt22-comet-da (Rei et al., 2022).

While GPT-4o yields major improvements in the CSI translation performance, GPT-3.5 and GPT-4o

[5] GPT-4o:https://platform.openai.com/docs/models/gpt-4o

Method	Non-CSIs	CSIs
Google Translate	**74.08**	64.48
GPT-3.5	72.88	64.34
GPT-4o	73.67	**65.97**

Table 3: Comparison of COMET scores across different translation systems for CSI and Non-CSI menu items. The prompt used: "Translate the [Chinese dish name] into English".

	Method	Precision	Recall	F1 Score
	CSI-1: Concrete CSIs			
Ours	Combined	64.9	34.0	44.7
	RTT	58.8	28.4	38.3
	CU	38.3	65.3	48.2
	HS	**86.3**	31.2	45.8
GPT	3.5	32.4	**80.4**	46.2
	4o	37.9	67.1	**48.5**
	CSI-2: Creatives CSIs			
Ours	Combined	66.1	53.1	58.9
	RTT	63.4	60.1	**61.7**
	CU	35.4	70.4	47.1
	HS	**68.6**	16.4	26.5
GPT	3.5	34.1	**82.0**	48.2
	4o	40.6	73.9	52.4
	CSI-3: Abstract CSIs			
Ours	Combined	81.4	68.6	74.4
	RTT	**81.7**	73.6	**77.4**
	CU	43.9	88.4	58.6
	HS	80.0	9.9	17.6
GPT	3.5	50.4	**94.3**	65.7
	4o	59.1	78.9	67.6

Table 4: Evaluation of CSI span identification accuracy by CSI category: precision, recall, and F1 scores.

show worse scores for non-CSIs than Google Translate. These results suggest that Google Translate is particularly strong at translating straightforward, culturally neutral content, likely due to its extensive and diverse training dataset which prioritizes general language accuracy over cultural nuances.

Interestingly, despite Google Translate's general strength in multilingual tasks (Zhu et al., 2024), GPT-4o shows better handling of CSIs, highlighting the benefits of pretraining at scale on diverse corpora from many cultures, as opposed to NMT systems that are typically trained on narrow-domain sentence-level parallel corpora.

6.3 Evaluation of CSI Span Identification

We further assess the capability of different methods to *pinpoint specific CSI spans* – a task we call **CSI Span Identification** – within dish names. This fine-grained analysis is crucial for understanding the elements that contribute to cultural specificity and translation complexity.

Table 4 shows GPT 4o as the best performer in CSI-1 and RTT as the best in other categories. This is likely due to RTT's strength in identifying CSIs, which are often figurative and lack general interpretations. However, the combined metrics only improved RTT's performance in CSI-1, likely because of low recall in HS. Moreover, CU underperforms in CSI-2, as those CSIs typically involve figurative messages in creative combinations of frequent words, which cannot be captured by frequency.

The combined method does not outperform the individual highest method as it requires majority agreement, where a single correct check is insufficient. HS shows high precision but low recall, likely because CSIs often have historical backgrounds, though the inverse is not always true.

6.4 Evaluation of Main Adaptation Strategies

This section examines whether external knowledge, such as recipes, can enhance MT of CSI-rich dish names. Four prompting strategies were tested: a) Default Recipe prompting, b) Recipe + Explain-then-Translate (EtT) prompting, c) Equivalents and d) Neutralisation. For the latter two, which are translation strategies, we try baselines with and without incorporation of recipes, to ablate the dependency on external knowledge. In Table 5, we see that while all our proposed methods yield overall improvements in performance, translation strategy-based methods – that do not involve any external knowledge – yield the largest gains, of up to +4.8 COMET points! Moreover, when recipes are added to these strategies, the gap widens even further, with the maximum gain reaching *as high as +7.87 COMET points* for our best performing *Recipe + Equivalents* strategy. The second trend we note is that the largest gains come from the more complex CSI-2 and CSI-3 categories, indicating the efficacy of our translation theory-inspired methods for translating highly culturally nuanced text. Finally, while the more advanced model GPT-4o naturally yields the largest improvements, we note that we get pretty good results with the far cheaper GPT-3.5 model too, indicating that our methods could be used quite economically.

Revisiting the relatively lower improvements in CSI-1 by examining GPT-generated translations, we find that the LLMs sometimes focus on irrelevant details in the provided recipes. In CSI-1, which involves shorter CSI terms, finding an exact match for dish names is harder, forcing the inclusion of noise in the recipe. For instance, the term "咕噜" *(Sweet and sour)* applies to various dishes

	GPT-3.5				GPT-4o			
	CSI-1	**CSI-2**	**CSI-3**	**Overall**	**CSI-1**	**CSI-2**	**CSI-3**	**Overall**

Table 6: Ablation study comparing COMET scores for GPT-3.5 and GPT-4o using different equivalent strategies across CSI categories. The overall score is calculated as the average of CSI-1, CSI-2, and CSI-3 scores for each method.

like pork, chicken, or fish, making it difficult to provide the correct ingredient. In contrast, CSI-2 and CSI-3 usually involve longer, more specific phrases like "蚂蚁上树” *(Fried vermicelli with pork)*, making it easier to find an exact recipe match, reduce noise, and majorly improve accuracy.

6.5 Evaluation of Individual Equivalent Strategies

We further perform an ablation analysis of the recipe and individual equivalent strategies, including cultural, descriptive and functional, against the baseline results.

Table 6 shows that for GPT-3.5, the functional equivalent strategy outperforms others, especially when combined with the recipe. For GPT-4o, both descriptive and functional strategies yield better results in CSI-2 and CSI-3, with descriptive strategy excelling in CSI-2 when a recipe is included. In CSI-3, "Recipe + Functional" strategy leads to a significant performance boost of +7.97.

Upon reviewing the translations, both descriptive and functional strategies align well with the gold standards for CSI-2 and CSI-3. However, due to its complexity, the descriptive strategy produces longer translations with trivial details for CSI-3, which is likely to negatively affect COMET scores.

6.6 Human Evaluation

We collect ratings from 10 native Chinese speakers fluent in English, based on the concept of cross-cultural adaptation on a scale of 0 to 10, alongside automatic quantitative metrics. We select the top-performing methods with recipes, as evaluated by COMET in Tables 5 and 6. We then randomly sample 15 entries with perfect agreement from each CSI category (1: Concrete, 2: Creative, 3: Abstract), totalling 45 entries.

The human evaluation results reveal a trend of performance improvement from CSI-1 to CSI-3 in GPT-3.5 and 4o. We use green to highlight cells with major improvements, i.e. over 1 point. Interestingly, for more complex CSIs (i.e. CSI-2 and CSI-3) we have larger improvements. We also observe that these trends align well with COMET trends in Table 5, noting that by both metrics, translation theory prompts yield significantly better results than basic prompting across categories.

Interestingly, human evaluators prefer “*Recipe + Neutralisation*" instead of “Recipe + Equivalent",

	GPT-3.5				GPT-4o			
	CSI-1	**CSI-2**	**CSI-3**	**Overall**	**CSI-1**	**CSI-2**	**CSI-3**	**Overall**
Baseline	6.33	3.88	3.18	4.47	6.22	4.23	3.65	4.70
Recipe-based Translation								
Recipe	-0.93	+0.67	+1.74	+0.49	-0.04	+0.80	+2.28	+1.01
Recipe + Explain-then-Translate	-0.03	+0.60	+1.35	+0.64	+0.43	+0.98	+1.68	+1.03
Recipe + Translation Studies Prompting								
Recipe + Functional	-1.15	+1.10	+1.71	+0.60	+0.75	+1.77	+2.14	+1.05
Recipe + Neutralisation	**+0.37**	**+1.21**	+1.03	+0.62	**+1.32**	**+2.83**	**+3.20**	**+1.95**
Recipe + Equivalent	-0.85	+0.62	**+2.05**	**+0.81**	+0.71	+0.99	+2.38	+1.36

Table 7: Difference in human evaluation of translation quality compared to baseline for different models and strategies across CSI categories. The overall score is calculated as the average of CSI-1, CSI-2, and CSI-3 scores for each method.

the highest in COMET. This preference may stem from the neutralisation definition used in this study, based on the findings of Amenador and Wang (2022). They note that neutralisation is the most common strategy employed by human translators for Chinese names, suggesting a familiarity that could influence the evaluators' preferences towards human-like translation outputs.

Table 8 illustrates the effectiveness of various translation strategies applied to the Chinese dish "三不沾", known for its non-stick quality when served, featuring osmanthus eggs. The full translation examples are provided in Appendix A.3.

Strategy	**Translation**
`Baseline`	Not sticky in three ways
`Equivalent`	Sweet Egg Pastry
`Neutralisation`	Osmanthus Egg Custard

Table 8: Selected Translations from GPT-4o Using Different Translation Strategies with Recipe.

"Sweet Egg Pastry" generated using the Equivalent strategy by GPT-4o, effectively conveys the essence of the dish by focusing on its key ingredients and flavour profile. "Osmanthus Egg Custard," produced through the Neutralisation strategy, is also an accurate translation as it highlights "Osmanthus egg," the main ingredient, and "Custard," indicating the dish's texture. In contrast, the baseline translation "Not sticky in three ways" fails to provide meaningful information about the dish, making it the weakest.

7 Discussion

The CSI categorisation can be applied to wider cultural domains that contain figurative elements. Future research can use this taxonomy to analyze how different translation methods perform on figurativeness and cultural specificity, suggesting a new framework for evaluating CSI translation. This is similar to the evaluating framework in cultural inference, categorising entailment in different levels to better assess an LLM's ability to understand cultural inference (Huang and Yang, 2023).

CSI automatic identification offers a cost-effective approach that outperforms GPT-based prompting in CSI-2 and 3. This method is versatile and applicable to both general and domain-specific CSIs, as it focuses on preserving meaning in translation. It could enhance the quality of translations in a wide variety of domains where maintaining cultural integrity is essential – like literature, media, marketing and cross-cultural communication.

The findings of this paper also demonstrate the effectiveness of prompt strategies inspired by translation studies in overcoming the challenges of translating CSIs, particularly when direct equivalents are lacking across cultures. This approach shows promise for using LLMs with tailored prompts, integrating human translation insights, and translating diverse cultural elements more effectively.

8 Conclusion

In this paper, we introduce the ChineseMenuCSI dataset for CSI-rich dishes and propose a detailed classification in the test set. The results show that LLMs outperformed NMT systems, while NMT is better for Non-CSI translations. Additionally, automatic methods are better than GPT-based prompting at identifying CSIs in most categories.

Incorporating translation studies and recipe details improves LLMs' translation of Chinese dish names. Equivalence strategies, aligned with popular restaurant translations, yield consistently high-quality results, while neutralisation, based on previous analyses, is well-received by evaluators.

Limitations

We acknowledge a few limitations of our study. Firstly, we use COMET as the primary automatic evaluation metric for CSIs. While COMET provides a robust evaluation, assessing cultural awareness may require an even deeper understanding of cultural backgrounds in both source and target languages, which COMET may not fully cover. Currently, in the absence of a metric that can evaluate text-to-text cultural similarity, we use COMET due to its high correlations with human judgment.

Secondly, while we only test zero-shot prompting for translation studies and recipe information, other research, such as Nayak et al. (2024), has demonstrated promising results using few-shot in-context learning strategies, which should also be explored.

Lastly, we only sample 45 menu entries from the test set, which can be relatively small compared to the studies with a larger test set. To achieve more robust and reliable results, increasing the number of human evaluators and the sample size of evaluation entries would be beneficial.

Ethical Considerations

In conducting this research, we adhere to ethical guidelines to ensure the integrity and responsibility of our work. The ChineseMenuCSI dataset is created by scraping publicly available restaurant websites, ensuring that no private or sensitive information is collected. We obtain data in compliance with the terms of use of the websites and anonymise any identifying details of the restaurants. The human annotators involved in this study are fully informed about the nature of the research and provide their consent. We make the dataset available for research purposes under a license that respects the rights of the original content creators.

A Appendix

A.1 Detailed Prompt Teamplates

Prompt Strategy: Recipe + Equivalents

User:

Similiar Recipe: [Recipe Instructions].

Based on the above recipe information, provide three translations for [Chinese dish name] based on the three translation strategies listed below and select the best one:

Cultural Equivalent: Substituting a source language term with a term from the target language that has similar cultural resonance and functionality.

Functional Equivalent: Rendering the source language's meaning, intent, and style into the target language in a culturally appropriate and understandable way. This strategy prioritizes the effect and function of the text in the target culture over a word-for-word translation, ensuring the translation fulfills the same purpose as the original.

Descriptive Equivalent: Providing an in-depth explanation of a term or concept that lacks a straightforward equivalent in the target language. The explanation could include details such as ingredients, culinary method, key characteristics, etc.

Figure 3: Recipe + Equivalents Detailed Prompt

Prompt Strategy: Recipe + Neutralisation

User:

Similiar Recipe: [Recipe Instructions].

Based on the above recipe information, provide a translation for [Chinese dish name] with the following translation strategy:

Menu Description Strategy: This strategy involves using culturally neutral language to describe or explain a cultural word, phrase, or rhetorical expression from the source text (ST). It answers the question, 'What is this?' and is similar to converting a metaphor to its literal meaning. The translations should include the key culinary method, ingredients, and characteristics.

Figure 4: Recipe + Neutralisation Detailed Prompt

A.2 Menu Parser

We develop a heuristic parser to extract dish information from the bilingual menu images by detecting price tags and segmenting the raw text into aligned content. To achieve this, we utilise Google Cloud Vision OCR[6] to extract text and bounding boxes from the menu images. Price tags serve as unique indicators for each dish's content, as we observe that most menus included prices alongside their respective dishes. These price tags are identified using regular expressions, such as "dd.dd" or "£dd.dd".

Given that the position of price tags relative to dish names can vary across menus, we calculate alignment scores based on the cosine similarity and the gap distance between the potentially aligned Chinese and English text and select the alignment with the highest score from all possible combinations. Each entry undergoes manual review to ensure accuracy and errors are corrected before subsequent steps.

A.3 Full Examples of Translation Prompts

Strategy	Translation
`Baseline`	Not sticky in three ways
`Reference`	Sweet Egg Pudding
`Recipe`	Three Non-Stick Delicacy: Traditional Imperial Egg Yolk Treat
`Recipe + EtT`	Imperial Non-Stick Egg Delight
`Equivalent`	Sweet, Sticky and Chewy
`Neutralisation`	Non-Sticky Sweet and Savory Egg Custard
`Recipe + Equivalent`	Sweet Egg Pastry
`Recipe + Neutralisation`	Osmanthus Egg Custard

Pitfalls and Outlooks in Using COMET

Vilém Zouhar★ [1] Pinzhen Chen★ [2] Tsz Kin Lam[2] Nikita Moghe[2] Barry Haddow[2]

vzouhar@ethz.ch {pinzhen.chen,tlam,nikita.moghe,bhaddow}@ed.ac.uk

Abstract

The COMET metric has blazed a trail in the machine translation community given its strong correlation with human judgements of translation quality. Its success stems from being a pre-trained multilingual model finetuned for quality assessment. However, it being a neural metric also gives rise to a set of pitfalls that may not be widely known. We investigate these unexpected behaviours from three aspects: 1) technical: obsolete software versions and compute precision; 2) data: empty content, language mismatch, and translationese at test time as well as distribution and domain biases in training; 3) usage and reporting: multi-reference support and model referencing in the literature. All of these problems imply that COMET scores may be not incomparable between papers or technical setups and we put forward our perspective on fixing each issue. Furthermore, we release the sacreCOMET package that can generate a signature for the software and model configuration as well as an appropriate citation. The goal of this work is to help the community make more sound use of the COMET metric.

1 Introduction

Automated metrics provide a cheap and scalable way of evaluating and benchmarking NLP models. In machine translation (MT), the evaluation protocol has moved from string matching metrics (BLEU, TER, chrF, inter alia; Papineni et al., 2002; Snover et al., 2006; Popović, 2015) to trained neural metrics (Shimanaka et al., 2018; Takahashi et al., 2020; Rei et al., 2020a; Sellam et al., 2020) with COMET being widely adopted. The trained metrics have been shown to correlate much better with human judgement (Freitag et al., 2021, 2022b, 2023), making them more reliable in estimating translation quality and ranking translation systems.

Nonetheless, the solution to translation evaluation is yet to be perfected. One problem is the haphazard use of the metric. Previously, Post (2018) showed that different usages and implementations of BLEU, e.g. tokenization and smoothing, lead to inconsistencies in scores. We suspect that the use of COMET might be sensitive to misconfigurations too, resulting in unexpected behaviours. Furthermore, trained MT metrics are optimized on a limited amount of data (usually valid machine translations), leading to overfitting and reduced robustness against corner cases. Contributions of this work are listed as follows:

- we reveal nine problems spanning technical issues, data biases, and model reporting;
- we show that inconsistent use of COMET leads to non-comparable scores across papers or setups;
- we release the sacreCOMET package for better reporting and reproducibility;
- we provide directions for future work on building learned metrics.

2 Background and Setup

Metric background. Publicly available human judgements of translation quality come from shared task annotation campaigns, where translations are evaluated with some annotation protocol. From 2017, in WMT, the protocol was a variant of direct assessment (DA; Graham et al., 2013) which has annotators providing a number from 0 (lowest) to 100 (highest) as the segment quality. This has been subsequently replaced by MQM and ESA protocols (Lommel et al., 2014; Kocmi et al., 2024d), though DA remains the most abundant data source for neural metric training.

Automated metrics aim to yield scores that correlate with human judgements of translations. Most metric scores are computed at the segment level and then aggregated at the system level to e.g. obtain system comparison. The evaluation of metrics is done with respect to the human judgements.

★Equal contributions.

COMET models. Metrics such as chrF or BLEU are heuristic algorithms that match n-grams between the translation and the reference to compute a score. In contrast, COMET is a machine learning model fine-tuned from a pre-trained multilingual language model, e.g. XLM-R (Conneau et al., 2020), with an additional regression head. A reference-based COMET model learns to regress from a tuple of [source, hypothesis, reference] to the human judgement score (from previous evaluation campaigns) at the segment level. The quality estimation (reference-free) version of COMET is prepared by omitting the reference from the input.

Most issues in this work are demonstrated using two COMET checkpoints unless noted otherwise: the reference-based COMET$_{22}^{\text{DA}}$ and the reference-free COMET$_{22}^{\text{kiwiDA}}$ (Rei et al., 2022a). Both metrics output to a normalized range between 0 and 1. The COMET framework `unbabel-comet` is of version 2.2.2 except when we test how different software versions affect COMET scores.

Data setup. We base our experiments on the general domain translation and metrics shared tasks of WMT from 2023 (Kocmi et al., 2023; Freitag et al., 2023). The translation directions in the paper are centred around En↔De and En↔Zh, though we occasionally include other translation directions for demonstrative purposes.

Whenever possible, we divide all scores, including DA and model outputs, such that their output is between 0 and 1.

3 Problems

In this section, we identify and test nine possible pitfalls or curious behaviours with COMET which are not all well-studied. In three groups, these are:

- **Technicality**: obsolete Python and COMET software versions as well as compute precisions could lead to inaccurate score computation.
- **Training and test data**: COMET as a neural metric, might be derailed by empty hypotheses, language mismatch, and translationese at test time. It may also follow the training data biases.
- **Tool usage and score interpretation**: COMET has no defined way of equipping multiple references when available which leaves room for research. From a bibliometric perspective, we reveal that some literature omits a clear reference to the checkpoint version or citation.

In addition, we discuss some final issues that need more attention from the community.

Python unbabel-comet	3.7.16 1.1.2	3.8.11 2.2.2	3.12.4 2.2.2
En→De	0.796	0.837	0.837
En→Zh	0.911	0.862	0.862
De→En	0.851	0.855	0.855
Zh→En	0.795	0.803	0.803

Table 1: COMET$_{22}^{\text{DA}}$ scores for WMT 23 Online-A under different package versions.

3.1 Software versions [technical]

The official installation of the COMET package requires Python 3.8 or above.[1] We demonstrate that neglecting this would lead to unexpected scores because the same COMET checkpoint can produce vastly different scores with previous COMET framework versions that are no longer supported.

Under several Python versions, executing the following code leads to different COMET package (`unbabel-comet`) versions being installed. Running the framework for translation evaluation will subsequently result in false conclusions as shown in Table 1's evaluation on WMT23 tests. The direct cause is that Python 3.7, which has been discontinued, only supports `unbabel-comet` versions up to 1.1.2. Nonetheless, we caution that the underlying factor is the version of `unbabel-comet` rather than Python.

```
$ pip install pip --upgrade
$ pip install unbabel-comet --upgrade

# will install
# unbabel-comet==1.1.2 under Python 3.7.16
# unbabel-comet==2.2.2 under Python 3.8.11
# unbabel-comet==2.2.2 under Python 3.12.4
```

Recommendation. Updating both Python and `unbabel-comet` to their latest versions is helpful and reporting the toolkit version aids reproducibility.

3.2 Numerical precision [technical]

Model quantization represents a model using lower-numerical precision data types so that the model consumes less memory and model passes can be computed faster. Such improvement in inference is directly beneficial to deployment efficiency; it is also useful in other complex procedures involving COMET scoring, such as data filtering, re-ranking, and Minimum Bayes Risk (MBR) decoding (Kumar and Byrne, 2004).

Despite the aforementioned advantages, model quantization is not a feature supported by the cur-

[1] github.com/Unbabel/COMET `332dfb0` as of Aug 2024.

		Precision	$\text{COMET}_{22}^{\text{DA}}$	MAE	τ_c	Acc	Time (s)

Table 2: System ranking with quantization on GPU and CPU. $\text{COMET}_{22}^{\text{DA}}$ is the absolute model score; MAE, τ_c, and Acc are mean average error, correlation, and accuracy with respect to human judgements; Time refers to computation time in seconds.

rent COMET framework except in a concurrent work (Gowda et al., 2024). We make minimal modifications to the software and investigate the effect of numerical precision on COMET scores on both CPU (FP32, FP16, and QINT8) and GPU (FP32 and FP16). When using FP16, we first load the model weights to FP32, followed by `.half()` call. This is because loading the weights directly in FP16 still incorrectly results in FP32 precision. For CPU inference with dynamic QINT8, we apply the quantization module `torch.ao.quantization` from PyTorch.

We use AMD Ryzen 9 5900X with NVIDIA GeForce RTX 3090 for GPU inference and a batch size of 8 in all settings (in practice a quantized model makes room for a larger batch size). Table 2 summarises the effect of numerical precision. In addition to reporting COMET scores, we also report (1) inference time in seconds (sec) as an efficiency measure; and (2) segment-level mean absolute error (MAE), segment-level Kendall's tau-c (τ_c), and system-level pairwise accuracy (Acc). Everything is compared to the human DA scores either on segment- or system-level. Technically, Kendall's τ_c calculates rank correlation on an ordinal scale with adjustments for ties and pairwise accuracy computes the proportion of system pairs that have the same ordering by a metric as by humans.

Our results show that there is no meaningful difference between FP32 and FP16 in both CPU and GPU devices up to 3 significant figures. On GPU, FP16 is about 30% faster in time, but unsurprisingly it does not provide any speed-up on CPU. Interestingly, on the CPU, dynamic QINT8 gives systematically higher COMET scores and shorter running times than FP32 and FP16. However, the much lower τ_c and pairwise accuracy indicate the lack of reliability at this precision. In addition to precision, we explored the effect of batch size and the choice of GPU or CPU during inference with results listed Appendix A. Whilst there are some fluctuations, they are mostly negligible. However, lower precision allows for higher batch size which usually directly corresponds to speed-up.

Recommendation. If GPU is available, it is feasible to run COMET with FP16 with a larger batch size for much faster inference without any quality loss. Otherwise, FP32 should be used.

3.3 Empty hypothesis [data]

An empty translation (a string of length 0) gets penalized heavily by string-based metrics because an empty string has zero surface overlap with the reference. However, neural metrics provide no such guarantee. We show that COMET assigns a positive instance-level score even if the hypothesis is an empty string as corroborated by Lo et al. (2023). Problematically, this score can even occasionally be higher than that of a genuine system translation.

In Table 3, we list COMET scores for system Online-A's hypotheses at WMT23 and a file full of empty lines. Furthermore, we compare them with completely incorrect translations to explicate the score magnitude in two ways:

- *Random hypothesis:* we shuffle WMT22's reference files at the sentence level in the respective translation directions. This provides us with high-quality human-written sentences. We sub-sample or over-sample if the number of lines in WMT22 is larger or smaller than the WMT23 size.
- *Random hypothesis (shuffled words):* we further shuffle the words at each line in the sentence-shuffled files, generating nonsensical sentences.

Sentence-shuffled hypotheses can be seen as fluent but extremely inadequate sentences whereas word-shuffled sentences are neither fluent nor adequate.

We observe that sentence-shuffled hypotheses attain comparable scores to empty ones, but word-shuffled hypotheses have the lowest scores across

	$\text{COMET}_{22}^{\text{DA}}$				$\text{COMET}_{22}^{\text{kiwiDA}}$			
Hypothesis (↓)	En→De	En→Zh	De→En	Zh→En	En→De	En→Zh	De→En	Zh→En
Real system (Online-A)	0.837	0.862	0.855	0.803	0.800	0.791	0.794	0.787
Empty hypothesis	0.335	0.392	0.353	0.374	0.315	0.319	0.537	0.467
Random hypothesis (fluent)	0.373	0.434	0.334	0.350	0.333	0.341	0.447	0.391
Random hypothesis (shuffled words)	0.244	0.419	0.264	0.347	0.232	0.325	0.307	0.385

Table 3: Absolute average COMET scores for WMT23 Online-A, empty hypotheses, and random sentences. Random sentences are either fluent but irrelevant or perturbed with words shuffled and thus non-fluent.

the majority of the translation directions. Empty and shuffled hypotheses, despite having much lower COMET than the valid translations, would not be assigned zero scores by $\text{COMET}_{22}^{\text{DA}}$ or $\text{COMET}_{22}^{\text{kiwiDA}}$, showing that COMET is more lenient than string overlap-based metrics in penalizing such irregularities.

We count the number of empty lines that score better than a translation from Online-A in Table 4. We observe roughly 0.25% such cases for most translation directions except for De→En's $\text{COMET}_{22}^{\text{kiwiDA}}$ score situating at 1.45%. Further, in Figure 1 we plot the distributions of COMET scores for Zh→En's empty and genuine translations with other translation directions in Appendix B. Noticeable overlaps are observed for $\text{COMET}_{22}^{\text{kiwiDA}}$ when translating into English.

Adhering to the DA protocol guidelines, this is not the proper behaviour because an empty hypothesis should receive a score of 0, to match *no meaning preserved*. This however is unsurprising with COMET, which has likely not seen empty hypotheses during training that would have received a score of 0 from a human annotator. Finally, even by relaxing the 0-score expectation, the metric should still assign the same score to all empty hypotheses regardless of the source. Since the distributions of empty hypotheses are nowhere close to a single vertical bar in Figure 1, it exposes the issue that segment-level COMET scores oddly hinge on the source sentence, as noted by Sun et al. (2020).

Recommendation. Force empty hypotheses to have 0 scores before aggregating. Also, a string-based metric like BLEU or chrF should be used to catch similarly malformed hypotheses.

3.4 Hypothesis language mismatch [data]

String overlap-based metrics can also score a hypothesis in a language different from the reference almost zero, especially with script mismatch. However, even for the reference-based COMET, there is no explicit way to enforce the intended target language. This poses an increasingly pronounced problem, especially for multilingual translation models as well as the recent large language models, in which the generated language cannot be as easily controlled (Zhang et al., 2023).

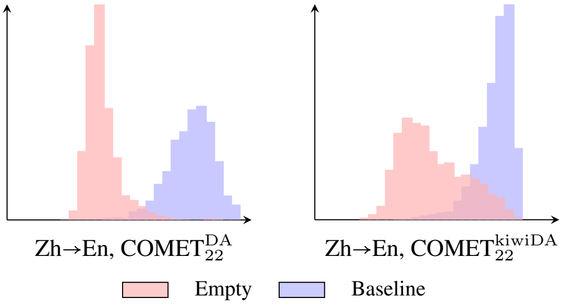

Figure 1: Distribution of instance-level scores for empty and baseline translations (x-axis: score; y-axis: count). See other translation directions in Appendix B.

	translation < empty	
	$\text{COMET}_{22}^{\text{DA}}$	$\text{COMET}_{22}^{\text{kiwiDA}}$
En→De	0 / 558	2 / 558
En→Ru	1 / 2075	0 / 2075
En→Uk	2 / 2075	1 / 2075
En→Zh	6 / 2075	2 / 2075
De→En	1 / 550	8 / 550
Ru→En	5 / 1724	6 / 1724
Uk→En	1 / 1827	5 / 1827
Zh→En	5 / 1977	1 / 1977

Table 4: Proportion of WMT23 Online-A's translations that are worse than an empty line for the same source, displayed as "empty/total".

We conduct experiments to understand if translation outputs in an incorrect language impact the score, and whether different mismatching languages can lead to distinct patterns. We use the translation directions En→Ru, En→Uk, and En→Zh in WMT23 which share the same English source input. Having Online-A's output in all three directions, we substitute hypotheses in a particular translation direction with those from another direction. A similar hypothesis was presented by Amrhein et al. (2022) which suggested that COMET metrics are not robust to hypothesis language mis-

	En→Ru	En→Uk	En→Zh
Correct lang.	0.853	0.832	0.862
Incorrect target lang.	Uk: 0.797 Zh: 0.536	Ru: 0.807 Zh: 0.540	Ru: 0.655 Uk: 0.644
Empty hyp.	0.316	0.329	0.391
Random hyp.	0.463	0.472	0.435

Table 5: COMET$_{22}^{\mathrm{DA}}$ scores for WMT23 Online-A's output in (1) correct, (2, 3) incorrect language, (4) empty outputs, (5) random, but fluent, output.

match. Our experiment setup offers a more detailed evaluation setup than their contrastive setup.

Table 5 presents COMET$_{22}^{\mathrm{DA}}$ scores for translations in correct and incorrect languages, as well as empty lines and random sentences in the correct language as "baselines", deemed as completely wrong translations. The pattern shows that when the hypothesis is in a language distant from the reference, the COMET score declines much more than when the hypothesis is in a similar language. A more concerning issue is that even when the hypotheses' language is completely wrong, the resulting COMET score can still be vastly higher than empty hypotheses or random sentences in the correct language. We omit COMET$_{22}^{\mathrm{kiwiDA}}$ because it does not have a mechanism to read a reference (language) making it inherently incapable of distinguishing output languages.

Recommendation. Run language identification and set hypotheses in an unexpected language to have a 0 COMET score before aggregating them system-level. Also, check with a string overlap-based metric like BLEU or chrF.

Lang	Score	Lang	Score	Lang	Score

Table 6: Average human DA score for each translation direction in WMT data up to 2023 (inclusive).

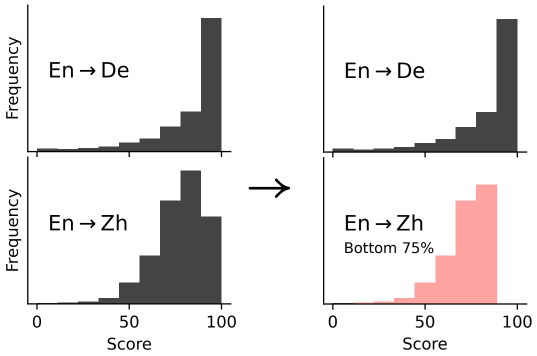

Figure 2: Setup of an experiment with bottom 75% of En→Zh scores which creates a bias in COMET$_{22}^{\mathrm{DA}}$. In the new data for En→Zh (bottom right) there are no translations with perfect scores. En→De data are unaffected.

3.5 Score distribution bias [data]

As the COMET metric is a machine learning model trained on human ratings of existing machine translations, it inherits many properties of statistical learning such as data (output score) distribution bias. The yearly WMT shared task receives submissions with varying quality and potentially varying quality ranges for different translation directions per year (from Koehn and Monz, 2006 to Freitag et al., 2023). This is attributed to diverse factors: the availability of data, source-target language similarity, the level of interest in languages, etc. The gap in translation quality will then propagate into skewed human judgement scores across translation directions. When a single COMET model learns to score all translation directions, it can overfit the score distribution w.r.t. a translation direction in addition to the quality of a translation hypothesis.

We first verify this in Table 6 which shows that WMT translation directions are associated with vastly different human DA scores (from 0.51 to 0.91). Empirically, we illustrate this issue using two high-resource directions En→De and En→Zh. As shown in Figure 2, we keep either the top- or bottom-75% of all scored translations to alter the score distribution for each direction, simulating the scenario where low- and high-performing system submissions are received for different directions. We then train different COMET models on the human train data before and after alteration as per Figure 2. Finally, we evaluate those checkpoints on the same test set and report results in Table 7.

As expected, for both En→De and En→Zh, training on the top or bottom-scoring data leads to increased or decreased COMET scores on the same set of hypotheses. Besides, we observe that altering scores in a particular translation direction incon-

Training data	En→De	En→Zh
All	0.770	0.770
Top-75% of En→De	0.790	0.770
Bot-75% of En→De	0.765	0.764
Top-75% of En→Zh	0.783	0.789
Bot-75% of En→Zh	0.772	0.751

Table 7: Average scores from COMET$_{22}^{\text{DA}}$ trained on data with top- or bottom-75% of scores kept in a particular direction.

sistently affects scores in another direction systematically. For example, removing the bottom 25% En→De scores "improves" the test-time score from 0.770 to 0.790 whilst En→Zh remains unaffected.

Finally, an empty translation should have the same score irrespective of the original source. Due to the statistical learning nature of the metric, this is not the case, as found in Section 3.3. Sun et al. (2020) and Zouhar et al. (2023) show that some meaningful correlation with human scores can be attained with just the source as the input. This shows, that there is a learned bias based on the prior difficulty of the source segment, which is undesirable for an objective evaluation metric.

Implication. A trivial conclusion is that COMET scores for different translation directions are not comparable. Nevertheless, we caution that the same phenomenon could happen for other features such as the domain, output style, etc. Although z-score re-scaling *could* mitigate this problem, it has not been a common practice since WMT22 and it would further contribute to non-objective scores (Knowles, 2021). Moreover, while z-scoring is straightforward for the translation direction, other latent, language-agnostic biases still exist.

3.6 Domain bias [data]

Neural metrics like COMET are biased towards particular domains, manifested by worse test performance on unseen domains (Zouhar et al., 2024a). Taking inspiration from previous work and our discussions on "latent biases", we now raise a question—can we create adversarial hypotheses at test time to exploit the domain bias in training time? Specifically, different domains in the training data are associated with different score ranges. By pretending that a translation is in a particular domain, it might manipulate its COMET score.

To make it explicit to COMET during training, we prepend the target translation with a tag of its domain—in our case, the year the WMT data originated. Note that in each iteration of WMT, systems get higher overall DA scores (e.g. 0.721 for 2019 and 0.749 for 2021). Table 8 illustrates our setup: during training, we tag the scored translation data with its year; during testing, we trial various year prefixes to understand the effect.

Train	`2020` Fire prevented from spreading
Test	`2019` Now I have to tell you a nice story.
	`2020` Now I have to tell you a nice story.
	`2021` Now I have to tell you a nice story.
	`2022` Now I have to tell you a nice story.
	`2023` Now I have to tell you a nice story.

Table 8: An illustration of year-as-a-domain tagging during training and testing.

Tag	Train	Test
2018	unseen	0.736
2019	0.721	0.737
2020	0.735	0.744
2021	0.749	0.749
2022	unseen	0.747
2023	unseen	0.747
2024	unseen	0.739
2025	unseen	0.747

Table 9: Average COMET$_{22}^{\text{DA}}$ scores for subsets in training and predictions on test data. During testing, the whole test set had a single tag, e.g. 2024, irrespective of the data origin.

One would expect the metric to produce the same score based solely on the translation quality. However, as shown in Table 9, by merely changing the year tag, we can influence the average score of the test set. During training, the model would be able to observe that 2019 is associated with the worst score and 2021 the best. During test time, the model follows this bias and also extrapolates it to upcoming years where it predicts an improvement in the average DA scores. While the differences appear small, they are on the same scale as the differences between years in the training data.

Implication. Our year-as-a-domain setting might be overly simple, but the vulnerability of COMET to latent biases cannot be neglected. Although Amrhein and Sennrich (2022) has shown that COMET is not sensitive to numbers, this work reveals that it can be systematically exploited in an artificial setting. We offer a more practical (adversarial) example that one may disguise biomedical domain translations as news translations to game COMET.

3.7 Lack of multi-reference support [usage]

In machine translation, there usually exist many valid translations for the same input. An effective metric should incorporate multiple ground truths

WMT23		$\text{COMET}_{22}^{\text{DA}}$				
		ref	ref (alt)	avg	max	agg
MQM	He→En	0.885	0.897	0.910	0.910	**0.949**
	En→De	0.974	0.936	0.974	**0.987**	0.974
	Zh→En	0.783	0.908	0.850	0.858	**0.950**
DA	En→De	0.885	**0.949**	0.910	0.897	0.910
	Zh→En	0.717	0.875	0.783	0.775	**0.883**
	De→En	0.901	0.912	**0.923**	**0.923**	0.912
	En→Zh	**0.933**	0.817	0.900	0.867	**0.933**
	Cs→Uk	0.846	0.802	**0.901**	0.890	0.868
	En→Cs	0.858	**0.875**	0.858	0.858	0.867
	En→Ja	**0.941**	0.824	0.934	0.934	0.926
	Ja→En	0.922	0.915	**0.928**	**0.928**	0.922

Table 10: Pairwise system-level accuracy for different strategies incorporating multiple references into $\text{COMET}_{22}^{\text{DA}}$. Evaluation is carried out on WMT23 with DA or MQM scores as human ground truths.

if available, thereby enhancing the accuracy and robustness of its evaluation. Existing metrics like BLEU or chrF rely on surface-level overlap to capture the ground truth space from multiple references while metrics like ParBLEU (Bawden et al., 2020) can automatically generate paraphrases of a given reference to be included during evaluation.

By design, only one reference can be used in COMET. Whilst one may argue that representing a text reference in the neural space can ease the restriction on word choices, it might still be beneficial to use multiple references to overcome defects in the base embedding model. Therefore, we test whether COMET can explicitly and reliably leverage multiple references. We identify three distinct ways in which multiple references have been incorporated in COMET in previous literature (Rei et al., 2020b; Zouhar and Bojar, 2024):

- **max**: Taking the maximum over the scores from multiple passes with different references.
- **avg**: Averaging the scores from multiple passes with different references.
- **agg**: Obtaining an aggregate score per example as follows. A quadruplet of source $\mathbf{s}$, hypothesis $\mathbf{h}$, reference $\mathbf{r}$, and alternative reference $\hat{\mathbf{r}}$ is fed to COMET six times in different [src, hyp, ref] arrangements: $[\mathbf{s},\mathbf{h},\mathbf{r}]$, $[\mathbf{r},\mathbf{h},\mathbf{s}]$, $[\mathbf{s},\mathbf{h},\hat{\mathbf{r}}]$, $[\hat{\mathbf{r}},\mathbf{h},\mathbf{s}]$, $[\mathbf{r},\mathbf{h},\hat{\mathbf{r}}]$, as well as $[\hat{\mathbf{r}},\mathbf{h},\mathbf{r}]$. Then, the average score from these six passes is multiplied by $(1-\sigma)$ where σ denotes the standard deviation.

We use additional references from the WMT23 test set if available (He→En) or the outputs from the best-scoring system in each direction in the metrics shared task (Freitag et al., 2023) as an alternative reference. We report pairwise system-level accuracy (Kocmi et al., 2021) for various translation directions in Table 10. Our results suggest that there is no single method that can consistently take advantage of the inclusion of multiple references with the existing COMET implementation. At a higher inference cost, the six-pass aggregation with COMET might have a tiny edge over other methods when MQM is treated as human ground truths, but it is also outperformed under DA by single-reference or other multi-reference methods.

As translation systems have greatly improved lately, the above pattern might be explained by Freitag et al. (2020)'s finding that high-quality translation outputs do not benefit from multi-reference evaluation. We also caution that these observations are highly dependent on the quality of the underlying references. As studied previously, obtaining high-quality references is not trivial (Freitag et al., 2020, 2023; Zouhar and Bojar, 2024). Our use of the top-performing system outputs as alternate references is fit for the purpose but not optimal.

Recommendation. Our recommendations for the inclusion of multiple references into COMET or even other neural metrics are aspirational as this topic warrants further investigation. Extending unified pre-training (Wan et al., 2022) with multiple references in the architecture as well as using training objectives more suitable for handling more than one references (Zheng et al., 2018; Fomicheva et al., 2020a) can be helpful.

3.8 Translationese [data]

COMET has been trained with human translations as references and machine translations as hypotheses, where both could be deemed "translationese" to a certain extent (Gellerstam, 1986).

Translationese in references. We first conduct an experiment to see if the translationese present in the reference would undermine system evaluation with COMET. We consider WMT's official reference as a standard version and Freitag et al. (2020)'s paraphrased reference as a less translationese reference (we use their "paraphrased as-much-as-possible" version). Experiments are carried out under two settings: (1) WMT19 En→De submissions scored by $\text{COMET}_{22}^{\text{DA}}$, and (2) WMT20 En→De submissions scored by $\text{COMET}_{20}^{\text{DA}}$ (Rei et al., 2020b). These two settings cover two scenarios—whether the test suite has been used in training the COMET model, or not. A breakdown

```
Please paraphrase the following text as
much as possible. Provide the paraphrase
without any explanation:

$HYPOTHESIS
```

Figure 3: Prompt template used to request a paraphrase from GPT-4o, where `$HYPOTHESIS` is replaced by individual hypotheses.

of COMET scores and rankings for individual systems are listed in Appendix C Tables 12 and 13.

The COMET scores decline dramatically when we switch the reference from the original one to the paraphrased one—aiming to reduce translationese. It means that COMET is indeed sensitive to such changes in the reference. Yet interestingly, the overall system ranking in either setting remains rather stable. We find a very high Kendall's τ_a of 0.9827 and 0.9833 on the system rankings in the two settings; pairwise accuracy computed against human judgements also maintained at 0.924. We conclude that translationese in the reference impacts absolute COMET scores but not system ranking. These patterns are consistent regardless of whether the model has been exposed to the test set.

Translationese in hypotheses. We then attempt to understand if a varying degree of translationese in the system outputs will influence system ranking by COMET. We run $\text{COMET}_{22}^{\text{DA}}$ and $\text{COMET}_{22}^{\text{kiwiDA}}$ on WMT19 En→De system outputs as well as their corresponding rephrased outputs against the same source and reference. To acquire paraphrases affordably, we shortlist the top-10 systems' translations in the previous experiment and we prompt GPT-4o using the prompt outlined in Figure 3.[2] We do not feed the source sentence to prevent the model from revising the quality.

Appendix Table 14 shows that both models yield the same system ranking when the original hypotheses are scored. After substituting the hypotheses with their paraphrases, the ranking has changed more under $\text{COMET}_{22}^{\text{kiwiDA}}$ which witnesses much lower pairwise accuracy and Kendall's τ_c compared to $\text{COMET}_{22}^{\text{DA}}$. This suggests that $\text{COMET}_{22}^{\text{kiwiDA}}$ is more sensitive to potential changes in the degree of translationese than $\text{COMET}_{22}^{\text{DA}}$.

Considerations. We note the limitations of our experiments. First, we assume that the paraphrased references are as good as the original ones and less translationese, but we did not verify this when paraphrasing the hypotheses. If the hypothesis quality has been affected, we also assume that the LLM paraphrasing process affects all system outputs in an equal magnitude. Second, the evaluations that anchor to human judgements assume that human evaluators provide assessment solely on the quality and do not overly insist on adequacy/translationese. Third, our comparison between $\text{COMET}_{22}^{\text{DA}}$ and $\text{COMET}_{22}^{\text{kiwiDA}}$ only shows that they do not behave the same in dealing with change in the degree of translationese in hypotheses.

3.9 Model reporting [usage]

Different COMET models can yield distinct results. Therefore it is important to always specify the specific model for sensible score interpretation and comparison. In this section, we examine to what extent this holds up in scientific literature.

We automate this bibliometric task with SemanticScholar API (Kinney et al., 2023). Starting with 1100 papers that cite one of the COMET papers, we obtain 417 papers from 2021 to 2024 that have an easily accessible PDF version.[3] We check if any of the *tables* contains the string `comet`. Within those papers, we check whether the COMET model information is contained in the PDF using a regular expression.[4] After further manual validation, we found that 50 of the examined papers do not report a specific COMET version. This establishes that *at least 12% of papers report COMET scores without specific model information.*

In addition, out of the almost 1000 papers running COMET in their evaluation, most only cite the first COMET paper (Rei et al., 2020a) instead of the paper that describes the specific models that are being used (Rei et al., 2020b, 2022b,a,c, 2023a,b; Glushkova et al., 2021; Wan et al., 2022; Alves et al., 2024; Guerreiro et al., 2023).

Recommendation. Always report the COMET version, ideally with a link. Also, cite the affiliated COMET paper as opposed to the first paper (Rei et al., 2020a), because different checkpoints have variations in training regimes that might be crucial in analysing the evaluation outcome.

[2] We accessed `gpt-4o-2024-08-06` via API in Aug 2024.

[3] Papers in 2020 did not have to report the specific model as there was only one available at the time. Further, we acknowledge potential bias to only papers with available PDFs.

[4] Case-insensitive: "`comet[ \-](da|20|21|22|23)|wmt(20|21|22|23)\-comet|xcomet\-|wmt\-da\-estimator`"

3.10 Discussions on other issues

Interpretation of significance. Statistical hypothesis test merely shows how likely the difference between the average of two model's scores on the same test set is caused by random fluctuation. Kocmi et al. (2024c) shows the significance of a difference between two metric scores can be made arbitrarily high and one can force $p \rightarrow 0$ by using a sizeable test set. This tells little about whether this difference is meaningful to a human reader. For this reason, we stress the use of `mt-thresholds` that converts differences in metric scores to how perceivable they are by human annotators.[5]

Averaging and subtracting COMET scores. Research nowadays favours experiments on multiple translation directions, as multilingual translation models and large language models become trendy. Recent papers are more often seen to report a (macro-)average COMET score as an aggregate measure across many directions, usually in Xx→En, En→Xx, and All→All. Whilst indicative, this is not entirely scientific because (1) the score range is inherently distinct for each translation direction and (2) there is no assurance that the scores are on a linear scale. Consequently, an outlying score in a single direction can distort the average, leading to a false claim. Likewise, absolute COMET score differences are not comparable if from different base numbers or directions. We suggest that, when multiple translation directions are of interest, in addition to averaged scores, practitioners can report the number of wins (against another system) as another aggregation of individual scores.

Optimizing to COMET. Owing to COMET's strong correlation with human judgement, recent works investigate the feasibility of using it in translation modelling directly. These strategies either include COMET in a distillation workflow (Finkelstein and Freitag, 2024; Guttmann et al., 2024), as a data filtering method (Peter et al., 2023), as a decoding method (Freitag et al., 2022a; Fernandes et al., 2022; Vernikos and Popescu-Belis, 2024) or as a training objective (Yan et al., 2023).

Nevertheless, COMET may cease to be a good measure if practitioners over-optimize a system towards it. As Yan et al. (2023) demonstrated, a model trained towards COMET can generate "universal translations" (hallucinations) preferred by COMET regardless of the source sentence. Recently, using COMET-based MBR decoding has become prevalent in shared tasks. For example, Unbabel-Tower70B at WMT24 also used MBR and dominated all automatic metrics but not so much under human evaluation (Kocmi et al., 2024a,b). MBR decoding could be seen as an automatic way to exploit bias in the scoring method, (currently COMET in most cases), so practitioners need to be aware of its shortcomings, disclose the use of such, and base system building on multiple (less correlated) metrics (Jon et al., 2023).

A novel issue is using automated metrics in human evaluation (Zouhar et al., 2024b) that collects data for metric training. This might create a similar effect as translationese in machine translation. The data could be biased by the particular quality estimator that is assisting annotators in the data collection process.

Sensitivity to sentence segmentation. Like most MT metrics, COMET works at the sentence level, but sometimes sentence-segmented input is not available. This is often the case in speech translation (ST) where sentence segmentation is treated as part of the task (Ahmad et al., 2024). To address the problem of mismatching segmentation between the system output and the reference, a common solution in ST is to re-segment the output using a minimum error rate method (Matusov et al., 2005) in order to force-align it with the reference. Forced alignment can introduce segmentation errors resulting in truncated (thus grammatically incorrect) sentences. There is evidence that COMET, as a metric reliant on sentence embeddings, is more sensitive to segmentation errors than string-based metrics, like BLEU, which rely purely on n-gram overlaps with no linguistic notion of a sentence (Amrhein and Haddow, 2022). In a recent comparison of COMET with human ranking, Sperber et al. (2024) suggested that COMET-based ranking is robust to segmentation errors but that a "more thorough study of this issue is needed".

Other metrics. Our work focused on COMET, the current most popular family of MT metrics. Nonetheless, our recommendations could apply to other neural metrics, like MetricX-23 (Juraska et al., 2023), because many issues we outlined are due to their statistical learning nature. Even beyond this, metric reporting and score interpretation in practice, e.g. software usage or averaging across multiple directions, can be problematic for string-matching metrics like BLEU or chrF too.

4 The SacreCOMET Package

To help alleviate problems in Sections 3.1 (software version), 3.2 (compute precision), and 3.9 (model reporting), we release a simple package sacreCOMET with two functionalities. Given a model name, the first functionality attempts to find the appropriate citation including a link to the paper and a BibTeX:

```
$ pip install sacrecomet
$ sacrecomet cite Unbabel/xcomet-xl

https://arxiv.org/abs/2310.10482
@misc{guerreiro2023xcomet,
 title={xCOMET: Transparent Machine
     Translation Evaluation through Fine-
     grained Error Detection},
 ...
```

The second functionality semi-automatically detects the local software versions to generate a signature for better reproducibility. Both functionalities can also be run in interactive mode.

```
$ sacrecomet --model unite-mup --prec fp32

Python3.11.8|Comet2.2.2|fp32|unite-mup
```

5 Future Work on Learned Metrics

- **Fixing data bias**: Learned metrics are sensitive to the training data distribution. Future metrics should aim to reduce the bias caused by the data selection process such that they are applicable to a range of MT systems.

- **Interpretability across languages**: Currently, practitioners cannot compare, or pedantically, aggregate scores in different translation directions. It would be useful to unify the scores to a single scale that can be interpreted independent of the language (similar to Kocmi et al., 2024c), e.g. to indicate X% of segments are production-ready.

- **Confidence-aware metrics:** As seen in works of Glushkova et al. (2021); Fomicheva et al. (2020b), it is possible to build metrics that output a confidence interval, though its usage in evaluation and modelling remains scarce.

- **Inference speed:** Learned metrics are getting better but at the cost of bulky models and increased inference time. These overheads should be taken into account when developing new models, such as the work of Rei et al. (2022b).

- **Representations:** Current COMET models are built upon off-the-shelf multilingual encoder models which are likely trained on human-written texts. However, this could bring in a domain mismatch—when translation hypotheses act as the input to metric models, they are not human-written but machine-translated.

- **Robustness**: Metrics should have the correct behaviour even in corner cases, be it empty output or incorrect language. Mapping all inputs (Amrhein et al., 2022, *inter alia)*, including partial or adversarial ones, evaluating the metrics, and coming up with methods to make them more robust would increase the metrics' adoption and trust.

- **Built-in QE:** In production, machine translation and quality estimation are commonly two different processes. In many applications, however, a single QE model is used for a single MT model. Quantifying how much is QE adaptation to a particular MT model useful is beneficial for a holistic understanding of QE metrics. Further, proposing methods for supervised quality estimation built into the MT could ease industry adoption. Beyond the work of Tomani et al. (2024), this remains largely unexplored.

- **Noise-aware training:** Human annotations are notoriously noisy. At the scale of WMT data, poor-quality annotations are unavoidable. The inter-annotator agreement for even robust annotations, such as ESA, remains low at $\tau_c{\approx}0.3$. The effect of data quality on learned metrics is so far unknown and methods for noise/uncertainty-aware training are under-studied.

6 Conclusion

COMET is currently one of the most powerful automatic metrics/quality estimators for machine translation, consistently achieving the top correlation with human judgement. In comparison to previous metrics, it is a statistical learning model and thus inherits all the related problems in addition to possible technical misconfigurations. We urge practitioners to consider more deeply the use of COMET in non-standard scenarios especially where such training bias might come into play. Beyond these issues, there has been confusion in the literature in reporting the correct COMET model and its correct setting. For improved consistency, we release an easy-to-use tool to assist practitioners.

Acknowledgments

A Batch size and GPU/CPU

We run the test inference on a combination of GPU or CPU with varying batch sizes (BS, 1 or 100). Results in Table 11 demonstrate that the tiny effects of these choices are negligible for COMET reporting.

Difference	MAE
BS=1, GPU – BS=1, GPU	0
BS=1, GPU – BS=64 GPU	2×10^{-7}
BS=1, GPU – BS=1, CPU	4×10^{-7}
BS=64, GPU – BS=64, CPU	4×10^{-7}

Table 11: MAE between segment-level COMET$_{22}^{\text{DA}}$ scores under various inference settings. The "BS=1, GPU" setting in the first row was run twice.

B Distribution of COMET scores for empty and valid hypothesis

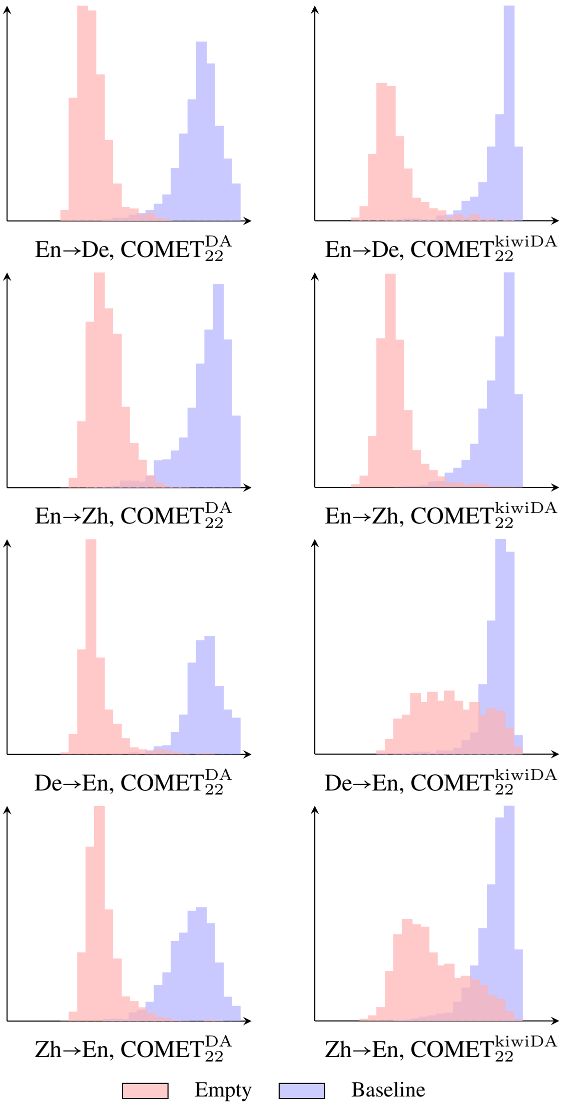

Figure 4: Distribution of instance-level scores for empty and baseline translations (x-axis: score; y-axis: count).

Abstract

Preference Optimization (PO) techniques are currently one of the state of the art techniques for fine-tuning large language models (LLMs) on pairwise preference feedback from human annotators. However, in machine translation, this sort of feedback can be difficult to solicit. Additionally, Kreutzer et al. (2018) have shown that, for machine translation, pairwise preferences are less reliable than other forms of human feedback, such as 5-point ratings.

We examine post-edits to see if they can be a source of reliable human preferences by construction. In PO, a human annotator is shown sequences s_1 and s_2 and asked for a preference judgment, while for post-editing, editors *create* s_1 and know that it should be better than s_2. We attempt to use these implicit preferences for PO and show that it helps the model move towards post-edit-like hypotheses and away from machine translation-like hypotheses. Furthermore, we show that best results are obtained by pre-training the model with supervised fine-tuning (SFT) on post-edits in order to promote post-edit-like hypotheses to the top output ranks.

1 Introduction

The current state of the art methods for training large language models offline on human preference data are Direct Preference Optimization (DPO) (Rafailov et al., 2023) or Identity Preference Optimization (IPO) (Gheshlaghi Azar et al., 2024). Instead of training a separate reward model and then performing reinforcement learning, these methods train directly on the collected preference data by deriving a directly optimizable loss function from the preference model.

However, in some domains, the pairwise preference annotations required for using these methods have been found to be less reliable than other annotation schemes. Kreutzer et al. (2018) find that inter-rater reliability for pairwise ranking of machine translation outputs to be less than that of 5-point rating. In the field of translation, there are many different dimensions on which one translation may be better than another, e.g. fluency, faithfulness, formality, terminology, etc. (Lommel et al., 2013). This poses a problem for human annotators when they are presented with two plausible translations.

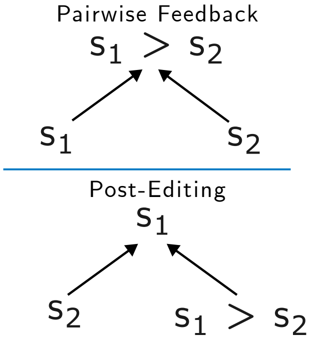

Figure 1: The generative process for preference optimization is that two sequences s_1 and s_2 are given, and a preference judgment $s_1 > s_2$ is generated (upper graph). The data generating process of post-editing yields reliable preferences by construction: Given s_2 and the implicit preference that $s_1 > s_2$, create s_1 (lower graph). We propose using the implicit preferences from post-editing for preference optimization.

We propose using the data generated by post-editing to yield reliable preferences by construction. The current generative process for preference data is that two sequences s_1 and s_2 are given, and a preference judgment $s_1 > s_2$ is sought, yielding the generative process $s_1 \rightarrow s_1 > s_2 \leftarrow s_2$. We propose using data generated by the following process: Given s_2 and the implicit preference that $s_1 > s_2$, create s_1, yielding the generative process $s_1 > s_2 \rightarrow s_1 \leftarrow s_2$ (see Fig. 1).

Post-editing is already a common practice in the translation community to clean up raw-MT outputs before publishing. Post-editors create new sequences that they prefer with regards to the qual-

Proceedings of the Ninth Conference on Machine Translation, pages 1289–1300
November 15-16, 2024 ©2024 Association for Computational Linguistics

ity expected in their domain. Typically, the original raw-MT output is discarded and the post-edit is published. If this data is used for training, the post-edit is treated as a new reference for supervised fine-tuning (SFT). This ignores, however, the fact that the post-edit is not just a new reference translation but also a quality judgment of what in the raw-MT was erroneous. Using PO objectives allows us to fine-tune an LLM to translate in a way that is more in line with the post-editors' implicit preferences. However, PO does not necessarily promote the preferred sequence to become the argmax output of the model, but rather re-ranks sequences within the model's probability space. If the two sequences are both unlikely under the model's output distribution, they will remain unlikely but their relative probability will respect the preferences. We show that best results are obtained by pre-training the model on post-edits with SFT, promoting post-edits to the top ranks, followed by fine-tuning with a PO loss. This combined training teaches the model to prefer and promote post-edits such that reference-like translations are produced but also dispreferred machine-translation-like hypotheses are avoided.

2 Related Work

Kreutzer et al. (2018) gather human feedback on machine translation outputs in the form of 5-point ratings and as pairwise preferences. They then use this feedback to train two reward models, one that is trained on the 5-point ratings and is trained with a regression loss to directly predict a reward value and one that is trained on pairwise preferences by fitting a Bradley-Terry model (Bradley and Terry, 1952) to the preferences as had been done by Christiano et al. (2017). These reward models are then used to train machine translation models. Kreutzer et al. (2018) find that ratings are more reliable than rankings and that reinforcement learning with a ratings-trained reward estimator yields better results than using rankings-trained reward estimates.

Berger et al. (2023) fine-tune a pre-trained NMT model on post-editing data by presenting the model with both the post-edit and the current MT hypothesis. At each epoch, the NMT model being trained generates translations for all training data. These generated outputs are then compared to the original post-edits with a token-level diff. Both sequences are then used as training examples for the NMT system. However, tokens that appear in the hypothesis but not the post-edit are given a negative weight in the loss function. On examples where the two sequences differ, the model gets both negative feedback, where the probability of that token is to be decreased, and positive feedback, where the probability should be increased.

Xu et al. (2024b) similarly present the model with a positive and negative example of machine translation outputs during training but use a modified version of the DPO (Rafailov et al., 2023) loss to optimize it. Their change to DPO adds an SFT term. The SFT term promotes the preferred sequence to be the argmax output of the model while the DPO part of the loss establishes the distance between the two sequences in log-probability space. The MT hypotheses that they generate come from two different LLMs; ALMA-13B-LoRA (Xu et al., 2024a) and GPT-4 (OpenAI et al., 2024). Additionally, they use reference translations from the original dataset. The preferences that they use are predicted by open-source quality estimation models KIWI-XXL (Rei et al., 2023) and XCOMET (Guerreiro et al., 2023).

3 Preference Optimization

3.1 Background

Using reinforcement learning with human feedback (RLHF) has recently re-emerged as a method for training LLMs to generate outputs that are preferred by human annotators (Ziegler et al. (2019), Ouyang et al. (2022), Bai et al. (2022), inter alia) without requiring handwritten demonstrations of preferred behavior which would be required for supervised fine-tuning (SFT). The general recipe is as follows: pre-train an LLM on in-domain data; generate multiple completions y for a single input x (or prompt); have human annotators rank or rate the completions; train a reward model to predict rankings or ratings given inputs and completions; use the trained reward model to predict rewards for reinforcement learning, frequently with proximal policy optimization (Schulman et al., 2017). Training a separate model to predict rewards for reinforcement learning is known as an actor-critic method.

The reward model in the previous works is structured as a Bradley-Terry model (Bradley and Terry, 1952), where the probability of preferring y_1 over y_2 is given by

$$p(y_1 \succ y_2|x) = \sigma(r_\theta(x, y_1) - r_\theta(x, y_2))$$

where σ is the logistic function and r_θ is the reward model that is trained on the pairwise rankings to give the preferred sequence a higher value. The reward model can then be used to estimate rewards for outputs sampled during online training.

This process requires training an additional model and hiring human annotators to perform ranking. DPO (Rafailov et al., 2023) is a technique that obviates the need for a secondary model by instead giving the model both the preferred and dispreferred sequences and optimizing a distance between the two sequence in log-probability space.

If handwritten demonstrations of preferred sequences are available, then SFT would typically be performed. The goal of SFT is to maximize the probability of the demonstrations under the model. For text generation, this is done by minimizing the negative log-probability of each token given all previous tokens in the sequence.

$$\mathcal{L}_{SFT}(y) = -\sum_{i=0}^{|y|} \log(\pi(y_i|y_{0:i-1}))$$

Minimizing this loss promotes the sequence y to be the argmax output of the model, while reinforcement learning increases or decreases the probability of a sequence with regard to the magnitude of its reward.

3.2 PO Objectives

The DPO loss (Rafailov et al., 2023) is based on the Bradley-Terry model of human preferences but, unlike actor-critic reinforcement learning techniques, it does not train a separate reward model. Instead they rewrite the reward function r in terms of the optimal policy and the baseline model. They notice that the theoretically optimal policy π_r, with a KL-divergence constraint, is equal to the baseline model with its output distribution re-weighted according to the reward function

$$\pi_r(y|x) = \frac{1}{Z(x)}\pi_{ref}(y|x)\exp\left(\frac{1}{\beta}r(x,y)\right)$$

where Z is the partition function, which normalizes the function to be a proper probability distribution. This formula can also be solved for the reward function r, such that rewards are expressed as the difference between two models' probability ratios. If this r is then inserted back into the Bradley-Terry model, it becomes

$$p(y_w \succ y_l|x) =$$
$$\sigma\left(\beta\log\left(\frac{\pi^*(y_w|x)}{\pi_{ref}(y_w|x)}\right) - \beta\log\left(\frac{\pi^*(y_l|x)}{\pi_{ref}(y_l|x)}\right)\right)$$

where y_w and y_l denote the preferred and dispreferred completion, respectively, and π^* is now the model we are training to be optimal under the reward function. This probability, $p(y_w \succ y_l|x)$ can be optimized by minimizing the negative log-probability. With regards to output probability, the loss monotonically decreases as y_w becomes more probable than y_l. Increasing the difference between the two always decreases the loss.

Gheshlaghi Azar et al. (2024) re-derive a similar loss with some theoretical advantages. Instead of training the model to be optimal under the Bradley-Terry derived reward function, they train the model to separate the two outputs by a fixed difference in log-probability space.

$$\mathcal{L}_{IPO}(y_w, y_l, x) =$$
$$+\left(\left(\log\left(\frac{\pi^*(y_w|x)}{\pi_{ref}(y_w|x)}\right) - \log\left(\frac{\pi^*(y_l|x)}{\pi_{ref}(y_l|x)}\right)\right) - \frac{1}{2\beta}\right)^2$$

Because this loss function is minimized when the log-probability ratio difference is exactly $(2\beta)^{-1}$, and will increase when the outputs move further apart in log-probability space, the authors claim an advantage for deterministic preferences, where the same preferences are seen multiple times during training. Because the preferences that we use are deterministic, we opt for the IPO paradigm of PO.

A follow-up work to DPO, focused specifically on machine translation, additively combines the DPO loss and the SFT loss (Xu et al., 2024b), which the authors call Contrastive Preference Optimization (CPO). Additionally, they perform an ad-hoc modification of the DPO loss by dropping the normalizer π_{ref} in the DPO loss so as to not perform a second forward pass on the reference model.

$$\mathcal{L}_{CPO}(y_w, y_l, x) = -\log(\pi^*(y_w|x))$$
$$-\log(\sigma(\beta\log(\pi^*(y_w|x)) - \beta\log(\pi^*(y_l|x))))$$

We use a reformulation of the CPO loss with the IPO training objective for our experiments because our preferences are deterministic. Additionally, we keep the normalizers in the IPO loss because these can be pre-computed in advance, instead of in a second forward pass, and incur only a negligible memory and speed penalty.

Our modified variant of the CPO loss, which we call dDPO for the deterministic preferences involved in post-editing, is

$$\mathcal{L}_{dCPO}(y_w, y_l, x) = -\log(\pi^*(y_w|x))$$
$$+\left(\left(\log\left(\frac{\pi^*(y_w|x)}{\pi_{ref}(y_w|x)}\right) - \log\left(\frac{\pi^*(y_l|x)}{\pi_{ref}(y_l|x)}\right)\right) - \frac{1}{2\beta}\right)^2$$

which is the SFT objective added to the IPO objective. When we refer to dCPO later in this paper, we are referring to this modified version of the CPO objective.

Table 1: Token level metrics comparing the WMT APE datasets' machine translations to the post-edits.

We fine-tune an LLM for the task of machine translation under five different conditions: SFT, IPO, dCPO, and pre-training with SFT followed by either IPO or dCPO, denoted as SFT→IPO and SFT→dCPO, respectively, and evaluate with the neural metrics XCOMET (Guerreiro et al., 2023) and MetricX (Juraska et al., 2023). Rafailov et al. (2023) pre-train their large language models on in-domain data such that they are already able to perform the requested task to begin with. For the task single-turn dialogue, they use the Anthropic Helpful and Harmless dialogue dataset but because no pre-training data is available, they perform SFT on the helpful answers as a pre-training step. This is similar to our conditions SFT→IPO and SFT→dCPO.

The LLM that we choose to fine-tune is Tower-Base by Alves et al. (2024). We make this choice because it is a multi-lingual LLM pre-trained on all languages we intend to work with and because the size of the model is still small enough to perform a full fine-tune with our resources[1]. We opt for Tower-Base instead of Tower-Instruct because Tower-Instruct has been instruction fine-tuned for various down-stream tasks and not just for machine translation. Using Tower-Base instead allows us to perform a SFT step on our own. We fine-tune in all scenarios with a minimal prompt "Translate English to German.\nEnglish: {Source}\nGerman:" for our German examples. Our Russian examples use a prompt with the language name changed. This prompt is used for both SFT and PO training objectives.

Our post-edits come from WMT Automatic Post-Editing (APE) shared tasks of previous years. These datasets contain triples of source, machine-translation (MT), and post-edit (PE). We focus on the language pairs En→De from 2020 and En→Ru from 2019. The En→De source data comes from Wikipedia and is translated by a black-box NMT system (Chatterjee et al., 2020). The En→Ru data comes from the information technology domain from Microsoft Office localization work and was translated by Microsoft's production NMT system (Chatterjee et al., 2019). The En→Ru data contains base64 encoded data and sequences long enough to cause out of memory errors. We therefore filter out sequences with fewer than 4 tokens, more than 128 tokens, or more than 500 characters from the En→Ru training data, leaving 9290 (source, mt, pe) triples for training. The En→De training data was already clean and all 7000 (source, mt, pe) triples were kept for training.

Table 1 shows the performance of the datasets' machine translations when compared to their post-edits in terms of token based metrics, BLEU, TER, and CHRF (Papineni et al. (2002), Snover et al. (2006), and Popović (2015)). We see that more edits were made to the German machine translations compared to the Russian machine translations. The Russian data has far more unedited sequences—of the 9290 examples we have in our Russian training data after filtering, 5263 are unedited or 56.7%. To compare, of the 7000 German training examples, 448 are unedited or just 6.4%. We keep the unedited data for training as the SFT and dCPO objectives can still take advantage of unedited data, but filter it out for our analysis later as it is impossible for a model to prefer an unedited "post-edit" over the machine translation.

We train with fully-sharded data parallelism (FSDP) in PyTorch using Accelerate (Gugger et al., 2022) across four GPUs with an effective batch size of 256 sequences. When possi-

[1] We train on a server with 4x Nvidia A40 GPUs with 48 GB of memory each. The system contains 256GB of RAM and 64 CPU cores.

Table 3: MetricX 23 XL results with and without references on the WMT 2020 En->DE and 2019 En->Ru test sets. Lower values are better. Results appear in line with XCOMET-XL and -XXL and reinforce our previous results.

ble, we shared hyperparameters across all runs and datasets. For example, both IPO and dCPO have β set to 0.1. Full hyper-parameters can be found in the Appendix A. We used reference-free XCOMET-XL as an early stopping criterion, which was run at the end of each epoch. During generation, we used greedy decoding.

Because PO techniques requires seeing both the preferred and the dis-preferred sequence during the same optimization step, we concatenate them together along the batch dimension so that both sequences are processed in the same forward pass. This doubling of sequences in each batch requires that the number of training examples per batch be halved and the number of gradient accumulation steps be doubled in order to have the same effective batch size. This incurs no additional memory penalty but doubles the time to see the same number of training examples.

Our initial experiments showed that string-based metrics actually decrease when using PO techniques but we did not observe a discernible quality difference. This is in line with the observations reported by (Xu et al., 2024b). Therefore, we evaluate with neural metrics so that evaluation could not be biased towards models that produce superficially similar translations. We evaluate with XCOMET-XL and -XXL (Guerreiro et al., 2023) and MetricX 23 (Juraska et al., 2023), both with and without references.

5 Results

Our XCOMET metric results are shown in Table 2. The evaluation shows that Tower Base is already competent at performing zero-shot translation for English to German, achieving reference-free XCOMET-XL and -XXL scores that are above the MT hypotheses contained in our dataset; 94.33 and 94.75, respectively. This is in spite of the fact that the model has not yet been instruction fine-tuned to perform zero-shot translation.

The lack of instruction fine-tuning is made obvious in the English to Russian results, where the model is unable to translate well prior to fine-tuning. Specifically, the Tower Base model frequently translated its instructions to Russian and ignored the source text, yielding lower scores. XCOMET-XL and -XXL seem to react differently to these non-translations with XCOMET-XXL punishing them more severely than XCOMET-XL.

Supervised fine-tuning is able to reach the level of the post-edits contained in the APE datasets when evaluating with reference-free evaluation. SFT surpasses the post-edits only with XCOMET-XL on the En→De data but this improvement is not significant. Here, we are evaluating the post-edits included in the dataset as if they were hypotheses for the source sentences.

IPO and dCPO are able to improve XCOMET-XL and -XXL scores for En→De above what the post-edits achieve, but only for -XXL is this improvement significant, as evaluated by pairwise bootstrap resampling implemented in the COMET package. For En→Ru, only dCPO is able to surpass post-edits and even then only for XCOMET-XL.

However, once we initialize the PO methods with the SFT model, we find our best results. SFT→dCPO is significantly better than both the MT and PE data from the dataset, the Tower Base model, and the SFT model for both En→De and Ru; while for just En→Ru, it is better than all other systems.

	$PE - MT$		
Model	Train	Dev	Test
Base	0.038	0.048	0.049
SFT	0.060	0.070	0.073
IPO	0.120	0.124	0.134
dCPO	0.110	0.115	0.124
SFT→IPO	0.144	0.144	0.157
SFT→dCPO	0.138	0.138	0.150

Table 4: This table shows the average values of the post-edit log-probabilities minus the machine translation log-probabilities for the English→German data. We see that the gap between PE and MT increases more with PO than it does with SFT.

Results with references do not differ drastically and can also be found in Table 2. We also evaluate with MetricX 23 XL (Juraska et al., 2023) and show our results in Table 3. The relations follow those of XCOMET and reinforce our conclusions.

6 Analysis

In addition to evaluating the fine-tuned models with neural metrics, we analyze the behavior of the models after training to see how the log-probabilities of the two sequences change compared to the baseline model. Additionally, we use the log-probabilities as a measure for model preferences. If one sequence is more probable, it is preferred by the model.

In our analysis, we remove machine translation and post-edit pairs where the post-edit remains unedited. This is because we are looking for differences in model behavior between machine translations and post-edits, which can not be done when they are the same sequence.

6.1 Log Probability Changes

Figures 2 and 3 are split violin plots showing the difference between log-probabilities before and after training, for German and Russian respectively. The left side of each violin shows the post-edit sequences' change from the baseline model's while the right side shows the machine translations' difference. This way we can examine how each training method affects the two sequence types individually. Additionally, we also measure the difference between the post-edits and machine translations after training in Tables 4 and 5 for German and Russian, respectively.

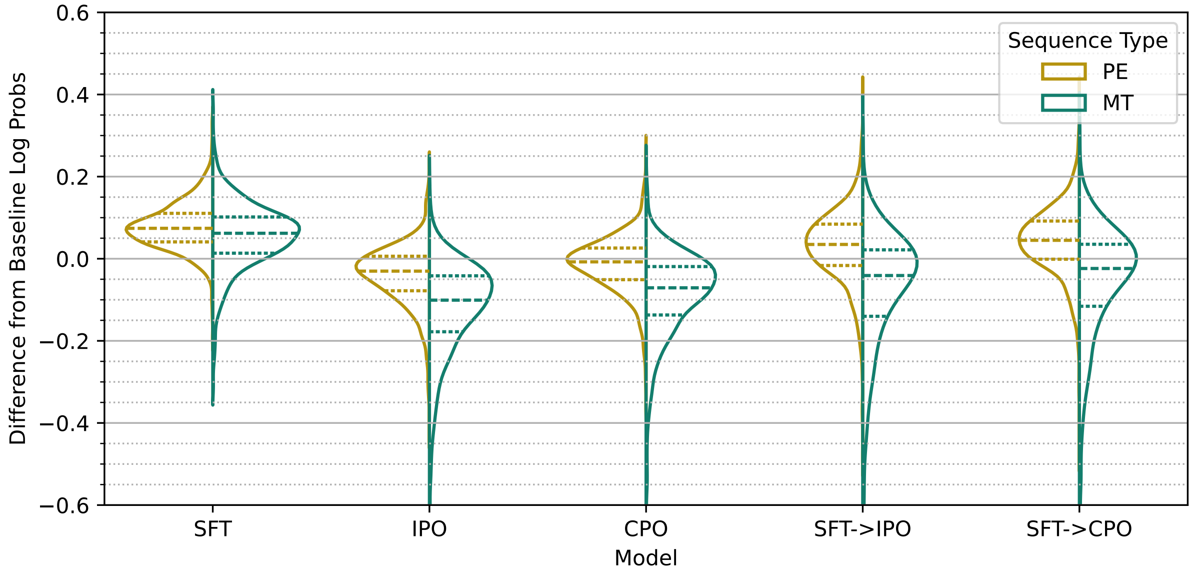

Figure 2: The difference of the models' averaged sequence log-probabilities from the baseline model's on the WMT 2020 En→De test data. Zero for PE is an average log-probability of -0.516 while for MT it is -0.565. This violin plot then shows displacement from these baseline values. Dashed horizontal lines indicate quartiles.

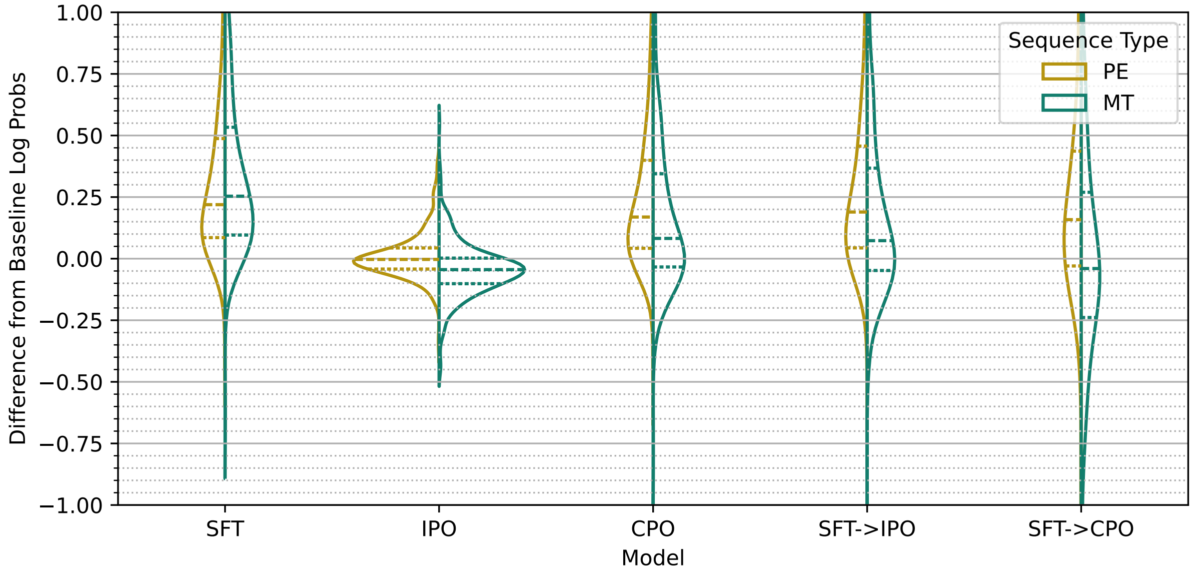

Figure 3: The difference of the models' averaged sequence log-probabilities from the baseline model's on the WMT 2019 En→Ru test data. Zero for PE is an average log-probability of -1.099 while for MT it is -1.260. This violin plot then shows displacement from these baseline values. Dashed horizontal lines indicate quartiles.

As we see in Figure 2, if we perform SFT on post-edits, as would typically be done when treating post-edits as new references, *both* the post-edits and the MT outputs become more likely under our fine-tuned model. Because the post-edits and MT outputs are highly correlated, they likely reside very close to each other in the model's hidden representation. This means, that with a smooth mapping from hidden representations to outputs, increasing the probability of the PE will also increase the probability of the MT sequence.

For the En→De IPO and dCPO runs, we see the post-edits stay close to the baseline while the MT is pushed further down in log-probability space. Additionally, the distance between the two sequences increases under PO compared to SFT. As shown in Table 4, the average distance that PEs are above MT outputs doubles after PO compared to SFT.

After the IPO training, both sequences become less likely as seen in the split violin plot for IPO in Figure 2. This method does not have the upwards pressure on the preferred sequences that SFT or dCPO does, so we hypothesize that the downward pressure on the MT output also drags the PE sequence down as well; similar to how SFT increases the probability of MT without training on it. Alternatively, it could be that in order to establish a greater distance between the sequences, probability mass has to be re-allocated to other possible sequences.

With the En→Ru data, we see that the MT sequences benefit *more* from training than the PE sequences do, even though they remain unseen, as shown by the violin plot for SFT in Figure 3. This corresponds to the smaller difference between PE and MT that we see for SFT when compared to Tower Base in Table 5. The need for more fine-tuning of the Tower Base model is also visible in the SFT, SFT-initialized, and dCPO models' larger displacement from the Tower Base log-probabilities. IPO remains close to the 0 point for both sequences because the only pressure for each sequence is for them to move further apart; which is more difficult with the large overlap between the machine-translations and post-edits.

En→Ru appears similar for IPO, where both sequences are moved down in log-probability space, however the violin plot for dCPO and the SFT initialized models have a displacement from the baseline similar to SFT. This is because the baseline model was unable to perform zero-shot translation for En→Ru and, since the dCPO loss includes an SFT term, it learned how to translate which moved all sequences upwards. Unlike SFT, post-edits benefit more than machine translations after dCPO training.

Finally for the En→De SFT initialized models, we see in Figure 2 that post-edits increase in probability over the baseline while machine translation outputs are held close to or below the baseline. The difference between PE and MT is increased here compared to the PO only conditions.

We find that this behavior generalizes also to the development and test sets as shown in Table 4. For En→Ru, the SFT→IPO model and the dCPO model both have post-edits and machine translation increase in likelihood compared to the baseline. This is again due to the baseline model being unable to perform zero-shot translation and both sequences become more likely after it is able to do so. SFT→dCPO appears similar but far more stretched out and with MT moved below the baseline. This model trained for much longer before reaching its early stopping criterion (SFT→dCPO stopped after 10 epochs, compared to SFT→IPO stopping after 2).

	$PE - MT$		
Model	Train	Dev	Test
Base	0.039	0.078	0.161
SFT	0.025	0.062	0.133
IPO	0.085	0.125	0.217
dCPO	0.101	0.140	0.240
SFT→IPO	0.110	0.151	0.263
SFT→dCPO	0.192	0.242	0.419

Table 5: This table shows the average values of the post-edit log-probabilities minus the machine translation log-probabilities for the En→Ru data. We see that the gap between PE and MT increases more with PO than it does with SFT.

The largest improvements in our XCOMET-XL and -XXL scores coincide with training methods that both move the post-edit up in log-probability space while also ensuring that the machine translations are less likely by enough of a margin. SFT on its own also increases the probability of machine translations and does not work to establish a margin between the two sequences. Additionally, this shows us that PO successfully moves the model towards generating post-edit-like translations rather than those like the machine translations.

6.2 Preference Changes

Changes in log-probabilities from the baseline model do not necessarily indicate whether the models' preferences have changed. It could be that, in (mt, pe) pairs where it is already the case that $pe > mt$, the distances between pe and mt increased, but examples where $mt > pe$ did not have their ordering changed. To that end, we also examine the baseline model's preference in terms of sequence probability—if a sequence's average log probability is strictly greater than that of another sequence, it is preferred. We plot preferences across all data splits for En→De in Figure 4 and for En→Ru in Figure 5. The exact values with corresponding confidence intervals are in Tables 6 and 7, respectively.

For both language pairs, we find that the Tower Base model does not have strong preferences. On the En→De data set, it prefers post-edits to ma-

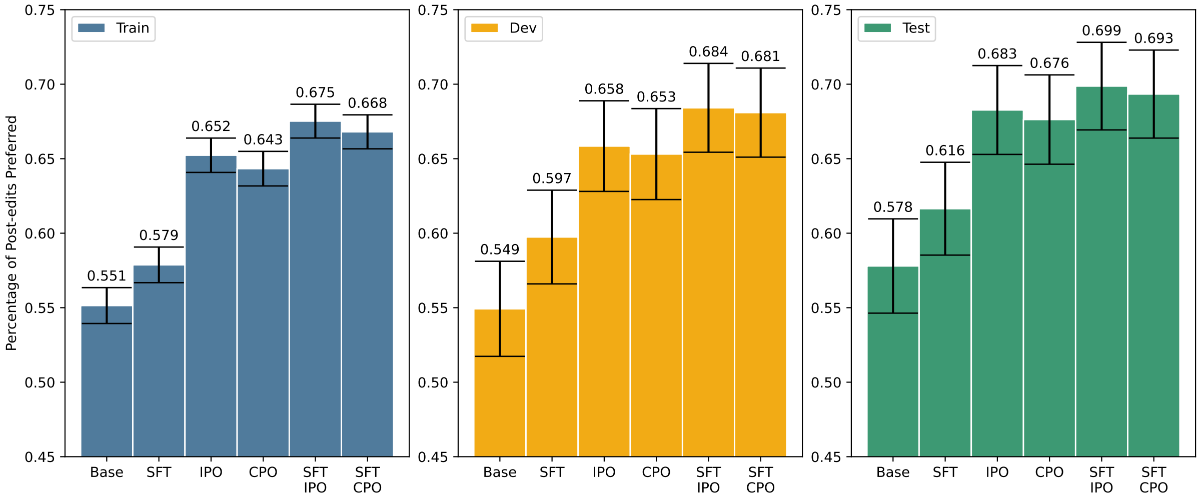

Figure 4: Here we show the percentage of training examples where the post-edit sequence is preferred in terms of average log-probability over the machine translation for the WMT En→De dataset. The black lines indicate the 95% confidence intervals for binomial distributed data—non-overlapping confidence intervals indicate a significant difference.

Method	**Train**	**Dev**	**Test**
Base	55.14% (53.94%, 56.35%)	54.93% (51.73%, 58.12%)	57.80% (54.64%, 60.96%)
SFT	57.88% (56.68%, 59.07%)	59.74% (56.60%, 62.89%)	61.65% (58.53%, 64.76%)
IPO	65.23% (64.08%, 66.39%)	65.85% (62.80%, 68.89%)	68.27% (65.29%, 71.25%)
dCPO	64.33% (63.17%, 65.49%)	65.31% (62.26%, 68.36%)	67.63% (64.63%, 70.63%)
SFT→IPO	67.52% (66.39%, 68.66%)	68.42% (65.43%, 71.40%)	69.87% (66.93%, 72.81%)
SFT→dCPO	66.80% (65.66%, 67.94%)	68.09% (65.10%, 71.08%)	69.34% (66.38%, 72.29%)

Table 6: Percentage of instances where post-edits are preferred over machine translations and their corresponding 95% confidence intervals for Train, Dev, and Test Splits for the WMT En→De 2020 APE Dataset. Non-overlapping confidence intervals correspond to statistically significant differences with $\alpha < 0.05$.

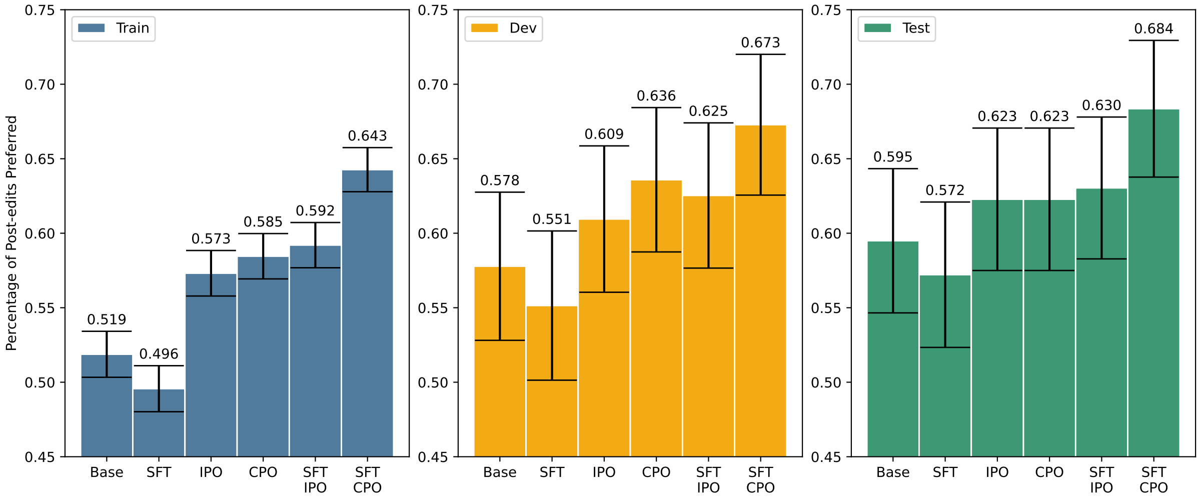

Figure 5: Here we show the percentage of training examples where the post-edit sequence is preferred in terms of average log-probability over the machine translation for the WMT En→Ru dataset.. The black lines indicate the 95% confidence intervals for binomial distributed data—non-overlapping confidence intervals indicate a significant difference.

chine translation 57.80% of the time on the test set

while for En→Ru this preference occurs 59.49%

Method	Train	Dev	Test
Base	51.87% (50.33%, 53.42%)	57.78% (52.81%, 62.76%)	59.49% (54.65%, 64.33%)
SFT	49.57% (48.02%, 51.11%)	55.15% (50.14%, 60.15%)	57.22% (52.34%, 62.09%)
IPO	57.31% (55.79%, 58.84%)	60.95% (56.04%, 65.86%)	62.28% (57.50%, 67.06%)
dCPO	58.46% (56.93%, 59.98%)	63.59% (58.74%, 68.43%)	62.28% (57.50%, 67.06%)
SFT→IPO	59.20% (57.68%, 60.72%)	62.53% (57.66%, 67.41%)	63.04% (58.28%, 67.80%)
SFT→dCPO	64.27% (62.79%, 65.75%)	67.28% (62.56%, 72.01%)	68.35% (63.77%, 72.94%)

Table 7: Percentage of instances where post-edits are preferred over machine translations and their corresponding 95% confidence intervals for Train, Dev, and Test Splits for the WMT En→Ru 2019 APE Dataset. Non-overlapping confidence intervals correspond to statistically significant differences with $\alpha < 0.05$.

of the time. For En→De, SFT significantly improves this preference on the training data but not on the development or test data. SFT actually seems to change the preferences in favor of machine translations on the En→Ru data; which also coincides with a decrease in the average distance between sequences and machine translations increasing in probability more.

When we train with IPO and dCPO on En→De, we find that both improve the preference for post-edits up to 68.27% on test data. The improvements above SFT are significant for both models on the train set while for dev, the confidence intervals overlap, and for test only IPO is significantly better. On En→Ru, we see a similar improvement in preferences but only on the training set are they significant.

Initializing with SFT and then training with PO on En→De yields the best improvements with 69.87% on test. Both SFT→IPO and SFT→dCPO are significantly better than SFT across all data splits. Again, En→Ru shows similar behavior with only the change on the training set being significant.

Across all data splits on En→De, IPO methods seem to establish a slightly stronger preference for post-edits which seems to be accounted for by increase in difference between the two sequence types as shown in Table 4. For En→Ru, dCPO is better at establishing this preference which also coincides with the increase in differences from Table 5.

7 Conclusion

Post-editing is part of common translation workflows before publishing to clean up raw-MT outputs. If the post-edits are used for training purposes, they are treated simply as new references and the MT output is treated as a by-product. Post-edits are created with an implicit preference in mind, that the PE should be better than the MT. We find that keeping both the PE and MT allows us to perform preference optimization techniques and improve translation quality with data that would otherwise be discarded.

We find that performing supervised fine-tuning using post-edits as references also increases the likelihood of the machine translations which remained unseen by the system. However, because the original machine translations were erroneous (in order to need correction), it is disadvantageous to increase their likelihood as well. Using PO techniques allows the model to establish a larger margin between the post-edit sequence and the machine translation sequence in log-probability space.

Increasing this margin coincides with significant improvements in neural translation metrics. We additionally find that we can measure the models' preferences in terms of sequence probability—if one sequence is more likely it is preferred. Models trained with SFT do not have a significant change in preferences compared to the baseline models but using PO teaches the model to prefer the post-edits above the machine translations.

In future work, we would like to examine the effect of the distance between post-edit and machine translation sequence probabilities. Currently, IPO sets a single distance for all sequence pairs but this may be sub-optimal when the sequences are correlated to different degrees. For example, if a post-edit and machine translation share a large prefix, the rest of the tokens in the sequences must account for the distance, while for non-overlapping sequences all tokens contribute to the distance between the log-probabilities.

A Hyperparameters

The hyperparameters for all runs are shown in Table 8. All hyperparameters are shared between runs.

Hyperparameter	Value
Max Epochs	20
Learning Rate	2e-6
Optimizer	AdamW
Learning Rate Scheduler	Cosine
Warm-up Ratio	0.1
Effective Batch Size	256
Max Gradient Norm	10.0
Mixed Precision	`bfloat16`
Early Stopping Criterion	XCOMET-XL w/o Refs
Early Stopping Patience	3
Early Stopping Epsilon	0.00001
Evaluation Frequency	Epoch
Max New Tokens	64
β*	0.1
Average Log-Probabilities	`True`
Normalize Loss	`True`

Table 8: Hyperparameters for all training runs. * indicates that this parameter only affects the preference optimization techniques

Translating Step-by-Step: Decomposing the Translation Process for Improved Translation Quality of Long-Form Texts

Abstract

In this paper we present a step-by-step approach to long-form text translation, drawing on established processes in translation studies. Instead of viewing machine translation as a single, monolithic task, we propose a framework that engages language models in a multi-turn interaction, encompassing pre-translation research, drafting, refining, and proofreading, resulting in progressively improved translations. Extensive automatic evaluations using Gemini 1.5 Pro across ten language pairs show that translating step-by-step yields large translation quality improvements over conventional zero-shot prompting approaches and earlier human-like baseline strategies, resulting in state-of-the-art results on WMT 2024.

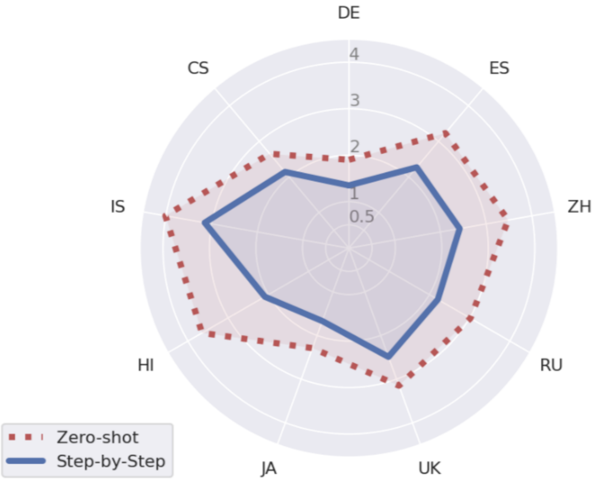

Figure 1: MetricX-23 quality improvements (where lower scores indicate better translation quality) on document-level translation on the WMT24 test set. Translate step-by-step with Gemini 1.5 Pro consistently outperforms zero-shot translation.

1 Introduction

Machine Translation (MT) has been traditionally seen as a sequence transduction task that maps a source text from one language to an equivalent translation in another language. While this simplified definition of the task served the modeling capabilities of statistical and neural machine translation systems for many years, recent advancements in large language modeling offer promise for redefining MT to align more closely with human translation processes. This shift prompts us back to a fundamental question: *what does a good translation process look like*?

Thankfully, this question has been a long-debated topic in the field of translation studies. Despite the lack of consensus around the nature of cognitive steps involved when humans translate, a common thread is apparent, i.e., translation is a multi-faceted *process* encompassing several sub-tasks that navigate a bilingual landscape. This view of translation finds a parallel in the rise of the "chain-of-thought" paradigm popularized by large language models (LLM) (Wei et al., 2022). That is, instead of attempting to generate the response to a complex task directly, LLMs are prompted to derive their final answer by decomposing the original task into several simpler sub-tasks.

But, what form would chain-of-thought take in the context of MT? While initial attempts to model the entire translation process using complex multi-stage processes has shown mixed results (Wu et al., 2024), explicitly modeling certain pre-translation or post-translation processes has led to more consistent gains in translation quality. On the pre-translation side, He et al. (2023) proposes to generate multiple translation candidates conditioned on self-generated translation-related knowledge. On the post-translation side, recent research threads prompt LLMs for refinement with (Feng et al., 2024; Xu et al., 2023b; Ki and Carpuat, 2024) or without (Chen et al., 2023) external quality estimation feedback.

Despite the promising results reported by prior work on decomposing and re-ranking MT with LLMs, it still remains unclear whether LLMs can

Proceedings of the Ninth Conference on Machine Translation, pages 1301–1317
November 15-16, 2024 ©2024 Association for Computational Linguistics

benefit from modeling the *entire spectrum of translation processes*. In this work, drawing on literature from translation studies, we view MT as a complex and iterative task adhering to distinct steps, i.e., pre-translation research, drafting, refining, and proofreading. Based on this framework, we ask: *How well can LLMs translate in a step-by-step manner that draws from translation processes*?

Taking Gemini 1.5 Pro (Reid et al., 2024) as a case study, we start by designing instruction prompts for various translation subtasks. Concretely, our framework implements a ***multi-turn*** interaction with Gemini that breaks down the translation process into four distinct stages. It begins by prompting the model to conduct background research that identifies potential challenges in translating the source text (***research*** phase). The next interaction focuses on drafting an initial translation prioritizing faithfulness to the source text (***drafting*** phase). This draft is then revised in subsequent turns, ensuring a polished final translation (***refinement*** and ***proofreading*** phases).

To align better with human translation processes, we test the *translate step-by-step* framework on long-form documents derived from the general MT shared tasks for WMT 2023 (Kocmi et al., 2023) and WMT 2024. We evaluate out-of-English translation for ten languages, namely Chinese (ZH), Ukrainian (UK), Russian (RU), Japanese (JA), Hebrew (HE), Czech (CS), German (DE), Hindi (HI), Icelandic (IS), and Spanish (ES). Extensive automatic evaluation according to both reference-based and QE-based versions of MetricX-23 (Juraska et al., 2023) show that translating step-by-step yields strong translation quality improvements across all languages and test sets studied (see Figure 1).

Table 1: List of prior work leveraging LLMs to improve translation quality by modeling either pre- or post-translation processes (PRE-TR. or POST-TR.). For each study we also note key aspects of their methodology: whether prompting strategies are developed on a separate development set (DEV.), whether the approach relies solely on the LLM's parametric knowledge (PARAM.), and the number of steps in the pipeline.

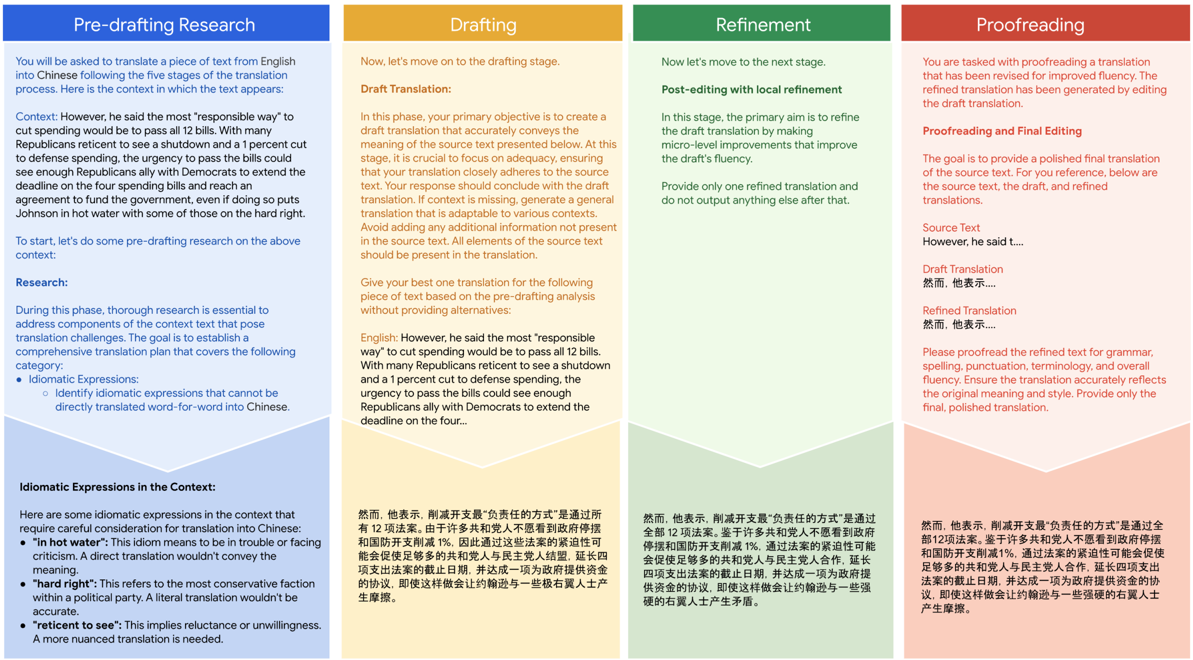
2 Background

With the recent rise of LLMs, machine translation is going through a gradual but significant paradigm shift. While much research is focusing on how LLMs' training data are improving their MT capabilities (Xu et al., 2023a; Alves et al., 2024), there are also many opportunities to improve how existing LLMs can be best used for translation. This becomes evident in recent research that explores ways to augment and refine MT to align better with human translation processes. To navigate the diverse landscape of LLM-driven research, we summarize key studies in Table 1 along their four most distinct dimensions:

- **Temporal Focus**: This differentiating factor is based on whether an LLM is engaged in the translation process before (pre-translation) or after (post-translation) an initial translation is produced (whether by the same LLM or a different system).
- **Parametric vs. External Knowledge**: This dimension focuses on whether LLMs rely solely on their internal, learned knowledge (encoded in their parameters) or whether they use external resources, i.e., dictionaries, knowledge bases, retrieval engines or QE-based metrics (Mallen et al., 2023).
- **Reported Prompt Development**: This dimension considers whether the prompting strategies are clearly developed on separate development sets, as reported in papers.[1]
- **Number of Steps**: This dimension counts the number of distinct steps that are used in multi-turn interactions with the LLM.

Table 1 shows a clear trend: most studies focus on post-translation refinement. These approaches predominantly rely on external feedback to identify and correct errors, using either automatic met-

[1] We include this column not to cast aspersions on previous work, but to encourage a culture moving forward where prompt-based research uses and reports a development set. From personal communication, some of the works receiving an "✗" here underwent little to no prompt optimization.



Pre-drafting Research

You will be asked to translate a piece of text from English into Chinese following the five stages of the translation process. Here is the context in which the text appears:

Context: However, he said the most "responsible way" to cut spending would be to pass all 12 bills. With many Republicans reticent to see a shutdown and a 1 percent cut to defense spending, the urgency to pass the bills could see enough Republicans ally with Democrats to extend the deadline on the four spending bills and reach an agreement to fund the government, even if doing so puts Johnson in hot water with some of those on the hard right.

To start, let's do some pre-drafting research on the above context:

Research:

During this phase, thorough research is essential to address components of the context text that pose translation challenges. The goal is to establish a comprehensive translation plan that covers the following category:

- Idiomatic Expressions:
    - Identify idiomatic expressions that cannot be directly translated word-for-word into Chinese.

Idiomatic Expressions in the Context:

Here are some idiomatic expressions in the context that require careful consideration for translation into Chinese:

- **"in hot water":** This idiom means to be in trouble or facing criticism. A direct translation wouldn't convey the meaning.
- **"hard right":** This refers to the most conservative faction within a political party. A literal translation wouldn't be accurate.
- **"reticent to see":** This implies reluctance or unwillingness. A more nuanced translation is needed.

Drafting

Now, let's move on to the drafting stage.

Draft Translation:

In this phase, your primary objective is to create a draft translation that accurately conveys the meaning of the source text presented below. At this stage, it is crucial to focus on adequacy, ensuring that your translation closely adheres to the source text. Your response should conclude with the draft translation. If context is missing, generate a general translation that is adaptable to various contexts. Avoid adding any additional information not present in the source text. All elements of the source text should be present in the translation.

Give your best one translation for the following piece of text based on the pre-drafting analysis without providing alternatives:

English: However, he said the most "responsible way" to cut spending would be to pass all 12 bills. With many Republicans reticent to see a shutdown and a 1 percent cut to defense spending, the urgency to pass the bills could see enough Republicans ally with Democrats to extend the deadline on the four...

然而，他表示，削减开支最“负责任的方式”是通过所有 12 项法案。由于许多共和党人不愿看到政府停摆和国防开支削减 1%，因此通过这些法案的紧迫性可能会促使足够多的共和党人与民主党人结盟，延长四项支出法案的截止日期，并达成一项为政府提供资金的协议，即使这样做会让约翰逊与一些极右翼人士产生摩擦。

Refinement

Now let's move to the next stage.

Post-editing with local refinement

In this stage, the primary aim is to refine the draft translation by making micro-level improvements that improve the draft's fluency.

Provide only one refined translation and do not output anything else after that.

然而，他表示，削减开支最“负责任的方式”是通过全部 12 项法案。鉴于许多共和党人不愿看到政府停摆和国防开支削减 1%，通过法案的紧迫性可能会促使足够多的共和党人与民主党人合作，延长四项支出法案的截止日期，并达成一项为政府提供资金的协议，即使这样做会让约翰逊与一些强硬的右翼人士产生矛盾。

Proofreading

You are tasked with proofreading a translation that has been revised for improved fluency. The refined translation has been generated by editing the draft translation.

Proofreading and Final Editing

The goal is to provide a polished final translation of the source text. For you reference, below are the source text, the draft, and refined translations.

Source Text
However, he said t....

Draft Translation
然而，他表示....

Refined Translation
然而，他表示....

Please proofread the refined text for grammar, spelling, punctuation, terminology, and overall fluency. Ensure the translation accurately reflects the original meaning and style. Provide only the final, polished translation.

然而，他表示，削减开支最“负责任的方式”是通过全部12项法案。鉴于许多共和党人不愿看到政府停摆和国防开支削减1%，通过法案的紧迫性可能会促使足够多的共和党人与民主党人合作，延长四项支出法案的截止日期，并达成一项为政府提供资金的协议，即使这样做会让约翰逊与一些强硬的右翼人士产生摩擦。

Figure 2: Translate Step-by-Step prompting framework. User prompts (top) and Gemini's responses (bottom) for the translation of an English document into Chinese. The full prompts for each step also appear in §A.3.

rics (Feng et al., 2024; Xu et al., 2023b; Huang et al., 2024) or human annotations of translation errors (Ki and Carpuat, 2024). A notable exception is the study of Chen et al. (2023), which shows that LLMs can iteratively refine their own outputs using only their parametric knowledge.

Comparatively fewer studies explore the pre-translation stage, investigating how LLMs can utilize background information to enhance their translation quality. He et al. (2023) explores this by prompting LLMs for different types of background information (similar examples, topics and keywords) related to the source text. However, they find that this knowledge alone is insufficient to improve the model's translation quality, and ultimately rely on external QE feedback for selection. In contrast, Li et al. (2024) operationalizes background research by incorporating idiom definitions retrieved from an external knowledge base.

A notable exception to the above is the recent work of Wu et al. (2024) which, similar to our approach, explores modeling the entire spectrum of translation processes. While conceptually aligned with our step-by-step approach, their framework is significantly more complex, with 30 distinct LLM roles interacting iteratively. Their use of non-standard metrics makes it difficult to gauge the method's success: the human evaluation does not give annotators source or reference texts, while the bilingual automatic evaluation collects only preference decisions using the same model family as the method being tested.

Overall, in contrast to prior work, which often relies on complex multi-stage processes and external resources, our goal is to streamline the translation process, ***unifying pre- and post-translation stages within one framework, by accessing only the LLM's parametric knowledge throughout***. We emphasize the methodological soundness of our pipeline by developing it on a separate development set, a practice not yet standardized in this area.

3 Translate Step-by-Step

Drawing on existing literature on translation studies (Borg, 2018), we design a series of staged prompts that attempt to map the translation process to instructions. This approach views translation as a multi-turn interaction with an LLM where each prompt guides the model's next action. Below, we describe those stages, along with what their function in the translation process is and how they are operationalized as instruction-following tasks. These stages are further illustrated in Figure 2.

Pre-translation Research Mirroring the human translation processes, our framework incorporates a pre-translation research stage. This stage primarily focuses on using the source text (Mossop, 2000) to identify potential translation challenges drawing on real-world knowledge and knowledge of the target language (Dimitrova, 2005). We model this stage by prompting the LLM to identify and explain phrases of the source text that cannot be translated word-for-word into the target language.

Drafting Following the pre-translation research, the next stage aims at producing a draft translation, i.e., "the first stab at the rewriting" (Bassnett and Bush., 2016). This stage represents an initial attempt at rendering the source text into the target language. To that end, we initiate a subsequent interaction and prompt the model to focus on adequacy at this stage, ensuring the draft faithfully captures the meaning of the source.

Refinement The *post-drafting* stages are defined as editing tasks, with the goal of improving the overall quality of the draft translation. We define the first post-drafting stage as a subsequent interaction where the LLM is prompted to improve the draft's fluency such that the text works on its own (Borg, 2018).

Proofreading At the final, post-drafting stage, we task the LLM with the role of proofreading the refined translation to ensure it delivers a polished translation. We model this stage as a new conversation with the LLM, rather than a subsequent interaction, drawing inspiration from human studies suggesting that proofreading requires a new perspective after a break from revising (Shih, 2013).

3.1 Lessons During Development

While developing the above method, we found two factors to be important for the success of this approach: working at the document level and representing multi-step interactions as conversations.

Working at the Document Level Our multi-step process became more effective as we moved from the segments provided by WMT to working on multi-segment documents (see §4 for details on the setup). This had a large effect on the pre-translation research step, changing it in two ways. First, some phrases that appeared idiomatic or difficult at the segment level disappeared, as their translations became clear with context. Second, the LLM began identifying larger phrases. The refinement step also improved according to automatic metrics. We verified that our shift to the document level was either neutral or an improvement for our baselines (§5.3).

Domain	Literary	News	Social	Speech
# Docs.	40	43	48	111
Avg. Length	192	184	164	73

Table 2: Per-domain statistics for WMT 2024.

Multi-step Interactions as Conversations Modern LLMs use special markers to indicate human versus assistant turns in multi-turn interactions. When building an automated process like translate step-by-step, for each step, one has the option to either use previous outputs to build a completely new query that summarizes all previous interactions, or to continue the conversation, allowing the LLM to see all previous steps with its own outputs clearly marked. With the exception of the proofreading step, we found that continuing the conversation improved performance. Also, breaking the conversation into smaller turns helps with modularity for ablations.

4 Experimental Setting

We start by evaluating the translate step-by-step approach on the task of document-level translation. The experimental setting is described below.

Model Settings Throughout our experiments we use Gemini 1.5 Pro. All model outputs are generated with greedy decoding. All model prompts are provided in Appendix A.3. In zero-shot mode, the model is instructed to translate the source text directly, without providing any explanations.

To effectively isolate the artifacts from pre-translation research, we employ a secondary model call. This call restructures the natural language output into a JSON object, simplifying the parsing process for extracting artifacts.

Evaluation Sets We use WMT 2023 as our ***development*** set. Any prompt development and stage ablation experiments are conducted on this dataset. For our final ***test*** set, we use the WMT 2024 datasets. Each of these datasets was built by translating a set of English documents into multiple languages.

Both datasets are segmented for sentence- or paragraph-level evaluation, but our approach focuses on translating with as much context as possible. Therefore, we use meta-data to merge the original segments into larger ones. Ideally, this would result in complete documents, but current neural metrics have token-count limits beyond which they truncate their inputs. To accommodate neural evaluation, we set a maximum length of 250 (English

Table 3: MetricX-23 evaluation results of translate step-by-step and its ablation variants on the WMT 2023 development datasets. We report both the reference-based and QE-based metric variants. Filled dots indicate active steps in the pipeline, while unfilled dots represent ablated steps. When all steps are ablated, the system defaults to zero-shot translation. Colored boxes highlight performance differences compared to zero-shot: blue shades indicate significant improvements at $p < 0.001$, green shades indicate significant improvements at $p < 0.05$, yellow shades indicate non-significant improvements ($p \geq 0.05$), while red shades indicate non-significant regressions ($p \geq 0.05$) against zero-shot. *Translate step-by-step surpasses zero-shot across the board, with each step incrementally improving translation quality.*

white-space separated) tokens each.[2] The resulting datasets consist of 192 documents of average token length 178 for WMT 2023 and, 243 documents of average token length 130 for WMT 2024, respectively. For WMT 2024 we also report per-domain results. Per-domain document counts and average lengths, as measured in English white-space separated tokens, are presented in Table 2.

Evaluation Metrics We evaluate our approach using MetricX-XXL-23 (Juraska et al., 2023), the metric adopted in the most recent WMT 2024 automatic evaluations. We report results on both the reference-based and the QE-based metric variants. Despite being trained at the sentence level, Deutsch et al. (2023) show that MetricX can effectively evaluate multi-sentence sequences, capped at its maximum window length. We note that MetricX is powered by mT5 (Xue et al., 2021), which minimizes the potential bias in favor of Gemini-generated translations.[3] We employ paired permutation tests to determine if the observed improvements across system pairs are statistically significant.[4]

5 Quantitative Results

We start by analyzing the importance of each step in the translate step-by-step pipeline. Ablation results on the WMT 2023 development sets are presented in §5.1. Next, the generalizability of our final step-by-step recipe is evaluated on the WMT 2024 test sets in §5.2, with comparison to prior work in §5.3.

5.1 Analyzing Step Importance

Automatic evaluation results on our development sets are presented in Table 3. Overall, translation artifacts extracted through the step-by-step process yield consistently better document translations compared to the zero-shot mode according to both reference- (lines 3–7 vs. 1) and QE-based (lines 10–14 vs. 8) versions of MetricX. Ablating the various steps from the pipeline gives insights into how each step contributes to the overall quality improvements. We describe those below.

Importance of Pre-translation Research Modelling pre-translation processes is crucial for achieving higher quality translations compared to the zero-shot. Simply prompting for a draft translation without asking for pre-translation research yields only small and non-significant improvements or even regressions over the zero-shot (lines 2 vs. 1

[2] We also present results for a shorter set of documents, with a maximum length of 150 tokens in Appendix A.1.

[3] We also report ChrF (Popović, 2015) in Appendix A.2.

[4] https://docs.scipy.org/doc/scipy/reference/generated/scipy.stats.permutation_test.html

and 9 vs. 8). This result rules out the possibility that any observed improvements are solely due to a better prompt for the draft translation, which was modified to emphasize faithfulness to the source (§3). However, combining the research and draft steps achieves consistently higher quality translations compared to zero-shot (lines 5 vs. 1 and 12 vs. 8). Importantly, those improvements are consistently statistical significant ($p < 0.0001$) across languages (measured by reference-based metrics), except for Hebrew, which shows non-significant improvements compared to zero-shot ($p \geq 0.05$).

Importance of Refinement Moving to the evaluation of the *refined* document translations, we notice an interesting trend. The refinement step consistently improves the translation quality, regardless of the initial translation it processes, i.e., the zero-shot (lines 3 vs. 1 and 10 vs. 8), the single-turn draft (lines 4 vs. 2 and 11 vs. 9), and the research-informed draft (lines 6 vs. 5 and 13 vs. 12). This demonstrates that the effectiveness of the refinement stage is not conditioned on the initial translation. However, the strongest quality improvements—reaching consistently high levels of statistical significance ($p < 0.001$) over the zero-shot translations—are observed when the refinement stage is combined with the pre-translation research (lines 6 vs. 1 and 13 vs. 8), highlighting that those stages bring complimentary benefits.

Importance of Proofreading Finally, the evaluation of the *proofreading* document translations, indicate that this stage contributes modest average improvements (lines 7 vs. 6 and 14 vs. 13). Unlike previous stages, the impact of proofreading appears to be more language dependent. Ukrainian stands out as the only language that clearly benefits from a proofreading stage, while others show only minor differences in quality compared to their refined translations.

5.2 Generalizability of Step-by-Step

Table 4 presents results on the WMT 2024 test set. Across the board, translating step-by-step exhibits the same trends noticed on our development set (as discussed in §5.1). This confirms the generalizability of our proposed approach, crucially, on a wider range of languages. Concretely, the draft translations outperform the zero-shot translations. The refined stages bring additional quality improvements across the board, with the proofreading stage contributing small improvements for most languages.

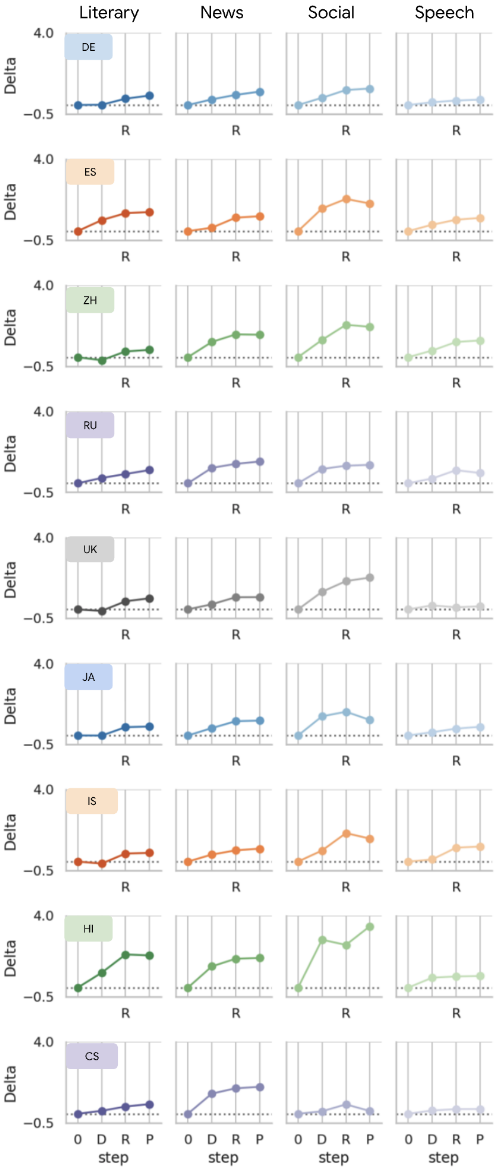

Figure 3: Domain-level comparison between zero-shot and step-by-step translations on WMT 2024 using reference-based MetricX-23. Each data point represents the delta from zero-shot (dotted horizontal line). The steps are denoted as follows: 0 (zero-shot), D (draft after research), R (refinement), and P (proofreading).

To better understand the robustness of our approach we present a per-domain analysis in Figure 3. As shown, translation quality improvements of step-by-step translations over zero-shot are observed across all domains, with speech showing the least and social the most significant gains.

5.3 Contextualizing Step-by-Step Gains

Having demonstrated how translate step-by-step improves long-form translation with LLMs over zero-shot translation, we now contextualize these gains by comparing our approach to two repre-

Table 4: MetricX-23 results comparing step-by-step (SBYS) with zero-shot on the WMT 2024 test datasets. When all steps are ablated, the system defaults to zero-shot translation. Colored boxes highlight performance differences compared to zero-shot: blue shades indicate significant improvements at $p < 0.001$, green shades indicate significant improvements at $p < 0.05$, while yellow shades indicate non-significant improvements ($p \geq 0.05$). *Translate step-by-step surpasses zero-shot, with each step incrementally improving translation quality.*

sentative baselines: a) methods that leverage non-parametric knowledge for best translation selection, and b) segment-level baselines that translate documents using the pre-defined segmentation provided in WMT 2024 test sets.

Conditions As a representative of the first class, we compare against MAPS (He et al., 2023). This baseline employs an LLM to analyze the source text for topic, keywords, and similar examples, generating three candidate translations conditioned on each knowledge type. Then, a QE metric selects the best candidate. To create a fair comparison, we re-implement their method using Gemini 1.5 Pro, using the prompts provided in their released code. To create an even stronger baseline, we perform candidate selection with the QE variant of MetricX-23, which we know correlates well with the final reference-based MetricX-23, creating an advantage for MAPS.

For the second class of baselines, we consider two approaches: a) zero-shot translation applied to each segment individually using Gemini 1.5 Pro, both with (ZERO-SHOT IN CONTEXT) and without (ZERO-SHOT) access to the full document in the input prompt, and b) a comparison with the segment-level translations from Unbabel-Tower70B, the top-performing system of WMT 2024 based on early automatic evaluations (Kocmi et al., 2024). To get comparable document-level metrics, before evaluation, we concatenate the segment-level translation back into the mini-documents, as described in §4.

We focus our comparisons on EN-DE, EN-JA, EN-ZH, as MAPS requires in-context demonstrations that were made available only for those languages by the original authors. For a fair comparison with Unbabel-Tower70B, we exclude the speech domain from our comparison, as WMT 2024 submissions were given ASR transcripts instead of human-sourced transcripts in this domain.

METHOD	DOC.	EN-DE		EN-ZH		EN-JA	
UNBABEL-TOWER70B	✗	1	1.42	1	2.77	2	2.16
ZERO-SHOT	✗	2	1.98	3	3.65	3	2.60
ZERO-SHOT IN CONTEXT	✗	2	1.86	2	3.33	2	2.19
ZERO-SHOT	✓	3	2.02	3	3.91	3	2.47
MAPS	✓	2	1.91	2	3.25	2	2.19
SBYS: *Research & Drafting*	✓	2	1.75	2	3.32	2	1.94
SBYS: *Refinement*	✓	1	1.41	1	2.73	1	1.58
SBYS: *Proofreading*	✓	1	1.27	1	2.75	1	1.73

Table 5: Comparison of step-by-step (SBYS) with representative baselines (lower scores are better) on WMT 2024 according to Metric-X (reference-based). The second column indicates whether translation is performed on the entire document or by merging segment-level translations. Numbered squares represent significance clusters (Freitag et al., 2023) at $p = 0.05$. *Translate step-by-step matches or exceeds all compared baselines, crucially, without accessing external resources.*

Results Table 5 compares step-by-step against various baselines. Notably, even the initial stage, where the draft translation is conditioned on cross-lingual research (SBYS: *Research & Drafting*) demonstrates competitive performance against MAPS, falling within the same statistical significance cluster. This highlights the effectiveness of our pre-translation strategy compared to the background information used by MAPS. Comparing the final, proofreading stage of step-by-step (SBYS: *Proofreading*) with MAPS reveals significant translation quality gains: 0.64 improvement for DE, 0.50 for ZH, and 0.46 for JA. Notably, these improvements are achieved even though MAPS uses the same QE model family as MetricX for final candidate selection, giving it an inherent advantage. In contrast, SBYS relies solely on the model's internal, parametric knowledge throughout the entire translation process.

Comparing the final, proofreading stage of step-by-step with the segment-level baselines helps put the improvements in perspective. Concretely, the segment-level zero-shot baselines (second and third lines in Table 5) fall significantly behind the step-by-step final translations (SBYS: *Proofreading*) across all languages by more than 0.7 and 0.4 MetricX points when compared to the out-of- and in-context variants, respectively. This demonstrates that simply translating documents at a finer granularity is not sufficient for boosting the LLM's translation quality.

Finally, comparing the final, proofreading stage of our approach with the merged translations from Unbabel-Tower70B, reveals that our approach achieves statistically comparable performance for Chinese and German (0.02 and 0.15 improvements respectively) and significantly better performance for Japanese (0.43 improvement). These improvements over the top-performing WMT 2024 system demonstrate the competitiveness of the step-by-step approach, especially given that the competing system relies on external QE metrics and computationally expensive decoding strategies to improve translation quality.

6 Qualitative Analysis

We conduct a qualitative analysis on a small subset of model outputs from all stages to understand the strengths and weaknesses of our step-by-step approach. To this end, we first compute the score difference between the final translation and the zero-shot output on WMT 2024 English to Chinese, and then randomly sample up to 5 examples from either end (i.e., examples for which the final translation quality either substantially improves or degrades over the zero-shot baseline).[5] One of the authors (native speaker of Chinese) manually inspected the sampled outputs and took notes on the salient properties of the pre-translation artifacts and the incremental changes from the different stages of the step-by-step process.

Pre-drafting For pre-drafting research, we observe that the LLM is highly capable of understanding the source in a wide variety of contexts. As showcased in Table 6, the LLM is able to correctly interpret slang (example 1: *cheeked up* in the context of making miniatures), recognize figurative usage (example 2: *the weather didn't cooperate* in the context of flying a plane), and detect humorous expressions (example 3). This strength is especially pronounced when even the references show clear signs of human translators misinterpreting the source (see the next subsection for full examples).

On the other hand, the LLM is also prone to over-generate and seems too eager to confirm with the given instruction to find instances of indirect translation. This resulted in false positives where a direct and literal translation is already adequate (example 4: *a bit dazed* can be directly translated into Chinese), and in some cases bizarre cultural commentaries (example 5 for asking to contextualize the texture of bubble gum).

Translations The observed understanding of the source texts seems to directly contribute to more fluent and context-appropriate translations. Table 13 in §A.4 shows several interesting examples. There are quite a few instances where the step-by-step approach produces the correct translation even when the reference fails to recognize the context the phrase appears in. For example, our method correctly interprets the meaning of *cheeked up* in the first example to be "having a full cheek" when the zero-shot translates it to *blushing* and the reference translates it to *talking nonsense*. Similarly for the second example, the term *threading* is correctly understood as a thread of posts on a social media platform by all step-by-step translations, whereas the zero-shot interpretes it as a computing terminology (as in *multithreading*) and the reference interprets it as *study*.

It is also evident that the refinement improves the fluency significantly. The third example shows that both the zero-shot and the draft translates the source literally. This entails preserving the original source structure and translating the source word *ridiculous* directly. The result is somewhat awkward and sounds like translationese, which is particularly jarring considering the social media domain of the source text. This issue is rectified by both the refined translation and the reference. On the other hand, the refinement process is not perfect and does regress to less fluent outputs at times (example 4). Another prominent failure mode typical of all LLM outputs is hallucinations. In the fifth example, the refinement adds "touching the bruise", which is not present in the source.

[5] The exact sample ranges of the score difference are [-6, -2] and [1, 6]. Examples from beyond these ranges typically demonstrate clear signs of model degeneration and are therefore excluded from this analysis.

	SOURCE SNIPPET	PRE-TRANSLATION RESEARCH	NOTES
1. ✔	trying my hand at miniatures redid the head! *[content omitted]* @user26 cheeked up. I love HER*	**“cheeked up”**: This slang term likely refers to making the miniature’s cheeks fuller or more prominent. A direct translation wouldn’t be accurate.	*Understanding source correctly in the context of making miniatures.*
2. ✔	#TeaganAir #pilot #flying #pa28 #PilotTraining *[content omitted]* Last week the weather didn’t cooperate so we’re back at it today.	**“The weather didn’t cooperate”**: This is a figurative way of saying the weather was not suitable for flying.	*Good example of indirect translation.*
3. ✔	It is nice to have art and entertainment to help us make sense of our life. @user32 I could perform a liver transplant thanks to Hospital Playlist.	**“I could perform a liver transplant thanks to Hospital Playlist”**: This is a humorous exaggeration, implying that the show provided a lot of information about liver transplants.	*Good humor detection.*
4. ✗	He was covered in cuts and scratches and seemed a bit dazed, but he didn’t seem too badly injured.	**“a bit dazed”**: This describes a state of confusion or disorientation. A literal translation might not convey the same meaning.	*Literal translation would do just fine.*
5. ✗	been really enjoying kneadatite (green stuff), it’s like sculpting with bubble gum but you get used to that and it’s tough and flexible when it cures	**“like sculpting with bubble gum”**: : This is a simile comparing the texture of Kneadatite to bubble gum. It needs to be translated in a way that makes sense to a Chinese audience who might not be familiar with the specific texture of bubble gum.	*Strange commentary on contextualizing the texture of bubble gum to a Chinese audience.*

Table 6: Samples of pre-translation research outputs along with notes from the author-annotator.

7 Conclusion

We introduce a step-by-step approach to long-form text translation using LLMs. Inspired by literature on translation studies, we decompose the translation process into distinct stages, modeling pre-translation research, drafting, refinement, and proofreading though a multi-turn interaction with Gemini 1.5 Pro. Extensive automatic evaluations on WMT 2023 and WMT 2024 tasks in ten languages demonstrate that our approach improves translation quality over directly translating the entire document with a single prompt.

Furthermore, comparison with competitive baselines, including similar human-like LLM-driven approaches and top-performing systems that employ segment-by-segment translation of a document, reveals the strong performance of our approach. Our findings highlight the potential of LLMs to progressively improve their translations, moving beyond the traditional view of machine translation as a monolithic sequence mapping task.

Limitations

While our study reveals promising step-by-step improvements across various languages and domains, we acknowledge the limitations of solely relying on automatic metrics for evaluation. While metric improvements give us a consistent signal, human evaluation is needed to further validate the effectiveness of the approach and reveal a more nuanced understanding of the translation properties introduced at each step. We also acknowledge that our analysis is based solely on one family of metrics, due to context window limitations of other neural metrics in evaluating longer texts.

Finally, our pipeline is developed and tested solely on Gemini. Since different LLMs might exhibit different instruction-following capabilities across languages, the generalizability of this approach to other LLMs requires further investigation.

Ethics Statement

This paper explores the use of LLMs to improve translation quality. In doing so, our approach starts from an initial translation that prioritizes faithfulness to the source text. Subsequent stages focus on improving fluency which, as they deviate more from the source, increase the risk of hallucinations (Guerreiro et al., 2023)—a critical issue in machine translation, potentially leading to misleading translations.

Moreover, the increasing fluency of machine translations presents new challenges when prioritized over adequacy (Martindale and Carpuat, 2018), as users might trust their outputs blindly, even when incorrect. This highlights the need for careful adoption of those translation systems and the developing of strategies that help users calibrate their trust appropriately.

A Appendices

A.1 Results on Shorter Documents

Table 9 presents automatic evaluation results of step-by-step on shorter documents, where segments are grouped together such that they do not exceed a token limit of 150 white-space separated tokens. The dataset statistics are presented in Table 10. We observe the same trends with the ones reported with larger documents in §5.

A.2 Results on ChrF

Tables 7 and 8 report ChrF scores on WMT 2023 and WMT 2024, respectively. As anticipated with string-based metrics, LLM translations which prioritize fluency receive lower scores compared to those that are by construction instructed to be closer to the source text. This behavior is in line with observations of prior work that employ similar human-like translation strategies with LLMs (Wu et al., 2024).

A.3 Prompts

Tables 11 and 12 present the complete prompts we used for our translate step-by-step framework and baselines. It has come to our attention that the prompts used in the experiments contain a few typographical errors. Preliminary results using revised prompts show comparable, if not slightly improved results (in the range of $0.1 - 0.2$ MetricX-23 score points), across all steps.

A.4 More example outputs

Table 13 gives more example outputs to support the discussion in §6.

PRE-TRANSLATION RESEARCH

You will be asked to translate a piece of text form English into Chinese following the five stages of the translation process. Here is the context in which the text appears:

Context: *placeholder source text*

To start, let’s do some pre-drafting research on the above context:

Research:
During this phase, thorough research is essential to address components of the context text that pose translation challenges. The goal is to establish a comprehensive translation plan that covers the following category:

- **Idiomatic Expressions:**
  - Identify idiomatic expressions that cannot be directly translated word-for-word into Chinese.

DRAFTING

Now, let’s move on to the drafting stage.

Draft Translation:
In this phase, your primary objective is to create a draft translation that accurately conveys the meaning of the source text presented below. At this stage, it is crucial to focus on adequacy, ensuring that your translation closely adheres to the source text. Your response should conclude with the draft translation. If context is missing, generate a general translation that is adaptable to various contexts. Avoid adding any additional information not present in the source text. All elements of the source text should be present in the translation.

Give your best one translation for the following piece of text based on the pre-drafting analysis without providing alternatives:

English: *placeholder source text*

REFINEMENT

Now let’s move to the next stage.

Post-editing with local refinement
In this stage, the primary aim is to refine the draft translation by making micro-level improvements that improve the draft’s fluency.

Provide only one refined translation and do not output anything else after that.

PROOFREADING

You are tasked with proofreading a translation that has been revised for improved fluency. The refined translation has been generated by editing the draft translation.

Proofreading and Final Editing
The goal is to provide a polished final translation of the source text. For you reference, below are the source text, the draft, and refined translations.

Source Text
placeholder source text

Draft Translation
placeholder draft translation

Refined Translation
placeholder draft refined translation

Please proofread the refined text for grammar, spelling, punctuation, terminology, and overall fluency. Ensure the translation accurately reflects the original meaning and style. Provide only the final, polished translation.

Table 11: Complete prompts used by the translate step-by-step pipeline.

ZERO-SHOT

You are asked to translate the text below into Chinese. Please output only the translation of the text without any other explanation.

English: *placeholder source text*
Chinese:

ZERO-SHOT IN CONTEXT

You are asked to translate the text below into Chinese. You are also given access to the context it appears.

Context: *placeholder document context*

Please output only the translation of the text without any other explanation.

English: *placeholder source text*
Chinese:

DRAFT JSON

Analyze the previous responses and create a JSON object that organizes the linguistic information they contain. This object should have two sections: “idiomatic_expressions", and “draft_translation":

- **“idiomatic_expressions"**:
  - This section should also be a list of dictionaries.
  - Each dictionary represents a phrase and has the keys: “source_phrase", “description", “translation", and “literal_translation".
  - The “translation" key should hold a list of all provided translations for the phrase.
  - If the response doesn’t provide a literal translation, use ‘null‘ for the “literal_translation" value.
  - If the response doesn’t identify relevant idiomatic expressions use ‘null‘ for the corresponding value.
  - Don’t include transliterated versions of the translations.
- **“draft_translation"**:
  - A string containing the draft translation.
  - If a translation includes multiple alternatives for the same source text, extract the first one.
  - Don’t include transliterated versions of the translations.
  - If the translation includes alternatives separated by "/", extract the first one.

Table 12: Prompts used for baseline comparisons (zero-shot and zero-shot in context) and structuring the pre-translation research translation artifacts.

1. ✔*Good example*	
SOURCE	@user26 cheeked up. I love HER*
REFERENCE	@user26 口出狂言。我喜欢她* *Talking nonsense. I like her**
ZERO-SHOT	@user26 脸红了。我爱她* *Blushing. I love her**
RESEARCH AND DRAFT	@user26 脸颊做得很饱满。我喜欢她* *The cheeks are very plump. I like her**
REFINEMENT	@user26 脸颊做得鼓鼓的，超可爱！我喜欢她* *The cheeks are very chubby, super cute! I like her**
NOTES	*Both the reference and the zero-shot misinterpreted the phrase "cheeked up" in the context of making miniatures. Both the draft and the refined version understood it correctly, with the latter being a bit more colloquial.*
2. ✔*Good example*	
SOURCE	I donked up my threading
REFERENCE	我完成了这部分学习 *I finished this part of study.*
ZERO-SHOT	我把我的线程搞砸了 *I messed up my threads [note: a terminology in computing].*
RESEARCH AND DRAFT	我搞砸了我的帖子顺序 *I messed up the order of my posts.*
REFINEMENT	我搞砸了帖子顺序 *I messed up the post order.*
NOTES	*The reference misinterpreted both "donked up" and "threading" in this context, and the zero-shot translation mistook the latter for the computing terminology.*
2. ✔*Good example*	
SOURCE	It is a ridiculous level.
REFERENCE	这关太难了。 *This level is too hard.*
ZERO-SHOT	这是一个荒谬的关卡。 *This is a ridiculous level.*
RESEARCH AND DRAFT	这是一个荒谬的关卡。 *This is a ridiculous level.*
REFINEMENT	这个关卡真是太难了。 *This level is really too hard.*
NOTES	*Zero-shot and draft translations are direct, literal, and stylistically awkward in Chinese, especially in the social media domain.*
4. ✗ *Bad example*	
SOURCE	Ivory chuckled from the memory.
REFERENCE	艾弗里回忆到这里，笑了起来。 *Ivory thought of this and laughed*
ZERO-SHOT	艾弗里想起这件事，不禁轻笑起来。 *Ivory thought of this and couldn't help starting to chuckle.*
RESEARCH AND DRAFT	艾弗里回想起当时的情景，不禁轻笑出声 *Ivory thought of the situation at that time and couldn't help letting out a chuckle.*
REFINEMENT	艾弗里摸了摸肩膀上上次留下的瘀伤，不禁轻笑出声。 *Ivory touched the bruise on the shoulder left from the last time and couldn't help letting out a chuckle.*
NOTES	*All translations did a good job translating the phrase "chuckled from the memory" fluently into Chinese, but the refinement hallucinated by adding "touched the bruise."*
5. ✗ *Bad example*	
SOURCE	one of them ran for something and grabbed it
REFERENCE	其中一个人跑过去抓起了什么东西 *One of them ran over and grabbed something.*
ZERO-SHOT	其中一个人跑去拿了什么东西 *One of them ran and grabbed something*
RESEARCH AND DRAFT	其中一个人跑到某个东西那里，抓起它 *One of them ran to something and grabbed it.*
REFINEMENT	其中一个人跑到某个东西那里，抓起它 *One of them ran to something and grabbed it.*
NOTES	*Although all translations are adequate and capture the semantic meaning of the source correctly, the draft and the refinement keep the original source structure and the resulting translation sounds like translationese.*

Abstract

Recent studies have showcased remarkable capabilities of decoder-only models in many NLP tasks, including translation. Yet, the machine translation field has been largely dominated by encoder-decoder models based on the Transformer architecture. As a consequence, scaling laws of encoder-decoder models for neural machine translation have already been well studied, but decoder-only models have received less attention. This work explores the scaling laws of decoder-only models on the multilingual and multidomain translation task. We trained a collection of six decoder-only models, ranging from 70M to 7B parameters, on a sentence-level, multilingual (8 languages) and multidomain (9 domains) dataset. We conducted a series of experiments showing that the loss of decoder-only models can be estimated using a scaling law similar to the one discovered for large language models, but we also show that this scaling law has difficulties to generalize to *too large models* or to a different data distribution. We also study different scaling methods and show that scaling the depth and the width of a model lead to similar test loss improvements, but with different impact on the model's efficiency.

1 Introduction

Most modern machine translation systems are based on Transformers (Vaswani et al., 2017), with an encoder-decoder architecture. Despite the tremendous advances made possible with the release of open-source decoder-only Large Language Models (LLMs) (Jiang et al., 2023; Biderman et al., 2023; Touvron et al., 2023), most NLP tasks still rely on encoder-decoder models. Based on the statistics obtained from the WMT23 shared task on general machine translation (Kocmi et al., 2023), 16 out of the 17 participants submitted a system based on an encoder-decoder model. Yet, recent studies show that decoder-only models can achieve comparable results (Gao et al., 2022; Fu et al., 2023), or even surpass state-of-the-art encoder-decoder systems, when properly finetuned (Xu et al., 2023). Moreover, the decoder-only architecture is easier to train on massive amounts of data as one can simply concatenate documents and feed as much relevant data as possible into the model during training ; while encoder-decoder models requires either to pad the inputs or rely on complex masking strategies (Raffel et al., 2020) to combine multiple inputs in the same sample.

Furthermore, the decoder architecture is much more flexible than the encoder-decoder architecture as decoders treat all tokens similarly, while encoder-decoders make a distinction between input (source) tokens and output (target) tokens, which are processed, respectively, by the encoder and the decoder. As a consequence, it is more tedious to apply complex *self-reasoning* mechanisms, such as chain-of-thought (Wei et al., 2022), or to interface it with external tools (Schick et al., 2024), because the outputs of such method (the *reasoning* process) should, preferably, be treated as inputs of the model. For the same reasons, it is much more computationally expensive to rely on an encoder-decoder for conversational purposes, making this architecture less efficient for modern workflows such as iterative translation. Indeed, at each round (the user's query and the system's answer) should be appended to the input side, and reprocessed by the encoder for the next round. Decoder-only models support it by design, without needing to recompute the representation of the ever-growing inputs. While we do not explore these directions in this work, we do leverage the flexibility of the decoder architecture to include input-or-output parameters. As we are tackling the multilingual and multidomain machine translation task, the model needs input tokens to represent the language direction and the domain. We propose to train the model to predict the source language and the domain so that, during inference, they can be seamlessly predicted or provided by

Proceedings of the Ninth Conference on Machine Translation, pages 1318–1331

the user.

Generally speaking, decoder-only models simply expect the input to be the whole discussion and process it in a single forward step. Causal masking enable efficient caching of already computed keys and values so inference is much cheaper. The main downside of decoder-only over encoder-decoder model is the potential inferior quality of the input representation, as input tokens attend only on past tokens. But it should not be a major issue, as generated tokens attend to the whole past sequence, they do have access to the same quantity of information as with an encoder-decoder model. In addition, previous work propose to update the attention mask so that input tokens can attend to all input tokens while generated tokens can attend only on past tokens (Tay et al., 2022; Raffel et al., 2020).

For all these reasons, we would like to embrace the decoder architecture for machine translation, even if it seems to be the exclusive preserve of encoder-decoder models. The flexibility and the simpler training setup of decoders should make them both more suitable and efficient for most real world applications, and the decoder architecture is more appropriate to answer the ever-growing demand for iterative, interactive and machine assisted translation workflow. To this aim, we study the scaling laws of neural machine translation models under different settings. Our contributions are as follow:

- We show that decoder-only models for translation follow the same scaling law as LLM
- Scaling laws do not scale uniformly across directions and domains and do not generalize well to other directions or domains
- Scaling width-wise and depth-wise yield similar improvements, but the former is more efficient
- We discovered a critical issue related to the packing of training samples in batches and propose a solution to fix it

2 Background

As the size, data requirement, and training costs of language models rise, it quickly becomes critical to estimate the *right* training configuration for a given training budget — expressed in number of floating point operations (FLOP) — required to train the model. Kaplan et al. (2020) discovered a power law relationship between the loss of a language model and its number of parameters, and that larger models perform better given the same amount of data. Even though most work in this area show that larger models tend to be more powerful, recent studies show that other parameters must be taken into account as well. For instance, the Chinchilla scaling law (Hoffmann et al., 2022) shows that model and dataset sizes are loosely tied and need to be scaled equally. In other words, even if increasing only the model size will most likely improve its performances, the compute-optimal solution often requires to also increase the quantity of training data, while preserving the same training cost. These findings had a great impact on LLM research, as researchers stopped increasing blindly the size of their models, in favor of more data, when it was necessary. For instance, the 176B BLOOM (Le Scao et al., 2022) model would probably have been trained very differently (or not at all) if this study was released sooner. As stated in the paper, “in light of revised scaling laws published during training, we decided to train the large models for an additional 25 billion tokens on repeated data”, the authors discovered that training such a big model was sub-optimal given the quantity of data they had. As a consequence, many researchers started to work on the collection of large, high quality datasets (Nguyen et al., 2024; Penedo et al., 2023) or on means to enhance existing datasets (Sorscher et al., 2022; Tirumala et al., 2024).

Most of these scaling laws studies focus exclusively on causal generative language models. While it’s likely that many of these findings could apply to translation models, the differences between the two tasks cannot be taken for granted. Translation is a lot stricter than causal language modeling since the model has to take into account each information in the source and precisely generate the target sentence without adding or omitting any information. Hence, many studies have naturally emerged to observe the scaling behavior of translation models (Gordon et al., 2021; Fernandes et al., 2023; Ghorbani et al., 2021). Yet, these works focus on encoder-decoder models. For instance, Gordon et al. (2021); Fernandes et al. (2023) showed that, when the encoder and the decoder are scaled proportionally, the model’s loss follow a power-law similar to the observation made on language models. Ghorbani et al. (2021) tackle the problem in a different setup, and propose to scale the encoder and the decoder individually. They show that encoder-scaling and decoder-scaling affect the model's performances differently, and they propose a new formula describing the scaling behavior of the cross-entropy loss as a bivariate function of encoder and decoder size. They found out that scaling decoder is, according to their experiments, always more beneficial, in terms of cross-entropy loss performance, than scaling the encoder.

Recently, Alves et al. (2024) introduced the TowerInstruct, an LLM based on a decoder architecture (LLama 2 (Touvron et al., 2023)) finetuned to handle several translation tasks. They show that a properly finetuned LLM can perform translation better than state-of-the-art models on high-resource languages. But the most promising aspect of this work is the inherent capacity of LLM to handle different tasks. They finetuned TowerInstruct so it can, for instance, clean source sentences before translating them, follow terminological constraints or respect a given level of language. However, this work is still empirical and we do not know, yet, the limits of such models. Inspired by the performances of TowerInstruct, an LLM finetuned for machine translation tasks, we study, in the following, the scaling behavior of decoder-based machine translation models trained from scratch. To this aim, we fit multiple scaling laws to see if translation models follow the same scaling laws as language modeling models (such as the Chinchilla law) or if they follow their own task-specific law.

3 Training methodology

We present in this section all details related to the training of our six models.

3.1 Data

To conduct our experiments, we collected many bilingual data from public repositories (CCMatrix (Schwenk et al., 2021b), WikiMatrix (Schwenk et al., 2021a), UN Parallel Corpus (Ziemski et al., 2016), Paracrawl (Bañón et al., 2020) and Europarl (Koehn, 2005)). We also included a subset of an in-house proprietary dataset collected over time, as well as a small portion of financial documents in order to observe the scaling behavior on domain-specific data. An overview of the dataset distribution is given in Table 1. The financial data is divided into 8 sub-domains, which are described in Appendix A. The data is made of bilingual texts with one sample being one sentence pair.

Pair	Domain	Sentences	Tokens
en–de	general	46.53 M	2694.16 M
	finance	1.29 M	65.93 M
en–es	general	51.88 M	3525.21 M
	finance	1.34 M	71.48 M

	finance	0.62 M	29.18 M
Total:	general	453.58 M	27 715.84 M
	finance	17.53 M	951.36 M
	all	471.11 M	28 667.20 M

Table 1: Distribution of the training dataset. It covers 8 languages over 11 language pairs and 9 domains (general + 8 financial sub-domains).

We applied temperature sampling ($t = 5$) in order to increase the visibility of under represented pairs. Given a collection $\mathcal{D}$ of datasets, the probability of choosing a sample from a dataset $D_i \in \mathcal{D}$ after temperature sampling is given by $P_t(D_i)$ and is calculated from the original dataset statistical distribution $P(D_i)$.

$$P(D_i) = \frac{N_i}{\sum_{j=0}^{|\mathcal{D}|} N_j}$$

$$T(D_i, t) = P(D_i)^{1.0/t}$$

where N_i is the size of dataset D_i and $T(D_i, t)$ is the factor by which the dataset D_i should be oversampled. The new size k_i of the oversampled dataset D_i is given by:

$$k_i = \left\lfloor \frac{T(D_i, t) \cdot \max_{j=0}^{|\mathcal{D}|}(N_j)}{\max_{j=0}^{|\mathcal{D}|}(T(D_j, t))} \right\rfloor$$

Finally, the probability of picking a sample from dataset D_i after temperature sampling is given by

$$P_t(D_i) = \frac{k_i}{\sum_{j=0}^{|D|} k_j}$$

Since the balance between general and financial is also extremely skewed, we applied the temperature sampling separately on the general and financial domains.

3.2 Tokenizer

As we planned to train a multilingual model, we trained a Byte-Level BPE tokenizer (Wei et al., 2021) from scratch because, according to the authors, it is expected to better share the tokens among the multiple languages, resulting in less rare tokens and, hence, better embeddings. The tokenizer has been trained on the whole, non-oversampled, dataset, and we set the vocabulary size to 100 000.

We also reserved a small set of special tokens representing the supported languages and domains. They are inserted inside the input sequence so the model knows this information while generating a translation. For instance, the *English language token* is `<lang_en>` and the *general domain token* is `<dom_general>`.

3.3 Data format

Each sample of the datasets has two categories of features: inputs and outputs. Input features are data that will be given during inference, and output features are data that should be predicted by the model. Hence, inputs are the source sentence and the target language (because the model needs to know the desired target language); and outputs are the source language, the domain and the translated sentence.

Predicting the source language is not required, but we decided to include it to give to the model the ability to automatically detect the source language, as it is a very common and handy feature of most commercial translation tools. One could argue that this should be an input parameter, but we decided that the model should be able to classify by itself the language of the source sentence. Yet, the source language token can still be given as input at inference time to force a particular language. This also apply to the domain token.

Since we plan to train a decoder-only model, training samples have been formatted such that the input tokens are first seen by the model, so the model has access to the whole input when generating the first output token. This is why we chose to encode the sentence pairs in the following format:

```
SOURCE </src> <target lang> <source
    lang> <domain> TARGET <eos>
```

where `</src>` and `<eos>` are special tokens used to indicate, respectively, the end of the source and target sequences.

This data format gives the possibility to either provide the source language if required, or let the model predict it automatically. For instance, in the real example below, the green part represents the mandatory input (source sentence and target language), the blue part the optional input (source language) and the gray part is the output generated by the model.

```
The buyer pays at an ATM. </src>
<lang_fr> <lang_en> <dom_general>
L'acheteur effectue le paiement sur les
bornes automatiques. <eos>
```

3.3.1 The <eos> token issue

All the models were trained in the same way LLM are trained. Sentence pairs were packed until the training batch was completely filled. These samples were separated by the usual end-of-sentence token <eos>. Ideally, one should also apply proper masking so tokens cannot attend to tokens from past sentence pairs. However, this features is not implemented in flash-attention 2 (Dao et al., 2022), so we trained the models without masks (except the causal mask). We expect the training task to be slightly more complex to solve, as the model now needs to learn to ignore every token before an <eos> token, but we decided that the gain in training speed is worthwhile.

Model	without <eos>	with <eos>
70M	30.80	41.11
160M	39.12	45.13
410M	40.85	46.82

Table 2: BLEU scores of the same models when sources are prefixed with and without the <eos> token.

Our experiments showed that the quality of translations generated by the models were far below our expectations. We found that the absence of the <eos> token before the source sentence was confusing the model, explaining the drop in translation quality shown in Table 2. The <eos> token, which was meant to signal the end of the translation, is actually also interpreted as a "start of translation" token. Indeed, during training, all sentence pairs (except the first one) are prefixed with the <eos> token. This phenomenon is clear in the example below, in which three sentence pairs are packed in the same training sample.

x_{1-1} x_{1-2} x_{1-3} </src> <tgtlang$_1$> <srclang$_1$>
y_{1-1} y_{1-2} **<eos>** x_{2-1} x_{2-2} </src> <tgtlang$_2$>
<srclang$_2$> y_{2-1} y_{2-2} **<eos>** x_{3-1} x_{3-2} x_{3-3}
</src> <tgtlang$_3$> <srclang$_3$> y_{3-1} y_{3-2} y_{3-3}
y_{3-4} **<eos>** x_{4-1} . . .

The impact of <eos> absence on the test loss can be seen in Figure 1. The model clearly outputs better translation when the source sentence is prefixed with an <eos> token. This is particularly blatant when comparing the 160M and 410M models, respectively with and without the <eos> token prefix. The 410M model, albeit being more than two times bigger than the 160M model, cannot generate better translations without the <eos> prefix.

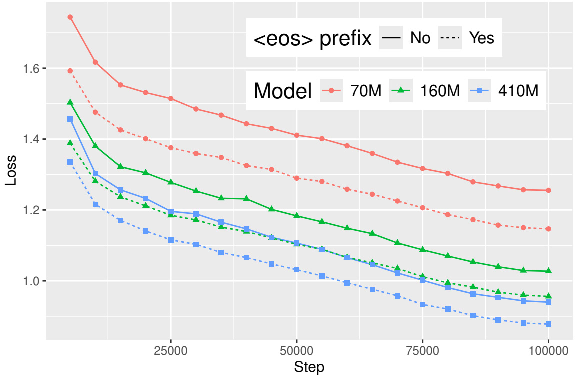

Figure 1: Test loss of our three smallest models (70M, 160M and 410M) with and without the <eos> prefix.

This problem should be negligible when training LLM, as documents are usually longer than sentence pairs, so <eos> tokens are scarcer. However, its impact will increase as batch size grows, since more sentence pairs can be packed into the same batch, making even more *obvious* that sentence pairs *should* start with an <eos> token. We experimented with a relatively small input length (512 tokens) and the absence of the <eos> token during inference already lead to significant drop in performance. Generally speaking, this issue should not be ignored when more than one sequence are packed in a single training sample. When possible, one should properly mask previous training samples. As it is not possible, currently, to leverage the state-of-the-art self-attention algorithms, we recommend to always prefix all source sentences with the same prefix token(s), both during training and inference. An alternative solution might be to prefix all sequences with a <bos> (begin of sentence) token, but we do not think it will solve this particular issue since the model will likely see that most sentence pairs start with the <eos><bos> sequence, which is still not the intended behavior. In the remaining of this paper, we will only consider translations generated with an <eos> prefix.

3.4 Training strategy

As we aim to train models dedicated to the translation task, we computed the loss only on target tokens, so the model learns to generate only text given a source sentence. This is different from pretrained language models as there is no notion of source and target sentence. The *target-only* strategy has proven to be effective for training text-to-text models (Touvron et al., 2023), and is also similar to the way loss of encoder-decoder models is calculated, which are commonly used for machine translation (Costa-jussà et al., 2022). Finally, we packed as many sentence pairs that we could in a single batch, in order to increase the training efficiency.

3.5 Model architectures

We used almost the same model architectures used in the Pythia suite (Biderman et al., 2023), the only difference being the number of attention head of the 160M model, as flash-attention expects a multiple of 8. We trained the models using the GPT-NeoX library (Andonian et al., 2023). We made a few changes to the data processing scripts in order to ignore source tokens during the loss computation. An overview of the different models we trained is given in Table 3.

All models are trained with a fixed batch size of 262 144 tokens (512 sequences of length 512 tokens) per GPU, on 8 Nvidia A100 GPUs. The models are trained in bfloat16 precision using the Adam optimizer with weight decay set to 0.1, 100 warmup steps and cosine learning rate decay. The maximum learning rate of sub-1B models is set to 1×10^{-3}, and 1×10^{-4} for larger model because of loss instabilities during the training.

The models are trained for 100 000 steps on approximately 210B tokens, although only half of them were actually used to train the model as we

Model	Non-embedding	Embedding	Layers	Dim	Heads	Max lr
70M	70 295 552	51 380 224	6	512	8	$1e^{-3}$
160M	162 126 336	77 070 336	12	768	16	$1e^{-3}$
410M	405 071 872	102 760 448	24	1024	16	$1e^{-3}$
610M	607 448 064	154 140 672	16	1536	16	$1e^{-3}$
1B	1 011 257 344	205 520 896	16	2048	8	$1e^{-4}$
6.9B	6 855 204 864	411 041 792	32	4096	32	$1e^{-4}$

Table 3: Architectures of the trained models. All models are trained with the very same setup (data, random seed, batch size, number of GPU, . . .). They closely follow the Pythia models but parameters counts do no match because of the bigger vocabulary size, which increases the size of both the embedding and classification layer.

do not take into account source tokens when calculating the loss.

4 Experiments and results

In this section, we will study the impact of variations in training data size and parameters count on the test loss, for all our models. We will also verify if these changes correlate with their real translation performances using standard metrics such as BLEU and COMET. We finally explore two different model scaling strategies.

4.1 Applying machine translation scaling law

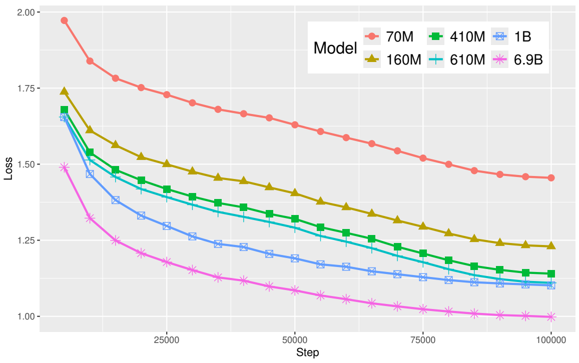

Figure 2: Test loss of all model checkpoints. Each step represents 512 training samples. Larger models always converge faster given the same amount of training data.

All existing scaling-laws studies show that larger models exhibit better generalization capabilities (Gordon et al., 2021; Fernandes et al., 2023; Ghorbani et al., 2021; Rae et al., 2021; Kaplan et al., 2020; Biderman et al., 2023). This study is no exception, as can be seen in Figure 2, larger decoder models always converge faster and require less training data to reach the same loss value.

We first fitted multiple curves following the setting of Ghorbani et al. (2021); Fernandes et al. (2023), who studied scaling laws for machine translation. The form of the law is given below:

$$L(N) = \alpha N^{-p} + \beta \tag{1}$$

where N is the number of trainable parameters, and the other variables are fitted by minimizing the huber loss (with a delta value of 0.01) using the BFGS algorithm from SciPy (Virtanen et al., 2020).

As shown in Figure 3, the test losses of our translation models can be realistically described by the power law fitted on observations made on all our models (the purple dotted line). This suggests that, indeed, performances of translation models follow a scaling law, that can be expressed by the formula above. We also fitted curves on less data points in order to verify if we could estimate the loss of the 6.9B model. Unfortunately, the fitted curves become deviate from the real observations as soon as we remove the data points from the largest model (the 6.9B model). This is extremely problematic, as the main goal of scaling laws is to estimate the performances of not-yet-trained larger models. Yet, we show that it is difficult to find a good estimation of the 6.9B model's performance without actually training it. For instance, the law fitted on the observations made on the subset 70M-160M-410M-610M-1B (in green) cannot give a good approximation of the *unseen* 6.9B model's performance, and the others are even worse. Therefore, we think one might be particularly cautious when applying such scaling laws to estimate larger models behaviors. Even if our law fitted on all data points seems to be a good estimator of the test loss, we think it will deviate from real observations as the model grows in size.

We also fitted scaling laws on a per-domain and per-direction basis, on all available data points. This is particularly interesting as it highlights discrepancies between domains and directions. As

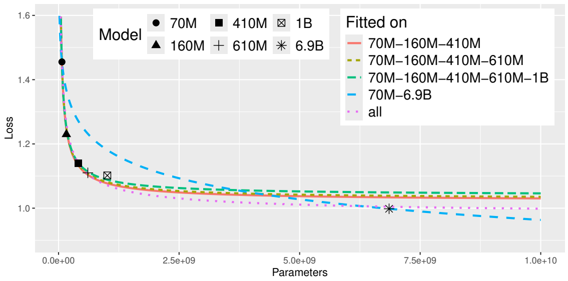

Figure 3: Test losses estimated by power law fitted on different subset of models. Laws fitted on all models and 70M-160M-410M-1B models subset match our observations.

shown in Figure 4, it seems to be significantly easier to translate sentences from the *kiid* (Key Investor Information Document) financial domain, but translating general domain sentences is the most difficult, even though the huge majority of our training set is from the general domain. We suspect this curve are, somehow, indicators of the diversity inside each domain. Indeed, *kiid* documents are, by law, all following the same structure and must contain a specific set of information, written in a certain way. On the contrary, *general* domain documents do not follow any rule, making this domain the most heterogeneous one, and thus the most difficult to translate. Other phenomena might explain the differences between these curves. For instance, we also think the presence of many very specific and rare words in the *regulatory* domain explains partly the lower translation quality in this domain.

We also fitted one curve per direction and observed similar phenomena, as shown in Figure 5. For example, our models seem to be better at translating from English to German than from English to French, although our training dataset contains twice as many English-French pairs (before oversampling).

These observations show that the scaling behavior of translation models depends on the training data distribution, and thus scaling laws estimated on a given dataset will not match the real scaling behavior on another one, although they might have the same general shape. For instance, it is not realistic to rely on a scaling law fitted on the en–fr direction to estimate the performances on the en–de direction.

4.2 Applying language modeling scaling law

So far, we experimented with a scaling law formula based on the model size only, ignoring the training dataset size. Even if we just showed that lower perplexity/loss can be obtained with fewer data samples (in the case of the en–fr and en–de directions), larger training datasets still tend to increase the overall models' quality. But, it's also a waste of computing resources to train a model on more data than required, this is why modern language modeling scaling formula take into account both the number of trainable parameter and the training dataset size. Hence, we fitted multiple Chinchilla laws following the setting of Hoffmann et al. (2022), whose form is given below, on various combinations of input data to see if it can be used to reliably predict model performances.

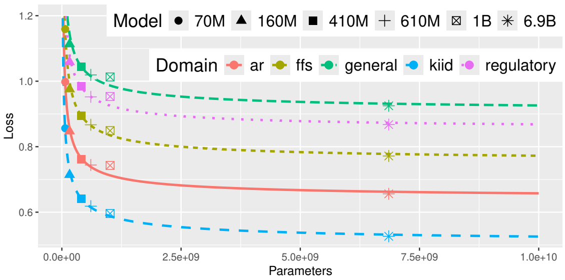

Figure 4: Scaling law fitted on the general domain and some financial subdomains. The law are fitted on the English-French direction only.

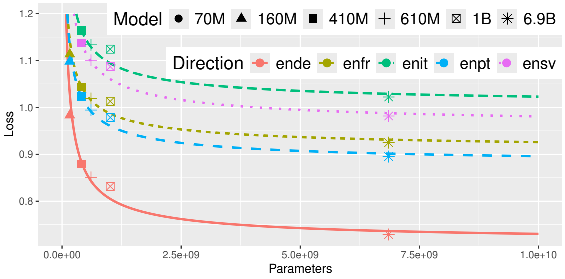

Figure 5: Scaling law fitted on the general domain for English-X direction.

$$L(N, D) = E + \frac{a}{N^{\alpha}} + \frac{b}{D^{\beta}} \qquad (2)$$

E, a, α, b and β are variables fitted by minimizing the huber loss (with a delta value of 0.01) using the `BFGS` algorithm from `SciPy` (Virtanen et al., 2020) ; N and D are, respectively, the number of non-embedding parameters of the model and the number of training samples. More details are given in the original paper.

As shown in Figure 6, the test loss of our translation models can be realistically described by the power law fitted on observations made on all our models (the purple dotted line). Furthermore, the

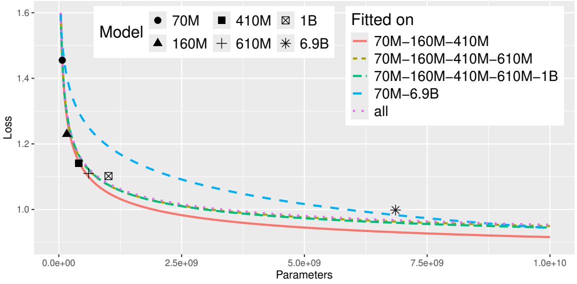

Figure 6: Test losses estimated by the Chinchilla law fitted on different model subsets. Curves deviate from the real observations when we remove too many data points to fit the curve.

general shape of the fitted curves is more stable, and thus more trustworthy. Indeed, the curve fitted on all models is very close to the one fitted without the 6.9B model, indicating that behaviors of larger models can be better estimated with this form of scaling law. However, as with the previous scaling law, the curve deviate from real observations when it is fitted on less data points. While it is not a surprising finding, it shows that scaling laws should not be trusted beyond a certain model size. However, we cannot provide a reasonable window in which the estimated loss is realistic.

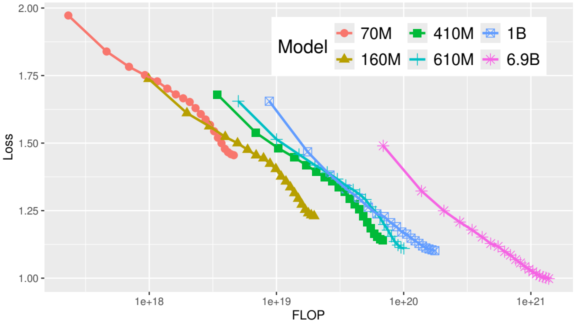

Figure 7: Test loss of all models, each data point represents 5k training steps, or 2.5M samples. Given a fixed FLOP, it's often more beneficial to increase the dataset size when possible.

These experiments shows two things. First, the test loss of decoder-based translation models follows a scaling law similar to language modeling models, as the curves fitted on all data points match the real observations. The form of the law (a power law) indicates that larger models will always generalize better, until a certain point where the curve will stay mostly flat. The second thing we show is that finding a good and universal estimation for the model's loss is very difficult, as fitted curves do not generalize well beyond an unknown model size.

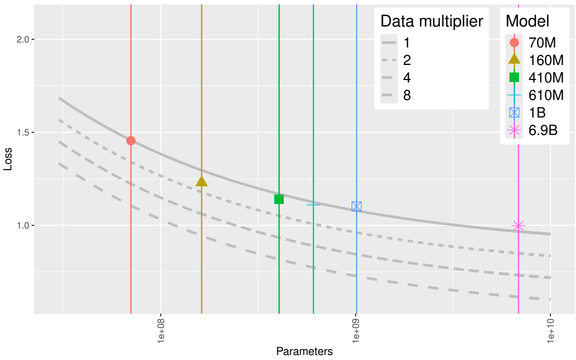

Figure 8: Estimation of models' test losses if they were trained on more data. According to the Chinchilla law fitted on all available observations, the 70M model should be on-par with the 410M performances with four times more data, and the 610M model should match the 6.9B model with only two times more data.

4.3 Correlating scaling law with real translation quality

Let us suppose we know the function modeling the real loss given a model size and an amount of training data. We still do not know if targeting lower loss values will actually improve the quality of the translations generated by the model. We provide in the following an empirical study showing the correlation between the model's loss and its translation performance. We computed BLEU (Papineni et al., 2002), COMET (Rei et al., 2022a) and CometKiwi (Rei et al., 2022b) scores for all six models, and we observed that, indeed, a lower loss does correlate with a performance increase, as shown in Table 4. This trend can be observed on the general domain for all directions, as shown in Appendix C. However, on the financial domain, CometKiwi does not always increase, it reaches a peak on the 610M model, then decreases. We conjecture that CometKiwi cannot correctly evaluate domain specific translations, as it is a reference-free model trained mainly on generalist sentences. We show in Appendix C that BLEU and COMET always increase with models' size, while CometKiwi often decreases at some point.

We also compare our models to well established LLM, and we show that smaller but specialized models clearly outperforms large and generalist LLM, as shown by our 410M model performing on par with `Llama 8B`. Our largest models are also real competitors to `Tower 7B`, even though it has been trained on much more data and specialized for machine translation. `Tower 7B` has the highest CometKiwi score, but as we just showed, it might

Model	BLEU	COMET	CometKiwi
General domain			
70M	29.62	81.31	80.72
160M	32.43	84.00	83.45
410M	33.60	84.81	84.14
610M	34.08	85.10	84.35
1B	34.42	85.10	84.33
6.9B	36.07†	85.88	84.82
Llama3.1 8B	30.43	84.82	84.47
Mistral 7B	23.26	80.08	82.29
Tower 7B	33.50	85.91†	85.02†
Tower 7B*	34.38	86.22	85.23
Financial domain			
70M	44.63	86.95	80.88
160M	49.02	88.27	81.80
410M	50.85	88.64	81.73
610M	52.00	88.85	81.71
1B	53.28	89.98‡	81.61
6.9B	58.34‡	89.62	81.35
Llama3.1 8B	34.99	84.42	81.75
Mistral 7B	38.93	76.52	76.17
Tower 7B	38.93	86.49	82.66‡
Tower 7B*	39.08	86.52	82.74

Table 4: Evaluation of the six models trained during this study on our in-house evaluation dataset. We reports both the scores on the general (G) domain and average over all financial (F) subdomains. We also include best performing LLM. As Tower has not been trained on Swedish, we also evaluate it after removing directions including Swedish (the Tower 7B* rows). Best scores on the general and financial domains are indicated by † and ‡ respectively.

not be reliable for specialized domains. Our models are obviously performing better on the financial domain, because only our models were finetuned on financial data. We also remark that Mistral's scores are quite low on the general domain, a quick manual inspection revealed that the model often give details and explanations about the produced translation, even when asked not to. As a consequence, we think that Mistral lower score is mostly caused by the model not following rigorously the instructions (see Appendix B).

So, while it certainly boost performances, increasing the model size is often not the optimal solution to improve the model's performance. The training dataset is also extremely important. Indeed, as can be observed in Figure 7, given a fixed FLOP budget, it is often preferable to increase the number of training samples. For instance, the 160M model appears to always be better than the 410M, 610M and 1B models given the same FLOP budget, as indicated by the 160M's curve being below other models' curves. This observation is also validated by the fitted law, as indicated in Figure 8. Most of the time, and according to the fitted Chinchilla law, it would have been better to just train our models on more data, instead of training larger models. For instance, we estimate that the 160M model would be on-par with the 410M model if trained on approximately twice as many data, which would not exceed the total number of FLOP of our current 410M model.

To conclude with, we find that scaling laws are a powerful tool to have a glimpse of what we can expect from a *relatively larger* model trained on the same dataset, but it will probably fail to predict the performances of *much larger* models, even if trained on a similar data distribution. It has to be kept in mind when using such scaling laws to plan a training budget: **at some point, the fitted law will fail**. Planning a training budget based on observations made on a 10B model might be fine to train a 70B model, but completely wrong for a 500B one. Furthermore, a given scaling law can only estimate the end performances of a model trained on the same data distribution used to fit the scaling law. For instance, we show in Figures 4 and 5 that laws fitted on different language directions or domains are very different, and thus should not be applied to estimate the performances of the model on another direction.

4.4 Scaling strategies

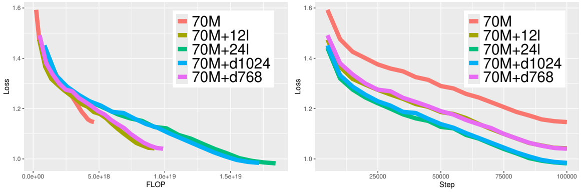

Figure 9: In our experiments, we increased the width and the depth of the 70M model so the additional cost in terms of FLOP is similar (left). Scaling the depth or the width can lead to similar performance gains (right). The two figures are similar, except that the loss decrease can be observed either through the FLOP budget prism (left) or throughout training time / size of dataset (right).

We also studied whether one should favor scaling the depth (increasing the number of layers) or the width (increasing the hidden size) of a decoder model. We took the smallest model as a baseline and scaled it depth-wise and width-wise so that the increase in parameters increased the total training FLOP by a similar amount, as illustrated in

Model	Layers	Dim	Non-embedding	Embedding	FLOP per s.	Samples per s.
70M	6	512	70 295 552	51 380 224	1.06×10^{14}	1170
70M+d768	6	768	119 599 104	77 070 336	1.74×10^{14}	900
70M+12l	12	512	89 209 856	51 380 224	1.37×10^{14}	760
70M+d1024	6	1024	178 339 840	102 760 448	2.43×10^{14}	725
70M+24l	24	512	127 038 464	51 380 224	1.6×10^{14}	445

Table 5: Sizes and architecture of models scaled in depth (70M+12l and 70M+24l) and models scaled in width (70M+d768 and 70M+d1024) compared to the base 70M model. Increasing the depth of the model has limited impact on the total parameters count, but decreases significantly the efficiency (higher FLOP per second but less training samples per second). Scaling the width of the model takes advantage of modern GPU architectures, but adds many trainable parameters.

Figure 9. An overview of the scaled model architectures can be seen in Table 5. Interestingly, we observed that both scaling methods yield the same performance improvement. As shown in Figure 9, given a similar FLOP cost, scaling the depth or the width seems to have the very same impact on the test loss.

Generally speaking, scaling depth-wise lead to smaller, but less efficient models. Indeed, modern hardware architecture can handle more efficiently large matrix products than many smaller matrix products. As shown in Table 5, width-scaled models are faster than depth-scaled models because the GPU can do more FLOP per second.

5 Conclusion

This work describes the behavior of decoder-only models on the multilingual multidomain machine translation task. We trained six models whose number of parameters range from 70M to 6.9B on sentence pairs in eight European languages. We found that scaling laws for machine translation cannot describe the general behavior of translation models, but they can still provide good estimation in a given domain, language-pair, and range of model sizes'. Indeed, We show that decoder-only models for translation tend to scale similarly as language models, as the Chinchilla law can also be applied to our models. As such, we recommend to train machine translation models using the same training recipes as large language models. While we think it is true for most, if not all, NLP tasks, more work need to be carried out to validate this hypothesis. However, we also highlight a critical limitation of scaling laws: they cannot generalize well beyond an unknown model and/or training dataset size. As models tend to be larger through time, it will be extremely important to find ways to detect early unreasonable deviations of the "reference" scaling laws on which larger models are build.

We also show that models scaled width-wise appear to be more FLOP efficient than models scaled depth-wise, while reaching almost the same loss. Our experiments need to be continued in order to see when increasing the depth of the model starts to be more valuable than increasing its width. But, generally speaking, increasing the linearly both the depth and the width seems to be a good trade-off between efficiency and parameters count.

Efficient training requires packing as many sentence pairs as possible in a training batch. We discovered that unexpected biases can be introduced if proper masking is not applied, that is to say, if sequences can attend to previous ones. Since it is not possible with current state-of-the-art optimization methods, one must carefully format the training input data. We suggest dropping the *end-of-sentence* token, commonly used to signal the end of text generation, in favor of a *start-of-translation* token signaling the start of a new source sentence and, therefore, the end of the generated target sentence.

This study has been conducted on sentence-level pairs only. While this setup is a bit outdated, it is still the first time a comprehensive study has been made on multilingual machine translation using decoder-only architectures. Nevertheless, we expect decoder models to be easy to adapt to the document-level translation task, as one can simply finetune a sentence-level decoder with non-shuffled sentence pairs from a corpus of parallel documents.

B Prompt templates

We used the following system prompt to generate translation with Llama, Tower and Mistral:

```
You are an expert translator.
    The user will ask you to
    produce translations,
    generate only the asked
    translation, do no justify
    nor explain anything.
```

We used the following instruction template to query the models:

```
Translate from {SOURCE_LANGE}
    to {TARGET_LANG} the text
    below.
{SOURCE_TEXT}
```

C Models' performances per direction

Performances of all models increase as parameters counts increase, regardless of the scoring method, as shown in Figures 10 and 11.

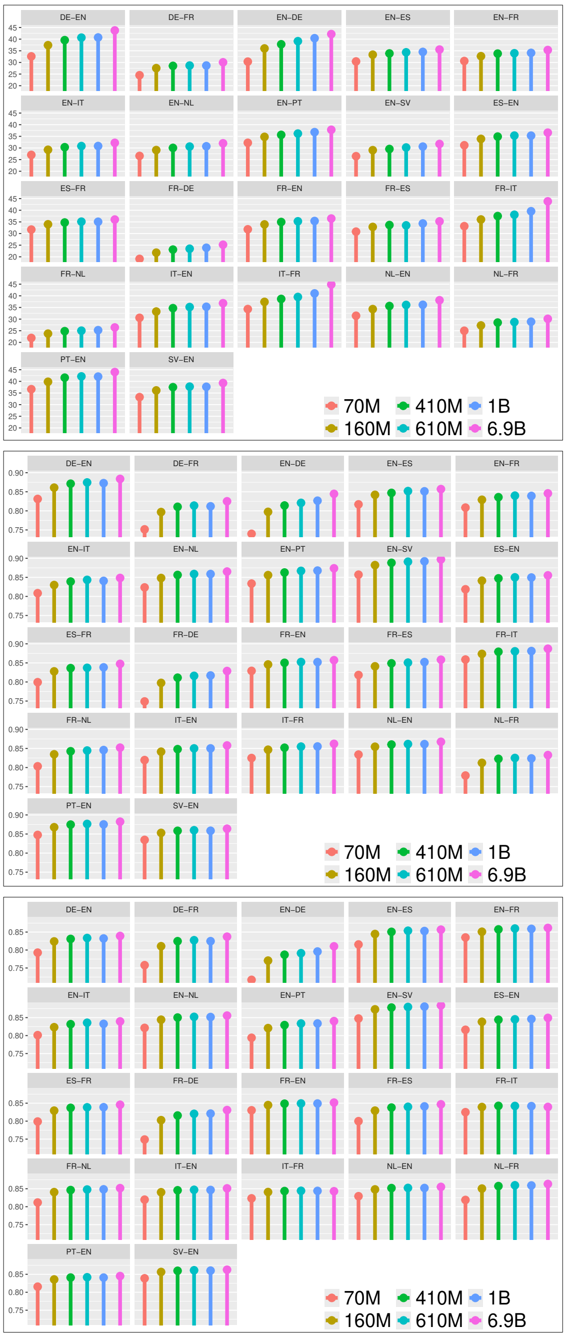

Figure 10: From top to bottom, BLEU, COMET and CometKiwi scores computed on the test dataset for all models and directions, on the general domain.

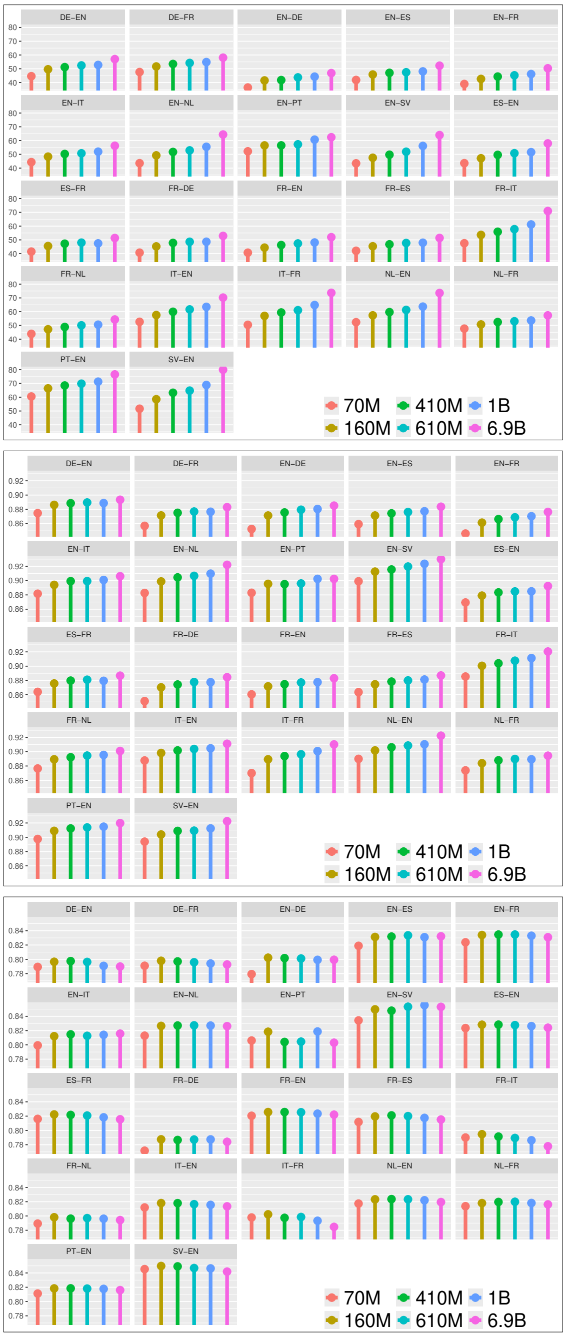

Figure 11: From top to bottom, BLEU, COMET and CometKiwi scores computed on the test dataset for all models and directions, averaged over all financial subdomains.

Shortcomings of LLMs for Low-Resource Translation: Retrieval and Understanding are Both the Problem

Abstract

This work investigates the in-context learning abilities of pretrained large language models (LLMs) when instructed to translate text from a low-resource language into a high-resource language as part of an automated machine translation pipeline. We conduct a set of experiments translating Southern Quechua to Spanish and examine the informativity of various types of context retrieved from a constrained database of digitized pedagogical materials (dictionaries and grammar lessons) and parallel corpora. Using both automatic and human evaluation of model output, we conduct ablation studies that manipulate (1) context type (morpheme translations, grammar descriptions, and corpus examples), (2) retrieval methods (automated vs. manual), and (3) model type. Our results suggest that even relatively small LLMs are capable of utilizing prompt context for zero-shot low-resource translation when provided a minimally sufficient amount of relevant linguistic information. However, the variable effects of context type, retrieval method, model type, and language-specific factors highlight the limitations of using even the best LLMs as translation systems for the majority of the world's 7,000+ languages and their speakers.

1 Introduction

Despite great progress in the quality of today's state of the art machine translation (MT) systems, constraints on the amount and kinds of data available in the majority of the world's 7,000+ languages have led to yet another disparity in access and support for speakers of these languages: low-resource MT continues to be a major challenge (Hendy et al., 2023; Nicholas and Bhatia, 2023; Robinson et al., 2023; Stap and Araabi, 2023). Although many languages lack the kinds of large, standardized corpora necessary for traditional MT methods, recent work suggests it may be possible to leverage a smaller amount of existing resources, for example pedagogical materials used for language instruction, to develop MT systems with Large Language Models (LLMs), albeit with varying results (Elsner and Needle, 2023; Tanzer et al., 2024; Zhang et al., 2024). These materials are often the result of community-driven or government-led initiatives to support language revitalization, reclamation, and mother-tongue education (Schreiner et al., 2020; Liu et al., 2022; Riestenberg et al., 2024). Such discrepancies in the needs and priorities of academic, commercial, and community-led efforts to develop digital resources and language technologies is what Gessler (2022) terms the "NLP Gap".

In this study, we investigate one way to lessen the NLP Gap, comparing LLMs' in-context learning abilities when translating from a low-resource language (a Peruvian variety of Southern Quechua) to a high-resource language (Spanish) using information retrieved from a database of pedagogical materials. We replicate results of earlier studies on a new language pair by comparing the effects of morpheme translations, sentences from a parallel corpus, and passages from a grammar instruction document on translation quality. We then conduct a more focused analysis by annotating translation outputs by hand using a modified MQM error typology (Burchardt, 2013). Finally, we conduct an ablation study on the effects of automated retrieval by manually constructing prompts using the same set of materials.

Our results suggest that while, unsurprisingly, translation quality improves with model size, such improvements seem to primarily be the result of previous exposure to the low-resource language during model pretraining, rather than an improved ability for the model to utilize prompt context, as evidenced by high scores in response to baseline (zero-shot) translation prompts. However, we also find evidence that in-context learning abilities may be inconsistent across different models of similar size. As found in previous studies, prompts contain-

Proceedings of the Ninth Conference on Machine Translation, pages 1332–1354
November 15-16, 2024 ©2024 Association for Computational Linguistics

ing morpheme and word-level translations reliably improve model outputs, but information from the grammar and corpus have a null or even negative effect on results. Human evaluation on a selection of outputs from two models – GPT-3.5 Turbo and GPT-4o – align with the quantitative measures we obtain using BLEURT (Sellam et al., 2020) as an automatic metric. Quantitative results also show an effect of automated retrieval on translation quality that is most evident in prompts containing morpheme translations and for models with lower baseline scores. Finally, we highlight a number of ethical concerns and limitations that arise from the proposed methods that are supported by our findings, and discuss the potential risks and challenges LLM-based methods for low-resource MT face moving forward.

2 LLMs for Machine Translation

Modern LLMs are now capable of translating many high-resource languages, but lack sufficient coverage of even modestly resourced languages to achieve comparable results without additional support (Kocmi et al., 2023). Retrieval-augmented generation (Rubin et al., 2022) may provide such support in the form of parallel sentences (Agrawal et al., 2022), dictionary definitions (Ghazvininejad et al., 2023; Lu et al., 2023) or other linguistic meta-knowledge such as a grammatical description. Retrieval-augmented methods offer exciting possibilities for low-resource translation, since the LLM might (in principle) be able to "teach itself" the language from learner-oriented resources produced by community members or language specialists.

Studies to date (Elsner and Needle, 2023; Reid et al., 2024; Zhang et al., 2024) experiment with four dimensions of variability: source language, LLM, type(s) of information retrieved, and retrieval method. Since the source languages in these studies have relatively little presence in public corpora or on the web, differing results across LLMs can tentatively be attributed to differences in their in-context learning and instruction-following abilities.

All studies find that word-level translations are helpful additions to prompts. Zhang et al. (2024) and Tanzer et al. (2024) also add sentence pairs from a parallel corpus, while Elsner and Needle (2023) add usage examples from a dictionary. Each improves results, although to a lesser degree. Elsner and Needle (2023) and Zhang et al. (2024) experiment with small fixed "grammar lesson" passages to provide explicit syntactic instruction, but find these ineffective. Tanzer et al. (2024) uses passages retrieved from a grammar book, also with relatively disappointing results. Reid et al. (2024) use the entire grammar book and a very long-context model to obtain better translations, but without exploring the role explicit grammar instruction actually plays in doing so.

Zhang et al. (2024) find that sentences from the corpus retrieved using BM25 embeddings (Robertson et al., 2009) work better than random ones. Tanzer et al. (2024), however, report that retrieval with longest common substring (LCS) matching outperforms embedding-based retrieval. Overall, the question of how to best retrieve relevant passages containing grammar material or sentences in a low-resource language is still open. This also complicates the interpretation of the mostly-negative results found for grammar passages. It is not clear whether these stem from poor retrieval, from the LLM's inability to process the retrieved content, or both. Moreover, although Reid et al. (2024) conducts human evaluation of the results for quality, to the best of our knowledge no study to date systematically investigates specific grammatical errors in the output.

Finally, each of these studies finds a significant decrease in LLMs' abilities to translate from a high-resource language into a low-resource language relative to experiments in the opposite direction. This is in line with McCoy et al. (2023), who find that while the accuracy of an LLM's output highly depends on the probability of both the input and the output text, output probability has a greater influence on model performance. We therefore focus this study on a single translation direction, instructing LLMs to output translations from a low-resource language into the language with which they are likely to have had more exposure during training, i.e, from Southern Quechua into Spanish, and leave the reverse direction for future work.

3 Quechuan Languages

Quechua is a family of languages Indigenous to the Andes in South America. This study focuses on varieties of Southern Quechua (S. Quechua, also known as *urin quechua* or *quechua sureño*) spoken in parts of Peru.[1] While previous studies investigated language-LLM pairs for which the baseline

[1] Unless noted otherwise, we use *Quechua* in this study to refer Southern Quechua and related varieties.

LLM lacked any pretrained knowledge, we find that newer LLMs can translate some S. Quechua sentences in a zero-shot setting. We expect this to be typical of many low-resource languages which, while often endangered, still may have some presence on the web.

Quechuan languages have by far the largest representation of all Indigenous Latin American languages in NLP research (Tonja et al., 2024) and are often included in ACL-affiliated workshops, datasets, and shared tasks (Cotterell et al., 2020; Ebrahimi et al., 2022, 2023). S. Quechua has a robust language toolkit (Rios, 2015), including the morphological parser we use in our pipeline. It has also been the subject of numerous studies on MT for both text and speech, developed in conjunction with monolingual and parallel corpora (Rios, 2015; Cardenas et al., 2018; Ortega et al., 2020; Zevallos et al., 2022). Nonetheless, such tools continue to face challenges, and Quechuan languages continue to lack the resources necessary to develop most of today's state of the art models.

Since Quechua is primarily spoken in South America, the majority of available digital resources, including all materials used in this study, use Spanish as the language of translation, explanation, and/or instruction. We therefore also use Spanish, rather than English or any other high-resource language, as the language of translation and prompting when testing our system.

3.1 Language-Specific Factors

While the proposed methods are general enough to be applied to any language pair, model outputs may reflect certain language-specific characteristics of the source and target languages, respectively. In this section, we provide a brief description of selected language-specific factors in S. Quechua as they relate to their translated Spanish counterparts. For a discussion of their potential effects on our results, please see Section 6.1.

3.1.1 Morphological Segmentation

S. Quechua is primarily agglutinating, i.e., much of the morphology may be described in terms of isomorphic form-meaning relationships, morphemes generally maintain a consistent form regardless of their phonological environment, and morpheme boundaries tend to be transparent. In contrast, morpheme segmentation in Spanish may be rendered opaque due to its fusional morphology and widespread use of conditioned allomorphy.

While LLMs are trained to process text via token-based rather than morpheme-based segmentation, it is possible that a lack of direct correspondence between the expression of morphosyntactic categories in S. Quechua and Spanish may affect a model's ability to leverage the information we provide as prompt context in our experiments. Correspondences in form and meaning across parallel usage examples may be particularly obscured, limiting the use of corpora designed for traditional MT methods. It may be possible to mitigate such issues with more advanced retrieval or prompting techniques, for example by explicitly instructing an LLM to conduct morphological analysis as part of the translation process, but we leave this for future work.

3.1.2 Syncretism and Polysemy

Although the language is primarily agglutinating, a number of morphemes in S. Quechua are syncretic, such that a given form may be used to express more than one grammatical category. For example, the 1SG.POSS marker, *-y*, shares the same form as both the 2SG.IMP marker and the infinitival marker, as illustrated in the following examples:

(1) ñaña-y
sister-1SG.POSS
'my sister'

(2) Mikhu-y!
eat-2SG.IMP
'Eat!'

(3) mikhu-y-ta muna-ni
eat-INF-ACC want-1SG
'I want to eat'

Similarly, words in S. Quechua may be polysemous, with the potential to express more than one meaning depending on their use in context. For example, the S. Quechua word *miski* (*misk'i*) may be translated as either *dulce* 'sweet' or *rico/a* 'delicious', and both *dulce* and *rico/a* are themselves polysemous in Spanish. *Dulce* may be used as an adjective, i.e., 'sweet', or a noun, i.e.,'candy', and *rico/a* may describe either richness in flavor, i.e., 'delicious', or in monetary wealth, i.e., 'rich'.

The exact forms displaying syncretism or polysemy must be identified on a language-specific basis, but the ambiguity they present poses a clear problem for our proposed methods in general, with potential effects on both retrieval and generation. We discuss this issue further in Section 6.1.

3.1.3 Variation

Both S. Quechua and Spanish are characterized by extensive regional and dialectal variation. In S. Quechua, this includes differences in orthographic and/or phonological conventions as well as the specific lexical items and expression of morphosyntactic content. For example, the S. Quechua word for 'dog' may be rendered orthographically as *alqo*, *allqo*, *allku*, *allqu*, or *ashko*, and the additive suffix may be expressed as either *-pas* or *-pis*, depending on the community. Variation in the attested usage of specific lexical items and morphemes across communities is also common in S. Quechua. For example, the evidential marker *-mi* /*-m* is frequently attested in the Peruvian variety of S. Quechua used in this study, but essentially absent in many Bolivian varieties.

Variation across Spanish-speaking communities may also affect models' abilities to produce translations that are both accurate and appropriate. The Andean Spanish reference translations used in this study do not appear to affect the results of our automatic evaluation. However, were the proposed methods to be applied in a realistic setting, it would be especially important to assess the degree of alignment between any prescriptive linguistic standards that have been implicitly acquired by the LLM and the usage conventions of the language community or communities of interest.

4 Methods

4.1 Data

We conduct experiments on a collection of 50 pairs of S. Quechua - Spanish sentences sourced from one of the author's personal notes. These were selected to highlight a range of specific grammatical phenomena at multiple levels of difficulty— they include simple clauses and tenses (Example (4)), as well as more advanced constructions such as those involving past participles (Example (5)) and simultaneous events (Example (6).

(4) qam allin-ta tusu-nki
you good-ACC dance-2SG
tu bailas bien
'you dance well'

> [TAREA] Traduce la siguiente frase del quechua al español. Responde sólo con la traducción:
> quechua: kay wasiqa turiypam
> español:

Figure 1: Example BASELINE prompt. English: *[TASK] Translate the following sentence from Quechua to Spanish. Respond only with the translation: Quechua: kay wasiqa turiypam; Spanish:*

(5) awa-sqa-y wali-qa sumaq-mi
knit-PP-1SG skirt-TOP great-ASSERTIVE
la falda que tejí es linda
'the skirt that I knit is pretty'

(6) qam-qa taki-ta uyari-spa
you-TOP song-ACC listen-SUBR
wasi-yki-ta picha-chka-nki
house-2.POSS-ACC clean-PROG-2SG
tú estás limpiando tu casa escuchando música
'you're cleaning your house listening to music'

The first author, a foreign-language student of S. Quechua, received permission from her instructor to use notes from their lessons for the study. All sentence pairs were inspected by the instructor, a native bilingual speaker of both S. Quechua and Peruvian Spanish, to eliminate any errors and confirm the accuracy of all reference translations.

4.2 Prompt Construction

As a baseline, each sentence is inserted into a prompt template that instructs the model in Spanish to translate the S. Quechua sentence into Spanish and respond only with the translation (Figure 1). We automate a process for building on this template and compare the effects of adding information from three different sources to the prompt context.

4.2.1 Morpheme Translations (MORPH)

We use a morphological parser (Rios, 2015) to segment each word of the source segment into morphemes, each with gloss symbols and a Spanish translation.[2] Some morphemes have multiple candidate meanings, all of which are retrieved. As an example, the word *rantikuq* is segmented as *ranti-ku-q* and glossed as "comprar.DB.VRoot-DB.VDeriv.+RflxInt+Ag.NS."

[2] We set aside valid concerns regarding the theoretical status of the *morpheme* for this study and define a morph(eme) loosely as a recognizable form-meaning pair that recurs in a language.

While numerous orthographic standards have been developed and promoted across Quechuan-speaking communities in South America, considerable variation in orthographic conventions may be found even within a particular community or variety (Rios and Castro Mamani, 2014). We discuss the implications of this for our results in Section 4.2.5.

We supplement the output from the parser using a Quechua-Spanish bilingual dictionary (Qheswa Simi Hamut'ana Kurak Suntur, 2005). We retrieve any dictionary entry whose headword exactly matches a morpheme in our segmentation. By default, we include all senses and any usage examples or contextual information in the dictionary entry as part of the prompt. We then concatenate the output of the parser with the retrieved dictionary entries and include this MORPH information as prompt context preceding the source sentence and baseline translation prompt.

4.2.2 Grammar Descriptions (GRAMMAR)

We also experiment with the inclusion of grammar lessons found in student-facing pedagogical materials, retrieving grammatical explanations relevant to each source sentence from a PDF document developed for students and teachers of S. Quechua (Pinto Tapia et al., 2005). The document is organized into short sections (1-3 sentences, plus paradigm tables or usage examples) that describe the particular grammatical concept associated with an affix in Quechua. For each source sentence, we retrieve sections associated with any affix listed in the document that is an exact match of a morpheme and include this in prompts using contextual information from the grammar. This improves on the methods described in Tanzer et al. (2024), who use LCS-based retrieval over an entire textbook, and Elsner and Needle 2023 and Zhang et al. 2024, whose grammatical description remains consistent across prompts regardless of the source text being translated.

4.2.3 Parallel Usage Examples (CORPUS)

Finally, we experiment with sentence-level examples from a S. Quechua-Spanish parallel corpus designed for traditional NLP tasks. We combine data made available via the AmericasNLP 2021 Shared Task on Open Machine Translation and the 2023 IWSLT shared task on low-resource SLT (Tiedemann, 2012; Agić and Vulić, 2019; Ortega et al., 2020; Mager et al., 2021; Agarwal et al., 2023). For each source sentence, we retrieve the three best matches from the corpus using a LCS search against the full source sentence.

4.2.4 Combined Prompt Types

Combinations of information from all three sources yields 8 total conditions, including the baseline. An example prompt from each information source is given in Appendix E.

4.2.5 Manually Revised Prompts

To compute a soft upper bound on the improvements possible with better retrieval, we conduct an additional set of experiments using manually revised prompts. We first examine the content retrieved from the morphological parser, dictionary, and grammar document and remove all instances of ambiguity and irrelevant or misleading information from the prompt context.[3]

For example, many S. Quechua speakers use the term *runasimi* (lit: 'people mouth', 'the people's language'), as an endonym for the language. The parser, however, returns only the literal decomposition (*runa* 'ser humanos'/'people' and *simi* 'boca'/'mouth'), and the dictionary does not list *runasimi* as a headword but rather as one of eight different senses of *simi*. We thus remove all such irrelevant examples and translations from the prompt and retain only the content indicating a translation of *runasimi* in the linguistic sense.

We also manually retrieve content from the dictionary and grammar documents that were overlooked by the automated retriever. For example, the verb *yanuy* 'to cook' does not appear as a headword in the dictionary, but rather as a regional variant of *wayk'uy* 'to cook'. We also eliminate content from the grammar that was retrieved because of syncretism, or mistakes that cascaded from the morphological parser to result in irrelevant retrievals.

We manually parse each source sentence to only retrieve and include relevant information in the prompt context. All content in the revised prompts is sourced from the same material available to the automated retriever systems, and we do not add any additional information or use supplemental materials of any sort to create the revised prompts.

[3] We do not experiment with retrieval methods for corpus examples, which were retrieved using LCS match in both conditions. Improving on LCS-based retrieval remains an open question in low-resource LLM-MT, and we leave this for future work.

4.3 Models

We experiment with three proprietary models, GPT-3.5 Turbo (gpt-3.5-turbo-0125, Brown et al., 2020), GPT-4o (gpt-4o, Achiam et al., 2023), and Gemini 1.5 Pro (gemini-1.5-pro, Reid et al., 2024), and one open-source model, Llama 3 (llama-3-8b-instruct, AI@Meta, 2024). We use the pretrained models with their default settings, and do not adjust hyperparameters or conduct any finetuning as part of our experiments.

4.4 Evaluation

We conduct both automatic and human evaluations to identify trends in model errors and outputs in the various experimental conditions. We calculate BLEURT and BLEU scores as automatic metrics, and report mean BLEURT scores across items as the primary quantitative measure of translation quality for each of the conditions and models. We also use an adapted MQM schema to conduct qualitative human evaluation of the outputs of GPT-3.5 and GPT-4o for all prompts using automatic retrieval.

Each item selected for human evaluation is annotated by at least one of the authors by comparing the model's output to the source text and reference translation. We refer to the complete MQM typology to design our own four-dimensional framework of commonly attested errors in LLM-MT, each with a defined set of specific subtypes. Precise definitions and examples for all error categories and subtypes may be found in Appendix D.

Many of the categories in our schema are defined as in the core MQM framework. However, to capture some of the key behaviors reported in previous studies on LLM-MT and to evaluate the effects of prompt type on model outputs, we make the following adjustments. First, we utilize the Addition and Omission errors defined as Accuracy subtypes in the original MQM typology, but distinguish these from three additional subtypes: Substitution - Incorrect Subject, Substitution - Incorrect Tense/Aspect/Modality (TAM), and Substitution - Other. This is intended to capture LLM translations that differ from the source in terms of discrete lexical material or case, person, number, and/or TAM markings while otherwise maintaining the lexical and structural content needed to appropriately translate the source text. Although they are not the only grammatical phenomena that may be similarly misrendered, we select subject and TAM markers for analysis as they are straightforward to identify and give a good indication of how well the LLMs cope with more abstract information about the meanings of functional morphemes.

Rather than including Mistranslation and MT Hallucination as Accuracy Error subtypes as in the original MQM typology, we define a separate Non-Translation category with three possible subtypes: Complete Mistranslation, Mistranslation with Lexical Correspondences, and Refusal. The third dimension of our typology, Model Error, was ultimately not used to classify any output in this study, but characterizes more generic model "misbehavior" such as failing to follow instructions, producing garbled text, or inappropriately generating content in the source language. Finally, Target Errors identify outputs that are ungrammatical, stylistically inappropriate, or semantically incoherent in the target language, regardless of their accuracy.

Detailed annotation guidelines were drafted and agreed upon to encourage consistency across annotators and experimental items. Annotators are instructed to identify and tag up to three specific errors for each translation output, with the exception of Target Errors, which do not count towards the three-error maximum. Each model output is also tagged for quality along a four-point scale as defined in Table 5.

Before proceeding with annotation over the larger dataset, both annotators also completed a test evaluation of the same 12 experimental items (96 sentences total) to assess inter-annotator agreement. Statistical measures ($\kappa = 0.72$ for quality judgments, $\alpha = 0.55$ for error categories) indicated some discrepancies in annotator judgments, especially for categories, since determining the three most important errors is especially subjective. These were identified and discussed, and agreement was ultimately deemed sufficient to proceed.

5 Results

5.1 Quality Metrics

We present BLEURT scores for prompts generated using automated retrieval in Table 1 and summarize human quality judgments for GPT-3.5 and GPT-4o with automated retrieval in Table 2. The complete distribution of BLEURT, BLEU, and human-annotated quality ratings for all of our experiments is provided in Appendix F. We find clear effects of LLM, prompt type, and retrieval method, as well as interactions among all three factors.

	GPT3.5	GPT4o	Gem.	Lla3
BASE	0.19	0.66	0.56	0.15

GRAMMAR	33	99
MORPH	79	102
C+G	41	101
C+M	75	110
G+M	68	100
C+G+M	77	109

Table 2: Human-annotated quality ratings summarized as $3 \times high + 2 \times med + low$. Shaded rows include morpheme contexts.

	GPT3.5	GPT4	Gem.	Lla3
G-AUTO	0.23	0.56	0.55	0.17
G-MAN	0.24	0.58	0.54	0.15
M-AUTO	0.44	0.54	0.61	0.39
M-MAN	0.56	0.63	0.66	0.49
CGM-AUTO	0.43	0.57	0.61	0.15
CGM-MAN	0.54	0.63	0.63	0.26

Table 3: Comparison of mean BLEURT scores for automatic versus manual retrieval of material in GRAMMAR, MORPH, and CORPUS-GRAMMAR-MORPH prompts.

Comparing across models, we find that Gemini and GPT-4o outperform Llama 3 and GPT-3.5 for every prompt type. This gap is highest for the least informative prompts, indicating that the Llama 3 and GPT-3.5 base models have relatively poor coverage of S. Quechua, while GPT-4o and Gemini have much better coverage. The effect is evident in both automatic and human quality evaluations.

Effects of prompt type are mediated by the quality of the pretrained model. Llama 3 and GPT-3.5 show a clear improvement in quality when MORPH information is included in the prompt. Gemini also improves when this information is added, but to a lesser extent. GPT-4o, on the other hand, performs best in response to the BASELINE (zero-shot) prompts, which attain the highest BLEURT scores across all models, prompt types, and retrieval methods evaluated in this study. In other words, providing additional information in the prompt's context actually *degrades* GPT-4o's ability to translate from S. Quechua to Spanish in all experimental conditions.

5.2 Effects of Automated Retrieval

To highlight the effects of automated retrieval on model output, we present BLEURT scores for a selection of prompt types and all four models in Table 3 (full scores may be found in Appendix F). The effect of manual retrieval for MORPH information is positive for all models, although this gap is smallest for Gemini (probably because its performance for these prompts is already highest). The effect for GRAMMAR prompts is either minor or negative.

5.3 Human Analysis of Translation Errors

The most common error type identified by the annotators is Substitution - Other, which includes a diverse assortment of lexical and phrasal incongruencies of varying degrees of severity. These are largely item-specific and therefore hard to characterize as a group. Using the error categories described in Section 4.4, we instead identify three more clearly interpretable phenomena and provide a detailed discussion of each in the following sections. We present counts for selected prompt types in Table 4, with examples in Appendix A and counts for all errors in Appendix G.

5.4 Mistranslations

Outright mistranslations are most common for GPT-3.5, making up 30 of the 50 responses in the BASE-

		BASE	MORPH	C+G+M
Mistranslation: complete + lexical correspondence	GPT-3.5	45	11	12
	GPT-4o	4	6	4
Target Fluency: grammar + coherence + style	GPT-3.5	0	14	10
	GPT-4o	3	13	9
Grammatical Divergence: subject + TAM	GPT-3.5	0	24	31
	GPT-4o	17	13	11

Table 4: Counts of human-annotated error types (per 50 sentences) by LLM and prompt type.

LINE condition. We also consider outputs that retain only minimal traces of the source content, which we label as Mistranslations with Lexical Correspondence. Approximately 1/3 of the 637 total errors tagged across all prompt types for GPT-3.5 are mistranslations of either type, roughly split between complete mistranslations and those with lexical correspondence (15.07% and 18.37%, respectively, of all errors tagged for GPT-3.5).

As reported in previous work, adding morpheme- and word-level translations to the prompt greatly reduces the rate of this kind of response. GPT-4o also produces drastically fewer mistranslations compared to its predecessor. However, it is notable that both models produce at least one mistranslation for each prompt type. In general, complete mistranslations are in fluent Spanish and contain no overt indications that something has been misrepresented. We return to the ethical implications of these errors in the Discussion.

We also note that many of the items tagged as Mistranslation with Lexical Correspondence show correspondence only for words that were already in Spanish in the source text. For example, some sentences contain Spanish loan names for the days of the week. While some of these errors are produced in deceptively fluent Spanish, we find many to be accompanied by semantic incoherence or ungrammaticality in the output. We discuss such target language fluency errors in the following section.

5.5 Target Fluency

Target Fluency errors occur when the output is not grammatical, coherent, or stylistically appropriate – for instance, if an output contains a nonsensical repetition or a verb with missing arguments. Outputs of this type bear a strong similarity to human "translationese" in that structural features of the source language may surface in the translation at the expense of naturalness (Koppel and Ordan, 2011; Freitag et al., 2019). Both GPT-3.5 and GPT-4o tend to produce more such outputs when the prompt is more informative – 10 to 20% of the time (5-10 instances per 50) in prompts with morpheme translations.

5.6 Grammatical Divergence

We group misrendered verbal subjects and tense/aspect/morphology (TAM) markers together as Grammatical Divergence errors. Such errors are distinct from the Target Fluency errors described in the previous section— the Spanish output is grammatical, but fails to accurately reflect the content from the source. TAM divergences are much more prevalent than divergences in subject; for instance, only one of GPT-4o's 13 Grammatical Divergence errors in the MORPH condition misrender the subject marker.

Grammatical Divergence errors are annotated only for sentences that are not mistranslated outright, so GPT-3.5 produces none of these in the BASELINE condition. For more informative prompts, it is clear that GPT-4o is better than GPT-3.5 at translating both functional and lexical meanings. However, a relatively large number of sentences (over 20%) still contain such an error even with the highest performing model and prompt type. The relatively small drop in error between different prompt types for GPT-4o suggests that neither the corpus-based usage examples nor example paradigms and descriptions from the grammar document can fully prevent this type of error.

6 Discussion

We observe large differences between LLMs, both in terms of the overall quality of their generated translations as well as the effects of prompt type on their outputs. GPT-4o and Gemini, which have the highest baseline scores, benefit least from additional information— BLEURT scores actually decrease when CORPUS and GRAMMAR information is included. This occurs even with manually curated prompts, suggesting it is not an effect of including irrelevant material. Nonetheless, the baseline results do not represent a ceiling on quality, since both models still produce errors in the BASELINE condition (GPT-4o produces 10 LOW-quality translations in our set of 50). These results suggest that even relevant grammar explanations, when written in prose with examples, do little to help the newest generation of LLMs to translate a low-resource language such as Southern Quechua.

Although GPT-4o and Gemini results are similar in many ways, we do find evidence for differences in their in-context learning abilities. Baseline prompts and the GPT-4o model produce the highest BLEURT scores across the dataset, but these outputs still show a number of errors characteristic of LLMs, particularly lexical substitution errors that are not necessarily corrected with the inclusion of more context. In contrast, Gemini, which has near-comparable performance across prompt types, shows an increase in scores when prompts include MORPH information, regardless of retrieval type, suggesting a greater ability to identify and utilize relevant word- and morph-level translations in the prompt's context. Previous work suggests that newer builds of GPT-4 are less capable of following instructions (Chen et al., 2023); such differences may be masked by the effects of pretraining when automatically evaluating translations. This suggests that researchers should continue to carefully select and compare among different LLMs when experimenting with retrieval-based translation.

6.1 Language-Specific Effects

We identify a number of translation errors of varying types that appear to be due to language-specific factors such as those discussed in Section 3.1. For example, we find an effect of polysemous lexical items for all prompt types in the outputs of both models on which we conduct human evaluation.

In the most straightforward cases, the model incorrectly generates an alternate sense of the word that is inappropriate given the content of the source sentence. We also find a number of instances in which the presence of such ambiguity has a cascading effect on lexical selection in the rest of the model's output. For example, when co-occuring with *miski* in the source text, the word *lawa* 'soup' is translated at times as *mazamorra*, a sweet porridge or pudding, *crema* 'cream', *miel* 'honey', *golosina* 'candy', or *dulces*, the nominal form of *dulce* meaning 'candy' or 'sweets.'

It may be possible to moderate such effects with additional refinement of the database structure and retrieval methods, which we leave for future work.

6.2 Ethical Concerns

Both our work and much of the previous work in this paradigm is motivated by the desire to close the "NLP Gap" among researchers, community members, and software developers interested in low-resource language technologies. Machine translation is listed as a welcome topic of research by some (though not all) members of American Indigenous communities (Mager et al., 2023), and is potentially an important tool for language learners (Jolley and Maimone, 2022). Even an imperfect translation system might be a useful tool for users with a clear understanding of its limitations. However, the systems evaluated in this work have two problematic tendencies that limit their potential for deployment in real community settings.

First, unfaithful translations often tend to be highly fluent (Section 5.4). While fluency ratings for older MT systems correlate well with accuracy scores, and have even been used as a proxy for overall translation quality (Gamon et al., 2005; Estrella et al., 2007), this correlation is reversed for our systems. LLMs are well-known for making false statements that seem plausible and authoritative (Bickmore et al., 2018; Dinan et al., 2021); this could be particularly problematic when they project illusions of expertise at the expense of an already marginalized group.

Second, some mistranslations identified in our study appear to draw on stereotypes of Indigenous groups (Appendix B). These are most apparent for the BASELINE system and GPT-3.5, but also (less frequently) occur with more informative prompts and better LLMs. Stereotypical sentences can involve flowery language with an emphasis on tradition or connectedness to nature (Erhart and Hall, 2019), as well as the unprompted addition of Indigenous Andean cultural customs and products (e.g., traditional medicine and chicha) to translations that are otherwise faithful to the source text. The overall effect is to exoticize Southern Quechua speakers and writers in ways that the original sentences do not. Similar stereotypes have also been noted in LLM-generated responses to open-ended prompts (Cheng et al., 2023; Delgado Solorzano and Toxtli, 2023; Shieh et al., 2024).

While we prompt models to output only the translation for evaluation purposes, models may have some capacity to explain or qualify their translations and give reminders for responsible use of the technology. Should a retrieval-based translation system ever be deployed in a real-world setting for language learning, its developers should maximize transparency by presenting the content of any retrieved information and its source to the user along with the translation, reminding users directly of potential inaccuracies, and offering vetted resources for additional fact-checking when available.

7 Conclusion

Our results suggest a number of key limitations and concerns regarding the use of LLMs in a low-resource MT context, and have greater implications for our understanding of the seemingly "humanlike" conceptual, analytical, and in-context learning abilities of LLMs.

For the majority of the world's languages and their speakers, powering and supplying LLMs with enough pretraining data to overcome their limitations is not feasible. We therefore offer the following suggestions to those looking to develop low-resource LLM-MT: (1) improve data structures and methods for interacting with a language-specific database for retrieval-aided generation, (2) continue analysis of the mechanisms driving in-context learning in LLMs, for example by comparing ICL to the effects of finetuning (Dai et al., 2023), and (3) experiment with prompt structures and techniques, for example by altering the order of information (Liu et al., 2024) or by iteratively prompting the model to guide its reasoning towards a suitable translation (Wang et al., 2022).

Finally, we wish to emphasize the continued risks of prematurely deploying this or similar methods in any low-resource language community, particularly given the vulnerability and disproportionate lack of resources many such communities face in domains where these technologies would likely be used. As AI research continues to rapidly develop, we urge those conducting it to increase community engagement, amplify the voices of those traditionally at a disadvantage, and collaboratively develop research infrastructures that may lessen the NLP Gap (Brinklow, 2021). While there's still much to be done before low-resource LLM-MT may be safely implemented, we believe such a tool has the potential to empower speakers of any variety, including nonstandard varieties of high-resource languages such as English, to develop technologies that reflect their preferences and serve their unique needs.

8 Limitations

Limitations on the scope and replicability of this work may be attributed to one or more characteristics of the data and models used in this study, in addition to limitations inherent to the respective identities of its authors. First, the automatic metrics (i.e., BLEURT and BLEU scores) that we report are limited in their statistical validity. We have conducted some constrained tests to explore potential variance in scores, but expenses associated with text generation using proprietary models such as those developed by OpenAI and Google on a larger dataset may be prohibitive. This is compounded by the widely-acknowledged "black box" nature of the models powering both LLMs and BLEURT, as well as an increasing opacity with respect to the exact content and methods used to pretrain modern state of the art LLMs. For this reason, we focus our discussion on those results that show clear trends in both the quantitative and human evaluations we conduct.

There are also some constraints on our study and its methodology that are largely tied to linguistic factors, such as variation in orthography (and the need for digitized text-based resources as a prerequisite) as well as the lexical and grammatical variation that may be found in all languages, particularly the low-resource varieties we wish to support. We discuss some of these factors in Sections 3.1 and 6.1. Our results suggest it may be possible to guide the outputs of LLMs towards the specific usage conventions of a given community, but this is itself limited by the content of the materials used to develop the database from which prompt contexts are retrieved.

Neither of the authors is a native speaker of any Quechua or Spanish varieties, and only one is a student of these languages and has relationships to Quechua speakers and communities. While we have strived to be consistent in the Quechua and Spanish varieties used in our study (both the dictionary and grammar materials were provided by the same instructor who shared and proofread the 50 sentence pairs we use, and we select a morphological parser and corpora intended for use with Southern Quechua), variation is widespread among and within Quechua-speaking communities, and we do not have access to a dictionary, grammar, morphological parser, and corpus developed by a unified and consistent set of authors. Future work should continue to explore ways to faithfully represent the diversity of linguistic conventions employed by communities interested in developing such technologies.

We acknowledge, as well, limitations that arise from the size of our dataset and database and the methods used to curate them. The 50 sentence pairs we use were selected to highlight a range of specific grammatical phenomena, not all of which were well represented in our database, and differ in their structural complexity. We are grateful for the guidance provided by the Quechua instructor whose lessons were a source for such examples and proofread the sentences before their inclusion in our experiments, but are limited by our status as non-native speakers. Human evaluation of model outputs was partially conducted using machine-translated English texts as references, but all annotations were inspected by the Spanish- and Quechua-speaking author who removed a small number of evaluations that reflected linguistic discrepancies between Quechua, Spanish, and English or inaccuracies in the machine-translated English.

9 Ethics Statement

We consulted the first author's Quechua instructor, Prof. Carmen Cazorla Zen, who gave us permission to use the sentences from the notes in this project and verified their accuracy. We cite the Quechua dictionary and grammar materials used to provide prompt information, and believe that our use of these materials is consonant with their original purpose. However, we do not distribute machine-readable versions of them as a contribution of this project, since this would violate the rights of the publisher. These materials were developed for use as pedagogical resources by institutions affiliated with the governments of Cuzco, Peru and Apurímac, Peru, respectively. Their authors were not contacted or consulted as part of the project.

We wish to acknowledge the delicate issue of academic *extractiveness* and its harmful impact on Indigenous and minority language communities and speakers. We are also aware of some of the controversial ideologies and policies associated with Qheswa Simi Hamut'ana Kuraq Suntur, the government-afilliated institution who published the dictionary we use in this study, and the potentially negative effects of government-sponsored linguistic standardization more broadly (see, e.g., Coronel Molina (2008) for an analysis of the effects of the institution's ideologies on revitalization efforts in Peru). We do not endorse such policies, and have sought to avoid representing the diversity of Southern Quechua-speaking communities as a monolith. Instead, we hope our continued efforts to improve methods for low-resource translation will empower speakers of Southern Quechua and other Indigenous and minority languages to develop language technologies capable of representing their own community's unique language variety to serve the unique needs of its speakers.

There are numerous ethical issues related to the training and use of LLMs, such as labor issues and energy costs. While these issues are inextricable from the methods used in this project, we believe the potential impact of making low-resource translation viable and accessible to minority language communities who want them (our primary goal in this line of research) outweighs the problems inherent in using LLMs at all. We discuss the potential risks of deploying systems like the ones described here further in Section 6.2 of the main text.

Acknowledgments

We thank Prof. Carmen Cazorla Zen, Professor of Quechua, for her help curating the data used in this study and for deepening our understanding of Southern Quechua and its speakers. We also thank Prof. Elvia Andía Grágeda, Professor of Quechua, for her instruction and advice, and the OSU Linguistics department for their feedback on a preliminary presentation of the work.

C Quality Descriptions

Quality	Description
High	Output is an accurate and/or acceptable translation of the source content.
Med	Output contains errors that prevent it from being an acceptable translation, but is generally high in quality otherwise.
Low	Output contains errors that prevent it from being an acceptable translation, with minor correspondences that vaguely identify it as relevant to the source.
None	Output does not appear to be relevant to the source.

Table 5: Quality Descriptions

D Annotation Error Typology

Dimension	Error	Description
Accuracy	Addition	Translation includes information not present in the source, but does not result in the displacement of source content.
Accuracy	Omission	Translation is missing content from the source.
Accuracy	Substitution - Subject	The translated segment contains content identified as relevant to the source in other spans, but substitutes novel subject markers for those present in the source in the highlighted span; Classify an error as a “substitution” when the error appears to result in both Addition and Omission errors that cannot be distinguished into two distinct spans.
Accuracy	Substitution - TAM	The translated segment contains content identified as relevant to the source in other spans, but substitutes novel TAM for those present in the source in the highlighted span; Classify an error as a “substitution” when the error appears to result in both Addition and Omission errors that cannot be distinguished into two distinct spans.
Accuracy	Substitution - Other	Substitution errors that do not involve mistranslated subject markers or TAM. See above.
Accuracy	Overtranslation	Error occurring in the target content that is inappropriately more specific than the source content.
Accuracy	Undertranslation	Error occurring in the target content that is inappropriately less specific than the source content.
Target Error	Grammar	Other spans in the translated segment may be identified as relevant to the source, but the highlighted span is not grammatical in the target language.
Target Error	Coherence	Other spans in the translated segment may be identified as relevant to the source, but the highlighted span is unnatural or incoherent in the target language.
Target Error	Style/Register	Other spans in the translated segment may be identified as relevant to the source, but the highlighted span is produced in a style or register that is inappropriate given the content.
Non-Translation	Complete Mistranslation	The entire segment is coherent in the target language but the core predicate shows no immediate connection to the reference translation.
Non-Translation	Mistranslation - Lexical Correspondence	The entire segment is coherent in the target language but only minor correspondences to the reference translation may be identified.
Non-Translation	Refusal	Model does not attempt to translate into the target language, e.g., because it "does not understand".
Model error	Garbled	Output does not contain coherent text in the target language.
Model error	ChattyGPT	Output contains translated content, but is wordy, over-explanatory, and/or abruptly truncated.

GRAMMAR-ONLY

[CONTEXTO]
ta: CASO ACUSATIVO. Su marca es –ta, esta es una marca de objeto directo con los verbos que no son de movimiento (quietud). Ejemplo:
Quyllur–ta qhawani Veo una estrella
T'anta–ta apay Lleva pan
Ñuqa quylluyta qhawani
Pedrucha t'antata rantin
En cambio con los verbos de movimiento –ta indica (hacia) que es igual a meta. Ejemplos:
Punu–ta rini Voy a Puno
Llaqta-ta risaq Iré al pueblo
Hamawt'anchis Punuta rinqa
Llanta umalliq llaqtata richkan
nki: FLEXIÓN DE TIEMPO. TIEMPO FUTURO. TIEMPO FUTURO. Los sufijos para cada una de las personas gramaticales son: saq, nki, nqa, sun, saqku, nkichis, nqaku; en singular y plural respectivamente.
Ejemplos:
Puklla-saq jugaré
Puklla-nki jugarás
Puklla-nqa jugará
Puklla-sun jugaremos
Puklla-saqku jugaremos
Puklla-nkichis Uds. jugarán
Puklla-nqaku ellos jugarán

Introducing the NewsPaLM MBR and QE Dataset: LLM-Generated High-Quality Parallel Data Outperforms Traditional Web-Crawled Data

Mara Finkelstein **David Vilar** **Markus Freitag**
Google
{marafin,vilar,freitag}@google.com

Abstract

Recent research in neural machine translation (NMT) has shown that training on high-quality machine-generated data can outperform training on human-generated data. This work accompanies the first-ever release of a LLM-generated, MBR-decoded and QE-reranked dataset with both sentence-level and multi-sentence examples.[1] We perform extensive experiments to demonstrate the quality of our dataset in terms of its downstream impact on NMT model performance. We find that training from scratch on our (machine-generated) dataset outperforms training on the (web-crawled) WMT'23 training dataset (which is 300 times larger), and also outperforms training on the top-quality subset of the WMT'23 training dataset. We also find that performing self-distillation by finetuning the LLM which generated this dataset outperforms the LLM's strong few-shot baseline. These findings corroborate the quality of our dataset, and demonstrate the value of high-quality machine-generated data in improving performance of NMT models.

1 Introduction

With the advent of large language models (LLMs), machine translation (MT) quality has improved dramatically (Kocmi et al., 2023a, 2024a), and performance tends to scale with model size (Gemini Team, 2024). While LLMs are now state-of-the-art translators, they are often impractical to use or serve, especially in high-traffic and/or resource-constrained settings. Thus, development of smaller, but still highly performant, MT models remains an active area of research. Recent work has shown that distillation of LLM translation quality, while requiring an expensive data generation process, is an effective approach (Li et al., 2024). In this work, we introduce a new LLM-generated dataset called `NewsPaLM`, which we make freely available.

In addition to the size of the teacher model, another key determinant of the quality of machine-generated translation data is the decoding method used. While beam search and greedy decoding are the most common decoding methods used for NMT, Eikema and Aziz (2020a) showed that maximum *a posteriori* (MAP) decoding methods are suboptimal, and instead proposed Minimum Bayes Risk (MBR) decoding. Unlike MAP decoding, MBR decoding does not aim to produce the translation with the highest estimated model probability. Instead, it chooses the translation that is estimated to have the highest quality with respect to a utility metric. A follow-up study by Freitag et al. (2022) showed that MBR decoding with neural utility metrics significantly outperforms beam search decoding, according to expert-based human evaluation.

The main drawback of MBR decoding is its high computational cost. In particular, the algorithm requires that, for every input query, a large number n of candidates be generated from the model, and then an (expensive) scoring function be computed on every pair of distinct candidates (n_i, n_j), for a total of $O(n^2)$ computations. QE reranking (Fernandes et al., 2022) is a more efficient alternative to MBR decoding. This decoding method instead reranks the candidate model predictions using a neural quality estimation (QE) metric, and requires only $O(n)$ computations.

Finkelstein and Freitag (2023) showed that finetuning NMT models on MBR-decoded and QE-reranked datasets is an effective technique for distillation (while finetuning on beam search-decoded datasets is not) and that, given a LLM teacher, MBR and QE distillation can outperform finetuning on human-generated references.

In this work, we generate sentence-level parallel data using MBR decoding and multi-sentence parallel data using QE reranking. In addition to detailing

[1] The dataset can be found at https://github.com/google-research/google-research/tree/master/newspalm_mbr_qe.

Proceedings of the Ninth Conference on Machine Translation, pages 1355–1372
November 15-16, 2024 ©2024 Association for Computational Linguistics

our dataset creation method, we also perform extensive experiments to demonstrate the quality of our dataset in terms of its downstream impact on NMT model performance.

Our contributions can be summarized as follows:

- We release our LLM-generated, sentence-level and multi-sentence, MBR and QE translation dataset.
- We demonstrate that our dataset is high-quality, by using it to train NMT models from scratch and comparing performance against baselines using human-generated parallel data. This is the first work to pretrain NMT models on MBR and QE data.
- We show that training on our dataset outperforms training on the web-crawled WMT'23 training dataset (which is 300 times larger than ours). Moreover, our dataset also outperforms (by an even larger margin) when compared against quality-based filtering of the WMT'23 dataset to match the size of our dataset.
- We also demonstrate our dataset's quality by performing self-distillation (using the PaLM-2 LLM from which this data was generated), and show that this outperforms the LLM's strong few-shot baseline. To our knowledge, this is the first work to investigate MBR finetuning a LLM.
- We investigate the effect of sentence-level versus multi-sentence MBR and QE training data on NMT model performance as a function of sequence length, and investigate the tradeoff between dataset size and model quality, during both pretraining and finetuning.

2 `NewsPaLM` Dataset

This paper accompanies a dataset release of sentence-level and multi-sentence English-German and German-English parallel data, generated from the (monolingual) Newscrawl corpus as made available for the WMT evaluation campaigns[2] using the *PaLM-2 Bison* LLM (Anil et al., 2023). We detail below the steps to create this dataset, which we call `NewsPaLM`.

The dataset construction process consisted of four steps, as described in the following sections.

2.1 Source-side Data Collection: Newscrawl

To construct the English and German source-side datasets, we first collected all Newscrawl data from 2007 to 2022, released as part of the WMT'23 Machine Translation Shared Task (Kocmi et al., 2023a). This is a large corpus of crawled news, with about 398 million and 507 million lines for English and German, respectively. For both of these languages, document-split versions of the dataset (with document boundaries intact) are available.

We collected both the sentence-level and document-level versions of the datasets. Basic preprocessing had already been applied to the sentence-level version, including removing lines with no ASCII letters and deduplication. This preprocessing was not applied to the document-level version. We performed minimal additional cleaning to fix incorrectly encoded characters.

2.2 Construction of "Blobs"

We used the document-split versions of the datasets to construct multi-sentence (i.e. "blob-level") examples. We refer to these examples as blobs, rather than paragraphs, since they do not respect paragraph boundaries but, rather, simply represent the concatenation of contiguous sentences up to a maximum length. In particular, we joined headlines using the separator "`\n\n`", and otherwise joined sentences with spaces, up to a maximum length of 512 tokens (using the PaLM-2 tokenizer; Anil et al. (2023)). The blobs respect document boundaries, each blob contains only complete sentences (no sentence fragments), and each blob may or may not contain a headline (depending on where in the document the blob comes from).

2.3 Cluster-Based Text Selection

The size of the Newscrawl full dataset and the high computational cost of the decoding techniques (§2.4) makes it impractical to process all the available data. In order to reduce the size of the data, while at the same time ensuring diversity in the samples, we follow a clustering-based sample selection approach. As a first step, we embed the source side of the data using XLM-RoBERTa (Conneau et al., 2020). We then apply Recursive Agglomerative Clustering (RAC) (Sumengen et al., 2021), an unsupervised clustering algorithm which is an efficient extension of Hierarchical Agglomerative Clustering. These algorithms are initialized by defining a set of clusters, each containing a single point from

[2] The Newscrawl data was downloaded from `https://data.statmt.org/news-crawl/`.

	EN → DE	DE → EN
Sentence-level	3,287	3,264
Blob-level	3,826	4,017

Table 1: Number of defined clusters per dataset.

the original data points. The guiding principle is to iteratively merge the two clusters which are closest to each other, until some stopping criterion is met, e.g. a maximum distance between the clusters to be merged. Note that this algorithm requires the number of clusters to be chosen as a hyperparameter, unlike other clustering algorithms like k-means which have the advantage that the number of clusters is defined by the algorithm itself. We selected the number of clusters shown in Table 1 for each of the data sets.

Once the clusters have been defined, we sample uniformly from them. In this way, we ensure that the diversity of the original dataset is maintained in the reduced sample.

2.4 MBR Decoding and QE Reranking

The preceding steps handle preparation of source-side data. To generate the target-side data from these sources, we used the *PaLM-2 Bison* LLM (Anil et al., 2023), 5-shot prompted with ICL examples from the newstest2021 test set (Akhbardeh et al., 2021). Note that unlike previous work which also used PaLM-2 to generate translation data for distillation (Finkelstein and Freitag, 2023), here we do not finetune on the translation task prior to data generation.

A key component of our data generation process is the decoding method. We generated the sentence-level data using MBR decoding and the blob-level data using QE reranking. Both MBR decoding and QE reranking can be decomposed into two steps: candidate list generation (Section § 2.4.1) and scoring (Section § 2.4.2).

2.4.1 Candidate List Generation

The first step in the decoding process is to generate a list of candidate model outputs, given a source segment. In this work, we used a candidate size of 512 and generated candidate translations using epsilon sampling (Hewitt et al., 2022) with $\varepsilon = 0.02$, which was shown to be the best sampling method for MBR decoding in Freitag et al. (2023).

2.4.2 MBR and QE scoring

Next, the best output is chosen based on a utility function. This step is where MBR decoding and QE reranking diverge. For MBR decoding, we use a reference-based utility metric $u_{mbr}(h, r)$, which estimates the quality of a candidate translation h conditioned on a reference translation r. Formally, given a set of hypotheses $\mathcal{H}$, the Minimum Bayes Risk (MBR) translation h^{mbr} is selected from the candidates in $\mathcal{H}$ according to

$$h^{mbr} = \arg\max_{h \in \mathcal{H}} \frac{1}{|\mathcal{H}|} \sum_{y \in \mathcal{H}} u_{mbr}(h, y).$$

For QE reranking, on the other hand, we use a reference-free (QE) utility metric $u_{qe}(h, s)$, which estimates the quality of a candidate translation h conditioned on the source s, rather than on the reference. We select the best QE translation h^{qe} of the source s from the candidates in $\mathcal{H}$ as

$$h^{qe} = \arg\max_{h \in \mathcal{H}} u_{qe}(h, s)$$

In this work, we used the *BLEURT* (Sellam et al., 2020) utility metric for MBR decoding and the *MetricX-QE* (Juraska et al., 2023) utility metric for QE reranking. Note that the maximum context length for *BLEURT* (candidate and reference combined) is 512, while for *MetricX-QE* (candidate and source combined), it is 1024. Given that the blob-level source-side data alone can contain up to 512 tokens, we could not use *BLEURT* as the utility function for this data. MBR decoding with *MetricX* is prohibitively expensive, hence our decision to perform QE reranking instead.

As a baseline against which to compare data generated using these state-of-the-art decoding methods, we also created accompanying sentence-level and blob-level datasets from the same source-side data using greedy decoding.

2.5 Dataset Statistics

Here we briefly present basic statistics about the four datasets we created (sentence-level and blob-level versions, for the en→de and de→en language pairs). See Appendix A for additional dataset statistics.

Table 2 shows the size (in number of examples) of each dataset. Note that each dataset has about 800 thousand to one million examples.

Table 3 shows the average length of source and target examples (in number of tokens, as defined by the `Moses` tokenizer) per dataset. For

	EN → DE	DE → EN
MBR SENT-LEVEL	998,435	1,022,344
QE BLOB-LEVEL	925,829	769,028

Table 2: Number of examples per dataset.

		Source	Target
EN → DE	SENTENCES	37.5	39.8
	BLOBS	364.5	339.8
DE → EN	SENTENCES	77.3	88.3
	BLOBS	288.4	323.4

Table 3: Average source and target lengths per dataset, computed using the Moses tokenizer.

English-German, the blob-level examples are about ten times longer than the sentence-level examples, while for German-English, they are about four times longer. Figure 1 shows the distribution of target example lengths for English-German. Note that the blob-level data distribution is shifted to the right of the sentence-level data distribution, as expected.

3 Experimental Setup

We perform a series of pretraining and finetuning experiments to validate the quality of our NewsPaLM dataset, and to contextualize its performance with respect to a much larger dataset of human-generated data. All of our experiments are performed on both English-German (en→de) and German-English (de→en).

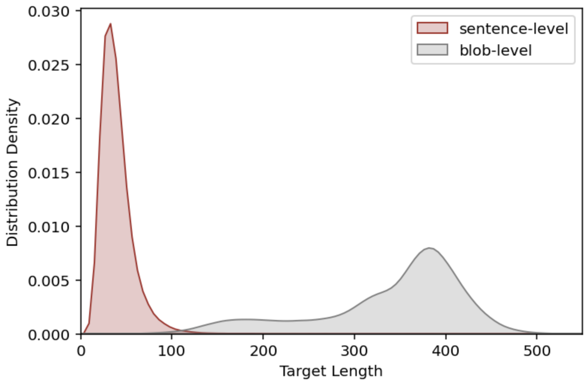

Figure 1: Distribution of English-German MBR sentence-level versus QE blob-level target lengths (computed using the Moses tokenizer).

3.1 Datasets

3.1.1 Training Data

As a baseline against which to compare our NewsPaLM dataset, we use the parallel WMT'23 training data (Kocmi et al., 2023b), which consists of 296 million sentence-level examples. A subset of this data (consisting of about 3 million sentences, from Europarl, News Commentary, and Rapid documents) contains document boundaries, which we use to construct blob-level examples using a procedure similar to the blob-level dataset creation process described in Section §2.2. That is, we partition the sentences into contiguous blocks, each of which has a total number of tokens up to a token limit of 512 (for each of source and target). In our experiments, this WMT'23 data is only used for pretraining.

The remainder of our pretraining and finetuning data comes from our (machine-generated) NewsPaLM dataset, described in Section §2. As an additional baseline, we compare the MBR-decoded and QE-reranked versions of this dataset against the greedy-decoded version. Note that for both language pairs (en→de and de→en), the sentence-level and blob-level NewsPaLM data combined contains less than 2 million examples (Table 2).

3.1.2 Development and Test Sets

For both language pairs, we use the sentence-level and paragraph-level versions of the newstest2021 test set (Farhad et al., 2021), as well as the (sentence-level) generalMT2022 test set (Kocmi et al., 2022), as our development sets for checkpoint picking. We report all results on the WMT'23 (Kocmi et al., 2023b) and WMT'24 (Kocmi et al., 2024b) test sets. Note that the WMT'23 and WMT'24 en→de test sets are paragraph-level.

3.2 Models

For both language pairs (en→de and de→en), we use a 602 million parameter Transformer encoder-decoder architecture, implemented in *Pax*[3]. The model has 8 encoder and 8 decoder layers (rather than 6), but otherwise is similar to the *transformer-big* setting in Vaswani et al. (2017), with model dimension of 1024, hidden dimension of 8192, and 16 multi-attention heads. We train without label smoothing. For each language pair, we use a bilingual vocabulary of 32k subword units trained on the WMT'23 training dataset (Kocmi et al., 2023b).

[3] https://github.com/google/paxml

The best (base and incremental) checkpoints were chosen to maximize *BLEURT* (Sellam et al., 2020) on the development set.

We also experiment with self-distillation of the *PaLM-2 Bison* (Anil et al., 2023) LLM, which is the model used to generate our datasets (see Section §2.4). We compare self-distillation (finetuning) against 5-shot prompting of this model (using the same ICL examples as during NewsPaLM dataset generation).

3.3 Evaluation

We evaluate our models on four automatic metrics: *MetricX* (Juraska et al., 2023), *Comet20* (Rei et al., 2020), *Comet22* (Rei et al., 2022), and *BLEURT* (Sellam et al., 2020). Note that for *MetricX*, lower scores are better, while for the remaining metrics, higher scores are better. Since the MBR data is generated using *BLEURT* as the utility function, and the QE data is generated using *MetricX*, the MBR-finetuned models may overfit to the *BLEURT* metric, while the QE-finetuned models may overfit to the *MetricX* metric. Thus, we primarily depend on the *Comet** metrics to measure model quality.

4 Results

4.1 Pretraining

We first experiment with training bilingual (en→de and de→en) encoder-decoder translation models (as described in §3.2) from scratch, to compare our NewsPaLM dataset (as described in §3.1.1) against the WMT'23 training dataset. As shown in Table 4, **pretraining on the NewsPaLM QE blob-level dataset** (which contains less than one million examples; Table 2) **outperforms pretraining on the entire WMT'23 training dataset**, which is more than 300 times larger. The NewsPaLM QE dataset achieves a *Comet22* score of 80.62 on the English-German WMT'23 test set (row 2c), while the WMT'23 training dataset achieves a score of 78.79 (row 1a).

Note that **training on the MBR sentence-level data** (row 2b) **underperforms training on the QE blob-level data** (row 2c). As shown in Figure 2, this is mostly due to a large drop in performance on longer sequence lengths. Thus, **exposure to multi-sentence data during training is essential to perform well on paragraph-level test sets**. Also note that during pretraining, we see no additional gains from mixing in the MBR sentence-level data relative to using the QE blob-level data only (rows 2c versus 2d).

We also experiment with pretraining on the greedy-decoded version of our NewsPaLM dataset, to compare against pretraining on the MBR-decoded and QE-reranked versions. Interestingly, the former (pretraining on the greedy-decoded data) outperforms the latter (pretraining on the MBR-decoded and QE-reranked versions), as shown in rows 2a versus 2d in Table 4. Based on manual inspection of examples, we hypothesize that the MBR-decoded and QE-reranked data is more free-style and harder for the model to learn than the greedy-decoded data. This is illustrated in Table 10 in the Appendix. If this were the case, the model would perform better by first learning the "easier" data (during pretraining), then adapting to the more free-style data during finetuning. We test this hypothesis by comparing two model training curricula: For the first, we pretrain on the greedy-decoded data and finetune on the MBR-decoded and QE-reranked data. For the second, we do the opposite: pretraining on the MBR-decoded and QE-reranked data and finetuning on the greedy decoded data. As we hypothesized, the **former model training curriculum (MBR and QE finetuning from the greedy-pretrained checkpoint) performed better** (Table 5).

We have seen that pretraining on a small and clean, synthetically-produced dataset (NewsPaLM) can outperform finetuning on a large and noisy, human-generated one (WMT'23 training dataset). However, previous work such as Peter et al. (2023) has shown that MT model performance can be boosted by selecting a high-quality subset of a large and noisy training corpus, using data selection techniques such as QE filtering. Thus, we perform QE filtering (using the *BLEURT-QE* metric, as in Peter et al. (2023)) to select the highest-quality examples in the WMT'23 (sentence-level) training dataset, while reducing its size to exactly match that of our (sentence-level) NewsPaLM dataset (of about one million examples). As shown in row 1b versus row 2b in Table 4, **training on the QE-filtered WMT'23 dataset substantially underperforms training on our MBR-decoded NewsPaLM dataset (of the same size)**, and also underperforms training on the full WMT'23 dataset. Note that this result does not contradict previous work showing the benefit of data filtering, since previous work did not reduce the dataset to such a small fraction (0.3%) of the original size. Thus, our

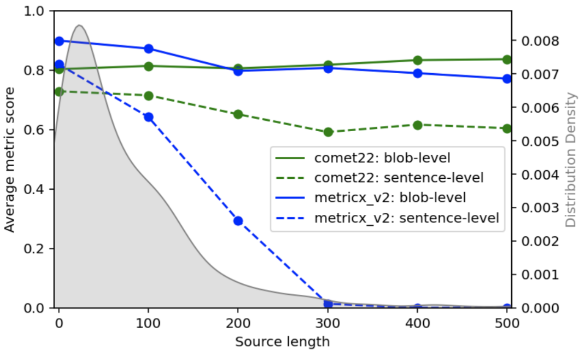

Figure 2: Comparison of pretraining performance on NewsPaLM MBR sentence-level dataset versus NewsPaLM QE blob-level dataset, bucketed by source length (WMT'23 en→de test set). Note that performance of the model trained on the blob-level data is stable across segment lengths, while performance of the model trained on the sentence-level data declines as segment length increases (according to both *MetricX* and *Comet22* metrics).

NewsPaLM dataset is highly efficient (which is one indicator of its quality), and its efficiency cannot be matched be selecting a high-quality subset of a large, noisy corpus.

4.2 Finetuning

Next, we experiment with how the different variants of our NewsPaLM dataset (and mixtures thereof) behave during finetuning (and whether this behavior differs from that observed during pretraining). Unless otherwise indicated, we initialize from the checkpoint pretrained on the WMT'23 training data (row 1a in Table 4). We report en→de and de→en results on the WMT'23 test set in Table 6, and refer the reader to Table 12 in Appendix B for pretraining and finetuning results on the WMT'24 en→de test set.

As shown in Table 6, **MBR and QE finetuning** (row 1d) **outperforms greedy finetuning** (row 1a), using the same mixture proportions (9:1) for the sentence-level and blob-level data. As shown in Table 5 and discussed in §4.1, MBR and QE finetuning from the greedy-pretrained checkpoint outperforms greedy finetuning from the MBR and QE-pretrained checkpoint as well. Also, note that for en→de, MBR and QE finetuning from the checkpoint pretrained on the WMT'23 training data (row 1d in Table 6) slightly underperforms initializing from the checkpoint pretrained on the greedy NewsPaLM dataset (row 1a in Table 5) according to the WMT'23 test set, but the opposite is the case according to the WMT'24 test set (see Tables 12 and 13 in Appendix B) and based on the de→en results on the WMT'23 test set.

Unlike during pretraining, **finetuning on the MBR sentence-level data outperforms finetuning on the QE blob-level data** (rows 1b versus 1c in Table 6), and we see no additional gains from mixing in the QE blob-level data relative to using the MBR sentence-level data only (rows 1b versus 1d). We hypothesize that the model learns to use long context (from the blob-level data) during pretraining, and it doesn't forget during finetuning, so blob-level data is less important during this stage.

We also experiment with finetuning the *PaLM-2 Bison* (Anil et al., 2023) LLM (as described in §3.2), which is the teacher model used to generate our NewsPaLM dataset. As shown in Table 6, **self-distillation via MBR (and QE) finetuning does indeed improve performance over the LLM's strong few-shot baseline** (rows 2a vs 2b). As with the encoder-decoder model, finetuning *PaLM-2 Bison* on the MBR data outperforms finetuning on the QE data (and outperforms finetuning on a mixture of the MBR and QE data). The improvement in performance of *PaLM-2 Bison* due to MBR finetuning is observed across all source length buckets (Figure 4 in Appendix B) and all domains in the WMT'23 and WMT'24 test sets (Tables 14 and 15 in Appendix B), despite the MBR data being sentence-level only and coming primarily from the news domain. MBR finetuning the *PaLM-2 Bison* model also outperforms MBR finetuning the much smaller encoder-decoder student (rows 1b vs 2b in Table 6), as expected.

4.3 Ablations

4.3.1 Effect of Dataset Size

Given the expense of creating LLM-generated, MBR-decoded datasets such as the ones presented in this work, we investigate how model performance scales with dataset size during both pretraining and finetuning. We randomly sample 25% of the MBR-decoded NewsPaLM dataset (for both en→de and de→en), then train on the subsampled dataset. As shown in Figure 3 (and Table 16 in Appendix B),***finetuning* on the subsampled dataset only took a small performance hit relative to finetuning on the full dataset, but *pretraining* took a large performance hit**. Thus, it is likely that pretraining performance would continue to improve had we generated a larger NewsPaLM dataset, while we would be unlikely to observe substantial incremental improvements in finetuning performance by increasing the dataset size. Also note

	Model	MetricX ↓	COMET22 ↑
en→de	1a) WMT'23 (all)	4.20	78.79

that the stability in finetuning performance under subsampling held up despite using the most efficient subset selection method (random, as opposed to e.g., QE filtering), another indicator supporting the high quality of our NewsPaLM dataset.

4.3.2 Effect of Cluster-based Data Selection

As described in §2.3, we used a clustering-based approach (sampling uniformly over the computed clusters) to select the subset of Newscrawl data which we used to generate the NewsPaLM dataset. To isolate the effect of our sample selection technique, we compare its performance against sampling uniformly from the original Newcrawl dataset distribution (i.e., without taking cluster information into account). Since our NewsPaLM dataset contains the subset of Newscrawl examples selected by sampling uniformly over the clusters, we approximate the above comparison as follows, selecting 25% of the NewsPaLM dataset in both cases:

- We sample uniformly from NewsPaLM to approximate cluster-guided sampling from the

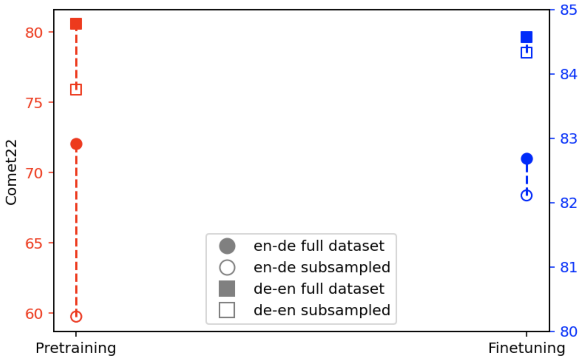

Figure 3: Comparison of model performance when pretraining and finetuning on the full versus subsampled NewsPaLM MBR dataset (WMT'23 test set). The subsampled dataset is 25% of the size of the full dataset, and was sampled randomly. Note that pretraining performance drops substantially when training on the subsampled dataset (for both en→de and de→en), while finetuning performance is minimally affected.

	Model	**MetricX ↓**	**COMET22 ↑**
en→de	1a) Greedy sentence-level + blob-level (9:1)	2.59	81.49
	1b) MBR sentence-level	2.30	**82.69**

	1d) MBR sentence-level + QE blob-level (9:1)	**2.26**	82.52
	2a) PaLM-2 five-shot (no finetuning)	1.62	84.54
	2b) PaLM-2 MBR sentence-level	**1.14**	**85.64**
	2c) PaLM-2 QE blob-level	1.47	84.77
	2d) PaLM-2 MBR sentence-level + QE blob-level (9:1)	1.17	85.54
de→en	1a) Greedy sentence-level + blob-level (9:1)	3.12	84.14
	1b) MBR sentence-level	2.91	**84.57**
	1c) QE blob-level	2.99	84.27
	1d) MBR sentence-level + QE blob-level (9:1)	**2.82**	84.53
	2a) PaLM-2 five-shot (no finetuning)	2.25	85.36
	2b) PaLM-2 MBR sentence-level	**1.91**	**86.26**
	2c) PaLM-2 QE blob-level	2.03	85.81
	2d) PaLM-2 MBR sentence-level + QE blob-level (9:1)	1.92	86.24

Table 6: Finetuning performance (WMT'23 test set). Unless otherwise indicated, performance is reported for the encoder-decoder model. For finetuning, this model was initialized from the checkpoint pretrained on the full WMT'23 training dataset (row 1a in Table 4). Results for *PaLM-2 Bison* few-shot prompting versus self-distillation using `NewsPaLM` MBR and QE data are reported in rows 2a-d.

full Newscrawl dataset.

- We use the original cluster sizes of the full Newscrawl dataset (computed prior to selecting the `NewsPaLM` subset), and sample from `NewsPaLM` according to this distribution. This approximates sampling from the full Newscrawl dataset *without* taking cluster information into account. Note that because the original cluster distribution was highly skewed, with most of the examples belonging to the top few clusters, we could not exactly match the original distribution while sampling 25% of the `NewsPaLM` dataset, but we chose the distribution to be the one which was closest to the original.

As shown in Table 7, using the cluster information in the subsampling procedure marginally improves results for en→de pretraining and finetuning, and for de→ en finetuning. (There is no clear signal for de→en pretraining; according to *MetricX*, using the cluster information helps, while according to *Comet22*, it hurts.)

5 Discussion

Training on LLM-generated, MBR-decoded and QE-reranked datasets is an established technique for leveraging monolingual data to improve NMT model quality (Finkelstein and Freitag (2023), Wang et al. (2024)). While this technique is highly effective, generating such datasets remains a substantial bottleneck, and is often prohibitively expensive. This work accompanies the first-ever open-source release of a LLM-generated, sentence-level and blob-level MBR and QE dataset. We measure the quality of our dataset in terms of its downstream impact on NMT model performance, both when training a NMT model from scratch and when finetuning.

We find that training from scratch on our MBR-decoded and QE-reranked `NewsPaLM` dataset outperforms training on the entire WMT'23 training dataset (which is 300 times larger), and also outperforms training on the top-quality subset of the WMT'23 training data (selected via QE filtering, and matching the size of our dataset). Moreover, we find that NMT models are unable to generalize well to multi-sentence queries without exposure to such data at training time, motivating the inclusion of blob-level data in our dataset.

We also find that MBR and QE finetuning outperform finetuning on the greedy-decoded version of our dataset. Unlike Finkelstein and Freitag (2023),

	Model	MetricX ↓	COMET22 ↑

	2a) FT: Sampling uniformly over clusters	**2.96**	**84.33**
	2b) FT: Sampling uniformly from original Newscrawl distribution	3.09	83.92

Table 7: Comparison of model performance when trained on subsampled `NewsPaLM` data with and without cluster-based data selection (WMT'23 test set). PT stands for Pretraining and FT, for Finetuning. Random subsampling of `NewsPaLM` approximates sampling uniformly across the Newscrawl clusters, while subsampling according to the Newscrawl cluster distribution approximates discarding cluster information and sampling randomly according to the original data distribution.

which only performs MBR and QE self-distillation using a small encoder-decoder NMT model, here we show that self-MBR and self-QE finetuning are effective for the much stronger *PaLM-2 Bison* LLM as well.

Finally, we show via subsampling experiments on our `NewsPaLM` dataset that pretraining versus finetuning performance scale very differently with dataset size: While finetuning performance only took a small hit when reducing our dataset to 25% of its original size, pretraining performance took a large hit. However, note that the full `NewsPaLM` dataset is already orders of magnitude smaller than most datasets used for NMT model training, including the WMT'23 training dataset.

6 Related Work

While MT research has traditionally relied on MAP decoding or generating k-best lists through beam search for MBR decoding, Eikema and Aziz (2020b) proposed an approximation of MBR decoding via unbiased sampling. Their method aims to address the limitations of MAP decoding (Eikema and Aziz, 2020b; Müller and Sennrich, 2021; Eikema and Aziz, 2022) by demonstrating that samples drawn from the NMT model align more faithfully with training data statistics when compared to beam search. Freitag et al. (2022) showed that using neural metrics results in significant improvements in translation quality. To the best of our knowledge, this is the first work that applies MBR decoding beyond the sentence level for the task of machine translation.

While the improvements in translation quality afforded by MBR are widely acknowledged, its high computational cost limits its application in practice. Different approaches have been proposed to speed up MBR computation, e.g. (Eikema and Aziz, 2022; Cheng and Vlachos, 2023; Jinnai and Ariu, 2024; Vamvas and Sennrich, 2024; Tomani et al., 2024). Similar in spirit to MBR decoding, QE-rescoring approaches (Fernandes et al., 2022) also directly optimize a utility function, with linear-time cost.

We approach the efficiency problem from a different perspective, carrying out a one-off expensive MBR decoding run, which can then be re-used for training and finetuning other models via knowledge distillation (Buciluǎ et al., 2006; Hinton et al., 2015). This technique has been a successful way to improve smaller systems by leveraging the capacities of bigger models, while retaining higher computational efficiency. The technique has been applied to numerous NLP tasks, including neural machine translation (Kim and Rush, 2016; Tan et al., 2018; Zhang et al., 2019; Jooste et al., 2022; Wan et al., 2024, inter alia). In the current era of LLMs, these models provide prime candidates for leveraging their impressive capabilities to improve other models. Yoo et al. (2021) use GPT3 for data augmentation in different classification tasks, in addition to using soft-labels predicted by the language model. Hsieh et al. (2023) propose to use “rationales” generated by PaLM to train a much smaller T5 model, achieving comparable or even superior performance. Li et al. (2024) use "selective" distillation to generate synthetic data using a variant of LLaMA-7B, expanding the coverage of training data for a translation model. Closer to our work, Finkelstein and Freitag (2023) propose to use MBR on a LLM to generate high-quality translations with which to train a dedicated translation model. As reference, (Xu et al., 2024) provides a much more comprehensive survey of knowledge distillation approaches using LLMs.

Another dimension related to our work is the area of data selection for NMT training. While a big amount of work has been focused on filtering noise from web-crawled data (e.g. Zaragoza-Bernabeu et al., 2022), there are also approaches aimed at improving the translation quality by limiting the training data to high-quality samples. Carpuat et al. (2017) use semantic divergence to select the most relevant portion of the training data, while (Peter et al., 2023) use QE metrics on the training data to select only high-quality sentence pairs. Xu et al. (2023) indeed show that only a small amount of high-quality multilingual and parallel data is needed for obtaining state-of-the art translation results finetuning a LLM. A similar approach was used by (Alves et al., 2024) to finetune LLaMA for translation and translation-related tasks.

One can also find different examples of clustering for data selection for NLP tasks. Aharoni and Goldberg (2020) showed that automatic clustering techniques can adequately recover semantic information from text corpora. Yu et al. (2023) use clustering for data selection to finetuning a LLM. Related to these approaches, nearest-neighbor machine translation (Khandelwal et al., 2021) uses distance measures between examples to select examples closer to the sentence to translate in an additional module of a translation system. (Agrawal et al., 2023) and (Vilar et al., 2023) use similar approaches to construct prompts for LLMs.

7 Conclusion

In this work, we have described the dataset creation process for the first-ever release of a LLM-generated MBR and QE dataset. We have shown that this dataset can be used to build a small and efficient, but high-quality, NMT model from scratch. In fact, training on this dataset outperforms training on the much larger, human-generated WMT'23 dataset. We have also shown that this dataset can improve NMT performance during finetuning, both for an encoder-decoder system and via self-distillation for an already highly performant LLM. We hope that this dataset will enable further distillation research by the wider community, even by those without resources to generate datasets from large teacher models using expensive decoding techniques.

There are many avenues for future work. This work presented the first investigation of multi-sentence (i.e., blob-level) QE finetuning, and a natural next step would be to move to the document level. The dataset creation process described here could also be continued iteratively, by generating a new MBR and QE dataset from the same LLM teacher, but after finetuning on the original version of the dataset (or the version from the previous iteration). While this would be expensive, it would likely yield further incremental improvements in dataset quality. Finally, there remain many open questions regarding how to optimally perform distillation of a stronger teacher model into a weaker student using MBR and QE data. For instance, rather than finetuning on a uniform mixture of all examples in the dataset, the student model's perplexity on these examples could be taken into account to select a subset of examples and/or to determine the optimal progression of examples to expose the student to during finetuning.

Limitations

The (target-side) data generation process was expensive, due to both using a LLM and a costly decoding method. For MBR dataset creation, computation of each dataset example required generation of n outputs from the LLM teacher model, and then $O(n^2)$ forward passes through the utility function, where n is the candidate size. For QE dataset generation, $O(n)$ forward passes through the utility function were required per example. Thus, the dataset construction method proposed here is not easily scalable to other language pairs and/or source-side data in the absence of substantial computing resources.

A Additional Dataset Statistics

Table 8 shows the average source-to-target length ratios for each of the NewsPaLM MBR and QE datasets. (See Table 3 in Section 2 for the average source lengths and average targets lengths of the NewsPaLM datasets.)

	Sentence-level	Blob-level
EN → DE	0.9604	1.0812
DE → EN	0.9009	0.9729

Table 8: Source-to-target length ratios per dataset, computed using the Moses tokenizer.

B Additional Results

Table 9 is an extension of Table 4 in Section 4.1, and shows pretraining results across all metrics (including *BLEURT* and *Comet20*) on the WMT'23 en→de and de→en test sets. Table 10 illustrates the stylistic differences between greedy and MBR decoding. Table 11 is an extension of Table 6 in Section 4.2, and shows finetuning results on the WMT'23 test set across all metrics. Table 12 shows all en→de pretraining and finetuning results on the WMT'24 test set. (Note that there does not exist a WMT'24 de→en test set.) Table 13 is the companion to Table 5 in Section 4, but on the WMT'24 (rather than WMT'23) test set.

Tables 14 and 15 show the pretraining and finetuning results on the en→de WMT'23 and WMT'24 test sets, respectively, broken out by domain. For WMT'23, the domains are *Mastodon*, *News*, *Speech*, and *User Review*. For WMT'24, the domains are *Literary*, *News*, *Social*, and *Speech*. Note that the models pretrained and finetuned on our NewsPaLM dataset perform especially strongly on the *News* domain, but the gains aren't limited to this domain.

Figure 4 shows the *PaLM-2 Bison* few-shot versus self-MBR-finetuned results on the en→de WMT'23 test set, bucketed by source segment length. Note that the gains in performance from self-distillation are consistent across all segment length buckets.

Table 16 accompanies Figure 3 in Section 4.3.1, and shows the results of the NewsPaLM subsampling ablations across all metrics.

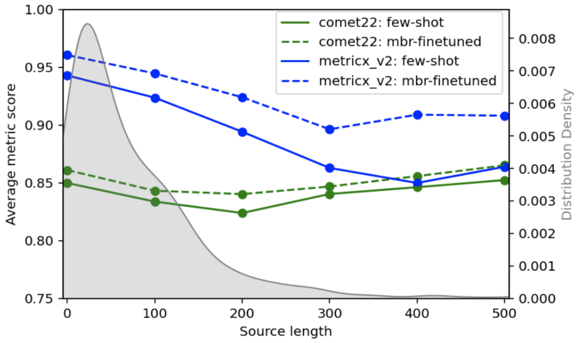

Figure 4: *PaLM-2 Bison* few-shot versus NewsPaLM MBR-finetuned performance bucketed by source length (en→de WMT'23 test set). Note that self-MBR finetuning (on sentence-level data only) improves performance across all source length buckets.

Table 9: Pretraining performance (WMT'23 test set).

Source	"While President Trump has not commented on Lewis' death, White House press secretary Kayleigh McEnany said in a tweet Saturday, [. . .]
Greedy	Während Präsident Trump sich nicht zu Lewis' Tod geäußert hat, sagte die Pressesprecherin des Weißen Hauses, Kayleigh McEnany, am Samstag in einem Tweet: [. . .]
MBR	Präsident Trump hat bislang keinen Kommentar zu Lewis' Tod abgegeben. Weißes Hauses-Pressesprecherin Kayleigh McEnany äußerte sich hingegen auf Twitter: [. . .]
Explanation	Greedy decoding closely follows the English sentence structure. MBR decoding produces a more natural German sentence, and also decides to introduce a sentence break.

Source	"If we follow the Hungarian philosopher Gáspár Miklós Tamás, with his very broad definition of fascism as ""a break with the enlightenment tradition of citizenship as a universal entitlement,"" the similarities sharpen."
Greedy	Wenn wir dem ungarischen Philosophen Gáspár Miklós Tamás mit seiner sehr weiten Definition von Faschismus als „Bruch mit der aufklärerischen Tradition der Staatsbürgerschaft als universellem Recht" folgen, werden die Ähnlichkeiten deutlicher.
MBR	Wenn man dem ungarischen Philosophen Gàspár Miklós Tamás folgt, der in seiner sehr breiten Definition des Faschismus eine „Verletzung der aufgeklärten Tradition des Bürgerstatus als universalem Recht" sieht, dann wird die Ähnlichkeit noch deutlicher.
Explanation	The MBR translation uses an impersonal form, which is preferred in German. The subordinate clause about the definition of fascism is also reformulated, resulting in a more natural structure.

Table 10: Comparison between translations generated with greedy and MBR decoding.

Abstract

Neural metrics for machine translation (MT) evaluation have become increasingly prominent due to their superior correlation with human judgments compared to traditional lexical metrics. Researchers have therefore utilized neural metrics through quality-informed decoding strategies, achieving better results than likelihood-based methods. With the rise of Large Language Models (LLMs), preference-based alignment techniques have gained attention for their potential to enhance translation quality by optimizing model weights directly on preferences induced by quality estimators. This study focuses on Contrastive Preference Optimization (CPO) and conducts extensive experiments to evaluate the impact of preference-based alignment on translation quality. Our findings indicate that while CPO consistently outperforms Supervised Fine-Tuning (SFT) on high-quality data with regard to the alignment metric, it may lead to instability across downstream evaluation metrics, particularly between neural and lexical ones. Additionally, we demonstrate that relying solely on the base model for generating candidate translations achieves performance comparable to using multiple external systems, while ensuring better consistency across downstream metrics.[1]

1 Introduction

Neural metrics for machine translation evaluation that are trained to mimic human preferences, such as BLEURT (Sellam et al., 2020), COMET (Rei et al., 2020, 2022a), or Metric-X (Juraska et al., 2023), have become increasingly prevalent. These metrics offer greater accuracy and better reflect human judgments compared to traditional lexical metrics (Mathur et al., 2020; Kocmi et al., 2021; Freitag et al., 2022b; Kocmi et al., 2024) like BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) or chrF (Popović, 2015), which mainly consider lexical overlap with a reference text. As such, researchers have attempted to leverage these improvements by integrating them directly into translation systems.

One appealing strategy to incorporate quality information to improve downstream translation performance involves using decoding strategies such as N-Best reranking and Minimum Bayes Risk (MBR) decoding (Kumar and Byrne, 2002, 2004; Eikema and Aziz, 2020; Fernandes et al., 2022; Freitag et al., 2022a). These techniques rely on generating multiple candidates to maximize a given quality metric at inference time, and research has shown that they consistently yield better results than likelihood-based decoding techniques (Eikema and Aziz, 2020; Koehn and Knowles, 2017; Ott et al., 2018).

With the rise of decoder-only LLMs in MT, quality-informed fine-tuning techniques have gained significant attention. Unlike decoding-based methods that inject quality information at inference time, fine-tuning modifies model weights using training sets induced with quality information. These approaches include filtering parallel training data based on a quality metric (Alves et al., 2024), distilling gains from more expensive quality-aware methods such as MBR (Finkelstein et al., 2024), or employing preference-based alignment techniques (Rafailov et al., 2024; Xu et al., 2024a), where the model learns preferences induced by quality metrics between candidate translations typically generated by multiple systems. In this work, we focus specifically on the latter.

Alignment techniques represent a paradigm shift from quality-aware inference time approaches, as they optimize the metric of interest *indirectly*. Understanding the impact of these approaches on translation quality is thus a relevant problem. While some studies have examined quality-

[1] All relevant preference datasets and aligned models, along with detailed evaluation metrics, are available at https://huggingface.co/collections/artefactory/translation-alignment-analysis.

Proceedings of the Ninth Conference on Machine Translation, pages 1373–1392
November 15-16, 2024 ©2024 Association for Computational Linguistics

informed decoding techniques and their influence on translation output (Amrhein and Sennrich, 2022), there is still a gap in our understanding of how preference-based fine-tuning affects translation quality.

In this work, we aim to bridge this gap by examining the properties of preference-based alignment techniques, with a particular focus on Contrastive Preference Optimization (CPO) (Xu et al., 2024a), which has been used successfully to achieve very competitive translation performance. Our analysis seeks to describe the effects of preference-based fine-tuning on downstream performance, specifically regarding alignment effectiveness, the interactions between optimized and non-optimized metrics, and the impact of using multiple candidate translation systems for generating preference data. Through extensive experimentation, we find that:

- Preference-based alignment globally outperforms Supervised Fine-Tuning (SFT) on high-quality data in terms of maximizing the alignment metric.
- However, preference-based alignment is highly sensitive to the choice of candidate systems used for generating preference data, affecting both the alignment metric and downstream metric consistency.
- Aligning a model using its own translations achieves performance comparable to employing multiple external systems, while ensuring better metric consistency and allowing for improved control over the alignment process.

2 Background

2.1 Quality-Informed Translation

Along with human evaluation, lexical metrics like BLEU (Papineni et al., 2002), chrF (Popović, 2015), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004) have long been used for translation evaluation. However, human evaluation is costly, and lexical metrics have been shown to correlate poorly with human judgements.

More recently, some neural metrics have emerged as a preferred method to mimic human preferences without relying on expensive human evaluation. The intuitive approach involves training an encoder model on human-annotated source-translation-reference triplets. Among the metrics most frequently mentioned in the literature are BLEURT (Yan et al., 2023), COMET (Rei et al., 2020), CometKiwi (Rei et al., 2022b), xCOMET (Guerreiro et al., 2023), and Metric-X (Juraska et al., 2023). They can be divided into two families: *reference-based* metrics, that include a human-written gold reference as an input to the scoring model, and *reference-free* metrics, which only require access to the source sentence and the generated translation. These neural metrics have proven particularly effective at scoring translations and achieve much higher correlation with human judgments than their lexical counterparts (Mathur et al., 2020; Kocmi et al., 2021; Freitag et al., 2022b; Kocmi et al., 2024).

These neural metrics have also been leveraged to improve translation models through decoding strategies. The approach involves sampling various candidate translations, scoring them according to a given metric, and selecting the one with the highest score. This methodology is exemplified by MBR decoding in the reference-based setting and N-best reranking in the reference-free setting (Fernandes et al., 2022; Freitag et al., 2022a).

2.2 Quality-Based Fine-Tuning

With the recent rise of decoder-only LLMs applied to translation tasks (Zhu et al., 2023; Jiao et al., 2023; Hendy et al., 2023; Kocmi et al., 2023; Freitag et al., 2023; Xu et al., 2023; Alves et al., 2023; Xu et al., 2024a; Alves et al., 2024), and with automatic metrics increasingly reflecting human judgments (Sellam et al., 2020; Rei et al., 2020; Juraska et al., 2023), quality-based fine-tuning has gained considerable traction. This approach shifts the objective from selecting the best candidate translation according to a metric at inference time to directly updating model weights through fine-tuning to produce the desired translations. A straightforward approach is to perform SFT on high-quality translations, evaluated and then filtered with respect to a metric of interest (Alves et al., 2024).

Another attractive alternative is Preference Optimization (PO) (Simianer, 2018; Rafailov et al., 2024; Xu et al., 2024a; Yang et al., 2023; Xu et al., 2024b; Wu et al., 2024), which focuses on learning preferences between chosen and rejected translations rather than simply increasing the likelihood of high-quality sentences. A popular PO method is Direct Preference Optimization (DPO) (Rafailov et al., 2024), which aims to maximize a scaled likelihood gap between a chosen and a rejected option.

More recently, CPO (Xu et al., 2024a) has emerged as a promising alternative, incorporating an SFT term into the DPO loss, effectively combining the strengths of both methods. Moreover, by removing the reference policy from the learning objective, it improves training efficiency.

3 Experimental Setup

Here, we detail our experimental setup, explaining how we built the preference data, and train and evaluate the models.

3.1 Preference Data

Preference datasets. To build a preference dataset, one needs candidate translations, an evaluation metric m to score these translations, and a method to select chosen and rejected hypotheses. We denote a candidate dataset by

$$\mathcal{D} = \{(x_i, \mathcal{Y}_i)\}_{i=1}^{N},$$

where x_i denotes the source sentence and $\mathcal{Y}_i$ is a set of candidate translations. One can then derive a preference dataset,

$$\mathcal{D}_{pref} = \{(x_i, y_i^r, y_i^c)\}_{i=1}^{N},$$

where $y_i^c \in \mathcal{Y}_i$ (chosen hypothesis) is a translation preferred to $y_i^r \in \mathcal{Y}_i$ (rejected hypothesis) according to a metric m and a given selection method.

Multi-system approach. In the multi-system scenario, we follow the setting outlined by Xu et al. (2024a). Candidate translations are generated using three different systems, namely ALMA-13B-LoRA (the base model we aim to align, referred to as Base) (Xu et al., 2023), GPT-4 (OpenAI, 2023), and the human-written gold reference (referred to as Ref). Formally, for all data samples,

$$\mathcal{Y}_i^{multi} = \left\{ y_i^{Ref}, y_i^{Base}, y_i^{GPT\text{-}4} \right\}.$$

Then, for each sample, the three translations are evaluated with regard to m. The one with highest (resp. lowest) score is selected as the chosen (resp. rejected) hypothesis. Formally,

$$y_i^c = \underset{y \in \mathcal{Y}_i^{multi}}{\arg\max}\, m(y) \wedge y_i^r = \underset{y \in \mathcal{Y}_i^{multi}}{\arg\min}\, m(y)$$

Mono-system approach. In the mono-system setting, we solely rely on the base model for candidate generation. For each source sentence, $K = 50$ candidates are top-p-sampled ($p = 0.6$) with a temperature $\tau = 0.9$,[2] and are then ranked based on evaluation metric m. For all samples, this results in a set of candidates

$$\mathcal{Y}_i^{mono} = \{y_i^1, \cdots, y_i^K\},$$

where $y_i^1 \preceq \cdots \preceq y_i^K$ are sorted in increasing quality order, with no loss of generality. Preference pairs are then derived to ensure that $y_i^r \preceq y_i^{Base} \preceq y_i^c$ holds for all samples. Further details on the construction of mono-system preference datasets are given in Section 5 and Appendix B.1.

Source dataset. We rely on the FLORES-200-based (Team et al., 2022) dataset used in Xu et al. (2024a) as a primary data source. It includes over 20000 translation pairs spanning six languages (English (`en`), Czech (`cs`), German (`de`), Icelandic (`is`), Russian (`ru`), and Chinese (`zh`)) and covering ten language directions, either into-English (`xx-en`) or out-of-English (`en-xx`).

Alignment metrics. In line with Xu et al. (2024a), we rely on reference-free neural metrics, namely xCOMET-QE-XXL (Guerreiro et al., 2023) (referred to as xCOMET-QE), and the WMT'23 version of CometKiwi-XXL (Rei et al., 2023) (denoted by CometKiwi), as well as on a reference-based lexical metric, chrF (Popović, 2015).

3.2 Training

Learning objective. We focus our diagnosis on CPO (Xu et al., 2024a), which combines a preference term with a likelihood term and achieves state-of-the-art performance in preference-based metric alignment for translation tasks. The empirical loss function is formally expressed as:

$$\mathcal{L}_{CPO} = -\frac{1}{N}\sum_{i=1}^{N}\left[\log\sigma\left(\beta\log\frac{\pi_\theta\left(y_i^c|x_i\right)}{\pi_\theta\left(y_i^r|x_i\right)}\right)\right] + \mathcal{L}_{SFT},$$

where $\mathcal{L}_{SFT} = -\frac{1}{N}\sum_{i=1}^{N}\left[\log\pi_\theta\left(y_i^c|x_i\right)\right]$ is the negative-log-likelihood loss applied to chosen translations, π_θ is the model to fine-tune, σ is the sigmoid function and β is a hyperparameter. In our experiments, CPO alignment is consistently compared to vanilla SFT on chosen translations.[3]

Training parameters. We replicate the exact same parameters as the ones outlined by Xu et al. (2024a). ALMA-13B-LoRA is LoRA fine-tuned

[2] These are the default parameters used in the ALMA paper (Xu et al., 2023, 2024a).

[3] All our models are trained using the code implementation provided by Xu et al. (2024a).

Table 1: Comparison between SFT on preferred translations and CPO in the multi-system setting, using xCOMET-QE, CometKiwi and chrF as alignment metrics. The same 3 metrics are reported for evaluation, separately for into-English (xx-en) and out-of-English (en-xx) translations on the WMT'22 dataset. Green shades indicate metric improvements over the base model, while red shades indicate metric decreases. We represent with (●) scenarios where the preference metric matches the evaluation metric. Values in *italic* font denote statistically significant differences between SFT- and CPO-based alignment at the 5% level, based on one-tailed paired Student's t-tests.

with rank 16 for one epoch, starting with a learning rate of 10^{-4}, using inverse square root decay and a batch size of 128. The β parameter of the CPO objective function is set equal to 0.1, in line with the original DPO paper by Rafailov et al. (2024).

3.3 Evaluation

Inference setup. Following other works on LLM-based translation (Alves et al., 2024; Briakou et al., 2024), all generations at inference time are produced using greedy decoding, as it provides maximum computational efficiency while preserving high output quality.[4]

Evaluation datasets. We evaluate our approaches on the WMT'22 test dataset, which consists of 17471 source-reference pairs and includes the same ten language pairs as the preference data. Evaluations on WMT'23 test data are provided in Appendix A.

Evaluation metrics. We use the same three metrics used to create the preference datasets: xCOMET-QE, CometKiwi, and chrF. Additional evaluation metrics are reported in Appendix A, specifically the reference-based version of Metric-X-Large (referred to as Metric-X) (Juraska et al., 2023), and BLEU (Papineni et al., 2002).

4 Multi-System Preference Fine-Tuning

We begin our analysis by focusing on the multi-system setting (Xu et al., 2024a), in which the chosen and rejected options are derived from a pool of three candidate systems consisting of ALMA-13B-LoRA (base model), GPT-4, and the gold reference.

4.1 Top-Level Analysis

Neural-based alignment improves downstream performance. Table 1 shows that when aligning with neural metrics (xCOMET-QE or CometKiwi), both SFT on preferred translations and CPO consistently improve performance on the alignment metric across language pairs. We also observe that aligning on xCOMET-QE improves results on CometKiwi, and vice-versa. We hypothesize this may be the result of high correlation between different neural metrics, as they are typically trained on similar data. Overall, these results demonstrate that alignment-based techniques can achieve similar objectives to those of quality-aware decoding approaches like MBR, even though the target metric is only indirectly optimized.

CPO induces adverse metric effects. In Table 1, we observe that when aligning with neural metrics, CPO yields significantly greater improvements on the alignment metric compared to SFT. The inclusion of the reject option seems to offer additional benefits over the traditional SFT objective

[4] Inference is performed using the vLLM library (Kwon et al., 2023).

Table 2: Impact of the systems used for candidate generation on WMT'22 performance in the multi-system setting after undergoing SFT and CPO optimization. Values in *italic* font denote statistically significant differences between all-systems-based alignment and alignment with one system removed, at the 5% significance level, based on one-tailed paired Student's t-tests. Evaluation metrics and color codes are the same as in Table 1.

in this context. However, aligning with CPO also introduces adverse effects between neural and lexical metrics for out-of-English translations. More specifically, and consistent with the findings of Xu et al. (2024a), aligning on neural metrics negatively impacts lexical metrics. Importantly, this is further evidence to support recommendations provided in (Kocmi et al., 2024): even though, in most cases, neural and lexical MT evaluation metrics should be positively correlated, we should employ caution when using the same metric for evaluation that was used during training/inference. Nevertheless and perhaps more interestingly, it turns out SFT does not produce such effects, raising the question of whether these contradictory evaluation dynamics seen with CPO stem from the learning objective itself or the mix of candidate systems used.

Lexical alignment fails to improve downstream performance. Table 1 shows that preference-based lexical alignment[5] behaves differently compared to neural alignment. Specifically, SFT results are roughly stagnant, showing a slight decrease in chrF for into-English translations and a slight increase for out-of-English translations. In contrast, CPO results in a steep drop across the metric board for both into- and out-of-English translations. Using the gold reference as the chosen system appears to impair downstream performance, especially when performing alignment using CPO.

4.2 Impact of the Candidate Systems

We now turn to investigating how much the success of alignment-based fine-tuning depends on the choice of the candidate systems. Unless otherwise specified, we use xCOMET-QE as the alignment metric and examine the performance impact of withdrawing systems from the candidate pool. We perform SFT and CPO on the newly created datasets. We report results in Table 2.

The choice of the candidate systems impacts alignment performance. Table 2 shows that for both SFT- and CPO-based methods, removing systems from the pool of candidates significantly af-

[5] When performing alignment using a lexical metric like chrF, the chosen translation is by definition the gold reference as long as it is present in the pool of candidates. The translation with the lowest chrF score among the remaining systems is then rejected.

Table 3: Impact of imposing the chosen system on WMT'22 downstream performance in the multi-system setting. Values in *italic* font denote statistically significant differences between SFT- and CPO-based alignment at the 5% significance level, based on one-tailed paired Student's t-tests. Evaluation metrics and color codes are the same as in Table 1.

fects performance on the alignment metric. This is particularly the case for out-of-English translation with CPO optimization. Notably, removing GPT-4 has the strongest negative impact on downstream xCOMET-QE. This is expected as it is the highest-quality system among the system candidates (see Table 11 in Appendix B).

Some candidate systems can be harmful to preference-based alignment. In Section 4.1, we observed CPO negatively impacts en-xx chrF when aligning on neural metrics, unlike SFT on preferred translations. Table 2 suggests this may stem from including gold references in the candidate system pool: removing them eliminates this adverse effect. We also noted in Section 4.1 that lexical alignment fails to improve downstream chrF, with sharp decreases with CPO. This issue is resolved by removing gold references. Overall, candidate system choice affects alignment effectiveness and downstream metric consistency, with CPO showing higher sensitivity to preference settings than SFT.

4.3 Impact of the Chosen System

To complement findings from Section 4.2 and further characterize the sensitivity of preference-based alignment, we propose examining downstream performance when the chosen system is fixed to a single system. We create three preference datasets based on xCOMET-QE, in which we either impose the base model, reference or GPT-4 as the chosen system. When applicable, the rejected translation is selected from the remaining systems (if one has a lower xCOMET-QE than the chosen system); otherwise, the sample is discarded.

CPO is not robust to the preference setting. In contrast to the observations made in Section 4.1, Table 3 shows that, under this setup, CPO fails to outperform SFT for both xx-en and en-xx translations. When systematically choosing base translations, CPO is unable to surpass the trivial SFT setting where the base model is fine-tuned on its own translations.[6] Moreove, downstream CPO performance significantly declines when gold references are chosen, underperforming the non-aligned model across all metrics, even including the alignment metric. These results reinforce the claims made in Section 4.2 and indicate a lack of robustness of CPO compared to SFT. In the following section (Section 5), we demonstrate that this instability observed with CPO can be mitigated by using a more normalized preference setting, relying only on the base model for candidate generation.

5 Mono-System Preference Fine-Tuning

So far, we have exclusively focused on multi-system alignment, which involves using external models for candidate generation and preference dataset building. Although this approach is common for metric alignment (Luong and Manning,

[6] As expected, performing SFT on a model's own greedy predictions has minimal impact on downstream performance.

Table 4: Comparison between multi- and mono-system fine-tuning on WMT'22 test data. Alignment is performed on xCOMET-QE for both SFT and CPO. Mono-system (opt.) denotes the model fine-tuned on optimized mono-system preference data. Values in *italic* font denote statistically significant differences between multi-system- and mono-system-based alignment at the 5% significance level. Evaluation metrics and color codes are the same as in Table 1, based on one-tailed paired Student's t-tests.

2015; Sennrich et al., 2016; Xu et al., 2024a), some works have shown that a model can be aligned effectively using only its own outputs (Yang et al., 2023; Yuan et al., 2024; Dubey et al., 2024). In this section, we propose to take a closer look at this strategy and identify its potential advantages and disadvantages compared to the multi-system approach. We use xCOMET-QE as the alignment metric. To ensure a fair comparison, we first generate the mono-system dataset to approximately replicate the properties of the multi-system dataset regarding the alignment metric.[7] Details on the construction of mono-system preference datasets are given in Section 3 and Appendix B.1.

5.1 Comparison With Multi-System Alignment

Mono-system alignment improves downstream performance. Table 4 shows that performing SFT and CPO on a mono-system dataset using xCOMET-QE for alignment results in improved downstream performance across all neural metrics compared to the base model, as observed in the multi-system scenario (Section 4.1). This finding highlights the effectiveness of alignment techniques even when using only the model's own translations for candidate generation, without needing access to high-quality external systems. This is particularly relevant in practical scenarios in which such access may be limited or unavailable.

CPO consistently outperforms SFT on neural metrics. Similar to when relying on multiple systems for candidate generation, we observe in Table 4 that CPO outperforms SFT regarding downstream performance on neural metrics. This finding reinforces the observation made in Section 4.1 and tends to confirm the superiority of the CPO objective over SFT on preferred translations in optimizing neural-based alignment performance.

Mono-system alignment slightly underperforms multi-system alignment. Table 4 shows that while mono-system alignment increases downstream performance on neural metrics, the improvement levels are not as high as in the multi-system setting. Despite the mono- and multi-system preference datasets being built with the same alignment metric properties, having translations from different distributions, particularly from GPT-4 (cf. Section 4.2 and Table 2), appears to add value for achieving optimized alignment effectiveness.

Removing external systems almost eliminates the adverse metric effects observed with CPO. In Section 4.1, we showed that multi-system neural alignment using CPO greatly impacts lexical performance for out-of-English translations. Table 4 demonstrates that mono-system alignment almost completely mitigates these negative effects. While there is still a slight decrease in en-xx chrF, it is much smaller compared to the multi-system scenario. This confirms the findings from Sections 4.2 and 4.3 that CPO is sensitive to the preference setting, but also shows that relying solely on candidate translations from the base model limits adverse ef-

[7] The created mono-system dataset has an average rejected/-chosen xCOMET-QE of $87.8/97.3$, compared to $87.9/97.2$ for the multi-system dataset (Table 11).

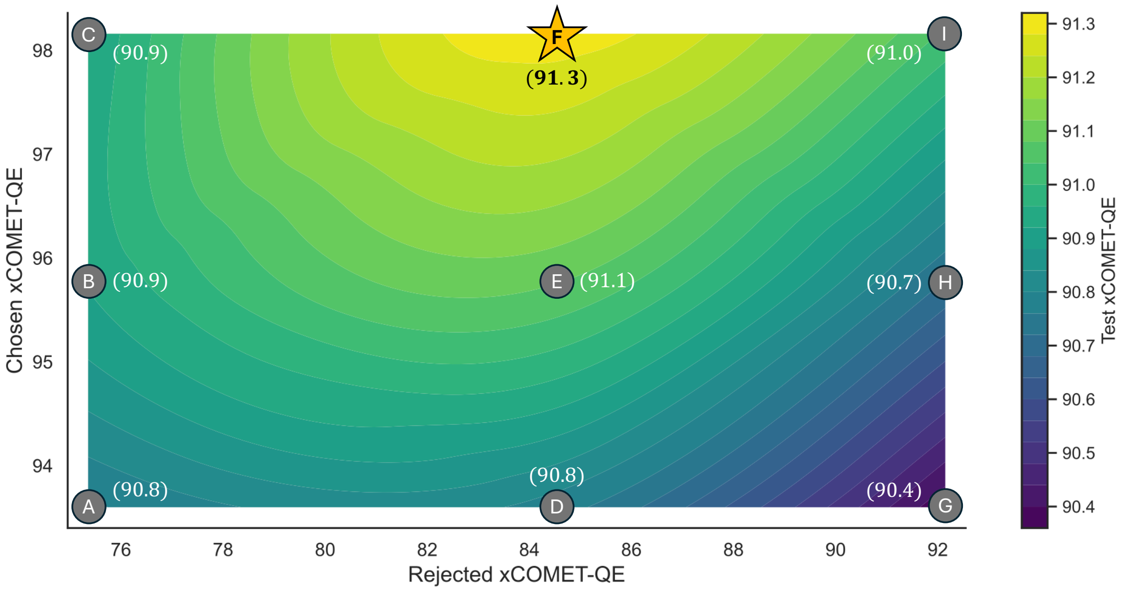

Figure 1: Impact of chosen and rejected option quality on downstream performance, using xCOMET-QE for alignment and evaluation. The chart is derived by linearly interpolating results from nine preference datasets (points A to I), each with different average rejected and chosen qualities. Test performance on WMT'22 (average across all language pairs) is reported in brackets. Example: point C (avg. rejected xCOMET-QE: 75.4, avg. chosen: 98.2) achieves 90.9 xCOMET-QE on WMT'22 test data.

fects on downstream metric consistency. A possible explanation is that candidate translations from the same system distribution tend to have similar properties, thereby reducing the likelihood of observing high lexical instability when performing alignment based on a neural metric like xCOMET-QE.

The mono-system approach offers better control over the alignment process. Specifically, mono-system alignment provides more fine-grained control over the respective qualities of the chosen and rejected options. This setting allows for tuning these qualities to maximize post-alignment performance, which is not possible when using a limited number of external systems. This aspect is further explored in the following section (Section 5.2).

5.2 Optimizing the Preference Data

In this final experiment, we examine how the quality of chosen and rejected options affects downstream performance. We build nine preference datasets, each with varying average xCOMET-QE scores for chosen and rejected options. The hypotheses' average qualities are categorized into three groups: High, Mid, and Low. As detailed in Section 3.1, the quality of the chosen (resp. rejected) option is always ensured to be above (resp. below) the quality of the base translation. The statistics of the created datasets are summarized in Appendix B.1 (Table 11).

The respective qualities of the rejected and chosen options have a significant impact on post-CPO performance. Figure 1 highlights the need to closely monitor the qualities of chosen and rejected options to fully leverage the mono-system approach. Specifically, several properties of preference data were found to negatively impact post-CPO performance: (i) a chosen option of too low quality, (ii) an extremely low or high quality of the rejected option, and (iii) too wide a gap between the qualities of the rejected and chosen options.

Optimizing preference data yields competitive performance to multi-system setting. Figure 1 shows that for effective metric alignment with CPO, the rejected option's quality should be moderate (neither too high nor too low), while the chosen option's quality should be as high as possible. Specifically, optimal test performance was obtained with rejected options average around 90% ($\Delta = -10\%$) of the base model's quality, and chosen options averaging around 105% ($\Delta = +5\%$). Under this scenario, we show that performance levels can match those in the multi-system setting while maintaining consistency with lexical scores (Table 4). However, these results also highlight the complexity of achieving optimal preference-based alignment and get the most of the reject option.

6 Conclusion

Our experiments revealed several key findings. Firstly, we showed that preference-based alignment, specifically using CPO, globally outperforms SFT on high-quality data in terms of improving neural evaluation metrics. However, we identified significant drawbacks when relying on multiple systems for preference data generation, revealing adverse effects between neural and lexical metrics, and highlighting a lack of robustness in preference-based alignment compared to the SFT approach. Finally, we showed that using candidate translations all originating from the same system distribution, specifically the base model, can be an effective strategy for gaining more control over preference-based fine-tuning. This approach achieves performance comparable to using multiple external systems while ensuring better consistency across evaluation metrics. In a nutshell, while preference-based alignment techniques hold promise for improving MT quality, careful consideration must be given to the choice of candidate translations, the learning objective, and the potential trade-offs regarding downstream metric consistency.

Limitations

In this work, we conducted extensive experiments to assess the impact of preference-based fine-tuning on downstream translation quality. For efficiency and practicality, we focused on the experimental setup detailed by Xu et al. (2024a), which utilizes three systems for candidate generation. Similarly, we used the same evaluation metrics and datasets. Future experiments could benefit from validating our findings using different model families, a broader range of alignment and evaluation metrics, and additional translation datasets, for instance including other languages.

Additionally, in the mono-system setting, we explored the impact of varying the qualities of chosen and rejected options and derived general insights on optimizing preference data. Further research could involve using different datasets, models, and alignment metrics to characterize more precisely the factors that influence downstream performance in this specific scenario. This approach could lead to a deeper mathematical understanding of the elements that affect performance in preference-based fine-tuning, resulting in more robust and scalable optimization techniques.

Finally, our evaluation relied on automatic metrics, both lexical and neural, with the latter closely approximating human judgments but still being unable to fully replace them. Given their imperfect correlation with human preferences, future work could benefit from additional human evaluation of outputs obtained via the approaches we studied to get an even deeper understanding of post-alignment downstream performance dynamics.

Ethics Statement

Our work aims to investigate the mechanisms of model alignment to enhance transparency in the field of automatic translation. We believe this effort improves the interpretability of model outputs, which is beneficial for ethical considerations. Additionally, our analysis is distinctly multilingual, with an emphasis on low-resource languages, contributing to expanding the scope of MT. We have identified no potential negative societal impacts from our work.

A Additional Results

In this section, we present results on WMT'23 test data. The findings in Tables 5, 6, 7 and 8 support the observations discussed in the main text for the WMT'22 dataset. In Tables 9 and 10, we also provide additional insights, split by language pairs, and include extra metrics, specifically Metric-X and BLEU.

Table 9: Comprehensive downstream evaluation for the WMT'22 dataset, reporting xCOMET-QE, CometKiwi, Metric-X, chrF, and BLEU scores for all models and language pairs. Learning objectives are indicated in **bold** font, candidate settings in *italics*, and alignment metrics are preceded by an arrow (→).

B Additional Data Details

B.1 Building Preference Datasets in the Mono-System Setting

Following the experimental setup detailed in the main text (Section 3), we here provide further details on the method used to construct mono-system preference datasets. As a reminder, after generating the K candidate translations for each source sentence, we have, for all $1 \leq i \leq N$,

$$\mathcal{Y}_i^{mono} = \{y_i^1, \cdots, y_i^K\},$$

where $y_i^1 \preceq \cdots \preceq y_i^K$ are assumed to be sorted in increasing metric score order. For each sample, we evaluate y_i^{Base} (the greedy-decoded translation) using metric m and check its rank in the set of candidate translations. We denote it by b_i. Sorted in increasing quality order, we thereby have

$$y_i^1 \preceq \cdots \preceq y_i^{b_i-1} \preceq y_i^{Base} \preceq y_i^{b_i} \preceq \cdots \preceq y_i^K.$$

Finally, to determine the chosen and rejected hypotheses, we select two offset parameters $o^r, o^c \in \mathbb{N}$, such that the chosen and rejected options are respectively

$$\begin{cases} y_i^c = y_i^{\min(K, b_i + o^c)} \\ y_i^r = y_i^{\max(1, b_i - o^r)} \end{cases}.$$

Intuitively, o^r and o^c control the average quality of the chosen and rejected options in the resulting preference dataset and ensure that the chosen (resp. rejected) option always has a higher (resp. lower) quality than the base translation. Table 11 presents the average quality properties for mono-system preference datasets, and compares them to the multi-system setting.

Quality or Quantity? On Data Scale and Diversity in Adapting Large Language Models for Low-Resource Translation

vivek.iyer@ed.ac.uk

Abstract

Despite the recent popularity of Large Language Models (LLMs) in Machine Translation (MT), their performance in low-resource languages (LRLs) still lags significantly behind Neural Machine Translation (NMT) models. In this work, we explore what it would take to adapt LLMs for the low-resource setting. Particularly, we re-examine the role of two factors: a) the importance and application of parallel data, and b) diversity in Supervised Fine-Tuning (SFT). Recently, parallel data has seen reduced use in adapting LLMs for MT, while data diversity has been embraced to promote transfer across languages and tasks. However, for low-resource LLM-MT, we show that the opposite is true for both considerations: a) *parallel data* is critical during both pre-training and SFT; b) diversity tends to cause *interference* instead of transfer. Our experiments with three LLMs across two low-resourced language groups—Indigenous American and North-East Indian—reveal consistent trends, underscoring the generalizability of our findings. We believe these insights will be valuable for scaling to massively multilingual LLM-MT models that can effectively serve LRLs.

1 Introduction

Large Language Models (LLMs) have been dominating recent research in Machine Translation (MT), showing good few-shot prompting (Garcia et al., 2023; Hendy et al., 2023) and stronger instruction-tuning (Alves et al., 2024; Xu et al., 2024) performances—recently even outperforming commercial Neural Machine Translation (NMT) models (Kocmi et al., 2024). However, LLM translation for low-resource languages (LRLs) still lags significantly behind NMT models (Robinson et al., 2023; Zhu et al., 2024b). While the strong performance of LLMs on high-resource languages can be attributed to the skewed language distribution during pre-training and the unintentional consumption of parallel data at scale (Briakou et al., 2023), no such relief exists for LRLs. This leads to the main question motivating this paper: *What would it take to adapt LLMs for low-resource MT*?

Recent work on LRL translation with LLMs has explored using resources like multilingual lexicons (Lu et al., 2023), word alignments (Mao and Yu, 2024) or linguistic tools (Zhang et al., 2024b). While effective, reliance on such tools hinders ease of extensibility across languages. Instead, in this work, we take inspiration from research done for high-resource translation with LLMs, where a 2-stage training paradigm of Continued Pre-Training (CPT), followed by small-scale Supervised Fine-Tuning (SFT; (Xu et al., 2024; Alves et al., 2024)) has been successful. Aiming to adapt this framework for low-resource MT, we re-examine the role of two factors influencing the performance of translation LLMs: a) *how best to leverage parallel data*, and b) *the interplay between diversity and transfer* during SFT (also known as 'instruction tuning').

Recently, the role of **parallel data at scale**, long viewed as fundamental to the success of NMT models, has come into question in the era of LLM-MT systems. Motivated by the modest gains of training on 300M parallel sentences (Yang et al., 2023),

and the surprising benefits of scaling *down* during SFT (Zhou et al., 2023), subsequent works have used only tens of thousands of human-written bitext for LLM-MT (Zhang et al., 2023b; Alves et al., 2024; Xu et al., 2024)—with SFT scaling laws further showing the early plateau of LLM-MT performance (Zhang et al., 2024a). Even more surprisingly, Zhu et al. (2024a) showed MT abilities emerging with just 32 SFT examples! However, these explorations concern LLMs pre-trained on several billions of tokens in the languages in question. We revisit these notions for low-resource MT and work with languages having datasets that are 2-3 orders of magnitude smaller. In Table 1 we compare the scale of the datasets used in our work and related research. We discover that for low-resource MT, *parallel data is critical* not just during CPT, but even more so during SFT—in direct contrast with research on high-resource languages (HRLs).

Next, **diversity** in tasks, prompts, and datasets during SFT has been shown to significantly improve model performance across a range of tasks (Mishra et al., 2022; Chung et al., 2024). MT instructions have been shown to not just boost translation performance in unseen languages (Muennighoff et al., 2023), but also enhance LLM capabilities across diverse multilingual generation tasks (Ranaldi and Pucci, 2023; Zhu et al., 2023). Inspired by these findings, we study if SFT diversity could benefit low-resource LLM-MT systems too. By conducting experiments across a range of tasks and language pairs with SFT datasets of varying compositions, we establish that *diversity leads to negative interference* and fine-tuning on multilingual MT is the optimal strategy. Further, we observe that training for more epochs on MT data is more effective than curating and training on a diverse dataset of the same size.

Our contributions are thus as follows:

1. In contrast to findings for high-resource LLM-MT (Xu et al., 2024), we observe that for LRLs, LLMs benefit hugely from scale of parallel data, during both CPT and SFT stages
2. Linguistic and task diversity during SFT leads to negative interference for LRL LLM-MT, with focused multilingual MT fine-tuning for more epochs being the most effective recipe.

To ensure the generalizability of our findings, we conduct 2 sets of experiments training multilingual LLMs on different sets of languages: a) 11 Indigenous American and b) 4 North East Indian languages, wherein the former follows a Latin script and the latter includes languages that do not. Our focus in this work is on the eng/spa → X directions since generation in an LRL is known to be a much harder task than in an HRL like English or Spanish, and we are interested in studying the challenges involved. We experiment with 3 base LLMs of varying sizes—Gemma 2B (Gemma Team et al., 2024), Mistral 7B (Jiang et al., 2023), and Llama 3 8B (Dubey et al., 2024), and observe that findings are mostly consistent across these models.

By applying our findings to 2-stage training, our methods achieved a +16.5 average chrF++ improvement over few-shot prompting—with the largest gains coming from the 8 least-resourced American languages in our setup, all of which have about 10K-50K parallel sentences each. We hope that the findings of this work will be useful when scaling to LLMs that can effectively translate into lower-resource languages.

2 Related Work

High-Resource Translation with LLMs There has been considerable interest in using LLMs as MT systems recently. Following initial success in prompting LLMs for high-resourced pairs (Vilar et al., 2023; Garcia et al., 2023; Hendy et al., 2023; Zhang et al., 2023a; Iyer et al., 2023), subsequent works have attempted to train LLMs on parallel data at scale (Yang et al., 2023; Lu et al., 2024), but these yielded modest gains and underperformed smaller encoder-decoder baselines such as NLLB-200 (Costa-jussà et al., 2022). Zhang et al. (2024a) showed through scaling laws for SFT that LLMs pre-trained at the order of 50B-300B tokens saturate in MT performance with 20K-30K instructions. Concurrently, Xu et al. (2024) discovered excess parallel data washed out LLM knowledge, so they proposed a 2-stage paradigm called ALMA that involved pre-training on scaled-up monolingual data, followed by SFT on much smaller high-quality bitext (~60K lines). ALMA outperformed NLLB-200. Following their success, Alves et al. (2024) adopted the ALMA framework to train Tower 7B for 10 high-resourced languages, outperforming ALMA and also matching GPT-4.

It is worth noting that Xu et al. (2024) did not include parallel data during CPT. However, inspired by research showing LLMs unintentionally consume parallel data at scale (Briakou et al., 2023), several works have included it at the order of several billions of tokens for the top 10-20 high-resource languages (Anil et al., 2023; Wei et al., 2023; Fujii et al., 2024; Alves et al., 2024). Concurrent work has explored pre-training on synthetic, code-switched parallel data for 101 languages (Lu et al., 2024) with a total of 400M sentences. This work explores the impact of parallel data exclusively for low-resource performance and experiments with 1M–13M parallel sentences (50M–750M tokens) during pre-training, two orders of magnitude smaller than prior work.

Low-Resource Explorations in LLM-MT LLMs have been shown to perform poorly in low-resource MT (Robinson et al., 2023; Zhu et al., 2024b). In response, there have been efforts to leverage external resources in the MT pipeline, including multilingual lexicons (Lu et al., 2023), rule-based linguistic tools (Zhang et al., 2024b), word alignments (Mao and Yu, 2024) and even entire grammar books (Reid et al., 2024). However, such approaches create dependencies on resources and hinder extensibility across languages. Instead, we focus on optimal data utilisation strategies during CPT and SFT, prioritizing extensibility.

Cross-Lingual Instruction Tuning There has been a body of work exploring multilingual instruction tuning that have touched on diversity and data scale, but most of it is limited to HRLs. MT examples were shown to improve cross-lingual generation (Ranaldi and Pucci, 2023; Zhu et al., 2023), while Chen et al. (2024) showed multilingual SFT on machine-translated Alpaca datasets matches or beats monolingual tuning. Kew et al. (2023) and Shaham et al. (2024) showed a small quantity of multilingual SFT data can improve cross-lingual generation capabilities in medium and high-resource languages, while Zhu et al. (2024a) showed only 32 examples in HRLs suffice to elicit MT capabilities from LLMs. In our work, we hypothesize that these findings have the common denominator of pre-training on HRLs at scale, and show that when moving to LRLs, these trends reverse and diversity is no longer beneficial.

3 Approach

We now describe our efforts to adapt the widely-used ALMA framework, originally designed for fine-tuning LLMs for HRL translation (Xu et al., 2024; Alves et al., 2024), for MT in LRLs.

3.1 Stage 1: Continued Pre-training (CPT)

CPT on Monolingual Data The objective of this stage is to 'teach' an LLM to model LRLs, which are scarce in the pre-training corpus. We conduct CPT on monolingual data with the standard Causal Language Modelling objective. We train with low-rank adaptation (LoRA) and attach rank 8 adapters to query and value matrices (Hu et al., 2022). We also fine-tune input and output embeddings.

CPT on Parallel Data In a scenario where monolingual data is scarce, it is crucial to investigate the most effective way to use parallel data—which, for our indigenous American languages, was found to surprisingly be more abundant than the former[1]. We investigate 3 methods of mixing all available parallel and monolingual data:

1. **All Mono**: Here, we merge monolingual data with only *the target side* of all available bitext—essentially using it as extra monolingual data

2. **Mono + parallel (concat)**: Here, we merge monolingual data with *concatenated source-target pairs* from parallel data. We prepend source and target language codes before concatenation and, following Guo et al. (2024), use a newline delimiter to separate them.

3. **Mono + parallel (separate)**: To ablate the impact of concatenation, we provide the source and target sides of parallel data as *separate* sentences, and shuffle with monolingual data.

We depict our approach in Figure 1. In the first technique, the motivation is that it might be hard for the LLM to learn to model concatenated sequences, given that they were likely scarce in the original pre-training corpus, with the added challenge of pre-training on 'new' low-resource languages. On the other hand, if the model is able to adapt to concatenated sequences, it could make the LLM more adjusted to the task of translation. Finally, the third method verifies whether the results of the 'concatenated' model are due to the concatenation itself, rather than simply being exposed to additional tokens in the source language. We use this terminology for all experiments in this work.

While these methods control how parallel data is incorporated in pre-training, we are also interested

[1] While monolingual online data is scarce, many translations of constitutions, articles etc. from Spanish do exist

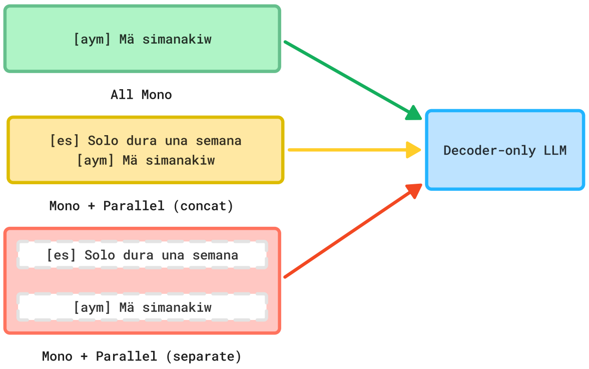

Figure 1: Strategies explored for incorporating parallel data during Continued Pre-Training. We show a Spanish (es) to Aymara (aym) example from our parallel data.

in adjusting the ratio of parallel to monolingual data in the corpus, particularly for the *'concat'* method given pre-training on 100% parallel data can be suboptimal (Alves et al., 2024). To get a desired mixing ratio for *'concat'*, we include bitext only until it comprises a given percentage of the training corpus. Once this threshold is crossed, we use the *'all mono'* method to include it as monolingual data instead. Next, we use temperature sampling (Arivazhagan et al., 2019) to control the language-wise distribution in our monolingual and parallel pre-training data, since these are quite heterogeneous and certain languages are extremely low-resourced. We sample monolingual and parallel data independently if using the 'concat' method, else we just mix them all together and shuffle at the instance level to create our final pre-training corpus.

3.2 Stage 2: Supervised Fine-Tuning (SFT)

Next, we fine-tune with LoRA on supervised instruction data and detail the tasks explored below. Note that we convert all instructions to the standard Alpaca format, and compute loss on the target tokens only (Taori et al., 2023).

Low-Resource MT Given our use case, the most intuitive task to include would be MT itself. The `instruction` for each example is chosen randomly from a set of translation prompts (Table 11), while the `input` and `output` fields are the source and target sentences respectively.

High-Resource MT Apart from MT data in the LRLs, we also experiment with adding HRL MT data since it is more abundant and of higher quality, known to be important during SFT (Xu et al., 2024). To explore the impact of transfer learning, we work with HRL data that is in some way related to the source/target language, e.g. Spanish-English data for experiments on Spanish-X. Instructions are formatted in the same way as the LRL data.

General-Purpose Instruction Tuning Apart from MT data, we also explore adding widely used general-purpose instruction tuning datasets, such as Alpaca (Taori et al., 2023) and Aya (Singh et al., 2024), and use data from high-resource languages (comprising the source side in our tasks) to improve the model's overall instruction-following capabilities. However, for the most part, we are unable to find similar data in the LRLs we experiment on.

Synthetic Cross-Lingual QA (XQA) We do not find any instruction tuning data for most LRLs, so we follow Iyer et al. (2024) to create synthetic Question Answering (QA) data. Starting from a parallel sentence pair (X, Y), where X is from an HRL (in our case, English/Spanish) and Y is from an LRL, we prompt an LLM (Mixtral-8x7B-Instruct (Jiang et al., 2024) in this work) to generate a question Q for which X would be an answer. Since X and Y are semantically equivalent, Y is treated as the answer to question Q. We add a requirement at the end of Q to generate in the target language. Thus, we use (Q, Y) as synthetic cross-lingual instruction data. We provide the templates used for generating XQA examples in Table 12.

4 Experiments and Discussions

We fine-tune 2 separate sets of multilingual LLMs for 2 different language groups to facilitate evaluation on test sets from 2 different low-resource MT shared tasks: AmericasNLP 2024 (Ebrahimi et al., 2024) and the Indic track of WMT 2023 (Pal et al., 2023). The former involves 11 Indigenous Central & South American languages, while the latter focuses on 4 North-East (NE) Indian languages. The first group includes Aymara (aym), Bribri (bzd), Asháninka (cni), Chatino (ctp), Guarani (grn), Huichol (hch), Nahuatl (nhe), Otomi (ote), Quechua (quy), Shipibo-Konibo (shp) and Tarahumara (tar). The second consists of Khasi (kha), Meitei (mni), Mizo (lus) and Assamese (asm). Our motivation in choosing these languages was to experiment with LRLs containing both Latin (American) and non-Latin (Indic) scripts; that also had widely used, high-quality test sets. We use the former for our main experiments and replicate the most interesting baselines in the Indic languages.

Lang	#Tokens	Lang	#Tokens	Lang	#Tokens

(b) North-East Indian Languages

Table 2: Monolingual data statistics, with token counts calculated using the Llama3 8B tokenizer. English and Spanish are included as replay data. Note that LRL token counts overestimate data sizes, due to poor tokenization, and cannot be directly compared with HRLs.

4.1 Data

Monolingual Data Table 2 shows the token counts for the monolingual data collected for the 2 language groups. We note that the American languages are very low-resource, with 6 of 11 having 5M tokens or less. The Indic languages have relatively more data, with Assamese being medium-resourced but still likely low-resource in the original LLM pre-training corpus. Assamese and Meitei follow the Assamese-Bengali script, while Mizo and Khasi use the Latin script. Using the Llama3 tokenizer, we observe average fertilities of 2.87 and 3.83 for the American and Indic languages respectively, almost 3x that of high-resource languages, illustrating the under-representation of non-Latin scripts in SOTA LLMs. Finally, we include some data in English and Spanish as *replay data* to prevent catastrophic forgetting (Ibrahim et al., 2024).

Parallel data We curate parallel data from various sources, for use in both CPT and SFT. Tables 3 and 4 show the sizes for the American and Indian languages respectively. Given that our primary exploration is for the American languages with limited spa-X data, we also sample eng-X and por-X from OPUS (Tiedemann, 2012). Note the heavily skewed language distribution, with the 3 HRLs constituting 80% of spa-X data and 96% of the overall data. The lesser skew for spa-X is due to the efforts of AmericasNLP to collect data for these pairs and the prevalence of Spanish in Latin American countries. A similar skew also exists for the Indic languages, with English-Khasi being the least-resourced pair. We list sources for all curated data, along with cleaning steps, in Appendix A.

4.2 Evaluation

To evaluate MT into the 11 American languages, we use AmericasNLP'23 validation sets (Ebrahimi et al., 2024) containing spa-X translation pairs. For the Indic pairs, we use the WMT 2023 test sets from the Indic track (Pal et al., 2023) which consist of eng-X pairs. Both evaluation datasets are multi-domain, as are the curated monolingual and parallel corpora. We show test set statistics in Table 5. Given the absence of neural metrics for these languages, we evaluate using ChrF++ (Popović, 2017), since both the American and Indic languages are morphologically rich wherein chrF++ is particularly effective (Popović, 2017). We use SacreBLEU (Post, 2018) for computing this. We also report confidence intervals with bootstrap resampling (Koehn, 2004), which we implement for the multilingual setting by computing the macro-average across all languages for each resample, and then computing the mean and variance across all resamples. We report the standard deviation as the confidence interval.

4.3 Experimental Settings

For temperature sampling our data, we use $\tau = 30$ for CPT and $\tau = 80$ for SFT. We used a batch size of 8 and gradient accumulation every 16 steps. We used a learning rate of 1e-4, with a cosine scheduler and a warmup ratio of 3%. We train all models on bf16 precision for 1 epoch. We use Llama-Factory (Zheng et al., 2024) for training and evaluating all models, with Deepspeed ZeRO3 (Rasley et al., 2020) for distributed training. For inference, we used a batch size of 16 with greedy decoding, since we found higher beam sizes yielded minimal gains.

4.4 Foundational Results

We first establish the importance of fine-tuning input and output embeddings in Table 6 and then show our foundational results for the American languages in Table 7, using 5-shot prompting as a baseline. Our findings are:

1. **Fine-tuning embeddings is critical.** Across the board, we observe that fine-tuning embeddings along with LoRA modules yields huge gains (Table 6), almost doubling chrF++ scores, indicating that this step is crucial to helping LLMs adapt to these new languages. Given this, we expect that full-weight fine-tuning would perform better, but stick to

	Total	HRL	LRL	aym	bzd	cni	ctp	grn	hch	nhe	oto	quy	shp	tar

Fine-Tuned Modules	**Gemma 2B**	**Mistral 7B**	**Llama3 8B**
LoRA only	4.5 ± 0.1	8.8 ± 0.2	8.3 ± 0.2
LoRA + embeddings	9.6 ± 0.3	15.6 ± 0.4	15.6 ± 0.4

Table 6: Impact of fine-tuning input/output embeddings along with LoRA adapters is shown. Both models follow the "CPT *all mono*, SFT" recipe from Table 7.

Method	**Gemma 2B**	**Mistral 7B**	**Llama3 8B**
5-shot prompting	2.8 ± 0.1	5.1 ± 0.1	3.9 ± 0.1
SFT only	8.7 ± 0.2	16.3 ± 0.4	14.8 ± 0.4
CPT *all mono*, SFT	9.6 ± 0.3	15.6 ± 0.4	15.6 ± 0.4
CPT *mono+parallel*, SFT	**10.1 ± 0.3**	**16.7 ± 0.4**	**17.2 ± 0.4**

Table 7: chrF++ scores for spa-X LLM-MT in the American languages, for LLMs of varying sizes. Both LoRA modules and embeddings are fine-tuned. For SFT, all models use 500K spa-X MT examples. Confidence estimates are computed using bootstrap resampling. *'mono+parallel'* uses concatenated bitext.

LoRA fine-tuning for cost-efficiency reasons. We fine-tune embeddings for all future results.

2. **Choosing larger base LLMs is crucial.** For under-represented (zero-resource) languages, is it more effective to train smaller LLMs with larger vocabularies (and thus, improved fertility), or vice versa?[2] We note that Gemma 2B has the largest vocabulary (256K tokens), followed by Llama3 (128K) and Mistral (32K tokens), resulting in improved fertility (2.36 vs 2.87 for Llama3/Mistral). Regardless, the larger models, Mistral 7B and Llama3 8B, vastly outperform the Gemma 2B model, suggesting fine-tuning smaller vocabulary LLMs like Mistral might be a better option from both cost and performance standpoints.

3. **SFT alone is effective, but CPT+SFT yields best results.** While SFT yields large gains over prompting, combining CPT and SFT seems optimal for both Gemma and Llama3, although the gap is smaller than that of high-resource MT (Xu et al., 2024), ostensibly due to the difference in scale. For Mistral, SFT alone seems to suffice—we hypothesize that this might be due to the smaller vocabulary being effectively fine-tuned on SFT data alone.

4. **Pre-training on parallel data yields major gains consistently.** Lastly, we observe that pre-training on a mixture of *concatenated* monolingual and parallel data (*'mono + parallel'*) yields statistically significant gains over converting both as monolingual data (ie. *'all mono'*; refer Section 3.1). This trend is consistent for all 3 LLMs, with larger gains for the more effective models Mistral and Llama3. We note that for 'mono+parallel', we mix parallel and monolingual data in a 1:1 ratio, since we observed it worked best empirically, and show in Table 14 how increasing the ratio of parallel data during CPT monotonically improves performance. Given these gains, we explore the importance of bitext for low-resource LLM-MT further in Section 4.5.

4.5 Analysis: Importance of Parallel Data

How important is concatenated parallel data at various scales of low-resource pre-training?

[2] We found it prohibitively expensive to fine-tune Gemma 7B which has a larger vocabulary *and* a larger capacity.

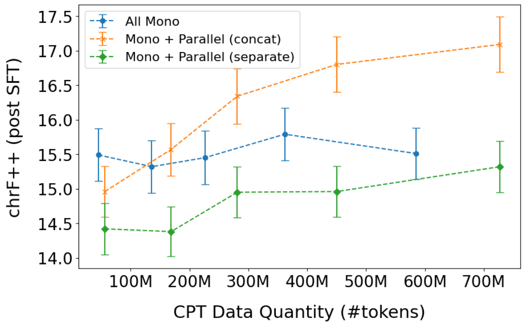

Figure 2: Comparing Llama3 8B models pre-trained on monolingual data alone versus those included parallel data too—concatenated, or as separate texts at various scales. All models were pre-trained on 1M, 3M, 5M, 8M, and 13M sentences respectively, and markers denote the corresponding token counts. The y-axis shows chrF++ post SFT on 500K spa-X MT data for 1 epoch.

Having seen improvements in pre-training on the entire corpus (consisting of 13M 'mono+parallel' sentences, or 730M tokens) in Table 7, we now study the importance of parallel data as we scale *down*—an important consideration when one moves to even lower-resource settings. We pre-train on subsets of varying sizes and mix monolingual and parallel data in 3 ways: 'All mono', 'mono+parallel (concat)' and 'mono+parallel (separate)', as defined in Section 3.1). We fine-tune all these pre-trained models on the same SFT dataset: 500K spa-X MT instructions, and plot the resulting chrF++ scores in Figure 2, including error bars from bootstrap resampling. We note that 'all mono' has different markers than the others, as the token counts on including both source and target-side data in the corpus are obviously larger than only the latter. We find that a) starting at around 5M sentences (~300M tokens), it is *consistently advantageous* to include concatenated parallel data during pre-training. b) Given 'mono+parallel (separate)' severely underperforms, we establish that it is **concatenation** that adapts the LLM for the task of MT, not the extra data alone. Our findings complement those of Alves et al. (2024), who also observe gains from pre-training on parallel data in the 1B to 20B tokens range, using 10 high-resourced European languages. In contrast, our focus here is on investigating the *minimum data threshold* at which CPT leveraging parallel data becomes beneficial.

How does scaling LRL parallel data during SFT impact performance? We now turn our focus to scaling during SFT, which has not yielded gains in high-resource LLM-MT after 20K-30K sentences (Zhang et al., 2024a). Motivated by our previous results, we re-examine this question for low-resource LLM-MT in Figure 3, wherein we evaluate at steps of 50K until ~1M SFT instructions, the point at which spa-X MT data runs out. Our findings are:

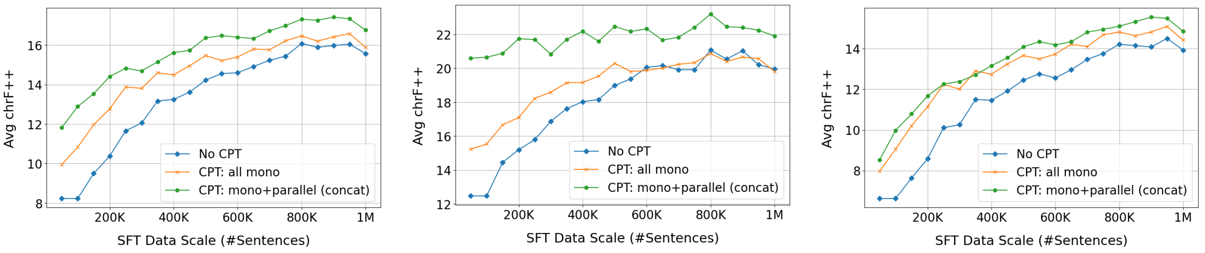
1. **Overall MT quality improves steadily with scale.** Unlike high-resource LLM-MT, we observe that, despite fluctuations, MT quality continues to grow until 1M sentences, particularly for LRLs, which have a steeper slope.

2. **The gains of CPT on parallel data carry over to SFT scaling, particularly for HRLs.** We observe that CPT on a mixture of concatenated monolingual and parallel data yields the largest initial gains, followed by CPT on monolingual-only data. We note that the former is particularly beneficial for HRLs, which have likely consumed a lot of parallel data during pre-training, and this helps them maintain a huge lead at lower SFT scales, suggesting that *concatenated parallel data teaches the LLM the task of translation and helps it adapt to MT more naturally during SFT*. Given the prevalence of bitext in LLM pre-training corpora (Briakou et al., 2023), the gains of concatenation would help explain why few-shot prompting (Garcia et al., 2023) and tiny-scale SFT (32 examples; c.f. Zhu et al. (2024a)) can elicit MT in the highest-resource languages!

3. **LRLs need SFT scaling much more than HRLs** So, while HRLs benefit hugely from CPT on bitext, the opposite is true for LRLs—the scarce amount of parallel data observed during CPT (see Table 3) is likely not enough to outperform 'all mono' pre-training. Instead, LLMs are far more responsive to the scale of LRL MT data during SFT, showing consistent performance improvement. Meanwhile, MT quality plateaus for the HRLs[3] (Figure 3b), suggesting that the 'less is more' (Zhou et al., 2023) trend popular in high-resource LLM-MT does *not* hold for LRLs, where *scale continues to remain the most effective option.*

For generalizability, we also provide scaling graphs for Mistral 7B in Figure 7 and report trends similar to Llama3. Moreover, we also compute

[3] although Aymara, Guarani and Quechua *are* LRLs for the original pre-training corpus of Mistral/Llama3



(a) Average (overall)

(b) Average (high-resource†)

(c) Average (low-resource$^\eta$)

Figure 3: Scaling up Llama3 8B models with different CPT recipes (no CPT, CPT with monolingual data, and CPT with a mixture of monolingual and parallel data) on MT data for the American languages. †'High-resource' refers to the relatively higher-resourced languages in our low-resource setup (Aymara, Guarani and Quechua) while the other 8 are grouped as low-resource$^\eta$.

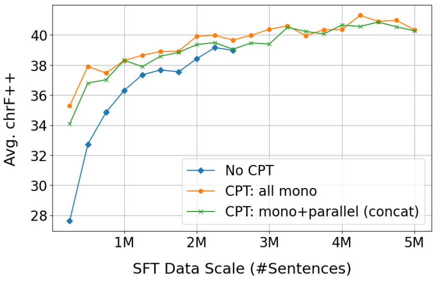


Figure 4: Scaling up Llama 3 8B models with the 3 CPT recipes for the 4 Indic languages, until 5M sentences. We were forced to stop training 'No CPT' at 2.5M sentences, constrained by budget.

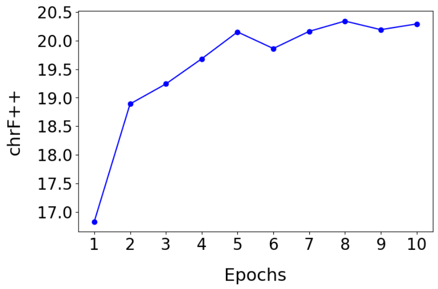

Figure 5: Epoch vs performance graph for low-resource LLM-MT. We use the entire 1M spa-X MT dataset, and plot average chrF++ for the Indigenous American languages, using Llama3 (Mono+Parallel (concat)) model.

scaling graphs for the 4 Indic languages in Figure 4 using the Llama3 model, until 5M eng-X sentences. Here, we observe that the gap between 'CPT: mono+parallel (concat)' and 'CPT (all mono)' is relatively lesser, and only significant until 500K sentences, at which point they start becoming comparable. This might be because the Indic parallel corpora used for CPT is relatively less diverse, consisting of only eng-X pairs in 4 languages, whereas our parallel data for the American languages is more heterogeneous (see Table 3)—which we observed to yield more gains in our preliminary experiments. Thus, we expect a more diverse corpus for the Indic languages to yield greater long-term gains, but we leave the verification of this to future work. In other respects, the trends are quite similar to the American languages: the gains of CPT carry over to SFT here too and interestingly, MT quality continues to improve until 5M SFT examples, once again in direct contrast to high-resourced LLM-MT research.

More epochs: Scale through repetition Finally, given the consistent gains from scale, we evaluate how effective data repetition could be during SFT. We train for up to 10 epochs on the entire 1M spa-X MT dataset and plot our results in Figure 5. We note a strong monotonic gain of +3.3 average chrF++ until 5 epochs, with the largest coming from the 1st to the 2nd epoch (+2.0 chrF++). While the graph does plateau later (likely due to overfitting) this shows how simply training for more epochs can be an easy way to boost performance, given the data constraints for LRLs.

4.6 Analysis: Diversity in SFT is not *always* helpful

We now look at the importance of *diversity* in SFT, which plays a significant role in boosting LLM performance during general-purpose fine-tuning (Sanh et al., 2022; Longpre et al., 2023), but has also been favoured in training LLM-MT systems (Alves et al., 2024). Alves et al. (2024) observed improved performance on non-MT tasks by including non-MT instructions, but mixed results on MT quality—concluding that the "transfer/interference relations between tasks are complex". In this work, we try to tease apart these interference relations and study the effect of non-MT tasks on low-resource translation in depth. In particular, we look at 3 kinds of

Method	All	HRL	LRL
Bilingual LLM-MT	14.51	24.55	10.75
Multilingual LLM-MT	18.73	23.59	16.90

Table 8: Average chrF++ of SFT on a single language pair (bilingual) vs all language pairs (multilingual). As before, “HRL” includes Aymara, Guarani and Quechua, while the other eight are grouped under LRL.

SFT Mixture	chrF++
Prompt Diversity	
500K spa-X MT (Same prompt)	16.18±0.37
500K spa-X MT (Random prompts)	**17.22±0.40**
Linguistic Diversity

500K spa-X MT	**17.22±0.40**

(a) Prompt, Linguistic and Task Diversity in American pairs

SFT Mixture	chrF++
250K spa-X MT + 250K Aya (asm, mni)	26.91 ± 0.42
250K spa-X MT + 250K Alpaca (eng)	28.02 ± 0.41
500K spa-X MT only	**29.57 ± 0.43**

(b) Task Diversity in Indic pairs

Table 9: Exploring interference due to diversity in SFT for our best Llama3 8B model (CPT on both monolingual and parallel data) on the American and Indic languages. The dataset size (example count) is prepended before each task. Scores shown are average chrF++.

diversity: *prompt*, *linguistic*, and *task* diversity, and examine their impact on MT quality when mixed in varying proportions in the SFT dataset.

Bilingual or Multilingual fine-tuning? First, we ask whether given some multilingual low-resource data and a fixed FLOPS budget, would it be beneficial to do SFT on multiple, diverse low-resource MT pairs (multilingual LLM-MT) or only on a single pair (bilingual LLM-MT)? For this experiment, we simply concatenate all available data for the multilingual setting, while the bilingual setting consists of fine-tuning separate models for each pair, with the base LLM being constant in both cases: Llama3 (CPT with mono+parallel data). We show our results in Table 8. We observe that, on average, multilingual SFT outperforms the bilingual models by +4 chrF++ points. Looking closer, we notice that these gains mostly come from the lower-resourced languages (detailed results in Table 13). This is potentially because the bilingual setting has too little data for effective FT in these languages, while the multilingual option offers better transfer and scale. For higher-resourced pairs, the opposite is true: the performance is slightly lower, ostensibly due to negative interference. This is not unlike conventional multilingual NMT models, such as NLLB, wherein high-resource MT can often be worse than bilingual baselines.

On Linguistic, Task and Prompt Diversity Inspired by the previous results showing target-side diversity in MT pairs boosts performance, we now broaden the scope of diversity during SFT. In Table 9a, we show varying mixtures of SFT data that all have the same size (500K examples) but are composed of different tasks. For *prompt diversity*, we ablate randomly sampling from a list of potential prompt templates (listed in Table 11) versus using a constant one (the first in Table 11). We observe a statistically significant gain in MT quality, similar to general-purpose SFT (Longpre et al., 2023).

Next, we study the more interesting question of *linguistic diversity*: can data in other MT pairs transfer for test languages? In one baseline, we divide our SFT dataset equally into spa-X, eng-X, and por-X MT examples, into the American languages (statistics in Table 3). In another baseline, we use Spanish-English data from ParaCrawl (Bañón et al., 2020) and combine a 250K sentence subset with 250K pairs from our usual spa-X MT data. We find that this type of linguistic diversity leads to interference, and significantly underperforms the 500K spa-X MT baseline. This suggests that while *target diversity* in related languages might help performance, source diversity or unrelated high-resource languages like English may not.

Then, we look at *task diversity*: can non-MT tasks that elicit better instruction-following and general reasoning capabilities in the source or target language, benefit LLM-MT in LRLs? We mix Aya and XQA (Section 3.2) instructions with a 250K subset of spa-X MT examples. We also include an ablation that, in place of curating non-MT data, merely trains for 2 epochs on the 250K spa-X MT subset. Here we also discover that general-purpose tasks lead to interference and that training for 2 epochs on 250K MT examples is a more effective strategy comparable to 1 epoch on 500K.

We also look at the impact of task diversity on the Indic languages in Table 9b. Here, we are able

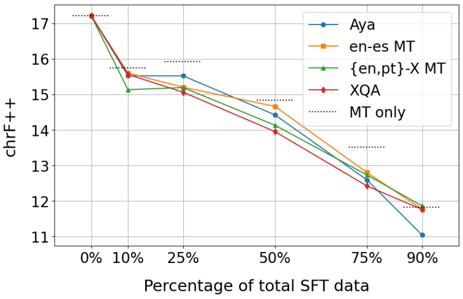

Figure 6: Mixing varying percentages of SFT tasks with spa-X MT, versus the impact on spa-X chrF++, for 500K examples. 'MT only' is a topline which *only* uses the spa-X MT data excluding all other tasks. Thus, it uses *lesser* data relatively and helps to estimate the interference of non-MT tasks on MT quality.

to find general-purpose instruction-tuning data in Assamese and Meitei, as mentioned in Section 3.2. Interestingly, including data in these *target languages*—the languages we want the model to be better at generating in—degrades performance the most! A similar amount of Alpaca data in English reduces performance far less, suggesting that reasoning in LRLs is such a hard task, that even data where the model *should* learn to generate in the languages of interest, is *worse* than generic English instruction-following data. Here, too, providing 500K spa-X examples is the most optimal strategy, underscoring the generalizability of our findings.

Does non-MT SFT always cause interference? Finally, we seek to establish conclusively if the negative results of diversity in Table 9a arise from factors like task mismatch or lack of quality; or if interference is simply *the norm* when fine-tuning on non-MT data for low-resourced LLMs. In Figure 6, we plot 5 graphs: the first 4 are graphs showing non-task-specific data (including XQA, Aya, {eng/por}-X MT and eng-spa MT) mixed in varying proportions with spa-X MT. Thus, for example, the second point of each plot represents 10% of that task mixed with 90% of spa-X MT, with the total always being 500K examples. We also include an ablation (dotted lines), which has the same quantity of spa-X MT data at each data point as other plots but without data from any other task listed.

We observe that *performance is always better using task-specific MT data*, and negative interference is indeed consistent. We conclude that transfer is challenging to achieve in low-resource settings, likely because at such scales, the LLM-MT model is still learning to generate translations, and reasoning is still a formidable challenge. Downstream performance in such settings depends not on the diversity/composition of the SFT dataset, but only on the amount of LRL MT data provided—making optimizing for *quantity* the most effective strategy.

4.7 Discussion: LLMs vs NMT models

For the Indigenous American languages, the current SOTA systems are NordicAlps (Attieh et al., 2024) and DC-DMV (DeGenaro and Lupicki, 2024) that report average chrF++ scores of 26.73 and 23.76 respectively. Both are NMT models. NordicAlps trained a multilingual model from scratch on varying mixtures of eng-spa and spa-x data at scale, with their most major gains (+4 chrF++ points) coming from a novel redundancy-driven tokenization method. DeGenaro and Lupicki (2024) fine-tune NLLB-200 using a variety of parallel data sources, but unlike us, they generate a large amount of synthetic data. Our best-performing model, Llama3 with CPT on parallel data and 5 epochs of SFT, yields a score of 20.93 in the best setting. While this is a gain of +17.06 chrF++ from a 5-shot prompted Llama3, it is also almost 6 chrF++ points behind the SOTA. Since ours was not a shared task effort, we did not attempt explorations with tokenization or synthetic data, which are concurrent to our findings and would likely boost performance further. Overall, our results suggest that low-resourced LLM-MT systems, while promising, are still behind the curve compared to SOTA NMT models.

5 Conclusion

In this paper, we approach low-resource LLM-MT from a data-centric perspective and study performance along two axes: i) the size of parallel data and ii) diversity in SFT tasks. Through experiments and analyses, we conclude that quantity plays a dominant role in downstream performance. Specifically, parallel data drives performance significantly during both CPT and SFT, with HRLs and LRLs displaying different behaviours—making bitext a critical resource even in the modern era of LLM-MT. Moreover, we establish that diversity (on multiple fronts) consistently declines MT quality, with multilingual fine-tuning on task-specific data being the most effective option, reaffirming our previous findings on the value of scale. We hope these findings will be useful considerations when scaling to massively multilingual LLMs of the future.

Limitations

One of the limitations of this work is that due to the unavailability of robust neural metrics for LRLs, we are forced to use string-based metrics like chrF++ as our primary evaluation metric. We note that while this is not optimal, it is also not unlike most other related works on low-resource translation, and chrF++ has been shown to align reasonably well with human assessment scores for morphologically rich languages. Secondly, we only focus on two specific language groups in this work. We expect that expanding the scope to a massively multilingual setting might yield even larger improvements, owing to scale and transfer learning.

A Data

A.1 Monolingual Data

We provide the detailed monolingual data statistics for the indigenous American languages used for CPT in Table 10. We collect this data from various sources. For the indigenous American languages, we use MADLAD-400 (Kudugunta et al., 2024), GLOT 500 (ImaniGooghari et al., 2023), Wikipedia, data curated by the University of Helsinki (De Gibert et al., 2023) and OCR data collected by Iyer et al. (2024). The English and Spanish data used for replay comes from Wikipedia and MADLAD-400 too. We use MADLAD-400 and GLOT 500 again for the Indic languages again, along with the verified split of Sangraha (Khan et al., 2024)—a large corpus for Indian languages.

A.2 Parallel Data

We provide the templates used for generating Machine Translation and XQA Instructions in Tables 11 and 12 respectively. For MT, we randomly use one of these prompts to create an instruction for doing SFT of our model. For XQA, the provided instructions are used to prompt Mixtral-8x-7B to generate a question, which is later used for creating the synthetic XQA datasets as described in Section 3.2.

We source the parallel data for generating these from the work of Iyer et al. (2024), which includes data sourced from AmericasNLP'23 official training datasets (Ebrahimi et al., 2024), NLLB-200 and FLORES-200 (Costa-jussà et al., 2022), OPUS (Tiedemann, 2009) and data curated by Helsinki in their 2023 submission (De Gibert et al., 2023).

A.2.1 Cleaning Parallel Data

Rule-based Filtering We clean parallel data by following standard filtering rules. First, we remove pairs with more digits or non-alphanumeric characters than alphabetic ones on either side. Then, we remove pairs where either the source or the target has less than 3 words or more than 120 words. To adjust for pairs containing partial or incomplete translations, we apply a combination of two filtering rules: a) for sentences with less than 25 words, the character length difference must be less than 65, and b) for those longer than 25 words, the character length ratio between either source and target, or vice versa, must be at most 1.55. Lastly, we filter our sentences with non-Latin characters in either sentence, as well as pairs with identical source and target sentences to create our final training dataset.

Neural Quality Estimation We also experimented with using neural quality estimation using models like LASER-3 (Heffernan et al., 2022). LASER-3 supports 3 of the 11 American languages—the HRLs (Aymara, Guarani and Quechua)—and we used it for scoring parallel sentences for these languages. We then sorted them in order of decreasing quality, calculated as the cosine similarity of LASER representations. For the other 8 LRLs, we used random scoring to simulate standard shuffling behaviour. We found that training on this 'sorted' data actually performed *worse* than our default baseline trained on unscored corpora, consistently at various SFT scales. As none of the authors spoke these languages, we could not substantively explain why, but we hypothesize that LASER representations might not be very reliable for these very LRLs, and might introduce certain undesirable biases in the sorted data, making the default baseline more robust to different kinds of bitext. In practice, we found that the standard rule-based filtering approaches worked best and thus, we stuck to them for cleaning our data.

Finally, we note that both our monolingual and parallel corpora span a variety of domains similar to our test data. Also, due to the paucity of data, we use all available sources.

B Results

B.1 Parallel vs Monolingual Data Ratio

In Table 14, we find that mixing higher ratios of parallel data with monolingual data either performs comparably or improves performance. We do not go higher than 50% since our parallel data runs out at this stage, and to ensure higher ratios we would have to oversample the existing dataset—which would not lead to a fair comparison with the other baselines. Nevertheless, given the monotonic trend, it would be interesting to explore if mixing higher ratios of parallel data continues to improve the performance even more. However, it is likely that there is some ceiling as to how much parallel data one should mix. For instance, Alves et al. (2024) show how a baseline trained on 100% parallel data underperforms compared to mixing it with monolingual data.

B.2 Scaling up SFT: Mistral 7B

Figure 7 shows the scaling behaviour of the Mistral 7B model with different pre-training recipes (no

Language	#Sentences	#Tokens	Language	#Sentences	#Tokens	Language	#Sentences	#Tokens

XQA Instruction

"Consider this sentence: {input}\nWhat kind of specific instruction X could this be the unique answer to? Output ONLY the instruction, followed by a newline."

Table 12: Template used for generating XQA instructions

Method	Avg	es-aym	es-bzd	es-cni	es-ctp	es-gn	es-hch	es-nhe	es-oto	es-quy	es-shp	es-tar
Bilingual LLM-MT	14.5	**21.2**	6.1	12.3	8.4	**27.9**	15.0	**14.1**	9.5	24.6	14.5	6.1
Multilingual LLM-MT	**18.7**	20.2	**15.8**	**18.0**	**26.0**	25.8	**21.6**	18.2	**11.2**	**24.9**	**14.8**	**9.5**

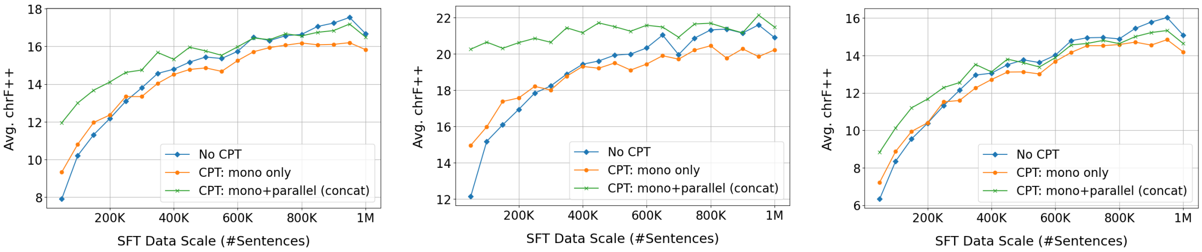
Table 13: Comparison of Bilingual and Multilingual Es-X FT (MT only) Methods

CPT, CPT with monolingual data, and CPT with a mixture of monolingual and parallel data), where terminology is the same as that defined in Section 3.1. We observe that the trends for Mistral are largely similar to Llama3:

1. 'No CPT' underperforms the CPT baseline, but they become comparable at about ~500K sentences. As hypothesised in Section 4.4, due to a 4x larger vocabulary, Llama3 has 4x more parameters to fine-tune[4], meaning our Llama3 models are likely more data hungry and retain the benefits of CPT over longer periods, but smaller models overfit sooner, leading to a shorter 'cross-over' threshold.

2. 'CPT (mono only)' consistently underperforms 'CPT (mono + parallel)', very similar to Llama3, lending further credence to our conclusion that concatenated parallel data adapts

[4] LoRA module parameters are negligible in comparison. For fine-tuning input and output embeddings, Llama3 has 128K * 4096 * 2 ≈ 1B parameters, whereas Mistral has 32K * 4096 * 2 ≈ 250M parameters. LoRA parameters are on the order of 3M, for comparison.



(a) Average (overall)

(b) Average (high-resource†)

(c) Average (low-resource$^{\eta}$)

Figure 7: Scaling up Mistral 7B models with different CPT recipes (no CPT, CPT with monolingual data, and CPT with a mixture of monolingual and parallel data) on MT data for the American languages. We observe that the trends are very similar to Llama3, with the sole exception that the gains of CPT diminish faster at around 500K sentences. This might be because Mistral, due to a 4x smaller vocabulary, gets fine-tuned effectively with less data. †'High-resource' refers to the relatively higher-resourced languages in our low-resource setup (Aymara, Guarani and Quechua) while the other 8 are grouped as low-resource$^{\eta}$.

Ratio	Gemma 2B	Mistral 7B	Llama3 8B
0%	9.6 ± 0.3	15.6 ± 0.4	15.6 ± 0.4
10%	10.1 ± 0.3	15.9 ± 0.4	16.5 ± 0.4
25%	10.1 ± 0.3	16.6 ± 0.4	16.6 ± 0.4
50%	10.1 ± 0.3	16.7 ± 0.4	17.2 ± 0.4

Table 14: Model Performance vs. Parallel Data Ratio. While the gap between ratios is not always statistically significant, it is clear that the trend is monotonic and having 50% parallel data is consistently better than 0% (ie. the fully monolingual setting).

the model to MT in a much better way

3. For HRLs, the performance plateaus quite quickly, while for LRLs SFT quality continues to grow with scale, once again following Llama3's trend

Our experiments with Mistral thus help in providing more evidence to support our claims with regard to the benefit of parallel data for low-resource LLM-MT systems.

B.3 Bilingual vs Multilingual LLM-MT: Detailed Results

We provide detailed, language-specific results for bilingual vs multilingual LLM-MT in Table 13. We observe that multilingual LLM-MT mostly outperforms bilingual baselines with the exception of 3 relatively higher-resourced languages (Aymara, Nahuatl and Guarani) where there is a bit of a gap.

Efficient Technical Term Translation: A Knowledge Distillation Approach for Parenthetical Terminology Translation

Abstract

This paper addresses the challenge of accurately translating technical terms, which are crucial for clear communication in specialized fields. We introduce the Parenthetical Terminology Translation (PTT) task, designed to mitigate potential inaccuracies by displaying the original term in parentheses alongside its translation. To implement this approach, we generated a representative PTT dataset using a collaborative approach with large language models and applied knowledge distillation to fine-tune traditional Neural Machine Translation (NMT) models and small-sized Large Language Models (sLMs). Additionally, we developed a novel evaluation metric to assess both overall translation accuracy and the correct parenthetical presentation of terms. Our findings indicate that sLMs did not consistently outperform NMT models, with fine-tuning proving more effective than few-shot prompting, particularly in models with continued pre-training in the target language. These insights contribute to the advancement of more reliable terminology translation methodologies.

1 Introduction

Terminology translation task is essential for understanding documents rich in technical terms, such as academic papers and technical reports. Traditionally, methods in the task have involved identifying term pairs in the source and target languages and using these pairs for training or post-editing purposes. However, challenges arise when there is no precise match for a term in the target language, or when new terms are used inconsistently. For instance, the term "fine-tuning" may be variably translated as "파인튜닝" or "미세조정" in Korean.

To address this, our research proposes a novel approach called Parenthetical Terminology Translation (PTT), which displays the original term in parentheses alongside its translation. This approach aims to mitigate reader confusion, especially when suitable translations are unavailable or translation accuracy is low. Although similar translation strategies using parenthetical form have been suggested in previous studies, effective technical solutions for this approach remain underexplored.

With the advent of advanced Large Language Models (LLMs), researchers have started exploring their potential for various tasks, including translation. LLMs can effectively support PTT through simple prompt usage, offering a promising solution for this approach. However, the practical application of LLMs is hindered by their high computational costs and latency, making them less feasible for real-time or large-scale deployment.

To mitigate these limitations, this study focuses on achieving the capabilities of LLMs using smaller, traditional Neural Machine Translation (NMT) models and small-sized Language Models (sLMs). We generated a high-quality PTT dataset using LLMs and distilled the knowledge by fine-tuning these smaller models with this dataset. This approach ensures that the benefits of LLMs can be harnessed without incurring high computational costs. Additionally, we evaluated the performance of various models and training methods to optimize model performance and efficiency, particularly for the specialized PTT task.

Our proposed task extends beyond mere translation accuracy; it also emphasizes the correct presentation of technical terms within parentheses, which is crucial for enhancing reader comprehension. To quantitatively evaluate this aspect, we introduced a novel metric specifically designed to assess the models' ability to accurately and effectively use parenthetical annotations. This metric not only evaluates translation quality but also ensures that technical terms are correctly presented, allowing for a robust comparison of model performance across different architectures and training techniques.

Thus, this paper makes three significant contributions to the field of terminology translation:

Proceedings of the Ninth Conference on Machine Translation, pages 1410–1427
November 15-16, 2024 ©2024 Association for Computational Linguistics

1. **Synthetic Data Generation**: We propose a collaborative framework using Large Language Models (LLMs) to generate well-curated datasets specifically for the English-Korean Parenthetical Terminology Translation (PTT) task. This framework employs multiple agents to create high-quality sentence pairs, enabling smaller models to perform the PTT task with high accuracy. By leveraging robust data from LLMs, the framework ensures consistency and precision, making it effective for handling domain-specific terminology.

2. **Knowledge Distillation and Model Comparison**: Utilizing these high-quality datasets, we fine-tuned various Neural Machine Translation (NMT) models and small-sized Language Models (sLMs). We then conduct a comprehensive performance analysis from diverse perspectives, highlighting the strengths and limitations of each model. This analysis provides valuable insights for future research and development in the field.

3. **New Evaluation Metric**: We introduce a novel evaluation metric that quantitatively assesses the ability of models to present appropriate terms within parentheses. This metric ensures contextual accuracy and reader comprehension, offering a robust framework for evaluating model performance in the context of PTT.

These contributions aim to advance the domain of terminology translation by providing practical and efficient solutions that leverage the strengths of both large and small language models. Our approach addresses the inherent challenges of the terminology translation task and paves the way for more accessible translation methodologies in technical and specialized fields.

2 Related Work

Terminology translation plays a crucial role in ensuring consistency and accuracy in specialized domains like technical and academic documentation. Early approaches, such as rule-based and statistical machine translation, effectively leveraged predefined glossaries and translation memories (Melby et al., 1999). While these methods successfully maintain consistency within certain contexts, they often struggle with out-of-domain (OOD) words and ambiguous terms (Och and Ney, 2003). Moreover, these approaches are less effective when dealing with domain-specific or emerging terms not covered by existing resources (Tiedemann, 2010; Tiedemann and Scherrer, 2017).

To maintain clarity and precision in academic and technical documentation, it is often necessary to preserve certain terms from the source language. This practice is particularly valuable in cases where the translated term may be unfamiliar to the reader or where retaining the original term is essential for legal or scientific accuracy (Moghadam and Far, 2015; Hasler et al., 2018; Michon et al., 2020). A further strategy to support this practice involves the strategic use of parentheses, where textual additions can help enhance translation quality and consistency through corpus-based improvements (Lin et al., 2008; Huang et al., 2017; Hawamdeh, 2018). Despite its potential benefits, the systematic implementation of this approach remains relatively underexplored in current research.

Recent studies have highlighted the effectiveness of knowledge distillation in transferring knowledge from large language models (LLMs) to smaller traditional translation models (Li et al., 2024; Enis and Hopkins, 2024). Through this process, datasets generated by a powerful teacher model are distilled into a student model, enabling small-sized models to perform specialized tasks like terminology translation. The multi-agent framework is particularly effective in generating targeted, high-quality datasets for specific tasks (Wu et al., 2023). Within this framework, different agents are assigned specialized roles, such as data generation and evaluation, collectively enhancing the quality and relevance of the resulting dataset. This collaborative process is essential for precise and context-aware data generation, which is crucial for training models to excel in specialized translation tasks.

3 Data Generation

To create a high-quality dataset for the Parenthetical Terminology Translation (PTT) task, we employed four collaborative agents—Writer, Translator, Evaluator, and Executor—utilizing the large language models (LLMs) GPT-4o-mini or GPT-4-turbo for each agent. Our goal was to generate English sentences containing technical terminologies alongside their Korean translations, with the original English terms included within parentheses. The overall framework is illustrated in Figure 1.

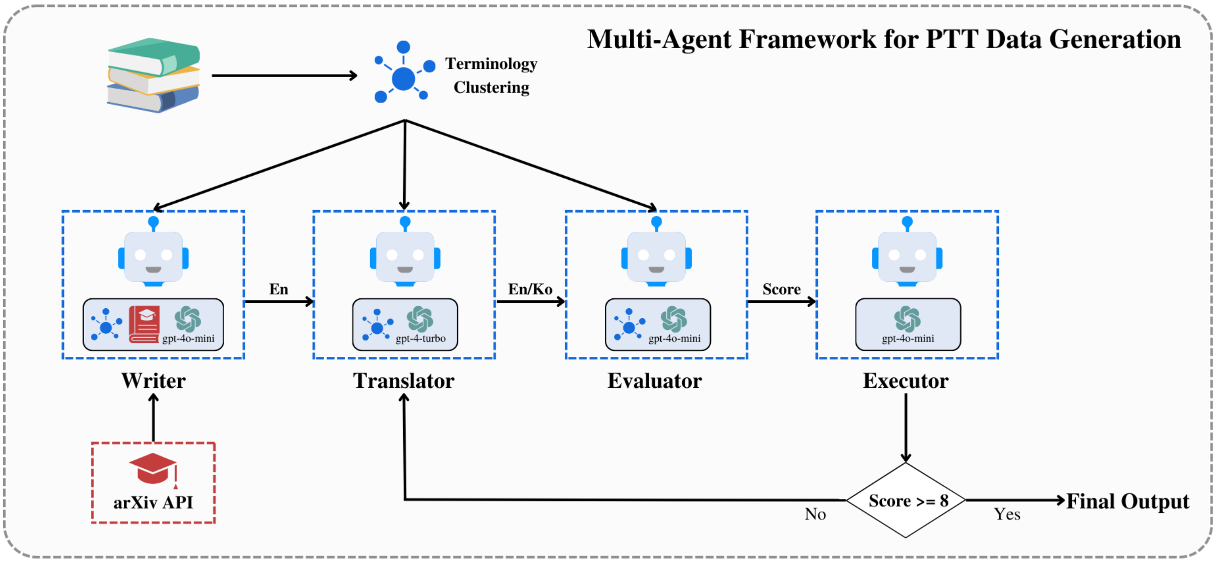

Figure 1: Multi-Agent Framework for generating a high-quality PTT dataset using four agents.

3.1 Writer

The Writer agent was responsible for creating academic English sentences that included the technical terms. To achieve this, we first compiled a comprehensive list of terms to be included in the dataset. Recognizing the rapid emergence of new terminology in the field of artificial intelligence (AI), we focused on terms frequently encountered in AI-related research. To ensure multiple terms could be incorporated into single sentences, we clustered similar domain-specific terms together.

Next, we utilized the arXiv API to find papers that contained all or some of the terms from each cluster. By including the summary of the most relevant paper in the prompt, we helped the Writer LLM understand the appropriate contexts in which these terms were used. This ensured that the generated sentences were contextually accurate and meaningful.

To enhance data diversity, the Writer were tasked with generating sentences where each term appeared either once or in conjunction with other terms. By combining these sentences post-generation, we facilitated the creation of sentences with various characteristics: sentences where terms appear only once, sentences containing different terms together, and sentences where the same term appears more than twice. This diversity allowed us to analyze the performance of PTT from multiple perspectives, ensuring a comprehensive evaluation of the models under different conditions. The complete prompt used for the Writer agent is provided in the Appendix (see Listing 1).

3.2 Translator

The Translator agent translated the English sentences into Korean, ensuring that each target term was followed by its original English term in parentheses to fulfill the PTT task requirements. To enhance accuracy, we employed the GPT-4 Turbo model, while other agents utilized GPT-4o-mini. Additionally, we applied one-shot prompting by providing a relevant example to guide the translation process. This approach helped maintain consistency and precision in the PTT task, ensuring that technical terms were accurately presented within parentheses. The complete prompt used for the Translator agent is provided in the Appendix (see Listing 2).

3.3 Evaluator/Executor

The Evaluator agent reviewed the translated sentences, scoring them from 0 to 10 based on the accuracy of term usage and overall translation quality. Then, The Executor agent transit the statement ‘If the score is less than 8: Response "translator". If the score is 8 or greater: Response "final output".‘ If a sentence scored below 8, the Evaluator suggested corrections, prompting the Translator to revise the translation. The Translator would then repeat the translation task until the Executor rated the sentence as ‘"final output"‘, ensuring the highest quality and consistency in the dataset. The complete prompt used for the Evaluator agent is provided in the Appendix (see Listing 3).

After the automatic data generation process, human reviewers conducted a final quality check to

Terms Set Index	0
Domain	AI (in-domain)

Source	By implementing adversarial training, researchers have demonstrated significant improvements in the performance of recurrent neural architectures against adversarial attacks. The integration of recurrent neural architectures with Bayesian optimization enhances the model's ability to learn from limited data while minimizing computational resources.
Target	적대적 훈련(adversarial training) 도입으로 연구자들은 적대적 공격에 대응하는 순환 신경 구조(recurrent neural architectures)의 성능 향상을 크게 입증하였습니다. 순환 신경 구조(recurrent neural architectures)와 베이지안 최적화(bayesian optimization)를 결합함으로써 모델이 제한된 데이터로부터 학습하는 능력을 향상시키고, 계산적 자원 사용을 최소화합니다.

Table 1: Sample of generated data from the AI domain (in-domain). Each entry includes the term set index, domain, source text, and the corresponding target translation. Red text highlights the targeted terms T_{Eng}, while blue text indicates the correct representation of terms T_{Kor} in the Korean translation.

ensure the dataset's reliability. Following this review, we combined seven sentences from each cluster into three composite sentences as mentioned earlier, resulting in 1,398 English-Korean paired sentences encompassing 233 term clusters (a total of 699 distinct terms). We split these 1,398 sentences into 1,116 for training, 144 for validation, and 138 for testing the performance. We carefully ensured that sentences containing the same terms were allocated to the same dataset, maintaining consistency and preventing data leakage across the splits. The sample data is provided in Table 1. The entire dataset is available on Hugging Face at https://huggingface.co/datasets/PrompTart/PTT_en_ko.

3.4 Out-of-Domain Evaluation Dataset

To evaluate the generalization ability of models in the PTT task, we generated additional datasets in domains beyond artificial intelligence (AI), specifically targeting biology and physics. The data generation process followed the same methodology as the in-domain training dataset to ensure consistency. In total, we generated 171 paired sentences for biology (subcellular processes), 60 for nanoscale physics, and 168 for high-energy physics. Each domain-specific dataset was curated by referencing relevant academic papers, providing authentic and contextually accurate examples. These out-of-domain datasets allowed for a comprehensive assessment of the models' robustness and adaptability across different specialized fields.

4 Knowledge Distillation

In this study, we applied knowledge distillation to fine-tune both traditional neural machine translation (NMT) models and small-sized large language models (sLMs) using the synthetic Parenthetical Terminology Translation (PTT) dataset generated in the previous step. Our goal was to evaluate the effectiveness of distillation techniques across various model architectures, sizes, and training methodologies, offering insights into how distilled models perform in specialized translation tasks.

4.1 Fine-tuning Traditional Machine Translation Models

To evaluate the performance of knowledge distillation on traditional neural machine translation models, we employed several widely used open-source models. We focused on encoder-decoder Transformer-based models that support Korean. Specifically, we tested the following models:

- mBART50 (Liu et al., 2020) : This multilingual NMT model is pre-trained on monolingual corpora from 50 languages and is fine-tuned for translation tasks. It consists of 611 million parameters.
- M2M100 (Fan et al., 2020): A large-scale multilingual NMT model trained on 2200 translation directions, enabling many-to-many translation across 100 languages. We tested the base version with 418 million parameters.
- NLLB-200 (Koishekenov et al., 2023): Known for its extensive language coverage,

this model is particularly useful for low-resource languages and inclusive translation services. We tested the distilled version with 600 million parameters.

The fine-tuning parameters were provided in the Appendix (see Table 5).

4.2 Fine-tuning small-sized Large Language Models

To effectively compare performance with NMT models, we also fine-tuned open-source small-sized large language models. Our goal was to evaluate various models from multiple perspectives to gain comprehensive insights into the PTT task. To ensure reproducibility and a broad evaluation, we selected four well-known and high-performing open-source LLMs:

- Llama 3 (Touvron et al., 2023): The latest iteration of the Llama series, this model further refines the architecture introduced in earlier versions, enhancing its performance on large-scale datasets. We evaluated the 8B and 70B versions in our experiments.

- Gemma 2 (Team et al., 2024): A next-generation multilingual model, Gemma 2 is designed to deliver high performance across diverse natural language tasks with an emphasis on efficiency. We assess the model by testing three versions: the smallest (2B), a mid-sized variant (9B), and a larger configuration (27B).

- Qwen 2 (Yang et al., 2024): An updated version of the Qwen series, Qwen 2 is developed with a strong focus on flexibility and adaptability to domain-specific tasks. It offers improved performance and efficiency, particularly in handling complex language modeling challenges. In this study, we analyzed the 1.5B, 7B, and 72B versions.

- Mistral (Jiang et al., 2023): Mistral is known for its streamlined design and high efficiency in multilingual tasks. We specifically evaluate the 7B version to examine how its architecture balances performance with computational efficiency.

To compare pre-trained models with those that have been further fine-tuned specifically for the Korean language, we also tested models that underwent continual pre-training (Ke et al., 2023) in Korean. This approach allowed us to assess the impact of additional language-specific pre-training on the models' performance in the Parenthetical Terminology Translation (PTT) task.

- beomi/Llama-3-Open-Ko-8B[1]: A specialized version of Llama 3 focused on Korean language tasks. This open-source model is fine-tuned to excel in Korean linguistic applications.

- beomi/Llama-3-KoEn-8B[2]: A bilingual version of Llama 3 tailored for both Korean and English language tasks. This model is designed to maintain balanced performance across both languages, making it versatile for multilingual applications.

Furthermore, we explored instruction-tuned versions of the aforementioned models using different training techniques, such as LoRA (Hu et al., 2021) and QLoRA (Dettmers et al., 2023). In addition, we applied few-shot prompting (Brown et al., 2020) to both the instruction-tuned models and a commercial LLM (GPT-4o) to compare the effects of fine-tuning versus prompting. This comprehensive evaluation provides valuable insights into how knowledge distillation, combined with various tuning and prompting strategies, can enhance translation accuracy while maintaining efficiency across diverse model architectures.

The hyper-parameters for fine-tuning and LoRA are detailed in the Appendix (see Table 5), while the full prompt used for few-shot prompting is identical to the Translator agent's prompt (Listing 2), with the exception that we did not provide a list of terms in this case.

5 Custom Evaluation Metric

This section introduces a novel metric designed specifically for the Parenthetical Terminology Translation (PTT) task, aimed at evaluating not only the accuracy of overall translation but also the correct presentation of the technical terms within parentheses.

For each sentence in the dataset, let T_{Eng} represent the list of all technical terms provided in the original English sentence, including duplicates

[1] https://huggingface.co/beomi/Llama-3-Open-Ko-8B

[2] https://huggingface.co/beomi/Llama-3-KoEn-8B

if the same term appears multiple times. Similarly, let T_{Kor} represent the list of those terms that are correctly translated into Korean and accompanied by their original English terms in parentheses. We define $|T_{\text{Eng}}|$ as the total number of technical terms in the English sentence (including duplicates), and $|T_{\text{Kor}}|$ as the number of correctly translated terms from T_{Eng} in the Korean sentence. The ratio of these terms is calculated as the weight $W_{\text{terms}} = \min\left(\frac{|T_{\text{Kor}}|}{|T_{\text{Eng}}|}, 1\right)$. This ratio is capped at 1 to ensure that no penalty is applied if more terms appear correctly in the Korean translation than in the original English sentence. The adjusted metric for the PTT task, M_{PTT}, is then computed by multiplying this clipped ratio with the original translation metric M, such that $M_{\text{PTT}} = W_{\text{terms}} \times M$. Finally, we average M_{PTT} across all sentence pairs in the dataset to obtain the final evaluation metric.

We employed BLEU (Papineni et al., 2002), COMET (Rei et al., 2020), and BERTScore (Zhang et al., 2020) as M to evaluate pure translation performance. The translation metrics are computed after removing the parenthetical terms, ensuring that we assess only the translation's accuracy and fluency. This approach allows us to maintain a focus on both the translation's quality and the correct handling of technical terms within parentheses.

6 Evaluation

6.1 Quantitative Analysis

The results presented in Table 2 provide a comprehensive overview of the quantitative performance of various models and training techniques on the in-domain Parenthetical Terminology Translation (PTT) dataset, while Table 3 presents results on the out-of-domain dataset. Key observations are summarized as follows:

1. **sLMs vs. NMT Models**: The performance comparison between small-sized Large Language Models (sLMs) and Neural Machine Translation (NMT) models reveals that sLMs do not consistently outperform NMT models, even though LLMs are often perceived as more advanced due to their architecture. For instance, mBART50 and M2M100, achieved weighted BLEU scores of 37.52 and 40.05, respectively, with corresponding weight indicate strong PTT performance. These scores were comparable or superior to those achieved by some sLMs, such as the Llama 3 8B and 70B models, which obtained similar weighted BLEU scores but required significantly larger model sizes.

2. **Instruction-Tuned vs. Base Models**: Within the same sLM families, base models generally slightly outperformed instruction-tuned models on the PTT task. For instance, the Llama 3 8B model with QLoRA achieved a weighted BLEU score of 38.88, while the instruction-tuned version (8B-it) with the same QLoRA technique scored slightly lower at 37.84. This trend suggests that instruction-tuned models, which are trained on a broad range of tasks, may not gain a specific advantage for the specialized requirements of the PTT task.

3. **Fine-Tuning vs. Prompt Engineering**: Applying prompt engineering instead of fine-tuning to instruction-tuned models, using a 1-shot prompting approach, resulted in very poor performance. For example, the Llama 3 8B-it scored only 0.523, and the Gemma 2-9B-it scored 0.342 on weight metric. Even the commercial LLM GPT-4o performed worse than other fine-tuned small models, underscoring the critical importance of fine-tuning for specialized tasks like PTT.

4. **Korean Continued Pre-trained Models**: Models that underwent continued pre-training in the target language (Korean) generally outperformed others, with the Llama-3-KoEn-8B-it achieving the highest score among all models. Although Llama-3-Open-Ko-8B, which was continued pre-trained exclusively in Korean, showed slightly lower performance with a weighted BLEU score of 39.869, it still performed well. This highlights the importance of bilingual proficiency in models for the PTT task, where handling both source and target languages effectively is crucial for success.

5. **Model Size and Out-of-Domain Performance**: In the in-domain dataset, model size had little impact on performance, with smaller models like Gemma 2 7B even outperforming larger ones like Gemma 2 27B. However, when tested on out-of-domain datasets, all models experienced significant performance drops, but larger models such as Gemma 2 27B or Llama 3 70B showed less decline, indicating better generalization capabilities.

Model	#Params	Training Techniques	W_{terms}	M_{PTT} (BLEU)	M_{PTT} (COMET)	M_{PTT} (BERT)
Open-source NMT systems						
mBART50	611M	Full Fine-Tuning	0.931	37.519	0.831	0.863
M2M100	418M	Full Fine-Tuning	0.958	40.048	0.855	0.889
NLLB-200	600M	Full Fine-Tuning	0.685	24.544	0.606	0.630

Table 2: Model performance metrics for in-domain test data. W_{terms} represents the average ratio of correctly translated terms with original English terms in parentheses. M_{PTT} (BLEU), M_{PTT} (COMET), and M_{PTT} (BERT) are the original tranlsation metrics adjusted using W_{terms} and averaged over all data. The suffix '-it' indicates instruct-tuned models. The top scores for each metric are highlighted in bold.

This suggests that while smaller models can be highly effective in specialized tasks, larger models are more versatile and better suited for handling diverse and unfamiliar datasets. The larger models' ability to retain higher performance levels in out-of-domain tasks underscores their capacity to adapt to a wider range of terminologies and contexts, making them more versatile in applications where data variability is a key challenge.

6.2 Qualitative Analysis

1. **Progression of PTT and Translation Skills**: As illustrated in Table 4 , most of the models, including M2M100, initially demonstrated strong proficiency in the PTT task, particularly in incorporating original terms within parentheses, as indicated by the high weight metrics in the earlier epochs. Over successive training epochs, the model's overall translation skills improved gradually, leading to better performance across all weighted metrics. A detailed illustration of these improvements is provided in the Appendix (see Table 6).

2. **Challenges with Less Common Terms**: Our analysis highlights a persistent challenge among models in accurately translating less common terms, especially proper nouns. As demonstrated in Table 7, terms like "de Finetti's theorem" were inconsistently translated across different models, reflecting the difficulty these models face when dealing with less familiar terminology. This inconsistency

Model	#Params	Training Techniques	W_{terms}	M_{PTT} (BLEU)	M_{PTT} (COMET)	M_{PTT} (BERT)

Table 3: Model performance metrics for out-of-domain test data. W_{terms} represents the average ratio of correctly translated terms with original English terms in parentheses. M_{PTT} (BLEU), M_{PTT} (COMET), and M_{PTT} (BERT) are the original tranlsation metrics adjusted using W_{terms} and averaged over all data. The suffix '-it' indicates instruct-tuned models. The top scores for each metric are highlighted in bold.

underscores the importance of the PTT task, which helps maintain translation accuracy by preserving original terms alongside their translations, thereby reducing the likelihood of incorrect interpretations.

3. **Out-of-Domain Translation Challenges**: Most models struggled with translating out-of-domain (OOD) sentences, as detailed in Table 8. They often failed to accurately translate OOD terms, frequently substituting them with unrelated or incorrectly adapted words, sometimes even drawing from other languages. These frequent mistranslations highlight the need for more robust training methods or supplementary mechanisms to improve the models' generalization ability for handling unseen datasets effectively.

7 Conclusion

In this study, we explored the Parenthetical Terminology Translation (PTT) task, a specialized translation problem that focuses on mitigating potential inaccuracies in term translation by displaying the original technical term in parentheses alongside its translation. To effectively evaluate this approach, we introduced a novel evaluation metric, M_{PTT}, designed to measure both the accuracy of overall translation and the proper parenthetical presentation, ensuring that technical terms are effectively communicated across languages.

To generate a high-quality dataset for this task, we utilized a collaborative approach involving Writer, Translator, Evaluator, and Executor agents, supported by large language models (GPT-4). This allowed us to create a diverse and contextually accurate dataset that reflects real-world usage of technical terms in artificial intelligence (AI), biology, and physics. We then applied knowledge distillation techniques to fine-tune both traditional Neural Machine Translation (NMT) models and small-sized Large Language Models (sLMs), comparing their performance across various model architectures, sizes, and training methods.

Epoch	Weight	Weighted BLEU	Weighted COMET	Weighted BERT Score
epoch 1	0.939	31.780	0.824	0.858
epoch 3	0.924	35.668	0.821	0.853
epoch 5	0.948	37.853	0.844	0.878
epoch 7	0.956	38.685	0.851	0.886
epoch 9	0.958	40.048	0.855	0.889

Table 4: Model performance metrics of the M2M100 model for test data across training epochs.

Our findings revealed that sLMs did not consistently outperform NMT models, challenging the assumption that more advanced architectures inherently lead to superior performance. Additionally, within the same sLM families, base models slightly outperformed instruction-tuned models, suggesting that broad task training may not offer advantages for specialized tasks like PTT. Fine-tuning proved crucial, as prompt engineering approaches like 1-shot prompting resulted in significantly poorer performance. Moreover, models with continued pretraining in Korean outperformed others, highlighting the importance of bilingual proficiency for the PTT task. While model size had little impact on in-domain performance, larger models demonstrated better generalization on out-of-domain datasets, suggesting they are more versatile and better suited for handling diverse and unfamiliar data. These insights contribute to optimizing models and training techniques for specialized translation tasks, offering practical guidance for future research and applications in terminology translation.

Limitations

Penalty Mechanism in Evaluation Metrics: The current approach to evaluating PTT performance involves simply multiplying translation metrics by a weight that reflects the presence of correctly parenthesized terms. However, this straightforward multiplication can disproportionately affect the overall performance scores. A more sophisticated penalty mechanism, such as using an exponential function, could provide a more balanced assessment by reducing the impact on the metric scores. Additionally, the current metric does not penalize the model for excessively parenthesizing trivial or unintended terms, which could lead to over-parenthesization. Future work could incorporate penalties for such cases, potentially by introducing concepts of recall and precision to refine the evaluation.

Potential Bias in the Dataset: The PTT dataset was generated using GPT-4, and the performance metrics were assessed with this dataset as the ground truth. This approach may introduce biases inherent to the GPT-4 model into the dataset, potentially affecting the robustness and generalizability of the models trained on it. To mitigate this, future research should consider generating datasets using a variety of models, ensuring a broader representation of translation styles and reducing the potential for model-specific biases.

Language Scope of the Study: This study focused exclusively on translation into Korean, which limits the generalizability of the findings across different languages. PTT performance might vary significantly with other languages due to differences in linguistic structures and translation challenges. Expanding the study to include translations into multiple languages would enable a more comprehensive analysis of the PTT task and provide insights into how the models perform across different linguistic contexts.

You are a professional paper writer.

[TERM1] = {terms[0]}
[TERM2] = {terms[1]}
[TERM3] = {terms[2]}

<reference>
{arxiv_summaries}
</reference>

<instruction>
- The request is to thoroughly review and cite the provided <reference> when writing
     theacademic paper.
- Write complex English sentences using the given technical terms.
- Use appropriate academic tone.
- Each sentence MUST be clear, accurate, and contextually appropriate for a
    scientific paper.
- Generate only in English.
</instruction>

## Output Format:
1.english: A sentence using terms [TERM1].
2.english: A sentence using terms [TERM2].
3.english: A sentence using terms [TERM3].
4.english: A sentence using terms [TERM1] and [TERM2].
5.english: A sentence using terms [TERM2] and [TERM3].
6.english: A sentence using terms [TERM1] and [TERM3].
7.english: A sentence using terms [TERM1], [TERM2], and [TERM3].

CAUTION: Ensure that exactly 7 sentences are generated.
```

Listing 1: Full Prompt of Writer

```
You are a professor specializing in AI, proficient in both Korean and English.

[TERM1] = {terms[0]}
[TERM2] = {terms[1]}
[TERM3] = {terms[2]}

<translation guideline>
- Translate while preserving the original term like 사전 훈련(pre-train).
- If there is an abbreviation, translate it like this Korean term(english term,
    abbreviation).
- Identify terms, acronyms, and concepts to keep in English.
- Maintain academic tone and technical accuracy in your translations.
- Ensure the translation is natural in Korean while accurately conveying the
    original meaning.
- Change all the letters within the parentheses in Korean sentences to lowercase.
- IMPORTANT: The terms corresponding to [TERM1], [TERM2], and [TERM3] MUST ALWAYS be
     enclosed in parentheses like this: Korean term(English term).
</translation guideline>

<example>
english: LLMs demonstrate new abilities such as in-context learning, instruction
    following, and multi-step reasoning, enabling them to learn new tasks, follow
    instructions, and effectively solve complex problems.
korean: LLM은 맥락 학습(in-context learning), 지시 사항 따르기(instruction following), 다단계 추론
(multi-step reasoning)과 같은 새로운 능력을 보여줌으로써 새로운 작업을 학습하고, 지시를 따르며,
복잡한 문제를 효과적으로 해결할 수 있습니다.
</example>

## Output Format:
1.korean: [Korean translation]
2.korean: [Korean translation]
...
( Continue this pattern for all 7 sentences )
```

Listing 2: Full Prompt of Translator

```
You're an expert evaluating English to Korean translations of research papers, with
    a specific focus on proper parenthetical translations of technical terms.

<criteria>
- The format for parenthetical translations should be: Korean term(English term).
- The specific terms {terms[0]}, {terms[1]} or {terms[2]} MUST ALWAYS be enclosed in
     parentheses in the Korean translation.
- Parentheses should be properly placed, ensuring consistency in parenthesizing
    across the entire sentence.
- Ensures the translation conveys the original meaning precisely and reads naturally
     and smoothly.
</criteria>

<instruction>
- Change all the letters within the parentheses in Korean sentences to lowercase.
- Evaluate the Korean translation of the provided English sentences.
- Check the consistency and correctness of parenthesization.
- Provide a score (0-10) based on the correctness and consistency of
    parenthesization as Korean term(English term).
- Offer specific improvement suggestions if the score is less than 10.
- DO NOT include any supplementary explanations.
- Check your output format again.
</instruction>

## Example Output:
english: The neural network uses backpropagation to optimize its weights.
korean: 신경망(neural network)은 역전파(backpropagation)를 사용하여 가중치(weight)를 최적화합니다.
score: 10/10
terms_check: [neural network: Yes, backpropagation: Yes, weight: Yes]
parentheses_count: 3
suggestions: No improvements needed / Suggest ensuring that "model compression" is
translated as "모델 압축(model compression)" and adjusting "모델 컴프레션" to "model compression"
for consistency and clarity.

## Example Format:
1.
english: [English text using term "{terms[0]}"]
korean: [Korean translation using parentheses]
score: [X/10]
terms_check: [{terms[0]}: Yes/No, {terms[1]}: Yes/No, {terms[2]}: Yes/No]
parentheses_count: [Number of parentheses pairs in the Korean translation]
suggestions: [Suggest capturing the original meaning and nuances in the translation
    while adjusting the structure for natural flow and grammar]
2.
english: [English text using terms "{terms[0]}" and "{terms[1]}"]
korean: [Korean translation]
3.
...
(Continue this pattern for all 7 sentences)
```

Listing 3: Full Prompt of Evaluator

Abstract

In Multimodal Machine Translation (MMT), the use of visual data has shown only marginal improvements compared to text-only models. Previously, the CoMMuTE dataset and associated metric were proposed to score models on tasks where the imagery is necessary to disambiguate between two possible translations for each ambiguous source sentence. In this work, we introduce new metrics within the CoMMuTE domain to provide deeper insights into image-aware translation models. Our proposed metrics differ from the previous CoMMuTE scoring method by 1) assessing the impact of multiple images on individual translations and 2) evaluating a model's ability to jointly select each translation for each image context. Our results challenge the conventional views of poor visual comprehension capabilities of MMT models and show that models can indeed meaningfully interpret visual information, though they may not leverage it sufficiently in the final decision.

1 Introduction

The use of multimodal data, combining visual and textual inputs, is becoming increasingly important in deep learning, especially in language modeling. Multimodal Machine Translation (MMT) presents a unique challenge in this area, as previous Machine Translation (MT) systems traditionally relied only on text. Despite the potential benefits of incorporating imagery, its efficacy in MMT remains controversial. Critics often view imagery as merely a regularizer rather than a core component of translation systems (Caglayan et al., 2016; Wu et al., 2021). This skepticism is fueled by results with the assumption that textual context alone suffices for most translation tasks (Caglayan et al., 2019).

To explore these concerns, the CoMMuTE dataset was developed to test MMT models on source sentences where visual context is essential for accurate selection between possible translations (Futeral et al., 2023). Their proposed evaluation metric scores a model's *preference/choice between two reference translations*, diverging from traditional metrics such as BLEU (Papineni et al., 2002) and Meteor (Banerjee and Lavie, 2005) that instead compare a generated translation against a single reference. Initial analyses using the CoMMuTE dataset and metric indicate that current models show only slight, or no, improvement over using text-only models (Futeral et al., 2023).

Building on this recent foundation, we introduce a new complementary evaluative CoMMuTE metric that assesses a model's understanding of varying imagery on *a fixed reference translation* (as described above in (Futeral et al., 2023)). We additionally provide two group metrics designed to evaluate a model's ability to jointly choose each translation given their associated image contexts.

Results with our proposed metrics demonstrate that in many circumstances, models can indeed effectively understand and properly interpret the visual information, even if the final translation decisions are unaffected. This suggests the significant potential for improvements in model design to further leverage visual information.

2 Related Work

In this section, we present an overview of recent advancements and methodologies in two critical areas of related research. We first explore how imagery can enhance translation capabilities in MMT and subsequently shift our focus to contrastive evaluation methods, which represent a shift from traditional single-reference comparisons to more nuanced assessments using multiple contrasting references.

2.1 Multimodal Machine Translation

MMT typically trains with datasets such as Multi30k (Elliott et al., 2016) to enhance trans-

Proceedings of the Ninth Conference on Machine Translation, pages 1428–1439
November 15-16, 2024 ©2024 Association for Computational Linguistics

lation capabilities, yet results are not largely improved with sufficient textual context (Caglayan et al., 2019). Research such as Elliott (2018) demonstrates that the replacement of associated images with random counterparts often does not significantly impact translation quality, suggesting a predominant reliance on textual data. A later study further indicated that imagery typically serves merely as a form of regularization in training current models (Wu et al., 2021).

When imagery is available at inference time, approaches such as Graph-MMT (Yin et al., 2020), VTLM (Caglayan et al., 2021), Gated Fusion (Wu et al., 2021), and VGAMT (Futeral et al., 2023) are applicable. These methods leverage diverse global visual features from sources such as ResNet-50 (He et al., 2016) and CLIP (Radford et al., 2021), as well as visual semantic features through advanced object detectors like MDETR (Kamath et al., 2021).

In scenarios lacking visual data at inference time, innovative models such as CLIP-Trans (Gupta et al., 2023), UVR-NMT (Zhang et al., 2020), and ImagiT (Long et al., 2021) instead strategically leverage image-text datasets only during their training phase. These models employ sophisticated mechanisms to enhance their semantic understanding during training such as aligning image-text embedding spaces and synthesizing visual features. By pretraining on multimodal data, these models acquire a nuanced understanding of complex semantic relationships that text alone might not fully encapsulate. Some models, such as CLIP-Trans, can be modified to support the use of imagery at inference time by replacing CLIP text embeddings with CLIP image embeddings.

There has also been notable progress in adapting pretrained language models (LMs) such as BERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019) for multimodal use. Techniques such as visually-conditioned masked language modeling (VMLM) are explored in various architectures (Chen et al., 2020; Lu et al., 2019; Su et al., 2020; Li et al., 2020; Zhou et al., 2021; Ni et al., 2021; Futeral et al., 2023). Furthermore, the development of adapters and other lightweight modules can significantly enhance multimodal capabilities of LMs (Houlsby et al., 2019; Eichenberg et al., 2022; Yang et al., 2022; Tsimpoukelli et al., 2021; Sung et al., 2022; Futeral et al., 2023).

2.2 Contrastive Evaluation

Contrastive evaluation methodologies have become crucial for nuanced assessments of translation systems. These methodologies utilize contrastive test sets designed to challenge models to correctly rank pairs of translations, helping distinguish between correct and incorrect alternatives (Futeral et al., 2023). Contrastive datasets have been used to evaluate linguistic phenomena including grammaticality (Sennrich, 2017), pronoun translation (Müller et al., 2018; Bawden et al., 2018; Voita et al., 2019), and multi-sense word disambiguation (Rios Gonzales et al., 2017; Raganato et al., 2019; Futeral et al., 2023). Moreover, the coherence of lexical usage across translations has been thoroughly explored (Bawden et al., 2018; Voita et al., 2019).

3 CoMMuTE Dataset and Metric

The CoMMuTE dataset (Futeral et al., 2023) was recently introduced to score an MMT model's preference between two given translations for an ambiguous source based on the provided imagery. Specifically, CoMMuTE is comprised of 154 ambiguous English sentences, each paired with two contrasting images and their respective translations, where the two translations are available in French, German, and Czech. Each instance in the dataset is structured as a tuple (s, i^a, t^a, i^b, t^b), where s is an ambiguous source sentence and (i^a, i^b) are images that disambiguate the sentence into two possible translations (t^a, t^b), respectively. For example, in Fig. 1, the English source sentence "That's lots of bucks!" could refer to either deer or dollars, and the image is needed to determine the appropriate context.

To specifically score such disambiguation capabilities, the authors proposed a metric, which we refer to as TextCoMMuTE (TC), that compares the model's preference for the correct translation over the incorrect translation based on a single provided image context.

The model's uncertainty in a translation t given a source s and an image i is quantified by perplexity, defined as

$$\mathcal{P}(s,i,t) = \exp\left(-\frac{1}{N}\sum_{k=1}^{N}\log p(t_k|s,i,t_{<k})\right) \tag{1}$$

Here, N is the number of tokens in the translation, t_k is the k-th token in the translation, and $p(t_k|s,i,t_{<k})$ denotes the conditional probability

of the k-th token given the source, image, and preceding tokens. In practice, this probability is approximated using the softmax of model outputs. Perplexity can be seen as a measure of uncertainty as it is the exponential of the negative mean log probability. Hence, *lower* perplexity is desired for a correct output versus an incorrect output.

The TC metric is then defined for a single image-translation triple (i^m, t^m, t^n) as

$$TC^{m,n} = \mathbb{1}\{\mathcal{P}(s, i^m, t^m) < \mathcal{P}(s, i^m, t^n)\} \quad (2)$$

where i^m and t^m correspond to the matching image/translation and t^n is the incorrect translation in the associated triple. Moreover, $\mathbb{1}$ is the indicator function that is 1 if the perplexity for the correct translation is less than that of the incorrect translation, and 0 otherwise.

Note that each of the 154 tuples in CoMMuTE yields 2 TC scores: $TC^{a,b}$ and $TC^{b,a}$. Hence, there are actually 308 individual TC scores for the dataset. An average is taken over the N=154 TC pairs as a summary statistic

$$TC = \frac{1}{2N} \sum_{j=1}^{N} \{TC^{a_j,b_j} + TC^{b_j,a_j}\} \quad (3)$$

Again, the TC score (Eqn. 3) views the two triples in each tuple *independently* even though both triples are associated with the same source sentence. TC scores range from 0-1 with 1 indicating correct disambiguation of all triples in the dataset. A text-only model scores a TC of 0.5 by definition (assuming no ties in perplexity) because for any tuple j in the dataset, exactly one of TC^{a_j,b_j} and TC^{b_j,a_j} will be 1 while the other is 0 (*i.e.*, the image makes no contribution to the translation preference for a given source).

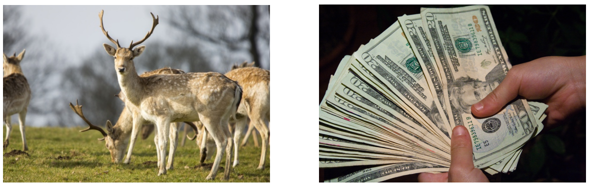
From an MMT perspective, this metric is insightful as translations with lower perplexities are typically more likely to be generated or appear higher in an n-best list.

4 Enhanced CoMMuTE Metrics

We now propose new complementary contrastive metrics to provide a more nuanced understanding of the interpretation of imagery for models with the CoMMuTE dataset.

4.1 ImageCoMMuTE

Rather than comparing two translations with the same image and source as is done with TC, we instead examine the contribution of two *different* images to the *same* translation. From this perspective, we can directly assess whether the correctly associated image is appropriately affecting model uncertainty (reducing the perplexity of its corresponding translation). For a source s, images (i^m, i^n), and a translation t^m, we define ImageCoMMuTE (IC) as



(a) French Translation a: *Il y a beaucoup de cerfs !*

(b) French Translation b: *Cela fait beaucoup de dollars !*

Figure 1: English Source: *That's lots of bucks!*

$$IC^{m,n} = \mathbb{1}\{\mathcal{P}(s, i^m, t^m) < \mathcal{P}(s, i^n, t^m)\} \quad (4)$$

where i^m is the correctly associated image and i^n is incorrectly associated image for translation t^m. Similar to TC, one can aggregate scores over a dataset by taking the mean of the N=154 pairs

$$IC = \frac{1}{2N} \sum_{j=1}^{N} \{IC^{a_j,b_j} + IC^{b_j,a_j}\} \quad (5)$$

Scores for IC range from 0-1, and a score of 0.5 indicates a random preference for the image context.

Our IC metric evaluates changes in model confidence for the *same* translation when presented with varying imagery. This approach directly assesses the interplay between imagery and text interpretation within the model. This differs from the work presented in Elliott (2018), where they assess average differences in model uncertainty, while we assess indicators of decisions. This IC metric also alleviates any possible concerns of the reliance on comparing perplexity averages and calibration *across* translations (as is done with TC). We will return to these potential issues in our discussion later. By maintaining a single reference translation across different visual contexts, our IC metric provides a more robust and precise measure of how imagery is understood by the model.

4.2 Group CoMMuTE

Though TC and IC are insightful metrics on their own, they both ignore the consistency desired for the underlying source-translation *pairs*. With TC, the set of both *translations* is independently processed twice (each time with a different image context). Similarly with IC, the set of both *images* is independently processed twice (each time with a different translation target). What is truly desired is that the model consistently and correctly understands *both* cases for each set jointly to demonstrate true understanding.

Therefore, we propose a new group variant for TC and IC. To evaluate consistency across the paired nature of the task, we define Group TextCoMMuTE (GTC) as

$$GTC^{a,b} = TC^{a,b} \cdot TC^{b,a} \tag{6}$$

and Group ImageCoMMuTE (GIC) as

$$GIC^{a,b} = IC^{a,b} \cdot IC^{b,a} \tag{7}$$

These group metrics function with a logical "AND" between the two independent triple scores, ensuring that a score of 1 reflects consistent and correct interpretations for the tuple as a whole. As earlier, one can also aggregate group scores using a mean with

$$GTC = \frac{1}{N}\sum_{j=1}^{N} GTC^{a_j,b_j} \tag{8}$$

$$GIC = \frac{1}{N}\sum_{j=1}^{N} GIC^{a_j,b_j} \tag{9}$$

These scores also yield values between 0-1.

Our primary goal is to assess if the model properly interprets and understands imagery for the translations. Group scores such as GTC and GIC are crucial because they assess consistent model behavior with different text-image combinations, indicating true comprehension rather than coincidental correctness.

5 Experiments and Results

We present a comprehensive assessment of the previous and new CoMMuTE metrics on three pretrained English-to-French MMT models. Our evaluation is structured to elucidate how well these models understand the imagery with respect to resolving ambiguities in the CoMMuTE dataset. We begin by evaluating performance on the original CoMMuTE dataset, followed by an assessment using an extended set of imagery we collected for each CoMMuTE tuple to reveal further strengths and weaknesses across models.

5.1 Models

We employed three English-to-French MMT models, each chosen for its unique approach to integrating visual data with textual information. Across all models, we preprocessed imagery by resizing the smaller edge to 224px (maintaining the aspect ratio) and then taking a center crop of 224px × 224px.

VGAMT. The authors of CoMMuTE proposed VGAMT (Futeral et al., 2023), enhancing a pretrained mBART MT model (Liu et al., 2020) by incorporating CLIP ViT-B/32 image embeddings and fine-tuning adapters. While VGAMT included an object detector and a visually guided attention mechanism, our evaluation focused on its simplified variant from their ablation study (Futeral et al., 2023), which solely uses CLIP image embeddings. This model was trained using both visual masked language modeling and MMT objectives, having 1B total parameters. In our experiments, we employed three VGAMT models provided by the authors, each trained with a different random seed.

CLIP-Trans. The authors (Gupta et al., 2023) align the embedding spaces of a pretrained mBART MT model (Liu et al., 2020) with a multilingual M-CLIP model (Carlsson et al., 2022) via a mapping network. The model first trains on an image-captioning task using M-CLIP image embeddings followed by text-only MT training with M-CLIP text embeddings. They also suggest that imagery can be utilized at inference time, substituting M-CLIP text embeddings with image embeddings, even though it is not directly trained on MMT. We used a model following this approach with 1.3B total parameters. In the experiments, we evaluated one CLIP-Trans model provided by the authors.

Gated Fusion. This model introduces a dynamic gating mechanism that adaptively combines image and text representations, with gate values ranging from 0 to 1 for image components (Wu et al., 2021). The model leverages ResNet-50 (He et al., 2016) image features and a tiny transformer for a total of 32M parameters (substantially smaller than CLIP-Trans and VGAMT). We trained the model solely on the Multi30K dataset (Elliott et al., 2016), adhering to the authors' training protocol. We observed that the gating mechanism frequently assigns low values, often near 0, which tends to minimize the impact of visual data. To better incorporate image content into the translation process, we trained additional variants with fixed gate values of 0.25, 0.5,

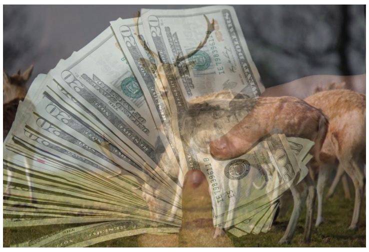


Figure 2: Mixed imagery from Fig. 1 used for a pseudo-text-only baseline.

and 0.75. Each of these variants was trained and evaluated using three different random seeds.

5.2 Baseline Results

We first conducted a baseline evaluation on the CoMMuTE dataset. The second and third columns in Table 1 display the mean TC and GTC scores taken across models with random seeds (standard deviations were very low in all cases). For reference, a pure text-only MT model will have TC=0.5 and GTC=0, since the model will always choose one translation over the other for each tuple.

VGAMT scores highest in these two metrics, with the CLIP-Trans and Gated Fusion variants scoring near text-only in TC. This model also scores the highest in BLEU on Multi30k, as reported in previous work (Futeral et al., 2023; Gupta et al., 2023). The GTC scores of all models are above 0%, suggesting that all models can consistently disambiguate at least some tuples, though the scores are low. The gate values within the default Gated Fusion model were inspected and found to be near 0 (as expected). Interestingly, we see that TC for Gated Fusion improves slightly with a fixed larger gate value of 0.25 indicating that the strength of imagery does have the potential to change translations.

5.3 Comparison with Ambiguous Imagery

We next examined how much the imagery affected model decisions in comparison to the underlying textual bias. We compared the changes in TC scores using the original image context pairs (from CoMMuTE) versus an ambiguous mixed image.

As MMT models are trained with both imagery and text, one cannot properly obtain a pure text-only result through simple methods such as passing a zero image or removing the image context from the tokens. To obtain a pseudo-text-only baseline, we employed a 50/50% "mixup" (Zhang et al., 2018) of the two image contexts for each tuple to create a single ambiguous image (see Fig. 2). Here, both image contexts are provided in a single image. However, there are other possible ways to create ambiguous imagery, such as arranging the images side-by-side. In Fig. 3, we see the perplexities of the correct translations using the mixed imagery typically fall between the perplexities using the correct and incorrect imagery, supporting the use of the mixed imagery as a baseline for comparison. We evaluated TC using this mixed image and also using the original images to get two competing TC scores for each image-translation triple. Note that the pseudo-text-only MMT model will score TC=0.5 (and GTC=0) by definition (we are using the same mixed image across two comparisons, and thus, preference does not change).

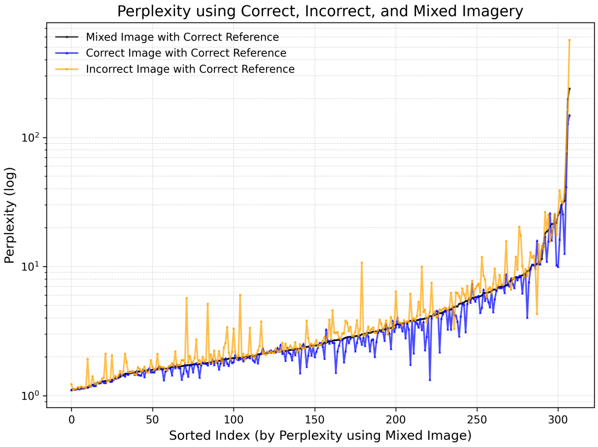

Figure 3: Perplexities of the correct translations using the correct image, the incorrect image, and the mixed image.

We measure changes in the score between the original images and the mixed image for each tuple using four consistency rates. The first two rates measure the percent of image-translation triples for which the original imagery and the mixed imagery gave different preferences for translations. That is, in these cases, the model's decision when using the original imagery was different from the model's decision when using the mixed imagery. The inconsistent positive rate (IPR) measures the percentage of image-translation triples that chose the right translation with the original imagery and the opposite/wrong translation with mixed imagery. The inconsistent negative rate (INR) measures the percentage of image-translation triples that chose the wrong translation with the original imagery and the opposite/right translation with mixed imagery. The performance of the remaining examples can be

Model	Mean TC ↑	Mean GTC ↑	IPR ↑	INR ↓	CPR ↑	CNR ↓
VGAMT	0.63	0.26	0.13	0.00	0.50	0.37
CLIP-Trans	0.51	0.03	0.01	0.00	0.50	0.49
Gated Fusion	0.50	0.02	0.01	0.01	0.49	0.49
Gated Fusion$_{0.25}$	0.52	0.10	0.07	0.05	0.45	0.43
Gated Fusion$_{0.5}$	0.50	0.07	0.05	0.05	0.45	0.45
Gated Fusion$_{0.75}$	0.49	0.02	0.02	0.04	0.46	0.48

Table 1: Baseline TC and GTC scores on the original CoMMuTE dataset, and consistency rates compared to pseudo-text-only baseline.

quantified by a consistent positive rate (CPR) and a consistent negative rate (CNR), measuring the percentage of triples whose correct and incorrect preferences did not change when using the original or mixed imagery. Since the corpus is evenly split into 2 ambiguities, these rates are bounded in [0, 0.5] with IPR + CNR = INR + CPR = 0.5.

The last four columns in Table 1 display the consistency rates using the pseudo-text-only baseline for each of the models. The VGAMT model scores the highest IPR of 0.13 with an INR of 0, indicating that the model corrected 13% of translations without any negative impact when using the original imagery. In contrast, the CLIP-Trans and Gated Fusion variants show smaller IPR and INR rates, suggesting that imagery has a weaker yet still noticeable effect on these models. The higher INR rates for Gated Fusion models indicate that imagery can actually hurt their performance.

By examining the CPR and CNR rates in the table, we see that imagery may not be significantly impactful in the decisions across all models. These rates only measure the proportion of image-translation triples (with the original imagery) that *agree* with the pseudo-text-only baseline (with the mixed imagery). They do not describe if the model associates correct/incorrect imagery with translation confidence. The model still might correctly associate the original imagery, giving lower perplexity of the correct translation (desired), but this change may not be drastic enough to overturn the model's underlying textual preference. This highlights the need for a metric, such as the proposed IC, to measure how confidence in a translation changes with correct and incorrect imagery.

5.4 ImageCoMMuTE Results

We next conducted an evaluation of the CoMMuTE dataset using our proposed IC and GIC metrics. Table 2 displays the mean IC and GIC scores taken across the models with random seeds. Note that IC and GIC metrics are undefined for a pure text-only MT model, and thus, we cannot compute the four consistency rates.

Model	Mean IC ↑	Mean GIC ↑
VGAMT	0.81	0.66
CLIP-Trans	0.58	0.22
Gated Fusion	0.51	0.11
Gated Fusion$_{0.25}$	0.51	0.12
Gated Fusion$_{0.5}$	0.50	0.13
Gated Fusion$_{0.75}$	0.50	0.11

Table 2: Baseline IC and GIC scores.

Model	TC	IC
VGAMT vs CLIP-Trans	0.39	0.18
VGAMT vs Gated Fusion$_{0.25}$	0.25	0.16
Gated Fusion$_{0.25}$ vs CLIP-Trans	0.36	0.32

Table 3: Intersection-Over-Union of failures as determined by TC and IC.

Our image-based metrics (IC and GIC) demonstrate that VGAMT interprets imagery most effectively, achieving 0.81 on IC and 0.66 on GIC, which are significantly higher than the TC of 0.63 and GTC of 0.26. Other models continue to score only slightly above 0.5. We find that of the models we tested, those that scored highest on MMT quality metrics also scored highest in our proposed metrics (as reported in (Futeral et al., 2023; Gupta et al., 2023)). These results demonstrate that VGAMT more appropriately adjusts uncertainty in a translation based on imagery.

We also investigated whether the different models made the same errors. We identified the image-translation triples where each model made errors in terms of TC and also for IC. We then calculated the intersection-over-union (IOU) between 2 models, which is a set similarity metric defined as the ratio of the number of image-translation triples common to both error sets for a given metric (intersection) to the total number of unique image-translation triples in both error sets (union). This metric helps quantify the similarity in errors across models as a scalar bounded in [0,1] where 1 signifies exact similarity in errors. The results in Table 3 reveal that models do not strongly make the same mistakes yet do share some overlap.

5.5 Extended CoMMuTE

We next extended the CoMMuTE dataset by incorporating additional images per translation in each tuple. This extension allows for a broader assessment of model performance across diverse image inputs and enables a search for images that could either improve or degrade the scores.

For each ambiguous source s, we manually generated two distinct, <u>un</u>ambiguous captions, c^a and c^b, which correspond directly to the translations t^a and t^b, respectively. For example, the English sentence “That’s lots of bucks!” is transformed to “a photo of deer” and “a photo of dollars”.

Utilizing these unambiguous captions, we then sourced corresponding images from the DataComp-12.8M dataset (Gadre et al., 2023), which comprises 12.8 million image-text pairs harvested from the Common Crawl (Common Crawl). The DataComp dataset serves as a foundation dataset for enhancing the training of CLIP models. We employ a CLIP ViT-B/32 model, pretrained on the LAION-5B dataset (Schuhmann et al., 2022), to retrieve images most similar (cosine similarity) to our unambiguous captions.

From this candidate set of imagery, the top 15 images that most closely aligned with each caption, adhering to a minimum dimension of 64 pixels and a maximum aspect ratio of 2.5, were retrieved automatically. We manually selected the four most representative images from this set (due to potentially noisy images retrieved). If fewer than 4 suitable images were found, additional images were sourced from Google Images. This method resulted in a total of 1540 images, providing 5 images (instead of just 1) for each unambiguous translation. Consequently, this extended CoMMuTE dataset includes the original source s, translations t^a and t^b, and now 5 images each for i^a and i^b.

With this extended CoMMuTE dataset, we examined if there existed subsets of imagery that could significantly increase or decrease the GIC score (as we deem GIC the most important metric for each model). For each tuple in our extended dataset, we identified the image pair (one image taken from each image set) that maximizes or minimizes the GIC score. As multiple pairs can meet the criteria, we select the pair that optimizes

$$\begin{aligned}\{\mathcal{P}(s, i^a, t^a) - \mathcal{P}(s, i^b, t^a)\} \quad + \\ \{\mathcal{P}(s, i^b, t^b) - \mathcal{P}(s, i^a, t^b)\}\end{aligned} \tag{10}$$

This expression reflects the confidence gaps for the translations. Given that a lower perplexity indicates a better result and considering the ordering of differences in Eqn. 10, we minimize (or maximize) this equation to maximize (or minimize) the GIC score accordingly. When seeking images to maximize the GIC score, we break ties by finding the image pair that *minimizes* Eqn. 10 (can be negative). When seeking images to minimize the GIC score, we break ties with the image pair that *maximizes* Eqn. 10. We refer to the image subset specifically tailored to maximize GIC as Image-Oracle. We also tracked the replacement rate (RR) of the number of images replaced from the original dataset.

As shown in Table 4, the maximal GIC image subsets show high effectiveness, with VGAMT scoring a Max IC of 0.96 and a Max GIC of 0.92. This suggests that the model can accurately interpret the intended visual signals in these particular image pairs for nearly all translations. This is further supported by the notably higher Max IC and GIC scores in the CLIP-Trans and Gated Fusion variants. Conversely, we see that sets of images can be found to hurt performance, especially in CLIP-Trans and Gated Fusion. Examples of replaced imagery can be seen in Fig. 4. Therefore, it is possible to have imagery that drastically improves or degrades the scores. We see that replacement rates are high, indicating that the original dataset is not prominent in these maximal/minimal subsets. The results with maximal/minimal GIC show that the model does indeed have an internal understanding of the imagery with respect to the translation task.

We would expect the Image-Oracle images that maximized GIC to similarly improve TC and GTC scores. However, Table 5 shows only minor improvements in TC and GTC across models. Thus, even though the IC and GIC metrics strongly indicate the image interpretability of the models, the TC and GTC metrics fail to highlight the potential contribution of imagery.

6 Discussion

This study introduced image-based and group metrics for CoMMuTE to better evaluate if models do

Model	Min IC ↑	Min GIC ↑	RR	Max IC ↑	Max GIC ↑	RR
VGAMT	0.59	0.33	0.80	0.96	0.92	0.71
CLIP-Trans	0.46	0.01	0.77	0.89	0.77	0.77
Gated Fusion	0.40	0.00	0.77	0.73	0.48	0.78
Gated Fusion$_{0.25}$	0.38	0.00	0.80	0.86	0.71	0.80
Gated Fusion$_{0.5}$	0.35	0.00	0.81	0.88	0.76	0.77
Gated Fusion$_{0.75}$	0.37	0.00	0.79	0.85	0.71	0.80

Table 4: Minimum and maximum IC and GIC scores along with replacement rates.

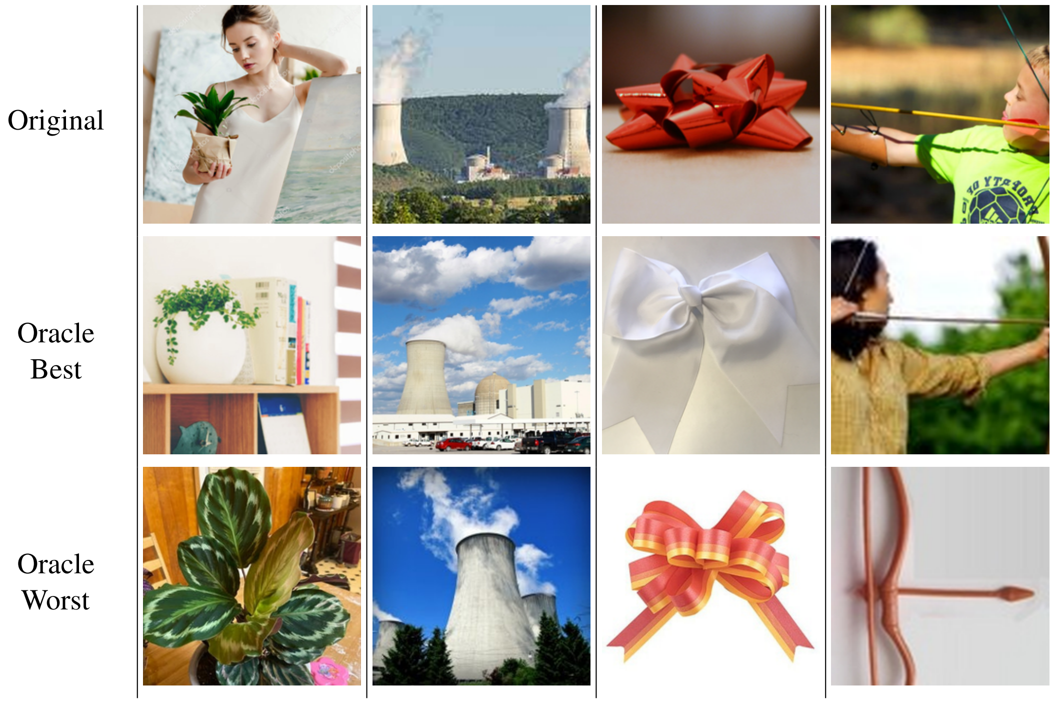

Figure 4: Examples from the CoMMuTE dataset with original imagery (top row), oracle best replacements (middle row), and oracle worst replacements (bottom row) as determined by VGAMT.

Model	Mean TC ↑	Mean GTC ↑
VGAMT	0.67	0.34
CLIP-Trans	0.52	0.05
Gated Fusion	0.51	0.02
Gated Fusion$_{0.25}$	0.64	0.28
Gated Fusion$_{0.5}$	0.59	0.18
Gated Fusion$_{0.75}$	0.56	0.12

Table 5: Image-Oracle TC and GTC scores.

Model	Mean TC ↑	Mean GTC ↑
VGAMT	0.66	0.32
CLIP-Trans	0.52	0.03
Gated Fusion	0.51	0.01
Gated Fusion$_{0.25}$	0.60	0.21
Gated Fusion$_{0.5}$	0.58	0.15
Gated Fusion$_{0.75}$	0.53	0.07

Table 6: Image-Oracle TC scores with the shared prefix removed in perplexity computation.

understand imagery in MMT. In this section, we explore possible reasons why TC scores are so much lower than IC and discuss future directions on how to further leverage the imagery to improve MMT.

There are two potential issues related to perplexity and calibration that may affect the TC/GTC scores. First, there is an assumption that perplexity is indeed an appropriate uncertainty metric to compare *two* translations. Perplexity is a transform of the mean log probability and, therefore, relies on averages where all tokens are weighted equally (Ueda et al., 2024). There may indeed be other better measures of uncertainty (Kauf and Ivanova, 2023). It is also assumed that the model is well calibrated to properly compare *across* translations.

One method to examine the effects of averages across sequences of different lengths in the perplex-

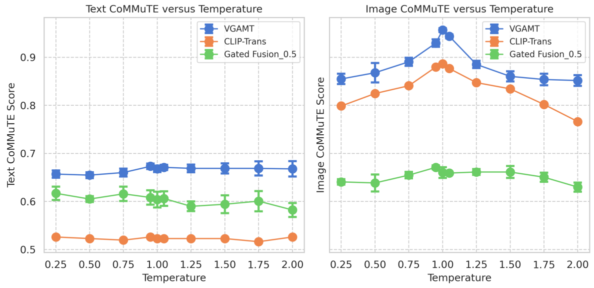

Figure 5: Calibration results using temperature scaling.

ity computation is to remove any shared prefix in t^a, t^b before computing perplexity and then compare to the results without prefix removal (original method). Ignoring common prefixes (while still weighting the remaining tokens equally) actually shows a slight degradation in scores (as illustrated in Table 6). These results suggest perplexity (a transform of mean log probability) does have some issues as a comparison method. However, this does not fully explain the low TC/GTC scores.

We also investigated the effects of model calibration using a simple global temperature scaling method (Guo et al., 2017) across a range of temperature values from 0.25 to 2. As shown in Fig. 5, the TC scores appear unaffected, indicating potential miscalibration, while IC scores suggest that models are relatively well-calibrated (at T=1). We also examined higher temperatures, which did not change the results, suggesting calibration does not appear to be primarily responsible for the TC/GTC degradation.

Therefore, given the stronger results from IC/GIC, we believe the main overall issue with TC/GTC is that the underlying textual preference/bias in these models is too strong and does not allow much influence from the imagery (which we have shown to be interpreted well by the models).

7 Recommendations for Future Work

One future area of work is the integration of imagery *earlier* in the model's architecture rather than appending them at the end of the processing chain (Wu et al., 2021; Gupta et al., 2023). Integrating image features earlier in the model's architecture could enhance the model's ability to better leverage the rich contextual cues provided by the imagery. This approach may result in translations that are more contextually nuanced, with increased attention to specific words critical for disambiguation.

Additionally, enhancing the impact of visual signals *within* the model could also prove beneficial. This could be achieved by adjusting the gate values in models that use gating mechanisms, such as Gated Fusion (Wu et al., 2021), to strengthen the influence of visual data. As demonstrated, setting a fixed gate value that prioritizes visual information could help in situations where visual context is crucial for disambiguating textual content. Even though the non-gated VGAMT was the top performer, there is still room for improvement by strengthening the role of imagery in the processing using some method of gating or amplification.

Earlier we have shown that the IOU of errors between model pairs did not have strong alignment. This diversity implies that ensembling different models could potentially mitigate individual weaknesses and enhance overall performance.

8 Conclusion

Our study challenges the widespread belief that visual cues are not generally very helpful to MMT. By employing our proposed IC and Group CoMMuTE metrics within an expanded CoMMuTE dataset, we have established a robust framework for assessing if visual information is understood in MMT systems. Our results reveal that while visual data does indeed support translation preferences, it is not leveraged significantly to enhance the outcomes over the underlying textual bias. Our findings mark a promising direction for future research in MMT, suggesting that further exploration could uncover ways to amplify this positive impact.

Acknowledgements. We thank the authors of CoMMuTE for providing their CLIP-only VGAMT models. We also thank Logan Frank and Robert Sunderhaft for their assistance.

Limitations

Firstly, we evaluated English-French translations in CoMMuTE. It remains to be seen whether the results generalize to other languages. Additionally, our evaluations were conducted on an extended set of 5 images, whereas larger sets (e.g., 100 images) would provide more robust insights. Furthermore, we relied on the default single reference translation for each image. Having additional translations for each image context would enable a more comprehensive evaluation.

Error Span Annotation:
A Balanced Approach for Human Evaluation of Machine Translation

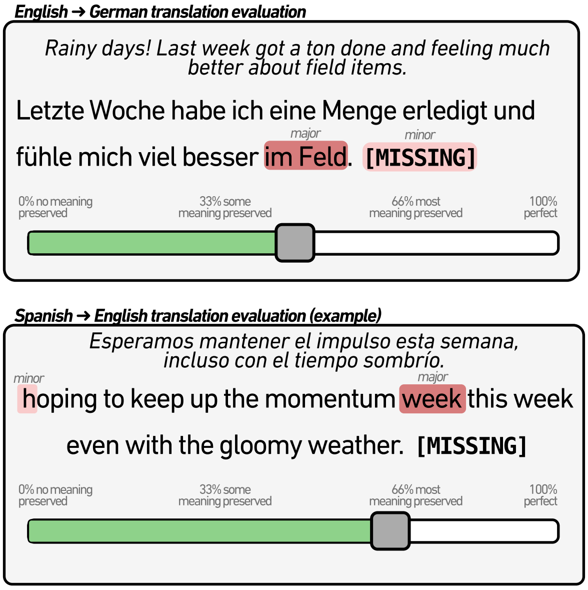
Abstract

High-quality Machine Translation (MT) evaluation relies heavily on human judgments. Comprehensive error classification methods, such as Multidimensional Quality Metrics (MQM), are expensive as they are time-consuming and can only be done by experts, whose availability may be limited especially for low-resource languages. On the other hand, just assigning overall scores, like Direct Assessment (DA), is simpler and faster and can be done by translators of any level, but is less reliable. In this paper, we introduce Error Span Annotation (ESA), a human evaluation protocol which combines the continuous rating of DA with the high-level error severity span marking of MQM. We validate ESA by comparing it to MQM and DA for 12 MT systems and one human reference translation (English to German) from WMT23. The results show that ESA offers faster and cheaper annotations than MQM at the same quality level, without the requirement of expensive MQM experts.

1 Introduction

While automatic evaluation metrics are important and invaluable tools for rapid development of Machine Translation (MT) systems, human assessment remains the gold standard of translation quality (Kocmi et al., 2023; Freitag et al., 2023). The translation quality is conceptually measured through adequacy (preservation of the original meaning) and fluency (grammaticality of the translated text; Koehn and Monz, 2006), and sometimes through comprehension (how readable or understandable the translation is; White et al., 1994).

Annotators are usually asked to assign a score on a particular quality aspect. Likert and 0–100 scale are often used for discrete and continuous scales.



English → German translation evaluation

Rainy days! Last week got a ton done and feeling much better about field items.

Figure 1: Stylized annotation user interface with Error Span Annotation (ESA). The annotator first marks errors with minor and major severity and then assigns a final score. This is more robust than asking for score directly.[1]

The most popular scoring method in machine translation field in recent years is Direct Assessment (DA; Graham et al., 2013), which is used to portray a human assessment of MT quality in the WMT shared tasks since 2016. Since 2022, the DA+SQM metric is used, namely direct assessment enriched with more objective Scalar Quality Metrics (SQM) guidelines (Kocmi et al., 2022).

Translation scores indicate the overall quality of a translation, but they can be subjective and do not provide details about the translation errors. The usual way to overcome this drawback is error classification: asking the evaluators to mark each translation error and assign an error tag from a set of predefined categories, such as *terminology* or *style*.

[1] Our experiments are on English→German. In Figure 1, Spanish→English is only an illustration for English-speaking readers. The first example, based on our data, omits *Rainy days!* and incorrectly translates *about field items* as *im Feld* (=*in the field*). The second example, for illustrative purposes, does not capitalize *H* and mistakenly adds extra *week*.

Proceedings of the Ninth Conference on Machine Translation, pages 1440–1453
November 15-16, 2024 ©2024 Association for Computational Linguistics

In recent years, the dominant error classification protocol is the Multidimensional Quality Metrics (MQM; Lommel et al., 2014; Freitag et al., 2021a). MQM error classification is the standard human metric in the WMT Metrics shared task since 2021 (Freitag et al., 2021b). While error classification provides interesting insights into the distribution of different types of errors, it requires much more time and effort, both for annotators and task organizers, who need to prepare the error taxonomy, annotation guidelines and training examples.

We present a new evaluation protocol based on highlighting errors and followed by assigning scores, Error Span Annotation (ESA), and compare it to the MQM error classification and DA+SQM scores. We compare MQM, DA+SQM and ESA annotations in parallel on a subset of English→German machine translation outputs from WMT23. We find that the proposed ESA protocol is faster and cheaper than MQM whilst providing the same usefulness in ranking MT systems.

2 Related work

Assigning overall scores was the very first method of manual MT evaluation (ALPAC, 1966; White et al., 1994), where the evaluators assessed some or all of the translation quality criteria at once: adequacy, comprehensibility, and fluency. The first WMT (Workshop/Conference on Machine Translation) shared task in 2006 and the subsequent task in 2007 adopted this technique and used adequacy and fluency scores as official metrics (Koehn and Monz, 2006; Callison-Burch et al., 2007). Later, Vilar et al. (2007) proposed binary ranking of two or more MT outputs, which became the official metric at WMT 2008 (Callison-Burch et al., 2008). It required less effort and showed better inter-annotator agreement than adequacy and fluency scores. This remained the official WMT metric until 2017 when it was replaced by continuous Direct Assessment (DA). DA (Graham et al., 2013) does not use discrete scales, but a continuous one between 0 and 100. Bojar et al. (2016) scrutinized the quality criteria and recommended to focus on adequacy and use fluency to break ties only. DA replaced ranking methods in 2017 (Bojar et al., 2017) and since 2022 (Kocmi et al., 2022) it is used with SQM guidelines (Freitag et al., 2021a) in a slightly modified version with more descriptive scale labels, which increased the inter-annotator agreement.

None of the described methods provides information about the erroneous or problematic parts of the translation. An early work of Vilar et al. (2006) analyzes errors in translation outputs assigning them to error classes from a predefined error typology. Most popular error typology recently is Multidimensional Quality Metrics (MQM; Lommel et al., 2014; Klubička et al., 2018; Freitag et al., 2021a), which is used in WMT metrics task since 2021 (Freitag et al., 2021b).

Several error span marking methods have been proposed recently (Kreutzer et al., 2020; Popović, 2020) as a less demanding error annotation approach than error classification. While it does not provide the fine-grained details about different error classes, it still gives the information about the position and amount of errors, and also enables further fine-grained analysis on the annotated data, if necessary (e.g. classification of already marked errors, identifying linguistic phenomena causing the errors, or focusing on particular error type). While the previously reported findings on this method are promising, no systematic comparison for the purposes of evaluating machine translation systems has been carried out so far. Furthermore, the simplified error marking method does not solve the challenges in determining how to appropriately weight individual errors to obtain segment-level scores, a problem that becomes particularly pronounced when extending the evaluation to document level.

This work combines the advantages of error annotation (like MQM) and assigning direct scores (like DA). The annotators are first asked to identify and mark all errors, and afterwards to assign an overall score. When deciding about the score, they are *primed* by the preceding error annotation and see all the marked errors that can be taken into consideration for the final score.

3 Comparison with DA+SQM and MQM

Our proposed method lies between DA+SQM and MQM protocols, so we provide a detailed comparison between the two before describing ESA in details in the next section.

While both DA+SQM and MQM generally exhibit low inter-annotator agreement (Knowles and Lo, 2024; Freitag et al., 2021a), DA+SQM scores have high variance, which needs to be compensated with higher number of annotations per system (Wei et al., 2022). On the other hand, MQM requires human experts trained with the MQM protocol and error classification. Trained experts can be twice as expensive as translators or bilingual speakers evaluating DA+SQM. The required expertise is a hard constraint which makes evaluation on some languages prohibitively expensive or not possible at all, especially low-resource languages. Furthermore, assigning a DA+SQM numerical score to a segment is anecdotally and intuitively much faster than MQM, where the evaluators need to mark each error span, classify it and assign severity. This altogether can make each MQM annotated segment up to approximately 10× more expensive.

DA+SQM is usually based on sentence-level scores, and the paragraph-level score is computed as the average of all sentence scores in the paragraph. Paragraph-level DA+SQM evaluation is possible, but evaluating an entire paragraph takes more time, substantially decreases the total number of collected scores, and is more demanding cognitively, which negatively impacts the inter-annotator agreement (Castilho, 2020). On the other hand, MQM as an error classification annotation is agnostic to the choice of annotation unit.

As an example, in App. Figure 6 we show the system ranking based on two approaches DA+SQM and MQM on Chinese-English (sentence-level evaluation) and English-German (paragraph-level evaluation) language pairs. Although both techniques reach same order of system clusters, DA+SQM produces much fewer clusters in paragraph-level setup, thus putting many systems within a single cluster. On the other hand, MQM is better able to distinguish different systems. To increase statistical power of DA+SQM, we would have to collect much more DA+SQM samples (Wei et al., 2022), which would further drive the cost up. In addition, DA is much more skewed towards fluency as opposed to adequacy (Martindale and Carpuat, 2018).

The cost difference was one of the main reason behind the high usage of DA+SQM at the WMT General MT shared task (Kocmi et al., 2023, 2022). For all these reasons, our hypothesis is that a new annotation protocol, ESA, which is between DA+SQM and MQM can provide better annotations than DA+SQM at a lower cost than MQM.

4 Error Span Annotation

Annotation process. In Error Span Annotation (ESA), the evaluators first mark all problematic parts (characters, words, phrases, sentences) in the translated text. For each marked span, they also provide one of the two severity levels: **major** (e.g. changed meaning) or **minor** (e.g. incorrect grammar, style; see Example 1). Because all error spans are marked in the translation, not the source text, we include a special tag for marking omission errors. This was an intentional choice over annotating the source text to make the annotation protocol forward-compatible with other translation modalities, such as audio and video translations.

Source/Translation+ESA	**Score**
SRC: ... I've entered the burrata dimension. TGT: ... ich habe die Burrata-Dimension eingegeben. gloss: *habe eingegeben(=I put in)* should be *bin eingetreten*	70%
SRC: Not like other tomb raider games TGT: Nicht wie andere Gräberüberfäller Spiele gloss: *Gräberüberfäller* overtranslates *Tomb Raider*	35%
SRC: (PERSON2) Yeah, so just know like- TGT: Ja, also weißt du einfach... [missing] gloss: *PERSON2* is missing	86%
SRC: All collards, kale, chard is transplanted. TGT: Alle Kohlköpfe, Grünkohl, Schmalz sind verpflanzt. gloss: *Kohlköpfe(=cabbages)* and *Schmalz(=lard)* are incorrect translations	17%

Example 1: ESA-annotated examples with associated manual score. The error severity distinction is between minor and major. The first example has a single error (confusion *eingeben(=put in)* as *enter* meaning *go in*) which also affects the auxiliary verb habe/bin. Thus, the same error is marked twice.

After the annotators mark all the error spans, they are asked to provide an overall score for the entire segment, on the scale from 0 to 100, reminiscent of DA+SQM. We implement the annotation interface in Appraise (Federmann, 2018) and show a screenshot in Figure 2. The full guidelines displayed to annotators are shown in Appendix A.

Segment-level scores. To rank systems, we need scalar values. There are two evident ways to extract them from ESA: (1) using the annotator's overall segment-level score directly, like DA+SQM, or (2) converting error span severity levels into a segment-level score, like MQM. By instructing the annotators to identify and mark all errors first, we *prime* them to be more accurate when assessing the overall quality of the segment—when making the decision about the score, they have already marked all errors in the segment and can see them, therefore they can take them into consideration.

MQM is primarily error diagnostics protocol which has been repurposed for translation segment scoring. The transition from MQM error spans into a single segment score has been proposed to be done with the formula based on error severity counts (Freitag et al., 2021a):

$$\text{MQM-like} = -5 \cdot \#\text{MAJOR} - 1 \cdot \#\text{MINOR}$$

Notice that this does not scale with different text sizes.[2] As an example, if translation of a segment has two major errors, it receives the score of -10. However, if the source is repeated twice and the corresponding translation as well, the score would be further decreased to -20. This is especially problematic for paragraph-level evaluation which features segments of different length. Additionally, the segment-level MQM score might not correspond with the segment-level translation quality, such as when marking one error affecting several places in the segment, as in Example 1 (top). To avoid such issues, we use the annotators' direct scores as the main scoring approach for the ESA protocol unless specified differently. The system-level scores for all human evaluation methods in this work are calculated as the average of all segment-level scores for particular system. We further revisit the score computation in App. Appendix B.1. In some analysis, we use ESA error spans to calculate MQM-like score, we refer to such scores as $\text{ESA}_{\text{spans}}$.

Advantages. Assigning overall scores is guided by errors in the translation, and through error marking, the annotator can first focus on direct highlighting of these issues instead of determining the overall score directly. The advantage of ESA over error classification is that it is less demanding, while still informative—the annotations can be further refined in subsequent analyses. Furthermore, the evaluators are not limited to any pre-defined annotation protocol and can highlight a larger range of errors. The error marking approach can be seen as *descriptive* (encouraging annotator subjectivity and capturing their individual beliefs) and the error classification as a *prescriptive* (discouraging annotator subjectivity and asking annotators to align with one specific belief, in this case the pre-defined error protocol), as per Rottger et al. (2022).

5 Experimental setup

We conduct experiments comparing the ESA protocol with MQM and DA+SQM protocols. We design them in a way which makes it comparable with the previously collected annotations for MQM^{WMT} and $\text{DA+SQM}^{\text{WMT}}$. For this reason, we reproduce the human evaluation campaign for the WMT23 English to German systems (Kocmi et al., 2023; Freitag et al., 2023) with ESA and our reimplementation of MQM.

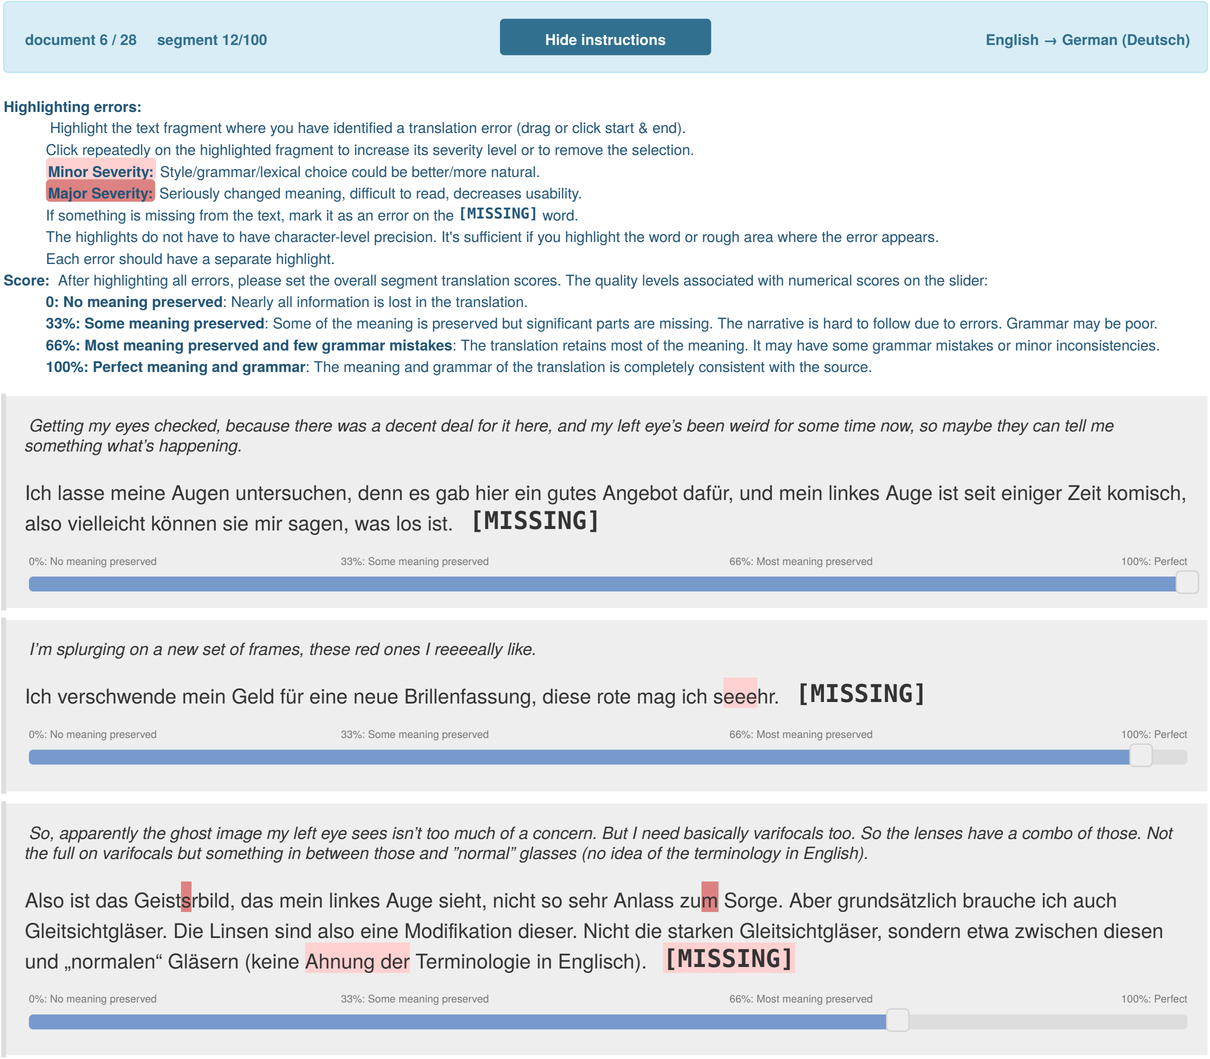
	ESA_1	ESA_2	MQM	MQM^{WMT}
# error spans	0.45	1.00	0.53	3.37
% minor	63%	68%	67%	67%
% major	37%	32%	33%	33%
Score (MQM-like)	81.8 (-1.1)	84.5 (-2.2)	(-1.2)	(-7.1)

Table 1: Average number of error spans per segment, ratio between minor and major errors, and scores across different annotation protocols.

The original campaign featured 13 translations of 557 source segments. To facilitate running multiple campaigns for proper comparison, we had to scale down and subsampled 207 segments per system (74 documents), which yields 2,691 segments in total. To keep the ESA annotation comparable to other protocols, we subsample by selecting a subset of documents evaluated by Freitag et al. (2023) keeping the entire documents. This differs from Freitag et al. (2023), who removed some paragraphs from the ends of long documents. In our analysis we only consider segments overlapping with both previous annotation collections, thus obtaining 2,027 annotations evaluated across all protocols. We note that the subsampling makes all annotations protocols statistically less powerful, but keeps them fair in terms of statistical power per evaluated segment. Therefore, clustering and final system ranking in our analysis differs from Kocmi et al. (2023); Freitag et al. (2023). To keep the study comparable with Kocmi et al. (2023), we use the Wilcoxon rank-sum test with $p<0.05$ when producing system clusters. However, as all systems are evaluated on the same set of segments, we advice to use Wilcoxon signed-rank test when employing ESA as proposed by Kocmi et al. (2021).

To analyze inter annotator agreement, we run ESA protocol twice with different sets of annotators. We hired 28 annotators to evaluate our protocols and each protocol was evaluated by different sets of experts to avoid bias. Specifically, we had 8 bilingual annotators for the initial run of ESA_1, 10 translators for ESA_2 (different vendor), and 10 annotators to evaluate MQM protocol. For MQM, we hired professionals already experienced with MQM annotation protocol, while for ESA, we hired translators or bilingual speakers. All of them were native speakers of the target language, German.

[2] Another weighting was proposed by Burchardt (2013) that is less prevalent in machine translation evaluation.



Highlighting errors:
Highlight the text fragment where you have identified a translation error (drag or click start & end).
Click repeatedly on the highlighted fragment to increase its severity level or to remove the selection.
Minor Severity: Style/grammar/lexical choice could be better/more natural.
Major Severity: Seriously changed meaning, difficult to read, decreases usability.
If something is missing from the text, mark it as an error on the `[MISSING]` word.
The highlights do not have to have character-level precision. It's sufficient if you highlight the word or rough area where the error appears.
Each error should have a separate highlight.

Score: After highlighting all errors, please set the overall segment translation scores. The quality levels associated with numerical scores on the slider:
0: No meaning preserved: Nearly all information is lost in the translation.
33%: Some meaning preserved: Some of the meaning is preserved but significant parts are missing. The narrative is hard to follow due to errors. Grammar may be poor.
66%: Most meaning preserved and few grammar mistakes: The translation retains most of the meaning. It may have some grammar mistakes or minor inconsistencies.
100%: Perfect meaning and grammar: The meaning and grammar of the translation is completely consistent with the source.

Getting my eyes checked, because there was a decent deal for it here, and my left eye's been weird for some time now, so maybe they can tell me something what's happening.

Ich lasse meine Augen untersuchen, denn es gab hier ein gutes Angebot dafür, und mein linkes Auge ist seit einiger Zeit komisch, also vielleicht können sie mir sagen, was los ist. **[MISSING]**

I'm splurging on a new set of frames, these red ones I reeeeally like.

Ich verschwende mein Geld für eine neue Brillenfassung, diese rote mag ich seeehr. **[MISSING]**

So, apparently the ghost image my left eye sees isn't too much of a concern. But I need basically varifocals too. So the lenses have a combo of those. Not the full on varifocals but something in between those and "normal" glasses (no idea of the terminology in English).

Also ist das Geistsrbild, das mein linkes Auge sieht, nicht so sehr Anlass zum Sorge. Aber grundsätzlich brauche ich auch Gleitsichtgläser. Die Linsen sind also eine Modifikation dieser. Nicht die starken Gleitsichtgläser, sondern etwa zwischen diesen und „normalen" Gläsern (keine Ahnung der Terminologie in Englisch). **[MISSING]**

Figure 2: Screenshot of the beginning of one annotated document in the ESA interface (following segments are not shown). By showing and annotating whole documents at the segment-level, the annotators see all the relevant context. Segment *reset* button and *completed* labels removed for brevity. See the interactive tutorial shown to all annotators in Appendix Figure 10.

6 Analysis

We first analyze the collected data, system ranking, agreement with other protocols, quality assurance, and finally the annotation time. The findings reveal that the ESA quality is comparable, if not better than MQM, takes less time, and does not require highly trained annotators.

6.1 Score distribution

As per Table 1, on average the ESA_1 annotators mark 0.45 error spans per segments, which is close to MQM's 0.53 error spans per segment. The second run of ESA_2 has more than double of error spans per segment, which could be the result of different characteristics of annotators group, specifically experienced annotators in ESA_1 versus translators in ESA_2. On the other hand, MQM^{WMT} contains 7x more errors per segment than our rerun of MQM. We attribute this difference primarily to the differences in annotation crowds, which further motivates our own evaluation of both MQM and ESA so that the annotations differ only in the annotation protocol and past MQM training. The severity levels are distributed similarly across campaigns. Important insights are in the score range distribution presented in Figure 3: the MQM-like score computation creates more skewed distribution around 0, which is in addition unbounded and can go to -infinity the longer the evaluated segment is, complicating modeling and comparisons. In contrast, the manual scores from annotators are spread out and guaranteed to be in [0, 100].

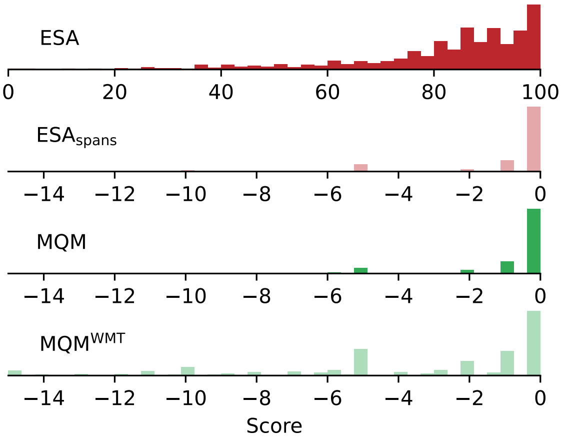


Figure 3: Distribution of scores for one annotation campaign. For ESA, we either use the manual score or $\text{ESA}_{\text{spans}}$ computation based on error severities. For MQMs, the distribution is clipped ≥ -15 for higher resolution.

6.2 System ranking capabilities

We now investigate how well different annotation protocols (ESA and MQM) can rank MT systems. For purpose of this experiment, we consider MQM^{WMT} which comes from an independent very high-quality annotation crowd and implementation, as the gold standard. Note that this creates a positive bias towards our implementation of MQM as opposed to ESA. In Appendix B.2 we show an evaluation without this gold standard assumption.

When comparing two protocols, we ideally want them to rank all systems in the same order. This is not always possible as some systems are very similar and cannot be significantly distinguished with the evaluated sample size. Another problem is that different protocols may weight different phenomena (e.g. fluency or adequacy) differently. To compare different protocols in the task of ranking systems, we use pairwise accuracy (Kocmi et al., 2021), which is also used in WMT Metrics shared task when comparing different automatic metrics (Freitag et al., 2023). Pairwise accuracy measures how many system pairs does a protocol rank the same way as MQM^{WMT}. As we have only 78 system pairs, any wrong system pair will change pairwise accuracy by 1.28%. Therefore, we also calculate Spearman's correlations as we mainly want protocols to have monotonic ranking.

In Figure 4, each subplot compares system-level scores between one protocol on x-axis and MQM^{WMT} on y-axis. Our repeated MQM experiment and ESA protocol rank systems identically (94.9%), while ESA has slighly higher Spearman's correlation with MQM^{WMT}. On the other hand, $\text{DA+SQM}^{\text{WMT}}$ significantly lacks behind both protocols. This suggest that our ESA protocol has comparable system ranking capabilities to MQM and is superior to $\text{DA+SQM}^{\text{WMT}}$.

The Figure 4 also shows, that relying on error spans only is not optimal, as $\text{ESA}_{\text{spans}}$ has lower accuracy and Spearman's correlation than ESA. We can notice that this is even lower than our rerun of MQM. This can be attributed to the evaluation crowd, where we used professional MQM annotators for MQM protocol, while we used bilingual speakers and translators for the ESA protocol.

Further focusing on the clustering, MQM^{WMT} significantly differentiates the top system from others (highlighted in orange), while $\text{DA+SQM}^{\text{WMT}}$ strongly puts this system into the second cluster. This system is human reference, which we assume should be of highest quality. The reduced number of clusters in contrast to Figure 6 is due to the lower sample size. This may be result of $\text{DA+SQM}^{\text{WMT}}$ higher sensitivity to fluency and style errors, which contribute to 60% of all errors in human reference as marked by MQM^{WMT}. This conflict in clustering is one of the critiques of $\text{DA+SQM}^{\text{WMT}}$ if we assume that human reference should be the highest scoring translation. For example, in Kocmi et al. (2023), human reference was the best translation only in 2 out of 8 language pairs.

	MQM^{WMT}
ESA_1	0.227
$\text{ESA}_{1\ \text{spans}}$	0.170
ESA_2	0.250
$\text{ESA}_{2\ \text{spans}}$	0.236
MQM	0.189
$\text{DA+SQM}^{\text{WMT}}$	0.209

Table 2: Kendall τ segment-level correlations between evaluation protocols.

6.3 Agreement with other protocols

We now compare how different protocols correspond on the segment-level. We use MQM^{WMT} as the gold standard to compare against because it was done independently outside of our setup and with high quality assurance. We analyze two aspects: (1) segment scores, and (2) spans, where we consider spans overlapping even with a single

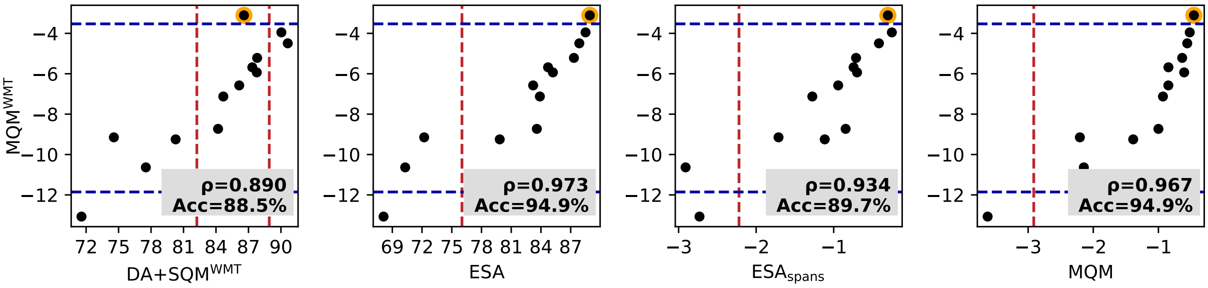

Figure 4: Each point represents a system, with the original MQM^{WMT} scores on the y-axis plotted against our rerun of $\text{DA+SQM}^{\text{WMT}}$ (first plot), ESA (second plot), $\text{ESA}_{\text{spans}}$ (third plot), and MQM (forth plot). Stripped lines indicate cluster separations determined by each method with alpha threshold 0.05. We compute Spearman correlation ρ and pairwise accuracy ACC.

character as a match. For this evaluation, we use Kendall τ variant C, which is more suitable for data with different underlying scales and many ties.

In Table 2, we see that although all protocols correlate similarly with MQM^{WMT}, our protocols obtain the highest τ for both runs. The segment-level correlation also confirms that relying only on the error spans is not optimal and $\text{ESA}_{\text{spans}}$ obtains lower Kendall score.

In Table 3 we focus on the annotated spans. We consider any spans that overlap as matching, irrespective of severity. Because different protocols have different average number of error spans, presenting just the size of the intersection would be misleading. Instead, we show normalized set similarity that is not symmetric. It answers the questions: *What proportion of samples in B were covered by A?* Both ESA and MQM cover MQM^{WMT} similarly, with 29% and 32% respectively. At the same time, MQM^{WMT} covers ESA and MQM with 93% and 85%.

↓A B→	ESA	MQM	MQM^{WMT}
ESA		77%	29%
MQM	85%		32%
MQM^{WMT}	93%	89%	

$|\boldsymbol{A} \cap \boldsymbol{B}|/|\boldsymbol{B}|$ (100% for $B = \emptyset$)

Table 3: Similarity between spans of different annotation protocols (one campaign) computed as percentage how much of B does A contain. For example, 93% of ESA spans were also in MQM. Any span that overlaps with another one is considered a hit, even if only with as single character.

6.4 Quality of annotations

Intra annotator agreement. We want the human evaluation protocol to consistently assign similar scores for the same translations over time. A good indicator of the annotation quality is how noisy and subjective it is, which is reflected by how much annotators agree on the same segments (inter annotator agreement) as well as how a single annotator agrees with themselves (intra annotator agreement). To measure intra-AA, we ask the same annotators to again annotate the same documents two months later. We prepare an identical campaign with the same distribution of systems in the same order as originally, asking the same annotators to redo it again for both ESA and MQM.

It is not obvious how to measure the agreements for protocols that have different features. One issue is the frequency of ties, where MQM has more ties than rating from ESA or $\text{DA+SQM}^{\text{WMT}}$.For example, MQM^{WMT} contains 30.8% no-errors, while $\text{DA+SQM}^{\text{WMT}}$ contains only 5.2% of score 100. Secondly, each protocol uses different range and distribution of scores, which makes calculation of agreement complicated. See App. Figure 7 to understand different distribution of scores.

Previous works comparing different protocols discretize the scale into bins (Graham et al., 2013; Freitag et al., 2021a), however, this approach is sensitive to subjective selection of bin sizes and benefits already discrete protocols. Instead, we propose to use Kendall's Tau-c correlation to measure inter-annotator agreement. Secondly, we also want to take into consideration that small changes in scores are less damaging than large shifts, therefore, we want inter annotator's scores to correlate linearly, ideally having identical score each time. To measure this, we use Pearson's correlation. Lastly, we measure recall of how often annotator mark *any* error in the same segment in contrast to leaving the segment without marked errors.

Table 4 shows that ESA has all scores higher than MQM. Higher Kendall and Pearson suggest that the task is easier for annotators to agree on the score. We expect the recall to be comparable for both techniques as the task is similar, we hypothesize that the drop in MQM could be explained by annotators saving time and skipping minor errors as the annotation is more complicated for MQM than ESA, which can be confirmed when looking at minor error's recall only.

Lastly, evaluating inter annotator agreement is heavily affected by the strategy of annotators, where different annotation strategy does not mean different performance of the task as Riley et al. (2024) showed. Secondly, the MQM$^{\text{WMT}}$ was collected with a different tooling and the documents have been presented to annotators in different order, which could also impact the inter annotator agreement.

	Intra AA		Inter AA	
	ESA	MQM	ESA	MQM
Kendall's Tau-c	0.149	0.109	0.254	0.116
Pearson	0.403	0.189	0.482	0.281
Error recall	69.6%	61.9%	66.6%	40.1%
Minor e. recall	70.7%	66.2%	67.7%	44.4%
Major e. recall	82.6%	82.1%	84.8%	62.9%

Table 4: Intra- and inter-annotator agreement on segment-level.

Inter annotator agreement. To measure how different annotators agree between themselves on the same protocol, we compare ESA$_1$ to ESA$_2$, where each protocol was evaluated by different group of annotators (bilingual annotators vs. translators). To calculate MQM's inter-annotator agreement, we compare our MQM run with MQM$^{\text{WMT}}$. However, the comparison is not as 1:1 as for ESA protocol. Our MQM was collected with different interface and system outputs have been shown to annotators in a different order. Results in Table 4 suggest, that ESA has also higher inter-annotator agreement than MQM. Unfortunately, we could not rerun DA+SQM protocol to calculate agreements, which needs to be reevaluated in future work.

Agreement on the error span. We now investigate how much MQM annotators agree on the error spans, error categories and severity levels. We evaluate from two angles: *intra*, where we check if the same annotator marks the same error spans or have overlapping parts, and *inter*, where we compare our MQM error spans to MQM$^{\text{WMT}}$. Table 5 shows that only in 30% of cases, the same annotator marked at least part of the same segment as an error regardless error severity and category. If we look at cases preserving severity and category, this number drops to 8.4%.

When comparing the inter annotator agreement, only 50% of errors are overlapping. This number is higher as the total number of errors in MQM$^{\text{WMT}}$ is 7× higher than in MQM, therefore it is more likely an error will have overlap.

	Intra AA	Inter AA
Any errors	29.3%	50.2%
Same severity	16.9%	23.7%
Same category	18.9%	24.1%
Same sev. + categ.	11.6%	10.0%
Same sev. + subcateg.	8.4%	-

Table 5: ESA intra- and inter-annotator agreement (frequency) on marking overlapping errors with same severities, categories or subcategories.

Quality control. To measure the quality of annotations, we added "attention checks" in the form of segments for which we can reliably check whether the annotator annotated them correctly or not. In random documents, we perturbed the translation by replacing part of it with random sequence of words of the same length introducing a major translation error. Within 100 segments annotated by the annotator, they see both original and perturbed versions of that document. We can control the annotation quality by checking if the perturbed documents received more error spans. We show a worked-out Example 2.

SRC: *Sie haben gestern das Treffen wieder verschoben.*
TGT: *He postponed the meeting again yesterday.*
TGT$^{\mathbf{P}}$: *He postponed the meeting squirrels tense.*

Example 2: An example of a perturbed translation **TGT**$^{\mathbf{P}}$ based on the original system translation **TGT**. The **TGT** has one error (*He* should be *You* or *They*) and **TGT**$^{\mathbf{P}}$ introduces one more errors (*squirrels tense*).

The MQM and ESA setups used the same perturbations and we show their results in Table 6. The scores comparing original and perturbed segments for ESA and MQM are vastly different,[3] showing that annotators paid attention to the quality control items. For ESA the original segment had a higher score than the perturbed one in 86% of cases, while for MQM in 78% of cases. When investigating

[3] The protocols use different scales, for example, one major error under MQM is −5 points, while 25 points in ESA represents quarter of the full scale.

whether an annotator marked the error span or not, MQM has higher recall than ESA, however, this is less crucial for ESA as annotator can adjust the ranking without marking the error.

		Original	Perturbed	OK
ESA	Score	79.5	52.6	86%
	Span count	0.85	1.86	54%
	Perturbation marked			56%
MQM	Score	-1.87	-6.49	78%
	Span count	0.66	1.68	70%
	Perturbation marked			76%

Table 6: Annotations assigned to perturbed attention check items (either scores or number of spans). **OK** is percentage in how many cases the non-perturbed item received a higher score or had fewer error spans, and how often the perturbed span was marked by the annotator.

6.5 Annotation time

One of the reasons behind development of the new protocol is reducing the time requirements of the evaluation. In this section, we analyze times on our experiments only, therefore our rerun of MQM in contrast to ESA. We do not include the times for DA+SQM and MQM$^{\text{WMT}}$ because they were done independently outside of our study and the time data are not available. Assessing the speed of annotations is challenging as annotators took breaks during the annotation (from short breaks taking several minutes up to several hours). This makes the evaluation of time problematic and we therefore investigate the time estimate in several ways. Counting all annotators together, the median time for annotation per single paragraph for MQM is 38 seconds and for ESA is 29 seconds, a reduction of 23%. However, as median time for each annotator fluctuates, we look at the average median time across annotators. **For MQM, the median is 49 seconds and for ESA it is 34 seconds, a reduction of 32%**. This can be contributed mainly to the less demanding error span annotation approach used in ESA.

We note that further speedups could be made by instructing the ESA annotators to not spend extra time e.g. marking multiple error-span annotations of a single grammatical phenomenon.

Speedup during annotations. Naturally, the reported total annotation time does not distinguish between the duration of the first and last annotations. In practice, annotators *learn* to perform the annotation task more effectively. In Figure 5 we show time per segment depending on how many segments the annotator already processed. For both MQM and ESA, there is a small learning effect. For MQM, with each segment, the annotator becomes 0.20s faster, while for ESA this is 0.17s.

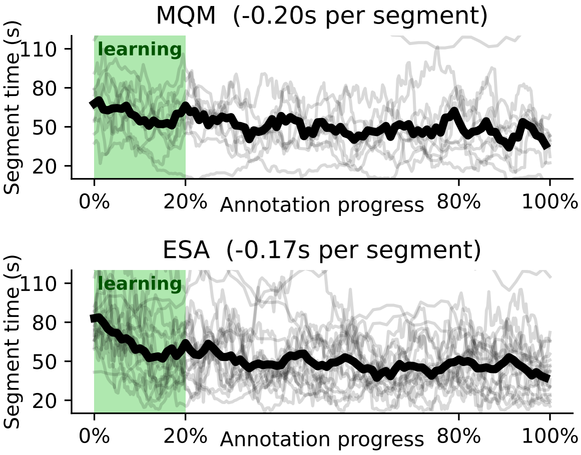

Figure 5: Time per segment with respect to progression in the annotation. The faint gray lines represent individual annotators, while the bold black line shows the average time. The lines are smoothed with a window of size 15 segments. We also compute the average speed at the beginning and at the end, which yields the *learned speedup*. This is how much the annotator speeds up after working on one segment.

7 Conclusion

Existing annotation protocols for machine translation evaluation are either expensive because they require expert labor (MQM), or they are noisy and less reliable (DA+SQM). To this end, we propose, describe, and analyze **Error Span Annotation (ESA)**, which builds on top of previous protocols to enable economic evaluation at scale. It works by asking the annotators to mark error spans, but with only the error severities and not types. In contrast to MQM, we also solicit final translation score. This is more reliable than DA+SQM, as the annotators are primed and informed about the translation errors to assess quality of longer documents.

We showed that our protocol has the higher inter and intra annotator agreement than MQM while being 32% faster. In addition, the protocol does not require annotators trained in MQM categorizations.

Lastly, we showed that relying only on error spans and not using the ranking score as we did in ESA$_{\text{spans}}$ produces suboptimal scoring, therefore the combination of error spans and ranking seems to produce the best results.

Limitations

A possible limitation in contrast to MQM is that now the system evaluation does not provide breakdown of error types, which could help practitioners in improving their systems. ESA does not provide this because the goal is *evaluation* and not *diagnosis*. Because of this and the costs of scaling expert labor, we are convinced that this is not a true shortcoming of ESA. Furthermore, the annotated errors can be further classified and analysed, if necessary.

Our experiments, for monetary reasons, were done only on one language pair, English→German. Nevertheless, it is unlikely that the results would be vastly different for other languages. The most difficult setup could be with Chinese, Japanese, and Korean texts that do not use spaces. However, we made a deliberate decision to allow highlighting of individual characters, as opposed to words, so that the user experience is unified across all languages. This was done in spite of speed improvements (selecting on the word level is easier than selecting individual character boundaries) in order to make the tool scalable to a large range of languages.

Ethics Statement

The annotators were paid a standard commercial translator wage in the respective country. The experts in the MQM annotation has been paid double the hourly wage. No personal data was collected and the showed data was screened for potentially disturbing content.

We follow up with a questionnaire asking annotators on their feedback. Almost all annotators specified that the annotation experience was positive and instructions were clear. The main concern they mentioned was that some documents have been too long to evaluate.

A User Guidelines

The following are annotation guidelines for our local ESA and MQM campaigns.

A.1 ESA (Error Span Annotations)

Higlighting errors: Highlight the text fragment where you have identified a translation error (drag or click start & end). Click repeatedly on the highlighted fragment to increase its severity level or to remove the selection.

- **Minor Severity:** Style/grammar/lexical choice could be better/more natural.
- **Major Severity:** Seriously changed meaning, difficult to read, decreases usability.

If something is missing from the text, mark it as an error on the **[MISSING]** word. The highlights do not have to have character-level precision. It's sufficient if you highlight the word or rough area where the error appears. Each error should have a separate highlight.

Score: After highlighting all errors, please set the overall segment translation scores. The quality levels associated with numerical scores on the slider:

- 0%: No meaning preserved: Nearly all information is lost in the translation.
- 33%: Some meaning preserved: Some of the meaning is preserved but significant parts are missing. The narrative is hard to follow due to errors. Grammar may be poor.
- 66%: Most meaning preserved and few grammar mistakes: The translation retains most of the meaning. It may have some grammar mistakes or minor inconsistencies.
- 100%: Perfect meaning and grammar: The meaning and grammar of the translation is completely consistent with the source.

A.2 MQM (Multidimensional Quality Metrics)

Higlighting errors: Highlight the text fragment where you have identified a translation error (drag or click start & end). Click repeatedly on the highlighted fragment to increase its severity level or to remove the selection.

- **Minor Severity**: Style/grammar/lexical choice could be better/more natural.
- **Major Severity**: Seriously changed meaning, difficult to read, decreases usability.

If something is missing from the text, mark it as an error on the **[MISSING]** word. The highlights do not have to have character-level precision. It's sufficient if you highlight the word or rough area where the error appears. Each error should have a separate highlight.

Error types: After highlighting an error fragment, you will be asked to select the specific error type (main category and subcategory). If you are unsure about which errors fall under which categories, please consult the typology definitions.

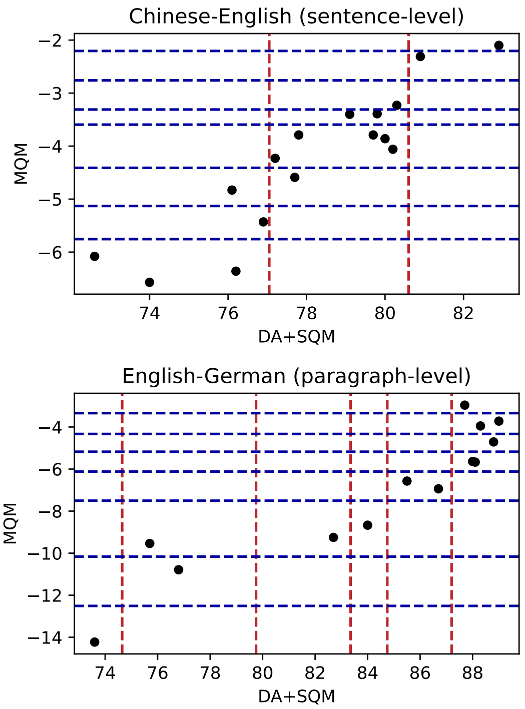

Figure 6: System scores illustrating differences between DA+SQM and MQM. Each point is a single system and dashed lines mark clusters. DA+SQM produces fewer clusters and groups many systems into one single cluster, while MQM better distinguishes different systems. Scores and clusters are from Kocmi et al. (2023).

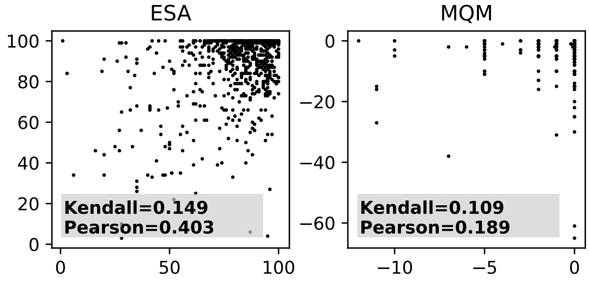

Figure 7: Intra annotator agreement; changes in scoring by the same annotator when evaluated again. Each point represents an annotated segment with x-axis being annotator's score assigned in March and y-axis their score assigned in May.

Feature	**Corr. with ESA score (ρ)**
Source token count	-0.16
Target token count	-0.06
Minor error count	-0.20
Major error count	-0.52
Missing error count	-0.45
Minor error count (normalized)	-0.13
Major error count (normalized)	-0.37
Missing error count (normalized)	-0.31

Table 7: Segment-level Pearson correlation of individual features with the ESA score.

B Additional results

B.1 From error spans to final score

To find out what influences the score, we show correlation between individual segment-level features in Table 7. On average, longer segments have lower translation quality. Importantly, the error counts normalized by segment length correlate less than the non-normalized counterparts. However, we note that the normalized scores are more continuous that the non-normalized MQM computation, as per Figure 3.

The MQM formula was crafted with respect to preserving system ranking and not segment-level matching from the same annotator (Freitag et al., 2021a). However, the construction of ESA allows us to revisit this problem as each annotator gives both the error spans and the final score. We scan for multiple minor/major ratios of error weights and show the results in Figure 8. We find that the optimal formula that optimizes the correlation between the direct score and the score from the spans has the following form: $\textsc{Seg.Score} = -1 \cdot \#\textsc{minor} - 4.8 \cdot \#\textsc{major}$, which is very close to the originally proposed 1:5 ratio. From Figure 8, the weight of the major error class seems to have a much bigger effect on the final translation score, suggesting that minor errors play a lesser role.

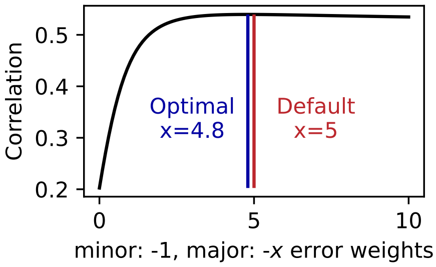

Figure 8: Correlation between direct ESA score and scores computed from error spans with minor errors having weight -1 and major errors $-x$.

B.2 Protocol evaluation without a gold standard

Evaluating the quality of a protocol without a target to compare to is difficult. In previous sections we assumed that MQM$^{\text{WMT}}$ is the gold standard, which might bias the evaluation in favor of MQM. Even though the results showed higher correlations of ESA with MQM$^{\text{WMT}}$. For completeness, we consider the methodology of Zouhar et al. (2024) which does not require target gold standard to compare the quality of annotation protocols.

The assumption is that annotation protocols have various levels of noise, but are unbiased in what they measure. Because MQM and DA+SQM might measure different things, we want to compare each to the perfect ranking of the particular thing they aim to measure. The linking hypothesis is that even noisy and low-quality annotation protocols would lead to the final system ranking with large enough data. Vice-versa, only robust annotation protocols would arrive at the final ranking with only a few data points per each system. This is formalized by the subset consistency accuracy. It is the system ranking accuracy on a subset of annotations with respect to the ranking induced by the full data from one annotation protocol.

We show the results in Figure 9. Out of the comparable lines, ESA (with direct scoring) achieves the highest subset consistency accuracy. In practice, this translates to needing fewer annotated examples to achieve the final system ranking. This directly corresponds to lower annotation costs.

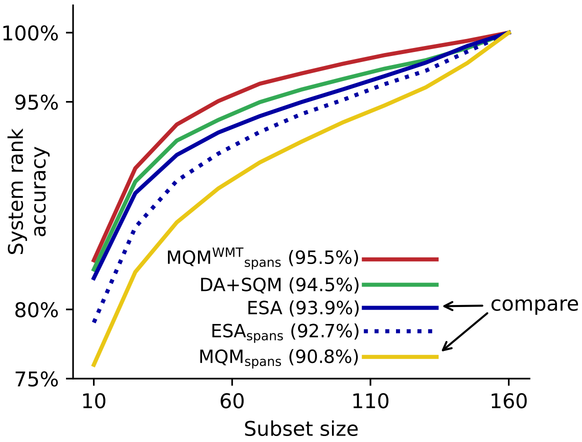

Figure 9: Subset consistency accuracy (Zouhar et al., 2024) of annotation protocols. E.g. with just 60 annotated segments, MQM$^{\text{WMT}}$ achieves 95% system ranking accuracy with its final ranking based on 160 annotated segments. Values in the legend are averages, corresponding to normalized area under the curve. The only comparable lines are ESA, ESA$_{\text{spans}}$, and MQM$_{\text{spans}}$ because they were run in the same setting with similar crowds.

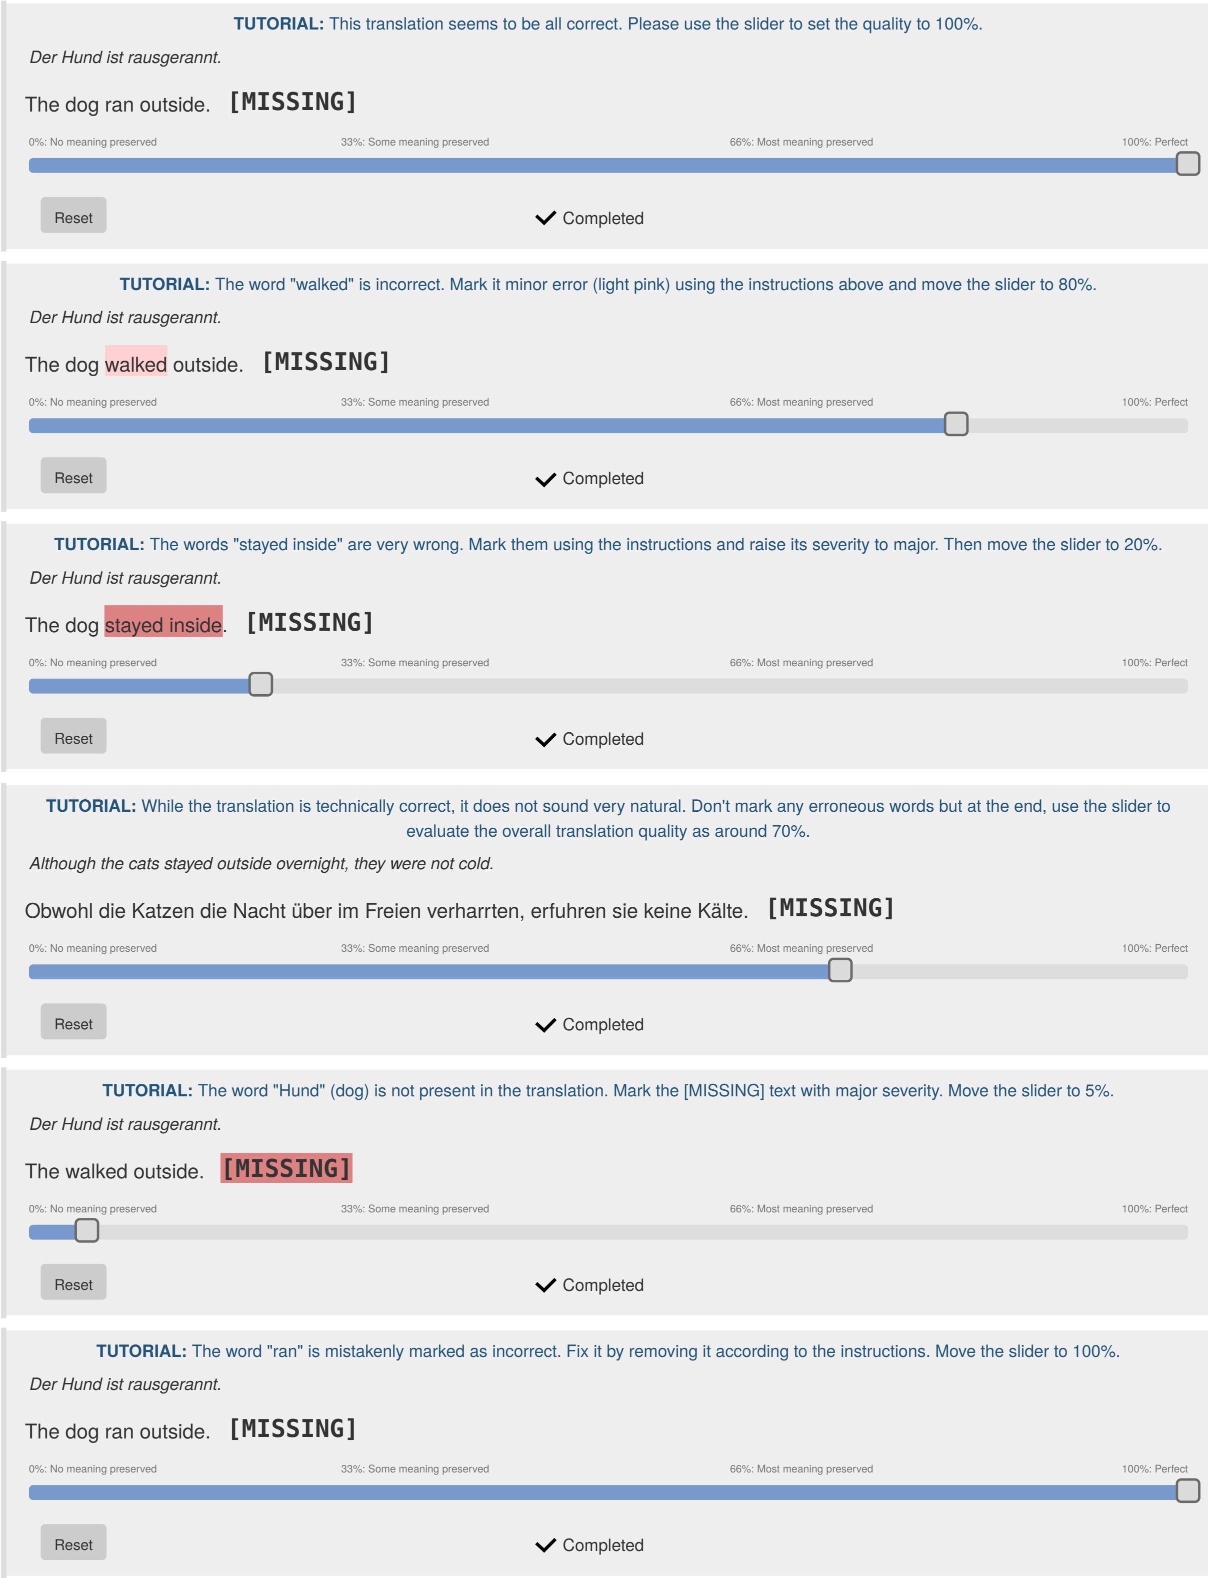

TUTORIAL: This translation seems to be all correct. Please use the slider to set the quality to 100%.

Der Hund ist rausgerannt.

The dog ran outside. **[MISSING]**

TUTORIAL: The word "walked" is incorrect. Mark it minor error (light pink) using the instructions above and move the slider to 80%.

Der Hund ist rausgerannt.

The dog walked outside. **[MISSING]**

TUTORIAL: The words "stayed inside" are very wrong. Mark them using the instructions and raise its severity to major. Then move the slider to 20%.

Der Hund ist rausgerannt.

The dog stayed inside. **[MISSING]**

TUTORIAL: While the translation is technically correct, it does not sound very natural. Don't mark any erroneous words but at the end, use the slider to evaluate the overall translation quality as around 70%.

Although the cats stayed outside overnight, they were not cold.

Obwohl die Katzen die Nacht über im Freien verharrten, erfuhren sie keine Kälte. **[MISSING]**

TUTORIAL: The word "Hund" (dog) is not present in the translation. Mark the [MISSING] text with major severity. Move the slider to 5%.

Der Hund ist rausgerannt.

The walked outside. **[MISSING]**

TUTORIAL: The word "ran" is mistakenly marked as incorrect. Fix it by removing it according to the instructions. Move the slider to 100%.

Der Hund ist rausgerannt.

The dog ran outside. **[MISSING]**

Neural Methods for Aligning Large-Scale Parallel Corpora from the Web for South and East Asian Languages

Philipp Koehn
Center for Language and Speech Processing
Johns Hopkins University
phi@jhu.edu

Abstract

We introduce neural methods and a toxicity filtering step to the hierarchical web mining approach of Paracrawl (Bañón et al., 2020), showing large improvements. We apply these methods to web-scale parallel corpus mining for 9 South and East Asian national languages, creating training resources for machine translation that yield better translation quality for most of these languages than existing publicly available datasets in OPUS. Our methods also generally lead to better results than the global mining approach of Schwenk et al. (2021).

1 Introduction

The goal of this work is to apply neural methods to the task of parallel corpus mining from the web and to create large useful parallel corpora for languages that have not received much attention. We demonstrate when applying these methods at scale, they yield better data resources than the two main existing approaches Paracrawl (Bañón et al., 2020) and CC-Matrix (Schwenk et al., 2021).

In addition to six Southeast Asian national languages (Burmese, Thai, Lao, Khmer, Vietnamese, Indonesian), we also included the South Asian languages Hindi and Nepali and the East Asian language Korean. These are mostly mid-resource languages, they have millions of speakers, mostly significant presence on the web, but have not received as much attention in the research community as European languages (Bañón et al., 2020), Indian languages (except, we also include Hindi) (Siripragada et al., 2020), Chinese (Ziemski et al., 2016; Zhai et al., 2020), and Japanese (Morishita et al., 2022).

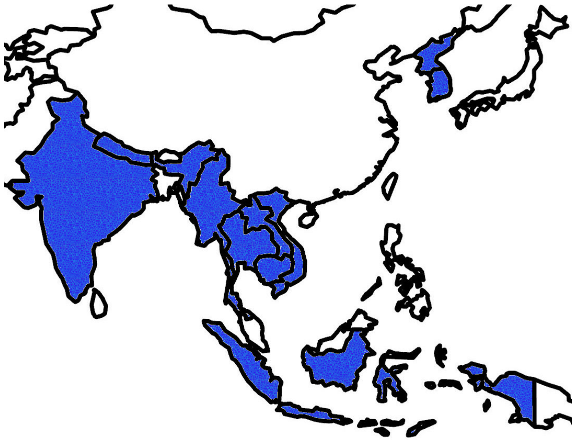

Figure 1: National languages covered: Hindi, Nepali, Burmese, Thai, Lao, Khmer, Vietnamese, Indonesian, Korean. We build parallel corpora for these languages paired with English.

Building on the work of the Paracrawl project (Bañón et al., 2020), we follow the same general sequence of steps: targeted web crawling, document alignment, sentence alignment, and parallel corpus filtering. Note that compared to the European-focused Paracrawl project, we deal with languages with fewer existing resources, mostly non-Latin scripts, and challenges such as lack of explicit word segmentation and even sentence boundary marking (in the case of Thai).

In contrast to Paracrawl, we deploy neural methods in three steps: document alignment with an efficient Marian (Junczys-Dowmunt et al., 2018) neural machine translation model distilled from the multilingual NLLB (NLLB Team et al., 2022) model, sentence alignment with Vecalign (Thompson and Koehn, 2019), and using LASER for parallel corpus filtering (Chaudhary et al., 2019). We also added a novel toxity filtering step.

We obtain large parallel corpora of 1.5–7.7 million sentence pairs per language. We validate the usefulness of these corpora by showing better machine translation quality of up to +18.2 BLEU compared to CC-Matrix (Schwenk et al., 2021) for 7 languages and up to +13.0 BLEU compared to other existing parallel corpora on OPUS[1] (Tiede-

[1] https://opus.nlpl.eu/

Proceedings of the Ninth Conference on Machine Translation, pages 1454–1466
November 15-16, 2024 ©2024 Association for Computational Linguistics

mann, 2009) for 6 languages (tied for another language). While this required significant computational resources, the effort was carried out using only CPUs and consumer-grade GPUs (GTX 1080ti).

2 Related Work

While the idea of mining the web for parallel data has been already pursued in the 20th century (Resnik, 1999), the initial large-scale efforts were limited to large companies such as Google (Uszkoreit et al., 2010) and Microsoft (Rarrick et al., 2011), or targeted efforts on specific domains such as the Canadian Hansards and Europarl (Koehn, 2005). More recently, large corpora have been released by broad web mining efforts, such as Paracrawl (Bañón et al., 2020) and CC-Matrix (Schwenk et al., 2021). A recent effort to assemble large-scale monolingual and parallel corpora is the EU Project High Performance Language Technologies (Aulamo et al., 2023).

Currently, there are two main approaches to extract parallel sentence pairs from web documents: hierarchical and global mining. In *hierarchical mining* (as in Paracrawl), the task is broken up into the steps of identifying websites with parallel text, document alignment within websites, sentence alignment within document pairs, and sentence pair filtering.

In contrast, in *global mining* (as in CC-Matrix), all content is split up into sentences, each sentence represented by a cross-lingual sentence embedding and stored in one index per language. Then, sentences in one language are used to query the index of sentences in another language, using nearest neighbor search. There are also efforts that lie in-between these two extremes, such as local mining in CC-Align (El-Kishky et al., 2020) where the hierarchical mining is followed up to the step of document alignment, and then sentences for each document are stored in an index and then queried regardless of the order of sentences in the document.

We follow the hierarchical mining approach. We believe that it leads to cleaner parallel corpora since it matches alignment with the underlying structure of the data. There has been varying amount of work on the steps in hierarchical mining. Matching documents pairs uses some similarity measure to compare the content of documents across languages. A common approach is to translate the non-English document into English and perform monolingual matching of words (Buck and Koehn, 2016) or n-grams (Dara and Lin, 2016; Uszkoreit et al., 2010). There have been some attempts to use document embeddings (Guo et al., 2019). Besides matching the URL (Le et al., 2016; El-Kishky et al., 2020) — e.g., `example.com/en/page.html` and `example.com/fr/page.html` — other structural information such the DOM-tree (Shi et al., 2006), links to the same images, links between pages, etc. have been rarely used.

Sentence alignment has been a rich field of research dating back to the 1990s (Brown et al., 1991; Gale and Church, 1993). This also requires a similarity measure, defined over sentences or sequences of sentences. Typical features are sentence length and matches in a bilingual dictionary (Moore, 2002; Varga et al., 2005). Sennrich and Volk (2010) translate the non-English sentence and match the translation against the English sentence using the BLEU score. Vecalign (Thompson and Koehn, 2019) is a sentence alignment method that relies on bilingual sentence embeddings and achieves linear run time with a coarse-to-fine dynamic programming algorithm.

Finally, a lot of effort has been spent on developing methods for filtering noisy parallel corpora which are particularly harmful for neural models (Khayrallah and Koehn, 2018). Four shared tasks were dedicated to this problem (Koehn et al., 2018, 2019, 2020; Sloto et al., 2023). Besides basic simple filtering rules based on sentence or token length and their ratios (Kurfalı and Östling, 2019; Soares and Costa-jussà, 2019), typically a scoring function is used. Popular methods are based on the scores obtained by force-decoding the sentence pair with a machine translation model (Junczys-Dowmunt, 2018), and the cosine distance between cross-lingual sentence embeddings (Chaudhary et al., 2019). Recently, the most successful approach are classifiers that distinguish between genuine parallel sentence pair and misalignments, typically based on neural sentence representations (Açarçiçek et al., 2020; Esplà-Gomis et al., 2020; Xu et al., 2020; Tan et al., 2023).

Filtering has been focused on impact on machine translation quality using traditional metrics. There has not been much published work on toxicity filtering (NLLB Team et al., 2022) — a task that is also hard to delineate and evaluate.

Model	Vietnamese			Nepali			Thai

Table 1: Speed/Quality trade-offs for different versions of NLLB, the model we distill. Translation time to translate the 1012 sentences of the Flores devtest set into English on a single GTX-1080 GPU (bottom). Official NLLB evaluations are in the top of the table. Based on these findings, we use the dense distilled 1 billion parameter model.

3 Methods

3.1 Targeted Crawling

We follow the Paracrawl approach of crawling a list of targeted web sites. The crawl list has been mainly obtained by using meta-data from CommonCrawl but also opportunistically extended over several years, e.g., by web searches for language-specific terms. Based on Commoncrawl statistics, any website that has pages in English and any of the targeted languages and somewhat balanced ratio was selected and crawled with `httrack`[2], an open source web copying tool. We only follow links to web pages on the same webdomain. We stop crawling after crawling 50,000 pages for each website, both to avoid downloading duplicate webpages and due to computational limitations of subsequent processing steps.

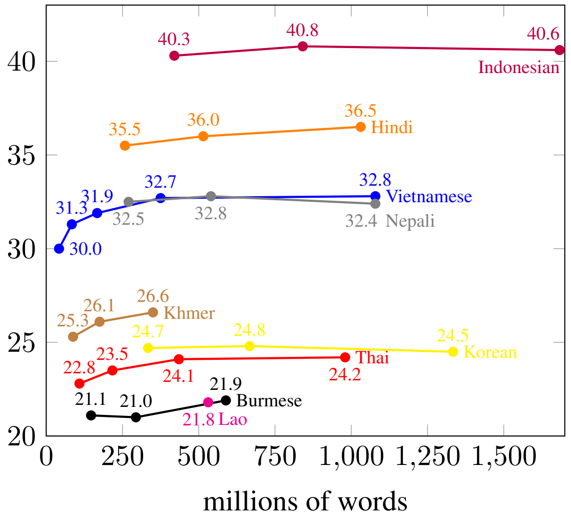

Figure 2: Amount of synthesized training data from the NLLB model and BLEU scores of distilled Marian models. For Lao, Khmer, and Burmese, we exhausted the monolingual data in mC4.

3.2 Distilling Machine Translation Models

Our document alignment approach requires the translation of all non-English web pages for a targeted language into English. Since this implies the translation of a massive volume of text, we need an efficient but still sufficiently high-quality machine translation model.

The multilingual machine translation model NLLB (NLLB Team et al., 2022) covers 200 languages, including all the languages we target here. It comes in versions with 600 million to 54 billion parameters. However, using even the smallest model would be computationally prohibitive given the scale of our effort and the limitations of our technical means. Hence, we decided to distill these models into an efficient model that can be run on CPU via data distillation. Specifically, we use the NLLB model to translate monolingual text and then use the resulting synthetic parallel corpus to train a faster model. The monolingual text for distillation is drawn from mC4[3] (Xue et al., 2021).

Table 1 shows machine translation quality scores and the time it takes to translate the 1012 sentences of the Flores-200 devtest set for three of our languages (Vietnamese, Nepali, and Thai) into English given different NLLB models. We explored the use of quantized parameters. However, we observed worse speed/quality trade-offs. We settled on using the dense distilled 1 billion parameter model. It

Korean	26.0	22.6	26.0	**26.5**

Table 2: BLEU scores for different data types for distillation: synthetic corpus generated by forward translation (X→English) or back translation (English→X). Forward translation fares better than backward translation, but combination of both is typically best.
We also checked if we can better system by adding OPUS data. This is the case for Khmer, Vietnamese, and Korean, so we use these system in our mining pipeline.

gives reasonable performance at translation speeds of about 500 words per second on GPU.

We explored how much data we need to distill to get a reasonable Marian system. As illustrated in Figure 2, system quality plateaus at around 1 billion words of distilled data. Note that we exhausted all monolingual data in mC4 for Lao, Khmer, and Burmese, so we distilled less data for these.

We generate synthetic parallel corpora by translating both from English and into English. The forward direction (X→English) is motivated by the idea of data distillation while backward translation (English→X) is well-established in the field of machine translation since it builds on authentic text on the target side. As shown in Table 2, we find that forward translation gives better results, but combining both forward and backward translation fares generally best.

We filter the synthesized corpus with LASER using a threshold of 1.05 (1.00 for Burmese and Lao, unfiltered for Hindi). See Section 3.5 for more details on this method. We also added all of OPUS to the training of Khmer, Vietnamese, and Korean distilled models. As shown in Table 2, adding OPUS data yielded better translation quality.

The configuration of Marian (Junczys-Dowmunt et al., 2018) is given in Appendix A. The model is trained with guided alignment training and a vocabulary shortlist. The translation model uses quantized parameters for efficient vector integer computations supported by Intel CPUs (8 bit, avx512). When translating web content, we observe translation speeds of about 1000 words per second in a single Intel Xeon Silver 4110 CPU core. Contrast that to 500 words per second on a GPU for the NLLB model: a roughly thousand-fold increase in translation speed when measured by sentences per compute core.

3.3 Document Alignment

Our document aligner follows the method by Buck and Koehn (2016). For a website where we found web pages in English and in the targeted language, we translate all the latter web pages into English and represent each document (i.e., web page) in form of word counts. Document similarity is measured by tf/idf-weighted cosine distance between these representations. A greedy algorithm iteratively finds the best matching document pair and removes them from the pool of documents. The process terminates if documents in either language are exhausted.

The main difference to the Paracrawl approach is the use of a very efficient neural translation model instead of a statistical Moses model. The neural model has higher translation quality and is faster.

3.4 Sentence Alignment

We used Vecalign (Thompson and Koehn, 2019) as sentence aligner. It uses the cosine-distance between LASER embeddings with modified CSLS scoring (normalizing by distance to randomly chosen neighbors). It is also constrained by the order of the sentences in the pair of documents. Just like other sentence aligners (Hunalign, Bleualign, etc.), it may skip and merge sentences but it is not allowed to reorder them. Hence, it combines a powerful sentence matching method with the structural bias coming from the fact that documents are in almost all cases translated in sequence.

Documents were split into sentences with NLTK's sentence tokenizer. Thai required special treatment due to its lack of marking of sentence boundaries. We used the library `pythainlp` (Phatthiyaphaibun et al., 2023) for sentence splitting. We use LASER3, the latest version (Heffernan et al., 2022), that supports all our languages.

3.5 Noise Filtering

The previous processing steps are geared towards high recall instead of high precision. In other words, we try to retain as much data as possible. This requires a final filtering step that removes

Language	1.00		1.05

Korean	228.1m	22.2	118.4m	**23.4**

Table 3: Impact of different thresholds in LASER-based filtering: Corpus size in million words and BLEU score.

noisy data, an open problem that has received much research attention.

We use LASER-based filtering (Chaudhary et al., 2019), using LASER3 (Heffernan et al., 2022). This method embeds sentences in a cross-lingual embedding space, so that an English sentence and its translation should have identical representations. Hence, the distance between an English sentence embedding and a non-English sentence embedding is a measure for their meaning similarity. The exact formula to compute similarity between the two embedding vectors is the cosine distance, normalized by how similar each vector is to its closest neighbors in the embedding space.

We carried out limited experiments with the filtering threshold and chose a value of 1.00 for Nepali, Burmese, Thai, Lao, and Khmer and 1.05 for Hindi, Vietnamese, Indonesian, and Korean. We note that the more permissive threshold (1.00) worked better for the smaller corpora (see Table 3). For some languages we tried even lower thresholds but that led to worse results.

3.6 Toxicity Filtering

While we are aiming to collect parallel data across the entire web, we do want to exclude toxic content, so that machine translation systems are not trained to produce offensive language. We narrow down the concept of excluded toxic content to pornographic web sites which not only feature derogatory and offensive language but are also often machine translated.

Toxicity filtering may be carried at several levels. We argue that filtering on the level of web sites will lead to the most robust results. Simple key word filtering on the sentence level has to contend with the fact that many words are ambiguous, and excluding all sentences that have, say, the word *sex* in them would eliminate many respectable uses of that term.

Hence, we take a more nuanced view of offensive vocabulary. We use tf/idf scores to identify English vocabulary that is typical for websites that have the substring *porn* in their domain name. This yields words that are very frequently used on such web sites compared to full crawl for a language pair. We start with a list of 100 terms for each language pair, merge that list and curate it to remove, for instance, terms that refer to ethnicities (e.g., *Asian*). This list comprises 141 words.

Using this words list, we proceed to filter out websites. We compute the average tf/idf score across all the words for each website, and if it is above a certain threshold (we use 0.02), we eliminate all content from that website.

4 Corpora

4.1 Corpus Statistics

We apply the processing pipeline to 9 languages. Table 4 gives detailed statistics. The pipeline succeeded to process between 5,854 (Burmese) and 32,765 (Vietnamese) website crawls. A small proportion (about 10%) of the crawls are repeat crawls, i.e., they crawled the same website again at a later time, typically after several months or even years.

The next step is document alignment, resulting in 492,723 (Lao) to 7,758,116 (Korean) document pairs. Then comes sentence alignment, creating a raw corpus of 7,513,409 (Lao) to 128,828,741 (Korean) sentence pairs.

This corpus is filtered and deduplicated. We report how many good sentence pairs are retained when applying filtering to corpora from each crawl — which also includes deduplication: ranging from 605,959 (Khmer) to 11,014,387 (Korean). Then, deduplication is done again on the corpus combined across all crawls, reducing these numbers further to 420,824 (Khmer) to 8,298,299 (Korean). These numbers are based on a filtering threshold of 1.05. For five of the languages we saw better results with a filtering threshold of 1.00, so we report these numbers as well. For Khmer, this retains 1,507,135 sentence pairs.

Working back from the filtered data, we can check how many document pairs had sentence pairs that survived quality filtering. For instance, this is the case for 4,035,376 of the 7,758,116 Korean–

Language	Crawls			Documents			Sentences

Korean	24,500	20,423	19,154	7,758,116	4,035,376	3,759,849	128,828,741	11,014,387	8,298,299	7,709,312

Table 4: Detailed statistics on the crawled datasets, in terms of number of crawls of websites, number of aligned document pairs, and sentence pairs. The numbers below *good* specify counts for these categories that have valid sentence pairs after LASER filtering with threshold 1.05 (extra rows for languages where we applied the threshold 1.00) and deduplication. For crawls and documents this number is inflated because the same good sentence pair may be in multiple documents and crawls. The deduplicated sentence pair count refers to a final global deduplication step. The table also reports these statistics after removing crawls due to toxic content.

Language	Ours	CC-Matrix	OPUS
Hindi	4.6m	15.1m	22.6m
Nepali	2.2m	19.6m	1.9m

(b) Number of English Words

Table 5: Size of parallel corpora, in millions, after length (≤80 words) and length ratio (≤9) filtering, compared to existing parallel data in OPUS (without CC-Matrix) and CC-Matrix.

English document pairs. Applying the same calculation for web crawls, 20,423 of the 24,500 Korean web crawls yielded at least one sentence pair in the final filtered corpus. Note that the number of crawls and documents after filtering is inflated because the same good sentence pair may be in multiple documents and crawls.

Finally, we remove toxic content from the corpus. This reduces only a small percentage of the data. The biggest reduction is for Korean–English, about 7%, from 8,298,299 to 7,709,312 sentence pairs.

4.2 Comparison to OPUS and CC-Matrix

We compare the size of the obtained corpora to pre-existing data sets in Table 5. We combined all corpora available in OPUS, the popular platform for parallel data. We separated out CC-Matrix (which is also available on OPUS) since it is the method that is most similar to our approach and it is also typically the largest corpus on OPUS. CC-Matrix collected parallel sentences by matching sets of sentences from CommonCrawl solely based on the similarity of their LASER embeddings.

The table shows the number of segments and number of English words for each language. We count the number of English words because it is a consistent measure across all languages and counting words for languages like Thai is problematic due to the lack of word spacing. The numbers are computed after another filtering step typically done for translation: we remove sentences longer than 80 words and sentence pairs where one sentence has more than 9 times as many words as the other.

Note that the sizes of the obtained corpora are smaller than CC-Matrix and only for Nepali,

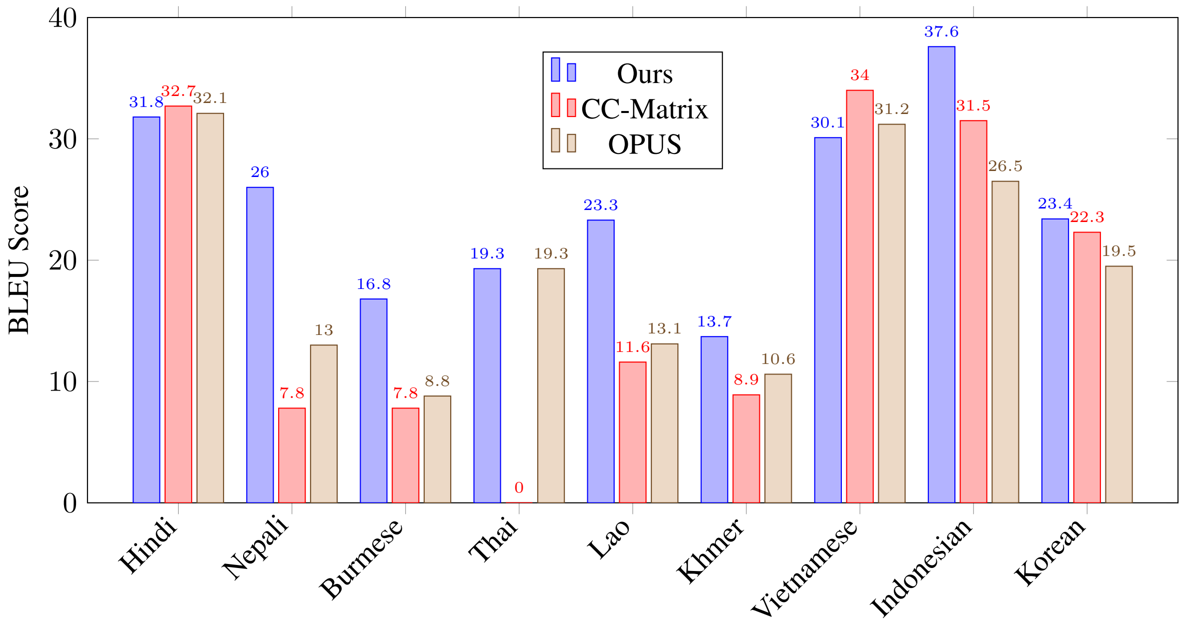

Figure 3: BLEU scores on neural machine translation systems build with our corpora, compared to existing corpora. We obtain better parallel corpora than anything previously existing for Nepali, Burmese, Lao, Khmer, Indonesian, and Korean, by a difference of +13.0, +8.0, +10.2, +3.1, +1.1 BLEU, respectively, compared to the better of CC-Matrix or OPUS (without CC-Matrix). Our Thai corpus matches OPUS, For Hindi and Vietnamese, existing corpora are better. CC-Matrix does not contain Thai.

Burmese, and Khmer bigger than what already exists in OPUS (excluding CC-Matrix). We obtain a larger Indonesian corpus than what exists in OPUS in terms of number of words but not in number of segments. Our smallest corpus is Khmer–English (1.3 million segment pairs, 23 million words), the largest corpus is Korean–English (8.2 million segment pairs, 118 million words). Note that CC-Matrix does not contain Thai.

5 Evaluation

Since our main motivation is to create parallel corpora for training machine translation systems, we evaluate them by training a system on each corpus and measuring each system's translation quality with spmBLEU (scarebleu `-tok flores200`) on Flores-200 (NLLB Team et al., 2022). We chose this test set and metric since they cover all our languages. Flores-200 comprises professional translations of English content drawn from Wikinews, Wikijunior, and Wikivoyage. We also computed scores with chrF++ which closely mirrors the spmBLEU results in terms of system ranking, so we do not report them here for sake of clarity.

Machine translation systems were trained using Marian (Junczys-Dowmunt et al., 2018) using the setup as for our distilled translation models (see Section 3.2).

Results are shown in Figure 3. By our measure, we obtain better parallel corpora than anything previously existing for Nepali, Burmese, Lao, Khmer, Indonesian, and Korean, by a difference of +13.0, +8.0, +10.2, +3.1, +1.1 BLEU, respectively, compared to the better of CC-Matrix or OPUS. Our Thai–English corpus is as good as what is currently in OPUS (±0). Only for Hindi and Vietnamese our data fares worse (–0.9 and –3.9 BLEU, respectively). We tried to investigate this discrepancy but did not gain any substantial insights.

It is worth noting that although our corpora are much smaller than CC-Matrix (by a factor of 2–8), we generally achieve better translation quality with them, indicating that the data is cleaner. These findings, however, allow only limited conclusions on the performance of the underlying methods (our hierarchical mining approach vs. the global mining approach of CC-Matrix) since they were executed on different, albeit quite similar, datasets (targeted crawling vs. pre-existing CommonCrawl).

A clean apples-to-apples comparison of the two approaches would be very difficult to carry given the scale of the data and the different data sources used. Nevertheless, we believe that the two large-scale efforts for these methods (CC-Matrix and

Language	Ours	CC-M	OPUS	OPUS+CC-M	Ours+OPUS	Ours+OPUS +CC-M	NLLB Distilled
Hindi	31.8	32.7	32.1	35.2	34.3	35.1	36.2
Nepali	26.0	7.8	13.0	21.5	25.2	25.8	33.6
Burmese	16.8	7.8	8.8	11.1	18.4	16.7	22.7
Thai	19.3	–	19.3	–	20.4	–	25.3

Indonesian	37.6	31.5	26.5	32.8	37.7	32.9	41.3
Korean	23.4	22.3	19.5	22.9	22.2	23.7	26.0

Table 6: Combining corpora: When combining our corpus with CC-Matrix and OPUS, we typically see improvements. The corpora are simply concatenated. The table reports spmBLEU scores on Flores-200 devtest for the models trained on the data.

ours) give strong evidence to the advantage of our approach.

6 Analysis

6.1 Combining Corpora

The three corpora we compare — OPUS, CC-Matrix, and ours — are obtained in quite different ways. Hence, we would expect that combining these corpora would lead to even better translation results.

Table 6 shows spmBLEU scores on Flores-200 devtest for the combinations OPUS+CC-Matrix, Ours+OPUS, and Ours+OPUS+CC-Matrix. For 3 languages (Khmer, Thai, and Korean) and almost Hindi–English, we do achieve the best results this way, while for Vietnamese the addition of our data slightly hurts (–0.5 BLEU) and for 3 languages (Burmese, Lao, Indonesian) the addition of the CC-Matrix corpus leads to worse results (–1.7, –1.3, and –4.8, respectively).

Note that we simply concatenated the corpora, and the CC-Matrix corpus has bigger impact on the results due to its typically larger size. There are many other ways to combine and weigh corpora which should be explored in future work by any researcher using this data.

6.2 Comparison with NLLB Distilled Data

Table 6 also contrasts the quality of the systems trained on the various combinations of corpora with systems built on data distilled with the NLLB model (these are the same numbers as in Table 2). Notably, the distilled data yields better quality systems for all languages except for Vietnamese. This observation is mirrored by Finkelstein et al. (2024)'s finding that a distilled data set synthesized from a PaLM-2 Bison LLM model outperforms WMT training data.

Language	Ours		Statistical	
	BLEU	Words	BLEU	Words
Nepali	26.0	32m	23.8	31m
Burmese	16.8	28m	11.5	13m
Khmer	13.7	23m	9.4	9m
Vietnamese	30.1	94m	31.1	123m
Korean	23.4	118m	21.8	88m

Table 7: Comparison of our neural methods with the statistical Paracrawl methods for document and sentence alignment.

However, it would be wrong to conclude that there is no need for crawled data and we should instead build our systems with synthetic data. Models such as NLLB rest on a vast collection of diverse data sources for training to achieve high quality, so crawled data is required to get started.

Nevertheless, this finding illustrate the complex data selection choices when it comes to building the best possible system for a given language pair and domain. We expect that future work will explore how to best combine and sequence the diverse set of data resources in more detail.

6.3 Comparison with Statistical Methods

Our pipeline makes two changes to the Paracrawl pipeline: use of a neural machine translation model for document alignment and sentence alignment based on neural sentence embeddings. Paracrawl uses a Moses-based statistical machine translation model and the lexicon-based Hunalign sentence aligner.

By running both the original pipeline and the pipeline with these changes, we can directly compare if the changes lead to an improved corpus. Results are shown in Table 7. We carried out this comparison only for 5 of the 9 languages due to the computation cost involved. Nevertheless, we covered both lower-resourced and higher-resourced languages. Except for Vietnamese (–1.0 BLEU), the neural methods lead to better results by a difference of +1.6 BLEU (Korean) to +5.3 BLEU (Burmese).

Since Vietnamese is an outlier here again (our new parallel corpus is also worse than CC-Matrix), we checked the execution of our pipeline for that language but could not find any obvious errors.

6.4 Computational Cost

We processed a total number of 127,064 web crawls. The size of the crawls has a very skewed distribution, with relatively few large crawls and a long tail of crawls that have only few web pages in the targeted languages. So, we can only make rough estimates about the processing cost.

Having said that, our document aligner takes about half an hour on average, of which half is spent on translation, summing up to about 2600 CPU days.

The sentence aligner takes about 6 minutes on average, the biggest computational cost being embedding of sentences with LASER, summing up to about 500 GPU days.

There is also signifcant time spent on extracting text from the web pages — we do not have reliable numbers on this. Note that this involves processing web crawls for which we ultimately do not find any content in the targeted languages and that are not included in our statistics here.

Sentence pair filtering takes tens of hours, training a neural model on a dataset takes a handful of days at most. Both these steps require a GPU.

7 Open Source Release

The corpora are available at the offical Paracrawl website http://www.paracrawl.eu/. Rachel Wicks created a document-aligned version of the corpus which is available at https://huggingface.co/datasets/jhu-clsp/paradocs using the approach outlined by Wicks et al. (2024).

8 Limitations

The motivating goal for this work was to create high-quality parallel corpora for important languages that have previously not received much attention. The languages were also chosen due to their large difference to English, often even using non-Latin writing systems.

Given the vast computational cost involved, we only have limited results on the comparison of methods. For instance, a more fine-grained demonstration of the effectiveness of the document aligner and sentence aligner in isolation would be useful. We do show that both in combination lead to better outcomes.

There are many more experiments that could be done with the data, such as more closely tracking how the quality of the machine translation model impacts the effectiveness of the document aligner. Another big area for follow-up research is how to best combine and filter different corpora for a language pair.

We are aware that much of the crawled data may stem from machine translation (Thompson et al., 2024). However, we argue that data quality is a better guide than the origin of the translations. Hence, we take a holistic filtering approach. See also work by Kreutzer et al. (2022) and Ranathunga et al. (2024) on the discussion of quality of web-crawled corpora.

Finally, the only measure of translation quality that we offer is the translation quality of a machine translation system trained on a dataset. While this is ultimately what is most important for the consumer of this data, it also ignores many other aspects of data quality, such as toxic content or bias. We added a toxicity filtering step but did not evaluate it, partly due to the vagaries of this task.

9 Risks

Our corpora may include harmful and violent content. It may also contain content that is copyrighted. We claim that our use of web-crawled data follows fair-use exceptions but we will remove data if any specific requests are made, thus slightly altering the composition of the data.

10 Conclusions

We deployed neural methods to the Paracrawl processing pipeline, demonstrated their superiority against the previous statistical methods and the global mining approach, added a novel toxicity filtering method, and created high-quality parallel corpora for South and East Asian languages. We show that for 7 of the 9 languages our data leads to improvements in translation quality when building neural machine translation systems, for some languages dramatically.

We also spend significant effort on distilling NLLB models, reducing the computational cost by roughly doubling translation speeds, while using only a single CPU core vs. a full GPU — or a thousand-fold speed increase when calculated in terms of compute cores.

We release[4] all our corpora and models open source, with a liberal license for commercial and research use.

Abstract

Recent advancements in NLP have resulted in models with specialized strengths, such as processing multimodal inputs or excelling in specific domains. However, real-world tasks, like multimodal translation, often require a combination of these strengths, such as handling both translation and image processing. While individual translation and vision models are powerful, they typically lack the ability to perform both tasks in a single system. Combining these models poses challenges, particularly due to differences in their vocabularies, which limit the effectiveness of traditional ensemble methods to post-generation techniques like N-best list re-ranking. In this work, we propose a novel zero-shot ensembling strategy that allows for the integration of different models during the decoding phase without the need for additional training. Our approach re-ranks beams during decoding by combining scores at the word level, using heuristics to predict when a word is completed. We demonstrate the effectiveness of this method in machine translation scenarios, showing that it enables the generation of translations that are both speech- and image-aware while also improving overall translation quality[1].

1 Introduction

A broad spectrum of Large Language Models (LLMs) are being developed at an increasing pace, with efforts focused alone or together on adapting them to specific domains (Roziere et al., 2023; Bolton et al., 2024; Colombo et al., 2024), enhancing their ability to process multiple modalities (Liu et al., 2023; Tang et al., 2023; Li et al., 2024; Beyer et al., 2024), or training general-purpose LLMs using high-quality data, advanced architectures, and larger numbers of parameters (Touvron et al., 2023; Dubey et al., 2024; Jiang et al., 2023a; Mesnard et al., 2024). As a result, numerous models are now publicly available, each with its own unique strengths and weaknesses.

Many use cases, such as image-aware translation in movie subtitling, require combining these strengths because visual cues can be essential for disambiguating the text and ensuring accurate translations.. Currently, LLMs, such as Tower (Alves et al., 2024), Alma-R (Xu et al., 2024a), and Madlad-400 (Kudugunta et al., 2024), excel at translation tasks (Kocmi et al., 2024), while models like PaliGemma (Beyer et al., 2024) and LLava (Li et al., 2024) are leading in vision-related tasks. To effectively address image-aware translation, it is essential to harness the strengths of both translation and vision models.

One way to address such a task is to train a multimodal LLM to enhance its translation capabilities without compromising its vision abilities or vice versa. However, this approach requires additional training and task-specific data. Another approach is to leverage ensembling the two models via shallow fusion (Gulcehre et al., 2015) or re-ranking the N-best list (Hasan et al., 2007). The disadvantage of shallow fusion is that it assumes both models share the same vocabulary, which is often not the case with current open-source models.

Additionally, re-ranking the N-best list is insufficient because it doesn't allow models to influence each other during decoding. For example, in Figure 1, translating from English to gender-marked language French using audio and transcript shows this limitation. The Speech Translation (ST) model correctly uses the speaker's voice to translate "fell" into the right gender form but misidentifies the name "Ples." On the other hand, the Machine Trans-

En tant qu'étudiante de premier cycle, je suis tombée amoureuse d'une d'elles, Mme Platt.

En tant qu'étudiante de premier cycle, je suis tombée amoureuse de l'une d'entre elles, Mme Ples.

As an undergraduate student, I **fell** in love with one of them... **Mrs. Ples**

Comme un étudiant de premier cycle, je suis tombé amoureux de l'un d'eux... Mme Ples.

Quand j ' étais étudiante en licence, je suis **tombée** amoureuse de l'un d'eux ... **Mme Ples**.

Figure 1: The source sentence to be translated is ambiguous because the translation of the word **"fell"** can be either masculine (**"tombé"**) or feminine (**"tombée"**), depending on the speaker's gender. Seamless-Large V2 (Barrault et al., 2023) utilizes audio cues to correctly determine the gender form but struggles to accurately translate the name **"Mrs Ples"** using audio alone. In contrast, the text translation model Madlad-400-10b-mt (Kudugunta et al., 2024) relies on the gold transcript to correctly translate the name but fails to resolve the gender ambiguity. By combining both models using our approach, the translation correctly captures both the gender form and the named entity.

lation (MT) model correctly translates the name but can't use the speaker's voice for gender disambiguation. Thus, re-ranking falls short, as the correct forms may not even be in the N-best list due to low probability with missing cues.

Furthermore, re-ranking during the decoding process is impractical because the hypotheses are partial and may not align with the tokenization of the ranker model, leading to incorrect probability estimates (Section 2.1). Thus, resolving vocabulary mismatches by mapping the vocabulary of one model to another (Minixhofer et al., 2024; Xu et al., 2024b) is necessary to allow the merging of probabilities during decoding. However, this approach requires significant additional training steps and can lead to deviations from the original model. Therefore, developing a plug-and-play approach that seamlessly combines different models without requiring additional training or task-specific data is highly advantageous.

This work aims to enable the ranker model to influence the decoding process (online) without any constraints compared to conventional offline N-best list re-ranking. We address this by ensuring that the ranker model only influences the scores for completed words and not for the last word if it is unfinished. Additionally, we propose using the ranker model to determine whether the last word is finished rather than relying on look-ahead approaches to maintain efficiency.

Our main contributions are summarized below:

1. **Online Re-Ranking Algorithm**: We introduce a novel re-ranking algorithm that operates at the word level during decoding at sub-word level, allowing for more accurate tokenization and better integration of information from different models

2. **Plug-and-Play Approach**: Our method does not require additional training or task-specific data, making it a flexible and practical solution for integrating multiple models with different strengths.

3. **Context-aware Translations**: We demonstrate through experiments including targeted multimodal test sets, which require information from both modalities, that our approach effectively combines the strengths of different models and improves translation quality (Illustrated in Figure 1).

2 Methodology

Given that many models are trained on different tasks, architectures, modalities, and data types, combining these models to leverage inputs from multiple modalities and facilitate knowledge sharing is highly beneficial. Moreover, it is ideal if the ensembling approaches satisfy the following constraints: 1) It should not rely on shared vocabularies for flexibility in choosing models and maximizing potential combinations. 2) Effective knowledge sharing should occur during decoding to better navigate the search space exploiting this knowledge at each step. 3) Avoid requiring additional training, parameters, or major dependence on task-specific data for maximum applicability and not cause deviations from the pre-trained model.

This section presents our algorithm for ensembling models with different vocabularies that satisfy the aforementioned constraints. First, we explain why re-ranking partial hypotheses can lead to incorrect probability estimates if the word is incomplete. Next, we introduce and justify a heuristic-based approach that predicts whether a hypothesis is at the end of a word, allowing for accurate re-ranking of completed words in partial hypotheses. Finally, we formally describe the complete algorithm, detailing how we merge probabilities from different models and how this process can be integrated with decoding strategies.

2.1 Challenges of Re-Ranking Partial Hypotheses

Current Neural Machine Translation (NMT) and LLM-based models can utilize various tokenization methods, such as byte-pair encoding (BPE) (Sennrich et al., 2016) or SentencePiece (Kudo and Richardson, 2018). These methods often result in distinct vocabularies due to variations in the data and tokenizer training processes. Despite these differences, techniques like re-ranking can still enable estimating the probability of sentences generated from another model. This is achieved by detokenizing the hypothesis from generator model and re-tokenizing it using the ranker model's vocabulary. This process enables the ranker model to produce accurate probability estimates based on its own tokenization scheme.

Now, consider the case of re-ranking while the hypotheses are still being decoded. Assume we have model $\mathcal{M}_G$ (the generator) and model $\mathcal{M}_R$ (the ranker), each using different tokenizers assign all the tokens in the sentence "Decoding is awesome" with a probability of p for a particular input. However, $\mathcal{M}_G$ tokenizes the sentence with sub-word tokens as "Dec od ing _is _awe some," while $\mathcal{M}_R$ would tokenize it as "Dec od ing _is _awes ome."

If we attempt to re-rank during the decoding process, $\mathcal{M}_R$ will provide correct probability estimates up until "_is" is generated. However, when the generator predicts "_awe," $\mathcal{M}_R$ would incorrectly estimate the probability because it expects "_awes" instead. Even though both models aim to generate the same sentence, this tokenization mismatch leads to incorrect probability estimates during the decoding process, making online re-ranking challenging.

2.2 End-of-Word Prediction in Decoding for Accurate Re-Ranking

While the partially generated hypothesis cannot be accurately ranked at every time step, consider the cases when each word is finished. At that time, we can re-rank the complete hypothesis as the last word is fully generated and the ranker model can tokenize the completed word as it would have done naturally, thereby providing accurate probability estimates. If we know that the last word is incomplete, we can use this information to wait and only rank the previously completed words. Knowing the end of the word enables more precise re-ranking during decoding, even with models that use different tokenization schemes.

Nonetheless, a significant challenge remains: how do we determine when the last word is completed? If the tokenizer places spaces at the right of characters, we could check the predicted token to see if it includes a space, signaling the end of a word. However, this approach is not universal, as many tokenizers do not follow this pattern, and we aim to develop a tokenizer-agnostic solution.

One alternative is to perform a look-ahead step to check if the word has been completed, but this method is also sub-optimal, as it would require decoding twice for each step in the generation process, significantly increasing computational complexity and reducing efficiency. We need a more efficient and generalizable method to determine when a word has been completed during decoding.

To address these challenges, we propose using the ranker model to predict the next token and determine if the word has been completed. This approach offers two key advantages.

Firstly, if the ranker model predicts a space as

Algorithm 1 Computing merged score of candidate with generator and ranker models.

```
procedure MERGESCORE
    Input: Generator tokens $g_1, g_2, g_3, \ldots, g_n$, Reranker tokens $r_1, r_2, r_3, \ldots, r_m$, Generator Model $\mathcal{M}_G$, Ranker model $\mathcal{M}_R$, Generator Input $\mathcal{I}_G$, Ranker Input $\mathcal{I}_R$, Re-ranking weight $\alpha$,
    Output: $merged\_score$
    $next\_tok \leftarrow \arg\max \log \mathcal{P}(y|r_1, \ldots, r_m; \mathcal{I}_R; \mathcal{M}_R)$
    if $next\_tok[0]$ == "_" or $next\_tok$ == "<eos>" then
        $full_G \leftarrow \frac{1}{n} \sum \log \mathcal{P}(g_1, g_2, \ldots, g_n|\mathcal{I}_G; \mathcal{M}_G)$    ▷ Generator Score for all words
        $full_R \leftarrow \frac{1}{m} \sum \log \mathcal{P}(r_1, r_2, \ldots, r_m|\mathcal{I}_R; \mathcal{M}_R)$    ▷ Ranker Score for all words
        $merged\_score \leftarrow (\alpha) \times full_G + (1-\alpha) \times full_R$
    else
        $[g_1, \ldots, g_j], [g_{j+1}, \ldots, g_n] \leftarrow$ split_candidate$(g_1, \ldots, g_n)$    ▷ Last word from j+1 token
        $[r_1, \ldots, r_k], [r_{k+1}, \ldots, r_m] \leftarrow$ split_candidate$(r_1, \ldots, r_m)$    ▷ Last word from k+1 token
        $prev_G \leftarrow \frac{1}{j} \sum \log \mathcal{P}(g_1, g_2, \ldots, g_j|\mathcal{I}_G; \mathcal{M}_G)$    ▷ Generator Score for previous words
        $prev_R \leftarrow \frac{1}{k} \sum \log \mathcal{P}(r_1, r_2, \ldots, r_k|\mathcal{I}_R; \mathcal{M}_R)$    ▷ Ranker Score for previous words
        $prev_{GR} \leftarrow (\alpha) \times prev_G + (1-\alpha) \times prev_R$
        $last_G \leftarrow \sum \log \mathcal{P}(g_{j+1}, \ldots, g_n|\mathcal{I}_G; \mathcal{M}_G)$
        $merged\_score \leftarrow \frac{1}{n}[prev_{GR} \times j + last_G]$    ▷ Re-normalized merged score
    end if
end procedure
```

the next top character, it indicates that the current last word has been completed. The hypothesis will be tokenized correctly, given that it is the prediction from the ranker model itself. Secondly, this prediction can be done together with the re-ranking process by simply also predicting the next token given the previous tokens of the current hypothesis to the ranker model.

This method is more efficient than the look-ahead approach, requiring only one pass of the generator and the ranker model. In contrast, the look-ahead method would require two passes of the generator and one pass of the ranker model. Using the ranker model in this way, we can ensure proper tokenization and accurate probability estimates during the decoding process (online) without additional computational overhead.

2.3 Integrating Online Re-Ranking with Search

This section formalizes achieving online re-ranking at a word level using beam search as an example of a decoding strategy. Note that the approach can also be applied to other strategies, with slight modifications when necessary.

A set of candidate sequences is typically maintained during the search, with the number of candidates equal to the configured beam size b. At each time step, for each of the b candidate sequences, the model computes likelihood scores for all possible token extensions based on the vocabulary size V. This results in a total of $b \times V$ possible extensions. From these $b \times V$ extensions, the top b sequences with the highest scores are selected to form the new set of candidate sequences. This process is repeated iteratively, updating the candidate sequences at each step until enough beams are generated that include end-of-sentence tokens or until a predefined length limit is reached.

To enable re-ranking during the decoding process, we need to adjust the scores of the possible extensions using the ranker model. Directly calculating the likelihood of all extensions would be computationally impractical. Therefore, we introduce a new parameter *topk*, which selects the top *topk* extensions for each beam during re-ranking.

Hence, at each time step, the generator model calculates the likelihood scores for all V possible extensions for each of the b candidate sequences, resulting in $b \times V$ extensions. Instead of re-ranking all $b \times V$ extensions, the top $topk$ extensions with the highest likelihood scores are selected for each beam. Thus, only $b \times topk$ extensions are considered during re-ranking. For the selected $b \times topk$ extensions, the ranker model estimates their scores and combines them with the original generator scores. For the remaining $b \times (V - topk)$ extensions, the scores are set to $-\infty$ (logically equivalent to discarding them) since they would not be selected in the top beams.

This method significantly reduces computational complexity while allowing effective re-ranking of the most promising candidate extensions, improving the decoding process.

At every decoding step, the problem can be reformulated as determining the merged score of the top candidates according to both models.

When calculating the merged score during decoding, it's essential to exclude the ranker model's probability if the last word in the current beam is incomplete. This prevents incomplete words from skewing the final score. For beams with incomplete final words, we combine the joint scores of the preceding words with the generator's score for the last word, ensuring proper normalization to address scale differences between finished and unfinished beams.

After computing the merged scores, we select the top extensions and repeat the process until all beams reach the end-of-sentence token. This method ensures that the final translation is based on fully formed words, optimizing the ranker model's effectiveness and maintaining consistent scoring across all candidates.

2.3.1 Unified Scoring with Generator and Ranker

The algorithm to compute the merged score is formally defined in Algorithm 1 and explained below.

Let us consider two models: the Generator $\mathcal{M}_G$ and the Ranker $\mathcal{M}_R$. Let $\mathcal{C}$ denote the current candidate for re-ranking and inputs $\mathcal{I}_G$ and $\mathcal{I}_R$ for $\mathcal{M}_G$ and $\mathcal{M}_R$ respectively.

Let the full candidate $\mathcal{C}$ consist of tokens $g_1, g_2, g_3, \ldots, g_n$ and $r_1, r_2, r_3, \ldots, r_m$ according to $\mathcal{M}_G$ and $\mathcal{M}_R$, respectively. Note that n and m denote the length of the sequence, and they may differ due to different tokenization.

The key idea is to rank and merge scores for completed words. We use the ranker model to predict the next token and determine if the last word is finished (**Line 4**).

If the last word is finished: We can calculate the probability of the full sequence in this case, similar to the case of N-best list re-ranking. First, we calculate the likelihood of the candidate by averaging the log probabilities for both the generator and the ranker (**Line 6-7**). Then, we merge the scores from both models to determine the final score for the candidate sequence using a hyper-parameter α for weighting (**Line 8**). This combined score considers the estimates from both models, allowing for contributions from both models.

If the last word is incomplete: We cannot rank the last word due to potential incorrect tokenization. However, we can still estimate the tokens preceding the last word using the ranker model and merge their probabilities. First, we split the candidate into previous and last words based on the ranker and generator (**Lines 10-11**). We compute the merged score for the previous words using the weighting parameter α (**Lines 12-14**). For the last word, we rely solely on the generator's scores. To address length normalization issues when combining scores from both models, we re-normalize the merged score for the previous words by multiplying it by the length of the previous word tokens j from the generator, adding the last word's score, and normalizing by the total length n (**Lines 15-16**).

This integration process ensures that the rerankers are utilized at the appropriate decoding stages, thereby enhancing the overall quality of the generated sequences by combining the strengths of both models.

3 Test Suites

The major advantage of combining models with different vocabularies zero-shot is that it leverages the strengths of available pre-trained models to generate more accurate and robust output. This is particularly relevant in multimodal scenarios, where unimodal systems excel in their respective modalities but are weaker or incapable of processing other modalities. Furthermore, it can also enhance quality compared to N-best list re-ranking when used as an ensembling technique as it waits until the complete sequence is generated. Hence, to validate our approach, we consider three MT scenarios as a test bed where quality can be improved by combining different sources and evaluating with targeted test sets that require information from both models. An overview of test suites is provided in Table 1.

3.1 Unimodal MT

We evaluate the use case of ensembling different LLM models to enhance translation quality. This is particularly relevant given the rapid development of various translation LLMs, where combining different systems can improve quality and robustness. We use the WMT 2022 *English* → *German* test set (Kocmi et al., 2022) to validate our approach and focus solely on assessing translation quality.

Test Set	Language Pair	# Examples	Phenomena
MuST-SHE	*En* → *Fr*	315 (1108)	Gender Disambiguation Translation
CoMMuTE	*En* → *De*	300	Word Disambiguation Translation
WMT22	*En* → *De*	2037	Translation

Table 1: Overview of test suites. For MuST-SHE, 315 examples are utterances where information is available in audio. However, we use the full test set with other types of bias when reporting translation quality.

3.2 Multimodal MT

Translating from English to gender-marked languages is challenging when the source text lacks clear gender cues. To evaluate bias in current NMT systems, Bentivogli et al. (2020) developed the *MuST-SHE* test suite, which includes examples with varying forms of gender bias. This suite features cases where gender information is conveyed through audio cues, such as the speaker's voice.

While End-to-End ST systems can handle such cases, they often fall short compared to advanced translation LLMs (Agarwal et al., 2023). Therefore, we use MuST-SHE for *English* → *French* to investigate if combining ST and translation LLMs can improve translation quality and address gender ambiguity.

Similarly, images can assist in disambiguating text and enhancing translation quality. However, translation LLMs typically do not process images, and vision LLMs alone are inadequate for translation tasks. We combine these models to leverage their strengths for better image-aware translations.

Existing vision translation test sets often lack ambiguity, making image inputs unnecessary (Vijayan et al., 2024). To address this, Futeral et al. (2023) introduced CoMMuTE, which features ambiguous source sentences with two images and their translations. We use CoMMuTE for *English* → *German* translation in a generative framework to evaluate if images can enhance translations without compromising overall quality.

4 Results

This section presents the experiments conducted using our ensembling approach across various test suites. Since each test suite has a distinct experimental setup, we will address them individually. First, we will specify the models and evaluation metrics applied in each scenario. Then, we will present the results and highlight our main findings.

4.1 Ensembling for Improving Translations

Models: We aim to combine two models that excel in translation but possess different strengths. For this purpose, we chose the *Madlad-10B*[2], an encoder-decoder architecture trained on extensive parallel data, and *ALMA-13B-R*[3], a decoder model trained using contrastive preference optimization and selecting high quality data (Xu et al., 2024b).

Metrics: As the models that we would like to ensemble are high quality, we report with several neural metrics to reliably validate the improvements. For reference-based we report with COMET (Rei et al., 2022a) and BLUERT (Sellam et al., 2020; Pu et al., 2021) whereas for reference-free we report with COMET-KIWI (Rei et al., 2022b), COMET-KIWI-XXL (Rei et al., 2023) and XCOMET-XXL (Guerreiro et al., 2023) metrics.

Hyper-parameters: We set the re-ranking weight α to 0.5 given that both models have high quality and should be weighted equally. Furthermore, we set the *topk* to 5 and the number of beams for the generator as 5.

To validate our combined model and online re-ranking approach, we compare it against several baselines. First, we check if the ensemble outperforms each individual model. Next, we evaluate if our method surpasses offline re-ranking techniques, indicating a more effective ranker influence and improved search space exploration during decoding.

We evaluate our approach using N-best list re-ranking, with *Madlad* as the generator and *Alma* as the ranker. We generate an N-best list of 25 hypotheses with α set to 0.5 to facilitate a fair

comparison between offline and online re-ranking methods. Additionally, we test a scenario where the N-best lists from both models are concatenated and jointly re-ranked on 50 hypotheses. We reports the results for the baselines and our approach in Table 2.

Ensembling enables to reach state-of-the-art quality: Both *Madlad* and *Alma* produce high-quality translations, though they still lag behind GPT-4 across all metrics. However, after applying offline re-ranking, their performance improves consistently, becoming competitive with GPT-4. When using our online re-ranking approach, the ensemble outperforms GPT-4 across all metrics and shows our proposed approach can improve the translation quality by a substantial margin.

Online re-ranking outperforms offline joint re-ranking: When *Madlad* serves as the generator and *Alma* as the ranker in our approach, the results are superior to those achieved with joint re-ranking, where both models are used simultaneously. Our approach enhances knowledge sharing and collaboration during the decoding process, leading to better translation quality.

4.1.1 Quality of N-best list

The primary motivation behind our approach was to influence the decoding process in real-time, rather than waiting until the end. If this is effective, we expect the N-best list to improve with online re-ranking. Additionally, using quality estimation should enhance the selection of the best hypothesis from the N-best list. To validate this, we utilize COMET-KIWI-XXL for selecting the best candidate from the top 5 beams of *Madlad*, comparing scenarios with and without online re-ranking and report the scores in Table 3.

We observe that integrating quality estimation significantly enhances Madlad's performance across all metrics. Using COMET-KIWI-XXL to select the best candidate from the top 5 beams improves score from $82.65 \rightarrow 86.45$. This improvement is also evident in the BLUERT score, increasing from $76.79 \rightarrow 77.78$. Additionally, comparing the top 5 beams with our approach, we find that the quality is superior, demonstrating that the early influence of *ALMA* in decoding. Furthermore, this allows to integration of multiple NMT models to generate the N-best list together and later combined with quality estimation for maximum performance.

4.2 Speech-Aware Translations

Models: To tackle gender ambiguity in text translation using speaker voice information, we combine a robust text translation model with a speech-based model that excels at disambiguating gender, even if it is not as strong in translation. We use the *Madlad* model (Kudugunta et al., 2024) for high-quality text translation with gold transcript and the *Seamless*[4] model for speech translation. Our approach employs *Madlad* as the *generator* and *Seamless* as the *ranker*, allowing us to leverage the speech model's ability to correct gendered forms in the translation.

However, we observed that the *Seamless* model exhibited a bias toward the masculine gender and struggled to effectively resolve gender ambiguities using speech. To mitigate this, we conducted additional fine-tuning using LoRA (Hu et al., 2021) on a balanced speaker dataset derived from MuST-C (TED talks) with gender annotations (Di Gangi et al., 2019; Gaido et al., 2020) (Training details in Appendix A.1). We remove talks that are present in MuST-SHE for no overlap. This "debiasing" process improved the model's ability to disambiguate gender based on speech. Consequently, we use the *Madlad* and adapted *Seamless* models to generate high-quality, speech-aware translations.

Metrics: To evaluate the effectiveness of our approach in disambiguating gender and improving translation quality, we use several key metrics. For gender disambiguation, we follow the methodology of Bentivogli et al. (2020) and report two metrics: accuracy (correct gender form is present) and coverage (either gender form is present).

For overall translation quality, we report BLEU (Papineni et al., 2002), ChrF2 (Popović, 2016) calculated using SacreBLEU (Post, 2018), and COMET (Rei et al., 2022a) (*wmt22-comet-da*) for brevity.

Additionally, we report *Sensitivity*, which measures the difference between the scores of correctly and incorrectly gendered references, as suggested by Bentivogli et al. (2020).

Hyper-parameters: For decoding with *Madlad*, we use beam search with 5 beams. Our proposed algorithm involves two key parameters: α and $topk$. We set $topk$ to 5, resulting in a total of 25 candidates being ranked by *Seamless* at each step.

We optimized α through grid search on the MuST-C development set (Appendix A.3) via offline re-ranking and setting it to 0.8 based on these results. We also create an N-best list of 25 hypotheses with α at 0.8 for offline comparison and perform joint re-ranking on the combined 50 N-best lists. Results are summarized in in Table 4.

***Madlad* and *Seamless* complement each other:** *Madlad* excels in overall translation quality (83.5) compared to *Seamless* (79.31). While *Seamless* initially favors masculine terms, fine-tuning on balanced data improves overall quality to 80.48, significantly reducing masculine bias (90.44 to 65.89) and increasing feminine representation (25.92 to 50.18). Thus, the adapted *Seamless* demonstrates improved gender disambiguation, though *Madlad* remains superior in overall translation. Hence, combining the models can be highly beneficial.

Online re-ranking improves overall translation quality: After re-ranking with N-best list, we see that the translation quality is improved when *Madlad* as a generator and *Seamless Bal* as a ranker model ($83.50 \rightarrow 83.66$). In the opposite scenario where *Seamless Bal* uses *Madlad* as a ranker model, the quality also improves ($80.48 \rightarrow 81.31$) but is lower than *Madlad* alone. However, during online re-ranking, we see that we achieved the best performance of 83.78. This suggests that our approach facilitates knowledge sharing between the models during decoding, leading to significant quality enhancements.

Balance between translation quality and gender disambiguation through online re-ranking We observe that the highest accuracies for feminine terms (1F) are achieved when *Seamless Bal* is employed as a generator. Nevertheless, the overall translation quality in these instances is considerably lower compared to scenarios where *Madlad* is the generator. By using *Madlad* as a generator, we attain a higher average 1F score of 60.32 compared to offline re-ranking without compromising overall translation quality and better distribution across gender. Moreover, we achieved the highest sensitivity score of 1.1 across all configurations. This shows that our approach can consistently perform better than traditional N-best list re-ranking.

While the scores for the disambiguation are not

.

high, we would like to highlight that we focused on combining the strengths of the models. However, one can use targeted systems such as Gaido et al. (2020) to further improve the performance for the desired tasks.

4.3 Image-Aware Translations

Models: To integrate image information for disambiguating source text, a robust multimodal machine translation (MT) system is essential. Initially, we experimented with the off-the-shelf instruction-tuned Llava model[5] (Li et al., 2024). While Llava provided reasonable results, its performance was sub-par for our needs. Consequently, we chose to fine-tune the *PaliGemma* model[6] (Beyer et al., 2024), which was originally trained to generate captions in multiple languages. We fine-tuned *PaliGemma* using the Multi30k image captions dataset (Elliott et al., 2016), adapting it with Q-LoRA (Appendix A.2) for enhanced image-aware translations (*PaliGemma-3B MT*).

Metrics: For evaluating this task, we use BLEU, ChrF2, and COMET scores, as we do not have specific annotations for words in the target sentences. To assess the impact of contextual information provided by the images, we also report the sensitivity metric △, to estimate how much the image context influences the translation quality.

Hyper-parameters: Vision LLMs require more memory because the image is encoded into a long sequence of tokens. Consequently, we were limited to using a beam size of 3 with a top-k of 3. Additionally, tuning the parameter α was challenging due to the lack of a dedicated ambiguous test set; using a standard test set would result in no weight being given to the vision model. Therefore, we report the oracle α of 0.9, which represents the best-performing weight on the test set, determined through a grid search with offline re-ranking. We report the scores in Table 5.

[5] https://huggingface.co/llava-hf/llava-v1.6-vicuna-13b-hf

[6] https://huggingface.co/google/paligemma-3b-ft-cococap-448

PaliGemma is highly sensitive to image context: We observe that the sensitivity △ of our fine-tuned *PaliGemma* model for MT is notably high across all metrics (e.g., 5.7 BLEU), demonstrating that the model is effectively using the image information to influence its translations. This suggests that *PaliGemma* does not disregard the visual context during translation. However, despite this sensitivity, *PaliGemma's* overall translation quality significantly lags behind that of *Madlad*, as indicated by the lower COMET score (difference of 3.32). This disparity highlights the potential benefit of combining the strengths of both models to achieve more accurate and image-aware translations.

No clear winner between offline and online re-ranking: Comparing offline and online re-ranking, we find that re-ranking with *PaliGemma* enhances translations, evidenced by a sensitivity △ increase of up to 1.28 COMET. There's also a slight improvement in overall translation quality after re-ranking. However, the difference between the two approaches is modest, especially given the small test set size of 300 examples.

We hypothesize two main factors behind the results. First, *Madlad* assigns very low probabilities to translations of ambiguous words it isn't biased toward, while *PaliGemma* avoids extremely high probabilities. As a result, merging probabilities tends to favor the incorrect translation with the highest overall score. Second, the test sentences are short, averaging 4-5 words, so the N-best list includes diverse variations, making offline re-ranking similar to the online approach. However, we believe our online re-ranking method could benefit longer sentences and stronger vision translation models.

5 Related Work

Fusion for MT: Integrating additional language models into MT systems via shallow or deep fusion, or through re-ranking, to improve translation quality is a well-studied area (Chen et al., 2006; Hasan et al., 2007; Gulcehre et al., 2015; Li and Jurafsky, 2016; Gulcehre et al., 2017; Herold et al., 2023). Stahlberg et al. (2018) explored advanced fusion method where an NMT model is trained from scratch while keeping a pre-trained language model fixed, allowing the model to learn only what is missing. There has also been growing interest in combining NMT with document-level language models (Stahlberg et al., 2019; Petrick et al., 2023; Hoang et al., 2024). Unlike previous works that utilize static weights for merging probabilities, Jean and Cho (2020) propose dynamic coefficients, which are crucial for effectively combining models with different strengths.

Ensembling: System combination, which involves merging multiple hypotheses to generate a better version, is one approach to leveraging the strengths of different models (Bangalore et al., 2001; Matusov et al., 2006; Heafield and Lavie, 2010; Freitag et al., 2014). Another approach is to merge model parameters (Junczys-Dowmunt et al., 2016) or distill knowledge from the models (Freitag et al., 2017). With the increasing diversity of LLMs, recent research has explored methods to combine them through vocabulary merging (Xu et al., 2024b), generating new outputs based on hypotheses (Jiang et al., 2023b), or dynamically selecting different models at each step (Shen et al., 2024).

Our work differs from these approaches as it neither relies on vocabulary matching nor requires additional training data.

6 Conclusion

We proposed a novel ensembling strategy that operates at the word level during the decoding process to enhance knowledge sharing. Our approach demonstrated significant benefits across multiple scenarios. It proved effective for ensembling translation systems, and even when combined with quality estimation models, it achieved state-of-the-art translation quality. Additionally, experiments on targeted multimodal test sets revealed that our method facilitates better knowledge sharing compared to traditional re-ranking techniques.

For future work, we propose to explore unsupervised dynamic selection, enabling models to generate outputs only when they are better equipped for the task. We believe this approach could address the current limitations and lead to more significant improvements in image-aware translation.

7 Limitations

The major limitation of this work is that we operate at word-level which is not compatible for several languages that are character based. Hence, it is not trivial to merge models for generating such languages. Further analysis is necessary on character-level tokenization to accurately re-rank during the decoding steps.

Another drawback is that, although re-ranking enhances translation quality, it incurs a latency cost. Unlike offline re-ranking, our approach employs the ranker model at each time step, resulting in significantly slower performance.

Finally, we focused mainly on ensembling the two models using static weights. However, since the models have different strengths, it is crucial to determine when to rely on one model or ensemble both. This dynamic approach would better exploit each model's strengths while avoiding the integration of their weaknesses.

A Appendix

A.1 Adapting Seamless

We use the gender annotations from Gaido et al. (2020) to select talks with feminine speaker pronouns and an equal amount of randomly sampled masculine talks that are in the training set. We use the huggingface transformer's library (Wolf et al., 2019) for fine-tuning Seamless. We use LoRA (Hu et al., 2021) to fine-tune Seamless on this data. We set the *rank* to 16, *lora_alpha* to 64 and *lora_dropout* to 0.1. We apply adapters on the following modules: *q_proj, v_proj, linear_q, linear_v*. We set *batch_size* to 16, *gradient_accumulation_steps* to 8 and train with *fp16* for 20 epochs validating at every 200 steps. The *learning_rate* is set to $1e^{-5}$. The other parameters are set to default in the transformers library.

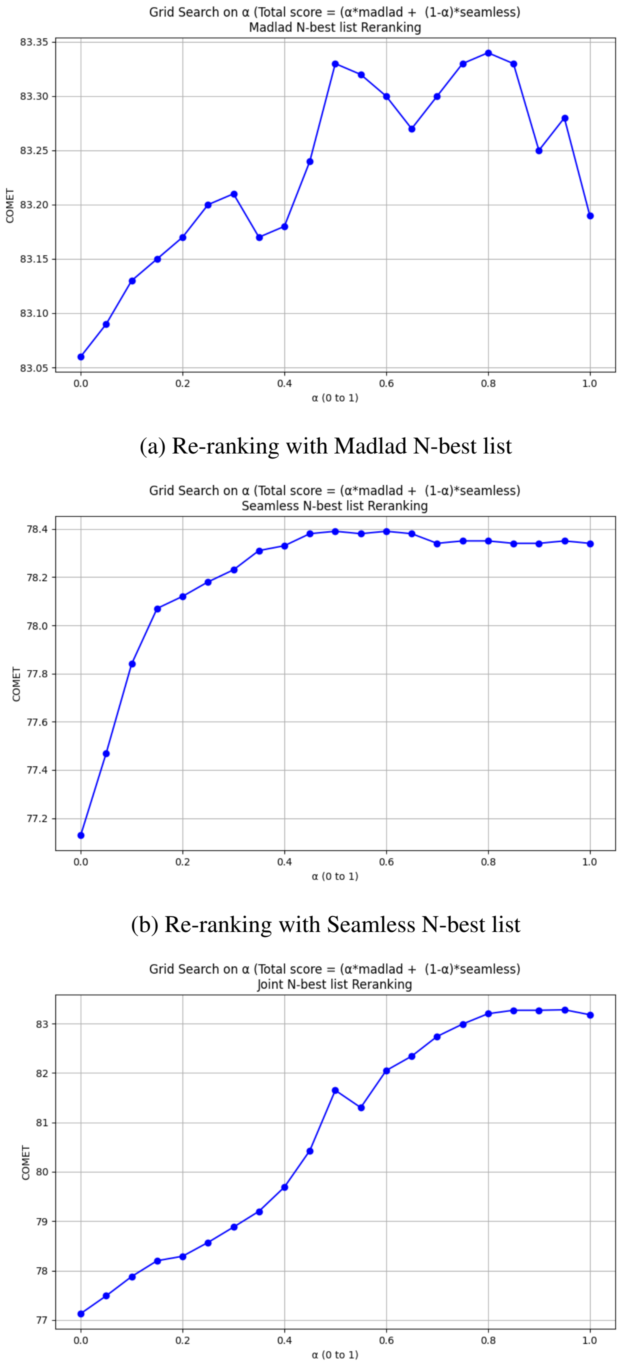
A.2 Adapting PaliGemma

We also fine-tune the PaliGemma model with the huggingface transformer's library (Wolf et al., 2019) but use Q-LoRA (Dettmers et al., 2023) with *4-bit* quantization as the vision models require more VRAM. We set the *rank* to 8, *lora_alpha* and *lora_dropout* to default. We apply adapters on the following modules: *q_proj, k_proj, v_proj, gate_proj, up_proj, down_proj*. We set *batch_size* to 2, *gradient_accumulation_steps* to 6 and train with *bf16* for 5 epochs validating at every 200 steps. The *learning_rate* is set to $2e^{-5}$ with *AdamW* optimizer. The other parameters are set to default in the transformers library.

A.3 Hyper-parameter Tuning for Speech-Aware Translations

To find the re-ranking weight α, we generate the 25-best list of *Madlad* and *Seamless* on the MuST-C development set. Then, we calculate the scores of the models on these hypothesis and perform a grid search to find the optimal weight. Here, $\alpha = 1$ means that the score is only from *Madlad* and $\alpha = 0.5$ means equal contribution. The grid search is plotted in Figure 2.

We see that α as 0.8 is always achieving higher scores. Furthermore, we see that using *Seamless* as generator (Figure 2b) leads to poor translation quality and α as 1. However, in the case of *Madlad* as a generator (Figure 2a), we see that α as 1 is not optimal showing that re-ranking with *Seamless* is indeed beneficial. Finally in the case of both models as generator (Figure 2c), we again see that α as 1 achieves highest quality showing that *Seamless* is not beneficial.



(a) Re-ranking with Madlad N-best list

(b) Re-ranking with Seamless N-best list

(c) Re-ranking with Joint N-best list

Figure 2: Grid Search on α with *Madlad* and *Seamless Bal* on the MuST-C development set with N-best lists from different generators and rankers.
